Other functionalities can be integrated into the fabricated plastic devices. For example, asymmetric microelectrode arrays can be inserted in the microchannels before thermal bonding [184]. Applying a stationary ac voltage of low amplitude, typically 1 Volt, a net fluid flow could be generated in a microchannel and the pumping velocity reaches a maximum at a frequency of 5 kHz. Within the degradation limit, increasing voltage at a fixed frequency induces a nonlinear rise of the pumping velocity. Other ac effects such as solution mixing and molecule separation and detection are expected. Finally, the demonstrated electrode arrays can be placed in different places on the microchannels, thereby providing an easy method for a high degree of system integration.

Nanoembossing can also be used to fabricate hybrid microfluidic devices such as PDMS placed on a plastic, silicon, or glass substrate. Now, a PDMS top layer is prepared and access holes to the reservoirs are punched by nanoembossing, substrates can be patterned with various functionalities that can be obtained with PDMS. Adhesion of PDMS to low roughness surfaces is excellent and a reversible water-tight seal can be obtained by conformal contact on glass, Si, plastic, as well as PDMS surfaces. For irreversible bonding, oxygen plasma exposure is sufficient. More sophisticated devices which contain valves and pumps were obtained by multilayer PDMS processing.

As one example, nanoimprint lithography has been used to pattern a silicon wafer with high density nanopillars integrated in a functional microchannel [54]. These structures were designed for the long DNA molecule separation. The array of stationary obstacles forces DNA molecules to snake their way through at different velocities according their size and yield improved separation performance. Figure 12 shows a schematic presentation of a microchannel for DNA molecular separation (a) and an area of the fabricated 320-nm period triangular array of 150-nm diameter SiO<sub>2</sub> pillars (b). They were obtained by trilayer nanoimprint lithography, followed by subsequent metal lift-off and RIE of SiO<sub>2</sub> in a CHF<sub>3</sub>/SF<sub>6</sub> gas mixture, allowing one to obtain a homogeneous pattern depth of 500 nm over a large area containing

**Figure 12.** Schematic representation of a microchannel for DNA molecular separation (a) and 150-nm dot arrays inserted in the microchannel obtained by nanoimprint lithography and dry etching of 500-nm silicon dioxide (b). both microchannels and nanopillars. Finally, the top PDMS part is fixed on the nanostructured SiO<sub>2</sub>/Si substrate by thermal bonding, after treating the top and bottom parts with oxygen plasma. Similar microfluidic devices could also be obtained based on the all plastic fabrication (Section 3).

More recently, nanoimprint lithography has been used to fabricate nanofluidic channels with a mold of 200-nm period grating obtained by interferometric lithography. After imprinting and etching, 85-nm wide trenches were produced and then sealed by either electron beam evaporation with a tilted sample wafer at various angles or sputtering deposition using a large source target. The channel width down to 10-nm could be achieved by a single step SiO<sub>2</sub> sputtering, thereby providing a way to confine biological molecules into ultrasmall spaces [185].

## 7. CONCLUSION

Nanoembossing is becoming a rapidly growing part of nanofabrication technology because of its ultrahigh resolution, parallel processing, and low cost. In particular, nanoimprint lithography has benefited from the impact of continuous scaling down of feature sizes in microelectronic circuits. In this chapter, we have reviewed several nanoembossing techniques and presented a number of application examples. They illustrated how nonconventional nanofabrication methods are profoundly changing the way of processing and the ability of device manufacturing, although these examples are far from the general interest of the nanoembossing techniques themselves. Much progress is expected on both sides of technological developments and device applications. Finally, nanoembossing is attractive not only for its lithography ability but also for its potentiality of molecular level processing. Nature makes tiny structures and complex patterns by self-organization and template replication. By addressing the molecular level, nanoembossing will be capable of covering much more broad applications areas.

## GLOSSARY

**Critical dimension** The width of a line or space that has been identified as critical to the device being fabricated.

**Glass transition temperature ( $T_g$ )** Amorphous phases such as glasses and plastics are rigid and brittle (like glass) below their glass transition temperature and elastics above it.

**Lift-off** A pattern transfer method used to obtain features on a wafer surface by first depositing a thin film of such as gold over a patterned resist layer and then dissolving the underlying resist, leaving only the portions that are deposited on the wafer surface.

**Lithography** A process to transfer a pattern from one medium to another, for example, transferring a pattern from a mold to a wafer.

**Mold** A plate with a pattern of etched and non-etched areas that can be used to deform mechanically a thin film of polymers on wafers or other materials.

**Photocurable polymers** Pre-polymer mixtures that can be polymerized at a rapid rate by exposure to light.

**Reactive ion etching** A pattern transfer method used to obtain features by both plasma etching and chemical reactions; Under appropriate conditions, reactive ion etch can give highly selectivity and a high degree of anisotropy.

**Resist** A thin film of material coated on wafers that is used to form patterns by lithography and then to mask or protect selected areas of a circuit board from etching, plating or coating processes.

**Resolution** The size of the smallest feature a system can clearly define on a resist layer; in many case the half pitch size of a periodic pattern is used to define the resolution.

**Thermoplastic polymers** They are softened when heated and reharden when cooled; Such a soften-harden sequence can be repeated for many times, subject to possible chemical degradation of the material.

**Thermosetting polymers** They become permanently hard once cured at elevated temperature, because of an irreversible chemical change.

**Tri-layer process** A lithography method used to obtain resist features of an improved profile; One first makes patterns on a top-layer thin film and then performs a pattern transfer by reactive ion etching of intermediate and bottom layers with different gases.

**Viscosity** An internal property of a fluid that describes a resistance to flow; the related shearing stress depends upon the velocity of the flow.

## 1. BACKGROUND

### 1.1. History

The art and science of thin film technology have been in existence for several millennia. For most of this period, this technology, in the form of gold beating, was used to create ornaments [1]. For example, leaf samples from Luxor dating to the Eighteenth Dynasty (1567–1320 B.C.) measured 0.3 micrometers in thickness ([2], quoted from Ref. [1]). It is thought that the modern revolution in thin film development and application began in 1857 [3] when Faraday exploded metal wires in an inert atmosphere fabricating the first evaporated thin films. These and subsequent films were found to have properties that either did not exist in, or were significantly enhanced from, the bulk form of the evaporated material. Subsequent studies led to the modern, widespread use of thin films in such fields as antireflection coatings, sensors, packaging, and, most significantly to this work, micro- and nanoelectronics.

### 1.2. Physical and Chemical Vapor Deposition

Thin films deposited in a vacuum environment (first carried out by Nahrwold in 1887 [4]) are widely used in the industry to ensure process quality and control. These vacuum-coating techniques may be broadly defined as chemical vapor deposition (CVD) or physical vapor deposition (PVD) processes. The differences between these two types of processes lie primarily with the pressure of the environment, the number of chemical reactions in the chamber or at the substrate surface, and the source material components. PVD relies on physical mechanisms (i.e., evaporation or collision impact) to bring source atoms into the gas phase and is conducted in a reduced pressure environment to ensure ballistic atom transport. During the time that atoms are ejected from the source material and collide with the substrate, they are collectively referred to as flux. The “physical” portion of PVD is diminished only in reactive PVD, whereby gas (often oxygen) is introduced into the chamber during deposition to react with the flux and change the stoichiometry of the growing film. In contrast, CVD requires gaseous precursors to react chemically at the substrate surface to form a thin film coating.

For the purposes of this chapter, we shall limit our discussion to PVD processes and in particular the deposition techniques of sputtering and evaporation. In sputtering, a working gas (typically argon) is ignited as plasma. Ionized particles are subsequently accelerated onto the target, whereby collisions at the surface dislodge target atoms to form a vapor flux. Typical chamber pressures are on the order of  $10^{-3}$  to  $10^{-2}$  Torr (0.1 to 1.0 Pa).

The flux vapor in evaporation processes is produced by thermal means, either resistive heating of a “boat” containing source material (i.e., thermal evaporation) or electron beam heating of the source material in a crucible (electron beam evaporation). Working pressures for evaporation are less than  $10^{-5}$  Torr ( $10^{-3}$  Pa), and typically on the order of  $10^{-6}$  Torr ( $10^{-4}$  Pa) for refractory metals.

For further information on thin film deposition processes and techniques (including sputtering and evaporation) we refer the interested reader to the numerous review articles and books that have been written on the subject [1, 4–7]. In this chapter, we are concerned with the differences in working pressure for sputtering and evaporation. One of the requirements for the glancing angle technique is near colinear flux (i.e., flux atoms arrive at the substrate following parallel trajectories from the source). Increasing the working gas or background pressure in the deposition chamber decreases the particle's mean free path. Hence, flux is more properly reported as the mean arrival angle of flux plus or minus its angular distribution (i.e.,  $\alpha \pm \Delta\alpha/2$ ). This chapter generally reports films deposited with near colinear flux ( $\Delta\alpha < 2^\circ$ ), and so the angular distribution is usually not stated except in Section 3.3 where its effects on growth are explicitly examined.

### 1.3. Film Nucleation and Growth

Let us first examine physical vapor deposition as it is typically performed. A typical thin film process evaporates or sputters a source material onto the substrate such that the flux arrives at normal incidence ( $\alpha = 0^\circ$ ). Incident atoms efficiently transfer their kinetic energy to the lattice and become loosely bound “adatoms.” These adatoms diffuse over the surface, exchanging energy with the lattice or adsorbed species, until they are either desorbed (through re-evaporation or sputtering) or become trapped at low-energy lattice sites. These incorporated adatoms subsequently readjust their positions within the lattice (referred to as bulk diffusion). Hence, films initiate as small nuclei randomly distributed on the substrate. Further flux deposition, coupled with the natural tendency of the system to minimize its total surface area (or energy), causes the small nuclei to increase in size and agglomerate into islands, eventually forming a continuous, dense, solid film [1, 8, 9].

Films deposited in this fashion exhibit columnar structure. The morphology of these columns is dependent on the conditions under which the structure was formed and is particularly sensitive to the ambient chamber pressure ( $P_c$ ), and the ratio of substrate temperature ( $T$ ) to the melting point of the source material ( $T_m$ ). This sensitivity should not be a surprise as the processes of desorption, surface diffusion, and bulk diffusion identified above are energy related. Each is dependent on characteristic diffusion and sublimation activation energies and hence has a magnitude which scales directly as  $T/T_m$ .

To help understand and describe the resulting film morphology, structure zone models (SZMs) have been built based on  $P_c$  and  $T/T_m$  [10, 11] (see also [1] for a summary). In addition to the energy related processes above, an additional mechanism governing film growth has also been identified: atomic shadowing. Inherently, this mechanism does not depend on the ambient energy but is rather a geometrical effect, determined solely by the surface roughness and the linearity of the incoming flux. Atomic shadowing can be present even when films are deposited at normal incidence, resulting in a typical thin film having a density less than its bulk value.

### 1.4. Deposition at Oblique Flux Incidence

The growth of a thin film becomes more interesting when the substrate is no longer perpendicular to the arriving flux. In this case, the non-normal flux incidence angle ( $\alpha$ ) magnifies the intrinsic shadowing mechanism on the substrate surface. SZMs do not explicitly account for variations in the arriving flux incidence angle, although they do exhibit the effect to a limited degree. Zone 1 morphology is observed to extend into higher  $T/T_m$  ratios at the higher argon pressure present during sputtering [11]. This observation is the direct consequence of the broadening of the angular distribution of vapor flux due to randomizing collisions with the background gas [12]. Obliquely deposited films exhibit considerable changes in their properties, which have orientation dependence. Film stress and density are altered (usually diminished) which introduces anisotropic dependencies into the thermal, electrical, magnetic (commercialized as metal evaporated videotape), and optical properties of the film [13, 14]. Although early researchers did not have access to the necessary tools to directly observe thin film morphologies at suboptical wavelengths, the origins of these anisotropic properties were speculated to be the result of a shadowing mechanism: “the area behind the crystallite is left vacant because it is in the crystallite's shadow” ([15], quoted from [16]). These speculations have now generally been accepted as accurate and are graphically illustrated in the comparison between a normal and obliquely deposited film shown in Figure 1.

At oblique incidence, the columnar morphology of the film is tilted toward the direction of incoming flux. The angle of column growth,  $\beta$ , is a monotonically increasing

**Figure 1.** In a standard thin film deposition process, vapor flux is incident normal to the substrate, resulting in a dense microstructure (a). If the substrate is tilted relative to the incident flux, the vapor arrives at an oblique angle ( $\alpha$ ) to the substrate normal. Under limited adatom diffusion, adatom shadowing at the substrate surface results in a porous film with columns inclined toward the vapor source (b). A  $\text{SiO}_2$  film deposited at  $\alpha = 85^\circ$  is shown in (c).

function of  $\alpha$ , where  $\beta < \alpha$ . This function depends not only on  $\alpha$  but also on the choice of material, chamber pressure, substrate temperature, and source to substrate separation. The tangent rule, derived empirically by Nieuwenhuizen and Haanstra [17] and shown in Eq. (1), adequately describes the relationship between  $\alpha$  and  $\beta$  for  $\alpha < 60^\circ$  [18, 19]:

$$\tan(\alpha) = 2 \tan(\beta) \quad (1)$$

Some researchers, notably Dirks and Leamy [20], have attempted to explain the tangent rule with varying degrees of success. Generally, however, “it is good to state that this rule does not have any physical meaning, it is merely a description which seems to fit a number of measurements” [16].

## 2. GLANCING ANGLE DEPOSITION

### 2.1. Transition from Oblique to Glancing Incidence

#### 2.1.1. Beginnings

Before 1996, most studies on oblique deposition had taken place at  $\alpha < 60^\circ$ , where the tangent rule is known to be reasonably accurate [16]. Given the tangent rule prediction that  $\beta \rightarrow 90^\circ$  as  $\alpha \rightarrow 90^\circ$ , the amount of film grown at higher flux incidence would be expected to be extremely small [21]. Hence, little interest was taken in the “glancing flux angle” regime. There were a few exceptions to this rule, including an early paper by Holland (1953) [22] investigating the reflectivity of aluminum deposited at a flux incidence of  $\alpha \leq 85^\circ$  and a paper by Cohen (1961) [23] who experimented with the magnetic anisotropy of films deposited at a “grazing angle.” Both these reports seem to show that films deposited at these highly oblique incidence angles did not have columnar angles described by the tangent rule, although a lack of scanning electron microscopy at the time did not allow for direct imaging of the film morphology. Despite this lack of direct imaging, the highly oblique incidence of their depositions leads us to believe that their films were the first to exhibit the highly porous structure characteristic of glancing angle deposition (GLAD) morphology.

Much later, a few studies [18, 24] continued this earlier work by examining the nature of the film morphology at these higher incidence angles. These researchers found that the shadowing mechanism was enhanced, resulting in highly separated columns and a resulting increase in film porosity. Contrary to the tangent rule, however, they found that the columnar angle did not approach  $90^\circ$  with increasing flux incidence but rather reached a maximum somewhat less (typically  $\beta = 60^\circ$ ). Additionally, the effective deposition rate at the substrate did not drop off to zero (as might be expected at extremely high incidence angles) but rather hovered between 0.2 to 0.5x that of a film grown at normal incidence.

#### 2.1.2. Tait's Rule

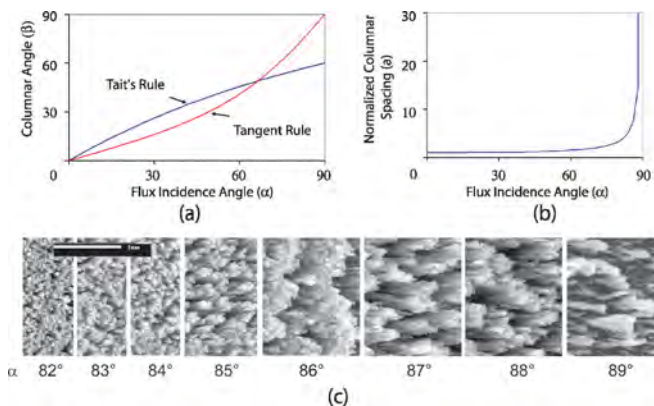

A simple geometrical approach showed that  $\alpha$  and  $\beta$  could be related for evaporated thin films growth at high incidence angles ( $\alpha > 60^\circ$ ) and limited surface diffusion [18].

This argument was based on observations of ballistic deposition models, which were found to closely resemble real thin film behavior. Hence, it was believed that a discrete particle, shadowing-based expression for columnar angle could be derived [25]. The expression [18], referred to as Tait's rule and shown in Eq. (2), assumed deposition on hemispherically topped columns (the most energetically favorable geometry for low temperature depositions). The center of the column portion receiving flux was then used to determine the direction of growth. A comparison between Tait's rule and the tangent rule is shown in Figure 2a.

$$\beta = \alpha - \sin^{-1}\left(\frac{1 - \cos \alpha}{2}\right) \quad (2)$$

Neither material effects, such as faceting, nor variance in column size (both are observed in real films) are considered. Nevertheless, this equation has been shown to predict  $\beta(\alpha)$  well for Fe and  $\text{MgF}_2$  films and correctly reproduced the general observation that  $\beta$  approaches a value less than  $90^\circ$  as  $\alpha \rightarrow 90^\circ$  [21]. An alternative approach describing  $\beta(\alpha)$  has been adopted by Hodgkinson [24] to correct for a weakness inherent in both Tait's rule and the tangent rule, that is, their being generalized functions of  $\beta(\alpha)$  irrespective of the material being deposited. Hodgkinson replaced the coefficient of  $\frac{1}{2}$  in Eq. (1) with an empirically determined function of  $\alpha$  to take into account the known dependence of column angle on source material. Although this method does allow flexibility for material specific growth, to simplify our treatment of the GLAD technique we will use the generalized case,  $\beta = \beta_{\text{Tait}}$ , as the predicted column angle.

In addition to being inclined relative to the substrate normal, columns grown at oblique incidence also exhibit separation from each other if the flux incidence angle is sufficiently large. A similar geometric model for the derived form of  $\beta(\alpha)$  can be applied to obtaining the normalized column separation,  $a$ , as a function of  $\alpha$ . This function is

**Figure 2.** The Tait model can be used to predict the effects of deposition angle ( $\alpha$ ) on both (a) the column angle,  $\beta$ , and (b) the normalized columnar spacing,  $a$ . A comparison between Tait's rule and the tangent rule is shown in (a). Note that the  $\beta$  curve describing Tait's rule reaches a value of  $60^\circ$  as  $\alpha \rightarrow 90^\circ$ . In the lower panel, a titanium film deposited at increasingly oblique angles of incidence is used to demonstrate these effects. Figure 2c reprinted with permission from [129], D. Vick et al., *Res. Signpost*, in press. © 2002, Research Signpost.

shown in Eq. (3) and assumes that the incident adatoms are small compared with the column diameter. This assumption results in a relatively small spacing between individual columns.

$$a = \frac{1}{2} \left[ 1 + \frac{1}{\cos \alpha} \right] \quad (3)$$

This expression shows that a dramatic increase in inter-columnar spacing occurs when  $\alpha > 80^\circ$  (i.e., the glancing angle regime). This effect is shown clearly in Figure 2, where both a plot of  $a$  vs  $\alpha$  (Figure 2b) and a titanium film deposited at progressively more oblique angles are illustrated: both  $\alpha$  and the columnar separation,  $a$ , are observed to correspondingly increase significantly for  $\alpha > 80^\circ$ . This property of increased separation of columns can be used to subsequently control the film growth and its resulting microstructure. Films deposited at  $\alpha < 80^\circ$  may be viewed as relatively dense by comparison.

### 2.1.3. Substrate Rotation

In 1959, Young and Kowal observed optical activity and circular Bragg reflection in fluorite films deposited with active rotation of the substrate about an axis normal to its center [26]. This axis will be subsequently referred to as  $\phi$ .

“The possibility of evaporating in vacuum an optically active film of an otherwise isotropic material, by oblique deposition on to a flat glass substrate revolving about its normal as an axis, is confirmed. The helically deposited fluorite films ranged up to about  $18 \mu\text{m}$  thick and turned the plane of polarization of a normally incident beam by as much as  $2.25^\circ$  at  $\lambda = 0.546 \mu\text{m}$ ” ([26], quoted from [27]).

At the time, scanning electron microscopy (SEM) was not available to directly observe the films fabricated by Young and Kowal, although the relatively conservative incidence angle ( $\alpha < 70^\circ$ ) of their deposition indicates that the structures would have been reasonably dense. However, this work represents one of the first attempts to “sculpture” film microstructures to enhance or change the resulting material properties. Unfortunately, their work went relatively unnoticed until recently.

In 1989, Motohiro and Taga [28] deposited columns at an oblique incidence angle of  $\alpha = 70^\circ$  and showed that these films undergo an abrupt transition when the substrate is rotated through  $180^\circ$ . For the initial portion of the film evolution, the column grows at a set angle  $\beta$  toward the flux source. At the point the substrate is rotated by  $180^\circ$ , the column abruptly changes direction so that the column inclination again points toward the incoming flux. Essentially, the column forms a chevron structure (i.e., a “V” lying on its side) where the interface between the two distinct column directions is referred to as the Motohiro–Taga interface [29]. A stacked series of Motohiro–Taga interfaces thus forms a zigzag structure. By significantly increasing the flux incidence angle, these zigzag/chevron structures can be grown isolated from each other as a highly porous medium [30].

Initially, it was assumed that either the tangent rule ( $\alpha < 60^\circ$ ) or Tait’s rule ( $\alpha > 60^\circ$ ) were valid for all types of columnar thin films grown at oblique incidence, including those with chevron microstructure. This assumption incorrectly assumed that errors introduced by differences between the

surface normal and the substrate normal were insignificant for oblique growth. Although for many types of microstructures this assumption is valid, in chevrons the growth plane changes significantly with each subsequent turn in the flux direction: the growth surface is no longer the substrate but the previous chevron “arm.” From the perspective of the new surface normal, flux appears to be arriving at a less oblique angle. A recursive algorithm has been developed to take into account the changes in surface normal with each additional arm grown in the chevron. This algorithm is captured in Eq. (4), which calculates the theoretical  $\beta$  for the  $n$ th arm given  $\beta$  for the previous arm.

$$\beta_n = \tan^{-1} \left[ \frac{\tan(\alpha + \beta_{n-1} - 90^\circ)}{2} \right] - \beta_{n-1} + 90^\circ \quad (4)$$

$\beta_n$  approaches an asymptotic limit as  $n \rightarrow \infty$ , which is typically greater than that described by Tait’s rule [31]. At low incidence angles, the correction factor introduced by Eq. (4) is not significant (i.e., the change in  $\beta$  is not observed in the earlier Motohiro–Taga films), although its effect becomes more apparent as the flux begins to arrive at glancing incidence. For example, if  $\alpha = 85^\circ$ , a swing in  $\beta$  of nearly  $8^\circ$  is observed between the initial arms of the chevron.

Theoretical work by Azzam [32], later expanded on by Lahktakia and Weiglhofer [33], continued the work of Motohiro and Taga by suggesting that a chiral response suitable for unique optical applications may be fabricated by coupling substrate rotation with oblique incidence. After experimental development of highly porous film structures [30] the term “sculptured thin film” (STF) [34] was coined to describe films where the microstructure is actively adjusted during deposition to manipulate its properties. This term is rapidly gaining some acceptance in the literature and is often used to describe relatively dense films fabricated using oblique incidence ( $\alpha < 75^\circ$ ) and substrate rotation [24, 35–37]. Earlier films such as the Young and Kowal experiments mentioned previously are considered to be among the first STFs fabricated.

### 2.1.4. Simple GLAD Structures

Earlier, we showed a figure of an obliquely deposited film to demonstrate the inclination of columns with respect to flux incidence (see Fig. 1). The growth of a structured thin film can be described succinctly by noting that columnar growth occurs in the plane parallel to that defined by the trajectory of the incoming vapor and the substrate normal and is henceforth referred to as the deposition plane. If this plane is moved (either by rotating the substrate and keeping the source fixed, or rotating the source and keeping the substrate fixed) the columnar growth direction can be controlled.

The first porous chiral structures were fabricated by utilizing highly oblique or specifically glancing angle flux incidence to separate the chiral structures and more actively control their resulting porosity and morphology [38]. From Figure 2, it is clear that the difference ( $\Delta = \alpha - \beta$ ) in columnar angle and flux incidence angle increases with increasing  $\alpha$ . More highly separated columns, and the resulting increase in film porosity, are a direct consequence of this

observation. If, for example,  $\alpha = \beta$ , columns would be inclined toward the source, yielding no separation. By choosing a point on the  $\beta$  vs  $\alpha$  plot, the porosity of the film can be easily tailored due to the increasing effect of shadowing on the substrate surface.

This technique, referred to here as glancing angle deposition [39], has since been used to fabricate a range of porous thin film morphologies with isolated microstructures, many of which have been built upon the four simple structures shown in Figure 3 and described below. For these and subsequent examples, the deposition rate,  $r$ , refers to the amount of film deposited at the position of the substrate, but on a plane that is held normal to the arriving flux. This definition is used because it describes the standard geometry for film growth measurements by a crystal thickness monitor.

- *Oblique columns*: Formed when substrate rotation about  $\varphi$  is zero. Porosity is introduced by glancing incidence flux
- *Chevron or zig-zags* [30]: Stacked Motohiro–Taga interfaces deposited at glancing incidence whereby a rotation about  $\varphi$  of  $180^\circ$  occurs for each arm of the chevron.
- *Helices* [38]: Formed when the substrate is rotated slowly and continuously relative to the deposition rate,  $r$ . Typically,  $\delta\varphi/\delta t \sim 0.1$  RPM for  $r \sim 10$  Å/sec. Each complete turn of the substrate results in a single turn of the helical structure. The speed of rotation determines the pitch length (i.e., slow rotation = longer pitch; fast rotation = smaller pitch).
- *Pillars or posts* [40]: A special case of helical growth, though usually treated as its own film morphology. If rotation is sufficiently fast (e.g.,  $\delta\varphi/\delta t > 1$  RPM for  $r = 10$  Å/sec), the pitch of the helix is so small that it

cannot be distinguished. The structure thus appears as a vertical column.

The structural details for all the above film types inherently depend on the source material being used, the substrate, crystallography, and other factors. Low melting point materials, for example, tend to have higher surface diffusion which blurs the distinctiveness of the helical pitch and thus require less rotational speed to form a structure resembling vertical columns. High melting point materials tend to have lower surface diffusion and so take higher rotational speeds to form posts. By utilizing glancing incidence, the user can control both the film porosity and structure, opening up a wide range of applications including, for example, sensing technologies, catalysts, optical devices, and biochip devices.

Some STF papers define the flux incidence and columnar angles relative to the substrate plane, using the symbols  $\chi_v$  for the flux incidence and  $\chi_c$  for the columnar angle. To avoid confusion, in this chapter we will consistently use  $\alpha$  and  $\beta$  defined relative to the substrate normal. This nomenclature is consistent with the majority of GLAD literature (i.e.,  $\alpha \equiv 90^\circ - \chi_v$  and  $\beta \equiv 90^\circ - \chi_c$ ), and the original paper defining the tangent rule [17]. Using these definitions, the flux angles used with the GLAD technique are typically in the regime of  $75^\circ$  or higher: GLAD films can be classified as “dense” for  $75^\circ < \alpha < 80^\circ$ , “porous” for  $80^\circ < \alpha < 85^\circ$ , and “superporous” for  $\alpha > 85^\circ$  [41].

## 2.2. Advanced GLAD Structures

### 2.2.1. Advanced Control System

The power of the GLAD technique does not arise from simply rotating the substrate at oblique incidence, but rather through the dynamic changing of the substrate through  $\alpha$  and/or  $\varphi$  during deposition at glancing incidence [42]. The external control apparatus for growth of GLAD films has evolved considerably since the early “proof-of-concept” experiments. Individual stepper motors, each controlled externally by software running on a single computer, allow the user to adjust both  $\alpha$  and  $\varphi$  independently while the film is being grown. Hence, a variety of microstructure forms can be programmed into the computer and subsequently grown. In addition, the control system can adapt to changing conditions within the deposition chamber through feedback provided by *in-situ* measurement of film growth by a crystal thickness monitor. This growth is reported back to the computer software which adjusts  $\alpha$  and  $\varphi$  accordingly. Figure 4 shows a schematic of the current GLAD setup without the feedback control blocks shown.

### 2.2.2. Pause–Spin Growth

Using this advanced control system, more specialized microstructures can be designed and fabricated in a one-step deposition process. For example, the standard morphological trend suggests that if  $\alpha$  is low, films are dense and the columnar structure is more vertical. If  $\alpha$  is high, films are porous and columns are inclined. The fabrication of separated vertical columns (see Fig. 3c) suggests that while the porosity may be intimately related to the deposition angle, the angle of inclination ( $\beta$ ) may be more dependent on the speed of substrate rotation.

**Figure 3.** Examples of the basic GLAD morphologies: (a) Zigzags or chevron structures fabricated from yttria stabilized zirconia ( $\text{ZrO}_2$ ) at  $\alpha = 85^\circ$ ; (b) helices of  $\text{SiO}$  deposited at  $\alpha = 85^\circ$ , and (c) vertical  $\text{SiO}_2$  posts at  $\alpha = 87^\circ$ .

**Figure 4.** The GLAD system schematic. Stepper motors are used to control both the tilt (polar) angle  $\alpha$  and the rotation (azimuthal) angle  $\varphi$  of the substrate holder. Reprinted with permission from [45], S. R. Kennedy et al., *Nanoletters* 2, 59 (2002). © 2002, American Chemical Society.

From the perspective of the film, pillars are grown when flux arrives isotropically from all azimuthal angles. Porosity is imposed by  $\alpha$ , but  $\beta$  is forced to zero because of the high rotational speed. Inclined columns of a desired porosity or separation can be fabricated at any  $\beta$  between zero and  $\beta_{\text{Tait}}$  by using a “spin–pause” approach. In this methodology, pure “paused” growth represents oblique columns (i.e., substrate is stationary), while pure “spin” growth represents vertical columns (i.e., substrate rotates at “infinite” speed). By alternating the phases of spun and paused growth, stacked layers of inclined and vertical columns can be formed. If the stacked layers are made sufficiently small, the individual “pitches” between layers become indistinguishable, and the structure appears as a smooth column. The angle of the resulting column can be set by adjusting the proportion of spun and paused phases of growth, while maintaining a desired porosity set by  $\alpha$ .

Helical growth can also be controlled to some extent. The angle at which a helical arm leaves the substrate is determined by Tait; in other words, it is fixed by  $\alpha$ . Using the pause–spin methodology, the radius and pitch of a helix can be manipulated without adjusting the porosity of the film.

### 2.2.3. Control of Columnar Cross-Sections

The cross-section of columns can also be controlled in a similar fashion. Ideally, posts are formed when the helical pitch ( $p$ ) equals zero; however, in reality this transition typically occurs when the pitch is less than 15 nm. If the column is cut perpendicular to its direction of growth, a circular cross-section occurs because the film sees flux coming from all directions at the same rate. If this rate were to become more anisotropic, the cross-section similarly becomes anisotropic (i.e., more ellipsoidal). Pausing or slowing down the rotation rate at positions along  $\varphi$  can bias the columnar cross-section at points. For example, if the substrate rotation is slowed (or stopped) at  $\varphi = 0$  and  $180^\circ$ , the result is a flattened

cross-section where the column thickness along the axis connecting  $0$  and  $180^\circ$  is significantly greater than that along the axis connecting  $90^\circ$  and  $270^\circ$  [41].

This process can be thought of as adding an artificial anisotropic component to the film growth. Obliquely grown columns also have a natural anisotropic component which can be observed by their tendency to “fan out” perpendicular to the deposition plane [16, 18, 43, 44]. This growth mechanism may be observed from the lower panel in Figure 2 and is probably a manifestation of the shadowing effect. Hence, the observed columnar cross-section is more a measure of whether the deposition rate factor or shadowing factor was dominant during film growth.

### 2.2.4. Other Advanced GLAD Structures

A number of film microstructures can be developed utilizing the advanced GLAD control system, including square spiral staircases (where each arm of the spiral is grown at  $90^\circ$  from the preceding arm) [45], superhelices (where a helical film is modulated by helical growth of higher pitch) [46], twisted ribbons (arguably pillars with a highly ellipsoidal cross section and relatively large pitch) [41], or microstructures with a capping layer [47]. Capping layers provide encapsulation and protection to the porous films beneath them and also allow for multilayer structures [48, 49], while square spirals, particularly when arranged as components in a lattice, have possible application as three-dimensional photonic bandgap filters [50]. Some of these structures will be revisited later in this chapter, while for the others we refer the interested reader to the appropriate references.

### 2.2.5. Periodic Structures

Typically, microstructures fabricated by GLAD are randomly distributed on the substrate. This feature is not detrimental for such applications as sensors, thermal barrier coatings, and catalytic devices. However, some optical (e.g., photonics crystals) [51–53] and magnetic applications [54] require a periodic lattice of structures in order to operate effectively. In addition, some of the fundamental properties of GLAD films are more easily acquired when the exact density of structures per unit area can be calculated [55].

The formation of randomly distributed GLAD structures on the substrate surface is inherently due to the nucleation stage of film growth, when energetically stable clusters of atoms seed randomly on the substrate and subsequently shadow the surrounding area. Recently, it was shown that near identical structures can be formed by enforcing this shadowing effect at the initial stages of film deposition through the use of substrates with a prefabricated seed layer [56]. In this case, the seed structures were created using electron beam lithography, while more recent efforts by other groups have shown that periodic pillars and oblique columns can be grown on plastic embossed substrates [57], and square spirals can be grown on seeds produced using standard photolithography [45]. It is expected that any process that creates small, regular mounds out of an appropriate material may serve as seed layers for a subsequent GLAD deposition to form periodic microstructures.

If the seed morphology is optimized with regard to material parameters (e.g., melting point), substrate temperature,

and the flux incidence angle, growth initially occurs predominantly at the seed sites. The highly oblique incidence of the flux and the subsequent competition effects at the surface force subsequent growth to also occur at these sites. These microstructures grow regularly for some time, the extent of which will be explored later in this chapter.

For most materials deposited by GLAD, surface shadowing is the dominant growth mechanism, allowing the optimal seed separation to be approximated by

$$\delta = t \tan(\alpha) \quad (5)$$

$\delta$  and  $t$  are the seed separation and height, respectively. Figure 5 illustrates the geometry of this expression, while examples of periodic GLAD structures are shown in Figure 6.

The growth of periodic structures, particularly those of helical microstructures, is found to be quite robust. Defects introduced into the lattice in the form of missing seeds or lines of seeds have little effect on the growth of structures surrounding the defect [56]. Defects transfer to the film (the extreme flux incidence angle ensures that there is no flux coverage of the seedless defect area), while the uniformity of the film is preserved outside of the defect area. Structures along the edge of defects tend to increase in density or thicken slightly to take up the flux that would otherwise have gone into the growth of their neighbors. This effect is marginal if the number of missing lattice points is limited to the distance enclosed by one or two seed periods. The demonstration of low defect periodic GLAD arrays is of particular significance, as it may be applied to the introduction of light-guiding structures for use in photonic bandgap devices (see Section 5.5.4).

**Figure 5.** The geometry of film growth for a randomly situated film (a) and periodic film (b) are compared. If the seed separation ( $\delta$ ) is optimized relative to the height of the seed ( $t$ ) and the angle of flux incidence ( $\alpha$ ), film growth occurs primarily at the seed sites. This seed separation is loosely based on Eq. (5). If  $\delta \gg \delta_{\text{optimized}}$ , or no seeds are present on the substrate, self-shadowing initializes film growth.

**Figure 6.** Examples of periodic GLAD morphologies grown at  $\alpha = 85^\circ$  are shown above: (a) nickel oblique columns with a lattice period of  $2 \mu\text{m}$ ; (b)  $\text{SiO}_2$  helices with a lattice period of  $600 \text{ nm}$ ; and (c)  $\text{SiO}_2$  posts with a lattice period of  $900 \text{ nm}$ . For the remaining part of this chapter, we will describe some of the fundamental growth properties of both randomly situated and periodic GLAD films. In addition to the flux incidence angle ( $\alpha$ ) and substrate rotation about  $\varphi$ , which clearly have significant effects on the overall film structure, a number of other parameters affecting growth will be discussed. We will close this chapter with a few application directions and our current understanding of how GLAD films are either demonstrated or expected to function within these fields.

### 3. GLAD FUNDAMENTALS

The isolated structures of GLAD films allow for the study of fundamental thin film growth behavior, particularly in regard to self-shadowing and surface energies. For example, by observing that the diameter of a helix arm gradually increases during deposition, one might assume a number of processes to be at work including [58]:

1. An increase in adatom diffusion length due to an increase in substrate temperature during growth.
2. An increase in the amount of material deposited on a given helix due to the suppression of neighboring structure growth (i.e., columnar competition).
3. Increase in scatter of incident flux between helices.
4. Bifurcation within a helix arm.
5. Preferential growth of fast growing crystal planes.

### 6. Recrystallization and growth of crystallites within a growing helix.

These processes show that not only is the geometry of the deposition system a factor during growth (due to its imposed effect on the shadowing mechanism at the substrate surface), but material properties such as crystallography, vapor pressure, etc. and the deposition technique itself (either sputtering or evaporation) all have strong roles to play in the form of the resulting film microstructure. In the section that follows, we will explore a number of these factors.

### 3.1. Competition, Scaling, and Growth Evolution

In common with solid thin films, GLAD microstructures exhibit self-affine or self-similar behavior [58, 59]. To illustrate this concept and give some insight into how a GLAD film evolves during its deposition, a SiO<sub>2</sub> post film (deposited at  $\alpha = 85^\circ$  with normal pitch set to 10 nm) is shown in Figure 7. The left side of the image shows the complete growth evolution as a side view, while on the right, slices of the film taken at various thickness intervals are displayed.

First we note that the separation of columns occurs early in the growth evolution, as the extreme shadowing at the substrate surface inhibits adatoms from filling in the voids between columns. This behavior is an extreme example of what is classically referred to as Zone 1 behavior: self-shadowing is the dominant growth mechanism, and adatom diffusion is limited [11]. A simple analogy, often referred to as the “grassy lawn” model, is often used to capture the essential concepts of these growth conditions [60]. Blades of grass (representing the columns) grow in proportion to the amount of light they receive (i.e., flux density). This circumstance introduces positive feedback into the growth; if a blade overgrows its neighbor, it receives more light flux and has a higher potential of shadowing its neighbors, thus suppressing their rate of growth. Similarly, adatom diffusion tends to smooth out the surface in the length scale over

**Figure 7.** The left side of the image shows an edge view of a SiO<sub>2</sub> post film. Plan views of the same film taken at various stages of growth are shown at the right. The representative film thickness of each slice is shown by a line. Reprinted with permission from [129], D. Vick et al., *Res. Signpost*, in press. © 2002, Research Signpost.

which it operates, while shadowing tends to magnify surface roughness [61].

In the SiO<sub>2</sub> film shown here (Fig. 7), column competition, extinction, and broadening can be seen as the film evolves. Transmission electron microscopy (TEM) images have suggested that column broadening correlates on the nanometer scale with bifurcation of the fibers that constitute the columns [62].

The similarity in column morphology suggests that the growth may obey a scaling law. Scanning probe microscopy can be used to quantify the interface width of the tops of films with topography  $h(x, y)$ . This interface width is defined as

$$w = \sqrt{\frac{1}{N} \sum_i^N (h_i - \bar{h})^2} \quad (6)$$

Experiments on fixed and rotated substrates have shown that these films obey a scaling law in the form

$$w(\bar{h}) \sim \bar{h}^\gamma \quad (7)$$

where  $\gamma$  is a growth exponent [63, 64].

### 3.2. Relationship between Flux Incidence and Film Density

The effect of columnar competition and thickening may pose a fundamental limitation on engineering microstructures. In addition, these effects may be detrimental for those applications that require a constant microstructure form throughout the film thickness. Through the use of periodic films and understanding how the film density is affected by flux incidence angle, the onset of competition and columnar thickening effects may be controlled.

Both simulated and experimental studies suggest that the film density ( $\rho$ ) is primarily a function of flux incidence angle [18, 65–68]. Measured densities reported between different laboratories can vary widely due to differences in the respective deposition processes and source materials. In addition, some laboratories report film density as a normalized value (i.e.,  $[\rho_0 - \rho(\alpha = 0^\circ)]/\rho(\alpha = 0^\circ)$ ), while others report densities relative to the bulk density ( $\rho_{\text{bulk}}$ ) of the source material. In the latter case, it is more critical that the system geometry be clearly represented. Generally, film density is observed to fall with increasing flux incidence angle. Decreases of up to 50% are commonly reported in  $\rho_0$  for films deposited between  $\alpha = 50^\circ$  and  $\alpha = 85^\circ$ . From Figure 2b it is clear that film density is most affected by the flux incidence angle when  $\alpha > 75^\circ$  (i.e., in the extremely oblique to glancing angle regime). In this regime, evaporated manganese has shown a reported change in  $\rho_0$  from 0.71 at  $\alpha = 75^\circ$  to 0.40 at  $\alpha = 87^\circ$  [68] while sputtered tungsten has shown a change in  $\rho_0$  of over 40% between a film deposited at  $\alpha = 75^\circ$  and a film deposited at  $\alpha = 85^\circ$  [18, 69].

All these studies, particularly those involving simulation, showed that neither seed period nor, in most cases, substrate rotation rates (see Section 3.4) has an effect on these characteristics.

To maintain a constant density at a given flux incidence angle, increases in the surviving pillar diameter ( $s$ ) are compensated by a corresponding increase in pillar separation

( $p$ ). The ratio of these two parameters is thought to be thickness invariant and dependent on the flux incidence angle ( $\alpha$ ); that is,  $s/p = \eta(\alpha)$  [64]. This property arises through the competitive effects linked to the constancy of flux density striking a given region on the substrate surface.

Films grown on prepatterned substrates may provide an opportunity to minimize columnar competition by optimizing the seed topography to the observed  $s/p$  ratio in randomly situated structures. Although a clearly defined diameter and period do not exist in these latter films, a measure of their values can be obtained. The “average” separation,  $d$ , of randomly situated columns can be determined by scanning probe measurements of GLAD film topography. This separation (governed loosely by Tait’s equation) can be found experimentally by explicitly measuring the distances between surviving columns and averaging the results. These measurements result in values on the order of a few hundred nanometers for film thicknesses of up to a one or two micrometers and with  $\alpha \sim 85^\circ$ . In a similar fashion, the “average” diameter of columns can also be calculated, although the results are not as definitive.

Promising results have indicated that the competitive effects in periodic films can be delayed compared to the randomly situated structures [65]. If periodic pillars deposited under the same deposition conditions and seed geometry are compared based on the spacing of individual seed elements, the following observations can be made:

1. Initial seed separations much larger than  $d$  (i.e., approaching one micrometer), result in larger pillar diameters and a corresponding decrease in intercolumnar competition.
2. Films grown on relatively dense seed arrays (i.e., seed periods less than 100 nm) show highly competitive growth.
3. At a given film thickness, the crossover between increased competitive behavior and increased pillar diameter appears to occur at  $d$ .

Column diameters and separations are based on the interplay of both self-shadowing and the adatom diffusion length of incoming flux. Based on the above observations, it is thought that the averages observed in a randomly growing film represent the optimized geometry for a given set of conditions (i.e.,  $s/d$  is the optimized  $s/p$  for a given  $\alpha$ ).

Let us consider a seed topography consisting of dots with 50 nm diameter, 80 nm height, and 600 nm separation. The flux incidence angle is set to  $85^\circ$ . Initially, a pillar film grown on this substrate will have a low  $s/p$  factor (i.e.,  $s/p = 0.08$ ) compared to a typical value of  $(s/p)_{\text{random}} = 0.4$  to 0.8 for a randomly situated film grown under the same conditions. To compensate for this discrepancy, the pillar diameter increases, effectively delaying the onset of columnar competition within the growth evolution. Competition effects are observed to occur more readily when the pillar diameter reaches a value determined by  $(s/p)_{\text{random}}$  (i.e., in this case  $s \sim 240$  to 480 nm).

It should be noted that competition effects are observed to be significantly diminished in randomly situated and periodic helices, specifically in relation to pillars grown on the same substrate topography. It is believed that this effect may be due to the self-correcting nature of helical growth and its

ability to adjust its pitch arm diameter to counter additional competitive pressures during growth.

### 3.3. Relationship between Flux Angular Distribution and Film Growth

In addition to the flux incidence angle, the angular flux distribution ( $\Delta\alpha$ ) of the incoming flux is also important to GLAD microstructure growth. To control film growth most effectively at glancing incidence, a narrow angular distribution of vapor flux centered at a known oblique incidence angle is required. Indeed, some research has suggested that for incidence angles greater than  $\alpha = 80^\circ$ , small variations in the flux incidence angle result in large changes in film densities [18]. The resulting film density tends to be most greatly influenced by that fraction of flux which is least oblique and, therefore, least subject to the shadowing mechanism.

For most of the applications and films shown in this chapter, electron beam evaporation has been used for film depositions. This process typically yields a flux beam geometry suitable for controlling microstructure growth at glancing angles. Unfortunately, high melting point materials (e.g., tungsten and molybdenum) are not easily deposited in this fashion, and a sputtering process may be required for growing GLAD films from these materials. Standard sputtered PVD generally deposits films with greater flux incidence distribution at the substrate due to the larger target size used and flux scattering off of the working gas. Techniques such as collimated sputtering [70, 71], ionized PVD [72], and low-pressure, long-throw (LPLT) sputtering [73] have been suggested to narrow  $\Delta\alpha$ . Although still not yielding as tight a flux beam geometry as present in typical evaporation processes, the last of these techniques, LPLT, has been used successfully to fabricate randomly situated chevrons [74], and both randomly distributed and periodic structures of helices and pillars [74, 75].

Periodic structures deposited by LPLT sputtering more easily identify the effect of increasing  $\Delta\alpha$  on GLAD film growth. Recent work has shown [75] the following film characteristics:

1. Quasi-helical microstructures are formed when the seed period ( $p$ ) is less than  $d$ .
2. Pillar microstructures are formed when  $p > d$ .

Hence, as the seed period increases, helical structures degenerate into posts. Why does this effect occur? Let us first consider what is meant when incident flux has a given angular flux distribution; for example, if  $\alpha = 85^\circ$  and  $\Delta\alpha = 4^\circ$ , the majority of flux arrives between  $\alpha_{\text{min}} = 83^\circ < x < \alpha_{\text{max}} = 87^\circ$ . Recall that a pillar is simply a helical microstructure within which the pitch is indistinguishable. Hence for large seed separations (i.e., on the order of  $1 \mu\text{m}$ ), although a helical structure may form at  $\alpha = 85^\circ$ , incoming flux arriving at the lower portion of the incidence range tends to “fill in” the helical pitch, smoothing out the resulting microstructure. At lower seed periods, shadowing by neighboring structures diminishes this “filling” effect, albeit at the expense of increased competition. As a result, when the seed period is less than  $d$ , quasi-helices are formed. When  $p > d$ , helices degenerate into posts, while a transitional region between pillars and quasi-helical behavior is observed to exist about  $p = d$ .

### 3.4. Relationship between Substrate Rotation and Film Growth

Substrate rotation is one of the primary means of manipulating the film morphology at glancing angles. As mentioned previously, the film density is not observed to be dependent on the speed of rotation about the  $\varphi$  axis for most materials.

Generally, substrate rotation affects GLAD morphology in the following fashion: Isolated posts are fabricated when flux arrives isotropically from all azimuthal angles (i.e.,  $\delta\varphi/\delta t$  is “infinite”); helices form at various pitch lengths when  $\delta\varphi/\delta t$  is decreased; and, finally, oblique columns are formed when  $\delta\varphi/\delta t = 0$ . This general relation between morphology and  $\delta\varphi/\delta t$  has been presented previously in Section 2.1.4 and is shown in Figure 8.

Recent research suggests that this morphological trend may not be applicable to all materials. Liu et al., studying under the Center for Materials for Information Technology (MINT) at the University of Alabama, found that the growth rate for cobalt increased [76], while iron films display leaflike columnar growth [77] at high rotational speeds ( $\delta\varphi/\delta t \sim 30$  RPM,  $\alpha = 75^\circ$ ). Their results were recently quantified by comparing aluminum, silicon, and silicon dioxide films grown at glancing angles with increasing rotational speeds [78]. This work relied on a gearbox which allowed for simultaneous deposition of six separate films over two orders of magnitude of rotation by stepping up or down the rotation about  $\varphi_n$  relative to the central driving axis,  $\varphi_c$ .

Silicon dioxide and silicon films were found to follow the general trend observed for most materials, while the structure of aluminum was found to be highly dependent on  $\delta\varphi/\delta t$ . The trend for aluminum is shown in Figure 9.

At low rotational speeds, aluminum films have “mushroomlike” growth, whereby with increasing thickness the film

**Figure 8.** Films of  $\text{SiO}_2$  grown with a deposition angle of  $\alpha = 85^\circ$ , and at various rotational speeds (shown below each image). Pillar growth occurs when  $\delta\varphi/\delta t > 1$  RPM (at a deposition rate of  $10 \text{ \AA}/\text{sec}$ ), while helical growth occurs more clearly for  $\delta\varphi/\delta t < 0.1$  RPM.

**Figure 9.** Aluminum films deposited at  $\alpha = 85^\circ$  at different  $\delta\varphi/\delta t$ . The films deposited at  $\delta\varphi/\delta t = 3.0$  RPM show a flattened out structure while the film deposited at  $\delta\varphi/\delta t = 42$  RPM shows peaked structures. Faceting is clearly visible in all the films, and TEM analysis that shows the film consists of a simple cubic, monocrystalline structure.

spreads out from a thin base. The tops of these structures are both flat and consistent in height with their neighbors.

As  $\delta\varphi/\delta t$  is increased, the number density of structures with a pyramidal faceted peak increases. Also observed is a corresponding increase in the average thickness of the film. Hence, at  $\delta\varphi/\delta t = 42$  RPM (for most materials, a pillar structure will typically form at 1 RPM, while a helix forms at 0.1 RPM using  $\alpha = 85^\circ$  as a reference), the peaked structures are in the majority, and the film thickness is almost twice that at  $\delta\varphi/\delta t = 3.0$  RPM.

This result, coupled with the previous study by Liu, suggests that the morphological structure is highly dependent on the propensity of the structures to form solid crystals. TEM analysis of the aluminum films showed them to have a simple cubic, monocrystalline structure. A similar analysis of silicon and silicon dioxide films shows both have amorphous structures, consistent with the statement that fiber bundling is thought to contribute to columnar competition in GLAD films [62].

One possible explanation for this behavior is the effective rate of adatom burial at increasing rates of substrate rotation at constant  $\alpha$  [78]. At glancing angles, the effective shadowing mechanism is enhanced. Because all films in a given rotation set were deposited simultaneously, it is not believed that differential temperatures across the individual samples are a factor. The burial rate seems to be dependent on the number of times the flux “visits” a particular spot on the substrate (i.e., at fast rotation, the burial rate increases relative to the slow rotation rate because a particular site is “visited” more often). Hence, different crystal planes are thought to be preferred as the diffusion length of adatoms decreases with  $\delta\varphi/\delta t$ .

Simulations indicate that the diffusion length of adatoms on structures with strongly preferred crystal planes changes with  $\delta\varphi/\delta t$  [78], while experimental results on chromium films deposited at a relatively conservative  $\alpha = 65^\circ$  show a similar result. Figure 10 shows that at high rotational speeds, the film surface shows a number of peaks typical of sputtered chrome surfaces. At low rotation speeds, the surface shows a smaller number of peaks with long channels linking film regions, seemingly indicating a longer effective diffusion length.

It is noted that if this result is confirmed, a similar effect should be apparent on the same materials deposited at lower rotational speeds with an increased deposition rate.

**Figure 10.** The potential effect of substrate rotational speed on adatom diffusion length is apparent from these images of chromium films deposited at  $\alpha = 65^\circ$ . At low rotational speeds, the surface of the film is smooth, while at faster speeds, the surface roughness increases.

### 3.5. Simulation Software

Simulations have been used as tools to describe obliquely deposited films at least since the pioneering work by Dirks and Leamy [20]. Although a number of simulation paradigms exist including continuum models [20], conservation of parallel momentum (primarily supported by a group of Japanese researchers starting with [79] and summarized in [80]), and angular dependent growth [81–83], ballistic deposition simulations have proven the most successful in describing the growth of thin films deposited with limited adatom diffusion and high mean free-path (the typical conditions in a GLAD chamber). In these simulations, particles are serially launched from just above the growing film. Each particle is allowed to follow straight-line trajectories until it strikes the substrate or the film. The subsequent surface diffusion is described by an equilibrium model whereby each particle is allowed to aggregate into the film after diffusing a distance determined by an algorithm which minimizes the surface curvature-dependent chemical potential.

Throughout most of the history of thin film simulation, insufficient computing power has limited software to simple two-dimensional [19, 27] and three-dimensional models [84, 85] which tended to exclude the effects of surface diffusion of adatoms over large scales. This exclusion is important as it is universally accepted that surface diffusion is very important to the growth of obliquely deposited films, as it is for all thin film growth processes. Over the last decade, however, this limitation has been lifted significantly, allowing for the creation of three-dimensional (3D) simulation programs to more properly model both adatom diffusion and the resulting porous thin film structures created at glancing incidence [67, 86]. Typically, for example, even films evaporated obliquely onto *stationary* substrates grow anisotropically, with flakelike morphology and significant growth fanning in the direction perpendicular to the incident flux and parallel to the substrate plane [16, 18, 43, 44].

Although a number of software packages have recently been developed, one simulator that has proven quite successful in the modeling of films deposited at glancing angles is the Monte Carlo ballistic simulator program, 3D-FILMS [67]. This progeny of the two-dimensional simulation package SIMBAD [87] was developed in part to model several aspects of porous thin films. In its simulations, 3D-FILMS models a film as a large number of identical units. Each unit has cubical geometry and represents the statistically averaged behavior of a large number of atoms (typically 1000). Nucleation, self-shadowing, adatom mobility, and a variety of other physical effects are all incorporated into this model, and simulated films can be displayed graphically as three-dimensional images.

Temporal dependence of the incident flux [ $\alpha(t)$ ,  $\varphi(t)$ ] can be introduced to reproduce most of the GLAD film morphologies observed experimentally including simple helices, post, and chevron structures, as well as multilayered and capped structures. Periodic arrays of films can be grown by setting the initial substrate topography to match the desired predefined seed layer geometry. See Figure 11.

A second 3D simulator, the Virtual Film Growth System (VFIGS), has also been recently reported [86]. This simulator, also built around the basic SIMBAD system and following a similar development framework as 3D-FILMS, was primarily created to understand the surface area of STFs (referred to in their work as dynamically obliquely deposited films). By simulating the growth of various film

**Figure 11.** 3D-FILMS simulations of different film morphologies deposited at the same flux incidence angle. These morphologies include: (a) helices; (b) a single helix from the simulation of (a); (c), (d) posts; (e) chevrons. A plot of the differential density as a function of height for the simulations at the left is shown in (f). Note that the simulation predicts that the resulting average film density is not dependent on microstructure form. Reprinted with permission from [67], T. Sny et al., *J. Vac. Sci. Technol. A* 18, 2507 (2000). © 2000, AVS—The Science & Technology Society.

morphologies from  $\alpha = 0^\circ$  through  $\alpha = 82^\circ$ , VFIGS found no significant dependency of either packing density or effective surface area on  $\varphi$ . These properties were found to be primarily a function of  $\alpha$ , and, although the packing density diminished in the expected fashion, the effective surface area was observed to increase sharply to a maximum at  $\alpha = 70^\circ$ .

Ballistic simulations of GLAD films have confirmed that only collimated flux and low diffusion length are needed to explain most aspects of these films including column morphology, column extinction and broadening, and bifurcation. In other words, self-shadowing is the primary growth mechanism. See Figure 12.

#### 4. FABRICATION PROCESSES FOR SPECIALIZED APPLICATIONS

One of the strengths of the GLAD process is that it can form a variety of microstructures using a one-step process. However, for some applications (i.e., the periodic films mentioned earlier), either pre- or postprocessing steps are required. In this section we describe a few tools that have been developed for application to GLAD films.

##### 4.1. Perforated Thin Films

There has been a great deal of research into the production of thin films perforated by an organized array of pores. Photoanodic etching has been used to produce  $2\ \mu\text{m}$  diameter pores,  $400\ \mu\text{m}$  deep into a silicon wafer [88], while phosphoric acid can be used to anodically etch high purity aluminum foils to produce regular patterns  $100\ \mu\text{m}$  deep over a limited area [89]. As a final example, Chelnokov used an optical drill to produce triangular lattices of deep pores in photoresist [90].

In all these cases, the perforated films were limited to a regular geometric cross-section (either circular or rectangular) extending perpendicularly into the substrate. GLAD films, however, can be used to provide a template for etching a wider range of geometries into the substrate in a few, simple steps (see Fig. 13) [91]. In the first step, the inverse form of the desired substrate geometry is fabricated using the GLAD process. For the example shown,  $\text{SiO}_2$  helices were deposited at  $\alpha = 85^\circ$  with a pitch of  $300\ \text{nm}$ . The second step requires the filling in of the GLAD template using photoresist, spin-on glass or another similar material to provide not only protection to the underlying substrate but a medium in which the pores can be etched. For our example,

**Figure 12.** Pseudo-SEM images were obtained using a plan perspective of 3D-FILMS simulations. The images are displayed as insets over SEM images of real films. Reprinted with permission from [64], D. Vick et al., *Mater. Res. Soc. Symp. Proc.*, 648, (2001). © 2001, Materials Research Society.

**Figure 13.** The stages involved in the fabrication of a perforated film: (a) template formation; (b) filling; (c) partial etch-back; and, finally, (d) template removal. Reprinted with permission from [91], K. D. Harris et al., *Electrochem. Solid-State Lett.* 4, C39 (2001). © 2001, Electrochemical Society.

HPR504 photoresist was used as the filler medium. To help aid the etching process, in the third step the filler medium is partially removed to reveal the tips of the GLAD structures. Timed immersion in a developer solution was used to remove the photoresist to partially expose the  $\text{SiO}_2$  helices. In the final step, the GLAD film is etched away using a suitable process (here, a 7:1 buffered oxide etch solution was used), to leave behind a mold of the film in the filler medium.

This process has been used successfully to not only create the helical pores shown in Figure 13 but also randomly oriented chevron pores and periodic helical pores.

Subsequent research has taken this process further by showing that it provides a clever means of fabricating GLAD-type microstructures from materials that are not easily deposited using that process. These materials, such as copper, have a low melting point and corresponding high adatom mobility when deposited on uncooled substrates. The high mobility of adatoms smoothes out the microstructure and diminishes the predominance of self-shadowing at the surface. In contrast, finely structured copper helices can be formed by electroplating copper back through a mold prepared by the above process. If the filler material is photoresist, for example, it can be easily etched away by acetone leaving an exact replica of the original template structure in copper [92].

##### 4.2. Raised Topography

In Section 2.2.5 we discussed the fabrication of periodic structures where a single microstructure (i.e., helix, oblique column etc.) made up each element of a larger array. If this seed element is much larger than  $a$ , the columnar separation described by Eq. (4), multiple structures will form on individual seed elements [93]. For most of the envisioned applications mentioned thus far, such multiplicity is an undesirable property, and seed arrays typically are optimized to avoid this circumstance.

However, if the standard GLAD process is applied to seed elements with dimensions several orders of magnitude larger than  $a$ , a wall of dense film is built up at the seed edges [94]. This effect is illustrated in the SEM images shown in Figure 14.

In these images, a helical GLAD film has been deposited on substrates containing arrays of 14  $\mu\text{m}$  tall mesas. Over the majority of the mesa tops, a porous, helical film is grown. At the edge, flux is accumulated as vapor hits at a less oblique angle (more normal). This effect results in a thick solid wall surrounding the porous region, and essentially a deposition in this fashion can be thought to fabricate a highly porous, self-sealing structure. If a complete seal is desired, a capping layer (see [47]) can be easily applied after the required film thickness is deposited. Seto et al. [94] found that walls form naturally around any raised pattern that exhibits sharp edges, and hence a variety of topographies such as T-junctions or via-connected chambers can also be formed. They suggest that such a structure may be suitable for microfluidics chromatography, nano-assay, lab-on-a-chip, biochemical, and other related applications.

### 4.3. Sharpening GLAD Microstructures Using Ion Milling

As a final example of some of the micro- and nanofabrication techniques that can be applied to the GLAD process, we mention the possibility of ion milling microstructures to sharpen their features.

The sputter yield of an ion beam is angularly dependent, with the maximum yield lying typically between  $30^\circ$  and  $60^\circ$ . When columns are milled uniformly across the tip surface

**Figure 14.**  $\text{SiO}_2$  GLAD helices deposited onto etched silicon mesa substrates (a) fabricate a porous helical film with a wall of film built up at the seed edges (b, c). Reprinted with permission from [94], M. Seto et al., *J. Mater. Chem.* 12, 2348 (2002). © 2002, Royal Society of Chemistry.

by a beam incident parallel to the substrate normal, the tips not only become slightly shorter (a perhaps undesirable consequence) but also significantly sharper. A recent article [95] showed that the radii of curvature for vertical columns of silicon and carbon could be decreased to less than 20 nm with a 1 kV (18 mA) ion beam treatment of just 10 minutes in a vacuum. This ion milling treatment produces films that exhibit superior field emission properties when compared to unmilled films.

These structures may be applied as field emitters, which provide electron sources in flat panel displays, plasma generators, analytical instrumentation, and power/high frequency devices. However, these films need not be useful for only field emission, for indeed their potential application could easily be limited by the growing and considerable interest in the possible field emission properties of nanotubes [96, 97]. The sharp features presented by the ends of the columns could find a use as SPM probe tip characterization surfaces, an area of growing importance as these tools become more common in industrial fabrication processes [98]. It has also been suggested that sharpened tips may be suitable for the more esoteric application of providing propulsion for microsattellites.

## 5. SOME PROPERTIES AND APPLICATIONS

### 5.1. Mechanical Properties

Nanoindentation measurements have been done on several films of varying pitch lengths to answer questions on whether GLAD films show resonance properties [55, 99]. Theoretical work indicates that a GLAD film fabricated from a suitable piezoelectric material may form a tunable chiral thin film laser [100], while experimental research has shown that the films undergo elastic deformation when small forces are applied to the surface, corresponding to a stiffness as low as 1/1000th that of a similarly deposited solid film.

Force displacement curves for one, two, and three turn  $\text{SiO}_2$  films have been obtained using a nanoindentation tip as a probe. This probe applied low force indentation measurements on the films over areas much larger than individual columns. To decrease the number of free variables, the thickness was left constant, resulting in pitches of 1900, 850, and 600 nm respectively. Using this technique, displacement at the maximum applied force amounted to less than 15% of the total film thickness. Indentations at the same site showed an overlapping displacement curve, indicating that the deflection is nondestructive or elastic for small deformations. The force–displacement curves for these films are shown in Figure 15.

Somewhat surprisingly, the dependence of film stiffness on spring geometry scales in a manner similar to a bed of macroscopic springs and is on the order of

$$k = \frac{Gs^4}{64R^3n} \left[ 1 - \frac{3s^2}{64R^2} + \frac{3+\nu}{2(1+\nu)} \tan^2(\alpha) \right]^{-1} \quad (8)$$

where  $G$  is the Shear modulus,  $s$  is the column diameter,  $R$  is the coil radius,  $n$  is the number of turns,  $\nu$  is Poisson's ratio, and  $\alpha$  is the rise angle [55]. Although measurements of helical parameters (e.g., coil diameter etc.) could

**Figure 15.** Force–displacement curves for single, double, and triple turn helical SiO thin films of comparable thickness. To contrast, an indentation curve for a dense SiO film is also shown. Reprinted with permission from [99], M. Seto et al., *J. Vac. Sci. Technol. B* 17, 2172 (1999). © 1999, Materials Research Society.

not be precisely obtained, the areal stiffnesses of experimental and theoretical films were comparable. These values were on the order of 10 to 18 N/m- $\mu\text{m}^2$  for one to three turn SiO helices, as opposed to the 18,500 N/m- $\mu\text{m}^2$  value for a similarly deposited dense SiO film. From Eq. (8), it is expected that helical films will exhibit a resonant frequency between 10 and 50 MHz and suggests that it may be feasible to engineer beds of microsprints with well-defined stiffness and mechanical response.

Periodic slanted posts can be used to aid in deflection measurements, by diminishing the error inherent within dimension values. These structures resemble cantilevers with rectangular cross-sections, of which an example was shown previously in Figure 6a. The theoretical expression for the displacement of this film is given by

$$\Delta x = \frac{FL^3 \cos^2(\alpha)}{3EI} \quad (9)$$

$F$  is the applied force,  $L$  is the cantilever length,  $\alpha$  is the rise angle,  $E$  is Young's modulus, and  $I$  is the moment of inertia (where for a rectangular cross-section,  $I = wt^3/12$ , where  $w$  is the width and  $t$  is the thickness) [55]. These structures deflected 80 nm under 27  $\mu\text{N}$  of applied force, while Eq. (9) predicted a deflection of 90 nm under the same conditions.

## 5.2. Thermal Properties

Capping and multilayer structures were introduced briefly in Section 2.2.4. It has been suggested that if multilayer GLAD film were constructed out of suitable materials, a thermal barrier coating (TBC) may result. Two types of TBCs are described in the literature:

1. A layer of yttria-stabilized zirconia (YSZ) is applied to a critical surface by plasma spraying, resulting in a highly porous microstructure [101]. Its thermal barrier properties, however, can be significantly reduced by repeated heating cycles that may induce stress, causing cracking due to differing thermal expansion coefficients.
2. Electron beam evaporation is used to deposit the film. The stress-induced deterioration is reduced by the presence of a laterally compliant columnar

microstructure with well-defined boundaries. Unfortunately, these films have less porosity than plasma sprayed coatings and, consequently, have diminished thermal protection.

TBCs deposited by oblique deposition may provide solutions to these problems, and, in particular, it has been suggested that a suitable GLAD structure may provide diminished stress induced deterioration while retaining the film's porosity.

A film was grown with alternating porous and dense layers of YSZ, as shown in Figure 16 [102]. YSZ is used because of its low thermal diffusivity. The inclusion of porosity into the film matrix would be expected to further lower the bulk thermal conductivity.

The thermal properties of these multilayer films were directly measured at the National Institute of Standards and Technology using two techniques. The first, referred to as the  $3\omega$  technique, introduces heat into the coating by an ac current of frequency  $\omega$  flowing through an evaporated resistor [103]. A fit of resistor voltage as a function of frequency yields the thermal conductivity. The second technique is called the Mirage technique. Here, an oscillating temperature was induced immediately above the film using a pulsed laser [104, 105]. A second probe laser aligned parallel to the surface underwent deflection in the boundary layer above the film surface, and the thermal diffusivity was then found by fitting amplitude and phase shift data to the solution of a three-dimensional diffusion equation.

The Mirage method was applied to a dense film of 1  $\mu\text{m}$  thickness, and yielded a room temperature thermal diffusivity of  $0.0053 \pm 0.0007 \text{ cm}^2/\text{s}$ . This value is comparable to those previously reported for YSZ TBCs [106]. Measurements on the GLAD film using both methods led to thermal diffusivity estimates of approximately 9% that of solid YSZ films. It is possible that this result may be improved by further optimizing this YSZ TBC fabrication process.

**Figure 16.** YSZ film structures grown from alternating porous and dense layers display a low thermal diffusivity. These films can be grown by dynamic alteration of the deposition angle,  $\alpha$ . Reprinted with permission from [102], K. D. Harris et al., *Surf. Coat. Technol.* 138, 185 (2001). © 2001, Elsevier.

The high thermal resistance of these films offers an alternative use for these film structures. Possibly, the resistance can be exploited as a heating source to increase the operating temperature and/or efficiency of devices created using it as a base.

### 5.3. Enhanced Surface Area Devices

Perhaps the easiest and most directly applicable products for GLAD films are enhanced surface area devices. These films inherently have an extremely high surface area relative to their bulk counterparts [68], which may make them ideal media for a number of applications including humidity sensors, catalysis media, chemical sensors, and lab-on-a-chip devices.

#### 5.3.1. Supercapacitors

High surface area ( $>1000 \text{ m}^2/\text{g}$ ) carbon-based capacitors are commercially available exhibiting specific capacitances of 100–200 F/g. These devices rely on the formation of an electrical double layer between the carbon surface and electrolyte to provide their capacitance [68].

Recently, efforts have been made to develop metal oxides as capacitor materials. These materials utilize a reversible redox reaction as the basis for their pseudo-capacitive behavior. These efforts have primarily focused on rubidium oxides, which have been shown to have specific capacitances of up to 770 F/g [107]. The problem with this material is that rubidium is expensive, leading to the exploration of less expensive alternatives such as  $\text{MnO}_2$ ,  $\text{NiO}$ , and  $\text{Co}_3\text{O}_4$  as faradaic capacitors. Sol-gel [108], colloidal suspensions [109], and electrochemical deposition [110, 111] have all been used to create capacitor media out of one or all of these materials. As examples, Chin et al. [109] observed a specific capacitance of 720 F/g using  $\text{MnO}_2$  via a colloidal solution. Hu et al. used anodic deposition of  $\text{NiO}/\text{CoO}$  mixtures to obtain 720 F/g [110], while a similar process on  $\text{MnO}_2$  resulted in a specific capacitance of 300 F/g [111].

The film microstructures described in this chapter may provide an alternative path for electrochemical capacitor development, based on their high surface area and the notion that vacuum deposition of thin metal films onto flexible substrates is both highly scalable and a well known manufacturing process [68].

Chevron structures have been used for most of the capacitance experiments to date due to its resemblance to the type of structure that would be expected from an obliquely angled multipass coating deposition process. For a 500 nm thick, four-turn chevron structure, the maximum specific capacitance obtained was  $225 \pm 25 \text{ F/g}$  at  $\alpha = 82^\circ$  [68]. Further work may be undertaken to improve the surface area of the films which they believe is the detrimental step in their process.

#### 5.3.2. Humidity and Chemical Sensors

Capacitance measurements on GLAD films are not new, and certainly other applications can arise by applying this property elsewhere. Two of these other applications are relative humidity detection [112, 113] and chemical sensing, where humidity or chemical concentrations are sensed as a

change in capacitance between two parallel plates. A humidity device of this style is typically termed a capacitive relative humidity (RH) sensor.

For these films, the interactions between sensing material, water moisture, and the applied field become strong, making the conventional equivalent circuit model insufficient to explain the observed results [112, 114–117]. Crucial microstructure related parameters are also important, including the diameter of pores and pore size distribution.

Shimizu et al. [115] introduced a computation program demonstrating the importance of these parameters to the sensing characteristics and were subsequently followed by Li [116] who used a similar approach to explain their porous  $\text{Sr}_{1-x}\text{La}_x\text{TiO}_3$  sensors. Khanna and Nahar incorporated the interactions between sensing materials, water moisture, and applied field using Sillars' medium theory [118] to successfully explain the sensing behavior of their porous  $\text{Al}_2\text{O}_3$  sensors fabricated by anodization [117]. Typically, though, these models assume a solid structure within which pores are etched. GLAD films present the opposite approach—essentially, a “void” within which solid structures are grown.

Reasonable capacitive RH characteristics can be obtained by sandwiching a GLAD  $\text{SiO}$  pillar film between two electrodes [113]. A model, based upon a modification of Sillars' medium theory and incorporating the influence of net heat adsorption of water molecules, the change in conductance on the surface of  $\text{SiO}$  film after water adsorption, water condensation in the pores of the sensors due to the capillary effect, changes in conductivity of the condensed water with RH, and the pore size distribution on the sensing characteristics of these devices, was developed and is applicable through an RH range from dry to saturation. This model shows that pore size distribution and porosity have critical effects on the sensing characteristics.

Early RH studies on GLAD films showed that a rapid response time of a few seconds could be obtained, with a capacitive range over five orders of magnitude. This range corresponded to relative humidities of 10% to 90%. Further work on these structures was conducted by Harris et al. at the University of Alberta, who decreased the response time to 25 ms by further optimizing some of the film deposition parameters and measurement techniques [119]. These results are several orders of magnitude quicker than capacitive RH sensors currently on the market. It is thought that the natural pore size in the upper capping layer tends to be near the optimal size for allowing moisture to either adsorb or escape depending on the humidity differential between the film structure and the surrounding air.

Work on humidity sensors opens up the possibility that by modifying the evaporant or using surface treatments, rapid detection of different gases using a similar process design may be obtainable. Engineering a device that incorporates a number of films grown from different materials, it may be possible to differentiate between different gas-borne species.

#### 5.3.3. Catalytic Media

Platinum films have been used as electrodes or catalysts in sensors [120, 121], direct methanol fuel cells [122, 123], and electrochemical deposition systems [124]. The first category

of these applications includes rapid detection of hydrocarbons at low concentrations and is of considerable interest to the automotive industry.

Ford Research Laboratory, in conjunction with the University of Alberta, is studying the catalytic behavior of porous GLAD films for microcalorimetric HC sensors [125]. This method compares the resistance changes between a membrane coated with a catalytic material (in their case platinum, or Pt) and a reference material, when both are subjected to hydrocarbons. Because of the high surface area of GLAD films, a magnification of the detection limit for these particles was expected. It was found, however, that although the performance of the tested films was superior to sputtered Pt films, they were not competitive with commercially available automotive honeycomb monoliths.

Although these results may be improved by optimizing the film thickness, the critical problem remaining is the significant degradation of both the GLAD and sputtered films after repeated use. This problem must be understood and addressed before GLAD films can seriously compete in this particular market.

Titania is a second catalytic material of interest. The columnar morphology in sputtered  $\text{TiO}_2$  has been shown to enhance both photocatalytic and photovoltaic efficiency [126, 127]. The Toyota Central Research and Development Laboratories assessed the photocatalytic activity of obliquely deposited  $\text{TiO}_2$  films on glass substrates [128]. Several film morphologies including chevrons, posts, and helices were fabricated. These films were evaluated by immersing the films in methylene blue solution, irradiating the samples with 350 nm wavelength light, and recording time dependent absorption spectra within the range  $200 < \lambda < 800$  nm.

Several films were tested with angles of incidence between  $0^\circ$  and  $82^\circ$ . All the obliquely deposited films performed slightly better than solid films, although the specific column morphology (i.e., chevron, post, and helical geometry) was not found to be as important as the deposition angle, which had an optimal value at  $\alpha = 70^\circ$ . This optimal value was confirmed by VFIGS simulations, which found  $\alpha = 70^\circ$  to yield a maximum in effective surface area regardless of the specific film morphology [86].

To explain how an optimal value may result from these films, a simplified argument is presented [129]. For many materials, structures of the film separate beyond  $\alpha = 70^\circ$ . If the porous film is treated as an arrangement of identical, isolated cylinders of height  $h$ , radius  $r$ , and occupying an area  $A$ , the resulting number density of columns is given by  $N = 1/A$ . The corresponding surface area of a single column thus scales as  $s \sim r(2h + r)$ , while the fractional density of the film scales as  $\eta \sim r^2/A$ . Hence, the surface area of the film per unit area of substrate scales as  $Ns \sim \eta(2h/r + 1)$ . Thus, for high surface areas, higher densities with long, narrow, isolated columns are preferred. As density is increased (i.e.,  $\alpha$  is decreased), the passages between film columns narrow and eventually close. The characteristic diffusion times for gaseous or liquid-borne species to enter or leave film must therefore increase.

As a result, there is a trade-off between the response time and the surface area for obliquely deposited films. In addition, the role of optical scattering of UV light on photocatalysis in porous films has yet to be assessed.

### 5.3.4. Lab-on-a-Chip

As a final example of enhanced surface area applications, we look at the current research activities taking place in molecular biology, particularly in the separation and identification of genetic materials and proteins. Presently, primarily capillary tubes with inner diameters of  $100 \mu\text{m}$  or more are used for this application [130]. These tubes do not lend themselves well to integration and require equipment which is large, expensive, and monofunctional. Microfluidic structures fabricated by photolithographic processes have been proposed as an alternative means by which genetic materials and proteins can be measured [131]. These structures have demonstrated performance which is similar to capillary tubes but have a compact size, promising increased speed and reduced cost while allowing far greater levels of integration. These areas of research have been termed the “lab-on-a-chip” concept [132].

A common feature to existing and conceived lab-on-a-chip analytical systems is the existence of microchannels. These channels not only provide passageways between different regions on the chip for fluid flow but typically incorporate filtering, separation, or high density reaction sites [133]. It has been shown that a porous  $\text{SiO}_2$  film can be grown in an etched microchannel (see Fig. 17) [134]. Precise alignment of the trench and source is required such that the flux arrives parallel to the trench direction, thus restricting the film morphology to either chevrons or oblique columns. Using this method, a surface area enhancement of two orders of magnitude was obtained.

The limitation in film morphology for this type of device may be removed through the use of raised topography, which was described in the previous section. If the channels are constructed as raised topography, a standard GLAD process can be used to form a variety of microstructure morphologies over the channel surface. This structure would be

**Figure 17.**  $\text{SiO}_2$  films are shown grown within an etched microchannel. Precise alignment of the flux and channel are required for proper microstructure growth. Reprinted with permission from [134], K. D. Harris et al., *J. Electrochem. Soc.* 147, 2002 (2000). © 2000, Electrochemical Society.

self-sealing at the edges and can be sealed on the top by depositing the appropriate capping layer.

#### 5.4. Magnetic Properties

It would not be unfair to say that the properties of magnetic microstructures are poorly understood. Although in recent years this understanding has grown immensely with the advent of better and faster computer simulations, much research still focuses on film characterization studies. What is well known, however, is that the microstructure of a magnetic thin film significantly affects its magnetic properties [54]. The ability to control the size, shape, orientation, and composition of the magnetic structure on a nanometer (or subdomain) scale offers a greater range in magnetic properties that can be controlled. This level of control can be applied not only to magnetic recording media (i.e., to increase storage densities) but also leads to the ability to test micromagnetic theories/modeling, and the fabrication of more innovative magnetic materials and devices.

Originally, it was thought that periodic GLAD pillars might serve as a suitable medium for high-density storage media. TEM and X-ray diffraction measurements of cobalt pillars grown on a chromium underlayer (to promote epitaxial growth in subsequent layers [135]) show the films to be monocrystalline, hexagonal close-packed structures with a strong crystal axis alignment perpendicular to the substrate. Reasonably defined periodic structures were shown to exhibit the equivalent of approximately 3 Gigabits/in<sup>2</sup>, assuming each particle consisted of a single bit [93]. Subsequent research using a TEM to etch a small sample indicated that nickel films might be grown with periods of less than 10 nm [58]. However, magnetic force microscopy imaging of the domain structure for these and previous films was inconclusive, and subsequent developments in this field (namely demonstrated storage density of over 25.7 Gigabits/in<sup>2</sup> in a commercial device by IBM, and potential research focusing on 1 Terabit/in<sup>2</sup> [136]) rapidly outpaced potential GLAD development.

Certainly, the possibility of growing unique microstructures for magnetic studies remains, and a few researchers have analyzed the hysteresis curves from several GLAD morphologies including columnar structures, helices, and posts [77, 93].

#### 5.5. Optical Properties

Optical properties of films deposited at both oblique and glancing angles have been a study of research for some time. Indeed, the initial experiments into sculptured thin films were borne through the possibility that the optical properties of a thin film could be manipulated by changing its structure [22, 26].

The application of the advanced GLAD technique to a deposition process can give the user considerable latitude in both planning and optimizing the optical properties of a thin film. Two simple examples are used here to introduce these concepts: rugate filters and diffraction gratings [137].

Rugate filters are fabricated when thin films exhibit a spatially modulated index of refraction. The GLAD technique can easily introduce this modulation by introducing

a density gradient across the film thickness (i.e., adjusting the flux incidence angle during deposition). By varying  $\alpha$  between 50° and 80°, filters have been fabricated which exhibit 82% reflection peaks and bandwidths of 50 nm centered at 460 nm [138]. The second example, diffraction gratings, results from the sinusoidal morphology at the cleaved edge of a helical film. This morphology acts like a diffraction grating oriented vertically.

These examples are not particular to the GLAD technique, however, and have been reported for less obliquely deposited films by other researchers (see, for instance, an example of a STF rugate in [139] and a Solč filter in [140]). It is hoped, however, that these references help introduce the reader to the power of simply rotating the substrate at oblique incidence to manipulate the optical properties of a thin film.

##### 5.5.1. Chirality in GLAD Structures

One of the unique properties of some GLAD film structures is their chirality, which is to say that their geometry is nonsymmetric [141]. A necessary and sufficient condition for chirality is that a chiral object cannot be superimposed by rotation and translation onto its mirror image. Some examples of chiral objects include Möbius strips, many types of complex molecules (generally organic substances), and, of course, one's hands. And, just like hands, chiral structures have a both a left- and right-handed version. Helical GLAD films (and their derivatives) are primary examples of chiral structures: their handedness depends on the direction of substrate rotation during deposition (i.e.,  $\varphi$  is clockwise or counterclockwise). An example of a left-handed GLAD helical film is shown in Figure 18.

The chiral nature of these GLAD structures becomes important when we consider the effect on their optical properties. Chiral crystals or molecular structures are known to exhibit optical activity, which is the rotation of the plane

**Figure 18.** An example of a chiral GLAD film. Here, a left-handed SiO<sub>2</sub> helical film with a pitch length of 410 nm and 8.4 turns is shown. Reprinted with permission from [129], D. Vick et al., Glancing angle deposition of thin films, *Res. Signpost*, in press. © 2002, Research Signpost.

of polarization of linearly polarized light [142]. The fundamentals of chiral optical activity were discovered in the mid-19th century, and were mostly studied by chemists who concentrated on natural optical activity (see [141] for a good review). This work led to Louis Pasteur's postulate stating that optical activity may arise due to the chirality of its molecules ([143], from [141]).

The chirality in a GLAD film, however, does not arise through the material but rather through the columnar shape (i.e., a form of artificial chiral media). Research on artificial chiral media initially occurred in the 1920s with experiments on wire spirals and microwave propagation [144, 145]. These results were later confirmed by Tinoco et al. [146, 147] who investigated electromagnetic activity with microwave radiation incident on copper wire helices in a box. The pitch length of these early studies was on the order of 1 centimeter, yielding electromagnetic (EM) activity in the microwave regime. In contrast, thin films (e.g., GLAD helices) can be fabricated with pitch lengths on the order of a few hundred nanometers, yielding EM activity in the visual spectrum ( $\lambda = 400$  to  $700$  nm).

### 5.5.2. Optical Activity

Earlier we mentioned work by Young and Kowal (1959) [26], who investigated optical activity by depositing films at oblique incidence ( $\alpha \sim 70^\circ$ ) onto rotating substrates. These films exhibited rotatory powers of around  $155^\circ/\text{mm}$  (as measured by the amount of angular rotation per thickness of film). In this and all examples that follow, the standard sign convention for optical rotation is used. If we define  $n_A$  as being the index of refraction of the structured material, while  $n_B$  is the index of refraction of the medium surrounding the material, a left-handed film with  $n_A > n_B$  produces a positive (clockwise, looking back at the light source) rotation in the plane of polarization for transmitted light. Its enantiomeric counterpart, a right-handed film produces a negative rotation. In the case where the structure is film material and the surrounding medium is air,  $n_A = n_{\text{film}}$  and  $n_B = n_{\text{air}}$ .

Young and Kowal's results were the first known work where artificial media showed an optical rotatory response. However, although advancement in the production and characterization of nonchiral, obliquely deposited films continued (primarily by groups in New Zealand [148] and Japan [28]), it was not until Robbie et al. [38] fabricated porous helical thin films using the GLAD technique that further spectroscopic measurements of optical activity in a chiral thin film were reported [149–151].

Leading up to Robbie's work, an extensive and growing body of work modeling the interaction of EM waves with chiral media had been reported (see for example, [152–154], and many other works by Lakhtakia). This theoretical modeling indicated that highly porous structures are not suitable for maximizing rotatory power. Experimental results have shown that GLAD films display an average rotatory power ranging from  $0.16^\circ/\mu\text{m}$  for  $\text{MgF}_2$  to  $1.05^\circ/\mu\text{m}$  for  $\text{Al}_2\text{O}_3$  [155], significantly less than that obtainable by denser films which have demonstrated rotation up to  $5^\circ/\mu\text{m}$  for titanium oxide films [156]. Perforated GLAD films, however, being the inverse of the GLAD template (described previously in Section 4.1), show a diminished porosity, while

maintaining the same geometric form. Analysis of optical rotation in right- and left-handed perforated films has found an improvement of up to three times over their GLAD templates. For example, right-handed perforated films had a measured rotation of  $3.93^\circ/\mu\text{m}$  compared to  $-1.53^\circ/\mu\text{m}$  for its template, and the left-handed perforated film had a measured rotation of  $-1.48^\circ/\mu\text{m}$  and  $0.49^\circ/\mu\text{m}$  for its template [92]. The measured power of the perforated film is the reversal of rotation displayed by their respective templates, since the refractive index gradient has been inverted with an air helix ( $n = 1$ ) surrounded by a photoresist matrix ( $n \sim 1.6$ ). The enhanced rotation in the right-handed film is not clear at this time, and both it and the generally stronger optical activity of the perforated films over their GLAD templates bear further study.

### 5.5.3. Liquid Crystal Hybrid Optics

Although the porous nature of GLAD films may not be the most optimal morphology for enhancing the rotatory power of thin films, it does allow for hybrid devices when combined with liquid crystals. These devices are not possible with dense films.

Optimizing the optical properties for liquid crystal (LC) devices requires control over the long-range orientation of the LC molecules. Two techniques serve as common examples of how this orientation is controlled. In the first, thin coatings of polyimides are applied to the substrate surface, which is subsequently rubbed to produce planar alignment of LCs [157]. In the second, obliquely deposited thin films are used as alignment layers to generate a certain "tilt" of LC molecules at the substrate [158, 159].

In both these examples, the influence on LC orientation is felt near the substrate surface only. Controlling the LC orientation in thicker switching cells (particularly with chiral or cholesteric LCs) becomes problematic and can lead to difficulties such as irreversible switching [160].

Techniques that are used to control the orientation of LC molecules through the film media make use of polymer-dispersed liquid crystals or photopolymerization. GLAD helical films can provide an alignment structure or "backbone" for the LC, inducing a chiral nematiclike ordering in nonchiral LC materials. GLAD films filled with birefringent materials such as nematic LCs, for example, show an enhanced transmission difference between left- and right-circularly polarized (LCP and RCP respectively) light [161]. This difference was removed when the films were filled with an isotropic liquid such as water or some polymer materials which had indices of refraction approximately matching the film material.

Switching cells were demonstrated using a  $\text{SiO}_2$  LC/GLAD hybrid [162, 163] fabricated by depositing the GLAD film on glass substrates with an indium tin-oxide (ITO) electrode. A counterelectrode was provided by another ITO coated glass substrate. When brought together, these two pieces form a "sandwich" which can subsequently be filled with LCs (see Fig. 19). Switching can then be accomplished by exploiting the dielectric anisotropy of the LCs. In the unaddressed state (no voltage applied), the LC orientation is controlled by the presence of the GLAD chiral films. Hence, an enhanced transmission is observed. In the

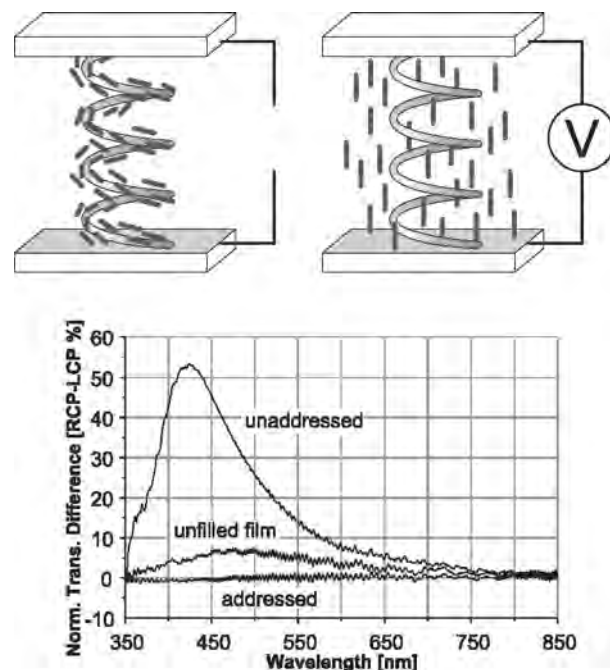

**Figure 19.** Electro-optic switching cells for GLAD/LC composites are constructed from two ITO coated glass substrates containing a LC filled GLAD thin film. The fill port is present to add the LCs after the GLAD film “sandwich” is fabricated. This port is plugged before use. Reprinted with permission from [162], J. C. Sit et al., *Liq. Cryst.* 27, 387 (2000). © 2000, International Society for Optical Engineering (SPIE).

addressed state (a 200 V<sub>pp</sub>, 1 kHz signal applied), the LCs align parallel to the applied field, and no transmission difference between LCP and RCP occurs. In this latter case, light transmitted through the cell along the helical axis (which is now parallel to the LCs) “sees” the ordinary refraction index  $n_0$  of the LC. If the  $n_0$  index matches with the index of refraction of the film, the cell appears to be a homogenous medium ( $n = n_0 = n_{\text{film}}$ ). Thus the chiral optical response vanished in the addressed mode. An illustration of both the addressed and unaddressed states is shown in Figure 20. The lower panel of this diagram shows the transmission difference observed between these two states.

Increasing the porosity of the films allows for a greater degree of LC filling, at the cost of a lower deposition rate (which is dependent on the cosine of  $\alpha$ ). Additionally, when the film microstructures become further separated, the order of LC molecules can become more randomized, resulting in a degradation of the film’s optical properties. These effects must be balanced in an optimal structure. This point has been found to occur at  $\alpha = 85^\circ$  for a similar film to the hybrid example described above [155].

Filling GLAD films with LCs has two beneficial side-effects: The matrix of LCs more closely matches the index of refraction of the film materials, resulting in less light scatter in the film/LC hybrid devices, and the risk of contamination by ambient humidity (which would degrade the effectiveness of the devices) is reduced [164].

**Figure 20.** Electro-optical switching in GLAD/LC composites consists of two steps: in the unaddressed state (top left), the LC is aligned by the chiral GLAD medium and exhibits a transmission difference between right and left circularly polarized light; when an electric field is applied (top right), the LC molecules align and the transmission difference disappears. Lower panel reprinted with permission from [162], J. C. Sit et al., *Liq. Cryst.* 27, 387 (2000). © 2000, International Society for Optical Engineering (SPIE). Upper panels reprinted with permission from [41], J. C. Sit, *Thin Film/Liquid Crystal Composite Optical Materials and Devices*, Ph.D. Thesis, University of Alberta, Edmonton, 2002.

#### 5.5.4. Photonic Bandgap Optics

A second optical application for GLAD films has been closely investigated. Photonic bandgap (PBG) crystals are artificial, periodic structures which exhibit the characteristics of a bandgap for light. In other words, the propagation of electromagnetic waves within the frequency range of the bandgap is restricted [51, 52, 165]. Hence, a photonic bandgap crystal is the light analogy to the bandgap in a semiconductor material which restricts electron movement based on their energies. This “stop-band” must lie in all directions in the lattice, requiring a three-dimensional structure. Three-dimensional photonic bandgap crystals with a periodicity which exhibit a stop-band falling in or near the visible spectrum are of particular interest.

Recently, it was proposed that a square spiral microstructure should exhibit a large 3D photonic bandgap [50, 166]. This structure consisted of a tetragonal lattice of square spiral posts and was based on the distortion of nonstandard diamond helices. It was suggested that the GLAD process might be ideally adapted to form this morphology.

Soon after this “challenge” was issued, the structures were fabricated using prepatterned substrates and advanced GLAD control [45]. These structures are shown in Figure 21. Here, photolithography was used to design substrate topography with lattice seed diameters of 500 nm and separations of 1  $\mu\text{m}$ . Further optimization of the process

**Figure 21.** A tetragonal square spiral GLAD film which has been suggested as a potential three-dimensional, photonic bandgap material. A side view of this film is shown in the inset. Reprinted with permission from [45], S. Kennedy et al., *Nanoletters* 2, 59 (2002). © 2002, American Chemical Society.

should yield a structure even closer to what the theory originally envisioned.

Photonic bandgap materials manipulate light through the introduction of lattice defects. These defects allow for the confinement and guiding of light, requirements for the application of these media in photonics and integrated optics. As mentioned in Section 2.2.5, these defects can be introduced into a periodic GLAD film without degradation to the microstructure growth [56]. Defects in the seed topography transfer to the film, as the extreme flux incidence angle ensures that there is little or no flux coverage over the non-seeded region. Provided that this defect area is not on the order of the shadowing distance cast by individual seeds, the uniformity of the periodic film is preserved.

A subsequent series of processing steps can be applied to the square spiral films to yield a structure that exhibits an even larger PBG. An inverse square spiral film, which can be fabricated using the perforated film recipe described in Section 4.1, is expected to have a PBG approximately twice the size of the standard structure ( $\sim 24\%$  of the central band frequency, compared with  $\sim 16\%$  [166] of the central band frequency exhibited by the standard structure). At the time of this publication, this structure has not yet been presented.

## 6. CONCLUSION

This review has introduced a promising and versatile tool for materials engineering at the submicrometer scale. GLAD films can be fabricated with relative ease from a variety of materials and are readily incorporated onto lithographically prepared and micromachined surfaces. Examples of such surfaces include interdigitated electrodes, microcantilevers, mesa arrays, and microfluidic channels. In some proposed applications, such as sensors, the films would play an active role in a device. Alternatively, the films may serve as supporting matrix for the active component (e.g., embedded liquid crystals), or as a template in a manufacturing stage

(e.g., porous membranes). The successful demonstration of low defect periodic GLAD arrays is of particular significance and could lead to a method for the manufacture of photonic bandgap devices. It will also be evident from this chapter that much work will be required on both fundamental and applied fronts before this technology fully matures. We may expect a rapid expansion of the field in the coming years as more researchers incorporate GLAD films into their processes and devices.

## LIST OF SYMBOLS

$\alpha$	The angle of incident flux at the substrate measured relative to the substrate normal.
$\Delta\alpha$	A measure of the angular distribution in flux incident at the substrate.
$a$	The normalized column separation as determined by Tait's rule.
$\beta$	Columnar angle measured relative to the substrate normal.
$\chi_c$	Columnar angle measured relative to the substrate plane.
$\chi_v$	The angle of incident flux measured relative to the substrate plane.
$\delta$	The optimized period of seed elements used to grow periodic GLAD structures. At this period, film growth occurs only at the locations of seed elements. In other words, $\delta \equiv p_{\text{optimized}}$ .
$d$	The "average" separation of randomly grown GLAD columns.
$\varphi$	Rotation angle about an axis located at the substrate center, and parallel to its normal.
$p$	The period of seed elements used to grow periodic GLAD structures.
$p_c$	Ambient chamber pressure. For evaporation, $p_c$ is less than $10^{-5}$ Torr ( $10^{-3}$ Pa) and typically on the order of $10^{-6}$ Torr ( $10^{-4}$ Pa) for refractory metals. For sputtering, $p_c$ is on the order of $10^{-3}$ to $10^{-2}$ Torr (0.1 to 1.0 Pa).
$\rho$	Thin film density.
$s$	The diameter of columns grown using the GLAD technique.
$T$	Substrate or film surface temperature.
$t$	The thickness (i.e., height) of individual seed elements used to grow periodic GLAD structures. This parameter, coupled with the flux incidence angle, helps determine the optimal seed period.
$T_m$	Melting temperature of source material.

## GLOSSARY

**3D-films** A 3D, Monte Carlo ballistic simulator, based on the SIMBAD program, which models the creation and dynamic evolution of 3D microstructures in PVD thin films.

**Adatoms** Incident atoms which have transferred their kinetic energy to the substrate lattice and become loosely bound to the surface.

**Ballistic deposition (BD)** Modeling which treats flux as arriving colinearly at the substrate surface. Adatom diffusion and surface shadowing are the primary growth mechanisms.

**Bulk diffusion** Movement of atoms within the film. This process is characteristic of Zone 3 films as described by the Movchan and Demchishin structure zone model.

**Chirality** Material property describing its nonsymmetric geometry. A chiral object cannot be superimposed by rotation and translation onto its mirror image.

**Collimated sputtering** The process by which sputtered atoms outside a desirable incidence angle range are mechanically inhibited from striking the substrate. A honeycomb sheet-metal array is placed perpendicular to and between the target and substrate plane. Although  $\Delta\alpha$  is minimized, the deposition rate at the substrate surface is significantly reduced.

**Column competition** The process by which thin film columns extinguish their neighbors due to shadowing at extremely oblique flux incidence angles. The resulting decrease in column number density is compensated by an increase in individual column diameters, leaving the overall film density constant.

**Columnar growth** The tendency of PVD thin films to grow columnar microstructures. These columns are oriented in the direction of the flux source.

**Chemical vapor deposition (CVD)** A volatile material compound reacts chemically with other gases to produce a nonvolatile solid that deposits onto a substrate as a film.

**Electron beam lithography (EBL)** Technique for creating extremely high resolution patterns. EBL consists of scanning an electron beam across a resist sensitive to electron irradiation, while controlling the beam to create any desired two-dimensional pattern. The technology is capable of creating an infinite number of patterns in a variety of materials at sub-50 nm resolution. However, although very versatile, EBL is more expensive and considerably slower than photolithography.

**Evaporation** The controlled transfer of gaseous atoms from a heated source to a substrate where film forms.

**Porosity** A solidity measurement for a thin film. This parameter is inversely proportional to the density of the thin film compared to its bulk counterpart and is sometimes used as an expression of surface area. Film porosity tends to increase with increasing flux incidence angle and, most significantly, within the glancing incidence regime ( $\alpha > 80^\circ$ ).

**Glancing angle deposition (GLAD)** The use of substrate rotation and flux incidence angle variation to fabricate a range of thin film morphologies with controlled structure and porosity. This technique requires columnar vapor flux to be deposited at extremely oblique incidence angles ( $\alpha > 80^\circ$ ).

**Incident flux** Term used to describe source vapor arriving at the substrate. Usually implies a directional component.

**Lab-on-a-chip** Chemical analyses wherein processing, transport, etc., occur in microchannel structures located on-chip.

**Liquid crystals (LC)** Term used for a type of organic molecule having inherent optical anisotropy. Strongly birefringent media are produced when the molecules are purposefully aligned.

**Low-pressure, long-throw (LPLT) sputtering** Technique by which the sputtering target and substrate are separated by a

relatively large distance (typically greater than 15 cm), and the plasma is ignited under low chamber pressures [ $p_c < 1$  m Torr (0.1 Pa)]. This process attempts to minimize  $\Delta\alpha$  by increasing the mean-free path of particles in the chamber. Flux arrives at the substrate with a linear trajectory, though not necessarily with an origin at the source due to collisions with the working gas atoms.

**Microfluidics** The study of microliter quantities of flowing fluids usually confined to microchannels.

**Movchan and Demchishin SZM** One of the first structure zone models to classify continuous film structure according to substrate temperature during deposition. Three “zones” of film texture are identified: Zone 1, where atomic shadowing effects predominate ( $T/T_m < 0.3$ ); Zone 2, where surface diffusion effects predominate ( $0.3 < T/T_m < 0.5$ ); and Zone 3, where bulk diffusion effects predominate ( $T/T_m > 0.5$ ).

**Motohiro–Taga interface** The transition region occurring when the column angle is abruptly altered through a change of flux incidence angle. The resulting microstructure is similar in form to a chevron, with the apex being the Motohiro–Taga interface.

**Nanoindentation** A process by which a small probe compresses a thin film surface to obtain force versus displacement curves under a variety of loading conditions.

**Normal incidence** A condition for deposition where the substrate is held perpendicular to the incident flux. This substrate configuration typically maximizes the film deposition rate while minimizing surface shadowing effects.

**Oblique deposition** A condition for deposition where the substrate is inclined relative to the incident flux. Columnar growth is inclined toward the flux source.

**Optical activity** Rotation of the plane of polarization for light transmitted through a material.

**Photonic bandgap (PBG) crystals** Artificial, periodic structures.

## ACKNOWLEDGMENTS

The authors thank our colleagues in the Nanotechnology and Microdevices Research Group in Electrical and Computer Engineering at the University of Alberta for their suggestions during the writing of this review. The contributions of Michael Colgan, Martin O. Jensen, Ken Harris, and Douglas Vick are particularly acknowledged for their assistance in editing the final manuscript. We also make special note of George D. Braybrook for his excellent SEM imaging of many of the structures presented in this chapter. This work has been supported in part by the Natural Sciences and Engineering Research Council of Canada (NSERC), Alberta Informatics Circle of Research Excellence (iCORE), and Micalyne, Inc.

## 1. INTRODUCTION

Nanofibers are solid-state linear nanomaterials characterized by flexibility and an aspect ratio greater than 1000:1. According to the National Science Foundation (NSF), nanomaterials are matters that have at least one dimension equal to or less than 100 nanometers. Therefore, nanofibers are fibers that have diameter equal to or less than 100 nm. Materials in fiber form are of great practical and fundamental importance. The combination of high specific surface area, flexibility, and superior directional strength makes fiber a preferred material form for many applications ranging from clothing to reinforcements for aerospace structures. Fibrous materials in nanometer scale are the fundamental building blocks of living systems. From the 1.5-nm double helix strand of DNA molecules, including cytoskeleton filaments with diameters around 30 nm, to sensory cells such as hair cells and rod cells of the eyes, nanoscale fibers form the extracellular matrices or the multifunctional structural backbone for tissues and organs. Specific junctions between these cells conduct electrical and chemical signals that result from various kinds of stimulation. The signals direct normal functions of the cells such as energy storage, information storage and retrieval, tissue regeneration, and sensing.

Analogous to nature's design, nanofibers of electronic polymers and their composites can provide fundamental

building blocks for the construction of devices and structures that perform unique new functions that serve the needs of mankind. Other areas expected to be impacted by the nanofiber based technology include drug delivery systems and scaffolds for tissue engineering, wires, capacitors, transistors and diodes for information technology, systems for energy transport, conversion and storage, such as batteries and fuel cells, and structural composites for aerospace structures.

Considering the potential opportunities provided by nanofibers, there is an increasing interest in nanofiber technology. Amongst the technologies including the template method [1, 48], vapor grown [2], phase separation [3], and electrospinning [4–20], electrospinning has attracted the most recent interest. Using the electrospinning process, Reneker and Chun [4] demonstrated the ability to fabricate nanofibers of organic polymers with diameters as small as 3 nm. These molecular bundles, self-assembled by electrospinning, have only six or seven molecules across the diameter of the fiber! Half of the 40 or so parallel molecules in the fiber are on the surface. Collaborative research in MacDiarmid and Ko's laboratory [5] demonstrated that blends of non-conductive polymers with conductive polyaniline polymers and nanofibers of pure conductive polymers can be electrospun. Additionally, *in-situ* methods can be used to deposit 25-nm-thick films of other conducting polymers, such as polypyrrole or polyaniline, on preformed insulating nanofibers. Carbon nanotubes, nanoplatelets, and ceramic nanoparticles may also be dispersed in polymer solutions, which are then electrospun to form composites in the form of continuous nanofibers and nanofibrous assemblies [6]. Specifically, the significance of fiber size effect has been recognized.

### 1.1. Effect of Fiber Size on Surface Area

One of the most significant characteristics of nanofibers is the enormous availability of surface area per unit mass. For fibers having diameters from 5 to 500 nm, as shown in Figure 1, the surface area per unit mass is around 10,000 to 1,000,000 m<sup>2</sup>/kg. In nanofibers that are 3 nm in diameter, and which contain about 40 molecules, about half of the molecules are on the surface. As seen in Figure 1, the high surface area of nanofibers provides a remarkable capacity

**Figure 1.** Effect of fiber diameter on surface area. Reprinted with permission from D. H. Reneker.

for the attachment or release of functional groups, absorbed molecules, ions, catalytic moieties, and nanometer-scale particles of many kinds.

## 1.2. Effect of Fiber Size on Bioactivity

Considering the importance of surfaces for cell adhesion and migration, experiments were carried out in the Fibrous Materials Laboratory at Drexel University using osteoblasts isolated from neonatal rat calvaria and grown to confluence in Ham's F-12 medium (GIBCO), supplemented with 12% Sigma fetal bovine on PLAGA sintered spheres, 3D braided filament bundles, and nanofibrils [7]. Four matrices were fabricated for the cell culture experiments. These matrices include, (1) 150- to 300- $\mu\text{m}$  PLAGA sintered spheres, (2) unidirectional bundles of 20- $\mu\text{m}$  filaments, (3) 3D braided structure consisting of 20 bundles of 20- $\mu\text{m}$  filaments, (4) nonwoven matrices consisting of nanofibrils. The most proliferate cell growth was observed for the nanofibrils scaffold as shown in the thymidine-time relationship illustrated in Figure 2.

## 1.3. Effect of Fiber Size on Electroactivity

The size of conductive fiber has an important effect on system response time to electronic stimuli and the current carrying capability of the fiber over metal contacts.

**Figure 2.** Effect of size on cell growth. Reprinted with permission from [47], F. Ko and C. Laurencin, "Society of Biomaterials Proceedings," 1998. © 1998, Society of Biomaterials.

In a doping-de-doping experiment, Norris et al. [8] found that polyaniline/PEO submicron fibrils had response time an order of magnitude faster than that of bulk polyaniline/PEO. There are three types of contact to a nano polymeric wire: ohmic, rectifying, and tunneling. Each is modified due to nano effects. There exist critical diameters for wires below which metal contact produces much higher barrier heights, thus showing much better rectification properties. According to Nabet (unpublished report), by reducing the size of a wire we can expect to simultaneously achieve better rectification properties as well as better transport in a nano wire. In a preliminary study [64], as shown in Figure 3, it was demonstrated, using submicron PEDT conductive fiber mat, that significant increase in conductivity occurs as the fiber diameter decreases. This could be due to intrinsic fiber conductivity effect or the geometric surface and packing density effect or both as a result of the reduction in fiber diameter.

## 1.4. Effect of Fiber Size on Strength

Materials in fiber form are unique in that they are stronger than bulk materials. As fiber diameter decreases, it has been well established in glass fiber science that the strength of the fiber increases exponentially due to the reduction of the probability of including flaws. As the diameter of matter gets even smaller as in the case of nanotubes, the strain energy per atom increases exponentially, contributing to the enormous strength of over 30 GPa for carbon nanotube.

Although the effect of fiber diameter has long been recognized, the practical generation of fibers down to the nanometer scale was not realized until the rediscovery and popularization of the electrospinning technology by Professor Darrell Reneker almost a decade ago [9]. The ability to create nanoscale fibers from a broad range of polymeric materials in a relatively simple manner using the electrospinning process coupled with the rapid growth of nanotechnology in recent years have greatly accelerated the growth of nanofiber technology. Although there are several alternate methods for generating fibers in a nanometer scale, none matches the popularity of the electrospinning technology due largely to the great simplicity of the electrospinning process. Accordingly, our review will be focused

**Figure 3.** Conductivity vs. fiber diameters of a PEDT polymer.

on the electrospinning technology. We will begin with a general overview of the electrospinning technology. The significance of the various processing parameters in solution electrospinning is discussed, followed by a review of the limited work on melt electrospinning. The structure and properties of the fibers produced by the electrospinning process are then examined with particular attention to the mechanical and chemical properties. There is a gradual recognition that the deceptively simple process requires a deeper scientific understanding and engineering development in order to capitalize on the benefits promised by the attainment of nanoscale and to translate the technology from a laboratory curiosity to a robust manufacturing process. Some of the initial efforts in modeling of electrospinning process are reviewed in Section 6. This chapter is closed with a review of the potential applications of nanofibers and a conclusion and projection of the future direction of nanofiber technology.

## 2. FORMATION OF NANOFIBERS

Perhaps the history of this subject begins in 1745 when Bose created an aerosol spray by applying a high potential to a liquid at the end of a glass capillary tube. The ideology behind what is now known as electrospinning was furthered when Lord Rayleigh calculated the maximum amount of charge which a drop of liquid can hold before the electrical force overcomes the surface tension of the drop [10]. On October 2, 1934, Anton Formhals [11] was issued a patent for a process capable of producing monofilament fibers on a micron size scale using the electrostatic forces generated in an electrical field on a variety of solutions. The patent describes how the solutions are passed through an electrical field formed between electrodes in a thin stream or in the form of droplets in order to separate them into groups of filaments. This process, later to become known as a variant of electrospinning, allows the threads, which are repelling each other when placed in the electrical field, to pile up parallel to each other on the filament collector in such a way that they can be unwound continuously in skeins or ropes of any desired length.

In December, 1969, Sir Geoffrey Taylor published a paper titled "Electrically driven jets" describing the shape of the droplet at the end of a tube filled with a viscous fluid when applied to an electrical field. Taylor first introduced the formation of a cone and the resulting jet that forms on the apex known nowadays as the "Taylor cone" [12].

Taylor's contribution was actually the measurement of the potential required to form the Taylor cone for a variety of viscous liquids and then the comparison of these measurements with mathematical calculations. In his paper the derivation began with the expression for the equilibrium state of a droplet at the end of a pressurized tube. The coefficients for the electrostatic potential were then generated by observing the deflection of charged solutions at the end of an inverted capillary:

$$V_c^2 = 4 \frac{H^2}{L^2} \left( \ln \frac{2L}{R} - \frac{3}{2} \right) (0.117\pi\gamma R) \quad (1)$$

where  $V_c$  is the critical voltage,  $H$  is the separation between the capillary and the ground,  $L$  is the length of the capillary,

$R$  is the radius of the capillary, and  $\gamma$  is the surface tension of the liquid.

A similar relationship was developed [13] for the potential required for the electrostatic spraying from hemispherical drop pendant from a capillary tube:

$$V = 300\sqrt{20\pi\gamma r} \quad (2)$$

where  $r$  is radius of the pendant drop. In each case, the conducting drop was assumed to be surrounded by air, and suspended at a stable distance from the capillary tube.

These equations are the appropriate physical models for the formation of a droplet of slightly conducting, monomeric fluids. By examining a small range of fluids, Taylor determined that a 49.3° equilibrium angle balanced the surface tension with the electrostatic forces, and used this value in his derivation. However, it was later shown that the conductivity and the viscosity of the fluid both play vital roles in the electrostatic atomization process and can greatly influence the equilibrium angle as well as other aspects of the process [4]. This dependence on conductivity and viscosity was missing from the previous two equations; however, this relationship between surface tension and applied voltage still serves as a useful guide for slightly conducting, medium-to-low viscosity solutions.

Baumgarten advanced the field by being amongst the first to take the existing atomization techniques and apply them to a polymer solution [14]. He was able to determine the voltage required in order to be capable of electrospinning a PAN/DMF solution, and he also observed a dependence of the fiber diameter on the solution viscosity described through the following equation:

$$d = \eta^{0.5} \quad (3)$$

where  $d$  is fiber diameter, and  $\eta$  is solution viscosity (in poise).

Baumgarten also showed that the diameter of the jet reached a minimum after an initial increase in field strength and then became much larger with increasing fields. This effect was caused by the feed rate of the polymer solution being pulled through the capillary and illustrates one of the many complexities of the electrospinning process. That is, increasing the field does increase the electrostatic stresses, therefore creating smaller diameter fibers, but it also reduces the size of the Taylor cone and draws more material out of the syringe.

Larrondo and Manley observed that the fiber diameter decreased with increasing melt temperature as a result of the decreasing value of the viscosity due to the free movement of the molecular chains. They were able to draw a qualitative correlation between diameter and viscosity [15]. They also determined that doubling the applied electric field decreased the fiber diameters by roughly half. Larrondo and Manley also showed that the strain rate in the spinning jet is an important parameter for orienting the polymer molecules along the fiber axis.

In 1986, another paper was published by Hayati et al. [16] studying the effect of the electric field and the surrounding environment on pendant drops and the factors affecting the formation of stable jets. In this paper it was concluded that

the liquids conductivity is a major factor in the electrostatic disruption of the surface. For example, with conducting liquids such as water, very unstable streams were produced. With insulating liquids such as paraffin oil, no disruption occurred due to lack of sufficient free ions in the bulk liquid. Stable jets having a conical base were only produced with semiconducting liquids (nonpolar liquids with dissolved ionic materials). They also concluded that the cone angle at the base of the jet increased, whereas its length decreased, with an increase in applied voltage. This was in agreement with the experimental results that Baumgarten was observing.

At higher voltages, there have been reports of secondary jets splaying from the primary jet. The number of these splays increases with an increase in the applied field. As the electric field is increased further, the shape of the droplet deforms and in some cases a phase is present in which the droplet simply drips onto the collection plate. Continuing to increase the applied electric field, a potential is reached that is slightly larger than that needed to cause instability of the liquid meniscus. At this critical potential, the liquid ejects either a small droplet or a long filament as was observed by Baumgarten and Lorrondo and Manley.

In case of an insulating liquid, the surface charge is small and hence no appreciable electrostatic force can build up at the interface. The liquid behaves as a dielectric in a nonuniform field which will seek the region of highest field intensity; in this case, the tip of the capillary. In the case of a highly conducting liquid such as water, when the voltage was increased, the pulsating and dripping modes could be observed. However, by further increasing the potential, very unstable streams were produced from the drop which whipped around in different directions. In case of semiconducting liquid such as Isopan M + butanol (conductivity =  $3.3 \times 10^{-7} \text{ S/m}^1$ ), the stable jets could be produced, using an applied voltage of 10–12.5 kV. With an increase in voltage, the conical base of the jet, near the capillary, expands as its cone angle widens, and the cone height becomes shorter.

By measuring the critical voltage for stable jet formation using these capillaries at a constant flow rate [12], it became clear that the small capillaries were most suitable for the formation of stable jets of highly conductive liquids. However, with low conductivity liquids, wide capillaries were needed in order to form a stable jet. For a conductivity in the intermediate range ( $7.14 \times 10^{-9}$  to  $2.22 \times 10^{-6} \Omega^{-1} \text{ m}^{-1}$ ), the effect of capillary diameter, at constant flow rate, altered the velocity of the liquid issuing from the capillary, the velocity being measured as the ratio of the mass flow rate to the cross-sectional area of the tube [16, 17].

The description of electrospinning phenomenon, as seen in Figure 4, was introduced by Smith in 1994 [18]. In his paper he derived the relationship between the capillary radius, capillary plane distance, and the applied voltage:

$$V_0 = A_1 \left[ \frac{2Tr \cos \theta_{0c}}{\epsilon_0} \right]^{0.5} \ln \left( \frac{4h}{r_c} \right) \quad (4)$$

where  $T$  is surface tension,  $\theta_0$  is cone half angle, and  $\epsilon_0$  is permittivity of free space.

Finally he reached the following three conclusions:

1. As capillary radius increases, the onset potential should increase.

Figure 4. Schematic of an electrospinning station.

2. As the plane distance increases, the onset potential should increase.
3. As the surface tension increases, the onset potential should increase.

In 1995, Doshi and Reneker [9] started using electrospinning as a technique to produce small diameter fibers. In their paper they used poly(p-phenylene terephthalamide) to produce Kevlar fibers with superior physical properties using a dry-jet-wet spinning technique assisted by electrostatic charges. Monofilament Kevlar fibers ranging from 13 to 18  $\mu\text{m}$  were produced with an applied voltage of 12 to 18 kV at a distance of 3 cm in a vertical arrangement.

Doshi and Reneker [9] then shortly described the electrospinning process, processing conditions, fiber morphology, and some of the possible uses of electrospun fibers made from polyethylene oxide (PEO) of (molecular weight)  $M_w = 145,000 \text{ g/mol}$ . They found that for viscosities below 800 centipoise, the polymer solution was too dilute to form a stable jet, and at viscosities higher than 4000 centipoise it was difficult to form fibers due to a lack of sufficient solvent in the solution.

Doshi and Reneker [9] used concentrations varying from 1% to 7%, by weight, and concluded that as the concentration increases, the required voltage to successfully spin is increased. For example, for concentrations of 2.5% and 5%, by weight, the required voltages to electrospin were 9 kV and 12 kV, respectively. This paper also observed that the diameter of the jet increased as the distance between the spinneret and the target decreased due to the shorter time period the stream had to elongate. More than 20 polymers including PEO, nylon, imides, DNA, aramids, and polyaniline have been electrospun by Reneker's group [4].

Buchko et al. [13] proved that polymeric solutions behave differently compared to monomeric liquids during electrostatic atomization in that they persist as elongated jets over a much greater distance. A wide variety of synthetic and natural polymers were electrospun from solution and several polymers including poly(propylene) and poly(ethylene) were

electrospun from the melt. One major difference in the production of fibers from different mediums is the final size. When electrospinning from solution, fibers on the nanometer scale have been successfully produced. On the other hand, melt spun fibers were considerably larger, ranging from tens to hundreds of microns [15].

Nanofibers of aromatic heterocyclic polybenzimidazole (PBI), with a diameter of 300 nm, were later produced by Kim and Reneker [10]. They produced sheets of nonwoven fabric about 8 cm wide and 50 cm long with a compressed thickness of a few microns. The mass per unit area of these sheets was a couple of  $\text{g/m}^2$ . The electro-spun PBI fibers were also found to be birefringent, which indicated that the molecules were to some degree aligned.

Although a vast majority of the research devoted to the production of nanofibers has concentrated on electrospinning, it is important to mention the other experiments that have been and continue to be utilized. It was shown that nanofibers can be made using a radiation polymerization of vinyl monomers trapped in clathrate crystals. This process does not yet allow for the formation of continuous nanofibers but allows for the formation of fibers several microns in length [1]. The architecture of the clathrates is quite similar to that of a tunnel. Multiple tunnels can be placed next to one another and it is possible to have highly oriented nanofibers once the polymerization has occurred.

Other research has mimicked the process to make carbon nanotubes to produce carbon nanofibers using a chemical vapor deposition (CVD) process. In a horizontal tubular reactor, benzene can be used for the carbon source, hydrogen as a carrying gas, and thiophene as the growth promoter. The tube is heated to 1373 K at a speed of 25 °C per minute allowing hydrogen gas to flow into the benzene solution containing thiophene and then into the reaction tube. The ratios of the above can be changed to affect the final diameter of the vapor grown carbon nanofibers [19]. Researchers have been able to successfully produce nanofibers in bulk ranging from 50 to 200 grams per experiment. Using this technology, fibers ranging from 50 nm to several hundred nanometers have been produced [2]. Again, the limiting aspect of this technology is the capability of producing continuous nanofibers.

One final method that has been used to produce nanofibers recently is a method called “islands in the sea” [3]. This method is a combination of two polymers, one implanted inside the other. Islands in the sea uses a special spinneret that allows two polymers to be extruded at once. One polymer acts as the core and another polymer acts as the sheath. Once the fiber(s) has been extruded from the melt, the sheath layer is dissolved using some known solvent, leaving behind several smaller core fibers. It is obvious that the more islands that can be packed into the sea, the smaller the end diameter will be. Hills Inc., in collaboration with North Carolina State University, has produced fibers with up to 3000 islands in the sea, resulting in fibers as small as 500 nm [20]. This may be the best and most efficient way to produce continuous and highly aligned nanofibers, but where this process suffers is the extreme cost that is experienced with such high-tech machinery.

## 3. SOLUTION ELECTROSPINNING

### 3.1. Introduction

Over the years, many papers have been published observing the effects of a single parameter on the electrospinning process. Researchers have developed a relationship between the molecular weight and the concentration to describe the spin-ability of PEO in an aqueous solution [9]. The observation was made that the jet will break up more readily when a lower viscosity solution is being used. Thus, the solution or melt viscosity was shown to affect both the processing window for electrospinning and the diameter of the fibers that were being produced.

Numerous polymers have been electrospun by several groups across the country as shown in Table 1. With solvents of varying pH, polymers with molecular weights ranging from 10,000 to 300,000 and above have been electrospun. An accurate statement can be, “If it has been made, someone has tried to electrospin it.”

### 3.2. Processing Parameters

#### 3.2.1. Voltage

One of the most important and recent studies made by Deitzel et al. [21, 53, 59] on the effect of processing variables on the morphology of electrospun nanofibers concluded that the morphology of the nanofibers produced from PEO is influenced strongly by parameters such as feed rate of the polymer solution, electrospinning voltage, and other properties of the solution such as concentration, viscosity, and surface tension. They also concurred that an increase in the voltage changed the shape of the surface from which the electrospinning jet originated. This shape change was correlated with an increase in the number of beaded defects forming amongst the electrospun fibers as seen in Figure 5.

**Table 1.** List of various polymers that have been electrospun.

Polymer	Solvent	Ref.
Rayon		[11]
Acrylic resin	dimethyl formamide	[14]
PE, PPE	melted	[15]
PEO	water	[4]
PPTA (Kevlar)	98% sulfuric acid	[42]
Polyester	1:1 dichloromethane: trifluoroacetic acid	[49]
DNA	70:30 water:ethanol	[27]
PAN	dimethyl formamide	[5]
Styrene-butadiene- styrene triblock	75:25 tetrahydrofuran/ dimethylformamide	[45]
PVA/nylon 6,6	n/a	[44, 61]
PAN and Pitch	dimethyl formamide	[43, 63]
PANi/PEO	chloroform	[8]
PEO	water	[21]
Silk	HFA-hydrate	[51, 54, 62]
CNT/PAN	DMF	[25]
Polyurethane	DMF	[58]
Nylon-6	95:5 HFIP/DMF	[60]
Poly(ethylene-co-vinyl alcohol)	2-propanol/water	[57]

Figure 5. Effect of viscosity on fiber morphology.

### 3.2.2. Concentration/Viscosity

Deitzel [53, 59] also noticed that the diameter of the electrospun PEO fibers increased with solution concentration according to the power law relationship while other noticed, as in Figure 6, that it followed the function of  $x^2$ . This observation was in agreement with others that observed that the polymer's ability to be electrospun was directly dependent on its viscosity. Also, general properties such as surface area of the electrospun fiber mats were evaluated. The textiles were found to have specific surface area in the range of 10–20 m<sup>2</sup>/g. It was also stated that the analysis of the produced fibers by WAXD and DSC showed poor development of any crystalline order.

### 3.2.3. Berry Number

In his study of intrinsic viscosity, Berry developed a number called the Berry Number (Be). Be was used as a measure of molecular conformation [22–24]. This number was the product of the intrinsic viscosity and concentration. Han [50] utilized the work of Berry in an attempt to further understand electrospinning. It has been well documented that the concentration has a major role on the electrospinning process. Han discovered, with PAN, that if the Be was lower than 1, beads would be formed because the viscosity of the solution would not be sufficient to hold together during the electrospinning process. In the other cases (a Be from 1 to 4), the fiber diameters steadily increased as seen in the below chart. Han's study was the first to use Be for electrospinning. It was

Figure 6. Effect of concentration on fiber diameter.

later shown by Ali that the Be is a function of the polymer being spun and the numbers are not contained between 1 and 4, but this remains an effective way to classify the polymer solution [25].

### 3.2.4. Alternative Fields

In another study, Deitzel et al. [26] tried to control the deposition area of the electrospun PEO fibers by using multiple field electrospinning apparatus that applied a secondary external field of the same polarity as the surface charge on the jet. This mechanism allowed for a greater control over the deposition of the electrospun fiber on a surface and permitted collection of the electrospun fibers in alternative forms to nonwoven mats. After analysis, the yarns produced using this new electrospinning technique indicated the presence of a slight molecular orientation and a poorly developed crystalline microstructure within the fibers.

In addition to what is listed above, there are many factors that can be altered in order to achieve different nanofibrous mats. Deitzel stated that increasing the voltage increased the number of beads that are observed on the created fibers. Other researchers have noted that increasing the voltage will also decrease the fiber size up to a critical value, after which the fiber size will begin to increase as a result of the diminishing Taylor cone.

### 3.2.5. Spinning Distance/Spinning Angle

Two other common parameters that are frequently changed are the spinning distance and the spinning angle. It is commonly noted that the further the increase between the anode and cathode, the finer the fiber diameter will be as a result of having more time and distance to elongate itself. Many angles have been experimented with, 0°, 45°, and 90° being the most common. Although little evidence was seen to affect fiber diameter, fiber uniformity was often increased at 45° because the flow rate was often decreased and gravity was not allowed to form as many beads.

### 3.2.6. Spinneret Diameter

As touched upon earlier, the spinneret diameter has a major effect on the size of the nanofibers produced. The smaller the spinneret, the smaller the fibers tended to be, but the smaller diameter also presented itself to be a problem when higher viscosity fluids were used. It is a constant trade-off between which type of material is being worked with and what size diameter is hoped to be obtained. In addition to the size of the spinneret used, shape has also been recorded to play a major role in electrospun samples. Whether the tip of the spinneret is flat like an extruder or sharp like a syringe, many interesting morphological features were discovered.

### 3.2.7. Annealing

One tactic that is used in the industrial production of fibers that is often overlooked in the realm of electrospinning is annealing. Annealing is a form of post-treatment that heats the polymer while stretched in order to allow the chains to align themselves, giving the fiber far superior mechanical properties. What little work that has been done in this area

has shown promising results, but the problem resides in the capability of isolating single samples to be annealed.

#### 4. MELT ELECTROSPINNING

There has been little work published in the area of melt electrospinning. The first work was published by Lorrondo and Manley in 1981 [15] and nothing has been published since. There are many papers that include solution or melt in their titles, but the work that has been done has concentrated exclusively on solution spun fibers. There are several groups throughout the world trying to break through with new results, including, but not limited to, Drexel University and the University of Akron.

Traditionally melt spun polymers such as polyester [49], polyethylene, and polypropylene have been attempted to be spun by several groups. These polymers have been spun using different temperatures, different voltages, and in different atmospheres. The main reason that there has been nothing published in the last 20 years is that it has been proven to be very difficult to produce fibers in the nano range. In solution spinning, it is believed that one major contributor to the decrease in diameter is the evaporation of the solvent. Solution spun fibers contain as much as 90% solvent and 10% polymer. Simply by understanding that polymer melts contain 0% solvent, an order of magnitude increase in fiber diameter is realized.

In addition to the lack of solvent that helps loosen up the molecular entanglements, melt spinning suffers other drawbacks. One of these hindrances is the effect of the temperature gradient between the polymer and the surrounding temperature. If the surrounding temperature is too cool, the ejected polymer will quench upon exiting the spinneret, preventing any decrease in diameter and orientation of molecular chains leading to improved mechanical properties. If the surrounding temperature is too hot, then the ejected polymer will fuse to itself upon collecting on the target.

Temperature of the melt is another key issue when melt electrospinning polymers. In solution, it has been readily shown that the electrospinning process is highly dependent on viscosity. Polymeric melts are inherently much more viscous than polymer solutions that are being electrospun. Therefore, in order to get the polymer melt to a viscosity that is capable of being electrospun, the melt temperature is often raised well above the melting temperature. If the polymer being used has a degradation temperature that is relatively close to the melting temperature, it will likely not be electrospun.

Analyzing the results that have been seen at conferences around the world, the same processing parameters that apply for solution spun nanofibers apply to melt spun nanofibers. Melt spinning continues to be a hot topic and would be the ideal way to make nanofibers by electrospinning because of the incredibly high yield as compared to solution electrospinning. As referenced before, the islands in the sea method is a form of melt spinning but may not be the most feasible of methods due to the extremely high cost of the machinery.

#### 5. STRUCTURE AND PROPERTIES

Table 2 represents the spectrum of instruments used to test nanofibers. As shown, instruments are capable of analyzing everything from a few angstroms in diameter to several meters. As more and more machines are used to study the characteristics of electrospun fibers, a better understanding of the process is being developed. In the future, more sophisticated machines will be developed to draw a more accurate portrait of the process, but until that time, researchers will have to be satisfied with what is at hand, such as the following.

The scanning electron microscope (SEM) is one of the most popular and powerful tools that has been used in the literature [4, 9, 15, 27] to measure the diameter of electrospun fibers as well as the general morphology. Kim and Reneker [10] showed that SEM could also be used to examine the fibers' cross section. They stated that the electrospun fibers are mostly circular in cross section but other shapes such as ribbons and coils could be produced. This method is extremely easy to use and more importantly, the sample size required to get useful data is extremely small, less than 1 mm<sup>2</sup>. One drawback of this equipment is that a gold coating is usually needed to enable viewing the fibers and this coating slightly alters the accuracy of the actual diameter. The gold sputtering process typically adds a 0.4-nm layer to the fibers. This can be ignored with larger diameter fibers but with a 4-nm fiber, it becomes more of a concern. Using an environmental scanning electron microscope (ESEM), the gold coating process can be skipped if the micrographs are taken in a low vacuum. However, if the general shape and size of the fibers are needed, SEM and ESEM are fast and easy ways to derive the information that is needed. Another methodology that has been utilized to measure the diameter of smaller diameter samples is transmission electron microscopy (TEM). Fang and Reneker [27] analyzed the electrospun DNA by using TEM and reported diameters as low as 62 nm.

Ko et al. [28] used the TEM to study the morphology and order versus disorder for the electrospun PAN fiber, PAN/CNT, and PAN/GNP nanocomposites. Also, Ye et al. [29] used TEM technique to study the alignment of single-walled carbon nanotubes (SWNT) in two different electrospun polymers (PLA and PAN), as seen in Figure 7, as well as to study the effect of the heat treatment of electrospun PAN/CNT composites on the alignment of the CNT.

Other researchers have utilized equipment such as X-ray diffraction (XRD) and differential scanning calorimetry (DSC) to observe whether there is any degree of crystallinity in the electrospun samples. To this day, the argument persists, with some parties arguing that the samples lack crystallinity while others say that the intense strains to which

**Table 2.** Instrumentation available at various size scales.

**Figure 7.** Carbon nanotubes inside of PLA (top) and PAN (bottom).

the samples are subjected are sure to produce highly crystalline samples. When spinning from solution, there have been some reports by Deitzel [21] that limited crystallization occurs but not to a high degree using PEO. On the other hand, when spinning from the melt, Lyons [65] demonstrated that a crystallization peak was observed in PET. This peak is consistent in what is seen in quenched polymer systems lacking crystallinity.

An important note to mention is the misnomer that is often associated with fibers on this scale. Researchers will often say that a 500-nm fiber was produced when in reality this is the same as a 0.5- $\mu\text{m}$  fiber. There are several groups that have been doing this with a variety of polymers, yet there are many other polymers that have been unable to break the 100-nm barrier. There have been reports from Reneker of producing fibers as small as 4 nm, yet while dealing with melt electrospinning, many of the fibers are on the micron scale.

Although most of the fibers that are produced through electrospinning are in the form of cylinders, there are occasions when tubes, ribbons, coils, and beaded structures can be produced. Tubes have been discovered by several groups and it was shown by Ali [25] that there was a high likelihood of forming tubes when electrospinning into water. In a similar fashion, ribbons are more than likely the result of collapsed tubes. Polymeric nanotubes elude reproducibility. Today, researchers are focusing on this problem and they are developing more advanced techniques that will allow for continuously produced nanotubes that can be used for drug delivery or hydrogen storage.

The most common way of collecting the nanofibers is in the form of 2D fibrous nonwoven mats. Mats such as these are well suited for filtration and tissue culturing but are not sufficient if single fibers or yarns are desired. It has been shown by Ko [30] that nanofibrous yarns can be directly produced from the electrospinning process under the precise processing parameters with certain polymers.

These yarns tended to be on the micron scale but were composed of numerous fibers that were on the nano scale that were naturally twisted together throughout the process to form the yarn. This was the first step in a positive

direction to one day being capable of producing woven and knitted fabric out of nanofibers.

## 5.1. Mechanical Properties

Measurement of elastic properties of electrospun fibers is very limited in the literature and only a few papers have worked with advanced techniques to determine the elastic properties of the material.

The atomic force microscope (AFM), invented by Binnig, Quate, and Gerber in 1986, was developed to exploit contact and noncontact forces for imaging surface topology and to study new physical phenomena at microscopic dimensions. The heart of the AFM is the cantilever and tip assembly, which is scanned with respect to the surface. For contact imaging the sample is scanned beneath the atomically sharp tip mounted on the cantilever providing a repulsive force. Atomic resolution can be obtained by very light contact and measuring the deflection of the cantilever due to the repulsion of contacting atomic shells of the tip and the sample [29]. Silicon device technology has introduced microfabrication techniques to produce silicon, silicon oxide, or silicon nitride micro-cantilevers of extremely small dimensions, on the scale of  $100\ \mu\text{m} \times 100\ \mu\text{m} \times 1\ \mu\text{m}$  thick. Micro-cantilevers exhibit force constants around 0.1 N/m. In contact imaging, the measurement of cantilever deflection is performed directly (quasi-statically) as the tip is being scanned over the surface [29]. Ko et al. [30] used this AFM technique to measure the elastic modulus of a single fiber produced from an electrospun PAN polymer solution. The atomic force microscope is one of the most powerful and useful techniques that has been used to measure the elastic properties of the electrospun fibers in addition to being able to determine diameter.

Kracke and Damaschke [31] used the AFM to measure the nanoelasticity of thin gold films. Later, Ali [25] showed in Figure 8 similar results obtained using AFM. They based the calculation of the modulus on the following relationships:

$$\frac{dF}{d\delta h} = \left( \frac{2}{\pi^{0.5}} \right) E^* A^{0.5} \quad (5)$$

$$\frac{1}{E^*} = \frac{(1 - \nu_1^2)}{E_1} + \frac{(1 - \nu_2^2)}{E_2} \quad (6)$$

**Figure 8.** Effect of carbon nanotubes in composites.

where  $E_1$ ,  $E_2$ ,  $\nu_1$ , and  $\nu_2$  are the elastic moduli and Poisson numbers of the sample and the tip, respectively,

$$A = \pi r^2 \quad (7)$$

$$F = 2rE^*\delta h \quad (8)$$

where  $r$  is tip radius, and  $\delta h$  is deformation between tip and sample.

Sundrarajan et al. [32] used the AFM technique to evaluate the elastic modulus of nanobeams as well as their bending strength. By using this technique, the measured values were comparable to those measured in bulk. Mechanical properties and the deformation behavior of materials having ultrafine microstructures can also be illustrated by using a nanoindentation machine following the same guidelines. Finally, micro-Raman spectroscopy (MRS) has been used to measure the load transfer in short-fiber, high-modulus/epoxy composites as a function of angle to loading direction [33] as well as to monitor the strain in short fiber composites as a result of fiber to fiber interactions.

## 5.2. Chemical Properties

Raman spectroscopy is one of the more powerful techniques used to detect the presented elements especially on the nano scale. It is also extremely useful in investigating the state of carbon in detail due to its sensitivity to changes in translational symmetry. Duchet et al. [34] used Raman spectroscopy to correlate the molecular structure of the nanoscopic tubules with their conducting properties. Raman spectroscopy has been used for the characterization of carbon nanotubes (CNT) by many researchers [35].

Rao et al. [36] reported that there are two frequencies or bands of the single-walled carbon nanotubes (SWCNT) that can be detected by Raman spectroscopy. One is known as the radial band at  $160 \text{ cm}^{-1}$  and the other is called the tangential band at  $1590 \text{ cm}^{-1}$ . They showed that the first band could be detected at higher Raman shift values ( $10 \text{ cm}^{-1}$  higher) when it was dispersed in a solution.

The ratio ( $I$  (D-band)/ $I$  (G-band)) has been cross-correlated to crystallite size using X-ray diffraction data. This correlation is given by the following equation:

$$L_a = 4.4 \left( \frac{I_D}{I_G} \right)^{-1} \quad (9)$$

where  $L_a$  is the crystallite size in (nm).

Also, Huang and Young [37] showed a linear relationship between the  $I_D/I_G$  band and the  $1/L_a$  for commercialized carbon fibers produced from both PAN and PITCH. In the same paper they showed that there is a variation of the Raman spectra between the skin and core regions. These spectra show that  $I_D/I_G$  decreases from core to skin, which indicates smaller crystallite values in the fiber core more so than on the skin.

Laser Raman spectra have been used by Matsumoto et al. [38] to examine the carbon nanofibers and films produced by hot filament-assisted sputtering and it was found that the films showed three Raman bands at 1581, 1368, and  $179 \text{ cm}^{-1}$ . In this paper they explained the Raman peaks as follows: the first two peaks belong to polycrystalline

graphite and the last peak corresponds to carbene, one of the allotropes of carbon.

## 6. MODELING OF THE ELECTROSPINNING PROCESS

It is crucial that there exists a theoretical understanding of the electrospinning process. With this knowledge, specific parameters can be fine-tuned in order to maximize the efficiency of the process. To date, there have only been a handful of attempts made to theoretically quantify the electrospinning process. In 1971, the first was perhaps Baumgarten who attempted to identify the electric field maps to determine the jet radius. This approach was crude and met only limited success. Ten years later Larrondo and Manley continued to define the velocity gradients and electric fields and also began the first work of molten bead deformation in an electric field.

An analytical modeling of a steady-state jet flow in the electrospinning process made by Spivak et al. [39, 47, 52] showed the applicability of using the power law asymptotic to a wide class of fluid described by the nonlinear Oswald-deWaele law. This group used a one-dimensional differential equation to represent their jet radius and, when compared against experimental results, fared quite well.

In 1999, Reneker et al. [40] submitted the first attempt at a mathematical model that predicted the path of an electrospun fiber from solution. What was unique about this submission is that the group incorporated the instability region and plotted its results in three dimensions. Although capable of predicting the path for the fiber to traverse to a relatively accurate degree, this model was not capable of determining the fiber's diameter upon hitting the target.

Shin et al. [41] continued work on this challenging puzzle by describing the jet behavior in terms of known fluid properties and operating conditions. One of the main differences between this group and the Reneker group is the incorporation of current. Shin et al. described the behavior of two competing instabilities and summarized their results that closely mimic experiment in terms of operating diagrams and delineating regimes of operation in electrospinning.

The evolution of the model has become more and more accurate, but there is still no exact model to predict what the ending fiber diameter will be. All of the models that have attempted to predict the fiber diameter focus on solution spinning; melt spinning has only recently been modeled by Lyons et al. [65]. Many questions, such as what happens to the charge on the fiber while in transit, remain unanswered and a totally accurate model may never be developed.

When a conducting liquid is supplied to a capillary nozzle at a low flow rate and when the interface between air and the liquid is charged to a sufficiently high electrical potential, the liquid meniscus takes the form of a stable cone, whose apex emits a microscopic jet. Farouk et al. (unpublished report) described an axisymmetric formulation of the flow and electric fields of the electrostatically driven meniscus through a capillary nozzle. Based on the governing equations, a numerical model has been developed to calculate the shape of the liquid cone and the resulting jet, the electric fields, and the surface charge density along the liquid surface. The liquid

properties, liquid flow rate, and electrode configuration are needed as input parameters. Two-dimensional axisymmetric equations of continuity, momentum, and Gauss' law are solved numerically.

## 7. APPLICATIONS OF NANOFIBERS

Today's researchers are trying to find as many uses as they can for electrospun fibers. To date, filtration is the primary market for these fibrous mats as researched by Gibson [46, 56]. There is an extremely small pore size that is capable of blocking most particles and hence is quite useful in the filtration industry. Today's society is also directing research toward making protective clothing for military personnel to protect against chemical agents. Nanofibrous mats also have an incredible amount of surface area and industries such as the composite and biomedical industries are taking advantage through usage as wound dressings, tissue scaffolds, and practically any form of reinforcement agent for composites.

Ko and Ali [28] have looked into forming carbon/carbon composites directly from the electrospinning line. PAN was electrospun and carbonized with nanotubes on the inside to form this triple carbon composite. If this fiber, or yarn in Ali's case, is placed in a carbon resin, triple carbon composites can be made and used in ballistic proof plates and helmets of the future.

The ideas are endless as to where an electrospun fiber or mat may be used in the future. The aerospace industry is currently working on developing space antennae, solar sails, light reflectors, and a variety of other devices used in the voids of space. In addition, MacDiarmid and Lec [5] have focused their efforts to the production of electronic systems and many forms of sensors. Biosensors have been an important element of the information revolution of the 20th century, and their role as an enabling factor of the incoming 21st century biotechnology and medical revolution will be essential. Modern biosensors developed with advanced microfabrication and signal processing techniques are becoming inexpensive, accurate, and reliable. Increasing miniaturization of biosensors leads to realization of complex analytical systems such as BioChemLab-on-a-Chip. This rapid progress in miniature devices and instrumentation development will significantly impact the practice of medical care as well as future advances in the chemical, pharmaceutical, and environmental industries.

Important sensor parameters such as sensitivity, selectivity, response time, reproducibility, and aging depend directly on the properties of the sensing film [42, 43]. Sensitivity is of particular interest, because there is a strong need for detection of gases and biological substances and organisms at low concentration. A lower sensor detection limit allows direct measurement of the vapor from explosives and drugs or the presence of a few bacteria and viruses. It is a well-known fact that the sensitivity of a film is proportional to the surface area of the film per unit mass. Therefore new technologies capable of producing thin films with large surface area are of particular interest. In reality, these mats are simply a form of nonwoven fabrics. With that in mind, these electrospun fabrics have the potential to be used in any application that nonwovens are currently being used, such as brake pads, postal envelopes, and insulation, to name a few.

## 8. SUMMARY

Electrospinning is a unique process that produces polymeric fibers having diameters ranging over several orders of magnitude, from the micrometer range typical of conventional fibers down to the nanometer range. Until now, the shape and pattern of produced fibers in all electrospun polymer solutions have taken an in-plane random pattern and are determined by the shape of the collector.

A notable phenomenon has been recognized under certain spinning conditions for PAN solution, which enable the production of continuous yarn containing partially oriented nanofibers. This phenomenon opened the door to achieve many objectives such as the production of carbon-carbon nanocomposites by dispersing CNT's of superior physical properties inside the PAN polymer solution and producing continuous carbon nanotube reinforced PAN based carbon nanocomposite fibrils.

The present study is an attempt to optimize the electrospinning process for truly nanoscale fibers (<100 nm) and understand the electromechanics of electrospinning. In today's labs, reproducibility seems to be a major factor. Many scientists are getting fibers on the nanoscale once or twice but fail to do so repeatedly. Therefore, it is critical that the mechanics behind the process are understood. Efforts from Reneker, Shin, Rutledge, and Lyons [39–41, 47, 55, 64] in the area of modeling will pave the way for future researchers to know what parameters can be altered to accurately develop the exact diameter that is desired.

It seems that the next great barrier to overcome is productivity. Today, the average productivity of nanofibers using a single spinneret is in the range of 0.1 g/hr. This value is incredibly slow, making this process completely unreasonable from an industrial point of view. Researchers have been working on scaling up the process by adding many more spinnerets and have experienced some success, but the productivity is still not as high as commercial nonwoven productivities. A reason for this low productivity is the low yield that is experienced from working with solutions (<10%). If electrospinning from the melt could produce nanofibers consistently, this problem would be overcome, but that has yet to be realized.

One thing that is certain is that the methodologies for producing nanofibers are in their infancy. Perhaps researchers will modify what is known today to form what is desired tomorrow or perhaps a better way to achieve the goal of reaching 100 nm consistently will be discovered. Hybrid processes, such as combining melt blowing and electrospinning may produce the best results to date. Along with new ways to produce the fibers, scientists will also develop better ways to collect and test the nanofibers. While the commercial value of electrospun nanofibers depends on the reproducibility and productivity, the true value of the current electrospinning activities is in their capability to generate nanoscale fibers, thus providing a means to facilitate an assessment of the nanoscale effect for a wide range of materials. Will the day come when people have shirts made from nanofibrous yarns? It is hard to say, but it is assured that researchers will continue to work hard to push this novel field to new limits in hopes of discovering the next big breakthrough.

## GLOSSARY

**Birefringent** The refraction of light in an anisotropic material in two slightly different directions to form two rays.

**Chemical vapor deposition** A chemical reaction which transforms gaseous molecules (precursor) into solid materials in the form of thin films or powders on the surface of a substrate.

**Clathrate crystals** Crystals that crystallize in such a way that cavities exist within their crystal structure.

**Electrospinning** A process in which a polymer solution of melt is exposed to an electric field. At a critical voltage, the electric field will overcome the surface tension of the polymer and a jet will be extruded.

**Electrostatic atomization** The use of an electric charge to form fine droplets from a liquid.

**Nanocomposite** A material that is composed of 2 or more materials that lead to properties that the individual components could not possess by themselves. One of the components must be a nanomaterial.

**Nanomaterials** A material that has at least one dimension that is less than 100 nanometers.

**Nonwoven** A sheet or web structure made by bonding or entangling fibers via mechanical, thermal, or chemical means, and combinations thereof.

**Osteoblasts** A bone forming cell.

**Oswald de-Waele Law** A power law non-newtonian viscosity model.

**Spinneret** A disc, with one or many fine holes, through which a spinning solution or molten polymer is forced to create a continuous fiber or yarn.

**Taylor cone** The structure that forms at the capillary when a liquid medium is exposed to an electric field as the voltage is increased to overcome the surface tension.

## ACKNOWLEDGMENTS

The author would like to acknowledge all of the scientists who are devoting their time to advance the field of electrospinning; in particular, the generous sharing of his knowledge in electrospinning by Professor Darrell Reneker is greatly appreciated. The opportunity provided by the Army Research Office through a MURI program enabled fruitful interaction with Professor Darrell Reneker and with Professor Alan MacDiarmid in the area of electroactive nanofibers. The recent support by NASA, NSF, NTI, and DARPA enables our exploration of the co-electrospinning technology in multifunctional nanofibers and nanocomposites. This support also enables the education of a new generation of students in the area of nanofiber technology.

## 1. INTRODUCTION

Nanofluidics can be defined as the study, description, and use of fluid flow around and inside nanoscale structures. Knowing and controlling the behavior of fluids in extremely small volumes is of crucial importance for the understanding of a large variety of problems in science, such as biological interactions, fracture propagation, tribology, and adhesion [1]. A good understanding of nanofluidics is essential for the efficient design and operation of new nanoscale devices, and may lead to new concepts that can be used for (bio)chemical synthesis, as well as methods for rapid, sensitive, and selective biochemical analysis. Although nanofluidics looks like a natural extension of the well-established field of microfluidics, the physical dimensions of this new and exciting field are on the order of the relevant length scales in fluidic environments, such as the size of large molecules and the size of the electrical double layer in aqueous solutions, which may lead to a completely different fluid behavior. In addition, the relevant distances are so small that diffusion processes are dominant in mass and heat transfer, and lead to extremely small timescales of (sub)milliseconds. All of these effects lead to new possibilities for manipulating, detecting, and analyzing (single) molecules in fluids.

Furthermore, macroscopic fluid properties such as surface tension, viscosity, and permittivity may take totally different values in nanoscale confinements, where most of the

fluid is close to a (mostly charged) wall. Although the theoretical description of fluid flow through nanochannels has been derived for porous media (in this review, referred to as ensembles of nanochannels), it is only through the recent upcoming of nanotechnologies that the behavior of fluid flow can be studied in individual nanoconfinements. Such nanoconfinements also allow the isolation and localization of single molecules within a very small volume, leading to exciting single-molecule detection principles.

The expectations of nanofluidics are therefore very high. Several scientific and technical breakthroughs are anticipated:

1. new approaches for molecular separation in nanochannels will be developed
2. chemical reactions with extremely small amounts of molecules (even down to single molecules) will be carried out and studied
3. new techniques for the detection and identification of individual molecules will be developed.

These phenomena may lead to breakthroughs in a variety of applications, ranging from high-throughput proteomics to the development of new drugs, and from new molecular filters to new methods for medical diagnostics and screening.

For an overview of the state of the art in, and application of, microfluidics, the reader is referred to several reviews on this topic [2–7]. From these reviews, it is clear that the single most important difference between micro- and macroscopic fluidics is in the magnitude of the Reynolds number ( $Re$ ): usually in microfluidic systems,  $Re < 100$ , therefore the flow is laminar. As such, fluid flows can be described very accurately; it is not surprising that, in microfluidics, the focus has been on constructing more or less complex fluid manifolds capable of carrying out, for example, sample preparation techniques on an extremely small scale, impossible to attain with conventional tools. Contrary to this rather engineering type of work carried out with microfluidic systems, with nanofluidics, the focus is much more on investigating and

understanding the new science involved. In the following sections, we will deal with fluidic manipulation principles with a focus on surface-related effects. This part will be followed by a more in-depth discussion on the fluid–surface interaction in the double layer. In the next section, various technologies for individual nanochannels and ensembles of these will be briefly addressed, whereas the last section deals with nanofluidic devices and applications.

## 2. NANOFUIDIC MANIPULATION PRINCIPLES

### 2.1. Physical Background of Downscaling Effects

Reducing the dimensions of the structures in which fluids are confined results in important effects due to an increased surface/volume ratio. The area will be, in fact, reduced to the power 2 and the volume to the power 3.

The importance of downscaling in fluid behavior can be readily appreciated by considering some of the dimensionless

numbers used in fluid dynamics. Table 1 shows some relevant dimensionless numbers; the dimensional parameters are listed in Table 2 [8]. Particularly interesting are those numbers expressing the relative importance of effects of forces such as inertia, surface tension, gravity, and viscous forces. The Reynolds number represents the ratio between inertia forces and viscous forces. It is used to describe the flow regimes: in microsystems, typical values for the Reynolds number are below 100, meaning that the flow is laminar (in circular macroducts, flow is observed to be laminar up to  $Re = 2100$  [9]). The decreased relevance of inertance in microfluidics is clear in the Weber number (We) as well. This number express the ratio of inertia forces to surface tension forces. With downscaling of dimensions, the Weber number drops, indicating that surface energy becomes a substantial factor in microsystems. The relative importance between viscous and surface tension effects can be determined by dividing the We by the Re number, obtaining what is called the capillary number (Ca). The Bond number (Bo) expresses the ratio between gravitational and surface tension forces, and it decreases with downscaling. Thermal diffusion (conduction) as well as mass diffusion are enhanced by downscaling;

**Table 1.** Overview of dimensionless numbers and their relation to the dimension length (at constant velocity). Reprinted with permission from [8].

Group	Abbreviation	Definition	Interpretation
Biot number	Bi	$\frac{h_T l}{k_T}$	Ratio of internal thermal resistance of a solid to the boundary layer thermal resistance
Mass transfer Biot number	$Bi_m$	$\frac{h_m l}{D_{AB}}$	Ratio of the internal species transfer resistance to the boundary layer species transfer resistance
Bond number	Bo	$\frac{g(\rho_l - \rho_v) l^2}{\sigma}$	Ratio of gravitational and surface tension forces
Euler number	Eu	$\frac{p}{(1/2)\rho v^2}$	Dimensionless pressure drop
Fourier number	Fo	$\frac{\alpha t}{l^2}$	Ratio of the heat conduction rate to the rate of thermal energy storage in a solid; dimensionless time
Mass transfer Fourier number	$Fo_m$	$\frac{D_{AB} t}{l^2}$	Ratio of the species diffusion rate to the rate of species storage
Grashof number	$Gr_L$	$\frac{g\beta\rho^2(T_s - T_\infty)l^3}{\mu^2}$	Ratio of buoyancy to viscous forces
Knudsen number	K	$\frac{l_{\text{free}}}{l}$	Ratio of the mean-free path of a gas and a characteristic length
Lewis number	Le	$\frac{D_{AB}}{\alpha}$	Ratio of the thermal and mass diffusivities
Nusselt number	$Nu_L$	$\frac{h_T l}{k_T}$	Dimensionless temperature gradient at the surface
Peclet number mass transfer	$Pe_D$	$\frac{v l}{D_{AB}}$	Ratio of mass transport by convection and by diffusion
Peclet number heat transfer	$Pe_\alpha$	$\frac{v l}{\alpha}$	Dimensionless independent heat transfer
Prandtl number	Pr	$\frac{c_p \mu}{k_T}$	Ratio of the momentum and thermal diffusivities
Reynolds number	$Re_L$	$\frac{\rho v l}{\mu}$	Ratio of the inertia and viscous forces
Schmidt number	Sc	$\frac{\mu}{\rho D_{AB}}$	Ratio of the momentum and mass diffusivities
Weber number	We	$\frac{\rho v^2 l}{\gamma}$	Ratio of inertia to surface tension forces

**Table 2.** Used dimensional parameters and their units.

Parameter	Description	Units
$\alpha$	thermal diffusivity	$\text{m}^2 \cdot \text{s}^{-1}$
$\beta$	thermal expansion coeff.	$\text{K}^{-1}$
$\varepsilon$	dielectric constant	$\text{C}^2 \cdot \text{N}^{-1} \cdot \text{m}^{-2}$
$\varepsilon_{ij}$	$ij$ oriented strain	—
$\phi$	flow rate	$\text{m}^3 \cdot \text{s}^{-1}$
$\mu$	dynamic viscosity	$\text{Pa} \cdot \text{s}$
$\sigma_{ij}$	$ij$ oriented stress	Pa
$\gamma$	surface tension	$\text{N} \cdot \text{m}^{-1}$
$\rho$	mass density	$\text{kg} \cdot \text{m}^{-3}$
$\tau$	shear stress	Pa
$\theta$	angular coordinate	—
$\zeta$	zeta potential	V
$a, b$	typical dimensions	m
$c_p$	spec. heat at const. pressure	$\text{J} \cdot \text{kg}^{-1} \cdot \text{K}^{-1}$
$D_{AB}$	mass diffusion coefficient	$\text{m}^2 \cdot \text{s}^{-1}$
$e$	electron charge	C
$E$	total applied potential	V
$\dot{E}$	power	$\text{J} \cdot \text{s}^{-1}$
$g$	constant of gravity	$\text{m} \cdot \text{s}^{-2}$
$h_m$	convection mass trans. coeff.	$\text{m} \cdot \text{s}^{-1}$
$h_T$	convection heat trans. coeff.	$\text{W} \cdot \text{m}^{-2} \cdot \text{K}^{-1}$
$K_b$	Boltzmann constant	$\text{J} \cdot \text{K}^{-1}$
$k_e$	specific conductance	$\Omega \cdot \text{m}^{-1}$
$k_T$	thermal conductivity	$\text{W} \cdot \text{m}^{-1} \cdot \text{K}^{-1}$
$l$	(characteristic) length	m
$n_0$	average ion concentration	—
$p$	pressure	Pa
$R_{\text{hyd}}$	hydraulic resistance	$\text{Pa} \cdot \text{s} \cdot \text{m}^{-3}$
$r$	radius	m
$T$	temperature	K
$t$	time	s
$v$	velocity	$\text{m} \cdot \text{s}^{-1}$
$x, y, z$	coordinates	m
$z$	ion valence	—

the dimensionless numbers related to these effects are the thermal and mass Fourier numbers ( $Fo, Fo_m$ ) and the Peclet numbers ( $Pe_\alpha, Pe_D$ ).

Physical effects becoming relevant at the microscale offer new design potentials.

## 2.2. Surface-Related Effects

Principles that use surface effects can be exploited as new fluid-handling mechanisms. Two main principles will be considered in this section: surface energy and double layer.

### 2.2.1. Surface Energy

The surface free energy of a fluid is the energy needed to bring a molecule from the interior to the surface of a fluid. This energy difference is caused by the differences in the interaction forces between a molecule and its neighboring molecules in the bulk of the fluid and at the surface (e.g., van der Waals forces, hydrogen bonds). Liquids tend to adopt shapes that minimize their surface area because molecules in the bulk of the fluid are in a favorable energy configuration. For this reason, droplets are spherical because a sphere is

the geometrical entity with the smallest surface/volume ratio [10]. The Laplace equation

$$P_{\text{in}} = P_{\text{out}} + 2 \frac{\gamma}{r}$$

where  $\gamma$  is the surface tension, shows that the pressure at the concave side of a curved surface is always greater than the pressure at the convex side, the difference decreasing to zero as the radius of curvature becomes infinite. The surface tension of a material is the coefficient between the infinitesimal quantity of work  $dw$  needed to change the area of a surface by an infinitesimal amount  $d\sigma$ :

$$dw = \gamma d\sigma$$

Surface energy can play a role in fluid mechanics when interfaces exist between different phases. The influence of surface energy, causing surface tension effects, is expressed by the Bond and Weber numbers (Table 1).

Surface tension has been indicated as a practical microactuation force in microelectromechanical systems (MEMS): being a unique type of force scaling directly to length (line force), it becomes dominant over pressure (surface force) or mass (body force) when the dimension of interest shrinks down to the micrometer and submicrometer scale. The passive control of surface tension has been demonstrated by chemical modification of surfaces [11, 12], and active control has been proposed for micro- and nanofluidic systems based on electrical [13], thermal [14], optical [15], and electrochemical [16] principles.

### 2.2.2. Double Layer

The double layer in a fluid medium is caused by the surface charge that is naturally present on any surface [17]. The surface charge induces the formation of an electric double layer by attracting oppositely charged ions from the solution. The double layer consists of immobile counterions close to the channel wall within the so-called Stern or Helmholtz layer, and others forming an atmosphere of ions in rapid thermal motion close to the surface, known as the diffuse electric double layer [18]. The plane separating the inner layer of counterions and the outer diffuse layer is called the Stern layer. The potential at this plane is close to the electrokinetic potential or zeta ( $\zeta$ ) potential, which is defined as the potential at the shear surface between the charged surface and the electrolyte solution [19], and is defined with respect to the bulk of the liquid. The shear surface itself is somewhat arbitrary, but characterized as the plane at which the mobile portion of the double layer can “slip” or flow past the charged surface.

In the case of glass or silicon nitride channel walls, charging of the wall can occur due to deprotonation of silanol groups at the surface.

When an electric field is imposed tangentially to the charged surface, two main effects can be distinguished [20]: electrophoresis (EP), which is the transport of ions through the bulk of the liquid, and electroosmosis (EO), also referred to as electroendoosmosis, which is the transport of the fluid due to the drag of the moving charged electric double layer. Another charge-related effect is the

streaming potential, which is the counterpart of electroosmosis, and refers to the charge displacement, and consequently the existence of an electric potential due to fluid transport.

**Double Layer and Double-Layer Overlap in Nanochannels** The surface-charge density  $\sigma_s$  is of critical importance in nanochannels because the enhanced surface-area-to-volume ratio implies that a significant fraction of the total charge is bound to the walls and is immobile. The surface-charge density determines the magnitude of the surface potential and the applicability of the Debye–Hückel [17] approximation for the description of the double-layer length. It also provides an experimental handle to manipulate the molecular processes that influence fluid transport in nanochannels [21]. With respect to the occurrence of double-layer overlap, the relevant parameter to consider is the product of the channel radius  $a$  and the inverse Debye length  $\kappa$ . The Debye length can be roughly approximated by

$$\kappa^{-1} = \sqrt{\frac{\varepsilon_0 \varepsilon_r k_B T}{e^2 \sum_i z_i^2 n_i^0}}$$

where  $\varepsilon_0$  is the permittivity of vacuum,  $\varepsilon_r$  is the relative permittivity of the liquid medium,  $k_B$  is the Boltzmann constant,  $T$  is the temperature,  $n_i^0$  is the number density of the  $i$ th ionic species in the bulk of the electrolyte solution, and  $z_i$  is the charge of the  $i$ th ionic species [17]. Two extreme situations are illustrated in Figure 1. When  $\kappa a < 1$ , the electrical double layer extends across the entire channel. In aqueous systems,  $\kappa^{-1}$  is very large, being limited by the autoprotolysis of water, which means that achieving channels with complete double-layer overlap requires diameters of several hundreds nanometers or less. Under conditions of complete double-layer overlap, the channel becomes virtually impermeable to ions with the same charge as the surface charge, making it a selective barrier for the transport of either cationic or anionic species. Alternatively, under conditions at which  $\kappa a > 1$ , the double layer is confined to a small region near the channel wall, and the center of the channel is electrically uncharged. Under these conditions, both anionic and cationic species can be transported through the nanochannel, although the channel may still retain some permselectivity when the double-layer length is of the same order of magnitude as the channel radius.

**Figure 1.** Schematic diagram showing (a) absence and (b) presence of double-layer overlap in a nanochannel.

## 2.3. Manipulation Principles

In this paragraph, important fluid manipulation principles, based on surface effects, such as electroosmosis, electrowetting, and bubble pumping, are explained in more detail. These principles have found wide application in microfluidic systems as actuation mechanisms, and are expected to play an important role in nanofluidic systems as well.

### 2.3.1. Electroosmosis

Electroosmosis can occur when the channel wall is charged, inducing the formation of an electric double layer by attracting oppositely charged ions from the solution. When an electric field is imposed tangentially to the surface, the electrical forces acting on the mobile charges in the double layer cause them to migrate toward the oppositely charged electrode. During their migration, these ions transport the surrounding solvent molecules, inducing the overall movement of solution known as electroosmotic flow (EOF). Due to differences in the magnitude of electrical and frictional forces within the double layer, a velocity gradient originates. The flow velocity is zero at the surface, and increases inside the double-layer region (Fig. 2). It reaches a maximum outside the diffuse layer  $v_\infty$ , which is given by the Schmoluchowski equation

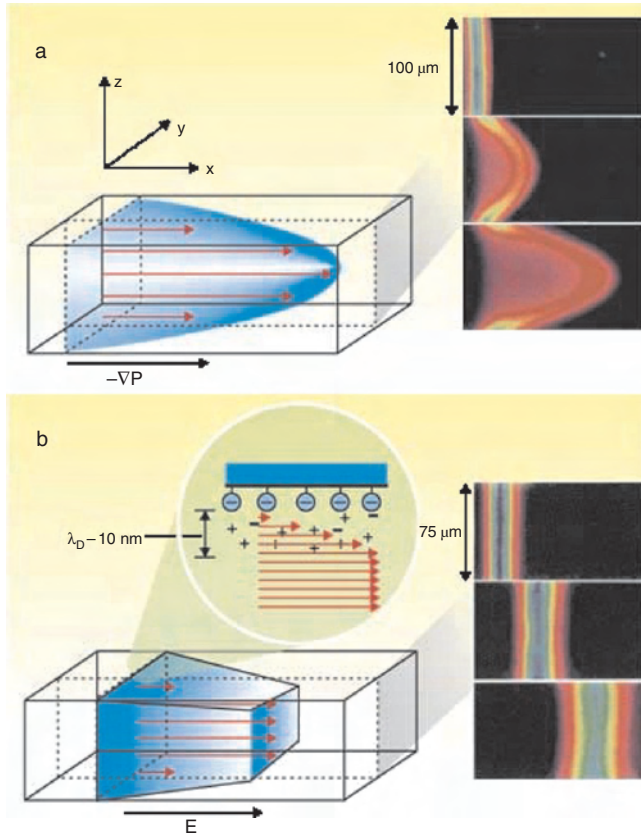

$$v_\infty = -\frac{\varepsilon \cdot \zeta}{\eta} \cdot E$$

where  $\varepsilon$  is the permittivity,  $\eta$  is the viscosity of the liquid, and  $E$  is the applied tangential field. In a microchannel, the velocity profile generated by EO is essentially flat across the channel [22, 23]. Figure 3 shows flow profiles in microchannels for pressure-driven [Fig. 3(a)] and EO-driven [Fig. 3(b)] fluids, pointing out the effects of the pumping mechanism on the distortion of a volume of fluid.

The theory of EOF in narrow cylindrical capillary tubes was discussed by Rice and Whitehead [24]. Under the assumption of a small surface potential, they derived an

**Figure 2.** Potential and flow velocity distribution  $\phi(x)$  and  $v(x)$  near a negatively charged wall. The velocity profile is the result of the electrical field  $E$  acting on the mobile charges in the double layer.  $1/\kappa$  is a measure for the double-layer thickness.

**Figure 3.** Flow profiles in microchannels. (a) A pressure gradient  $-\nabla P$  along a channel generates a parabolic or Poiseuille flow profile in the channel. The velocity of the flow varies across the entire cross-sectional area of the channel. On the right is an experimental measurement of the distortion of a volume of fluid in a Poiseuille flow. The frames show the state of the volume of fluid 0, 66, and 165 ms after the excitation of a fluorescent molecule. (b) In electroosmotic (EO) flow in a channel, motion is induced by an applied electric field  $E$ . The flow speed only varies within the so-called Debye screening layer of thickness  $\lambda_D$ . On the right is an experimental measurement of the distortion of a volume of fluid in an EO flow. The frames show the state of the fluorescent volume of fluid 0, 66, and 165 ms after the excitation of a fluorescent molecule. Reprinted with permission from [23], G. M. Whitesides and A. D. Stroock, *Phys. Today* 54, 42 (2001). © 2001, American Institute of Physics.

expression for the electroosmotic velocity  $u$  in a capillary tube of radius  $a$ , which reads

$$u(r) = -\frac{\varepsilon_0 \varepsilon_r \zeta E}{\eta} \left( 1 - \frac{I_0(\kappa r)}{I_0(\kappa a)} \right)$$

Here,  $\varepsilon_0$  is the permittivity of vacuum,  $\varepsilon_r$  is the relative permittivity of the liquid, and  $r$  represents the distance from the channel center.  $I_0$  indicates the zero-order modified Bessel function of the first kind. Asymptotic expansions show that the functions in brackets approach unity for large values of  $\kappa a$  [25]. The potential  $\zeta$  at the plane of shear between the immobile surface and the mobile part of the double layer of an unconfined solid-liquid interface can be written as

$$\zeta = \frac{2k_B T}{ze} \sinh^{-1} \left( \frac{\sigma_s \kappa^{-1} ze}{2\varepsilon_0 \varepsilon_r k_B T} \right)$$

where  $k_B$  is the Boltzmann constant,  $T$  is the temperature,  $\sigma_s$  is the surface charge density, and  $z$  is the valence of a symmetrical  $z:z$  electrolyte salt such as NaCl ( $z = 1$ ) or  $\text{MgSO}_4$  ( $z = 2$ ) [17]. In small channels, the electroosmotic flow velocity is retarded considerably by double-layer overlap. Even when  $\kappa a = 10$ , the cross-sectional average velocity is already reduced by about 20% in comparison with the EOF velocity in microchannels. At values  $\kappa a$  less than 10, the cross-sectional average velocity decreases rapidly with a further decrease of  $\kappa a$ .

Wei et al. studied the  $I-V$  characteristics of quartz nanopipet electrodes with orifice radii between 20 nm and 20  $\mu\text{m}$  in dilute KCl solutions, and applied potentials between  $-0.4$  and  $+0.4$  V [26]. They observed asymmetrical  $I-V$  behavior under conditions of partial double-layer overlap, while electroosmosis was the main mode of fluid transport through the orifice. The asymmetry was explained by a combination of double-layer overlap and geometrical asymmetry of the electrode orifice. This illustrates the possibility to design nanochannels with rectified electroosmotic flow characteristics.

In microfluidics, EOF is widely used for sample handling in capillary electrophoresis (CE) systems [27].

### 2.3.2. Electrowetting

By electrowetting, a surface can be switched electrically from a hydrophobic state into a hydrophilic state, thus enabling the manipulation of liquid in contact with the surface. Electrowetting is expressed by a change of the contact angle  $\theta$  of a droplet on a surface when an electric field is applied between the droplet and a counterelectrode underneath the droplet.

First reports on this *electrowetting* effect include Minnema et al. [28] from Philips Research Laboratories, who used an insulator between the liquid and the counterelectrode, and Beni et al. [29] from Bell Laboratories who measured the effect with the liquid directly on the metal counterelectrode. For the configuration shown in Figure 4 (liquid on insulator), the electrowetting effect can be explained by an extra term in the free energy of the system due to the electrical energy stored in the insulator [30]. This results in a modification of Young's equation, and can be interpreted as an effective lowering of the surface free energy of the

**Figure 4.** Configuration for electrowetting (liquid on insulator). A conducting aqueous droplet is placed on a hydrophobic insulator of thickness  $d$ . Electrowetting is induced by a voltage difference  $U$  between the droplet and an electrode below the insulator. Electrowetting results in a reduction of the contact angle  $\theta$  as indicated by the dashed contour.

solid–liquid interface  $\gamma_{SL}$  by the electrowetting energy term  $\gamma_{EW}$ :

$$\gamma_{LV} \cos \theta = \gamma_{SV} - \gamma_{SL} + \gamma_{EW} \quad (1)$$

Here,  $\gamma_{LV}$  and  $\gamma_{SV}$  are the surface free energy of the liquid–vapor and the solid–vapor interface, respectively. The electrowetting term equals the electrostatic energy stored in the insulator per unit area below the droplet:

$$\gamma_{EW} = \frac{1}{2} \cdot \frac{\epsilon \cdot U^2}{d} \quad (2)$$

where  $\epsilon$  is the permittivity of the insulator. Equations (1) and (2) can be rewritten to obtain a relationship between  $\theta$  and  $U$ :

$$\gamma_{LV} [\cos \theta(U) - \cos \theta_0] = \frac{1}{2} \cdot \frac{\epsilon \cdot U^2}{d}$$

where  $\theta_0$  is the contact angle at 0 V applied.

Verheijen et al. [30] reported a reduction of the contact angle of an aqueous droplet from 119° at 0 V applied down to 60° at  $\pm 240$  V applied. The voltages were applied across a 10  $\mu\text{m}$  thick parylene insulator layer and a thin hydrophobic fluoropolymer top coating impregnated with silicone oil to reduce the contact-angle hysteresis. Prins and colleagues [13] employed electrowetting inside microchannels, and generated pressures up to 800 Pa in arrays of channels with a diameter of about 350  $\mu\text{m}$  by applying voltages up to  $\pm 250$  V across a similar coated insulator system as the one used by Verheijen. Pollack and co-workers [31] managed to move droplets of aqueous KCl solution squeezed between two glass plates containing electrodes which were covered by hydrophobic insulating layers. They reached droplet velocities up to 3 cm/s at 55 V actuation voltage. In a similar configuration, Cho et al. [32] accomplished four fundamental microfluidic operations by electrowetting-on-dielectric: creating, transporting, cutting, and merging of liquid droplets. An actuation voltage of 25 V was required while using a 100 nm silicon dioxide insulator covered by a 20 nm hydrophobic Teflon coating. Washizu [33] could move, sort, and fuse droplets by means of electrostatic actuation. The droplets were placed on top of an array of electrodes covered by a smooth hydrophobic insulator layer, and were actuated by capacitive coupling. Torkkeli et al. [34] improved the speed of electrostatic transport of water droplets by employing superhydrophobic surfaces to reduce the sliding force of the droplets.

**Bubble Pumping** When a gas bubble is introduced in a region of changing diameter, and the bubble is large enough to be confined, surface tension forces will cause it to move to the region of larger diameter, moving the liquid in front and behind it [35]. Recently, this principle was implemented on milliscale in a circular symmetrical configuration [36], and flow rates on the order of 1  $\mu\text{L/s}$  were obtained. Usually, the bubbles are generated inside closed liquid channels by boiling liquid or by electrochemical gas generation [35–39], thereby limiting the nature and composition of liquids to be used. A more generic pumping mechanism is the surface-tension-directed gas injection in a hydrophilic microchannel [40]. The surface-tension control is based on geometrical

variation of the cross section of the hydrophilic channel, and requires no hydrophobic patches inside the channel. The working scheme of the pump is illustrated in Figure 5. Surface-tension forces cause the injected air to go into the taller part of the channel. The liquid volume displaced in a single pump stroke was 40 pL, and can be further reduced by reducing the size of the microchannel between the gas inlet and exhaust [40].

### 3. FLUID–SURFACE INTERACTION IN THE DOUBLE LAYER

The Navier–Stokes and Nernst–Planck equations are generally applicable to model flows of fluids and ions in systems of arbitrary geometry, including nanochannels [41].

**Figure 5.** Longitudinal cross section of a microchannel explaining the principle of operation, with  $h_1$  and  $h_2$  the channel height in the shallow and deep part of the channel, respectively,  $p_0$  ambient pressure, and  $p_{act}$  actuation overpressure. (A) The microchannel includes a liquid inlet and outlet and a gas injector. The injector is located at the position where the channel height changes. (B) After adding a liquid droplet to the inlet, the empty channel will be filled by capillary forces. (C) Injected gas will move toward the higher channel part because there the capillary counterpressure is lowest. (D) Once the gas reaches the outlet, the liquid is ejected, and a temporary gas flow between the gas injector and outlet is maintained. (E) When the gas pressure drops, the microchannel will refill by capillary forces. (F) The starting situation, (B) is obtained again. Reprinted with permission from [40], N. R. Tas et al., *Anal. Chem.* 74, 2224 (2002). © 2002, American Chemical Society.

However, the predominant feature associated with the latter type of geometry is the occurrence of double layers and double-layer overlap. Sophisticated models like the charge-regulation model [42] incorporate the dynamic interactions between ions from the double layer and bound surface charges on the surface. Since the surface concentration of solute ions is a function of surface potential, the surface charge is related to the surface potential via surface association and dissociation reactions. For example, for an aqueous NaCl solution inside a channel with charged-surface sites  $S^-$ , the following four association–dissociation reactions between mobile ions and surface sites have to be taken into account: (1)  $SH = S^- + H^+$ , (2)  $S^- + Na^+ = S-Na$ , (3)  $SH_2^+ = SH + H^+$ , and (4)  $SH_2^+ + Cl^- = SH_2Cl$ . The equilibrium constant of each possible reaction must be known, and must be incorporated in the description. For the example described above, the surface-charge density can be expressed as  $\sigma_s = e([SH_2^+] - [S^-])$ , where  $e$  is the elementary electron charge and  $[Q]$  denotes the concentration of species  $Q$ . Most ions are known to exhibit some kind of interaction with bound surface charges. Specific interactions between surfaces and solutes are also known [17].

Most existing surface complexation models have been developed for unconfined solid–water interfaces, where overlap of the electrical double layer does not occur. However, a recent experimental study of ion adsorption on mesoporous alumina indicates that nanoscale confinement has a considerable effect on ion adsorption [43]. The effect is most likely explained by the overlap of the electrical double layer. It was found that the surface charge per mass on mesoporous alumina was as much as 45 times higher than on dense alumina particles. These findings show that the development of surface charge in nanochannel geometries may not be predictable *a priori* by the currently existing models for surface–liquid interactions.

While the double layer can be described using the well-known Poisson–Boltzmann equation [17], the simplest descriptions of double layers consider ions as simple point charges. Since the number of ions at the channel wall is higher than in the bulk, an unlimited number of ions could be accommodated in the interfacial region. This is physically impossible, and therefore it becomes necessary to assign a volume to the ions at high electrolyte concentration and/or small channel size. The spatial requirement for an ion is characterized by its hydrated radius, and both undissociated and dissociated hydrated electrolytes can be distinguished [44]. The expression for the distribution of dissociated ions from a binary electrolyte can be written in a modified form of the Boltzmann equation:

$$\frac{n_i}{n_i^b} \left( \frac{v^{-1} - \sum_i n_i^b}{v^{-1} - \sum_i n_i} \right) = \exp \left( -\frac{z_i e \varphi(r)}{k_B T} - \frac{\Delta F_i}{k_B T} \right)$$

where  $n_i$  is the number density of the  $i$ th ionic species near the charged interface,  $v^{-1}$  is the inverse volume of the hydrated ion, and  $\varphi(r)$  is the local electrical potential relative to the potential in the uncharged bulk of the electrolyte solution.  $\Delta F_i$  indicates the hydration-free energy of the  $i$ th ion, a term that is associated with the change of dielectric permittivity of the solvent medium surrounding the ion [44].

It is noted that surface diffusion of sorbed ions is a known phenomenon, but the typical diffusion coefficients associated with this process are typically  $10^4$ – $10^5$  times smaller than the corresponding self-diffusion coefficients in water, so that it does not contribute significantly to the total ionic fluxes, even in very narrow channels with a high surface-area-to-volume ratio [45].

## 4. TECHNOLOGIES FOR NANOFUIDICS

In this review, nanochannels are defined as straight channels with at least one dimension of the cross section in the submicron range (1D nanochannels). We divide nanochannels into nanochannels that can be addressed and used as a unit (“singularly addressable nanochannels”) and channels that exist as an ensemble (“ensembles of nanochannels”), the latter being porous membranes. Among the singularly addressable nanochannels, a further distinction can be made: channels fabricated with Micro System Technology (MST) where dimensions are pushed to the resolution limits (“top down” approach), and channels produced with new synthetic strategies and self-assembly processes (“bottom-up” approach). In this and the following paragraphs, fabrication techniques and the application of nanochannels will be presented according to the above-explained distinctions.

### 4.1. Singularly Addressable Nanochannels

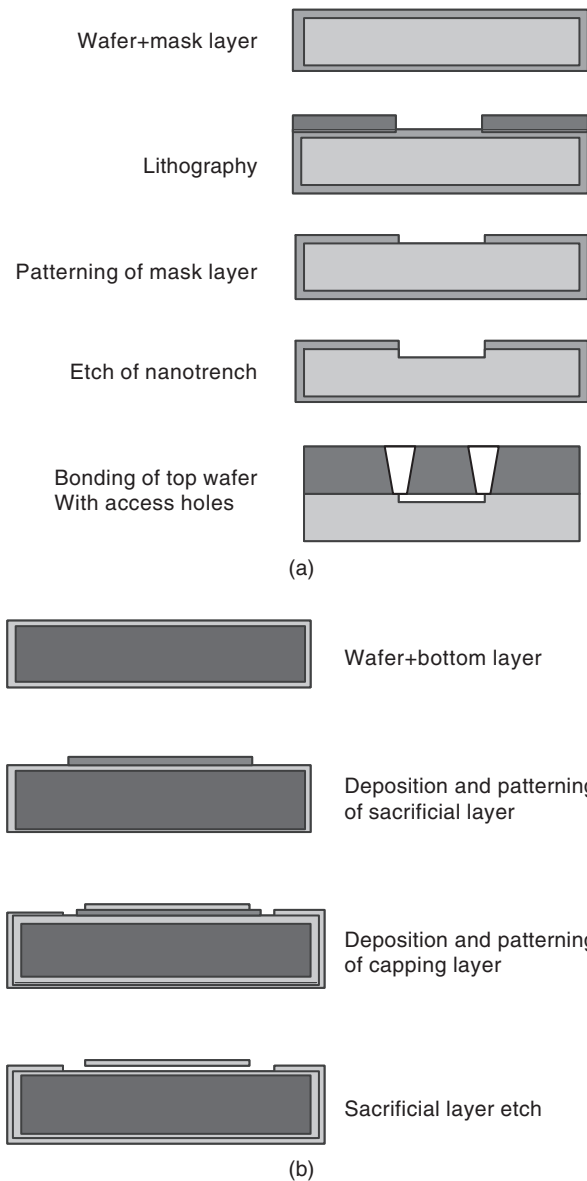

#### 4.1.1. Top-Down Approach

Processes and methods from the semiconductor industry have been successfully applied for the construction of a variety of microsystems. The same top-down approach used in Micro System Technology can be used to fabricate nanosystems. An overview of channel fabrication techniques was recently described by Rasmussen [46]. Technologies for the fabrication of nanochannels are extensively discussed in the chapter by Jansen et al. in this encyclopedia. Here, we will briefly summarize the two main strategies for the fabrication of nanochannels: surface and bulk nanomachining.

**Bulk Machining** In bulk machining, the channel is created in a substrate wafer by way of removing (etching) trenches. Typically, this is done by standard photolithography followed by wet or dry etching of the substrate material. The formed space is closed by bonding another wafer on top of the first one [Fig. 6(a)]. Different bonding methods are found, depending on the bulk material used: polymer bonding for plastic substrates, anodic bonding for alkaline-containing glasses such as Pyrex, eutectic bonding for metallic alloys, fusion bonding for glass, and direct bonding for highly polished substrates such as silicon. In the bonding technique, in general, microvoids should be prevented because they can cause leakage of the fluid from the nanochannel.

With this technique, shallow sub-100 nm trenches are etched in a wafer, and covered by another wafer to form 1D nanochannels. The width of the channel is determined by the resolution of the photolithographic process used. A scanning electron micrograph of channel cross section fabricated using bulk machining is shown in Figure 7.

**Figure 6.** Basic fabrication processes for nanochannels. (a) Bulk machining. (b) Surface machining.

**Surface Machining** In surface machining, structures can be obtained on the surface of a wafer by the successive deposition, photopatterning, and etching of a sacrificial layer and a structural layer. In order to fabricate a channel, a patterned and buried sacrificial layer is removed/etched to form the inner part of a channel: a process known as sacrificial layer etching. The essence of this technique is the selective removal of the patterned sacrificial layer to create the inner space of the fluidic channel, leaving the surrounding material to constitute the walls of the channel [Fig. 6(b)]. A variety of sacrificial materials can produce nanochannels, including silicon oxide/nitride [47–49], polysilicon [50, 51], and polymer [52]. Scanning electron micrographs of channel cross sections fabricated using the differential etching are shown in Figure 8. As in the case of bulk machining,

**Figure 7.** Scanning electron micrograph of 50 nm deep channel in  $\langle 110 \rangle$  silicon bonded with silicon cover wafer. Reprinted with permission from [99], J. Haneveld et al., “Proceedings of MME’ 02 Micromechanics Europe,” 2002, pp. 47–50. © 2002,

the width of the channel is determined by the resolution of the photolithographic process used.

However, recently, two new methods have been developed to fabricate nanochannels by conventional micromachining,

**Figure 8.** Scanning electron micrographs of channel across sections fabricated using the differential etching between Si and  $\text{Si}_3\text{N}_4$  in a TMAH-water solution. (a) 1 μm wide, 100 nm high. (b) 0.5 μm wide, 100 nm high. Reprinted with permission from [51], M. G. Stern et al., *J. Vac. Sci. Technol. B* 15, 2887 (1997). © 1997, American Vacuum Society.

with the width of the channels restricted to the submicrometer scale, while using standard photolithography with a resolution on the order of  $1\ \mu\text{m}$  [53]. Both methods are based on the sacrificial layer etching, as schematically explained in Figure 9(A),(C). Scanning electron microscope (SEM) photographs of the fabricated channels are shown in Figure 9(B),(D).

#### 4.1.2. Bottom-Up Approach

Carbon nanotubes (CNTs) are graphene sheets rolled up into cylinders of only a few nanometers in diameter and an extremely high length-to-width aspect ratio.

They were first observed in 1991 by Sumio Iijima at the NEC Fundamental Research Laboratory in Tsukuba, Japan, while inspecting with a high-resolution transmission electron microscope the soot created in an electrical discharge between two carbon electrodes. These so-called multiwall carbon nanotubes (MWCNTs) consisted of several concentric tubes of carbon nested inside each other. Two years later, in 1993, Iijima's group at NEC and Donald Bethune's group at IBM's Almaden Research Center in California independently observed single-wall carbon nanotubes (SWCNTs) just 1–2 nm in diameter. Nanotubes can be produced by evaporation of solid carbon in arc discharge, laser ablation, catalytic chemical vapor deposition of carbon-containing gases, and catalytic decomposition of fullerenes. A detailed description of manufacturing techniques for CNT falls outside the purpose of this chapter; recently, an extensive review appeared [54].

#### 4.2. Ensembles of Nanochannels

Nanotubular membranes are generally made by template-directed syntheses, with either polycarbonate nuclear track-etched (PCTE) membranes or anodic aluminum oxide films as templates [55, 56]. Commercial  $6\ \mu\text{m}$  thick PCTE membranes with channel densities of  $5\text{--}10 \cdot 10^8\ \text{cm}^{-2}$  and channel diameters down to 10 nm are available. Due to the random nature of the pore production process, the pore direction can deviate from the surface normal up to  $30^\circ$ , while some channels may even intersect somewhere inside the PCTE film. Anodic alumina membranes are also commercially available. They are  $\sim 50\ \mu\text{m}$  thick, and contain cylindrical pores of uniform diameter that are arranged in a hexagonal array. They are prepared by anodization of aluminum metal foils in acidic solutions, and have porosities of 25–40%, which is much higher than in PCTE. The channel diameter can be controlled by the applied voltage during anodization, and is typically between 20 and 200 nm.

### 5. REALIZATIONS AND APPLICATIONS

The recent popularity of nanotechnologies has made possible the development of individual nanoconfinements in which fluid flow can be studied and used in new applications. As this is a relatively new field, there are only few reported applications as yet. More is known on fluid flow through nanochannels in porous media.

**Figure 9.** Fabrication of 2D confined nanochannels. (A) Method 1 is based on the formation of a nanowire on the side wall of a step. The nanowire is subsequently encapsulated, and finally it is removed by chemical etching to create the nanochannel. (B) SEM photograph of a nanochannel fabricated by method 1. The height and width of the channel are approximately 90 and 40 nm, respectively. (C) Method 2 is based on the etching of a sacrificial strip separating the substrate and the capping layer. During drying of the structure, the capping layer is pulled down by the capillary forces of the remaining liquid, and once brought in contact with the substrate, adheres permanently, forming a nanochannel. (D) SEM photograph of a nanochannel fabricated by method 2. The height and width of the channel are approximately 50 and 400 nm, respectively. Reprinted with permission from [53], N. R. Tas et al., *Nano Lett.* 2, 1031 (2002). © 2002, American Chemical Society.

## 5.1. Singularly Addressable Nanochannels

### 5.1.1. Top-Down Approach

Stern et al. [51] described the design and fabrication of a chemical charge-coupled device (CCD), which is based on the application of electrostatic fields in nanocapillary channels smaller than the Debye length, in order to concentrate ions by stepping them down the channels. Channels down to a height of only 20 nm were fabricated by sacrificial etching of an amorphous silicon layer in a tetramethylammonium hydroxide (TMAH) solution. Turner et al. [57] described the fabrication of a monolithic nanofluidic sieving structure for DNA electrophoresis, by means of the sacrificial layer technique. An array of pillars, 100 nm in diameter and separated by 100 nm spacing, was formed by etching holes in the 400 nm thick sacrificial polysilicon layer, subsequent filling of the holes by the silicon nitride capping layer, and finally sacrificial layer etching of the polysilicon in a TMAH solution. Electron beam lithography was used to define the holes. The pillar array was successfully employed to separate two different DNA chain lengths (43 and 7.2 kbase) by electrophoresis. A similar pillar array was used to study the motion of DNA molecules, caused by confinement-mediated entropic forces [58]. Chou et al. [59] used a nanofluidic sieving structure, consisting of a two-dimensional array of obstacles (Fig. 10) whose asymmetric disposition rectifies the Brownian motion of molecules driven through the devices, causing them to follow paths that depend on their diffusion coefficient. A 6% resolution in molecular length could be achieved in the 15–30 kbp range.

Han et al. [60, 61] presented the mechanism of entropic trapping to induce effective mobility differences between different sized DNA molecules. The trapping occurred in a nanochannel consisting of alternating thick and thin regions when the molecules moved from the thick to the thin region. The nanochannel with variable depths was defined and etched using two-level photolithography. The channel was closed by anodic bonding of a Pyrex coverslip. In the thick regions (0.65–1.6  $\mu\text{m}$  height), the DNA molecules

**Figure 10.** Scanning electron micrograph of the array of obstacles. The obstacles are 0.35  $\mu\text{m}$  high and measure  $1.5 \times 6.0 \mu\text{m}$ . The gap between adjacent obstacles is 1.5  $\mu\text{m}$ . An electric field propels the molecules directly through the gaps between the posts with velocity  $v$ . Transverse Brownian motion may cause a molecule to skip one channel to the right if it diffuses through displacement  $a_R$  or, very rarely, one channel to the left if it diffuses through  $a_L$ . Reprinted with permission from [59], C. F. Chou et al., *Proc. Nat. Acad. Sci. USA* 96, 13762 (1999). © 1999,

can relax to their equilibrium spherical shape. As a result, they are entropically hindered from entering the thin region (90 nm height) of the channel. Two different DNA types, T2 (164 kbp) and T7 (37.9 kbp), could successfully be separated by entropic trapping, with a trapping lifetime of T7 to T2 DNA of 1.7–1.9 at the same electric field. In another experiment, the same group managed to separate mixtures with up to eight different types of DNA, in the range of 5–48 kbp [62] (Fig. 11).

Baba and colleagues [63] demonstrated “size exclusion chromatography”-type separation of DNA molecules in a channel with alternating regions with empty space and patterned nanopillar arrays. With such a device, they could separate 5 and 10 kbp DNA molecules. 80  $\mu\text{m}$  wide and 360 nm high channels were made on a silicon wafer by dry etching from a nanopattern of the calixarene resist fabricated by electron beam lithography [64].

Foquet et al. [65] reported the use of nanochannels to confine the electrically driven flow DNA fragments through the optical detection volume of a confocal microscope (Fig. 12). For DNA fragment sizing, channel regions with a height of 270 nm and a width of 1  $\mu\text{m}$  were fabricated

**Figure 11.** Nanofluidic separation device with many entropic traps. (A) Cross-sectional schematic diagram of the device. Electrophoresed DNA molecules are trapped whenever they meet a thin region because their radius of gyration ( $R_g$ ) is much larger than the thin region depth (here,  $t_d$  and  $t_s$  are the thick and thin region depths, respectively). (B) Top view of the device in operation. Trapped DNA molecules eventually escape, with a probability of escape proportional to the length of the slit that the DNA molecule covers ( $w_a$  and  $w_b$ ). Larger molecules have a higher escape probability because they cover wider regions of the slit ( $w_b > w_a$ ). (C) Experimental setup. Reservoirs are made at both ends of the channel, and filled with DNA solution. Reprinted with permission from [62], J. Han and H. G. Craighead, *Science* 288, 1026 (2001). © 2000, American Association for the Advancement of Science.

**Figure 12.** The image presents a picture taken with an intensified CCD camera of the single molecule sizing device. The outline of the capillary has been added for clarity. with the sacrificial layer technology, using material optically transparent and with low fluorescence background. The small channel dimensions facilitate single molecule detection, and minimize events of the simultaneous passage of more than one molecule through the measurement volume. The size of the fluorescent-labeled DNA molecules was determined from the number of photons per photon burst, each burst coinciding with the passage of a single DNA molecule.

Interesting fabrication techniques for the confinement of biological molecules in ultra small spaces were shown by Cao and colleagues [66]. High-density arrays of nanofluidic channels (Fig. 13) were fabricated using nanoimprint lithography (NIL), reactive ion etching, and nonuniform deposition to both reduce the cross section of the nanochannels and, if desired, seal the channels. The resulting sealed channels had a cross section as small as  $10 \text{ nm} \times 50 \text{ nm}$ .

Kameoka et al. [67] presented a refractive index sensor based on photon tunneling in a nanofluidic channel. A nanochannel was etched into a glass wafer, and enclosed by bonding of a second glass wafer to the first. The channel height is less than or comparable to the wavelength of the laser light used, allowing light transmission by photon tunneling if the angle of incidence of the laser light is larger than the critical angle. The photon tunneling probability depends strongly on the refractive index of the material in the nanofluidic channel, and can therefore be used to measure chemical composition changes of the fluid in the test volume.

Nanofluidic pumps and flow sensors can be used in applications where accurate dosing of a chemical substance is required. Wu et al. [49] reported the fabrication and

successful testing of a thermal flow sensor fabricated on top of a surface micromachined channel. The sensor uses boron-doped polysilicon thin-film resistors embedded in the silicon nitride wall of a microchannel as the sensing and heating elements. The sensors have demonstrated a flow rate resolution of 0.4 nL/min, as well as the capability to detect microbubbles in the liquid.

Chmela et al. presented an on-chip hydrodynamic chromatography (HDC) system consisting of a shallow, large aspect ratio separation channel ( $1 \mu\text{m}$  deep and  $1000 \mu\text{m}$  wide) fabricated using silicon and glass microtechnology [68]. The basic principle is that, in narrow conduits with a laminar flow, large molecules or particles (size 0.002–0.2 of the conduit size) are transported faster than smaller ones as they cannot fully access slow-flow regions near the conduit walls.

Ramsey and co-workers investigated the electrokinetic (EK) transport of fluids and macromolecules through nanometer-confined channels fabricated using standard photolithography and wet chemical etching techniques [69, 70]. Experimental measurements of electroosmotic mobilities under electrical double-layer overlap conditions showed that the mobilities are reduced, in qualitative agreement with the theory [71]. The authors reported the use of EK transport under double-layer overlap conditions to generate hydraulic pressure, and to separate 100 and 1000 base pair fragments of dsDNA in solution. This could be achieved because of the flow profile in the nanochannel and the hydrodynamic radius of the two sizes of dsDNA molecules (Fig. 14). Unlike the case at microscale, the EK-induced flow profile for the submicron deep channel the authors used

**Figure 14.** Electrokinetic migration of 100 and 1000 base pair dsDNA at two different channel depths (9.5  $\mu\text{m}$  and 320 nm). Reprinted with permission from [70], J. M. Ramsey et al., "Proceedings of Micro Total Analysis Systems 2002," 2002, pp. 314–316. © 2002, Kluwer Academic.

(320 nm) is expected to have a parabolic character. The smaller molecules can, therefore, approach the channel walls more closely, and experience lower flow velocity than the larger molecules.

Kitamori and colleagues [72] studied the behavior of aqueous solutions of rhodamine 6G, sulforhodamine 101, and rhodamine B in nanometer-sized fused silica channels. By using time-resolved spectroscopy, the spectra of the solutions were determined in the nanochannels, and compared to those obtained in microchannels. From the analysis of the fluorescent decays, it was suggested that the solutions had lower dielectric constants and higher viscosities in the nanometer-sized channels. The channels were fabricated on fused silica substrates by a fast atom beam (FAB) etching method and hydrofluoric bonding of cover plates.

### 5.1.2. Bottom-Up Approach

The inner hollow cavity of carbon nanotubes offers the possibility for intriguing nanoscale experiments if it could be filled with other materials in a systematic way [73]. Interesting experiments concerning the capillarity of carbon nanotubes have been carried out. Ajayan et al. [74], Dujardin et al. [73], and Ugarte et al. [75] reported capillarity-induced filling of carbon nanotubes by molten materials (liquid metals, salts, or oxides). Dujardin and colleagues [73] proved that

nanotubes can be wet and filled by substances with low surface tension, the upper limit of the surface tension being less than 200 mN/m. The wetting cutoff value of the surface tension is still sufficiently high to allow wetting by water ( $\gamma \sim 72$  nN/m) and most organic solvents ( $\gamma < 72$  nN/m). Ugarte and co-workers [75] filled open carbon nanotubes with molten silver nitrate by capillary forces. They concluded that there is a size constraint on the capillary filling of nanotubes, the capillarity being reduced for narrow tubes and the wetting depending on the cavity size. They explained this as a result of the increase of the nanotube–salt interface energy with decreasing curvature of the nanotube walls. The authors continued, demonstrating the formation of chains of silver nanobeads separated by high-pressure gas pockets as a result of the silver nitrate decomposition *in-situ* in an electron microscope

Gogotsi et al. and Megaridis et al. [76–78] observed the complex behavior of the gas–liquid interface of aqueous liquid inclusions in carbon nanotubes, upon heating by an electron beam in the transmission electron microscope (TEM). The carbon nanotubes used were produced by hydrothermal synthesis, and had a wall thickness in the 10–25 nm range and an outer diameter of about 100 nm (Fig. 15).

Sun and Crooks employed a 100  $\mu\text{m}$  long single carbon nanochannel with 150 nm diameter embedded in an epoxy matrix as a Coulter counter [79]. Polystyrene particles of  $\sim 60$  nm diameter were used as probes to study the hydrodynamic, electrophoretic, and diffusive transport properties of the nanochannel. The inner surface of the nanotube was found to be essentially charge neutral, so that electroosmotic effects could be neglected. The authors pointed out the advantage of using a single straight nanochannel to obtain information about fundamental modes of transport.

**Figure 15.** TEM micrograph sequence of a typical carbon nanotube portion showing the reversible volume contraction/expansion of a liquid entrapment upon heating/cooling achieved by manipulating the illuminating electron beam. (a) Initial shape of liquid at temperature  $T_a$ . (b) Inclusion gets thinner upon heating at  $T_b > T_a$ . (c) Liquid returns to its initial size upon cooling at  $T_c < T_b$ . (d) Heating is repeated ( $T_d > T_c$ ), resulting in a renewed contraction of the liquid volume. Reprinted with permission from [76], Y. Gogotsi et al., *Appl. Phys. Lett.* 79, 1021 (2001). © 2001, American Institute of Physics.

## 5.2. Ensembles of Nanofluidic Channels as Selective Interconnects

The discussion presented here is limited to ensembles of one-dimensional channels with sub-200 nm radial dimensions.

One of the pioneering works on fluid transport through nanochannels was performed by Martin and co-workers [80, 81]. The internal pore walls of PCTE membranes were coated with a gold layer using the electroless deposition technique, which yielded straight metallic nanotubules with channel diameters of 0.8–10 nm. They placed a membrane between two KF electrolyte solutions of different concentrations, and varied the electrical potential of the membrane relative to the reference potential in the solution with the higher electrolyte concentration. Depending on the sign of the membrane potential relative to the reference electrode, the membrane exhibited complete anion- or cation-permselective behavior. This effect was attributed to double-layer overlap inside the nanotubules, by which means ions of the same sign as the membrane are rejected. The extent of membrane permselectivity can be expressed quantitatively by the transference numbers for cations ( $t_+$ ) and anions ( $t_-$ ). For a 1:1 salt such as KF, the potential  $E_m$  over the membrane is given by

$$E_m = \frac{k_B T}{e} (t_+ - t_-) \ln\left(\frac{a_h}{a_l}\right)$$

where  $a_h$  and  $a_l$  are the activities of the salt at high and low concentration, respectively [82]. The equation indicates that  $E_m$  is positive when the tubules are predominantly cation permselective ( $t_+ > t_-$ ), and negative when they are anion permselective ( $t_+ < t_-$ ). Figure 16 illustrates a series of  $E_m$  values measured at different applied potentials, which proves that Au nanotubules can function as electronically

**Figure 16.** Variation of  $E_m$  with potential applied to a gold-nanotubule membrane (1 mM KF on the low concentration side; 10 mM on the high side of the membrane; tubule radius  $\sim 1.1$  nm). The dashed lines indicate the expected  $E_m$  values for ideal cation- and anion-permselective behavior. Reprinted with permission from [80], M. Nishizawa et al., *Science* 268, 700 (1995). © 1995, American Association for the Advancement of Science.

switchable ion-exchange membranes. Studies on the permeabilities of complex cationic and anionic species of  $\sim 1$  nm diameter showed high tunability of the fluxes with variation of potential [83]. Some selected data are listed in Table 3. It was shown that the permeability in 1.5 nm channels was mainly due to electrostatic rather than to steric effects. Another external handle to effect molecular transport in nanosized channels is pH. Bluhm et al. studied the diffusion of mono-, di-, and trivalent cations across anodic alumina membranes with pore diameters of 20 and 100 nm as a function of ionic strength and pH [84, 85]. It was concluded that the cation diffusion coefficients decreased with cation valency, which was attributed to the larger electrostatic interactions between the cations and the positively charged alumina surface at pH below 9. The diffusion rates could be enhanced by increasing the pH of the electrolyte solution from 5 to 8, as this leads to a decrease of the positive surface charge density on the alumina pore walls, and thus to a decreased electrostatic repulsion between cations and the channel wall [84]. Bohn and co-workers also studied the influence of electrolyte strength and pH on the permeability of cationic, anionic, and neutral species in aqueous buffer solution [21, 86]. Further control over the pH dependence of the surface-charge density can be obtained by employing self-assembled monolayers (SAMs) on the pore walls [83, 84]. Stroeve and co-workers modified the surface chemistry of Au-coated 8 nm nanotubular PCTE membranes with a covalently bonded monolayer of acid-functional thiols HS-(CH<sub>2</sub>)<sub>10</sub>-COOH [87]. The diffusion of benzene sulfonate anions was shown to be highly dependent on the external pH of the solution, in contrast to anion diffusion through bare or Au-coated PCTE membranes. This effect is illustrated in Figure 17, and was attributed to the pH-dependent ionization of the surface carboxylic groups in the SAMs and electrostatic interactions between the anions and the surface charge. Cysteine, a thiol-functional amino acid with an isoelectric point around 6.0, was also employed as a surface-modifying agent [83, 88, 89]. Here, the permeating cationic species showed high fluxes at pH 12, where cysteine is negatively charged, and low flux at pH 2, where cysteine is positively charged. The opposite trend with pH was observed for anionic species [88]. The concept of size-based separation was elaborated in a study on size-based protein separation by gold nanotubule membranes [90].

**Table 3.** Flux data of complex ionic species through 1.5 nm gold nanotubular membranes versus potential  $E$  applied to the membrane. Background electrolyte 0.5 mM KF. Concentration of permeation ion 2.5 mM. Ru(bpy)<sub>3</sub><sup>2+</sup> = ruthenium tris-(2,2'-bipyridine) cation; BTA<sup>+</sup> = benzyl tributyl-ammonium cation; NDS<sup>2-</sup> = 2,6-naphthalene disulfonate anion; PTS<sup>-</sup> = p-toluene sulfonate anion.

Permeate ion	Flux ( $10^{-9}$ mol $\cdot$ cm <sup>-2</sup> $\cdot$ s <sup>-1</sup> )		
	$E = -400$ mV	$E = 0$	$E = +400$ mV
Ru(bpy) <sub>3</sub> <sup>2+</sup>	0.30	0.09	0.08
BTA <sup>+</sup>	0.34	0.19	0.11
NDS <sup>2-</sup>	0.002	0.01	0.03
PTS <sup>-</sup>	0.04	0.13	0.20

The Au nanotubule inner diameter was controlled by variation of deposition time of the gold layer inside the PCTE nanochannels. It was shown that the low-molecular-weight protein lysine ( $M_w = 14$  kg/mol) was transported preferentially over high-molecular-weight bovine serum albumin ( $M_w = 67$  kg/mol) through nanochannels of 23 nm diameter. The transport of nonhydrophilic molecules can be enhanced by the covalent attachment of a hydrophobic SAM on the internal channel walls [80, 81, 91, 92]. This allows the preferential separation of *neutral* molecules based on their degree of hydrophobicity/hydrophilicity. Derivatization of gold nanotubules using the hydrophobic thiol HS-C<sub>16</sub>H<sub>33</sub> showed an enhanced transport rate of hydrophobic solvents [91]. Flux and selectivity data for hydrophobic toluene and hydrophilic pyridine through nanotubules modified with hydrophobic and hydrophilic SAMs are listed in Table 4. A similar approach can be utilized to selectively separate *chiral* neutral molecules, as was demonstrated recently [93]. In view of the fact that chiral enantiomers exhibit chemically and physically identical behavior, and are therefore very difficult to separate by simple means, the proposed concept appears very promising. Silica nanotubes were chemically

**Table 4.** Flux and selectivity data for toluene and pyridine through Au nanotubule membranes modified with hydrophobic (–C<sub>16</sub>H<sub>33</sub>) and hydrophilic (–C<sub>2</sub>H<sub>4</sub>OH) SAMs.

Thiol	Channel diameter (nm)	Flux ( $10^{-9}$ mol · cm <sup>-2</sup> · min <sup>-1</sup> )	
		Pyridine	Toluene
HS–C <sub>2</sub> H <sub>4</sub> –OH	3.0	7.0	2.6
HS–C <sub>16</sub> H <sub>33</sub>	3.0	0.46	28
HS–C <sub>2</sub> H <sub>4</sub> –OH	2.0	5.6	0.61
HS–C <sub>16</sub> H <sub>33</sub>	2.0	0.1	20

synthesized within the 20–35 nm diameter channels of an anodic alumina membrane. An antibody that selectively binds to only one of the enantiomers of a mixture of a clinical drug was chemically bonded to the channel walls of the silica nanotubes, after which the membrane became selectively permeable to the enantiomer that can attach to the antibody. Dynamic control over the channel diameter was demonstrated by Ito et al. [94]. Ionizable thiol-functionalized poly-(L-glutamic) acid polypeptides were covalently bonded to the internal channel walls of a gold-coated PCTE membrane. The polypeptides respond to changes of pH and ionic strength by a conformational change: at low pH, they become positively charged, and fold to form a relatively short ( $\sim$ 1.5 nm)  $\alpha$ -helical coil. Upon deprotonation at high pH, the polypeptide chains form a relatively extended ( $\sim$ 16 nm) random structure. The water permeation rate through the channels can thus be reversibly regulated by pH since the channel diameter can be made larger or smaller. The effect becomes less pronounced at high ionic strength, as illustrated in Figure 18.

The application of carbon nanotubes as nanofluidic channels has been limited so far [79, 95, 96]. Ensembles of straight parallel carbon nanotubes can be formed by the thermal decomposition of ethylene or propylene in an anodic alumina film [97, 98]. EOF studies were performed on  $\sim$ 60  $\mu$ m long carbon nanotubes with an inner diameter of 120–200 nm [95, 96], which is too large for complete double-layer overlap to occur. The direction of the EOF indicated that the as-synthesized tubes have a negative surface charge between pH 3 and 7.2, and the EOF velocity was found to vary linearly with applied current density [95]. An electrochemical derivatization method was used to covalently attach acidic (negative) carboxylate groups to the channel walls, thus increasing the negative surface-charge density and  $\zeta$  potential. In this way, the EOF rate could be increased in comparison with the as-synthesized tubes [96].

## GLOSSARY

**Carbon nanotube (CNT)** Carbon nanotubes are graphene sheets rolled-up into cylinders with diameters as small as one nanometer. A single-wall carbon nanotube (SWCNT) is a graphene sheet rolled-over into a cylinder with typical diameter on the order of 1.4 nm. A multi-wall carbon nanotube (MWCNT) consists of concentric cylinders with an interlayer spacing of 3.4 Å and a diameter typically on the order of 10–20 nm. The lengths of the two types of tubes can be up to hundreds of microns or even centimeters. The intriguing electrical and mechanical properties of carbon nanotubes have led to an explosion of research efforts worldwide.

**Double layer, electric double layer (EDL)** The region near a charged surface where counter-ions and co-ions in a polar medium are preferentially distributed, such that the net charge density is not zero. According to the Stern model, a plane (Stern plane) splits the EDL into an inner, compact layer considered to be immobile, and an outer, diffuse layer in which the ions are mobile.

**Electroosmosis (EO)** The movement of ionic conducting fluids through a capillary or a channel under the influence of an applied electric field. An electric field applied along the capillary/channel generates the movement of a thin layer of fluid at the channel walls where a small separation of charges occurs due to the equilibrium adsorption and desorption of ions. As the layer of fluid moves, it drags the fluid bulk resulting in an essentially flat velocity profile across the channel.

**Electrophoresis (EP)** The movement of charged particles suspended in a liquid under the influence of an applied electric field. Particles can be separated by electrophoresis on the basis of their relative electrical charges.

**Microelectromechanical systems (MEMS)** Electromechanical systems fabricated using materials and techniques developed in the integrated circuit (IC) industry. MEMS contain both electronic circuits and mechanical parts with dimensions in the micron range such as transducers, valves, and motors.

**Microsystem technology (MST)** Similar to MEMS with or without the electronic circuitry (e.g. optical, mechanical or fluidic structures).

**Reynolds number (Re)** Dimensionless number that represents the ratio of inertia forces to viscous forces. The Reynolds number of a fluid flow characterizes the regime of the flow as laminar or turbulent.

**Scanning electron microscopy (SEM)** A scanning electron microscope is a type of electron microscope capable of producing high resolution images of a sample. In electron microscopes (EMs) a focused beam of electrons is used to image the specimen and gain information as to its structure and composition. EMs were developed to achieve resolutions higher than those of light microscopes. SEM usually monitors secondary electrons which are emitted from the surface due to excitation by the primary electron beam. The first scanning electron microscope (SEM) was developed in 1942 and it was commercially available around 1965. See also TEM.

**Self-assembled monolayer (SAMs)** SAMs are monomolecular layers of a compound bound to a surface in a highly

organized fashion and with a bond whose strength typically varies between ionic and covalent. The process of self assembly is thermodynamically driven and capable of self repairing: if the layer immersed in the solution of the same compound is damaged, new molecules can replace the empty spaces on the surface. Examples are thiolates, sulfides and dithiols self assembling on gold. The monolayers formed by trialkoxysilanes on glass are erroneously defined as self assembling layers. In fact the coupling to the surface is covalent and not reversible. The concept of monolayer was introduced in 1917 when Langmuir studied film formed by amphiphiles spreading on water. He realized the film had the thickness of one molecule.

**Surface tension** The energy stored at the surface of liquids. The surface tension of a material is the energy needed to increase the surface of a unit area. It arises because of the difference in the intermolecular forces between molecules in the bulk of the liquid and molecules at the surface of the liquid. As the molecules in the bulk of the liquids are in favorable energy configuration, surface tension tries to minimize the surface area, resulting in liquids forming spherical droplets. Surface tension is measured in newtons per meter ( $\text{Nm}^{-1}$ ) which are equivalent to joules per square metre ( $\text{Jm}^{-2}$ ).

**Transmission electron microscopy (TEM)** It is an imaging technique whereby an image of a specimen is produced on a fluorescent screen or layer of photographic film by electrons focused on the specimen and travelling through the specimen. The transmission electron microscope (TEM) was developed by Max Knoll and Ernst Ruska in Germany in 1931. It was the first type of electron microscope to be developed. As its name suggests, the TEM is patterned on the Light Transmission Microscope: the image is produced by detecting electrons that are transmitted through the sample.

**Zeta potential ( $\zeta$ )** The electric potential at the shear plane in the electric double layer. The zeta potential is defined with respect to the potential of the bulk of the solution.

## 1. INTRODUCTION

Nanofluids are a new kind of heat transfer fluid containing a very small quantity of nanoparticles that are uniformly and stably suspended in a liquid. The dispersion of a tiny amount, yet tremendous number, of solid nanoparticles in traditional fluids dramatically changes their thermal conductivities. The average size of particles used in nanofluids may vary from 1 to 100 nm. The goal of thermal nanofluids is to achieve the highest possible thermal conductivities at the smallest possible concentrations of the smallest possible nanoparticles (preferably <10 nm). A typical nanofluid may contain very low concentrations (preferably <1% by volume) of solid nanoparticles and no surfactants or other dispersing chemicals. This creative combination of solid nanoparticles and liquid molecules has become an emerging

interdisciplinary field where nanoscience and thermal engineering meet.

Choi coined the term “nanofluids” for this new class of solid/liquid suspensions, developed primarily for heat transfer applications [1]. However, biologists and physicists have used the term nanofluids for different kinds of fluids. For biologists, nanofluids are nanometer-sized bioparticles such as DNA, RNA, and protein molecules in aqueous solutions [2, 3]. For physicists, fluids confined in a nanometer-sized container such as slit nanopores are called nanofluids [4–8].

The primary objectives of current nanofluids R&D are to exploit the unique properties of nanoparticles to develop heat transfer fluids that possess stable particle dispersion and high thermal conductivity, to characterize the transport properties and heat transfer performance of nanofluids, and to develop nanofluid technology for increasing the thermal transport of industrial heat transfer fluids. In this chapter, we address thermal nanofluids, particularly as related to heat transfer applications, and cover the literature on thermal nanofluids published in English since the pioneering work of Choi [1], with focus on the thermal conductivity.

Section 2 provides background on nanofluids, including their emergence in conjunction with a major trend in science and technology, the motivation and concept behind nanofluids, the advantages and new issues on the use of nanoparticles compared to micro- and mesoparticles, and the potential benefits of nanofluids.

Section 3 gives a brief review of the methods used for making nanoparticles to be dispersed in nanofluids and their characterization.

Section 4 presents a brief review of dispersion techniques and reviews the two methods (two-step and single-step) for making nanofluids.

Section 5 reviews the techniques used for measuring the thermal conductivity of nanofluids and the thermal conductivity data obtained with these techniques. This section also treats other transport properties and convection heat transfer of nanofluids.

Section 6 summarizes the conventional models for the thermal conductivity of solid/liquid suspensions and the great discrepancy between measured and predicted thermal conductivity, particularly for copper and nanotube nanofluids. Also covered are potential mechanisms for the enhanced thermal conductivity in nanofluids and molecular dynamics simulations of energy transport in nanoparticles and at the solid/liquid interface.

In Section 7 promising areas for future basic and applied research are identified, potential impacts and applications are suggested, and the interdisciplinary nature of nanotechnology is described.

Finally, in Section 8 we summarize key points of our review.

## 2. BACKGROUND OF NANOFUIDS

In 1959 Nobel prize winner Richard Feynman presented the concept of micromachines at the annual meeting of the American Physical Society held at the California Institute of Technology. Since then, miniaturization has been a clear and major trend in modern science and technology. Almost 40 years later, another Nobel prize winner, H. Rohrer, presented the chances and challenges of the “nanoage” [9]. The steady miniaturization trend has dropped from the millimeter scale of the early 1950s to the present-day atomic scale [10]. As the age of “bigger is better” gives way to the age of “smaller is better,” microelectromechanical systems and nanotechnology are rapidly emerging as the new revolution in miniaturization and as the technology to bring about a second industrial revolution. It is estimated that nanotechnology is at a similar level of development as computer/information technology was in the 1950s [11]. Nanofluids are an outgrowth of these trends in miniaturization and nanotechnology.

With an ever-increasing thermal load caused by the movement toward smaller features for microelectronic devices, more power output for engines, and brighter beams for optical devices, cooling for maintaining the desired performance and reliability of such devices is one of the crucial issues in high-tech industries such as microelectronics and transportation. The conventional method to increase cooling rates is to use extended surfaces such as fins and microchannels [12]. Choi et al. [13] performed an analysis of a silicon microchannel heat exchanger and predicted that power densities of approximately  $2000 \text{ W/cm}^2$  could be readily managed with the use of subcooled liquid nitrogen in microchannel heat exchangers (for a review of microscale heat transfer, see [14]). However, the pressure drop in the microchannels increases significantly as the diameter of the flow passage decreases, and eventually a cryogenic system is needed for liquid nitrogen cooling. Therefore, new and innovative concepts are needed for ultrahigh performance cooling.

Modern fabrication technology provides great opportunities to process and produce materials at the nanoscale.

The thermal, mechanical, optical, magnetic, and electrical properties of nanophase materials are superior to those of conventional materials with coarse grain structures. Consequently, nanophase materials have drawn considerable attention from material scientists and engineers alike. Major advances would be obtained if the coolant flowing in the microchannels were to contain these nanoscale particles to enhance heat transfer. Thus, taking a different tack from extended surface approaches and exploiting the unique properties of nanoparticles, Argonne National Laboratory (ANL) has pioneered ultrahigh thermal conductivity fluids, called nanofluids, by suspending nanoparticles in conventional coolants [1].

Thermal conductivities of traditional heat transfer fluids such as lubricants, engine coolants, and water are inherently low. With increasing global competition, industries have a strong need to develop energy-efficient heat transfer fluids with significantly higher thermal conductivities than are now available. Metals in solid form have orders-of-magnitude higher thermal conductivities than those of fluids. For example, the thermal conductivity of carbon multiwalled nanotubes (MWNTs) at room temperature [15] is about 20,000 times greater than that of engine oil, as shown in Figure 1. Therefore, the thermal conductivities of fluids that contain suspended solid metallic particles could be significantly higher than those of conventional heat transfer fluids.

In fact, numerous theoretical and experimental studies of the effective thermal conductivity of dispersions that contain solid particles have been conducted since Maxwell’s theoretical work was published about 100 years ago [16]. However, the studies on thermal conductivity of suspensions have been confined to millimeter- or micrometer-sized particles. The major problem with suspensions containing millimeter- or micrometer-sized particles is the rapid settling of these particles. If the fluid is circulated to prevent much settling, the microparticles would damage the walls of the pipe, wearing them thin. In contrast, nanoparticles remain in suspension almost indefinitely. Because nanoparticles are so small, they may act very much like molecules in solution, dramatically reducing erosion and clogging. Furthermore, microparticles are too large for microsystems, as mentioned before.

**Figure 1.** Thermal conductivities at 300 K of typical solids, including multiwalled carbon nanotubes and liquids.

A tiny size, along with a large specific surface area, makes nanoparticles attractive for coolant applications. When dispersed into liquids, nanoparticles bring about desirable novel properties such as high stability, high effective thermal conductivities, and less clogging and abrasion. The two novel features of nanofluids are well-suspended particles and thermal conductivities far above those of traditional solid/liquid suspensions. These features make nanofluids strong candidates for the next generation of coolants for improving the design and performance of thermal management systems.

However, as particle size is reduced down to the nanoscale, agglomeration is a new, serious issue, demanding new concepts for making nanofluids. For example, oxide nanoparticles have been dispersed in fluids. However, when dispersants such as alkali or acid were used, some of the original properties of the liquids were diminished or eliminated. Therefore, it is desirable to eliminate the use of chemicals with nanofluids for practical thermal systems. Until recently, the real challenge facing nanoscale thermal engineers was not only to create particles small enough that they would remain suspended for long periods of time but also to disperse them without agglomeration. This challenge was met when copper nanofluids were produced in a single step—an innovative way to make small and nonagglomerating metallic nanoparticles and to directly disperse them into liquids. This accomplishment has demonstrated that stable and highly conductive nanofluids can be produced at one-order-of-magnitude lower concentrations compared with traditional solid/liquid suspensions [17]. Most recently, multiwalled carbon nanotubes have been dispersed in oil and achieved the highest conductivity enhancement ever measured [18]. These developments have helped nanofluids become an emerging and active research area in nanoscale science, engineering, and technology.

Thermal scientists and engineers have been working for decades to develop more efficient heat transfer fluids for a variety of thermal systems. For example, improved engine oils and coolants would make engine cooling systems smaller and lighter, and consequently, lower fuel demands and emissions would do less damage to the environment. The impact of nanofluid technology is expected to be significant, considering that heat transfer performance is vital in numerous multibillion dollar industries. Potential benefits of nanofluids include:

- *Improved heat transfer and stability:* The much larger relative surface areas of nanophase powders, when compared with those of conventional powders, should markedly improve the heat transfer capabilities and stability of the suspensions. Furthermore, microparticles have most of their atoms far beneath their surface and cannot rapidly participate in heat transfer, but nanoparticles finer than 20 nm in diameter have ~20% of their atoms on their surface, allowing them to absorb and transfer heat efficiently.
- *Microchannel cooling:* “Tiny” particles well dispersed into a conventional fluid can significantly improve its ability to transfer heat. Moreover, when “tiny” means no larger than a few nanometers, this opens up the possibility of using nanoparticles in microchannels for many high-heat-load applications. A microchannel heat

exchanger with nanofluids would make a dramatic breakthrough in the development of advanced cooling technology because of a desirable combination of both large heat transfer area and high thermal conductivity [19]. In contrast, conventional meso- and microparticles cannot be used in microchannel flow passages.

- *Minimal clogging:* Micrometer-sized particles cannot be used in practical heat transfer equipment because of severe clogging problems. However, nanoparticles are believed to be ideally suited for applications in which fluids should flow through small passages without clogging, because the nanoparticles are so small that they are expected to behave like molecules of liquid.
- *Miniaturized systems:* Nanofluid technology will support the current industrial trend toward component and system miniaturization by enabling the design of smaller and lighter heat exchanger systems. Miniaturized systems will reduce the inventory of heat transfer fluid.
- *Cost and energy savings:* Successful employment of nanofluids will result in significant energy and cost savings because heat exchange systems can be made smaller and lighter.
- *Dramatically reduced pumping power:* To improve the heat transfer of a conventional fluid by a factor of 2, pumping power must be increased by a factor of about 10. However, if a nanoparticle-based fluid with a thermal conductivity about three times that of a conventional fluid were used in the same heat transfer equipment, the rate of heat transfer would be doubled [1]. Therefore, the potential savings in pumping power is significant with nanofluids.

The next-generation coolants based on nanofluids will likely play an important role in the future cooling applications. We believe that through interdisciplinary research and development, the dreams of designing highly conductive fluids containing very small amounts of nanoparticles, which do not settle in liquids, will come true, and the potential benefits will be realized. Nanofluid technology will thus be an exciting new technology of the 21st century.

### 3. MAKING OF NANOPARTICLES

#### 3.1. Synthesis

Nanoparticles, one of the smallest human-made objects, have unique mechanical, thermal, electronic, magnetic, optical, and chemical (catalytic) properties that are significantly different from those of the same material in bulk. They are the subject of extensive research and development because of their potential applications in many fields, such as nanofluids, electro/magneto/optical devices, catalysts, ceramics, and biological sensors. Various techniques have been developed to synthesize nanoparticles such as mechanical attrition, microemulsion synthesis, inverse micelle techniques, or precipitation techniques (for a review of various synthesis techniques, see [20]); however, most nanoparticles used in nanofluids have been synthesized by physical synthesis techniques, such as the inert-gas-condensation (IGC) process, or chemical synthesis techniques, such as chemical vapor deposition.

Various investigators have produced nanocrystalline  $\text{Al}_2\text{O}_3$  and  $\text{CuO}$  powders using the IGC process [21–26]. Nanoparticles of metals or ceramics in the size range 2–200 nm are generated by the IGC method in which the material is evaporated into a low-density, inert gas [27–30]. Vapors condense and coagulate to form nanoparticles as they diffuse rapidly from the hot source into the surrounding gas, and nanoparticles are transported and deposited by thermophoretic diffusion on a cold finger. After collection, reactant gases such as oxygen can be introduced to produce oxides. Particles are scraped from the cold finger and dispersed into a liquid. However, agglomerated nanoparticles are difficult to disperse in liquids. Because the IGC is a bottom-up approach to nanotechnology, nanoparticle production rates have been very small. The IGC has been a valuable tool for research, but not for production of nanoparticles in large quantities. However, recently the gas condensation technique has been scaled up to produce large quantities of nanoparticles [31]. Nanopowders produced in bulk at low prices can now be used to make nanofluids by the two-step method.

Although the IGC technique works well for oxide nanoparticles, it is not as effective for metal nanoparticles such as copper because agglomeration of individual particles has become a serious problem. Agglomeration of individual particles can be minimized by the direct evaporation–condensation (DEC) method for making and dispersing nanoparticles, as described in Section 4.2. Nanocrystalline  $\text{Cu}$  powders used in various studies [17, 21, 22] were produced by the DEC process.

Also recently,  $\text{SiC}$  nanoparticles were produced by a laser-induced vapor-deposition method using  $\text{SiH}_4$  and  $\text{C}_2\text{H}_4$  as sponsors [32]. The  $\text{SiC}$  nanoparticles were then heated at 650 °C for 30 min, leached with a 5% HF solution, and repeatedly washed with deionized water to eliminate excess carbon on the surface.

One of the best materials produced so far for nanofluids by chemical methods is the MWNTs [18]. Such particles were produced in a chemical vapor deposition reactor, using xylene as the primary carbon source and ferrocene as the iron catalyst [33].

### 3.2. Characterization

Nanoparticle characterization tools, such as transmission electron microscopy (TEM) and scanning electron microscopy (SEM), reveal nanoparticle size and size distribution. TEM was used to characterize nanoparticle sizes and morphologies of agglomerated powders [17, 21–23, 26, 32, 34]. Most nanoparticles used in nanofluids are spherical and their typical size is <40 nm in diameter. One important finding from the TEM studies is that oxide nanoparticles agglomerate to form much larger particles than primary particles.

Choi et al. [18] used high-resolution scanning electron microscopy to show that metallic MWNTs have a mean diameter of ~25 nm and length of ~50  $\mu\text{m}$  (an average aspect ratio ~2000) and contained an average of 30 annular layers. The nanotubes were typically straight in their as-grown form.

Xie et al. [25] used an automated X-ray diffractometer to determine the crystalline phases of alumina nanoparticles and a nitrogen adsorption apparatus to measure the specific surface area of the nanoparticles by the Brunauer–Emmett–Teller method.

Most investigators have used TEM to characterize nanoparticle sizes and morphologies of agglomerated powders. However, dynamic light scattering can be used for the particle size and size distribution measurement of colloidal particles between 3 nm and 5  $\mu\text{m}$  [35, 36]. When fine particles are illuminated by monochromatic light, a fluctuating scattering intensity occurs due to Brownian motion of the particles. The fluctuation is correlated to the diffusion coefficient of the particles. The particle size can be determined because it is inversely proportional to the diffusion coefficient.

## 4. MAKING OF NANOFLUIDS

Techniques for suspending nanoparticles in liquids are crucial to making stable nanofluids. The nanoparticles used in nanofluids come in a wide size range. However, most of them are between 10 and 40 nm. Nanoparticles do away with the old limitation of rapid settling of microparticles. But they pose a new challenge: if nanoparticles become too small, they can easily agglomerate before dispersion, and agglomerates of nanoparticles can settle rapidly just as microparticles do. Therefore, to create a stable nanofluid, the particles should be small enough to be suspended by Brownian motion, or the particles must be protected against aggregation by electric charges, protective coatings, or other means. Because aggregation of particles occurs more easily at high particle concentrations (>20% by volume), low concentration is highly desirable for nanofluids.

Two techniques are used to make nanofluids. First is the traditional two-step method (described in Section 4.1), which first makes nanoparticles as described in the previous section and then disperses them into the base fluid. Second is the new single-step DEC method (described in Section 4.2), which simultaneously makes and disperses the nanoparticles directly into the base fluid. Most researchers have produced oxide nanofluids by the two-step technique. Although the two-step technique works well for oxide nanoparticles, it is not as effective for metal nanoparticles. For nanofluids containing high-conductivity metals, the single-step DEC technique is preferable.

### 4.1. Dispersion of Nanoparticles in Liquids

Before we discuss the various techniques, let us first take a simple colloidal approach and evaluate what are the important factors in making a stable dispersion. Consider a “bare” spherical particle with density  $\rho_p$  and radius  $r_p$ , which is to be dispersed into a fluid with density  $\rho_f$  and viscosity  $\eta_f$ . From Stokes–Einstein theory [37], we can calculate the rate of particle sedimentation or creaming,  $v$ , as

$$v = 2r_p^2|\rho_p - \rho_f|g/9\eta_f \quad (1)$$

This equation indicates that the key to stable particle dispersion is a small  $r_p$ , a small density difference, and a high

fluid viscosity. The latter two are difficult to control or achieve, especially the third item, since higher viscosity is to be avoided in most heat transfer fluids. Careful selection of the nanoparticle and fluid materials may help in minimizing the density difference. A successful dispersion technique should be able to keep the primary particles from agglomerating or aggregating, or to break down large particles into smaller ones. In addition to particle size, density difference, and fluid viscosity, many other factors affect the stability of the dispersions, such as mechanical or sonic energy input, particle surface charge, the presence of surface modifiers (surfactants), and the chemical and rheological properties of the base liquid. A combination of these approaches will be sufficient to suspend nanoparticles in liquids.

The techniques used by researchers to disperse nanoparticles, or any small particles, into liquids can be categorized into two general types: physical and chemical [37, 38].

#### 4.1.1. Physical Methods

In physical processing, two kinds of stabilization methods can be considered: mechanical and ultrasonic dispersion. One means of mechanical dispersion is applying shear force to pull agglomerates apart—high shear mixing. Usually narrow passages and/or relatively high rates of flow are required to generate high shear. For that purpose, a rotor-and-stator construction is used. This includes a high-speed mixer, homogenizer, microfluidizer, Kady mill, and colloid mill. Another means of mechanical dispersion is high-impact mixing, which applies much higher energy to break the tightly bound aggregates apart or to shatter coherent solids into smaller pieces. Usually a grinding material of small particle size is used to exert an impact on the material or particles to be dispersed. Examples include attritor and ball-and-pebble mill.

Ultrasonication is also widely used in making nanofluids. Ultrasonics is a form of mechanical vibratory energy which propagates through a liquid medium as elastic waves. The ultrasonic interactions within a suspension could be mechanical, thermal, or chemical. The activator converts the regular-line frequency to a much higher level (e.g., 20,000 Hz), which is eventually converted into mechanical vibrations in the tips of various shapes (horns). A conventional bath-type sonicator provides less energy density than the tip-type one. The tip of the horn is immersed in a liquid in which the ultrasonic vibrations cause cavitation, which stirs the dispersion or breaks the agglomerates.

#### 4.1.2. Chemical Methods

Chemical methods are always applied as processing aids to the aforementioned physical methods. Long-range, attractive forces resulting from van der Waals interactions between like particles are always attractive and ubiquitous. To overcome van der Waals attraction between particles, an energy barrier is imposed around the primary particles so they cannot aggregate or agglomerate together easily [37]. Thus, if the repulsive barrier is much greater than  $k_b T$ , where  $k_b$  is Boltzmann's constant and  $T$  is temperature, particles repel one another on close approach and are well dispersed.

There are two kinds of stabilization methods: electrostatic and steric dispersion. In electrostatic dispersion, like electrostatic charges of sufficient magnitude are spread on the

surfaces of suspended particles to repel one another and remain in stable suspension, rather than form aggregates. Electrostatic stabilization is based on the famous Deryaguin-Landau-Verwey-Overbeek (DLVO) theory, which predicts the stability of particles suspended in polar liquids where electrolytes or other ionic species (such as detergents) are used [39–41]. However, since the concentration range for stabilization is critical, excessive or insufficient electrolyte may even induce agglomeration, especially where bivalent or trivalent metal ions are involved. Adjusting the pH of an aqueous system can also create electrostatic repulsion. The addition of dispersants such as acid or alkali into a liquid promotes the formation of finely dispersed nanoparticles. However, chemical dispersants have their limits. For example, particles usually settle in a week because of reduced zeta potential. (Zeta potential is defined as the measurement of electrokinetic forces that cause suspended particles to repel each other as a function of increased surface charge density.) For practical thermal systems, it is desirable to eliminate the use of chemicals for electrostatic dispersion. With alkali or acid, some of the original properties of liquids are diminished or eliminated.

Steric stabilization prevents the nanoparticles from getting close enough to coalesce and precipitate by means of dispersants such as surfactants (an acronym for surface active agents), polymers, or polymeric surfactants. All these molecules consist of an anchor moiety and a stabilizing moiety. The anchor moiety “attacks” the particle and adsorbs on the particle surface; the long tail of the molecule creates a steric repulsion for the approaching particles. Commonly used polymeric surfactants for nonaqueous systems may have anchor moieties such as polyarylonitrile, polyoxyethylene, polyethylene, polypropylene, poly(vinyl chloride), poly(methyl methacrylate), and polyacrylamide, and stabilizing moieties such as polystyrene, poly(lauryl methacrylate), poly(12-hydroxystearic acid), polydimethylsiloxane, polyisobutylene, *cis*-1:4-polyisoprene, poly(vinyl acetate), and poly(vinyl methyl ether). Commonly used polymeric surfactants for aqueous systems may have anchor moieties such as polystyrene, poly(vinyl acetate), poly(methyl methacrylate), polydimethylsiloxane, poly(vinyl chloride), and polyethylene, and stabilizing moieties such as polyoxyethylene, poly(vinyl alcohol), poly(acrylic acid), poly(methacrylic acid), polyacrylamide, poly(vinyl pyrrolidone), poly(ethylene imine), and poly(4-vinylpyridine).

Chemical modification on the particle surface is another widely used technology for improved dispersion [42]. This can be done by adding functional groups (hydroxyl, carboxyl, mercapto, etc.) onto the surface of the particles for better anchoring of the surfactants or grafting of a chain (for example, an octadecyl group) onto the particle surface to make a permanent bond. In the latter case, external surfactants may not be necessary due to the presence of the grafted group(s).

Very recently, Tohver et al. reported a new colloid stabilization mechanism, named “nanoparticle halos” [43], which uses highly charged nanoparticles to stabilize negligibly charged colloidal particles. Although this method is intended for stabilizing colloidal particles, further research may lead to its application with nanofluids.

Nearly all the nanofluids reported in the open literature are produced by the two-step method, except copper

nanofluids, which are produced by the one-step DEC process with and without the aid of thioglycolic acid [17]. Excellent suspension properties are also observed, with no significant settling of  $\text{Al}_2\text{O}_3$  and  $\text{CuO}$  nanoparticles occurring in stationary nanofluids over time periods longer than several days.

Various investigators have dispersed commercially available copper and aluminum oxide nanoparticles into base fluids (such as water, ethylene glycol, engine oil, or pump oil) in a mixing container, with or without use of ultrasonic vibration [21–26, 32]. Wang et al. [24] used a number of dispersion techniques, including an ultrasonic bath, to disperse  $\text{Al}_2\text{O}_3$  and  $\text{CuO}$  nanopowders into water, vacuum pump fluid, engine oil, and ethylene glycol and showed that the thermal conductivity of nanofluids depends on the dispersion technique, which might change the morphology of the nanoparticles. They also found that the nanofluids were stable when the volume fraction was  $<5\%$ , but became flocculated when the volume fraction was  $>10\%$ .

Xuan and Li used the two-step process to disperse 100-nm Cu nanoparticles in water or transformer oil [34]. The suspensions were vibrated for 10 hr in an ultrasonic vibrator. Still, they had to use a large amount of dispersants to make stable suspensions. Water-based Cu nanofluids were stable with laurate salt at 9 wt%, and transformer oil-based Cu nanofluids needed oleic acid up to 22 wt% to stabilize the nanoparticles in the mineral oil. Xie et al. [32] prepared nanofluids of SiC of different sizes and shapes in water or ethylene glycol through ultrasonication and magnetic stirring. Lockwood et al. [44] studied soot particles in used diesel engine oils as a model system and compared them with nanofluids made by dispersing carbon black particles into engine oils.

Recently, nanotube-in-oil suspensions were produced by the two-step method [18]: first, MWNTs were generated in a chemical vapor deposition reactor; then the MWNTs were dispersed into a synthetic poly( $\alpha$ -olefin) oil. The metallic MWNTs, which were typically straight in their as-grown form (Fig. 2), had a mean diameter of  $\sim 25$  nm and a length

**Figure 2.** Scanning electron photomicrograph of multiwall nanotubes used in MWNT-in-oil nanofluids. A conventional gold sputtering technique was employed to coat sample. Photo taken by a high-resolution HITACHI S-2700 scanning electron microscope. Scale bar is 800 nm. Reprinted with permission from [18], S. U. S. Choi et al., *Appl. Phys. Lett.* 79, 2252 (2001). © 2001, American Institute of Physics.

**Figure 3.** Nanotube nanofluids with and without dispersant produced by a two-step method. Because the synthetic polyalphaolefin oil does not wet the nanotubes, two distinctly different products were produced: (a) nanotubes quickly settle without use of a proper dispersant, and (b) nanotubes are well dispersed and suspended in the oil with succinimide dispersant (5 wt%), and the very stable nanotube nanofluid produced by this method is thus suitable for thermal conductivity measurements and future heat transfer applications.

of  $\sim 50$   $\mu\text{m}$  (for an average aspect ratio of  $\sim 2000$ ) and contained an average of 30 annular layers.

Because synthetic oil does not wet the nanotubes well enough (as demonstrated by the clear separation in Fig. 3a), a small amount of dispersant (5 wt%) was added to the oil to wet the nanotubes completely. This resulted in well-dispersed and stable nanotube nanofluids, as seen in Figure 3b. Loadings of up to 1 vol% were produced for thermal conductivity measurements.

#### 4.2. Direct Evaporation–Condensation Method

Conventional dispersion methods, such as electrostatic and steric stabilization of particles, use a dispersing chemical (acid, base, or surfactant) to prevent particle agglomeration and settling. Surfactants used in the steric stabilization of particles will change the physical and chemical properties of nanofluids, but not by much. In contrast, even a small amount of an acid (e.g., HCl) or base (e.g., NaOH) used to control pH in the electrostatic repulsion method may cause serious problems. Although the stability of nanoparticles can be controlled electrostatically for a certain time, typically one week, the particles eventually settle due to the large density difference. Electrostatic repulsion by itself is not enough for stabilizing the nanofluids. Furthermore, stabilizing nanoparticles by adding acids or bases may not be a practical means to produce nanofluids for commercial use. The suspensions with such chemicals are difficult to use in practical thermal systems due to high or low pH values. These pH values can cause corrosion and salt deposition on a heat transfer surface and other problems. Another problem with using acid or base is that they can change other liquid properties. A serious problem with oxide nanoparticles is the high concentrations (approximately 10 times those of metallic nanoparticles) needed to achieve high thermal conductivity enhancement.

Agglomeration of individual particles can be minimized by condensing the vapors from a heated source directly into a flowing low-vapor-pressure fluid. This approach is called “vacuum evaporation onto a running oil substrate” [45], a modification of which was developed recently [46]. The DEC system built at ANL was based on this modified process [17, 21, 22]. For nanofluids containing high conductivity metals, the single-step DEC technique is preferable to gas-condensation processing. Indeed, excellent results were attained when the nanoparticles from pure copper were generated and directly dispersed into a liquid in a single step. As shown in Figure 4, this method resulted in very small (an average diameter of less than 10 nm) particles with little agglomeration. In this one-step process, the materials scientists heated copper to a vapor inside a vacuum chamber. A cooled heat transfer fluid was placed in the chamber, and the copper vapor condensed when it touched the cooled fluid, forming <10 nm nanoparticles in the fluid.

Although nanoparticles produced by the single-step DEC method stay suspended in a liquid significantly longer than those produced by the two-step process, the DEC method is limited to low-vapor-pressure fluids. This is the case even though the liquid is cooled to prevent an undesirable increase in vapor pressure during the evaporation–condensation process due to radiant heating from the resistively heated evaporation source in a crucible. Another problem with metal nanoparticles is their oxidation, which reduces the thermal conductivity of metal nanofluids. Despite these shortcomings, this new approach, unlike previous work dispersing nanoparticles in liquids, uses size control alone to create long-term stable nanofluids and, thus, does not require surfactants or electrostatic control. An ANL nanofluid team was the first to employ size control alone to create nanofluids that are both stable and highly conductive at extremely low particle loadings (<1 vol%). Therefore, the DEC process is promising for producing nanofluids with nonagglomerating nanoparticles that possess the sought-for properties (i.e., stability, with or without acids or bases, and high thermal conductivity at small particle concentrations, while other properties remain unchanged).

**Figure 4.** Bright-field transmission electron micrograph of Cu nanoparticles produced by direct evaporation into ethylene glycol. Very little agglomeration occurs with this processing method. Reprinted with permission from [17], J. A. Eastman et al., *Appl. Phys. Lett.* 78, 718 (2001). © 2001, American Institute of Physics.

Eastman et al. added a small amount of thioglycolic acid (<1 vol%) to the nanofluids produced by the DEC method, primarily to improve their thermal conductivity [17]. This result shows that establishing good thermal interactions between solid nanoparticles and liquid molecules at the nanometer scale is critical in developing nanofluids. Note that thioglycolic acid ( $\text{HSCH}_2\text{COOH}$ ) is relatively weak compared to HCl or NaOH.

### 4.3. Electrohydrodynamic Spraying System

An electrohydrodynamic spraying system, or electrospray, can generate airborne nanoparticles in the size range of 2–100 nm with a production rate of up to 10 billion particles/s [47, 48]. This system could be used to develop a new method for making nanofluids containing highly charged particles that would not aggregate. These charged nanoparticles can be directly introduced into base fluids. The droplet size and the particle generation rate are functions of the liquid feed rate and the electrical conductivity of the spray solution/suspension. Colloidal suspensions of metal, oxide, and polymer nanoparticles have also been sprayed to form dispersed nanoparticles without aggregation [48]. A dual capillary approach has also been used to provide a sheath liquid of varying conductivity [49]. The sheath liquid can be made with desirable coating materials for producing coated nanoparticles. Recently, a multiple-nozzle approach has been developed to increase the throughput for producing nanoparticles by over 1000 times [50].

## 5. MEASUREMENTS IN NANOFLUIDS

### 5.1. Methods of Measuring Thermal Conductivity

The thermal conductivity of nanofluids has been measured by transient hot-wire (THW), temperature oscillation (TO), and steady-state (SS) methods. The first is the most widely used measurement technique for the thermal conductivity of nanofluids [17, 18, 21–23, 25, 32, 34, 44]. An advantage of THW over SS techniques is the elimination of problems associated with convection since the THW measurement lasts for a period on the order of seconds. The other two methods have been used to measure the thermal conductivity of oxide nanofluids [24, 26].

The THW method is quite accurate in determining thermal conductivities [51, 52]. Briefly, the THW system employs a thin metal line suspended symmetrically in a liquid in a vertical cylindrical container. The wire is used as both heater and thermometer. Platinum is used for the hot wire because its resistance/temperature relationship is well known over a wide temperature range [53]. When used in electrically conducting fluids, the Pt wire is coated with an electrically insulating and thermally conducting epoxy adhesive [52]. Instead of a two-wire compensation system [54], a long hot wire (wire length-to-diameter ratio of  $\sim 3000$ ) can be used as a hot-wire sensor to minimize end conduction loss. The THW method determines the thermal conductivity of nanofluids by measuring the temperature rise of a straight Pt wire in the nanofluid sample in response to a direct current. Because

the thermal conductivity of the liquid is inversely proportional to the slope of the temperature/time response of the wire, conductivity can be calculated by measuring the slope of the straight line [23]. The THW cell requires a very small volume (<60 ml) of nanofluids and is ideal for thermal conductivity measurements of scarce nanofluids samples. Lee et al. [23] performed calibration experiments for ethylene glycol in the temperature range of 290–310 K and at atmospheric pressure and reproduced literature values [55] with an error of <1.5%.

The thermal conductivity of fluids has been measured by the SS method since 1931 [56]. The one-dimensional, parallel-plate SS method was used by Wang et al. [24] to measure the thermal conductivity of oxide nanofluids. A test nanofluid is placed in the liquid cell sandwiched between an upper heater plate and a lower plate, both made of copper. For better control of the temperature surrounding the liquid cell, the liquid cell is housed in a larger cell made of aluminum. The upper heater plate is centered and separated from the inside wall of the aluminum cell by three small glass spacers. Small holes are drilled into the copper plates and the outer aluminum cell. Precalibrated E-type thermocouples are inserted into these holes to measure the temperatures. The thermocouples in the top and lower copper plates are located very close to the lower surface of the upper plate and to the upper surface of the lower plate. Because the thermal conductivity of copper is much higher than that of the liquid, these thermocouples measure temperatures at the surfaces of the plates.

The SS thermal conductivity apparatus has a simple construction, and the thermal conductivity can be determined in a straightforward manner from the one-dimensional heat conduction equation relating the power input to the heater, the temperature difference between the two copper plates, and the geometry of the liquid cell. However, this method is time consuming and requires many corrections for accurate measurements. Yet the experimental error estimated for water and ethylene glycol by comparing the measured thermal conductivity with the published data [57] is  $\pm 3\%$  in the temperature range of 20 to 40 °C [24].

Using the TO method, Das et al. have measured the thermal properties of  $\text{Al}_2\text{O}_3$  and CuO nanofluids as a function of temperature [26]. This purely thermal method measures temperature oscillations at the fluid sample, as outlined in a paper by Czarnetzki and Roetzel [58]. When used with nanofluids, this method has been found to be accurate and to prevent natural convection. More important, room-temperature thermal conductivity data for  $\text{Al}_2\text{O}_3$  and CuO nanofluids agree with the data of Lee et al. [23], even though their THW method differs from the TO technique of Das et al.

## 5.2. Measured Thermal Conductivities

The effective thermal conductivities of nanofluids containing different volume concentrations, materials, and sizes of solid nanoparticles dispersed in various base fluids have been experimentally investigated. The experimental results show that the effective thermal conductivities of all these nanofluids are much improved compared with those of base fluids. Among the tested nanofluids, copper-in-ethylene glycol and

nanotube-in-oil types have the highest thermal conductivity enhancement at the same concentration.

### 5.2.1. Oxide Ceramic Nanofluids

The thermal conductivities of oxide ceramic nanofluids with low particle concentrations (1–5 vol%) were studied experimentally. Lee et al. measured the thermal conductivities of water and ethylene-glycol-based nanofluids containing copper oxide and aluminum oxide nanoparticles and found that these nanofluids have substantially higher thermal conductivities than the same liquids without nanoparticles [23]. The maximum improvement in the thermal conductivity of ethylene glycol (20%) was seen when 4 vol% CuO nanoparticles with average diameter 35 nm were dispersed in this fluid.

Wang et al. [24] measured the effective thermal conductivity of nanofluids with 28 nm  $\text{Al}_2\text{O}_3$  and 23 nm CuO nanoparticles dispersed in distilled water, vacuum pump fluid (TKO-W/7, Kurt J. Lesker Company, Clairton, PA), ethylene glycol, and engine oil (Pennzoil 10W-30). The experimental results show that the effective thermal conductivity of nanofluids increases with decreasing particle size and depends on the dispersion technique.

Most recently, Xie et al. [25] measured the thermal conductivity of nanofluids containing alumina nanoparticles of 12.2–302 nm diameter and found that it depends on the size of the nanoparticle, the pH of the aqueous suspension, and the thermal conductivity of the base fluids.

Using the temperature oscillation technique, Das et al. [26] explored the temperature dependence of the thermal conductivity of water-based nanofluids containing  $\text{Al}_2\text{O}_3$  or CuO nanoparticles. This measurement confirmed the high level of thermal conductivity enhancement at room temperature reported by others [23]. More important was the discovery of a two- to fourfold increase in thermal conductivity enhancement for nanofluids over a small temperature range, 21 to 51 °C. Furthermore, nanofluids containing smaller CuO nanoparticles show more enhancement with temperature. Das et al. suggested that the strong temperature dependence of thermal conductivity is due to the motion of nanoparticles. This discovery, implying that that nanofluids could be smart fluids “sensing” their thermal environment, makes them even more attractive as coolants for devices with high energy density.

### 5.2.2. Nonoxide Ceramic Nanofluids

Xie et al. [32] measured the thermal conductivities of water and ethylene-glycol-based nanofluids containing 26 and 600-nm SiC nanoparticles. The measured data for small-size (26-nm) SiC particle suspensions were  $\sim 20\%$  greater than the value calculated with the Hamilton and Crosser model [59]. However, the model does predict the thermal conductivity of large-size (600-nm) SiC particle suspensions.

### 5.2.3. Metallic Nanofluids

Very stable and highly conductive copper nanofluids were produced by the single-step method [17]. Loadings of up to approximately 0.5 vol% of copper nanoparticles with an average diameter of less than 10 nm were dispersed into ethylene glycol with little agglomeration. For some nanofluids, a small amount of thioglycolic acid (<1 vol%) was added

to further improve the particle dispersion. The thermal conductivity of copper nanofluids was measured at room temperature [17, 22]. Figure 5 shows the measured thermal conductivity of Cu-containing ethylene glycol nanofluids as a function of nanoparticle volume fraction. The effective thermal conductivity of the nanofluid is plotted relative to that of its base fluid ( $k_e$  is the effective thermal conductivity of nanofluids, and  $k_f$  is the thermal conductivity of the base fluid). Figure 5 also shows the thermal conductivity enhancement of ethylene glycol +  $\text{Al}_2\text{O}_3$  and ethylene glycol + CuO [23]. These measurements showed for the first time that metallic nanoparticles increase the effective thermal conductivity by a significant amount over the same volume fraction of oxide nanoparticles. Also, nanofluids containing thioglycolic acid as a stabilizing agent showed dramatically improved behavior compared to nonacid-containing nanofluids. Approximately 0.3 vol% Cu nanoparticles of <10 nm diameter and <1 vol% thioglycolic acid in ethylene glycol improved the effective thermal conductivity by 40%. Interestingly, fresh copper nanofluids exhibited slightly higher conductivities than fluids that were stored up to two months prior to measurement.

Xuan and Li [34] dispersed 100-nm Cu nanoparticles into water and transformer oil by the two-step method with dispersants. Their thermal conductivity data are much lower than those of the nanofluids containing 10-nm Cu nanoparticles dispersed into ethylene glycol by the single-step method [17], possibly due to the different (two vs single step) dispersion techniques.

#### 5.2.4. MWNT Nanofluids

Recently, MWNT-in-oil suspensions with loadings of up to 1 vol% nanotubes were produced by the two-step method, and their thermal conductivity was measured at room temperature [18]. Figure 6 shows the measured thermal conductivity of MWNT-in-oil nanofluids as a function of nanotube volume fraction. Clearly, nanotubes yield an extremely large increase in thermal conductivity (up to a 150% increase in conductivity of oil at approximately 1 vol% nanotubes),

**Figure 5.** Thermal conductivity enhancement of copper, copper oxide, and alumina particles in ethylene glycol. Significantly greater enhancements are seen for nanofluids consisting of <10-nm diameter Cu nanoparticles than for either CuO or  $\text{Al}_2\text{O}_3$  nanoparticles of average diameter 35 nm. Reprinted with permission from [17], J. A. Eastman et al., *Appl. Phys. Lett.* 78, 718 (2001). © 2001, American Institute of Physics.

**Figure 6.** Thermal conductivity enhancement of MWNT-in-oil nanofluids. Dispersion of a very small amount of nanotubes produces a remarkable change in effective thermal conductivity of the base fluid, with the thermal conductivity ratio exceeding 2.5 at 1 vol% nanotubes. Comparison of measured data for nanotube suspensions (solid circles) and those predicted by theories (dotted lines) shows that the measured values are one order of magnitude greater than predictions at 1 vol% nanotubes. Because all calculated values are almost identical at the low volume fractions, some of the calculated values are reproduced on an expanded scale in the inset, where line A = Hamilton and Crosser [59]; line B = Bonnecaze and Brady [61, 62]; line C = Maxwell [16]. Reprinted with permission from [18], S. U. S. Choi et al., *Appl. Phys. Lett.* 79, 2252 (2001). © 2001, American Institute of Physics.

which is by far the highest thermal conductivity enhancement ever achieved in a liquid. Similar results have been reported for polymer/nanotube composites [60]. In Figure 6, we see another anomaly. The measured thermal conductivity is nonlinear with nanotube loadings, while all theoretical predictions clearly show a linear relationship [16, 59, 61, 62]. This nonlinear behavior is not expected in conventional fluid suspensions of micrometer-sized particles at such low concentrations. Our experiments imply the existence of nanotube/nanotube interactions, even at extremely low nanotube volume fractions (<1 vol%), possibly because of the astronomical number of nanotubes in the liquid and the extremely high aspect ratio ( $\sim 2000$ ) of the carbon nanotubes.

Several investigators have reported augmentation of the effective thermal conductivities of suspensions with millimeter-sized polystyrene particles under laminar flow [63, 64]. We expect that the effective thermal conductivities of nanofluids under flow conditions might be higher than the experimental results for stationary nanofluids.

#### 5.2.5. Summary

Copper nanoparticles and carbon nanotubes dramatically enhance the thermal conductivity of base fluids. Adding  $\sim 0.3$  vol% of 10-nm copper nanoparticles to ethylene glycol increases its thermal conductivity up to 40%. Nanotubes yield by far the highest thermal conductivity enhancement ever achieved in a liquid: a 150% increase in the conductivity of oil at  $\sim 1$  vol% of 25-nm nanotubes. Oxide nanofluids have the lowest thermal conductivity. Because ceramic oxides are abrasive, they are the least desirable materials for heat transfer applications.

In comparison with oxide nanofluids, the solid concentrations in copper or nanotube nanofluids are one order of magnitude lower for a comparable thermal conductivity enhancement. It should be possible to make the copper or

nanotube nanofluids less viscous than oxide nanofluids of comparable performance. Note that the only nanofluids that can compete in terms of thermal conductivity enhancement with nanotubes are those containing copper and acid produced by Eastman et al. [17]. However, since the degradation of Cu reduces the thermal-conductivity enhancement, nanotubes are, up to now, the best material for use in nanofluids.

Table 1 summarizes the typical nanofluids covered in this chapter, including the materials for nanoparticles and base fluids, dispersion methods, maximum thermal conductivity ratio, and references.

### 5.3. Viscosity

Wang et al. measured the viscosity of water-based nanofluids containing  $\text{Al}_2\text{O}_3$  nanoparticles dispersed by different techniques, that is, mechanical blending (Method I), coating of particles with polymers (Method II), and filtration (Method III) [24]. The solutions dispersed by Methods II and III had lower viscosities, indicating that the particles are better dispersed. The  $\text{Al}_2\text{O}_3$ /water nanofluids achieved a viscosity increase of  $\sim 30\%$  at 3 vol%  $\text{Al}_2\text{O}_3$ , compared to that of water alone. In contrast, the viscosity of  $\text{Al}_2\text{O}_3$ /water used by Pak and Cho [65] was three times higher than that of water. This large discrepancy could occur because Pak and Cho used acid or base in their test fluids and an electrostatic repulsion technique. Compared with the  $\text{Al}_2\text{O}_3$ /water system, the  $\text{Al}_2\text{O}_3$ /ethylene glycol system had a similar viscosity increase, but a higher thermal conductivity increase.

### 5.4. Convection Heat Transfer

Because nanofluids are rather new, relatively few theoretical and experimental studies have been done on their convective

heat transfer coefficients under flow conditions [1, 22, 34, 65, 66].

Assuming that only the thermal conductivity of the nanofluid system varies, and other properties (such as the specific heat, density, and dynamic viscosity) are the same as for the base fluid, Choi [1] estimated the enhancement of heat transfer due to increased thermal conductivity. His theoretical study of the heat transfer enhancement of nanofluids with copper nanoparticles showed that they will dramatically reduce the required heat-exchanger pumping power. For example, to improve the heat transfer of a conventional fluid by a factor of 2, the pumping power should be increased by a factor of about 10. However, if a nanoparticle-based fluid with a thermal conductivity of about three times that of a conventional fluid were used in the same heat transfer equipment, the rate of heat transfer would be doubled.

Xuan and Li [34] and Xuan and Roetzel [66] have proposed two causes of enhanced heat transfer by nanofluids: the enhanced thermal dispersion due to the chaotic movement of nanoparticles and the enhanced thermal conductivity of nanofluids considered by Choi [1].

Pak and Cho [65] dispersed  $\text{Al}_2\text{O}_3$  and  $\text{TiO}_2$  nanoparticles in water and measured the turbulent friction and heat transfer behavior of the dispersed fluids in round-tube flow. They showed that the Nusselt number increased with increasing volume fraction and the Reynolds number. However, the convective heat transfer coefficient of the dispersed fluid at a volume concentration of 3% was 12% smaller than that of pure water when tested under the condition of constant average velocity. This finding may be due to the large difference in the viscosity of the dispersed fluids used by Pak and Cho [65] and by Wang et al. [24], as discussed in Section 5.3.

**Table 1.** Dispersion methods and maximum thermal conductivity ratio for wide range of nanofluids covered in this chapter.

Nanomaterials	Base fluids	Dispersion methods	Maximum $k_e/k_f$ (at loading of vol%)	Ref.
Cu	ethylene glycol	one-step method, thioglycolic acid	1.4 (0.3)	[17]
Multiwalled carbon nanotubes	synthetic base oil, PAO	two-step method, polymer	2.57 (1)	[18]
$\text{Al}_2\text{O}_3$	water	two-step method	1.09 (4)	[23]
CuO	ethylene glycol	two-step method	1.19 (5)	
	water	two-step method	1.12 (3.4)	[23]
	ethylene glycol		1.22 (4)	
$\text{Al}_2\text{O}_3$	ethylene glycol	two-step method with mechanical/ultrasonic mixing	1.4 (8)	[24]
$\text{Al}_2\text{O}_3$	water	two-step method with filtration	1.12 (3)	[24]
CuO	ethylene glycol	two-step method with mechanical/ultrasonic mixing	1.54 (14.7)	[24]
$\text{Al}_2\text{O}_3$	ethylene glycol	two-step method	1.29 (5)	[25]
$\text{Al}_2\text{O}_3$	water	two-step method	1.24 (4)	[26]
CuO	water	two-step method	1.36 (4)	[26]
SiC	DI $\text{H}_2\text{O}$	two-step method	1.23 (4)	[32]
Copper	transformer oil	two-step method oleic acid	1.43 (7.5)	[34]
Copper	water	two-step method laurate salt	1.76 (7.5)	[34]
Soot particles	diesel engine oil	motor oil dispersant	1.14 (1.7)	[44]

Note: Effective thermal conductivity of nanofluids  $k_e$  and thermal conductivity of base fluid  $k_f$ .

Heat transfer tests have been conducted to assess the thermal performance of CuO/water suspensions under flow conditions [22]. At fixed flow rates, the heat transfer coefficient of water containing less than 1 vol% of CuO nanoparticles was improved by >15% compared to that of water without nanoparticles.

Although the convective heat transfer coefficient of oxide nanoparticles/water suspensions has been determined, the heat transfer of the most promising metallic and nanotube nanofluids has not been reported yet.

## 6. MODELS AND MECHANISMS

### 6.1. Effective Thermal Conductivity Models

The problem of predicting the effective properties of two-phase materials has a long history dating back to J. C. Maxwell [16]. Since then, various theories and a large number of models have been developed to predict the thermal conductivity of solid/liquid suspensions [59, 61, 62, 67–70]. While the Maxwell equation only takes the particle volume concentration and the thermal conductivities of particle and liquid into account, other classical models extended the Maxwell model to include the effects of particle shape [59], particle–particle interactions [61, 62, 67–69], and particle distribution [70]. In their numerical simulation, Bonnecaze and Brady considered near- and far-field interactions among two or more particles [61, 62]. For random dispersions of spheres, their simulation results agreed with Jeffrey's equation [67] up to a volume fraction of 20%, while Maxwell's equation [16] gave results within 3% of their calculation for  $\alpha = 10$ , where  $\alpha$  is the ratio of the thermal conductivity of the particle to that of the liquid.

All these mathematical and numerical models predict almost identical enhancements at the low concentrations (<5 vol%) in nanofluids. Therefore, the Maxwell model can be used as representative of all classical models. The calculated results in Figure 7 show that  $k_e/k_f$  depends on the volume fraction of particles and the  $k_p/k_f$  ratio (where  $k_e$  is the effective thermal conductivity of suspensions,  $k_f$  is the

**Figure 7.** Predicted thermal conductivity enhancements for nanofluids with different ratios of particle-to-liquid thermal conductivity. Maxwell's model predicts that the effective thermal conductivity of suspensions increases with the volume fraction of the solid particles and the ratio of particle-to-liquid thermal conductivity.

thermal conductivity of the base fluid, and  $k_p$  is the thermal conductivity of particles). In most nanofluids, the  $k_p/k_f$  ratio exceeds 10. Therefore, the predicted conductivity enhancement from classical models is <5% at 1 vol%, <20% at 5 vol%, and <80% at 20 vol%, as shown in Figure 7. However, the measured thermal conductivity enhancement for the nanofluids is much higher than predicted by existing models.

To compare the measured thermal conductivity data with model predictions, the weight fraction of nanoparticles  $\phi_w$  must be converted to the volume fraction  $\phi_v$  using the conversion formula

$$\phi_v = \frac{\rho_f \phi_w}{\rho_f \phi_w + \rho_p (1 - \phi_w)} \quad (2)$$

where  $\rho_p$  is the particle density, and  $\rho_f$  is the base fluid density.

Figure 8 compares the normalized thermal conductivity data for Cu-in-ethylene glycol (EG), MWNT-in-oil, CuO-in-EG, and  $\text{Al}_2\text{O}_3$ -in-EG samples [17, 18, 23] with estimates based on Maxwell's equation. All calculated values are almost identical for the four nanofluids listed in Figure 8. Also, Cu nanofluids contain a small quantity of thioglycolic acid (<1 vol%) to further improve the particle dispersion behavior and, consequently, to further enhance conductivity. Surprisingly, the observed thermal conductivity enhancement with the copper nanoparticles and nanotubes is an order of magnitude higher than predicted from existing theories, represented by Maxwell's model in Figure 8. In contrast, the agreement between measured and predicted enhancement is good for oxide nanofluids. However, Lee et al. [23] and Wang et al. [24], among others, have shown that the model predictions for oxide nanofluids begin to diverge from the experimental data at low volume fractions.

This large gap between measured and predicted thermal conductivity clearly suggests that conventional heat conduction models for solid/liquid suspensions are inadequate. Several mechanisms that could be responsible for thermal transport in nanofluids have been proposed, as described in the next section.

**Figure 8.** Comparison of measured thermal conductivity ratios [17–18, 23] with estimated ratio from Maxwell [16] as function of nanoparticle volume fraction.

## 6.2. Potential Mechanisms for Enhanced Conductivity

Although the classical models for effective thermal conductivity have been successfully verified by experimental data for mixtures with low concentrations [62], the experimental data used in these comparisons included large (mm or  $\mu\text{m}$ ) particles [71, 72]. Therefore, it is not surprising that these theories, which were developed for fluids with particles that are three to six orders of magnitude larger than nanoparticles, cannot accurately predict the thermal conductivity of nanofluids. Only recently have nanoparticles of 50 nm or less become available to investigators. Experiments with nanofluids have shown that existing theories, models, and correlations for thermal conductivity are limited and often contradictory when applied to fluids that contain nanoparticles. Wang et al. [24] and Koblinski et al. [73] have proposed various mechanisms which could enhance thermal transport in nanofluids.

Wang et al. [24] suggested that the microscopic motion of nanoparticles, surface properties, and structural effects may cause enhanced heat transfer in nanofluids. In the classical models, the particles are assumed to be stationary when there is no bulk motion of the fluids. In nanofluids, the microscopic motion of nanoparticles induced by the van der Waals force, the stochastic force (causing the Brownian motion of particles), the electrostatic force, and the hydrodynamic force can be significant. Wang et al. showed that Brownian motion does not contribute significantly to energy transport in nanofluids. However, they indicated that the electric double layer [74] and van der Waals force could have strong electrokinetic effects on the movement of metal oxide nanoparticles dispersed in water. Using transmission electron microscopy, they also found that some particles adhere to form a chain structure and suggested that heat transfer could be enhanced due to this structure.

Koblinski et al. [73] have studied four possible mechanisms for the anomalous increase in nanofluid heat transfer: Brownian motion of the particles, molecular-level layering of the liquid at the liquid/particle interface, the heat transport in the nanoparticles, and the effects of nanoparticle clustering. Like Wang et al. [24], they showed that the effect of Brownian motion on enhanced energy transport in nanofluids is insignificant. However, they showed that the effects of the interface layering of liquid molecules and nanoparticle clustering could provide paths for rapid heat transport. Furthermore, using the molecular dynamics (MD) simulation technique they demonstrated that inside solid particles, heat moves in a ballistic manner, rather than by diffusion. Figure 9 shows a comparison of the autocorrelation functions of the heat flux associated with the solid  $J_{Q_s}$  and liquid  $J_{Q_l}$  parts of the suspension ( $J_Q = J_{Q_s} + J_{Q_l}$ ). The curves indicate monotonic decay of correlations in liquid and oscillatory decay in solid, a signature of ballistic phonons moving back and forth inside the particle. They verified that the period of oscillations corresponds to the time needed for a phonon to travel across the particle, and that it scales with increasing particle size. This new finding is significant when one considers that the central assumption of classical approaches to the prediction of the effective thermal conductivity of a particle-in-liquid suspension is that the

**Figure 9.** Heat current autocorrelation functions for liquid (dashed line) and particle (solid line). Curves indicate monotonic decay of correlations in liquid and oscillatory decay in solid, a signature of ballistic phonons moving back and forth inside the particle. heat transport in each phase is governed by the diffusion equation.

## 6.3. Thermal Transport in Nanocomposite Systems

As discussed previously, the existing understanding of the thermal conductivity of composites and mixtures is derived from *continuum-level* phenomenological formulations which are based on the diffusive heat transport mechanism and typically incorporate only the particle shape and volume fraction with no effects of solid-liquid interfaces or particle mobility taken into account. This approach, while providing a good description of systems with micrometer or larger particles, fails to describe thermal transport of nanofluids.

Modeling and simulations based on the *atomic-level* MD method, where one directly monitors the movement of atoms and associated heat fluxes, can be used to develop a fundamental understanding of the thermal transport properties of nanofluids and nanocomposites. The MD method is particularly appropriate in this context as it avoids assumptions underlying continuum-level formulations, which may be inapplicable for nanometer-sized grains. Furthermore, atomistic simulations allow for “numerical experiments” and detailed characterization, which are experimentally very difficult if not impossible. For example, in a simulation, the interaction energy between the solid particles and fluid can be continuously varied to probe its relative importance systematically.

In view of the fact that macroscopic-based theories have been successful in the description of heat transport, the literature on the atomic-level simulation of heat transport in nanocomposites is rather limited. However, with regard to solid-solid composites, there is a substantial amount of modeling work related to so-called superlattices involving alternating layers of two solid materials. (See, for example, [75].) Here, MD simulations are providing important information,

such as the thermal conductivity dependence on layer spacing and stress [76], scattering of heat-carrying phonons at solid–solid interfaces, and phonon interference effects [77].

For solid–liquid nanocomposites (nanofluids), MD simulations have demonstrated that, inside crystalline solid particles, heat moves in a ballistic manner that involves multiple scattering from the solid/liquid interface [73]. This scattering is associated with the mean free path of the phonon in crystalline solids typically being larger than the typical nanoparticle size. This result suggests that the macroscopic thermal conductivity of the solid might not be a relevant parameter, while the interfacial transmission coefficient might be (i.e., how much heat is able to go through the solid/liquid interface rather than reflect back into the particle), thereby not contributing to macroscopic heat transport.

The solid/liquid interfacial resistance was studied by means of nonequilibrium MD simulations in which a temperature gradient is imposed [78]. These simulations reveal that the strength of the bonding between liquid and solid atoms plays a key role in determining the interfacial thermal resistance. Moreover, it was found that the functional dependence of the thermal resistance on the strength of the liquid–solid interactions exhibits two distinct regimes: exponential dependence for weak bonding (i.e., nonwetting liquid) and power law dependence for strong bonding (i.e., wetting liquid). These findings indicate that nanocomposites or nanofluids characterized by weak atomic bonding at the particle–matrix interfaces will exhibit high thermal resistance. By contrast, for the wetting systems the interfacial resistance will be small and equivalent to a temperature drop in a liquid over several atomic distances ( $\sim 1$  nm) and thus will play a minor role in the case of nanometer-size particles.

Even the limited research on MD simulations of heat transport in nanoscale composites has provided important guidelines for the design of conductive materials. For example, as discussed, MD simulations indicate that the macroscopic thermal conductivity of solid particles might be much less important than the thermal resistance of the solid/liquid interface. We envision that atomic-level modeling and simulations will provide further insights into the origin of the unusual thermal transport properties of nanofluids and other nanocomposites. They will also contribute to the formulation of continuum-level models capable of describing thermal transport in nanoscale composites at larger time and length scales, those accessible to MD simulation.

## 7. FUTURE DIRECTIONS

The anomalous thermal conductivity data for copper and nanotube nanofluids in comparison to predictions by conventional models have raised fundamental questions such as: Why is there such a large gap between data and predictions? What are the mechanisms for increased thermal conductivity? Several mechanisms that could be responsible for thermal transport in nanofluids have been described in the previous section. However, at present, none of them is able to explain adequately the thermal conductivity behavior of nanofluids. Therefore, the mysteries of nanoparticles in fluids remain unsolved, presenting new opportunities and challenges for scientists and engineers. Such research could lead to a major breakthrough in solid/liquid composites for

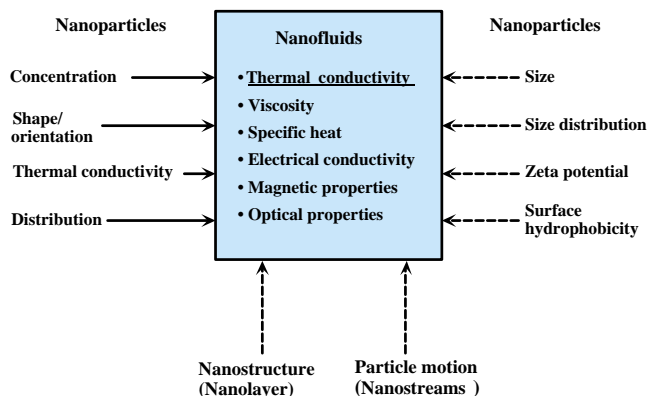

numerous engineering applications, such as coolant for automobiles, air conditioning, and supercomputers.

According to the models currently used for traditional solid/liquid suspensions, the particle concentration, shape and orientation, distribution, particle–particle interactions, and thermal conductivity of particle and liquid can affect how well solid/liquid suspensions conduct heat. However, the conventional models do not account for particle size, polydispersity index, zeta potential, surface hydrophobicity, particle motion, and nanostructure, which may be key parameters for nanofluids with nanoparticles. As proposed in Figure 10, new models of the thermal conductivity and other properties of nanofluids should include such parameters as nanoparticle motion and nanostructure, as well as particle size and surface characteristics. This clearly demonstrates the interdisciplinary demands of nanofluid science and technology.

One of the greatest challenges for nanofluid research is to develop a tool that will measure the thermal conductance between two nanoparticles that are suspended in liquid less than 50 nm apart. This new tool is needed to better understand the physics responsible for the anomalous increase in conductivity and to validate a new model. Achieving this goal is more challenging than measuring the thermal conductivity of nanotubes [15].

At present, measurements of the heat transfer coefficients of nanofluids are limited to nanofluids containing oxide ceramic nanoparticles. Even greater effects are expected for nanofluids that contain metal nanoparticles and carbon nanotubes. Therefore, there is an urgent need to measure the heat transfer coefficients of these promising nanofluids. Furthermore, nanofluid research has been focused on the thermal characterization of nanofluids without evaporation or condensation. However, nanoparticles in nanofluids can play a vital role in two-phase heat transfer systems. Therefore, there is a great need to characterize nanofluids in boiling and condensation heat transfer.

Applied research on nanofluids is a newly emerging field. Nanoparticles can be added to motor oils, antifreeze

**Figure 10.** Schematic for modeling of nanofluids. Classical models for traditional solid/liquid suspensions account for the particle concentration, shape, orientation, and distribution, as well as particle–particle interactions, and the thermal conductivity of the particle and liquid. In addition to these parameters, new models of the thermal conductivity and other properties of nanofluids should include such parameters as nanoparticle motion, nanostructure, particle size, and surface characteristics.

coolants, automatic transmission fluids, greases, metal-working fluids, and refrigerants. However, technical hurdles such as stability, toxicity, corrosion, particulate formation, emission, fouling, etc. make the applied research challenging. Use of nanoparticle materials for applied research is made even more difficult since the environmental regulations do not favor the introduction of certain metals or metal oxides. Future R&D efforts should focus on the selection of appropriate nanoparticles for the fluid system, the scalable *in-situ* production of nanoparticles in the fluid system, and the adverse thickening effect brought up by nanoparticles.

Since nanoparticles offer several interesting properties which the bulk materials do not possess, such as thermal enhancement, lubrication improvement, chemical activity, and catalytic effect, nanofluids have a spectrum of potential applications. Nanofluids are being developed mainly for applications in automobile engine oils and coolants, but they may also be applicable for cooling electronic devices, laser diode heat sinks, and welding machines. Preliminary tests have shown that nanofluids may solve a number of problems plaguing the heating, ventilation, and air conditioning industry and may change the design of the vehicle radiator completely.

Lee and Choi [19] estimated the performance of microchannel heat exchangers with water, liquid nitrogen, and nanofluids as the working fluids and showed the superiority of the nanofluid-cooled exchanger. As a spin-off of the nanofluid applied research, Lockwood et al. [44] studied the effect of soot loading on the thermal characteristics of diesel engine oils, where the soot-containing diesel engine oil is considered as a practical nanofluid.

Besides the thermal benefits, nanofluids when used in a housing with moving metal parts may provide a lubrication benefit [79]. Hu and Dong [80] report that titanium oxide nanoparticles in oil, unlike conventional particles, reduce the friction coefficient and increase wear resistance.

Nanofluids may find medical applications such as drug delivery and localized cancer treatment [81]. For such medical applications nanoparticles need to be coated with biocompatible materials such as silica, carbon, or  $\text{TiO}_2$ .

At present, copper nanoparticles and carbon nanotubes are very promising for nanofluids. However, copper nanoparticles can only be produced by a very slow single-step process. Also, carbon nanotubes are still expensive to produce, although several firms are looking for production methods that would be viable on a commercial scale. Producing small (1–10 nm) nanoparticles cheaply and dispersing them without agglomeration is the key hurdle to commercialization.

If high-volume, low-cost production methods for nanofluids are developed for industrial applications, nanofluids hold significant potential for revolutionizing industries that are dependent on the performance of fluids that transfer heat faster and consume less power for pumping. Nanofluid technology will thus be an emerging and exciting technology of the 21st century.

## 8. CONCLUDING REMARKS

Traditional heat transfer fluids used in thermal management systems (coolants and oils) are not efficient. Technologies with the potential to improve the fluid's thermal properties

are thus of great interest. Although dispersing solid particles in liquids to enhance the thermal conductivity of liquids has a long history dating back about 100 years, only small effects were observed until recently. Exploiting the unique properties of nanoparticles to develop stable and high-thermal-conductivity fluids, ANL developed nanofluids, a new class of heat transfer fluid prepared by suspending nanometer-size particles in conventional fluids.

Two techniques are used to make nanofluids: the single-step DEC method, which simultaneously makes and disperses the nanoparticles directly into the base fluid, and the two-step method, which first makes nanoparticles and then disperses them into the base fluid. Although the two-step technique works well for oxide nanoparticles, it is not as effective for metal nanoparticles. A unique nanofluid production system has been designed and developed for DEC of metals into low-vapor-pressure liquids. For nanofluids containing high conductivity metals, the single-step DEC technique is preferable to gas-condensation processing.

The thermal conductivity of nanofluids with low particle concentrations (1–5 vol%) was measured by three techniques. The experimental results show that these nanofluids have substantially higher thermal conductivities than the same liquids without nanoparticles.

Overall, copper nanofluids produced by the single-step method and carbon nanotube nanofluids produced by the two-step method are very promising. They could provide a giant leap in cooling power because, compared to oxide nanoparticles which are the traditional materials for solid/liquid suspensions, the volume fraction of copper nanoparticles or carbon nanotubes is reduced by one order of magnitude at comparable conductivity enhancement. Indeed, these two kinds of nanofluids set the distance from oxide nanofluids in that, despite very low volume fractions (<0.01) of nanoparticles, their effect on suspension thermal conductivity is dramatic. Furthermore, the discovery of the strong temperature dependence of the thermal conductivity of nanofluids is exciting because that makes nanofluids even more attractive as coolants for devices with high energy density.

Because the thermal conductivity of copper and nanotube nanofluids is one order of magnitude greater than predicted by existing models, nanofluids offer numerous opportunities for solving interesting, basic scientific questions. Some of the key challenges are to understand the fundamental mechanisms of the enhanced thermal conductivity of nanofluids and to develop new models which can link particle size, polydispersity index, zeta potential, surface hydrophobicity, particle motion, nanostructure, etc. to the properties of nanofluids. Experimentally, we need to develop a tool to measure the thermal conductance between two nanoparticles that are suspended in liquid less than 50 nm apart. This new tool is needed to better understand the physics responsible for the anomalous increase in conductivity and to validate a new model.

While we are focusing on long-term basic research in nanofluids and tools to measure thermal conductivities at the nanoscale, we need to maintain our efforts on short-term goals that are more application specific. As cooling is becoming increasingly important in many applications, the two salient features of nanofluids—well-suspended particles

and thermal conductivities far above those of traditional solid/liquid suspensions—make nanofluids strong candidates for the next generation of coolants. However, we are still in the research stage mainly because, for industrial applications of nanofluids, we need to develop high-volume, low-cost production methods. Producing small (1–10 nm) nanoparticles cheaply and dispersing them without agglomeration will open up new areas of research, including heat transfer in flow, and will facilitate development of commercial products.

Finally, we wish to emphasize that nanofluids are an emerging interdisciplinary field where nanoscience and thermal engineering meet and could prove to be a key for new technology of the 21st century.

## GLOSSARY

**Agglomerate** A collection of primary particles or aggregates joined at their edges or corners, with a specific surface area not markedly different from the sum of the areas of the constituents.

**Aggregate** A group of primary particles joined at their faces, with a specific surface area significantly less than the sum of the area of their constituents.

**Bright field** Use of a brightly lighted background for generating a micrograph.

**Brownian motion** The random motion of micro- or nanoparticles in a fluid owing to thermal agitation.

**Brunauer-Emmett-Teller method** The method used to measure the specific surface areas of nanoparticles as well as other materials.

**Chemical vapor deposition (CVD)** Technique used for making nanoparticles and nanotubes as a result of thermochemical vapor-phase reactions.

**DLVO theory** The Deryaguin-Landau-Verwey-Overbeek (DLVO) theory predicts, based on the concept of long-range attractive and repulsive forces, the stability of particles suspended in polar liquids containing electrolytes or other ionic species (such as detergents).

**Dynamic light scattering (DLS)** A method used to determine the particle size and size distribution of colloidal particles between 3 nm and 5  $\mu\text{m}$ . The scattered light is employed to measure the rate of diffusion of the particles. The data for the particle's motion in a liquid are processed to derive the "Stokes radius" or "hydrodynamic radius" of the particle.

**Effective thermal conductivity** The observed thermal conductivity of a solid-liquid suspension. This apparent property includes the thermal resistance at the solid-liquid interface.

**Electric double layer** A double layer of charge carriers such as electrons or ions formed at a solid-liquid interface. It consists of charge carriers of one charge type fixed to the surface of the solid (the rigid part) and an equal number of mobile charge carriers of the opposite charge, which are distributed in the liquid (the diffuse part).

**Electrostatic force** Force on a charged particle in an electrostatic field.

**Functional group** Functional group such as hydroxyl (-OH), carboxyl (-COOH), and mercapto (-SH) consisting of a group of atoms responsible for the characteristic reactions

of a compound. Functional groups are added onto the surface of nanoparticles for better anchoring of the surfactants or grafting of a chain (for example, an octadecyl group) onto the nanoparticle surface to make a permanent bond.

**Inert-gas condensation (IGC)** A physical synthesis technique for making nanoparticles. In the IGC process, the material is evaporated into a low-density inert gas, and vapors diffuse rapidly from the hot source into the surrounding gas, condense, and coagulate to form nanoparticles. Nanoparticles are transported and deposited by thermophoretic diffusion on a cold finger.

**Mean free path of phonon** The average distance traveled between collisions of phonons in a crystal.

**Miniaturization** Reduction in the size of a device, system, or package.

**Nanofluids** A new kind of heat transfer fluid containing a very small quantity of nanoparticles that are uniformly and stably suspended in a liquid. Also referred to as nanoparticle-dispersed fluids and solid-liquid nanocomposites.

**Nanoparticles** Nanometer-sized particles. Nanoparticles, one of the smallest human-made objects, have unique mechanical, thermal, electronic, magnetic, optical, and chemical properties, which strongly depend on particle size and significantly differ from those of the same material in bulk. Nanoparticles are one of the building blocks of nanotechnology.

**Nanoparticle halos** When highly charged nanoparticles are dispersed into a suspension of negligibly charged colloidal particles, they form "halo"-like structure around the colloidal particles and thus stabilize the whole dispersion.

**Scanning electron microscopy (SEM)** A type of electron microscope in which a beam of primary electrons scans a specimen, and the intensity of secondary electrons generated at the point of impact of the beam on the specimen is measured. This signal is used to modulate a separate electron beam which scans, at the same frequency as the scanning of the specimen, a TV monitor in which a perspective image of the specimen is formed.

**Sputtering** The process by which some of the atoms of the cathode in an evacuated enclosure are ejected as a result of bombardment by heavy positive ions to coat a uniform layer of a metal (such as gold) on an object (such as glass, plastic, metal, or carbon nanotube) in vacuum.

**Surface charge density** The number of electric charges per unit surface area of a nanoparticle.

**Time autocorrelation function** The correlation of the same quantity at various times. For the equilibrium fluctuations of the heat flux  $J_Q(t)$ , the autocorrelation function measures the magnitude of these fluctuations and the lifetime of the correlated heat movement. Macroscopic thermal conductivity is proportional to the time integral of the heat flux autocorrelation function.

**Transmission electron microscope (TEM)** A type of electron microscope in which an electron beam is focused by magnetic lenses and transmitted through a thin specimen. A large image of the small specimen is formed on a fluorescent screen by the scattering of electrons out of the beams.

**van der Waals force** An attractive force between atoms or nonpolar molecules resulting from three factors: dipole-dipole interaction, dipole-induced dipole interaction, and quantum-mechanical electron correlation in atoms and molecules without dipoles.

**X-ray diffractometer** An instrument used to determine the crystal structure of materials such as nanoparticles by passing X-rays through them and measuring the intensities of the diffracted beams at different angles.

**Zeta potential** The electrokinetic potential that exists across the solid-liquid interface. The electrokinetic forces cause suspended particles to repel each other depending on surface charge density. The Zeta potential of particles can be determined by microscopic observation of the migration velocity of suspended particles in the electric field. Knowledge of the Zeta potential is important for determining the stability of suspended particles.

## 1. INTRODUCTION

In cosmos and in nature, maelstrom, spiral, helical, or coil structures, such as a whirled air (typhoons), whirled seawater, vine plants, shellfish, proteins, DNA, etc. are commonly observed. The helical/spiral shapes are also commonly observed in artificial water screws, spiral staircases, retaining screws, bolts/nuts, screw dislocations in solids, etc. Furthermore, electromagnetic waves, spirit or mind, economic cycles, etc. have also a helical/spiral motion pattern. That is, three-dimensional (3D)-helical/spiral structures are the fundamental structure of many natural objects, including science and human livings. The helical morphology of DNA or proteins has essential and critical functional roles in living bodies. Recently, the double helix-shaped DNA, single-helix-shaped proteins, or chiral carbon nanotubes have been attracting attention in biotechnology and nanotechnology [1–3]. Materials with 3D-helical/spiral structures with micrometer to nanometer order dimensions have not been commercially available. Motojima and Chen have prepared regularly coiled carbon fibers (carbon coils) with 3D-helical/spiral structures, which are similar structures to all things in the cosmos, with high coil yield. We named them “cosmomimetic carbon coils” for these carbon coils after “biomimetics” [1]. The helical/spiral materials are expected to have novel functionality and many potential applications such as tunable microdevices/sensors, electromagnetic absorbers, energy changing materials, hydrogen absorbers, chiral catalysts, activators of organisms, etc. In addition to their potential applications, the growth mechanism is very interesting from the scientific point of view.

Although some helical/spiral-formed fibers are referred to in comprehensive reviews on the vapor grown carbon

fibers, by Rodriguez [4] and de Jong and Geus [5], up to now, there has not been any comprehensive review on nanohelical/spiral materials.

In this chapter, we will introduce the preparation processes, morphologies, microstructures, and properties of the helical/spiral-structured substances such as carbon nanocoils and ceramic nanocoils/nanotubes. We also discuss the growth mechanism of the helical/spiral structure and predict the possible applications.

## 2. CARBON NANOCOILS

### 2.1. Introduction

In 1953, Davis and co-workers [6, 7] were the first to report the vapor growth of thin carbon fibers twisted together in the form of a rope. The observation of helical/spiral-coiled carbon nanofibers, with a coil diameter of several micrometers to several nanometers (referred to as “carbon nanocoils” hereafter), from vapor phase using a chemical vapor deposition (CVD) process, were then reported by some carbon filament researchers. Since from the 1970s to the 1980s, Baker and co-workers reported the observation of carbon twisted fibers among the Fe-group metal-catalyzed vapor grown carbon filaments. Furthermore, they extensively studied the effects of H<sub>2</sub>, Cu, Pt, Sn, and other oxides on the growth of carbon filaments and observed the growth of helical carbon filaments. However, before 1990, carbon coils grown by the CVD process were extremely accidental, reproducibility was very poor, and the production was almost excluded as anomalous and unpreferable deposits with helical/spiral forms.

In 1990, Motojima and co-workers [8] first found that regular-coiled carbon fibers (carbon nanocoils) could be obtained with high reproducibility by the catalytic pyrolysis of acetylene containing a small amount of sulfur impurities over transition metal catalysts, and then they extensively examined the preparation conditions, morphology, growth mechanisms, and some properties in detail. Meanwhile, Motojima and co-workers [9–11] also first found that very regularly coiled silicon nitride (Si<sub>3</sub>N<sub>4</sub>) fibers could be obtained by the CVD process. After then, various ceramic coils such as metal carbides, nitrides, and oxides were prepared by the CVD, sol/gel, diffusion, template processes, etc.

Since 2000, carbon coils have attracted interest and carbon coils with diverse morphologies have been reported by many researchers. Among various preparation processes, the CVD process is the process with the most potential for the large-scale preparation of pure carbon coils. So the preparation of carbon coils has been mainly carried out using various CVD reaction systems, mainly using Fe-group metal catalysts and acetylene or ethylene carbon sources.

In this section, we will first summarize some of the earlier literature in which the growth of helical-coiled carbon fibers is referred. Thereafter, we will present recent research progress in the preparation (processes and conditions), morphology, microstructure, and some properties, and we will discuss the growth mechanism. Finally we will predict the potential applications of the carbon nanocoils.

## 2.2. Preparation, Morphology, and Microstructure

In 1953, Davis and co-workers [6, 7] first reported the vapor growth of thin carbon fibers twisted together in the form of a rope (helical threads) by the disproportionation of CO over iron compound catalysts at 450 °C. The obtained helical threads are apparently hollow and are probably formed by coiling of flat ribbons. In 1958, Hillert and Lange [12] reported the growth of a single helical thread and combinations of three helical thread, parallel, or twisted forms from N<sub>2</sub>-heptane source gas mixtures at 1000 °C using Fe catalyst. In 1972, Baker and co-workers [13] reported the growth of twisted carbon fibers with a coil diameter of about 60 nm from a C<sub>2</sub>H<sub>2</sub>/H<sub>2</sub> (or O<sub>2</sub>) gas mixture at 870–1100 K using the Ni catalyst. They introduced H<sub>2</sub> or O<sub>2</sub> to the reaction system preventing Ni particles from being deactivated and found that the catalytic activity of the Ni particles for filament growth ceased after approximately 15 s at 870 K, but it could be regenerated by exposure to H<sub>2</sub> at 1100 K or O<sub>2</sub> at 1000 K. Boehm [14] also obtained carbon braided fibers with herringbone structure by the disproportionation of CO at 650 °C over Fe(CO)<sub>5</sub> or Ni(CO)<sub>4</sub> catalyst. He proposed a growth model for the helical fiber formation, in which he suggested that iron carbide formed on the disorganized carbon, and braided fibers formed on the crystal faces of iron carbide.

In recent years, Park and Baker [15, 16] paid much attention to the growth of carbon filaments by decomposition of ethylene over Fe-group alloy catalysts. During their investigation of the decomposition of a C<sub>2</sub>H<sub>4</sub>/CO/H<sub>2</sub> gas mixture over a series of Fe/Ni catalysts, and detailed analysis of both the gaseous products and the amount of the deposited solid carbons, they revealed that co-adsorption of the two carbon-containing gases produced major modifications in the behavior of the bimetallic catalyst surfaces. It was evident that the addition of CO to a C<sub>2</sub>H<sub>4</sub>/H<sub>2</sub> gas mixture resulted in a substantial increase in the decomposition of the olefin over all the bimetallic catalyst powders with this effect being most pronounced on the Fe-rich systems. The major product from this series of Fe/Ni catalysts was found to be solid carbon in the form of various filamentous structures, including twisted carbon nanocoils with 200 nm diameter produced from the interaction of an Fe catalyst with a C<sub>2</sub>H<sub>4</sub>/CO/H<sub>2</sub>(3:1:1) gas mixture at a 600 °C. A growth tip with bidirectional mode

can be seen, as can the tightly coiled nature of filaments grown with 200 nm diameter from the interaction of an Fe–Ni(2:8) catalyst with a C<sub>2</sub>H<sub>4</sub>/CO/H<sub>2</sub>(3:1:1) gas mixture at 600 °C.

Great attention has been paid to the effect of the impurity on the catalytic effect of Fe-group metals. Baker and co-workers [17] studied the influence of Sn on Fe catalyst and obtained spiral carbon filaments from acetylene at above 800 °C by using the Sn/Fe (Sn coated Fe foils) catalyst. The filaments were nearly all spiraling with a constant coil pitch and commonly branched. Two spiral filaments generally grew from a catalyst particle in opposite directions. Branching of filaments was frequently observed. They found that the addition of Sn into Fe can prevent the catalyst from being poisoned. Baker and Waite [18] also studied the preparation of carbon filaments by the Pt/Fe alloy-catalyzed pyrolysis of C<sub>2</sub>H<sub>2</sub> and found that using this alloy at 690 K, which is a much lower temperature than that using pure Fe, carbon filament grew two orders of magnitude faster than pure Fe. But at a higher temperature, 1175 K, and using ethylene as a carbon source, the growth of very short coils was observed.

In 1984, Galuszka and Back [19] studied the catalytic activity of Fe films formed by thermal decomposition of a solution of ferric nitrate in the presence of mercury vapor. They found that this iron catalyst induced the formation of filamentous carbon during the pyrolysis of methane and that oxidation–reduction of the sputtered iron was shown to lead to fragmentation of the films into particles with a size suitable for the growth of filaments. Among the deposits the springlike single-helix carbon nanofibers were observed.

In 1992, Kim and co-workers [20] used a Cu/Ni (1:1) as the catalyst and acetylene as the carbon source for obtaining the carbon fibers and found that two filaments grew from opposite faces of the catalyst particle at identical rates. Furthermore, during the major part of the growth process, the filaments were relatively smooth and tended to form into large loops. Over a period of time it became clear that many of the filaments were slowly decreasing in width, as a result of catalyst material being dissipated within the structure, and this behavior frequently resulted in the creation of secondary smaller filaments on the parent growth. Furthermore, they also suggested that when the particles reached a size of about a third of the original value, the filaments appeared to undergo a further change in shape and simultaneously started to rotate on an axis perpendicular to the direction of filament growth, causing the filament to acquire a spiral form. When the catalyst is Ni-rich, Cu/Ni (1:1), supported on graphite, 2 Torr, C<sub>2</sub>H<sub>2</sub>, bidirectional filaments with a spiraling mode grew. But when Cu-rich, Cu/Ni (7:3) + C<sub>2</sub>H<sub>4</sub>/H<sub>2</sub>(1:4) at 600 °C, Cu-rich particles tend to grow in a spiral conformation.

Furthermore, in 1997, Krishnankutty and co-workers [21] continued to report the effect of Cu on the structural characteristics of the carbon filaments produced from Fe-catalyzed decomposition of ethylene. Carbon filaments were produced by the decomposition of ethylene over unsupported Fe/Cu catalyst powders in the presence of varying amounts of H<sub>2</sub> at 500–800 °C. Helical coils could be obtained using a Fe/Cu (3:7) catalyst and C<sub>2</sub>H<sub>4</sub>/H<sub>2</sub> (1:4) at 500–600 °C. With catalysts rich in Cu, it was apparent

that although the resulting carbon filaments continued to grow via bidirectional mode, there was a subtle difference in that they acquired a helical conformation. The herringbone arrangement of the graphite platelets is indicated in the catalyst grain present on the fiber tip. Two structures, herringbone (platelets oriented at an angle with respect to the fiber axis with smooth surfaces) and tubular arrangements models, are presented. The effects of Cu in Ni catalysts have been also reported by Bernado and co-workers [22, 23] and Jong and co-workers [24] recently.

Hernadi and co-workers [25] reported the growth of carbon coils in preparation of carbon nanotubes from acetylene at 700 °C over Fe/silica supported catalyst. The carbon coil is a single-helix coil and has a coil diameter of about 80 nm and a coil pitch of about 160 nm as shown in Figure 1. Grobert and co-workers [26] obtained carbon nanocoils by the pyrolysis of solid organic precursor (for example, 2-amino-4, 6-dichloro-*s*-triazine, *s*-triamono-triazine) at 950–1050 °C using laser patterned thin metal (Fe, Co, Ni) as the catalyst and silica substrate. The obtained nanocoils have a coil diameter of 1.2–0.6  $\mu\text{m}$  and a coil pitch of 3–0.3  $\mu\text{m}$  as shown in Figure 2a. Simulated single-walled corkscrew-like carbon nanotubes produced by interspersing five- and seven-membered rings judiciously within the mainly hexagonal network is also depicted in Figure 2b.

Recently, Chesnokov and co-workers [27] reported the growth regularities and mechanism of symmetric twisted carbon filaments formed from butadiene-1, 3 on Ni–Cu/MgO-catalyst at 450 °C. Dissymmetrical spirally twisted carbon filaments have been shown to grow from a single Ni/Cu alloy particle. They suggested that as the filaments grow, a microphase of metastable nickel carbide ( $\text{Ni}_3\text{C}$ ) forms on the particle's frontal side, whereas the crystal particle of Ni/Cu alloy possesses a series of twinning planes (111) that are parallel to the dissymmetry plane of the crystal and separate the blocks of twins from a face-centered structure.

Although it is well known that sulfur acts as a poison for many Ni catalyzed reactions, it is now being recognized that

**Figure 1.** Carbon nanotubes formed in the decomposition of acetylene at 700 °C over Fe/silica (ion-adsorption precipitation using pH = 9 as initial solution, but the pH was close to 7 before filtration) catalyst.

**Figure 2.** (a) Scanning electron microscope image of carbon nanocoils generated by pyrolysis of melamine over Co “aged” catalyst substrate (in air). (b) Simulated single-walled corkscrew-shaped carbon nanotube produced by interspersing five- and seven-membered rings judiciously within the mainly hexagonal network [26].

certain benefits can be derived from following a partial and well controlled sulfidation treatment of the metal. Owens and co-workers [28] reported the effect of sulfur on the interaction of Ni with ethylene. They found the enhancement in carbon filament growth following pretreatment of Ni in low levels of  $\text{H}_2\text{S}$  (4–50 ppm) is related to a reconstruction of the metal surface. The inhibition of catalytic activity resulting from a more severe pretreatment in  $\text{H}_2\text{S}$  is ascribed to the formation of a 2D or 3D bulk sulfide. They considered that re-adsorption of S on Ni induced some major perturbations in the morphological characteristics of the filamentous carbon deposits, which are generated in the form of regularly coiled structures. In contrast, those produced from unadulterated metal particles were found to be relatively straight. This change in growth mode indicates that sulfur is modifying the diffusion characteristics of carbon species through the catalyst particle.

Motojima and co-workers [8] first found that the regularly coiled carbon coils could be obtained with high reproducibility by the catalytic pyrolysis of acetylene, containing a small amount of S impurity, and then extensively examined the relationship between coil yield and preparation conditions, as well as morphology, growth mechanism, and some properties in detail. This process makes it possible to prepare carbon coils in semimass while, to our knowledge, the coil yield of carbon nanocoils is rarely reported by other research group so far. These results are comprehensively presented in the following section.

Figureiredo and co-workers [29] obtained carbon nanocoils by Co-catalyzed pyrolysis of acetylene. The obtained nanocoils are single-helix coils and have very small coil diameters of about 60 nm as can be seen in Figure 3. Rodoriguez and co-workers [30] prepared carbon filaments by pyrolysis of ethane containing a  $\text{H}_2\text{S}$  at 815 to 865 °C using Fe/Ni catalyst. It was observed that a dramatic change occurred in catalyst activity and selectivity when 50 ppm  $\text{H}_2\text{S}$  was added

**Figure 3.** Helical filaments formed during the reaction of cobalt with acetylene [29].

to the ethane feed. Graphite shell-like deposits were predominant in the case of the Fe/Ni (5:5) catalyst, while carbon nanofibers in the case of the Fe/Ni (8:2) catalyst were predominant. Carbon nanocoils with a coil diameter of about 700 nm and a coil pitch of about 400 nm were obtained by the pyrolysis of ethane at 815 °C using the Fe/Ni(8:2) catalyst.

Amelinckx and co-workers [31] prepared helix-shaped carbon tubules by the Co-catalyzed pyrolysis of acetylene and examined in detail the morphology and microstructure. The different morphologies and transmission electron microscopy (TEM) images of a tubule are shown in Figures 4 and 5, respectively. Figure 4a shows the helix-shaped tubules having pitches of different magnitudes. Figure 4b shows the complicated interaction between straight and helix-shaped tubules. Figure 4c shows the parallel arrangement of a straight and a helix-shaped tubule, presumably kept together by van der Waals attraction. Figure 4d shows the coiled tubule intercoiling with itself after having made a U-turn. Figure 4e shows the straight tubules making

**Figure 4.** Graphite tubules grown by the Co-catalyzed decomposition of acetylene, exhibiting various shapes [31].

**Figure 5.** High-resolution images of a helix-shaped tubule containing 11 graphene tubules as shown Figure 4a [31].

a closed loop, the straight ends sticking together. Figure 4f shows the bundle of parallel straight tubules and one helix. Figure 4g shows the planar spiral-shaped tubule. It can be seen that these tubules are a multiwalled nanotube. They also introduced the concept of a spatial-velocity hodograph to explain the growth mechanism of the helix-shaped carbon tubules as shown in Section 2.6.

Krishnankutty and co-workers [21] reported the effect of Cu addition on the decomposition of  $C_2H_4$  in  $H_2$  over Fe catalyst at 450–800 °C. The addition of only 2 wt% Cu to Fe caused a 20-fold increase in the amount of carbon filaments formed compared to that produced on pure Fe at 600 °C. They suggested that this behavior is probably caused by inducing electronic perturbations in the Fe atoms, which results in a modification in the chemisorption characteristics of  $C_2H_2$  on such a surface. Carbon coils with a coil diameter of 1.5  $\mu m$  were obtained by the Fe/Cu (3:7)-catalyzed pyrolysis of ethylene at 500–600 °C as shown in Figure 6. The TEM image showed that there are two structures: a herringbone structure in which platelets are oriented at an angle with respect to the fiber axis as shown in Figure 7a and a tubular structure in Figure 7b. These structures are very indicative of the carbon coils as well as carbon nanotubes.

Mao and Xie [32] reported that carbon nanotubes with a coil diameter below 100 nm could be obtained from acetylene (10% in  $N_2$ ) at 650 °C in 150 Torr using a Co-implanted

**Figure 6.** Transmission electron micrograph showing the appearance of carbon filaments produced from the Fe/Cu (3:7) catalyzed decomposition of an ethylene/hydrogen (1:4) mixture at 600 °C [21].

**Figure 7.** Schematic diagram highlighting the essential steps involved in the catalytic growth of carbon filaments from decomposition of a hydrocarbon and the alignment of graphite platelets in the filament structures: (a) herringbone and (b) tubular arrangements [21].

Ge substrate (Co dose:  $1 \times 10^{17} \text{ cm}^{-2}$ ). The formation of these helical nanotubes is considered to be attributed to the different growth velocities of the tubes from different facets of the nanoparticle catalysts as proposed by Amelinckx et al. [31].

Cesar and co-workers [34] reported the synthesis and characterization of twisted carbon filaments with a coil diameter of less than 80 nm by the catalytic pyrolysis of propane using the  $\text{Pd}_3\text{P}$  colloid catalyst at 600 °C. The structure of the filament was amorphous.

Zhang and co-workers [35] prepared carbon tubule nanocoils by the catalytic pyrolysis of propane using Fe-coated indium-tin-oxide (ITO)/glass substrate as the catalyst at 700 °C. The nanocoils usually consist of two or more tubules and each of them grows with its own diameter and pitch. The tubules mostly consist of graphene sheets, and most of the coils have an external diameter range from several tens to several hundred nanometers, most of them are several hundred nanometers. But when using  $\text{Fe}/\text{InO}_x$  or  $\text{Fe}/\text{SnO}_x$  as the catalysts, the coil yield was very low. It is considered that Fe plays an important role in the growth of the carbon tubes, while In, Sn, O, and/or their alloys contribute to the formation of the coils.

Pan and co-workers [36] reported the synthesis of carbon nanocoils by the electroplated Fe/ITO substrate catalyzed pyrolysis of acetylene at 650–800 °C. The fine Fe particles can be effectively mixed with the ITO in this method, which caused the highly efficient growth of small-sized carbon nanocoils with a 100 nm coil diameter. Pan and co-workers [37] also discussed the effects of Fe and indium in the ITO on the growth of carbon tubule nanocoils. It is found that Fe additions lead to the growth of carbon nanotubes, while ITO induces their helical growth. The yield of carbon nanocoils is determined by the elemental ratio of Sn and In, and high yield is obtained at  $\text{Sn}/(\text{Sn} + \text{In}) = 0.1\text{--}0.35$ .

Lee and co-workers [38] reported the growth of carbon nanofibers by the pyrolysis of acetylene using a Ni-deposited sodalime glass as the catalyst at 500 °C. The diameters of carbon nanofibers are uniformly distributed in the range between 50 and 60 nm. Most of the carbon nanofibers are curved or bent in shape, but some are twisted. They

consisted of defective graphitic sheets with a herringbone structure.

Wang and co-workers [39] reported the growth of helical-shaped filaments with a coil diameter of 50–100 nm from a gas mixture of  $\text{C}_6\text{H}_6\text{--H}_2\text{--Ar}$  at below 520 °C using Fe(or Co, Ni)/ $\gamma\text{-Al}_2\text{O}_3$  catalysts by microwave plasma-enhanced CVD. Xie and co-workers [40] also reported the growth of the carbon coils with coil diameters of 5–6  $\mu\text{m}$  by the Ni catalytic pyrolysis of acetylene at 700 °C by the microwave plasma CVD process. Using the plasma CVD process, the addition of sulfur impurity in the reaction atmospheres is not necessary for obtaining carbon coils.

Hernadi and co-workers [41] reported the growth of carbon nanocoils with coil diameters of about 200 nm by the unsupported  $\text{SnO}$ -doped  $\text{Fe}_3\text{C}$  catalytic pyrolysis of acetylene. Figure 8 shows the carbon nanocoil with different morphologies obtained by them.

Bai [42] reported the preferential growth of nanotubes/nanofibers and nanocoils with controlled diameters by the catalytic pyrolysis of acetylene at 650 °C. Catalyst nanoparticles of a Fe, Co, and Ni were dispersed on the anodized Al plate substrate ( $\text{Al}_2\text{O}_3$  thickness deposited on Al plate: a few  $\mu\text{m}$ ), in which a Fe, Co, and Ni sulfate solution was electrochemically impregnated into the nanopores present in an anodized Al plate to deposit fine metal particle. The gas mixture of  $\text{C}_2\text{H}_2$ ,  $\text{N}_2$ , and  $\text{H}_2$  (5%) + Ar(95%) flowed onto a quartz reaction tube at a flow rate of 850 sccm. The concentration of  $\text{C}_2\text{H}_2$  was about 5%. A carbon nanocoil with a coil diameter of 200 nm coil, a coil pitch of 160 nm, and a fiber diameter of about 160 nm was obtained using very fine catalyst particles in the 5–15 nm pores obtained under ac short time electrochemical metal deposition. Carbon coils with a coil diameter of 1.5  $\mu\text{m}$ , a coil pitch of 250 nm, and a fiber diameter of about 200 nm were obtained by longer metal particle deposition times (1 min). Carbon coils with a coil diameter of 16  $\mu\text{m}$ , a coil pitch of 1  $\mu\text{m}$ , and a fiber diameter of about 500 nm were obtained with very thin layers composed of large metal particles under 2 min dc deposition conditions.

**Figure 8.** EM image of carbon deposit over  $\text{Fe}_3\text{C}(\text{+SnCl}_2)$  [41].

Raman spectroscopy analysis on the carbon coils showed the multiwalled nanotube's nature.

Schliermann and co-workers [43] studied the online-monitoring of gas phase reactions during nanofiber synthesis by fast chromatography. They found that carbon coils grew at the restricted reaction conditions. Hernadi and co-workers [44] prepared the carbon coils with a coil diameter of 100–200 nm and a specific surface area of 44–129 m<sup>2</sup>/g from acetylene using the unsupported SnO-doped Fe<sub>3</sub>C (direct precipitation) catalyst at 600–800 °C. Jong and co-workers [24] prepared the carbon nanotubes from a CH<sub>4</sub>/H<sub>2</sub> gas mixture at ~ 600 °C using the Ni/Cu catalyst by microwave plasma CVD and found that the use of high Cu content catalyst (Cu = 60–80%) results in the growth of helical fibers.

Motojima and co-workers [8, 45–56] examined in detail of the morphology and microstructure of the carbon coils. Figure 9 shows the tip part of the carbon coils obtained using a Ni catalyst [46].

A Ni<sub>3</sub>C catalyst grain is always on the tip part of the carbon coils (arrow), and the catalyst grain is the exclusive growth point. Figures 10 and 11 show the enlarged view of the carbon coils [9]. The carbon coils are generally double coils similar to a DNA, and the coil number right-clockwise and left-clockwise is almost the same. Figures 12 and 13 show the carbon coils with interesting morphologies [57]. The growth of a single coil or multiple coils such as shown in Figure 14 was also sometimes observed. Recently, Motojima and co-workers [58, 59] succeeded in preparing carbon nanocoils with a coil diameter of several hundred to several ten nm in large scale using a magnetic CVD process or various catalysts such as Au, Ni/Au, etc. We also studied on the growth of carbon nanocoils by ceramics supported metal catalyzed methods using various metal catalysts such as Fe, Ni, Co, Cu, and supporters such as Al<sub>2</sub>O<sub>3</sub>, amorphous SiO<sub>2</sub>, and molecular sieves. The carbon nanocoils have generally two coiling forms: twisted forms and springlike helix forms such as shown in Figure 15. Using different catalytic systems, many kinds of carbon nanocoils with different morphologies were obtained. Figure 16 shows the tip part of the carbon nanocoils. Two coils [one is right-clockwise coiled and the other is left-clockwise coiled (twisted)] grew from

**Figure 9.** Tip part of the carbon coils obtained using Ni catalyst [1, 46]. Arrow indicates a Ni catalyst grain.

**Figure 10.** (R) Right-clockwise coiled regular double carbon microcoil. (L) Left-clockwise coiled regular double carbon microcoil. Each has a circular or elliptical fiber cross section [1].

a Ni/Al<sub>2</sub>O<sub>3</sub> catalyst grain (arrow). Figure 17 shows the tip part of the carbon coils obtained using the Ni–Fe/molecular sieve catalyst; one coil with fringe on the surface grew from the catalyst grains. The coils in which the chirality and coil axis alternate regularly were prepared by using the Ni–Fe/molecular sieves or WS<sub>2</sub> catalyst by controlled CVD conditions, and the representative coils are shown in Figures 18 and 19. Double twisted carbon nanofibers as well as 2D zigzag nanofibers were also observed in the Ni/Fe catalyzed deposits (Fig. 20).

### 2.3. Large-Scale Preparation of Carbon Nanocoils

In 1990, Motojima and co-workers [8] first found that regularly coiled carbon coils could be obtained with high reproducibility by the catalytic pyrolysis of acetylene containing a small amount of impurities and then extensively examined in detail the preparation conditions, morphology, growth mechanism, and some properties. It was found that the addition of an optimum amount of impurity such as sulfur or phosphorus in the source hydrocarbons is indispensable for obtaining carbon coils with high reproducibility and high coil yield. Between 1993 and 1995, we used phosphorus {PCl<sub>3</sub>,

$\text{PH}_3$ ,  $(\text{C}_2\text{H}_5\text{O})_3\text{P}$  and sulfur compound impurities (thiophene tetrahydrothiophene, diethylsulfide, hydrogen sulfide, and carbon disulfide) to achieve high yield and good reproducibility, and the maximum coil yield was obtained using a thiophene [60–62]. Since 1995 we have tried to prepare carbon microcoils, using various powders or plates of transition metal carbides such as Co, Cr, Fe, Hf, Mn, Mo, Nb, Ta, Ti, V, and W, Ni single crystal plate,  $\text{MoS}_2$ , and  $\text{Ti}_2\text{O}_3$  [62–67]. The results showed that except for Fe, all these metals can be used to obtain carbon coils, but the yield is lower than using a Ni catalyst. Among the carbides used, only TiC powder was effective, but the yield was quite low [63].  $\text{MoS}_2$  and  $\text{Ti}_2\text{O}_3$  were also effective. Since 1996 [63, 67–73], for producing carbon coils efficiently and economically, extensive efforts were made to improve the reaction device and to optimize the reaction conditions (temperature, gas flow pattern, flow rate of acetylene, thiophene,  $\text{N}_2$  and  $\text{H}_2$ ). Multiple gas inlet reactors [72] were developed for the mass-production of the carbon coils. Using this reactor, a coil yield of  $0.2 \text{ kg/m}^2$ -substrate could be obtained.

## 2.4. Preparation Process

The carbon coils are usually prepared by a conventional CVD process. Other preparation processes than the conventional CVD are reported as follows.

### 2.4.1. Laser CVD

Hishikawa and co-workers [74] prepared carbon coils with a coil diameter of  $3 \mu\text{m}$  by the laser CVD process using  $\text{CO}_2$  laser from allene ( $\text{C}_3\text{H}_4$ ) + sulfur hexafluoride ( $\text{SF}_6$ ) gas mixtures using the Fe catalyst.

### 2.4.2. Hot-Filament CVD

Motojima and co-workers [75] prepared carbon fibrillform nanocoils by Zn- or Ni-coated Cu catalyzed pyrolysis of ethylene at  $600 \text{ }^\circ\text{C}$  using the hot-filament CVD process.

### 2.4.3. Microwave-Plasma CVD

Xie and co-workers [40] prepared carbon coils with a coil diameter  $3.5\ \mu\text{m}$  and a fiber diameter of  $200\ \text{nm}$  by the Ni catalyzed pyrolysis of acetylene at  $700\ ^\circ\text{C}$  by the microwave-CVD process. The carbon coils are amorphous and specific surface area is  $62\ \text{m}^2/\text{g}$ .

### 2.4.4. Plasma and Catalyst Technology Process

Motojima and co-workers [61] prepared carbon coils with irregularly coiled form or with very wide coil pitch of  $10\text{--}30\ \mu\text{m}$  by the Ni-catalyzed pyrolysis hydrocarbons at  $770\ ^\circ\text{C}$  using a novel plasma and catalyst technology reactor. It was found that hydrocarbons such as methane, propane, and ethylene were decomposed under plasma and catalyst atmospheres to form acetylene as the main decomposition product, and then this acetylene was further decomposed to form carbon coils.

### 2.4.5. Supersonic CVD

Motojima and co-workers [59, 77] prepared carbon coils under the application of ultrasonic waves in the reaction zone and found that the coil yield and density increased with the application of ultrasonic waves, and that the optimum frequency was  $23\text{--}28\ \text{kHz}$ .

### 2.4.6. Electromagnetic CVD

In the conventional CVD process, an ac electric heater, from which electromagnetic waves (EM) are emitted, is generally used. Furthermore, the carbon coils can significantly absorb EM waves. Accordingly, it can be reasonably expected that the application of EM field as well as bias voltage in the reaction atmosphere may significantly affect the growth of carbon coils. Motojima and co-workers [59, 69, 78–81] first reported on the effect of the EM waves and bias voltage on the growth and properties of the carbon coils. It was found that the coil yield outstandingly increased by applying EM field and bias voltage on the reaction atmosphere.

### 2.4.7. Rotation CVD

Motojima and co-workers [70] reported the preparation of carbon coils using the rotation substrate CVD process.

### 2.4.8. Electroplating Process

Bai [42] obtained carbon nanocoils with a coil diameter of  $35\ \text{nm}$  and a coil pitch of  $30\ \text{nm}$  by the electrolysis of NaCl at  $810\ ^\circ\text{C}$ , showing that the CVD process is not the only way to get coiled carbon fibers.

## 2.5. Microstructure [82–85]

X-ray diffraction (XRD) patterns of the as-grown carbon coils are shown in Figure 21 as well as that of an amorphous pitch-based activated carbon fiber. It can be seen that the carbon coil is almost amorphous. Figure 22 shows the Raman spectra of the as-grown carbon coils obtained by a conventional CVD process and by application of high magnetic field in the reaction atmosphere. It can be seen

**Figure 21.** XRD patterns. (a) Pitch-based activated carbon, (b) as grown carbon fibers.

that the D-band and G-band intensity is almost the same, indicating an amorphous state, while the strength of the G-band against the D-band increases with increasing applied magnetic strength. Figure 23 shows the TEM image of the as-grown carbon coils. The development of distinct graphite layers cannot be observed while very short-range orderings can be seen. Figure 24 shows the XRD pattern of the heat treated carbon coils in  $\text{N}_2$  or  $\text{Co} + \text{CO}_2$  atmosphere. The amorphous as-grown carbon coils graphitized by the heat treatment without changing coiling morphology, and the graphite coils can be obtained at heat-treatment above  $2500\ ^\circ\text{C}$ . The schematic model of the graphite coils is shown in Figure 25. The graphite coils have distinct graphite layers ( $d = 0.339\ \text{nm}$ ) with an inclination of  $10\text{--}40^\circ$  versus the fiber axis to form a “herringbone” structure.

## 2.6. Growth Mechanism

Why a vapor grown carbon fiber (VGCF) is sometimes successively curled, twisted, or coiled to form “carbon coils” is very interesting from the theoretical and scientific point of view. In an early stage of the research on the VGCF, the

**Figure 22.** Raman spectra of carbon coils. (a–d): Carbon coils prepared with application of high magnetic field of 2–5 Tesla. (e) As-grown carbon coils.

Figure 23. TEM image of the as-grown carbon coils.

growth of the carbon coils with helical, spiral, threadlike, or twisted forms was very rare and extremely accidental, and the reproducibility was very poor. Thus the production was almost excluded as the helical/spiral or twisted form is unusual. Furthermore, the versatile potential applications of the carbon coils were not known and recognized in those days. The reproducibility of the growth of carbon coils from vapor phase was afterward outstandingly improved, and nowadays the carbon coil is semi-mass-produced. The growth mechanism of the VGCF with a straight form has been proposed by many researchers. It may be considered

Figure 24. XRD patterns of as-grown and heat-treated carbon coils.

Figure 25. Schematic image of the herringbone structure of the graphite coil: (A) 3D image, (B) 2D image showing graphite layers. (a) Catalyst grain, (b) Graphite layers, (c) Fiber axis [82].

that the growth of carbon coils with various morphologies is the general growth pattern of a VGCF and a straight VGCF is the rather special case. Accordingly, the growth mechanism of the carbon coils has also been proposed by those researchers as well as the establishment of the preparation processes of the carbon coils.

In this section, the growth models or mechanisms of the carbon coils are reviewed.

### 2.6.1. Boehm's Mechanism

Boehm [14] proposed a schematic growth model of filamentary carbon on iron carbide with two active faces at oblique. He considered that if the catalyst particle has an angular shape as shown in Figure 26, a curved carbon fiber would grow from the active crystal faces due to the different diffusion path lengths in the carbide crystals resulting in the growth of helical growth forms if strands grow to any length, and double helices would result if two adjacent crystal faces are active.

### 2.6.2. Baker's Branching Mechanism

Baker and co-workers [17] obtained spiral carbon filaments from acetylene at above 800 °C using the Sn/Fe (Sn coated Fe foils) catalyst. Branching of carbon filaments was common as shown in Figure 27. They suggested the principle means of relieving the stress created by the fact that filaments were often forced against the mass of deposit in two directions, and when this stress became too great the particle was squeezed out from between these two filaments and began to propagate a new pair.

### 2.6.3. Baker's Filament Growth Model

Baker and Chludzinski [81] examined the effect of the various metal oxide additives to the Ni-Fe catalyst on the inhibition of the growth of carbon filaments using  $C_2H_2$  as a source gas. Many filaments formed in the presence of  $TiO_2$  (Ni-Fe/ $TiO_2$  catalyst) were in a spiral conformation, where the catalyst particle was located within the filament, which grew from two faces of the particle in opposite directions.

**Figure 26.** Schematics representation of growth mechanism of filamentary carbon on iron carbide (a) on rectangular carbide particle, (b) on carbide particle with two active faces at oblique angle [14, 29].

**2.6.4. Downs–Baker Mechanism**

Downs and Baker [86] obtained various carbon filaments (e.g., branched, spiral, helical, with coil diameter of about 100 nm) using carbon fibers as the substrate as schematically shown in Figure 28. They also proposed the growth mechanism of the coils.

**2.6.5. Kim–Baker Mechanism**

Kim and co-workers [20] reported the growth of coiled carbon fibers using  $C_2H_2$  and Cu/Ni(1:1) at 700 °C. Two filaments grew from opposite faces of the catalyst particles

**Figure 27.** Bifilament morphology of coiled carbon fiber observed in the Sn/Fe system. [17, 29].

**Figure 28.** Schematic representation of different types of growth morphologies observed in carbon filaments [86]. (a) Whisker-like, (b) branched, (c) spiral, (d) helical.

at identical rates. Furthermore, during the major part of the growth process, the filaments were relatively smooth and tended to form into large loops. The catalyst particles reached a size of about a third of the original value; they appeared to undergo a further change in shape and simultaneously started to rotate on an axis perpendicular to the direction of filament growth, causing the filament to acquire a spiral form. This action normally continued for a relatively short time, being the prelude to catalyst deactivation. This phenomenon was observed at all growth temperatures.

**2.6.6. Amelinckx’s Mechanism**

Amelinckx and co-workers [31] examined in detail the different coiling morphologies of the graphite tubes grown by the Co-catalyzed decomposition of acetylene and proposed a new model based on the concept of the spatial-velocity hodograph to describe quantitatively the extrusion of a carbon tubule from a catalytic particle as shown in Figure 29. The coiled fibers were generally found to be hollow tubes consisting of concentric cylindrical graphene sheets. The tubules can adopt various shapes such as straight, curved, planar-spiral, and helix, often with a remarkably constant coil pitch. It is generally accepted that the tubules grow by the extrusion of carbon, dissolved in a metallic catalyst particle that is supersaturated in carbon at one part of the surface. The most detailed description of this growth process was given by Baker [87].

**Figure 29.** Successive stages in the extrusion of carbon according to the hodograph of the extrusion velocities for the case of a uniform bent tubule [31].

### 2.6.7. Owens's Mechanism

Although it is well known that sulfur acts as a poison for many Ni-catalyzed reactions, Owens and co-workers [28] observed that certain benefits of sulfur can be derived from following a partial and well controlled sulfidization treatment of the metal catalyst for the growth of carbon filaments by the nickel catalyzed decomposition of  $C_2H_4/H_2$  mixtures. That is, the pretreatment of Ni in low levels of  $H_2S$  (4–50 ppm) results in a reconstruction of the metal surface and thus induces some major perturbations in the morphological characteristics of the filamentous carbon deposit to regularly form coils. This change in growth mode indicates that sulfur is modifying the diffusion characteristics of carbon species through the catalyst particle.

### 2.6.8. Fonseca–Dunlop Mechanism

Fonseca and co-workers [88, 89] reported a model of perfectly graphitizable coiled carbon nanotubes and discussed the growth mechanism of the coiled carbon nanotubes. The presence of a large amount of curved and coiled nanotubes among the straight tubes produced by the catalytic method stimulated several studies on the theoretical aspect of the coiling mechanism [88, 90–93]. It was proposed that the curving and coiling of the straight tubes can be accomplished by the occurrence of knees (i.e., two straight cylindrical tube sections of the same diameters connecting at an angle). Such knees can be obtained via the insertion in the plane of the knee of diametrically opposed pentagonal and heptagonal carbon rings in the hexagonal networks. The heptagon is on the inner side of the knee and the pentagon is on the outer side. The possibility of such a construction was predicted by Dunlap [94–96]. Theoretical models of curved nanotubes forming toroids of irregular diameters have also been described by Ihara and Itoh [97]. Fonseca suggested a growth mechanism on a catalyst at a molecular level using the heptagon–pentagon construction of Dunlap [95]. Dunlap explained the formation of curved nanotubes, tori, or coils by this concept. Dunlap also observed that the diameter range of the young tube (1 min) is about the same as that of the old ones (80 min). For a long time exposure (5 h) of the tubules to the reaction conditions, only amorphous carbon was deposited on the outer layer and no tubes with higher diameters were observed.

### 2.6.9. Li's Mechanism

Li and co-workers [98] obtained coiled nanotubes by the Fe-catalyzed pyrolysis of acetylene at 973 K and examined the morphology and microstructure in detail. The obtained

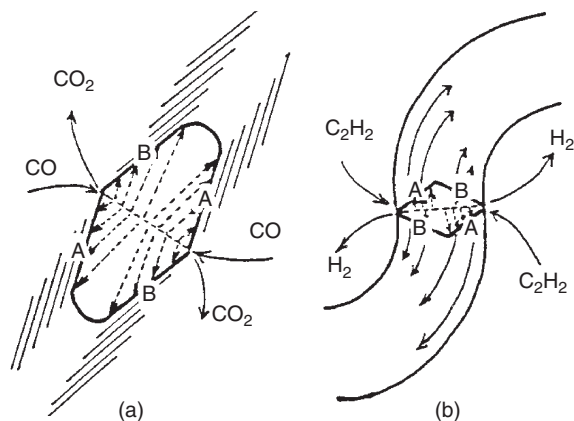

coil was a single coil and has a 70 nm coil diameter and a 130 nm coil pitch. It was suggested that the formation of the coiled nanotubes was due to the mismatch between the extrusion velocity by the catalyst particle and the rate of carbon deposition.

### 2.6.10. Motojima's Anisotropy Mechanism

Motojima and co-workers [1, 50, 99] proposed the two- and three-dimensional growth mechanism of the carbon coils based on the anisotropic deposition of carbon on the different catalyst crystal planes. Figure 30 shows the tip part of the carbon coils obtained in an initial growth stage. It can be seen that two carbon fibers grew from a catalyst grain (white part) and curled to form double coils. Figure 31 shows the schematic 2D-growth model. If the catalytic activity of a crystal plane A of a catalyst grain is larger than that of B, the grown fiber will be curled to the right direction to form carbon coils. On the other hand, if there is no difference in catalytic activity between crystal planes A and B, a straight carbon fiber grows. Figure 32 shows the 3D-growth model. Six carbon fibers grew basically from six crystal planes following coalescence to form two fibers. That is, one fiber is formed from fine carbons deposited from three crystal planes, in which three crystal faces may have different catalytic activities. Motojima and co-workers [45, 99] have found that a different crystal face of a Ni single crystal has different catalytic activity for the growth of carbon coil, and the coil yield was 10.2% for Ni(100), 6.7% for Ni(111), and 3.2% for Ni(110). Circular carbon coils with circular fiber cross section are predominantly formed during the initial growth stage and then change to flat coils with increasing reaction time because of the change in the catalyst shape from cubic to slender form. A change in the catalyst form may be effected by the electromagnetic field (force) emitted from the outer electric heater as schematically shown by Chen and co-workers [100]. Yang and Chen [101] reported that for the carbon filament growth using the Ni-catalyzed pyrolysis of methane at 700 °C, the most preferable crystal plane for graphite precipitation was Ni(111) followed by Ni(111) > (311) > (100) > (110). Accordingly, the grown carbon fiber curls such that the fiber plane deposited from higher catalytic plane is outer part of the curled fibers to

**Figure 30.** Tip of the carbon coils grown on a Ni catalyst in the initial reaction stage [63].

**Figure 31.** 2D-schematic growth model of (a) straight carbon fiber and (b) carbon coil [136].

from carbon coils. The coil diameter is determined by the difference in catalytic activities of A and B, and coil pitch by the difference in B and A or C.

**2.6.11. Chesnokov’s Mechanism**

Chesnokov and co-workers [27] proposed the growth mechanism of the symmetrical helical filamentous carbon fibers obtained by the decomposition of butadiene-1,3 over Ni-Cu/MaO catalyst at 723 K. Figure 33 shows the schematic growth model. In the initial growth stage, butadiene-1, 3 decomposes to form carbon and hydrogen atoms. Carbon atoms diffuse into the Ni/Cu alloy bulk and gradually oversaturate to nucleate and form metastable Ni<sub>3</sub>C on the frontal side of the alloy particle. Planes (111) of Ni/Cu alloy are the most preferable for the graphite nucleation since graphite (002) and alloy (111) planes, which determine the filament growth direction, are similar in symmetry and interatomic distances [27]. Intensive carbon atom diffusion flow toward the crystallization center then occurs, which results

**Figure 32.** 3D-schematic growth model of carbon coils [1]. A, B, and C show the different crystal faces.

**Figure 33.** Schematic diagram of the growth mechanism of helix filamentous carbon produced from butadiene-1,3 on Ni-Cu crystals [27].

in dislocation of metal atoms and thus distorts the spherical shape of the particle to an elongated form. As can be seen in Figure 23, different carbon atoms pass via unequal diffusion from the places where they enter the alloy particle through the Ni<sub>3</sub>C phase to different surface patches where graphite phase grows. This results in different growth rates and filament twisting [27].

**2.6.12. Chiral Nanotube**

Liu and Cowley [102] reported on the electronic structure of chiral nanotubes. Akagi and co-workers [103] studied general features of the electronic states of helically coiled cages of graphite layers by simple tight-binding models. Ihara and Itoh [97] reviewed the recent status of research of helical and toroidal forms, which contain pentagons, hexagons, and heptagons of carbon atom. Figure 34 shows the schematic model of a helically coiled form of C<sub>360</sub>. The atomic arrangements of the structures of the helically coiled forms of the carbon cage for the single layer, which are found to be thermodynamically stable by molecular-dynamics simulations, are compared to those of the experimentally helically coiled forms of single and multilayers graphite forms that recently have been experimentally observed.

**Figure 34.** Helically coiled form C<sub>360</sub> [97]. One pitch contains a torus C<sub>360</sub>. (a) Coil length = 12.9 Å and (b) coil length = 13.23 Å. The tiling pattern of heptagons in the inner ridge line is changed, though the pattern of pentagons in the outer ridge line remains upon changing the coil length.

## 2.7. Properties

### 2.7.1. Mechanical Properties

The mechanical properties of the carbon coils were evaluated in detail by Motojima and co-workers [46, 104–108]. The circular carbon coils with a circular fiber cross sections and with large coil diameter can be extended elastically up to 4.5–15 times original coil length, while flat coils with flat or rectangular fiber cross sections can only be extended up to 1.5 times the original length. For example, the carbon coil can be extended to nearly straight form as shown in Figure 35 [108]. The carbon coils extend linearly with increasing applied load. The rupture strength of the as-grown carbon coils is 42–114 MPa. The rigidities of the circular and flat as-grown carbon coils are 22–46 GPa and 22–33 GPa, respectively.

### 2.7.2. Electric Properties

The bulk (powder) electrical resistivity of the as-grown carbon coil decreases with increasing the bulk density and is 1–10  $\pi/\text{cm}$  for bulk density 0.3  $\text{g}/\text{cm}^3$  and 0.1–0.2  $\pi/\text{cm}$  for 0.6  $\text{g}/\text{cm}^3$  as shown in Figure 36 [82]. The resistivity of the bulk carbon coils can be decreased steeply with the surface coating by carbon [83], TiC [109], TiN [110], ZrC [104], NbC [111], and TaC [112] but not by graphitizing at high temperature heat treatment [82]. Kaneto and co-workers [113, 114] examined the electrical conductivity of the carbon coils in detail. The electrical conductivity along the helical axis of a piece of carbon coil is 30–100 S/cm. This conductivity is rather small compared with multiwalled carbon nanotubes. Figure 37 shows the current–voltage (*i*-*v*) curve of a piece of carbon coil. The (*i*-*v*) characteristics indicate that the current shows superlinear dependence on the applied voltage at high fields. The fact is explained by heating of the coil by electrical power, because of the higher conductivity at higher temperature, or the high field effect. The temperature dependence of conductivity showed that one of the possible transport mechanisms is the 3D variable range hopping model. Kaneto and co-workers [114] also examined the electrical conductivities of the carbon coils under various gas atmospheres. The conductivity of a single coil increased by 5–20% upon evacuation for several minutes. Furthermore,

Figure 35. Extended carbon coils [108].

Figure 36. Bulk electrical resistivity obtained at room temperature in air [82].

the conductivity increased by 1–2% upon exposure to iodine (oxidative) gas for several minutes. On the other hand, upon exposure to ammonia (reductive) gas from the vacuum, the conductivity decreased nearly to the same value of the air atmosphere. However, the degree of conductivity was found to be small compared with the case of other  $\pi$  conjugated systems such as conducting polymer.

Fujii and co-workers [115, 116] examined the magnetoresistance of the as-grown and heat-treated carbon coils in the magnetic field in the range from 0 to 12 Tesla at 290 K. The magnetoresistance of the as-grown carbon coil does not change under strong magnetic field up to 12 Tesla. On the other hand, the magnetoresistance is negative for specimens

Figure 37. Voltage–current (*i*-*v*) characteristics of a carbon coil [113, 114]:  $l_0$ : coil length before stretch,  $l$ : coil length after stretch,  $R$ : electrical resistivity.

heat-treated at 1500 °C and 2000 °C and positive for specimens heat-treated at 2500 °C and 3000 °C. The absolute value of the magnetoresistance ratio  $\{R(B) - R(0)\}/R(0)$  increased with increasing magnetic field, 40% at parallel magnetic field of 12 T, and 5% at 5 T, and 14% under transverse magnetic field of 12 T as shown in Figure 38.

### 2.7.3. Field Emission Properties

Pan and co-workers [117] reported on the field emission properties of carbon tubule nanocoils. The carbon nanocoils show the low turn-on field of 180 V at a 130  $\mu\text{m}$  gap and high emission current of  $10^{-3}$  A/cm<sup>2</sup> at 300 V as shown in Figure 39 and also shows excellent stability of emission for over 250 hr. These values are sufficient for commercializing the carbon-nanofiber-based field emission displays. Accordingly, the carbon nanocoil is expected to be a novel attractive candidate for the fabrication of flat panel field emission displays.

### 2.7.4. Electromagnetic Properties

It is considered that the carbon coil is a promising candidate as a novel EM wave absorber, especially in the GHz range, because of its microcoiling morphology. That is, the microcoiling morphology is the most effective and ideal one for the generation of inductive current by Faraday's law resulting in absorption of EM waves. Actually, the carbon coils can absorb EM waves in the GHz region without reflection. Motojima and co-workers [47, 83, 118–120] examined the absorption ability (reflection loss) of EM waves, especially in the GHz regions, in detail. The as-grown carbon coils can strongly absorb the EM waves of 13.9 and 16.3 GHz, and the reflection loss is below  $-40$  dB (99.99% absorption). The absorption region can be broadened by addition of other additives. Figure 40 shows the reflection loss of the CMC-containing PMMA (polymethylmetacrylate) beads for 75–105 GHz regions. It can be seen that the reflection loss below  $-30$  dB (99.9% absorption) of EM waves can be obtained by only 1 wt% addition in the PMMA beads.

**Figure 38.** Effect of magnetic field on the magnetoresistance of a heat-treated carbon coil (graphite coil): Temperature: heat-treated temperature. Parallel and transverse: the direction of magnetic field is parallel and transverse (vertical) to the coil axis, respectively [116].

**Figure 39.** Curve of the emission current density vs applied voltage for a typical nanocoil field emitter [117]: The low turn-on voltage and high current density are obtained.

The higher addition above 2 wt% or lower addition below 0.5 wt% results in lower reflection loss. Du and co-workers [121] examined microwave electromagnetic characteristics of a microcoiled carbon fiber/paraffin wax composite in Ku band frequencies (12.4–18 GHz).

### 2.7.5. Chemical Properties

The carbon coil become oxidized at about 450 °C in air, and the weight significantly decreases with increasing temperature and burn out at 700 °C [122]. On the other hand, the graphite coils obtained by the heat treatment of as-grown carbon coils at 3000 °C for 6 hr in CO + CO<sub>2</sub> become oxidized at about 700 °C in air. The oxidation behaviors of the as-grown and heat-treated carbon coils are examined in detail to improve the surface inertness and enhance the

**Figure 40.** Reflection loss of the CMC-impregnated PMMA bead. CMC content: (a) 0 wt%, (b) 1 wt%, (c) 2 wt%, (d) 3 wt%.

chemically active sites [54, 122, 123]. The graphite coil is stable up to about 1200 °C in Ar atmosphere. However, the graphite coil is partially oxidized by the small amount of oxygen impurity included in Ar at the contact part of two graphite layers in which large inner stress may be impressed to form on amorphous state. Shibagaki and Motojima [54, 123] examined in detail the partial oxidation characteristics of the surface of the carbon coils, under low O<sub>2</sub> flow rate at 450–820 °C to improve the surface chemical activities.

### 2.7.6. Thermal Properties [82, 106, 123]

The carbon coils can be heat-treated up to 1000–3000 °C in CO + CO<sub>2</sub>, Ar, or N<sub>2</sub> atmosphere to form graphite coils with full preservation of the coiling patterns of the carbon coils. The elasticity of the as-grown carbon coils is reduced by the heat treatment and became brittle. The ruptured cross section of the fiber which composes the circular graphite coil takes either a trigonal pyramid-like form or a negative pyramidal hollow. On the other hand, the ruptured cross section of the flat graphite coils either has rooflike extrusion or is hollow. These characteristic patterns suggest a growth mechanism of the carbon coils. Many distinct striations, declined at 40–50 deg against fiber axis, can be seen on the surface. The TEM image of the tip part of the ruptured fibers shows that distinct graphite layers ( $d = 0.339$  nm) are developed with an inclination of 35–40 deg versus the fiber axis to form a “herringbone” structure. The lattice parameter is  $a = 0.2464$  nm and  $c = 0.6772$  nm. The “ $c$ ” value is slightly larger than the reported value for graphite of 0.6714 nm while the  $a$  value is the same as that of graphite ( $a = 0.2463$  nm). Raman spectra show that the graphite layers of the graphite coils are not more developed than the 100–200 μm long VGCF. This may be caused by the presence of some disorders in the graphite layers and/or the smaller submicrometer width of the graphite layers in the graphite coils.

## 3. CERAMIC NANOCOILS/NANOTUBES

### 3.1. Introduction

Ceramic materials with a 3D nanocoiled or nanotubed structure (referred to as “ceramic coils” hereafter) are not commercially available. Ceramic coils are very interesting as new functional materials with many potential applications, such as light weight thermal barriers, heat exchangers, gas separation materials, absorbers for electromagnetic waves, microsensors, electrodes materials, catalysts, etc. The growth of various coiled ceramic fibers by CVD process has sometimes been observed with mixing straight fibers so far. These coiled fibers are generally very irregularly coiled, and the growth is extremely accidental and without reproducibility. On the other hand, Motojima and co-workers [9, 10, 124, 125] first found that very regularly coiled silicon nitride (Si<sub>3</sub>N<sub>4</sub>) fibers could be obtained with good reproducibility by the CVD process. After then, they prepared various ceramic coils such as metal carbides, nitrides, and oxides using a carbon coil as a template with high yield. Growth of various ceramic coils by the CVD process, electroplating, or the biomimetic process has also been reported by some researchers.

In this section, preparation, morphology, growth mechanism, and some properties of various ceramic coils/tubes are reviewed.

### 3.2. SiC and Si<sub>3</sub>N<sub>4</sub>

The vapor growth of the helical SiC fibers was first reported by Addamiano [126]. He found that the coiled crystals of 2H-SiC grew in mixing in a mass of straight 2H-SiC whiskers during the hydrogen reduction of methyltrichlorosilane at 1400–1430 °C on graphite substrate. After then, Kang and co-workers [127] reported that irregularly coiled SiC whiskers grew among the straight or irregularly curled SiC fibers during the carbothermal reduction of SiO<sub>2</sub> by carbon at 1500 °C under Ar + CO atmosphere. The springlike SiC whiskers did not grow in the presence of Fe impurity but grew in NaCl impurity. It was suspected that the formation of the springlike whiskers should be closely related to the presence of chlorine impurity.

Motojima and co-workers [68] prepared the SiC coils using a powder mixture of SiO and cooked rice husks at 1400–1450 °C. The SiC coils were triple coils with a 0.5–1 μm coil diameter and a 10–100 μm coil length. Motojima and co-workers [47, 106, 128, 129] also easily prepared the SiC coils by the vapor phase diffusion process using a carbon coil as a template.

Motojima and co-workers [9, 10, 124] first prepared very regularly coiled silicon nitride (Si<sub>3</sub>N<sub>4</sub>) fibers by the Fe-catalyzed CVD process using a Si<sub>2</sub>Cl<sub>6</sub> + NH<sub>3</sub> (or N<sub>2</sub>) + H<sub>2</sub> gas mixture at 1200 °C on a graphite substrate. The Si<sub>3</sub>N<sub>4</sub> coils are single-helix coils and have a coil diameter of 10–15 μm and a coil pitch of 3–5 μm as shown in Figure 41. The coils have a crystalline Si<sub>3</sub>N<sub>4</sub> core surrounded by an amorphous Si<sub>3</sub>N<sub>4</sub> clad [130] and have excellent elastic and mechanical properties [26, 131–133]. Iwanaga and co-workers [134] review the ceramic microcoils including the Si<sub>3</sub>N<sub>4</sub> coils. Vogt and co-workers [135] prepared the microcoiled Si<sub>3</sub>N<sub>4</sub> fibers by the reaction of SiO<sub>2</sub> with NH<sub>3</sub> at 1400 and found that addition of Fe and W impurity in SiO<sub>2</sub> partly promotes the growth of the microcoiled Si<sub>3</sub>N<sub>4</sub> fibers. The Si<sub>3</sub>N<sub>4</sub> coils obtained by them are single-helix coils with a fiber diameter of 2–10 μm and a coil diameter of 5–20 μm.

**Figure 41.** Si<sub>3</sub>N<sub>4</sub> microcoils prepared by a Fe-catalyzed CVD process [9, 10].

### 3.3. TiC, TiN

Motojima and co-workers [136] prepared a TiC microcoil by the CVD process using a source gas mixture of  $\text{TiCl}_4 + \text{H}_2 + \text{PCl}_3$  and a Si + Pd catalyst dispersed on a graphite substrate at 1050 °C. The TiC coils were double-helix coils similar to DNA and have a coil diameter of 1–5  $\mu\text{m}$  and a coil length of 20–150  $\mu\text{m}$ . Motojima and co-workers [47, 109, 128, 129, 137] also obtained TiC coils by a vapor phase diffusion process (titanizing or nitriding) using carbon coils as the template, with full preservation of the coiling morphology of the source carbon coils. The bulk (powder) electrical resistivity of the TiC coils decreased with increasing titanizing ratio and attained 0.01  $\Omega \text{ cm}$  at a bulk density of 1.4  $\text{g/cm}^3$ . Addition of the  $\text{N}_2$  or  $\text{NH}_3$  gases resulted in the formation of TiN microcoils because the nitride phase is thermodynamically more stable than the carbide phase.

### 3.4. ZrC, ZrN

Motojima and co-workers [104, 129] prepared ZrC and ZrN coils by the vapor phase diffusion process using the carbon coils as a template. Depending on the reaction conditions, ZrC/C(carbon coil)/ZrC composite coils to a single phase ZrC coil could be obtained, with full preservation of the coiling morphology of the carbon coil and coil yield 100%. Addition of  $\text{N}_2$  or  $\text{NH}_3$  gases in the reaction atmosphere resulted in the formation of ZrN coils.

### 3.5. NbC, NbN, TaC, TaN, HfC

Motojima and co-workers [47, 106] obtained NbC coils by the vapor phase diffusion process using the carbon coils as the template. Depending on the reaction conditions, NbC/C(carbon coil)/NbC composite coils to single phase NbC coils could be obtained, with full preservation of the coiling morphology of the carbon coil and coil yield 100%. Addition of the  $\text{N}_2$  or  $\text{NH}_3$  gases resulted in the formation of a ZbN/C(carbon coils)/NbN–NbN coils/tubes [138, 139]. The carbides or nitrides of Ta or Hf were also obtained using similar processes [47, 106, 112, 116, 129, 138].

### 3.6. SiO<sub>2</sub>, TiO<sub>2</sub>

Robbie and co-workers [9, 140] found that porous and chiral films of  $\text{SiO}_2$  could be obtained by the GLAD (glancing angle deposition) process using electron-beam evaporation onto the glass substrates coated with an ITO transparent conductor. They showed that using the GLAD process, the microstructure parameters such as helical rise angle, pitch, and handedness could easily be controlled, and structures such as pitch gradients and stacked layers of different pitch and/or handedness were also easily produced. For example, the pitch in a helical GLAD films can be controlled by the ratio of deposition rate to substrate rotation rate, while the handedness can be controlled by the direction of rotation. Figure 42 shows an example of a chiral GLAD  $\text{SiO}_2$  film [141]. This film has left-handed helical columns with 8.4 turns and pitch  $p = 410$ . Robbie and co-workers [140, 142] also obtained chiral liquid crystal films by embedding LC into the porous and chiral  $\text{SiO}_2$  films. Helical/spiral forms are also frequently observed in materials such quartz

**Figure 42.** Example of a chiral GLAD  $\text{SiO}_2$  film [140]. A left-handed helical film with 8.4 turns of pitch 410 nm is shown. The film pitch is the thickness of one turn of the helix and relates to the wavelength at which peak chiral optical activity is observed.

[143]. Yang and co-workers prepared hollow helicoids made of hexagonal mesoporous silica [144]. Research group of Shinkai studied the preparation of silica fibrils with a novel double stranded helical structure by sol–gel transcription of twisted bilayer ribbons formed by cationic gemini surfactants [145]. Motojima and co-workers [146] prepared  $\text{TiO}_2$  microcoils/tubes by sol–gel and CVD processes using a carbon coils as a template as shown in Figure 43.

### 3.7. Miscellaneous

Gleize and co-workers [147] prepared tubular BN fibers with a helical form by a CVD process using  $\text{B}_2\text{H}_6 + \text{NH}_3$  (or  $\text{N}_2$ ) at 1100 °C using the  $\text{ZrB}_2$  catalyst. The thickness of tubular fiber is 0.1  $\mu\text{m}$ , coil diameter is 0.2  $\mu\text{m}$ , and coil length is 5  $\mu\text{m}$ . Johansson and co-workers [148] proposed a

**Figure 43.**  $\text{TiO}_2$  helical coils obtained using a carbon coils as a template.

new method for the preparation of three-dimensional structures in free space, a laser-assisted CVD process with a high-resolution micropositioning system. In this process, a linear three-axis micropositioning system and laser beam which was focused on the tip of the growing point are used. Using this process, they prepared a 3D-boron spring with spring diameter of 350  $\mu\text{m}$  from a gas mixture of  $\text{BCl}_3 + \text{H}_2$  gas mixture. This boron spring has high mechanical properties such as an elastic modulus of 420–450 GPa, fracture strain of 2.7–3.7%, and a fracture stress of 12–17 GPa. Jiang and co-workers prepared AN whiskers with wavy (helical) structure by the SHS (self-propagating high-temperature synthesis) method [149]. The growth of helical fibers of GaP[150], GaAs[151, 152], MnAs[153], ZnS[151], Cu[154], Cu–Zn[154], and  $(\text{SrBa})\text{CO}_3$  [155] from a vapor phase was also reported. Furthermore, the helical calcium carbonates, barium sulfate, and silica were also prepared by the biomimetic process [156–160].

#### 4. APPLICATIONS

Downs and Baker [86] first predicted that the unique structural conformations of helical form which can frequently be found in vapor grown carbon filaments will open up numerous possibilities in the fabrication of new functional materials. Lakeman and co-workers [159] prepared micro-coiled carbon fibers with coil diameters of several hundred micrometer and coil pitches of about 100  $\mu\text{m}$  for the application to the semiconducting infrared detection elements. Pan and co-workers [117] showed that the carbon nanocoils are expected to be novel attractive candidates for the fabrication of a flat panel field emission display. Motojima and Iwanaga [118] showed that the carbon coils have an excellent EM absorption ability, especially in GHz regions. The helical carbon coils will have versatile applications such as EM absorbers, field emitters, hydrogen absorption–desorption materials, energy exchanging materials, tunable microdevices, microsensors, microactuators, micromachines, chiral catalysts, extend–contractable electrodes, reinforcements for soft and/or extendable materials, hydrogen storage materials, activators for organisms, etc.

#### GLOSSARY

**Carbon microcoil** Carbon microcoil (CMC) is a kind of vapor grown carbon fiber obtained by the catalytic pyrolysis of hydrocarbons or disproportionation of CO. The CMC generally has the double-helix coiling morphology similar to DNA, and has a coil diameter of 1–50  $\mu\text{m}$  and a coil length of 0.1–20 mm. The as-grown CMC is almost amorphous and has no pore (tube) in the fiber axis.

**Carbon nanocoil** Carbon nanocoil (CNC) has the generally single-helix morphology with a small coil diameter of 10–500 nm.

**Ceramic microcoil** Ceramic microcoil is generally tuberos ceramic fibers with 3D herical/spiral structure and coil diameter of micrometer order, and can be prepared directly by the chemical vapor deposition (CVD) process, or indirectly by the sol–gel or CVD processes using carbon microcoils/nanocoils or chiral polymers as the templates.

**Coiling-chirality** “Chirality” is generally used in the mean of optical isomerism (enantiomer) with mirror-symmetry of *levo*-rotatory (*l*) and *dextro*-rotatory (*d*). On the other hand three dimensional chiral/coiling morphology has two kind of coiling patterns, right clockwise and left clockwise coiling patterns in mirror symmetry, and they are not superimposed with each other. Accordingly, two kinds of coiling patterns are referred to as a coiling-chirality.

**Cosmomimetic carbon coil** Three dimensional (3D) helical/spiral structures are commonly observed in all objects in cosmos, nature, living bodies, electromagnetic waves, economic cycles, etc. That is, 3D helical/spiral structure is a fundamental structure in all things in the cosmos. Accordingly, the carbon microcoils or nanocoils with 3D helical spiral structure is referred to as “cosmomimetic carbon coil” after the term of “biomimetics”.

**Helix, spiral, coiling** “Helix” is used mainly in the field of living polymers such as DNA or protein, or synthetic polymers, while the terms of “spiral”, “coiling” or “screw” are used in the fields of general substances or materials. The terms of helix, spiral and coiling represent the same means of the three dimensional forms or morphologies such as springs, coils, screws, whirlpools, vortex, etc.

## 1. INTRODUCTION

Since an icosahedral phase was found in a rapidly solidified  $\text{Al}_{84}\text{Mn}_{16}$  alloy [1], a large number of icosahedral alloys have been synthesized in metastable and thermodynamically stable states [2], and the novel structure has been interpreted on the basis of a quasicrystal [3]. It has been reported that the icosahedral quasicrystalline phase is formed in Al- [4–6], Mg- [7], Zn- [8], Ga- [9], Pd- [10], and Ti-based [11]

systems, and so on. It is important to search for a new icosahedral alloy, and to clarify its formation mechanism and fundamental properties because the icosahedral atomic configuration is different from the conventional crystalline structure, leading to a unique property. High hardness, a high Young's modulus, a high elevated temperature strength, low coefficient thermal conductivity, and high resistance against oxidation have been reported in icosahedral quasicrystals originating from the three-dimensional quasiperiodic lattice [12–14]. The structure control, such as volume fraction, grain size, and distribution of icosahedral particles, must be required for the improvement of these properties, and can create new unique properties [15]. It is expected that they can be achieved by the formation of a nanometer-scale icosahedral phase (nanoicosahedral quasicrystal).

The formation of a nanoicosahedral phase is effective by quasicrystallization from the amorphous or glassy structure [16–18] because the homogeneous structure consisting of icosahedral and amorphous or glassy phases can be obtained, and the volume fraction and grain size of the icosahedral particles are easily controlled by changing the annealing condition. The first discovery of icosahedral phase formation from an amorphous state was reported in the  $\text{Pd}_{60}\text{U}_{20}\text{Si}_{20}$  alloy in 1985 [10]. The  $\text{Pd}_{60}\text{U}_{20}\text{Si}_{20}$  amorphous alloy has two exothermic reactions at near 753 and 813 K in the differential scanning calorimetry (DSC) curve [19]. The first one corresponds to the transformation from an amorphous to an icosahedral phase. The precipitated icosahedral particles can grow in the diameter range over 100 nm by annealing. It was found that the icosahedral phase is also obtained from an amorphous state in Al–Si–Mn alloys [5, 20–24]. The  $\text{Al}_{55}\text{Si}_{25}\text{Mn}_{20}$  amorphous alloy, which is a typical icosahedral phase-forming alloy composition, also has a two-stage crystallization process [25]. The icosahedral phase is formed by the first exothermic reaction at approximately 650 K, and grows easily to a diameter of approximately 500 nm. Both of the icosahedral phases in the  $\text{Pd}_{60}\text{U}_{20}\text{Si}_{20}$  and  $\text{Al}_{55}\text{Si}_{25}\text{Mn}_{20}$  alloys decompose to stable crystalline phases through the second exothermic reaction.

Tsai et al. reported the formation of a stable icosahedral phase from the amorphous  $\text{Al}_{75}\text{Cu}_{15}\text{V}_{10}$  alloy [26]. The icosahedral phase is precipitated from the amorphous state through the single exothermic stage, and is melted at about 835 K. The grain size of the icosahedral phase in the alloy is approximately 1  $\mu\text{m}$  in diameter due to its high stability. The above-described icosahedral phases precipitated from the amorphous states have a relatively small nucleation rate and a large growth rate [27, 28]. It is therefore difficult to obtain a unique structure consisting of the nanoicosahedral particles embedded in the amorphous matrix.

It has been thought that the formation of an icosahedral phase from an amorphous state is attributed to the existence of quenched-in nuclei with an icosahedral-like structure [19, 27, 28]. The presumption has also been supported by several experimental and theoretical approaches, where the icosahedral and amorphous phases have a local structural similarity, and the stability of the icosahedral phase is related to the short-range icosahedral order already present in a supercooled liquid [9, 29–32].

The formation of an icosahedral phase in the bulk glass-forming alloy was reported in  $\text{Zr}_{69.5}\text{Al}_{7.5}\text{Ni}_{11}\text{Cu}_{12}$  in 1996 [33]. The  $\text{Zr}_{69.5}\text{Al}_{7.5}\text{Ni}_{11}\text{Cu}_{12}$  glassy alloy has a large supercooled liquid region of 55 K [34], which is defined as the temperature gap between glass transition  $T_g$  and crystallization  $T_x$ . The crystallization proceeds through two-stage reactions, and the first one corresponds to the formation of a quasicrystal. The icosahedral particles are distributed homogeneously in the glassy matrix, and the grain size of the icosahedral phase is approximately 100 nm at a volume fraction of 25%. The maximum nucleation rate for the icosahedral phase formation is about  $5 \times 10^{18} \text{ m}^{-3} \cdot \text{s}^{-1}$ , which is 20 times larger than that in an  $\text{Al}_{75}\text{Cu}_{15}\text{V}_{10}$  amorphous alloy ( $2.4 \times 10^{17} \text{ m}^{-3} \cdot \text{s}^{-1}$ ) and  $10^7$  times larger than that in a  $\text{Pd}_{58.5}\text{U}_{20.6}\text{Si}_{20.6}$  amorphous alloy [35]. However, Zhang et al. reported that the reproducibility of the icosahedral phase formation in the  $\text{Zr}_{69.5}\text{Al}_{7.5}\text{Ni}_{11}\text{Cu}_{12}$  glassy alloy is poor [36]. Subsequently, the enhancement of an icosahedral phase formation by the existence of oxygen impurity was noticed [37–39]. In these studies, the primary phase changes drastically to the icosahedral phase in oxygen contents above 1000 mass ppm in the  $\text{Zr}_{65}\text{Al}_{7.5}\text{Cu}_{27.5}$  glassy alloy and 1600 mass ppm in the  $\text{Zr}_{65}\text{Al}_{7.5}\text{Ni}_{10}\text{Cu}_{17.5}$  glassy alloy. The further reports also indicate that the icosahedral quasicrystal formation is induced by the presence of oxygen contamination in the  $\text{Zr}_{69.5}\text{Al}_{7.5}\text{Ni}_{11}\text{Cu}_{12}$  glassy alloy [40–42].

In 1998, Xing et al. also reported the formation of an icosahedral phase in the  $\text{Zr}_{57}\text{Al}_{10}\text{Ni}_8\text{Cu}_{20}\text{Ti}_5$  glassy alloy with a low oxygen content of approximately 900 mass ppm [43]. They clarified that the transformation of the alloy changes from a single step into two- or three-stage crystallization reactions with decreasing quenching rate. The icosahedral phase formation is significant in a low quenching rate. In particular, the crystalline  $\text{Zr}_2\text{Cu}$  and  $\text{Zr}_2\text{Ni}$  phases are precipitated as main phases in the primary crystallization stage, and a small amount of quasicrystalline phase can be observed in the melt-spun ribbon of 30  $\mu\text{m}$  thickness with a high cooling rate. They supposed that the supercooled  $\text{Zr}_{57}\text{Al}_{10}\text{Ni}_8\text{Cu}_{20}\text{Ti}_5$  melt has a tendency to develop an icosahedral short-range order, which is favored at a low cooling rate. The icosahedral phase was characterized as a nanoscale

quasicrystalline (nanoquasicrystalline) particle in their further studies in 1999 [44]. In the primary crystallization stage, the icosahedral phase has a very fine grain size with a diameter of 2–10 nm in the  $\text{Zr}_{57}\text{Al}_{10}\text{Ni}_8\text{Cu}_{20}\text{Ti}_5$  glassy alloy, and the size increases significantly to 100 nm in diameter with decreasing Ti content in the  $\text{Zr}_{59}\text{Al}_{10}\text{Ni}_8\text{Cu}_{20}\text{Ti}_3$  glassy alloy. The result is recognized as the first finding of the formation of a nanoicosahedral phase; however, strong dependence of the quenching rate indicates the low stability of the icosahedral phase and difficulty of structure control, which leads to a limitation of the shape of materials.

Although these reports have led to the possibility of the nanoicosahedral phase from the glassy phase, the formation condition has not been established due to their poor reproducibility and/or low stability. Based on the systematic approaches for the study of the transformation behavior in glassy alloys, it is expected that the nanoicosahedral phase can be formed by the elimination of impurity and the addition of elements. This chapter describes the formation of a nanoicosahedral phase devitified from the Zr- and Hf-based glassy alloys by the decline of a high glass-forming ability (GFA), which describes the important investigation of the stability of the glassy state, as well as the novel nanoquasicrystal-dispersive bulk glassy alloy with unique mechanical properties.

## 2. FORMATION OF NANOICOSAHEDRAL PHASE BY ADDITION OF ELEMENTS IN Zr-BASED GLASSY ALLOYS

### 2.1. Change in Transformation Behavior

Chen, Inoue, and co-workers found in 1999 [45, 46] the reproducible formation of a nanoicosahedral quasicrystalline phase as a primary precipitation phase in  $\text{Zr}_{65}\text{Al}_{7.5}\text{Ni}_{10}\text{Cu}_{12.5}(\text{Ag}, \text{Pd}, \text{Au}, \text{and Pt})_5$  glassy alloys with an oxygen content less than 700 mass ppm. Figure 1 shows DSC curves of the as-spun  $\text{Zr}_{65}\text{Al}_{7.5}\text{Ni}_{10}\text{Cu}_{12.5}(\text{Ag}, \text{Pd}, \text{Au}, \text{and Pt})_5$  alloys. It is well known that a single-crystallization reaction is observed in the  $\text{Zr}_{65}\text{Al}_{7.5}\text{Ni}_{10}\text{Cu}_{17.5}$  glassy alloy [37, 47]. By noble metal addition, the crystallization process is clearly separated into two or more exothermic reactions, remaining with a significant glass transition. This phenomenon is similar to those in the icosahedral quasicrystal-forming  $\text{Zr}_{69.5}\text{Al}_{7.5}\text{Ni}_{11}\text{Cu}_{12}$  and  $\text{Zr}_{57}\text{Al}_{10}\text{Ni}_8\text{Cu}_{20}\text{Ti}_5$  glassy alloys. The X-ray diffraction (XRD) patterns of the  $\text{Zr}_{65}\text{Al}_{7.5}\text{Ni}_{10}\text{Cu}_{12.5}(\text{Ag}, \text{Pd}, \text{Au}, \text{and Pt})_5$  glassy alloys annealed for 180 s at temperatures just above the first exothermic peak are shown in Figure 2. Sharp diffraction peaks are observed, accompanied by a broad peak originating from the residual glassy phase. All of the diffraction peaks in the patterns are identified as an icosahedral quasicrystalline phase. The bright-field transmission electron microscopy (TEM) images [(a), (c)] and selected-area electron diffraction patterns (SADPs) [(b), (d)] of the alloys containing Pd [(a), (b)] and Pt [(c), (d)] annealed for 120 s at 773 and 753 K, respectively, are shown in Figure 3. Spherical particles with a size of approximately 40 nm for the former and 25 nm for the latter are dispersed homogeneously in the glassy matrices. The SADPs taken from a region

of 1  $\mu\text{m}$  diameter can be identified as a mixture of icosahedral and glassy phases. For further confirmation of the icosahedral phase formation, nanobeam diffraction (NBD) patterns using the beam diameter of 2.4 nm have been performed. The NBD patterns in the alloys containing Pd, Au, and Pt revealing the three kinds of quasiperiodic five-,

three-, and twofold symmetries are reported [46]. Therefore, it is realized that the nanoicosahedral phase can be formed by the addition of noble metals such as Ag, Pd, Au, or Pt in the  $Zr_{65}Al_{7.5}Ni_{10}Cu_{12.5}$  glassy alloy. A nanoicosahedral phase formation was found in the noble metal (NM) contents of 5–17.5at% in the  $Zr_{65}Al_{7.5}Ni_{10}Cu_{17.5-x}NM_x$  glassy alloys [47–49]. It has also been reported that the nanoicosahedral phase formation has a high stability, and does not depend on the quenching rate for the glassy phase [47, 50]. Lee et al. have clarified that the nanoicosahedral phase transforms into stable crystalline phases of tetragonal  $Zr_2Cu$  and hexagonal  $Zr_6NiAl_2$  through the second exothermic reaction [51, 52].

## 2.2. Formation Factor for Nanoicosahedral Phase

We can expect that the formation factor is clarified by these results, which exhibit the precipitation of the nanoicosahedral phase by the addition of Ti, Ag, Pd, Au, or Pt in Zr–Al–Ni–Cu glassy alloys. Since the noble metals have a strong chemical affinity with Zr, a weak affinity with Ni or Cu, and Ti has no chemical affinity with Zr [53], it is suggested that the addition of elements with a positive or weak mixing enthalpy with one of the constitutional elements in

the Zr–Al–Ni–Cu multicomponent glassy alloy is effective for icosahedral phase formation. In order to examine the formation factor for the icosahedral phase, the transformation of the melt-spun Zr–Al–Ni–Cu–(Nb, Ta, and V) glassy alloys has been investigated [54]. Since the Nb, Ta, and V have a weak or positive chemical affinity with Zr or Cu and a relatively strong affinity with Ni [53], the same effect as those for noble metal addition is expected. DSC curves of the melt-spun  $Zr_{65}Al_{7.5}Ni_{10}Cu_{12.5}X_5$  ( $X = Nb, Ta, \text{ and } V$ ) glassy alloys denote the two or three exothermic reactions after the glass transition for all alloys. The crystallization behavior with a two- or three-stage reaction is similar to those of  $Zr_{65}Al_{7.5}Ni_{10}Cu_{12.5}M_5$  ( $M = Ag, Pd, Au, \text{ and } Pt$ ) glassy alloys [46]. It was clarified that all of the diffraction peaks can be identified as icosahedral phase in the XRD patterns in the Nb, Ta, and V alloys in the annealed state, subject to the transformation due to the first exothermic peak. These icosahedral phases have a very fine grain size in the diameter range less than 50 nm [54]. Very recently, a nanoicosahedral phase formation in a Zr–Al–Ni–Cu–Mo glassy alloy has been found [55], where the mixing enthalpies of Mo with Cu and Ni are +19 and  $-7 \text{ kJ} \cdot \text{mol}^{-1}$ , respectively [53]. The additional elements for the nanoicosahedral phase formation in the Zr–Al–Ni–Cu glassy alloy are summarized in Table 1 [44–46, 54–60]. The table contains the atomic radii and mixing enthalpies with Zr, Al, Ni, and Cu of the additional elements. It is found that all of the additional elements have weak or positive mixing enthalpies, with at least one of the constitutional elements in a Zr–Al–Ni–Cu glassy alloy. Wanderka et al. have reported nanoicosahedral phase formation in a  $Zr_{46.8}Ti_{8.2}Cu_{7.5}Ni_{10}Be_{27.5}$  glassy alloy with a high GFA [61]. This result also satisfies the above criterion.

### 2.3. Effect of Additional Elements on Nucleation and Growth of Nanoicosahedral Phase

Figure 4 shows an Arrhenius plot between the logarithm of the grain growth rate of the primary phase and the reciprocal of the temperature for the  $Zr_{65}Al_{7.5}Ni_{10}Cu_{7.5}Ag_{10}$

and  $Zr_{65}Al_{7.5}Ni_{10}Cu_{17.5}$  glassy alloys [62]. The primary phase is a nanoicosahedral phase in the  $Zr_{65}Al_{7.5}Ni_{10}Cu_{7.5}Ag_{10}$  glassy alloy and a metastable fcc  $Zr_2Ni$  phase in the  $Zr_{65}Al_{7.5}Ni_{10}Cu_{17.5}$  glassy alloy [63]. Their grain growth rates were measured in a time range shorter than the collision among the particles, where the growth rates are found to be constant [64]. Each plot yields a linear relation whose slopes give the activation energy for a grain growth  $Q$  of  $352 \text{ kJ} \cdot \text{mol}^{-1}$  for the  $Zr_{65}Al_{7.5}Ni_{10}Cu_{7.5}Ag_{10}$  glassy alloy and  $382 \text{ kJ} \cdot \text{mol}^{-1}$  for the  $Zr_{65}Al_{7.5}Ni_{10}Cu_{17.5}$  glassy alloy, respectively, by the following equation

$$u = u_0 \exp(-Q/RT) \quad (1)$$

where  $u$  is the grain growth rate,  $u_0$  is a pre-exponential factor, and  $R$  is the gas constant. The activation energy for the growth of the icosahedral phase in the  $Zr_{65}Al_{7.5}Ni_{10}Cu_{7.5}Ag_{10}$  glass is nearly equal to that of the fcc  $Zr_2Ni$  phase in the  $Zr_{65}Al_{7.5}Ni_{10}Cu_{17.5}$  glass, suggesting a similar grain growth mode in both alloys. However, the grain growth rate of the fcc  $Zr_2Ni$  phase is approximately ten times higher than that of the icosahedral phase, which indicates that Ag is effective for the suppression of grain growth.

As shown in Figure 3, the icosahedral particles with a spherical morphology are distributed homogeneously in the Zr–Al–Ni–Cu–NM glassy alloys. Assuming homogeneous nucleation at the initial crystallization stage at temperatures above  $T_g$ , for the phase transformation with isotropic constant growth rate  $u$  and homogeneous nucleation under steady-state conditions, the volume fraction transformed  $y$  during isothermal annealing is given by [65, 66]

$$y = 1 - \exp(-\pi I_v u^3 t_a^4 / 3) \quad (2)$$

where  $t_a$  is the isothermal annealing time and  $I_v$  is the homogeneous nucleation rate. Therefore, we can calculate  $I_v$  from

$$I_v = (-3/\pi u^3 t_a^4) \ln(1 - y) \quad (3)$$

**Table 1.** Additional elements for nanoicosahedral phase formation in Zr–Al–Ni–Cu glassy alloy [44–46, 54–60].

**Figure 4.** Arrhenius plot of the logarithm of grain growth rate of the primary phases and the reciprocal of temperature for the  $Zr_{65}Al_{7.5}Ni_{10}Cu_{7.5}Ag_{10}$  and  $Zr_{65}Al_{7.5}Ni_{10}Cu_{17.5}$  glassy alloys. Reprinted with permission from [62], J. Saida et al., *Philos. Mag. Lett.* 80, 737 (2000). © 2000, Taylor & Francis Ltd.

A  $y$  value of 0.2 is used for the steady state, which is obtained from the DSC thermogram of isothermal annealing, and  $u$  is calculated at various temperatures from the Arrhenius relation shown in Figure 4 from the relation

$$\ln u = -4.23 \times 10^4 T^{-1} + 40.1 \quad (4)$$

for the growth of the icosahedral phase in the  $Zr_{65}Al_{7.5}Ni_{10}Cu_{7.5}Ag_{10}$  glass and

$$\ln u = -4.59 \times 10^4 T^{-1} + 43.7 \quad (5)$$

for the growth of the fcc  $Zr_2Ni$  phase in the  $Zr_{65}Al_{7.5}Ni_{10}Cu_{17.5}$  glass, respectively. The growth rate  $u$  of the fcc  $Zr_2Ni$  phase is  $1.1 \times 10^{-8} \text{ m} \cdot \text{s}^{-1}$ , which is approximately ten times larger than that of the icosahedral phase ( $1.3 \times 10^{-9} \text{ m} \cdot \text{s}^{-1}$ ) at  $T_x$ . The calculated nucleation rate at  $T_x$  of the nanoicosahedral phase ( $3.8 \times 10^{20} \text{ m}^{-3} \cdot \text{s}^{-1}$ ) is approximately  $10^4$  times higher than that of the fcc  $Zr_2Ni$  phase ( $2.6 \times 10^{16} \text{ m}^{-3} \cdot \text{s}^{-1}$ ). The calculated homogeneous nucleation rate is plotted against the reciprocal of annealing temperature in Figure 5. The nucleation rate of the nanoicosahedral phase increases monotonously with increasing annealing temperature up to 695 K in the  $Zr_{65}Al_{7.5}Ni_{10}Cu_{7.5}Ag_{10}$  glassy alloy. It has a maximum value of  $4.4 \times 10^{20} \text{ m}^{-3} \cdot \text{s}^{-1}$  at 695 K, and then decreases slightly with an increase of temperature. This value is approximately  $10^2$  times higher than those of  $Zr_{69.5}Al_{7.5}Ni_{11}Cu_{12}$ ,  $Pd_{58.8}U_{20.6}Si_{20.6}$ , and  $Al_{75}Cu_{15}V_{10}$  alloys, in which an icosahedral phase is transformed from an amorphous state [28, 34, 35]. The nucleation rate of the fcc  $Zr_2Ni$  phase in the  $Zr_{65}Al_{7.5}Ni_{10}Cu_{17.5}$  glassy alloy increases slightly with increasing annealing temperature, whereas the value of the nucleation rate is approximately  $10^{16} \text{ m}^{-3} \cdot \text{s}^{-1}$  over the entire temperature range. Therefore, the nucleation rate increases  $10^4$  times by the addition of 10at% Ag in the Zr–Al–Ni–Cu glassy alloy.

**Figure 5.** Calculated homogeneous nucleation rate against the reciprocal of temperature for the  $Zr_{65}Al_{7.5}Ni_{10}Cu_{7.5}Ag_{10}$  and  $Zr_{65}Al_{7.5}Ni_{10}Cu_{17.5}$  glassy alloys. Reprinted with permission from [62], J. Saida et al., *Philos. Mag. Lett.* 80, 737 (2000). © 2000, Taylor & Francis Ltd.

In order to clarify the influence of the noble metal content in the Zr–Al–Ni–Cu glassy alloys on the nucleation, it was examined in the  $Zr_{65}Al_{7.5}Ni_{10}Cu_{17.5-x}Pd_x$  ( $x = 0, 5, 10,$  and  $17.5$ ) glassy alloys [67]. The calculated homogeneous nucleation rate  $I_v$  of the primary phase at  $T_x$  in the  $Zr_{65}Al_{7.5}Ni_{10}Cu_{17.5-x}Pd_x$  ( $x = 0, 5, 10,$  and  $17.5$ ) glassy alloys is plotted in Figure 6. It is found that the  $I_v$  increases significantly to  $(2.9 \pm 0.3) \times 10^{18} \text{ m}^{-3} \cdot \text{s}^{-1}$  for the precipitation of the nanoicosahedral phase by the addition of only 5at% Pd, and increases almost linearly with increasing Pd content. The  $I_v$  increases to  $(1.1 \pm 0.3) \times 10^{20} \text{ m}^{-3} \cdot \text{s}^{-1}$  for  $x = 10$  and  $(2.9 \pm 0.3) \times 10^{22} \text{ m}^{-3} \cdot \text{s}^{-1}$  for  $x = 17.5$ . The nucleation rate of the nanoicosahedral phase at Pd=5 at% is nearly equal to that of the icosahedral phase in the  $Zr_{69.5}Al_{7.5}Ni_{11}Cu_{12}$  glassy alloy, which contains a large amount of oxygen impurity [34]. The  $I_v$  is  $(2.6 \pm 0.3) \times 10^{16} \text{ m}^{-3} \cdot \text{s}^{-1}$  for the precipitation of the fcc  $Zr_2Ni$  phase at  $x = 0$ . The significant increase of the nucleation rate by the addition of Pd seems to be attributed to the strong chemical affinity between Zr and Pd. The decrease of the grain growth rate of the primary phase with increasing Pd content has also been reported [67].

Thus, we can realize that noble metal addition is effective for the increase in the nucleation rate and the decrease in the grain growth rate. It is concluded that the noble metal plays the role of the enhancement of the precipitation of nanoicosahedral grains by the suppression of the long-range rearrangement of constitutional elements to form the ordinary crystalline phase.

#### 2.4. Precipitation Process of Nanoicosahedral Phase

The precipitation behavior of the nanoicosahedral phase from the glassy state has been investigated. The redistribution behavior of the constituent elements during the precipitation of the nanoicosahedral phase has been clarified by nanobeam energy dispersive X-ray spectroscopy (EDX) analysis in the  $Zr_{65}Al_{7.5}Ni_{10}Cu_{7.5}Pd_{10}$  glassy alloy [68]. It is reported that the Al and Pd contents remain almost

**Figure 6.** Change in homogeneous nucleation rate for the  $Zr_{65}Al_{7.5}Ni_{10}Cu_{17.5}Pd_x$  ( $x = 0, 5, 10,$  and  $17.5$ ) glassy alloys. Reprinted with permission from [67], J. Saida et al., *Mater. Trans. JIM* 41, 1505 (2000). © 2000, Japan Institute of Metals.

unchanged, but the Ni and Cu elements are rejected from the icosahedral phase to the remaining glassy phase, and the Zr element is enriched to the icosahedral phase. The necessity for the redistribution among the constituent elements is expected to cause a low growth rate. The redistribution behavior is consistent with the results that the growth rate of the nanoicosahedral phase decreases significantly with increasing Pd content, and is much lower than that for the crystalline phase [67].

The precipitation kinetics of the nanoicosahedral phase also have been analyzed in the framework of the Johnson–Mehl–Avrami (J–M–A) relation [65, 69]. When the data at the transformation ratios ( $Y$ ) ranging from 0.2 to 0.8 are used, one can see a rather good linearity in the wide temperature range in the relation between  $\ln(-\ln(1 - Y))$  and  $\ln(t_a)$ . The Avrami exponent ( $n$  value) corresponding to the slope of the linear relation is in the range of 2.5–3.6, and can be approximated as 3.0, indicating the diffusion-controlled mode with an increasing nucleation rate [70]. This result is supported by the rearrangement of constitutional elements during nanoquasicrystallization.

### 3. FORMATION OF NANOICOSAHEDRAL PHASE BY CHANGING COMPOSITION IN Zr-BASED GLASSY ALLOYS

As described in Table 1, all of the additional elements for the nanoicosahedral phase formation have positive mixing enthalpies, with at least one of the constitutional elements in a Zr–Al–Ni–Cu glassy alloy. It is interpreted that the icosahedral phase can be formed by deviating from the three component rules for a high GFA, which are described as: (1) multicomponent systems consisting of more than three elements, (2) a significant difference in atomic size ratios above about 12% among the three main constituent elements, and (3) negative heats of mixing among the three main constituent elements [71]. These results also indicate that an icosahedral phase may precipitate by slight deviation from the alloy composition with the highest GFA [72]. In the DSC curves of the melt-spun  $\text{Zr}_{65+x}\text{Al}_{7.5}\text{Ni}_{10}\text{Cu}_{17.5-x}$  ( $x = 0-9$ ) glassy alloys, the crystallization process changes from the single step in the alloys with  $x = 0-4$  into two- or three-stage exothermic reactions in the alloys above  $x = 5$ , accompanied by a significant decrease in the crystallization temperature. It is well known that an fcc  $\text{Zr}_2\text{Ni}$  phase with a large unit cell of  $a = 1.227$  nm is precipitated in the primary phase at the initial crystallization stage in the  $\text{Zr}_{65}\text{Al}_{7.5}\text{Ni}_{10}\text{Cu}_{17.5}$  glassy alloy [63]. It has been clarified that a weak diffraction peak corresponding to an icosahedral phase is observed in addition to the mixture phases of fcc  $\text{Zr}_2\text{Ni}$ ,  $\text{Zr}_2\text{Cu}$ , and  $\text{Zr}_6\text{NiAl}_2$  in the primary crystallization stage of the alloys with  $x = 1$  and 2 annealed for 120 s at  $T_x$ . Subsequently, a single icosahedral phase is formed in the alloys with  $x = 3-6$ . The intensity of the diffraction peaks corresponding to the icosahedral phase decreases significantly, and the bcc Zr phase is precipitated in the alloys with  $x > 7$ . Finally, no icosahedral phase is observed in the alloy with  $x = 9$ .

Figure 7 shows the bright-field TEM image (a) and SADP (b) of the  $\text{Zr}_{70}\text{Al}_{7.5}\text{Ni}_{10}\text{Cu}_{12.5}$  ( $x = 5$ ) alloy annealed for 60 s at 710 K. Dendritic particles with diameters of 500–2000 nm

are observed. The SADP clearly reveals the quasiperiodic five-fold symmetry, indicating the icosahedral structure. A similar result for the formation of the icosahedral phase has been reported in previous studies for the  $\text{Zr}_{69.5}\text{Al}_{7.5}\text{Ni}_{11}\text{Cu}_{12}$  alloy by Köster et al., containing an oxygen impurity over approximately 1000 mass ppm, where the icosahedral phase has a spherical morphology with a diameter of 50–200 nm [33, 34]. The difference in grain size for the icosahedral phase seems to be attributable to a difference in the number of nuclei due to the oxygen impurity [39]. The redistribution of the constituent elements in the alloy during crystallization has been examined by nanobeam EDX. The average compositions of five data points in the residual glassy phase and the icosahedral phase are  $\text{Zr}_{74.6}\text{Al}_{6.9}\text{Ni}_{8.5}\text{Cu}_{10.0}$  and  $\text{Zr}_{78.7}\text{Al}_{6.7}\text{Ni}_{5.1}\text{Cu}_{9.5}$ , respectively. These results indicate that redistribution of the constituent elements is necessary during the quasicrystallization reaction, which is one important factor for the high stability of the supercooled liquid state. However, only the Zr and Cu elements are redistributed for the icosahedral phase formation, which is in contrast to the redistribution of all constituent elements during the precipitation of the fcc  $\text{Zr}_2\text{Ni}$  phase in the  $\text{Zr}_{65}\text{Al}_{7.5}\text{Ni}_{10}\text{Cu}_{17.5}$  glassy alloy [63]. It is presumed that the difference in the redistribution behavior contributes to the difference in the GFA of these alloys.

With a slightly increasing Zr concentration in the  $\text{Zr}_{65+x}\text{Al}_{7.5}\text{Ni}_{10}\text{Cu}_{17.5-x}$  ( $x = 0-9$ ) glassy alloys, the nanoicosahedral phase is precipitated, and a single icosahedral phase is observed as the primary phase in the alloys with  $3 \leq x \leq 6$ . These results indicate that a slight deviation from a high GFA is effective for nanoicosahedral phase formation.

### 4. NANOICOSAHEDRAL PHASE IN TERNARY AND BINARY ALLOY SYSTEMS

#### 4.1. Zr–TM–NM and Zr–NM–NM Ternary Systems

The addition of noble metals in Zr–Al–Ni–Cu glassy alloys is concluded to play an important role in the formation of a nanoicosahedral phase. This is confirmed from the result that

**Figure 7.** Bright-field TEM image (a) and SADP (b) of the  $\text{Zr}_{70}\text{Al}_{7.5}\text{Ni}_{10}\text{Cu}_{12.5}$  glassy alloy annealed for 120 s at 710 K [72].

the icosahedral phase formation is recognized in Zr-based ternary alloys with high noble metal concentrations. The first report about the formation of a nanoicosahedral phase was given in the Zr–Ni–(Pd, Au, or Pt) ternary glassy alloys in 2000 [73]. The crystallization proceeds through two exothermic peaks in the  $Zr_{70}Ni_{10}M_{20}$  ( $M = Pd, Au, \text{ or } Pt$ ) glassy alloys, and the first reaction corresponds to the precipitation of a nanoicosahedral phase from the glassy state. The bright-field TEM image (a) and SADP (b) of the  $Zr_{70}Ni_{10}Pd_{20}$  alloy annealed for 120 s at 700 K are shown in Figure 8. Very fine particles in the diameter range from 5 to 20 nm are seen over the whole area. The precipitates have a nearly spherical morphology, and are homogeneously distributed. The SADP taken from a region of 1  $\mu\text{m}$  in diameter can be identified as an icosahedral single phase. A similar structure consisting of the icosahedral single phase is also obtained for the alloys containing Au, or Pt. The three kinds of NBD patterns revealing quasiperiodic five-, three-, and twofold symmetries are obtained in all of the alloys, which can be identified as the icosahedral structure. Thus, it is clarified that the icosahedral phase is formed in the  $Zr_{70}Ni_{10}(Pd, Au, \text{ or } Pt)_{20}$  alloy systems. Matsushita et al. have reported nanoicosahedral phase formation in the  $Zr_{70}(Fe, Co, \text{ or } Cu)_{10}Pd_{20}$  glassy alloys [74]. These results indicate that a high noble metal content in the Zr–TM (transition metal)-based glassy alloys is effective for the enhancement of nanoquasicrystal-forming ability.

Murty et al. reported the formation of a nanoicosahedral phase in a  $Zr_{70}Cu_{23}Pd_7$  glassy alloy [75], and subsequently, nanoicosahedral phase formation in Zr–Cu-based alloys with low noble metal content has been clarified in the  $Zr_{70}Cu_{20}(Rh \text{ or } Ir)_{10}$  glassy alloys by Li et al. [76, 77]. In their recent study, the  $Zr_{70}Cu_{27.5}Rh_{2.5}$  glassy alloy is found to transform into the nanoicosahedral phase as the primary phase [78]. These reports are interpreted as the significant effect of the noble metals on the nanoicosahedral phase-forming ability in the Zr–Cu glassy alloys. The influence of the addition of noble metals less than 2.5at% on the transformation behavior correlated with the local structure in the Zr-based glassy alloys is discussed later in this chapter. Nanoicosahedral phase formation in the Zr–NM-based ternary alloys has been reported in the  $Zr_{75}Pt_{10}Pd_{15}$  and  $Zr_{70}Au_{10}Pd_{20}$  glassy alloys [79]. It was found that the icosahedral particles in the Zr–NM-based ternary alloys have an

**Figure 8.** Bright-field TEM image (a) and SADP (b) of the  $Zr_{70}Ni_{10}Pd_{20}$  glassy alloy annealed for 120 s at 700 K. Reprinted with permission from [73], J. Saida et al., *Appl. Phys. Lett.* 76, 3558 (2000). © 2000, American Institute of Physics.

extremely fine grain size with a diameter less than 10 nm [80], which indicates the high nucleation rate of the icosahedral phase.

## 4.2. Zr–NM Binary Systems

### 4.2.1. Formation of Nanoicosahedral Phase in $Zr_{70}Pd_{30}$ Glassy and $Zr_{80}Pt_{20}$ Amorphous Alloys

The nanoicosahedral phase in the Zr–NM (NM = Pd, Pt) binary alloy systems has been reported by the authors, Saida et al., and Murty et al. [81–83]. The rapidly quenched  $Zr_{70}Pd_{30}$  and  $Zr_{80}Pt_{20}$  alloys have an amorphous structure at a Cu roll speed of 50  $\text{m} \cdot \text{s}^{-1}$  in the single-roller melt-spinning technique. The crystallization proceeds through two exothermic reactions, followed by the glass transition in the  $Zr_{70}Pd_{30}$  glassy alloy.  $T_x$ , corresponding to the onset temperature of the first exothermic peak, is 723 K. The temperature interval between the two exothermic peaks is approximately 80 K. Although the two-stage crystallization process is also observed in the  $Zr_{80}Pt_{20}$  amorphous alloy, the exothermic peaks are weaker and broader than those in the  $Zr_{70}Pd_{30}$  glassy alloy, and the glass transition disappears. The onset temperature of the first exothermic peak is 717 K, and the peak temperatures of the two exothermic reactions are 757 and 923 K, respectively. The XRD peaks of the  $Zr_{70}Pd_{30}$  and  $Zr_{80}Pt_{20}$  alloys subjected to the annealing treatment corresponding to the first exothermic reaction are identified as the icosahedral structure. Bright-field TEM images, SADPs taken from the region of 1  $\mu\text{m}$  in diameter, and NBD patterns of the  $Zr_{70}Pd_{30}$  alloy annealed for 120 s at 740 K [(a)–(e)] and the  $Zr_{80}Pt_{20}$  alloy annealed for 120 s at 840 K [(f)–(j)] are shown in Figure 9, respectively. Fine particles with diameters less than 20 nm are distributed homogeneously over the whole area in both alloys. The reflection rings in the SADP are characterized as an icosahedral structure. The NBD patterns revealing the five-, three-, and twofold symmetries are also obtained from the precipitated particles, which can be confirmed as an icosahedral structure. Since no diffraction patterns corresponding to other crystalline phases are obtained in both alloys, it is concluded that the first exothermic peak is due to the transformation from an amorphous phase to the nanoicosahedral phase.

For the evaluation of the thermal stability of the nanoicosahedral phase, the structure of the  $Zr_{70}Pd_{30}$  glassy and  $Zr_{80}Pt_{20}$  amorphous alloys subjected to annealing, corresponding to the transformation at the second exothermic peak, was examined [84]. The diffraction peaks of only the  $Zr_2Pd$  phase are recognized in the  $Zr_{70}Pd_{30}$  alloy. In the  $Zr_{80}Pt_{20}$  alloy, mixture phases of Zr, ZrPt,  $Zr_5Pt_3$ , and  $Zr_9Pt_{11}$  are identified. Neither the residual existence of an icosahedral phase nor broad peaks due to an amorphous phase is recognized in both alloys, indicating that the icosahedral phase is a metastable phase. It is therefore concluded that the transformation of the  $Zr_{70}Pd_{30}$  glassy and  $Zr_{80}Pt_{20}$  amorphous alloys can be expressed as follows:

glassy phase  $\rightarrow$  nanoicosahedral phase

$\rightarrow Zr_2Pd$  for the  $Zr_{70}Pd_{30}$  glassy alloy

**Figure 9.** Bright-field TEM images, SADPs, and NBD patterns of the  $Zr_{70}Pd_{30}$  glassy alloy annealed for 120 s at 740 K (a)–(e) and the  $Zr_{80}Pt_{20}$  amorphous alloy annealed for 120 s at 840 K (f)–(j) [81]. and

amorphous phase  $\rightarrow$  nanoicosahedral phase  
 $\rightarrow Zr + ZrPt + Zr_5Pt_3 + Zr_9Pt_{11}$   
 for the  $Zr_{80}Pt_{20}$   
 amorphous alloy [84].

#### 4.2.2. Structural Change with Quenching Rate in $Zr_{80}Pt_{20}$ Alloy

The structure of the melt-spun  $Zr_{80}Pt_{20}$  ribbons prepared by changing the Cu roll speed in the range of 50–10  $m \cdot s^{-1}$  has been reported by the authors [85]. As shown for XRD patterns in Figure 10, no sharp diffraction peaks due to a crystalline phase are contained in the sample prepared at 50  $m \cdot s^{-1}$ , while a mixture of  $ZrPt$ ,  $Zr_5Pt_3$ , and  $Zr_9Pt_{11}$  phases is formed at a roll speed of 20  $m \cdot s^{-1}$ . At a roll

**Figure 10.** XRD patterns of the melt-spun  $Zr_{80}Pt_{20}$  alloy with various roll speeds [82]. Reprinted with permission from [84], J. Saida et al., *J. Appl. Phys.* 90, 4717 (2001). © 2001, American Institute of Physics.

speed of 10  $m \cdot s^{-1}$ , sharp diffraction peaks of the hcp Zr phase appear in addition to the crystalline phases observed at 20  $m \cdot s^{-1}$ . In contrast, we have found that the icosahedral phase is formed at roll speeds of 40 and 30  $m \cdot s^{-1}$ , and no extra peaks corresponding to a crystalline phase are seen. In the bright-field TEM images of the as-spun samples prepared at roll speeds of 40 and 30  $m \cdot s^{-1}$ , very fine particles of diameters less than 10 nm are precipitated over the entire area [82]. The particles have a nearly spherical morphology, and are homogeneously distributed. The NBD patterns revealing the quasiperiodic symmetries reflected from the icosahedral structure are obtained from the precipitates.

#### 4.2.3. Redistribution Behavior During Nanoquasicrystallization in $Zr_{70}Pd_{30}$ Glassy and $Zr_{80}Pt_{20}$ Amorphous Alloys

The compositional changes during the precipitation of a nanoicosahedral phase in  $Zr_{70}Pd_{30}$  and  $Zr_{80}Pt_{20}$  alloys have been examined by nanobeam EDX with a beam diameter of approximately 5 nm [84]. In the  $Zr_{70}Pd_{30}$  alloy, an average composition of five data points in the icosahedral phase is  $Zr_{74.1}Pd_{25.9}$ , which is slightly different from that ( $Zr_{70.9}Pd_{29.1}$ ) in the residual glassy phase. It is clarified that the slight rejection of Pd (approximately 3at%) from the icosahedral phase is necessary for the precipitation and growth of the nanoicosahedral particles. Similar results were obtained by the three-dimensional atom probe (3DAP) technique [86]. In contrast, the same average composition of  $Zr_{79.5}Pt_{20.5}$  is analyzed in the icosahedral and residual amorphous phases in the  $Zr_{80}Pt_{20}$  alloy. These results indicate

the absence of significant redistribution of the constitutional elements during the transformation from an amorphous to a nanoicosahedral phase. We point out that the difference of the rearrangement behaviors during nanoquasicrystallization is correlated with the difference of the exothermic reaction in the DSC curves between the alloys. Heat of the first exothermic reaction in the  $Zr_{70}Pd_{30}$  glassy alloy is calculated to be  $1.66 \text{ kJ} \cdot \text{mol}^{-1}$ , which is considerably larger than that ( $0.99 \text{ kJ} \cdot \text{mol}^{-1}$ ) in the  $Zr_{80}Pt_{20}$  amorphous alloy. The absence of a significant rearrangement seems to be one of the factors for the low heat of quasicrystallization in the  $Zr_{80}Pt_{20}$  amorphous alloy.

#### 4.2.4. Kinetics of Transformation from Glass to Nanoicosahedral Phase in $Zr_{70}Pd_{30}$ Glassy Alloy

The transformation kinetics from the glassy phase to the nanoicosahedral phase have been examined at different temperatures below  $T_x$  of the  $Zr_{70}Pd_{30}$  glassy alloy [87]. The kinetics of the structural transition are analyzed in the framework of the J–M–A equation [65, 69]. The  $n$  value is in the range from 2.9 to 3.2 in the temperature range of 700–715 K, and can be approximated as 3.0 in the J–M–A plots of the  $Zr_{70}Pd_{30}$  glassy alloy. It was reported that the  $n$  value is about 3.0 for the precipitation of the icosahedral phase in the supercooled liquid region of the  $Zr_{65}Al_{7.5}Ni_{10}Cu_{7.5}Pd_{10}$  glassy alloy [68], in agreement with the result in the binary alloy. It is suggested that the transformation proceeds through the diffusion-controlled growth mode with increasing nucleation rate [70]. The compositional change analyzed by nanobeam EDX is consistent with the diffusion-controlled transformation mode. The extremely fine grain size of the icosahedral phase, less than 20 nm in the annealed state, is realized by the increase of the nucleation rate with a continuation of the transformation. However, the J–M–A plots are slightly curved at a late stage of the transformation, indicating a decrease of the Avrami exponent [87]. The change of the Avrami exponent with transformation implies the possibility of the existence of the quenched-in nuclei in the glassy state [19, 28].

The authors have clarified the grain growth kinetics of the nanoicosahedral phase [84]. The icosahedral phase grows almost linearly with increasing annealing time at temperatures between 700 and 715 K. The maximum grain size of the icosahedral phase is approximately 24 nm. With increasing temperature from 700 to 715 K, the growth rate increases from  $1.0 \times 10^{-10}$  to  $2.6 \times 10^{-10} \text{ m} \cdot \text{s}^{-1}$ . The growth rates have nearly the same order as those ( $7.6 \times 10^{-11}$ – $6.7 \times 10^{-10} \text{ m} \cdot \text{s}^{-1}$ ) of the nanoicosahedral phase in the  $Zr_{65}Al_{7.5}Ni_{10}Cu_{7.5}Ag_{10}$  glassy alloy [64]. The change in the growth rate with annealing temperature in the  $Zr_{70}Pd_{30}$  glassy alloy is considerably lower than that in the  $Zr_{65}Al_{7.5}Ni_{10}Cu_{7.5}Ag_{10}$  glassy alloy. These growth rates of nanoicosahedral particles are also approximately ten times smaller than that of the metastable fcc  $Zr_2Ni$  phase in the  $Zr_{65}Al_{7.5}Ni_{10}Cu_{17.5}$  glassy alloy [62]. These results indicate the significant suppression of the grain growth of the nanoicosahedral phase. It is therefore concluded that the formation of the icosahedral phase with nanometer scale is

attributed to a high nucleation rate and a low grain growth rate during the transformation.

The Arrhenius plot of the logarithm of the grain growth rate versus the reciprocal of the annealing temperature yields a linear relationship, whose slope gives an activation energy for the grain growth  $Q$  of  $270 \text{ kJ} \cdot \text{mol}^{-1}$  according to Eq. (1). The activation energy for grain growth is the same as that calculated from the incubation time of quasicrystallization [87], which is in correlation with the initial stage of nucleation. Moreover, it is much smaller than those of the metastable fcc  $Zr_2Ni$  phase in the  $Zr_{65}Al_{7.5}Ni_{10}Cu_{17.5}$  glassy ( $382 \text{ kJ} \cdot \text{mol}^{-1}$ ) and the nanoicosahedral phase in the  $Zr_{65}Al_{7.5}Ni_{10}Cu_{7.5}Ag_{10}$  glassy ( $352 \text{ kJ} \cdot \text{mol}^{-1}$ ) alloys [62], where the differences in the  $Q$  are attributed to the number of components involved in the rearrangements through the grain growth among the alloy systems [33, 88]. Meanwhile, the activation energy of  $270 \text{ kJ} \cdot \text{mol}^{-1}$  is significantly low considering the necessity of rearrangements of Zr and/or Pd [89]. We suggest that the precipitation of the icosahedral phase proceeds without large-scale atomic rearrangements, implying the existence of an icosahedral short- and/or medium-range order in the glassy state [19, 28, 90–93].

## 5. NANOICSAHEDRAL PHASE FORMATION IN GLASSY ALLOYS EXCEPT Zr-BASED SYSTEMS

After the discoveries of the formation of a nanoicosahedral phase in various Zr-based alloys, the quasicrystallization from the glassy state, except for a Zr-based alloy, has been investigated. The first report was presented by Louzguine et al. in the Hf-based glassy alloy in 2000 [94], where the Hf belongs to the same 4A column in the periodic table with Zr. They reported that the nanoicosahedral particles with a diameter of approximately 10 nm are precipitated as a primary phase in the  $Hf_{65}Al_{7.5}Ni_{10}(Pd \text{ or } Au)_{17.5}$  glassy alloy [94, 95]. Li et al. have reported that the nanoicosahedral phase is formed in the  $Hf_{65}Al_{7.5}Ni_{10}Cu_{12.5}(Pd \text{ or } Pt)_5$ ,  $Hf_{59}Al_{10}Ni_8Cu_{20}Ti_3$ ,  $Hf_{60}Ni_{15}Cu_{10}Ti_{15}$ , and  $Hf_{69.5}Al_{7.5}Ni_{11}Cu_{12}$  glassy alloys [96–100]. Recently, nanoicosahedral phase formation has also been reported in Hf–(Cu, Ni)–(Pd, Pt) ternary and Hf–Pd binary glassy alloys by Li et al. [101–107].

It is realized that these discoveries are achieved by the same approach in Zr-based glassy alloys, that is, the nanoicosahedral phase is formed in the Hf-based glassy alloys by the addition of a small amount of an element with a weak or positive chemical affinity with the constituent elements or by the slight deviation from the composition with a high GFA.

In Ti-based alloys, icosahedral phase formation was found in the as-quenched or annealed state in the Ti–Ni, T–Zr–(Ni or Fe), and Ti–Ni–Cu–Si alloys in the period 1985–1996 [11, 108–113]. However, these icosahedral phases have not been recognized as a nanoicosahedral phase due to the comparatively large grain size. Since Kim and Kelton found the formation of a nanoicosahedral phase in an amorphous matrix of the melt-spun  $Ti_{53}Zr_{27}Co_{20}$  alloy in 1996 [114], it has been reported in the multicomponent system in the as-quenched state of a Ti–Zr–(Ni)–Cu alloy [115, 116].

Recently, Wang et al. have also discovered the formation of a nanoicosahedral phase transformed from the amorphous state in the  $\text{Ti}_{60}(\text{Zr or Hf})_{15}\text{Ni}_{15}\text{Cu}_{10}$  alloy [117]. A typical structure of the nanoicosahedral phase with a diameter less than 50 nm in the  $\text{Ti}_{60}\text{Hf}_{15}\text{Ni}_{15}\text{Cu}_{10}$  amorphous alloy is shown in [117]. It is pointed out that the volume fraction of the nanoicosahedral phase can be easily controlled by changing the annealing condition, and it is expected that the nanoicosahedral phase will devitrify from Ti-based glassy alloys with a high GFA in the near future.

## 6. CORRELATION BETWEEN LOCAL STRUCTURE IN GLASSY STATE AND NANOICOSAHEDRAL PHASE FORMATION

### 6.1. Transformation of Glassy Alloys in Low Concentration of Additional Elements

The transformation behavior has been examined for Zr–Al–Ni–Cu glassy alloys with various Pd contents below 4at% to clarify the role of noble metal in the icosahedral phase formation [118]. DSC curves of the melt-spun  $\text{Zr}_{65}\text{Al}_{7.5}\text{Ni}_{10}\text{Cu}_{17.5-x}\text{Pd}_x$  ( $x = 0-4$ ) glassy alloys contain two exothermic peaks for the alloys of Pd contents more than 2at%, and the temperature gap between the two reactions increases with increasing Pd content. In the 1at% Pd alloy, the exothermic reaction has a single peak. However, the peak is broader than that of the non-Pd-containing alloy, indicating the separation of the crystallization reaction. The XRD patterns of the samples annealed for 30 s at  $T_x$ , leading to the precipitation of the primary phase, are shown in Figure 11. For Pd contents above 2at%, all of the diffraction peaks are recognized as a single icosahedral phase. In

**Figure 11.** XRD patterns of the  $\text{Zr}_{65}\text{Al}_{7.5}\text{Ni}_{10}\text{Cu}_{17.5-x}\text{Pd}_x$  ( $x = 0-4$ ) glassy alloys annealed for 30 s near  $T_x$ . Reprinted with permission from [118], J. Saida et al., *Mater. Trans. JIM* 42, 1497 (2001). © 2001, Japan Institute of Metals.

the  $\text{Zr}_{65}\text{Al}_{7.5}\text{Ni}_{10}\text{Cu}_{16.5}\text{Pd}_1$  glassy alloy, the primary phase is concluded to be a mixture of an icosahedral and fcc  $\text{Zr}_2\text{Ni}$  phases.

For further investigation on the microstructure and composition of the two metastable phases, TEM and nanobeam EDX analyses were performed. The bright-field TEM images [(a) and (c)] and SADP [(b) and (d)] of the  $\text{Zr}_{65}\text{Al}_{7.5}\text{Ni}_{10}\text{Cu}_{16.5}\text{Pd}_1$  glassy alloy annealed for 30 s at 750 K are shown in Figure 12. Two types of particles are observed in Figure 12(a) and (c). The particles in Figure 12(a) have a dendrite structure in the diameter range of 500–1000 nm in the glassy matrix. The SADP taken from the particles clearly denotes twofold icosahedral symmetry, as shown in Figure 12(b). In Figure 12(c), a precipitated particle is also observed in the glassy matrix, whose SADP shown in Figure 12(d) can be identified as the fcc  $\text{Zr}_2\text{Ni}$  phase along the  $[\bar{1}16]$  zone axis. Both precipitates are isolated from each other and homogeneously distributed in the glassy matrix. A similar structure has been obtained in the  $\text{Zr}_{65}\text{Al}_{7.5}\text{Ni}_{10}\text{Cu}_{16.5}(\text{Ag, Au, Pt, or Ta})_1$  glassy alloys [119, 120]. The average compositions of five data points analyzed by nanobeam EDX for the icosahedral, fcc  $\text{Zr}_2\text{Ni}$ , and residual glassy phases are  $\text{Zr}_{72.7}\text{Al}_{7.3}\text{Ni}_{6.9}\text{Cu}_{12.0}\text{Pd}_{1.1}$ ,  $\text{Zr}_{69.3}\text{Al}_{6.9}\text{Ni}_{11.6}\text{Cu}_{11.2}\text{Pd}_{1.0}$ , and  $\text{Zr}_{63.9}\text{Al}_{6.8}\text{Ni}_{10.1}\text{Cu}_{18.5}\text{Pd}_{0.7}$ , respectively. Considering that the icosahedral and fcc  $\text{Zr}_2\text{Ni}$  phases have a similar Pd content and the precipitates consisting of the two metastable phases are isolated from each other at the initial crystallization stage, it is implied that the local structure does not change by the addition of 1at% Pd. Therefore, we can realize that the icosahedral phase is formed without a significant local structural change by the addition of Pd into the Zr–Al–Ni–Cu glassy alloy.

A similar structure is obtained in the alloy whose composition slightly deviates from the  $\text{Zr}_{65}\text{Al}_{7.5}\text{Ni}_{10}\text{Cu}_{17.5}$

**Figure 12.** Bright-field TEM images (a), (c) and SADPs (b), (d) of the  $\text{Zr}_{65}\text{Al}_{7.5}\text{Ni}_{10}\text{Cu}_{16.5}\text{Pd}_1$  glassy alloy annealed for 30 s at 750 K. glassy alloy. Figure 13 shows the XRD pattern of the  $Zr_{66}Al_{7.5}Ni_{10}Cu_{16.5}$  glassy alloy annealed for 30 s at 735 K. As the primary phase, two phases of an icosahedral and fcc  $Zr_2Ni$  are confirmed. The bright-field TEM images [(a) and (c)] and SADPs [(b) and (d)] of the  $Zr_{66}Al_{7.5}Ni_{10}Cu_{16.5}$  glassy alloy annealed for 30 s at 735 K are shown in Figure 14. Two types of particles are precipitated in (a) and (c). The SADP taken from the particles in (a) clearly denotes the fivefold icosahedral symmetry as shown in (b), indicating the icosahedral structure. The SADP shown in (d), taken from the particle in (c), can be identified as an fcc  $Zr_2Ni$  phase along the  $[\bar{1}16]$  zone axis. Both precipitates are also isolated from each other, and are homogeneously distributed in the glassy matrix, which is regarded as the same structure as those in the 1at% noble metal-containing Zr–Al–Ni–Cu glassy alloy.

## 6.2. Local Structure in Glassy State for Nanoicosahedral Phase Formation

These results suggest that the fcc  $Zr_2Ni$  and icosahedral phases originate from the same local structure in the glassy state [121]. Figure 15(a) shows a schematic drawing of the unit cell of the fcc  $Zr_2Ni$  structure [122]. This crystalline structure, which is called a *big-cube phase*, has a large lattice parameter of 1.227 nm, and contains 64 Zr and 32 Ni atoms [123, 124]. The structure consists of an icosahedral clusters of Zr and Ni atoms [108, 109]. As an example, two icosahedral clusters around Zr and Ni are extracted from the unit cell in Figure 15(b). Considering that the fcc  $Zr_2Ni$  and icosahedral phases contain an icosahedron in the unit cell, we point out that a local icosahedral order exists in the Zr–Al–Ni–Cu glassy alloys with a small amount of noble metal addition or a slight deviation of the composition from those with a high GFA, and can grow as a nanoicosahedral quasicrystalline phase under high nucleation rates. It is presumed that the slight deviation from the composition with a high GFA is effective for the enhancement of the distortion of the icosahedron in the unit cell of an fcc  $Zr_2Ni$  structure, which is also one of the factors for the precipitation of a nanoicosahedral phase in the Zr–Al–Ni–Cu glassy alloys.

Based on the previously reported experimental data for Zr-based glassy alloys, it has been clarified that the glassy alloys can have: (1) a higher degree of dense randomly

**Figure 13.** XRD pattern of the  $Zr_{66}Al_{7.5}Ni_{10}Cu_{16.5}$  glassy alloy annealed for 30 s at 735 K.

**Figure 14.** Bright-field TEM images (a), (c) and SADPs (b), (d) of the  $Zr_{66}Al_{7.5}Ni_{10}Cu_{16.5}$  glassy alloy annealed for 30 s at 735 K.

packed atomic configurations; (2) new local atomic configurations, which are different from those of the corresponding final crystalline phases; and (3) homogeneous atomic configurations with attractive interaction on a long-range scale [125]. It is noted that the existence of a local icosahedral order satisfies the above-described criteria.

## 6.3. Direct Observation and Structure Analysis of Icosahedral Local Structure by HRTEM Observation

In order to confirm the icosahedral local structure, a high-resolution transmission electron microscopy (HRTEM) observation was performed in the nanoquasicrystal-forming glassy alloys. Figure 16 shows HRTEM images and the SADP of the as-quenched  $Zr_{65}Al_{7.5}Ni_{10}Cu_{7.5}Pd_{10}$  [(a), (b)] and  $Hf_{65}Al_{7.5}Ni_{10}Cu_{12.5}Pd_5$  [(c), (d)] glassy alloys [121]. The SADP consists of only a halo ring, indicating a glassy

**Figure 15.** Schematic illustrations of the fcc  $Zr_2Ni$  phase (a) and icosahedral local atomic configuration in the fcc  $Zr_2Ni$  phase (b) [122].

**Figure 16.** HRTEM images and SADPs of the as-quenched  $Zr_{65}Al_{7.5}Ni_{10}Cu_{7.5}Pd_{10}$  (a), (b) and  $Hf_{65}Al_{7.5}Ni_{10}Cu_{12.5}Pd_5$  (c), (d) glassy alloys. Reprinted with permission from [121], J. Saida et al., *J. Mater. Res.* 16, 3389 (2001). © 2001, Materials Research Society.

structure. It is found that the HRTEM images have some features of local regions, which are circled in Figure 16(a) and (c). The size of the encircled local regions is below 2 nm. NBD patterns revealing a halo ring are obtained from the encircled local region. The encircled local regions have a similar feature to those in the dense random packed (DRP) structure in the glassy alloy. However, the size of the region is considerably larger than that in the DRP structure, indicating the possibility of the local ordered region. Very recently, Xing et al. have reported a similar HRTEM image in the as-quenched  $Zr_{54.5}Ti_{7.5}Cu_{20}Ni_8Al_{10}$  glassy alloy [92], in which the icosahedral phase is also formed in the annealed state. They suggest that the local region is recognized as an ordered structure, which is indicative of an icosahedral short- and/or medium-range order. Moreover, a similar structure was reported in the simulation results where the icosahedral short-range order is assumed to exist in the glassy state [126]. It may be thought, therefore, that the local regions observed in the as-quenched  $Zr_{65}Al_{7.5}Ni_{10}Cu_{7.5}Pd_{10}$  and  $Hf_{65}Al_{7.5}Ni_{10}Cu_{12.5}Pd_5$  glassy alloys are realized as an icosahedral local structure. For further identification of the local region, HRTEM observation was applied for the simple system of a nanoquasicrystal-forming Zr–Pd binary alloy [127].

Figure 17 shows the HRTEM image (a) and SADP (b) taken from the 1  $\mu\text{m}$  diameter region of the  $Zr_{70}Pd_{30}$  glassy

**Figure 17.** HRTEM image (a) and SADP (b) of the as-quenched  $Zr_{70}Pd_{30}$  glassy alloy. Reprinted with permission from [127], J. Saida et al., *Appl. Phys. Lett.* 79, 412 (2001). © 2001, American Institute of Physics.

alloy. Since the SADP consists of the halo ring, and no diffraction spots can be observed, it is recognized as a glassy structure containing no obvious precipitations in the matrix. In the HRTEM images, features of the local ordered regions, which are circled in the figure, which are the same as those in the multicomponent alloys, are found. The size of the ordered regions is approximately 2 nm in diameter. No NBD patterns, except for a halo ring from the ordered region, can be obtained. The identification of the structure of the ordered regions was carried out by HRTEM observation for the  $Zr_{70}Pd_{30}$  glassy alloy annealed at low temperatures below  $T_x$ . The HRTEM image (a), the SADP taken from the 1  $\mu\text{m}$  region in diameter (b), and the NBD pattern with a beam diameter of 1 nm (c) of the  $Zr_{70}Pd_{30}$  glassy alloy annealed for 120 s at 690 K are shown in Figure 18. The SADP consists of only a halo ring, indicating that the glassy structure remains in the annealing condition. Moreover, no precipitates corresponding to a crystalline or quasicrystalline phase can be seen in the HRTEM image. The same ordered regions as that in the as-quenched sample are confirmed, as marked with a circle in Figure 17(a). The ordered region grows slightly, as is evidenced by the change in diameter

**Figure 18.** HRTEM image (a), SADP (b), and NBD pattern (c) of the  $Zr_{70}Pd_{30}$  glassy alloy annealed for 120 s at 690 K. Reprinted with permission from [127], J. Saida et al., *Appl. Phys. Lett.* 79, 412 (2001). © 2001, American Institute of Physics.

of 3–4 nm. Although the NBD pattern taken from the ordered region (marked with A in the HRTEM image) in Figure 18(c) reveals weak reflection spots due to the small area and fine electron beam, we can identify it as the five-fold symmetry originating from the icosahedral structure. These results are regarded as evidence for the existence of an icosahedral local structure in the  $Zr_{70}Pd_{30}$  glassy alloy. Recently, the icosahedral local structure in the  $Zr_{70}Pd_{30}$  glassy alloy was studied by structural analysis [122, 128, 129]. It is suggested that the icosahedral local structure in the glassy state is attributed to the high stability of the icosahedral atomic configuration during the cooling process from the melt. The stable icosahedral local structure seems to lead to the restraint of the rearrangements of constitutional elements to form a periodic crystalline phase.

The HRTEM image (a) and NBD pattern with a beam diameter of 1 nm (b) for the  $Zr_{70}Pd_{30}$  glassy alloy annealed for 120 s at 710 K are shown in Figure 19 for the investigation of the growth process of an icosahedral medium-range order. The precipitated particle with a diameter of approximately 12 nm is observed in the center of the HRTEM image. The NBD pattern taken from the precipitate clearly indicates the fivefold symmetry, which is identified as an icosahedral quasicrystalline phase. The icosahedral local structure is also detected simultaneously around the interface between the icosahedral particle and the glassy phase, as marked with circles in the image. We suggest that the nanoicosahedral quasicrystalline particle grows from the icosahedral local structure by assimilating the medium-range orders. As discussed in the redistribution behavior through nanoquasicrystallization, the average compositional difference between the icosahedral phase and the residual glassy phase is slight (approximately 3at%) in the  $Zr_{70}Pd_{30}$  glassy alloy [84, 86]. It is therefore realized that the icosahedral local structure grows easily to the icosahedral quasicrystalline phase, which is the dominant factor for the formation of a nanoicosahedral phase.

## 7. ORIGIN OF FORMATION OF ICOSAHEDRAL LOCAL STRUCTURE

### 7.1. Nanoicosahedral Phase Formation of Zr–Cu Glassy Alloys by Addition of Small Amount of NMs

In these investigations, it is concluded that the novel local structure with an icosahedral atomic configuration exists in the Zr- and Hf-based glassy alloys. The origin of the icosahedral local structure, which correlates with the stability of the supercooled liquid state, has been studied in the Zr–(Cu, Ni) alloys [130]. For this purpose, the primary precipitated phase in the  $Zr_{70}Cu_{30-x}Pd_x$  ( $x = 0, 0.5, 1,$  and 10at%) melt-spun ribbons has been investigated. A single sharp exothermic reaction is observed after the distinct glass transition in the DSC curve of the  $Zr_{70}Cu_{30}$  alloy. Although we can see no significant change in the crystallization peak by the addition of 0.5at% Pd, the exothermic reaction is clearly separated into two or three peaks by the addition of 1 and 10at% Pd, with the remainder of the glass transition. The separation of the exothermic peak in the 10at% Pd-containing alloy is more distinct than that in the 1at% Pd-containing alloy. XRD patterns of the samples annealed at temperatures near  $T_x$  are given in [130]. Very sharp diffraction peaks are observed, and all of them are identified as a tetragonal  $Zr_2Cu$  ( $a = 0.322$  nm and  $c = 1.118$  nm) phase in the  $Zr_{70}Cu_{30}$  glassy alloy. Meanwhile, it is found that the diffraction peaks, in addition to the halo peak in the  $Zr_{70}Cu_{30-x}Pd_x$  ( $x = 0.5, 1,$  and 10) alloys, are completely different from those in the  $Zr_{70}Cu_{30}$  alloy. All diffraction peaks in the Pd-containing glassy alloys can be identified as an icosahedral phase. Figure 20 shows the bright-field TEM image (a) and NBD pattern with a beam diameter of 2.4 nm (b) of the  $Zr_{70}Cu_{29}Pd_1$  glassy alloy annealed for 120 s at 620 K. Very fine particles in the diameter range less than 50 nm are precipitated in the  $Zr_{70}Cu_{29}Pd_1$  alloy, indicating a high nucleation rate. The particles have a nearly spherical morphology. The NBD pattern taken from the particle shown in (b) clearly indicates fivefold quasiperiodic symmetry, which is identified as the nanoicosahedral phase. Similar TEM images and NBD patterns are obtained in the annealed  $Zr_{70}Cu_{29.5}Pd_{0.5}$  and

**Figure 20.** Bright-field TEM image and NBD pattern of the  $Zr_{70}Cu_{29}Pd_1$  glassy alloy annealed for 120 s at 620 K. Reprinted with permission from [119], J. Saida et al., *Mater. Trans. JIM* 43, 1937 (2002). © 2002, Japan Institute of Metals.

Zr<sub>70</sub>Cu<sub>20</sub>Pd<sub>10</sub> alloys. The nanoicosahedral phase formation by the addition of 1at% Au or Pt in a Zr<sub>70</sub>Cu<sub>30</sub> alloy has also been reported [119]. These results are in good agreement with those in the Zr<sub>65</sub>Al<sub>7.5</sub>Ni<sub>10</sub>Cu<sub>16.5</sub>(Ag, Pd, Au, or Pt)<sub>1</sub> glassy alloys [119]. Thus, it is concluded that the nanoicosahedral phase is formed as a primary metastable phase by substituting Pd for only 0.5at% Cu in the Zr<sub>70</sub>Cu<sub>30</sub> glassy alloy. However, no icosahedral phase formation is observed in the Zr<sub>70</sub>Ni<sub>30</sub> alloy by the addition of Pd less than 10at% [119, 130].

## 7.2. Local Structure Analysis

In order to examine the local structure of the melt-spun Zr<sub>70</sub>Cu<sub>30</sub> and Zr<sub>70</sub>Ni<sub>30</sub> alloys, an XRD analysis was performed [130]. The interference functions  $Q_i(Q)$  for the melt-spun Zr<sub>70</sub>Cu<sub>30</sub> and Zr<sub>70</sub>Ni<sub>30</sub> alloys exhibit a difference in the higher  $Q$  value, indicating the difference of the local structure in the short and/or medium range. Radial distribution functions (RDFs) for the melt-spun Zr<sub>70</sub>Cu<sub>30</sub> (a) and Zr<sub>70</sub>Ni<sub>30</sub> (b) alloys are shown in Figure 21. It is seen that the RDFs are completely different in the first peaks. The first peak in the RDF of the Zr<sub>70</sub>Ni<sub>30</sub> alloy is clearly separated into two peaks, which correspond to the components of Zr–Zr and Zr–Ni pairs. These results suggest that the Zr–Ni pair in the Zr<sub>70</sub>Ni<sub>30</sub> alloy has a strong chemical affinity as compared with the Zr–Cu pair in the Zr<sub>70</sub>Cu<sub>30</sub> alloy. All of the structural parameters for both samples in the as-quenched state are summarized in Table 2. Data for crystallized phases are also given in the table, calculated from the results in [131]. Atomic distances and coordination numbers in the RDF fitting of the melt-spun Zr<sub>70</sub>Ni<sub>30</sub> alloy are almost the same as those in the calculated results of the tetragonal Zr<sub>2</sub>Ni phase, implying that the local structure in the Zr<sub>70</sub>Ni<sub>30</sub> amorphous alloy is similar to the tetragonal Zr<sub>2</sub>Ni structure. In contrast, the distance and coordination number of the Cu–Cu pair in the melt-spun Zr<sub>70</sub>Cu<sub>30</sub> alloy are 0.256 nm and 2.9, respectively, which are different from those (0.322 nm and 4.0) in the tetragonal Zr<sub>2</sub>Cu phase. These results indicate that the local structure in the Zr<sub>70</sub>Cu<sub>30</sub>

Figure 21. RDFs for the melt-spun Zr<sub>70</sub>Cu<sub>30</sub> (a) and Zr<sub>70</sub>Ni<sub>30</sub> (b) alloys.

glassy alloy differs from the tetragonal Zr<sub>2</sub>Cu structure. Considering that the nanoicosahedral phase is precipitated from the glassy state as a primary phase in the Zr<sub>70</sub>Cu<sub>30</sub> glassy alloy by the addition of only 0.5at% Pd, it is suggested that an icosahedral local atomic configuration exists in the glassy state. Since the coordination number around Zr in the glassy state is approximately 12, the icosahedral local atomic configuration may be formed around the Zr atom.

## 7.3. Correlation Between Stability of Glassy State and Local Structure of Zr–(Cu or Ni) Glassy Alloys

The authors have pointed out that the difference in the local structure of the melt-spun Zr<sub>70</sub>Cu<sub>30</sub> and Zr<sub>70</sub>Ni<sub>30</sub> alloys leads to the difference in the stability of the glassy state. It is well known that a high GFA is attributed to the high stability of the supercooled liquid state [132]. From the distinct glass transition prior to crystallization in the melt-spun Zr<sub>70</sub>Cu<sub>30</sub> alloy, it is suggested that the icosahedral local structure correlates with the high stability of the glassy state, and it retards the rearrangement of the constitutional elements for crystallization. The melt-spun Zr<sub>70</sub>Ni<sub>30</sub> alloy without a distinct glass transition [133] has a tetragonal Zr<sub>2</sub>Ni-like local structure by RDF analysis. However, it was reported that a glass transition is observed in the rapidly quenched Zr–Ni alloys in a wide compositional range by the addition of a small amount of Al [134], implying the introduction of a novel local structure with an icosahedral atomic configuration. Structural study of the Zr<sub>60</sub>Ni<sub>25</sub>Al<sub>15</sub> glassy alloy also reveals the change in the local structure by the addition of Al [135]. The total coordination number around Zr in the as-quenched state is estimated to be 12.5, which is different from those in the crystallized state (13.1), as well as in the melt-spun Zr<sub>70</sub>Ni<sub>30</sub> alloy (10.7). Since the coordination number of 12.5 around Zr in the Zr<sub>60</sub>Ni<sub>25</sub>Al<sub>15</sub> glassy alloy is similar to that (12.4) in the Zr<sub>70</sub>Cu<sub>30</sub> glassy alloy, it suggests the formation of an icosahedral local structure. In order to investigate the local structure and its correlation with the stability of the glassy state, the transformation behavior was examined in the Zr<sub>60</sub>Ni<sub>25-z</sub>Al<sub>15</sub> glassy alloys containing small amounts of Pd [130]. A very wide supercooled liquid region with a temperature interval of approximately 100 K between the glass transition and crystallization temperatures is observed in all of the DSC curves of the melt-spun Zr<sub>60</sub>Ni<sub>25-z</sub>Al<sub>15</sub>Pd<sub>z</sub> ( $z = 0-5$ ) glassy alloys. Although the crystallization proceeds through the single sharp exothermic peak for Pd contents less than 3at%, the peak gets slightly broader and shifts to higher temperatures with increasing Pd content. The crystallization reaction changes drastically to three peaks at Pd = 5at%. For the determination of the primary phase correlated with the local structure in the glassy state, these alloys were annealed for a short time near the crystallization temperature. XRD patterns of the samples annealed for 120 s in the temperature range of 775–795 K are presented in [130]. The hexagonal Zr<sub>6</sub>NiAl<sub>2</sub> phase ( $a = 0.792$  nm and  $c = 0.334$  nm) is formed as the main precipitation phase at the initial crystallization stage in the Zr<sub>60</sub>Ni<sub>25</sub>Al<sub>15</sub> and Zr<sub>60</sub>Ni<sub>24</sub>Al<sub>15</sub>Pd<sub>1</sub> glassy alloys. A small amount of the fcc Zr<sub>2</sub>Ni ( $a = 1.227$  nm) phase is also observed in the alloys [136]. It is found that

Note: Data for crystallized phases are also given, calculated from results in [131].

additional diffraction peaks of the icosahedral phase are obtained in the XRD pattern at a Pd content of 3at%. Finally, all of the XRD peaks of the  $Zr_{60}Ni_{20}Al_{15}Pd_5$  glassy alloy are identified as an icosahedral phase. Figure 22 shows the bright-field TEM image (a) and NBD pattern (b) of the  $Zr_{60}Ni_{20}Al_{15}Pd_5$  glassy alloy annealed for 120 s at 780 K. Fine spherical particles less than 100 nm in diameter are precipitated, where the NBD pattern is characterized as quasiperiodic fivefold symmetry. Thus, it is clarified that a nanoicosahedral phase is formed in the  $Zr_{60}Ni_{25}Al_{15}$  glassy alloy by substituting Pd for Ni. The nanoicosahedral phase is precipitated with the  $Zr_6NiAl_2$  phase of a Pd content of 3at% and as a single phase in the 5at% Pd-containing alloy. Meanwhile, nanoicosahedral phase formation was reported in the  $Zr_{70}Ni_{20}Al_{10}$  glassy alloy by the addition of only 1at% Pd substituted for Al [137]. Since the coordination number around Zr in the  $Zr_6NiAl_2$  crystalline phase is calculated to be approximately 14 [138], which does not coincide with the experimental results (12.5), it is strongly suggested that the local structure in the glassy state takes an icosahedral atomic configuration around Zr in the  $Zr_{60}Ni_{25}Al_{15}$  glassy alloy.

Comparing the transformation behaviors among the Zr–Cu, Zr–Ni, and Zr–Ni–Al alloys, the correlation between the appearance of the supercooled liquid state before crystallization and the nanoicosahedral phase formation as a primary phase is suggested. We conclude that icosahedral local structure exists in the Zr–Cu and Zr–Ni–Al glassy

alloys, and stabilizes the supercooled liquid state by retarding the atomic rearrangements for the formation of stable crystalline phases.

## 8. MECHANICAL PROPERTIES OF NANOICOSAHEDRAL PHASE DISPERSED BULK GLASSY ALLOYS

The formation of a nanoicosahedral phase from the glassy state has also brought us new composite materials consisting of the nanoicosahedral and glassy phases. The improvement of mechanical properties by dispersing the nanoicosahedral particle in the glassy matrix has been studied by Inoue et al. [68, 139]. They prepared cylindrical  $Zr_{65}Al_{7.5}Ni_{10}Cu_{12.5}Ag_5$  rods with diameters of 3, 4, and 5 mm by copper mold casting. It is confirmed that the cast glassy alloy rods exhibit the same two-stage crystallization reaction as that for the melt-spun glassy alloy ribbon. By changing the annealing condition, they controlled the volume fraction of the nanoicosahedral phase in the cast 5at% Ag alloy rod with a diameter of 3 mm. The volume fraction of the nanoicosahedral phase was calculated by the change of the heat of crystallization. Figure 23 shows the Vickers hardness ( $H_v$ ), Young's modulus ( $E$ ), tensile fracture strength ( $\sigma_f$ ), and fracture elongation including elastic elongation ( $\epsilon_f$ ) as a function of volume fraction ( $V_f$ ) of the nanoicosahedral phase for the 5at% Ag alloy rod [140]. The  $\sigma_f$  and  $\epsilon_f$  increase almost linearly with increasing  $V_f$  in the  $V_f$  range up to 45%, and then decrease in the higher  $V_f$  range, although the  $H_v$  and  $E$  values increase monotonously over the whole  $V_f$  range. It is noticed that the dispersion of the nanoicosahedral phase causes a dispersion hardening as well as a dispersion ductilization. Figure 24 shows the fracture surface of the cast 5at% Ag alloy rods in the as-cast glassy single phase [(a) and (b)] and the mixed phases with  $V_f$  of 45% [(c) and (d)] [140]. The fracture of the mixed phase alloy takes place through a maximum shear plane which is declined by about 45° to the direction of tensile load, in agreement with that for the glassy single-phase alloy. However, one can see a difference in the vein pattern on the fracture surface. That is, the mixed phase alloy has considerably smaller spacings among the veins, and a more developed vein pattern subjected to a higher degree of viscous

**Figure 22.** Bright-field TEM image (a) and NBD pattern (b) of the  $Zr_{60}Ni_{20}Al_{15}Pd_5$  glassy alloy annealed for 120 s at 780 K.

**Figure 23.** Vickers hardness ( $H_v$ ), Young's modulus ( $E$ ), tensile fracture strength ( $\sigma_f$ ), and fracture elongation including elastic elongation ( $\epsilon_f$ ) as a function of volume fraction ( $V_f$ ) of the nanoicosahedral phase for the  $Zr_{65}Al_{7.5}Ni_{10}Cu_{12.5}Ag_5$  alloy rod [140]. flow as compared with the glassy single-phase alloy. Similar improvement of the mechanical properties is also recognized for the  $Zr_{65}Al_{7.5}Ni_{10}Cu_{7.5}Pd_{10}$  alloy. In the compressive stress-strain curves of the  $Zr_{65}Al_{7.5}Ni_{10}Cu_{7.5}Pd_{10}$  alloy in as-cast glassy and annealing-induced nanoicosahedral-based states [46, 139], the Young's modulus, compressive yield strength, compressive fracture strength, and fracture elongation, including elastic elongation, are estimated to be 85 GPa, 1510 MPa, 1640 MPa, and 2.2% for the glassy alloy and 88 GPa, 1780 MPa, 1830 MPa, and 3.1%, respectively, for the nanoicosahedral-based alloy, indicating a distinct increase in strength and ductility by the dispersion of nanoicosahedral particles into the glassy phase. Figure 25 shows the fracture mode and fracture surface of the glassy single-phase [(a) and (b)] and nanoquasicrystalline phase [(c) and (d)] alloys [46, 139]. Although the shear-type fracture mode typical for the glassy single phase remains unchanged, even in the nanoquasicrystalline base alloy, the vein pattern on the fracture surface has smaller distances between the veins and larger vein diameters. Based on the experimental results, it is suggested that deformation followed by adiabatic fracture takes place in the intergranular glassy phase along the maximum shear plane [139]. Table 3 summarizes the reason for the improvement of strength and ductility by the dispersion of nanoicosahedral particles in the glassy phase [68]. In the deformation and fracture mode shown in Figure 25, the intergranular glassy phase must have good ductility. It has been reported that the good ductility of the  $Zr$ - $Al$ - $Ni$ - $Cu$  glassy alloys is independent of the sample preparation method and heat treatment, being an inherent property resulting from the atomic configurations [125]. The high interface strength between the

**Figure 24.** Fracture surface of the cast  $Zr_{65}Al_{7.5}Ni_{10}Cu_{12.5}Ag_5$  alloy rods in the as-cast glassy single phase (a), (b) and the mixed phases with  $V_f$  of 45% (c), (d) [140]. **Table 3.** Reasons for improvement of strength and ductility by dispersion of nanoicosahedral particles in glassy phase [68].

---

Mechanisms for high strength and high ductility of bulk glassy alloys containing nanoscale compound particles

---

1. Nanocrystalline particle effect
    - a. perfect crystal effect (ideal high strength)
    - b. nanoscale effect (suppression of shear deformation in glassy matrix)
    - c. low interfacial energy effect (highly dense packing at the interface)
  2. Metallic glassy phase effect
    - a. insensitivity effect to structural relaxation (large allowance to crystalline phase)
    - b. compressive residual stress effect (difference in thermal expansion coefficient)
    - c. multiaxis stress effect (increase in deformability)
    - d. localized deformation effect (work softening due to an increase in temperature)
- 

glassy matrix and nanoicosahedral particles is obtained by the highly packed interface atomic configuration resulting from the lower glassy/icosahedral interface energy as compared with the solid/solid interface energy. The existence of the high density of nanoicosahedral particles enables us to generate a multiaxis stress state in the remaining glassy phase, leading to an increase in deformability. The water-quenching treatment from the annealing temperature in the supercooled liquid region causes the introduction of a compressive residual stress field in the remaining glassy phase just near the nanoicosahedral particles because of the significant difference in the coefficients of thermal expansion. Furthermore, the localization of deformation into the remaining glassy phase gives rise to an increase in temperature in the remaining glassy phase, leading to an increase in deformability due to the heating-induced softening. The combination of the above-described five factors is presumed to result in improvements of strength and ductility for the nanoicosahedral-based glassy alloys. Similar dispersion strengthening and dispersion ductilization phenomena have also been obtained in Zr-based mixed structure alloys consisting of glass + nanoscale compound phases and glass + ceramic particles [141–154]. It is therefore concluded that the improvement of strength and ductility by the dispersed particles in the Zr-based glassy phase is independent of the structure and component of the particles.

Ishihara and Inoue have studied the superplastic deformation in the nanoicosahedral particles dispersing Zr-based bulk glassy alloys [155]. They reported that the  $Zr_{65}Al_{7.5}Ni_{10}Cu_{12.5}Ag_5$  and  $Zr_{65}Al_{7.5}Ni_{10}Cu_{12.5}Pd_5$  bulk glassy alloys exhibit an elongation of 400–450% at a strain rate of  $1 \times 10^{-3} \text{ s}^{-1}$  near  $T_g$  (673 K), which is considerably larger than that (270–340%) in the  $Zr_{65}Al_{7.5}Ni_{10}Cu_{17.5}$  bulk glassy alloy at strain rates of  $3 \times 10^{-3}$ – $5 \times 10^{-2} \text{ s}^{-1}$  in the supercooled liquid region [156]. These results show that the precipitation of the nanoicosahedral phase is effective for the enhancement of superplasticity. Thus, the application of the mechanisms for dispersion strengthening and ductilization is expected to enable the future fabrication of a new material with improved engineering properties.

## 9. CONCLUSION

The formation and properties of a nanoicosahedral phase from a glassy state are reviewed. The discoveries of the precipitation of the nanoicosahedral particles devitrified from glassy alloys lead to important investigations in the stability of the glassy state. It is clarified that the formation of a nanoicosahedral phase in Zr- and Hf-based glassy alloys is attributed to their novel local structure with an icosahedral atomic configuration. The nanoicosahedral phase precipitates from this novel icosahedral local structure by the enhancement of nucleation due to the slight deviation from the composition with a high GFA. We conclude that the icosahedral local structure originating from the Zr–Cu and Zr–Ni–Al glassy alloys stabilizes the supercooled liquid state by retarding the atomic rearrangements for the formation of stable crystalline phases. It is expected that the stability of the icosahedral local structure will be clarified compared with other local structures in terms of their simulation or energy calculation in the near future. These results will bring us the complete clarification of the factors for a high GFA and nanoicosahedral phase formation. Finally, the improvement of the mechanical strength by the dispersion of nanoicosahedral particles in a glassy matrix is expected to enable the fabrication of a new material with further improved engineering properties.

## GLOSSARY

**Glass-forming ability (GFA)** Ability to form glassy structure during cooling from melt. The empirical conditions for a high GFA have been suggested by one of the authors (Inoue).

**Local structure** Local atomic configuration with short and/or medium range in the metallic glass (glassy alloy). It is not identified as a crystalline or quasicrystalline phase due to the absence of a long-range periodic structure.

**Nanobeam electron diffraction (NBD)** Diffraction method using the electron beam a few nanometers in diameter. This method is useful for structure identification for a nanoscale crystalline or quasicrystalline phase.

**Nanoicosahedral quasicrystal** Nanoscale phase exhibiting a forbidden fivefold symmetry with a long-range order similar to the one of the crystals. The icosahedral quasicrystal was discovered in 1984 by Shechtman et al.

**Supercooled liquid state** Liquid state at the temperature below melting point. A high GFA is equivalent to a high stability of the supercooled liquid state.

## 1. INTRODUCTION

In recent molecular biology and biotechnology, cell or biomolecule separation is considered as one of the most complex and difficult tasks. New separation technologies capable of treating dilute solutions in both small and large-scale processes, even in the presence of particulate matter, are necessary for the future development of biochemistry and biotechnology at all levels. A magnetic separation technique using nanomagnetic particles, among several available bioseparation techniques, has been considered one of the most promising techniques and could be used in a wide range of applications if the technique is appropriately developed.

Conventional magnetic separation methods have been used for long time as a standard technique in a variety of laboratory and industrial applications, which include the enrichment of low grade iron ore, removal of weakly magnetic colored impurities from kaolin clay, removal of magnetic pollutants from the stack gases from several industrial processes, desulphurization of coal and removal of ferromagnetic impurities from large volumes of boiler water in both conventional and nuclear power plants. Their applications to biochemistry and biotechnology, however, have been restricted and of limited use up to the 1970s. Since then, magnetic separation, labeling, and targeting techniques have

found many useful and interesting applications in various areas of bioscience and biotechnology, which are now being used routinely in molecular biology, cell biology, and microbiology and intensive research is being performed in other areas employing the unique properties of magnetic particles.

The idea of using magnetic separation techniques in cell separation is not new, but it has enjoyed a resurgence of interest over the last decade [1–5]. This has primarily been brought about by the development of new magnetic particles with improved properties for various cell separation procedures such as cancer cell separation. Many researchers have also reported feasibility of magnetic beads for immunomagnetic cell separation [6–10], immunoassay, and drug delivery application [11–14]. The basic concept of magnetic separation technology is described in Figure 1. The most attractive aspect of the magnetic separation technique in biochemistry and biotechnology is ease of manipulation of biomolecules, which are immobilized on magnetic particles. Once target biological cells or molecules are immobilized on magnetic particles, the target biomolecules can be separated from a sample solution, flexibly manipulated in various reagents, and easily transported to a desired location by controlling magnetic fields produced from a permanent magnet or an electromagnet. Another advantage is large surface area of immobilization substrate that results in high population of target biological molecules due to large binding site and high detection signal.

In this chapter, nanomagnetism will be briefly introduced and magnetic separation techniques using nanomagnetic particles will be reviewed including recent developments in lab-on-a-chip applications.

## 2. SUPERPARAMAGNETISM IN NANOMAGNETICS

In recent years, the phenomenon of superparamagnetism in a system of small ferromagnetic particles has attracted much attention due to its relevance both in technological applications as well as in understanding the fundamental physics. Technologically, as the density of magnetic information storage devices increases, the size of the ferromagnetic region

**Figure 1.** Basic concept of magnetic separation technique.

approaches the superparamagnetic limit. From the fundamental point of view, the relaxation and switching behavior of a system of small, single domain ferromagnetic particles is not well understood, partly because of the complicated nature of the interactions among the particles [15–17].

Superparamagnetism is a well-known phenomenon and can be simply described as the lack of hysteresis in the magnetization curve. As the word describes, the superparamagnetic material reveals “super” paramagnetic property.

On the atomic scale, all bodies contain spinning electrons that move around in orbits, and these electrons also produce magnetic fields to make the material paramagnetic or diamagnetic. In most atoms the magnetic moments due to the orbital and spinning motions of the electrons cancel. If the cancellation is not complete, the material is said to be “paramagnetic.” The so-called transition elements, like manganese, are examples of paramagnetic substances. When such a substance is placed in a magnetic field, its atoms are subjected to a torque that tends to align them with the field, but thermal agitation tends to destroy the alignment. In diamagnetic materials, the elementary moments are not permanent but are induced according to the Faraday induction law. All materials are diamagnetic, but orientational polarization may predominate.

Most magnetic devices use ferromagnetic materials, such as iron, in which the magnetization can be orders of magnitude larger than that of either paramagnetic or diamagnetic substances. This large magnetization is attributed to electron spin and is associated with group phenomena in which all the elementary moments in a small region, known as a domain, are aligned. The magnetization of one domain may be oriented at random with respect to that of a neighboring domain. The large magnetizations that are characteristic of ferromagnetic materials are the result of the collective orientation of whole domains.

While paramagnetism and diamagnetism comply linearly as most dielectrics do, ferromagnetic materials are not only highly nonlinear, but their behavior also depends on their previous magnetic history which is also called hysteresis because the aligned magnetic domains may not be restored immediately after removing external magnetic fields.

Extremely fine ferromagnetic particles of single domain or smaller than a domain size, however, do not have such a hysteresis effect because there is no domain to be aligned.

The substance in this region is called a superparamagnetic particle. This concept can be understood by the Néel relaxation or the magnetic relaxation time [18–20]. The Néel time relaxation  $\tau_N$  is correlated with the material properties of the particles by the effective anisotropy constant  $K_{ef}$  and with the mean magnetic volume  $V_m$  of the particles as

$$\tau_N = \tau_0 \exp\left(\frac{K_{ef} V_m}{k_B T}\right) \quad (1)$$

where  $k_B$  is Boltzmann’s constant,  $T$  is the temperature, and  $\tau_0$  is the relaxation time at infinite temperature. For magnetite  $\tau_0$  has the order of magnitude  $10^{-9}$  s. If the volume of particle is small enough then  $\tau_N$  will be almost zero, which means ideally no magnetic hysteresis. For instance, a cobalt (Co) particle of 6.8 nm size has  $10^{-1}$  s of magnetic relaxation time at room temperature but the same particle of 9.0 nm size has  $3.2 \times 10^9$  s, which is about 100 years, of magnetic relaxation time [21].

### 3. MAGNETIC PARTICLES AND MAGNETIC SEPARATION

The basic concept in magnetic separations in biotechnologies including lab-on-a-chip systems is to selectively bind the biomaterial of interest, such as a specific cell, protein, or DNA fragments, to a magnetic particle and then separate it from its surrounding matrix using a magnetic field for manipulation or purification of biological cells/molecules. Magnetic beads of iron oxide ( $\text{Fe}_2\text{O}_3$  or  $\text{Fe}_3\text{O}_4$ ) with diameters ranging from a few nanometers to a few micrometers are typically used for such separations. These magnetic particles are called “superparamagnetic” particles, meaning that they are attracted to a magnetic field but retain no residual magnetism after the field is removed. The material, which is halfway between ferromagnetic and paramagnetic, has superparamagnetism. As the size of magnetic elements scales below the few tens of nanometer range, a superparamagnetic phase emerges in which the room temperature thermal energy overcomes the magnetostatic energy well of the element, resulting in zero hysteresis. In other words, although the element itself is a single-domain ferromagnet, the ability of an individual magnetic domain to store magnetization orientation information is lost when its dimension is below a threshold. Therefore, suspended superparamagnetic particles tagged to the biomaterial of interest can be removed from a matrix using a magnetic field, but they do not agglomerate or stay suspended in the solution after removal of the magnetic field. If the magnetic components (generally iron oxide) are small enough, they will respond to a magnetic field but are incapable of becoming independently magnetic. This is important, as it results in particles that are attracted to a magnetic field yet lose all attraction for each other in the absence of a magnetic field—allowing efficient separation and complete resuspension. Figure 2 illustrates a general structure of magnetic beads that contain superparamagnetic nanoparticles in a polymeric shell and Figure 3 illustrates magnetic separation/resuspension due to superparamagnetism of nanomagnetic particles.

**Figure 2.** General structure of superparamagnetic beads.

With few exceptions, most magnetic particles fall into three broad classes: unmodified (or naked) particles, chemically derivatized particles with general specificity ligands, and chemically derivatized particles with specific recognition groups. General specificity particles are largely produced as substrates to attach a variety of affinity ligands. Magnetic

beads are available with a variety of ligands, such as oligo-(dT), streptavidin, or protein-A, attached. Magnetic beads can also be coated with highly specific recognition groups like antibodies for very specialized applications.

According to electromagnetic field theory, the magnetization density  $\vec{M}$  is introduced to account for the effects of magnetizable materials. The most common constitutive law for  $\vec{M}$  takes the form

$$\vec{M} = \chi_m \vec{H} \quad (2)$$

where  $\chi_m$  is the magnetic susceptibility and  $\vec{H}$  is the magnetic field intensity. Equation (2) is based on the assumption that the material is both isotropic and linear, in other words, that  $\vec{M}$  is proportional to  $\vec{H}$  and in the same direction, which is reasonably true in superparamagnetic materials. Assuming  $N$  as the number of atoms in unit volume and  $\vec{m}$  as the magnetic moment,  $\vec{H}$  can be also expressed as

$$\vec{M} = N \vec{m} \quad (3)$$

The magnetic beads are assumed to be spherical and have a low density in the suspension. Interactions between the particles are not considered. For this case, the magnetic force  $\vec{F}$  has the form

$$\vec{F} = \nabla U = \nabla(\vec{m} \cdot \vec{B}) \quad (4)$$

where  $U$  is the magnetic energy. Applying basic vector calculation, Eq. (4) can be rewritten as

$$\vec{F} = \vec{B} \times (\nabla \times \vec{m}) + \vec{m} \times (\nabla \times \vec{B}) + (\vec{B} \cdot \nabla) \vec{m} + (\vec{m} \cdot \nabla) \vec{B} \quad (5)$$

Based on the assumption that there is no interaction between the particles, the first and the third terms vanish. In addition, absence of the source current at the location of  $\vec{m}$  makes the second term zero. Combining Eqs. (2) and (3) into (5), the magnetic force of attraction from the field on the particle is of the form

$$\vec{F} = (\vec{m} \cdot \nabla) \vec{B} = V \chi_m (\vec{H} \cdot \nabla) \vec{B} \quad (6)$$

where  $V$  is the volume of the particle.

Choosing the  $x$  direction along the channel, the  $x$ -directional force is

$$F_x = V \chi_m \left( H_x \frac{\partial}{\partial x} + H_y \frac{\partial}{\partial y} \right) B_x = V \chi_m \left( H_x \frac{\partial B_x}{\partial x} + H_y \frac{\partial B_x}{\partial y} \right) \quad (7)$$

From the equation, since  $V$  and  $\chi_m$  depend on the selected magnetic beads, the controllable parameters of the separation device are the strength ( $H_x$  and  $H_y$ ) and the gradient ( $\partial B_x / \partial x$  and  $\partial B_x / \partial y$ ) of the magnetic field. The field depends on the performance of the inductive component, which is limited by the allowable size and planar fabrication process. The field strength is, however, usually limited in a microstructure because it is not easy to apply a large current due to its small size, although the field gradient is easier to maximize by choosing an appropriate structure or geometry.

**Figure 3.** Illustration for magnetic separation and resuspension of superparamagnetic beads: (a) magnetic beads are attracted; (b) magnetic beads are held; (c) magnetic beads start to disperse; (d) magnetic beads are resuspended in liquid suspension.

#### 4. NANOMAGNETIC PARTICLES IN BIOMEDICAL APPLICATIONS

Magnetic separations in biology and biotechnology have diversified in recent years, leading to a bewildering array of different particles, affinity mechanisms, and processes. Applications in the nucleic acid realm include products for mRNA isolation from cells or previously purified total RNA preparations, solid-phase cDNA library construction, double-stranded and single-stranded DNA purification, solid phase DNA sequencing, and a variety of hybridization-based methodologies. Magnetic beads also are finding uses in protein purification, immunology, and the isolation of a wide range of specific mammalian cells, bacteria, viruses, sub-cellular organelles, and individual proteins. There are also products that employ nanomagnetic particles for more conventional isolation and purification methods such as affinity and ion exchange and charcoal trapping of small analytes.

A common use of superparamagnetic nanoparticles is for immunospecific cell separations [22–27]. Specific antibody and nanomagnetic particles are mixed together first to immobilize the antibody onto the surface of nanomagnetic particles. The antibody-tagged, nanomagnetic particles are then incubated with a solution containing the cells, proteins, and/or antigens of interest. The nanomagnetic particles bind to the surfaces of the desired cells, and/or proteins, and these biomolecules can then be collected in a magnetic field by collecting the nanomagnetic particles. Methods of this type have been used to isolate or remove numerous cell types, including lymphocytes (cells that control immune response), tumor cells, or specific antigens. In addition to loading microparticles with superparamagnetic nanoparticles, other examples of tagging the desired biomaterial with individual nanoparticles have been reported. An example of immunospecific cell separation is shown in Figure 4.

The other application area is mRNA isolation from cells or previously purified total RNA preparations, solid-phase cDNA library construction, double-stranded and single-stranded DNA purification, solid phase DNA sequencing, and a variety of hybridization-based methodologies [28].

Other uses of nanomagnetic particles in biotechnology include delivery of anticancer drugs to tumors [29]. The idea of drug delivery is that radioactive anticancer materials are immobilized on magnetic particles, which are injected into the body. Then, by placing a magnet to the position of tumor, the anticancer drugs will be collected on a localized area to selectively attack tumor cells as illustrated in Figure 5.

#### 5. BIOSAMPLING IN LAB-ON-A-CHIP USING NANOMAGNETIC PARTICLES

Recent achievements in MEMS (microelectromechanical systems) research make it possible to adopt the magnetic separation technology for biocell separation in microfluidic systems or lab-on-a-chip. There are many advantages using lab-on-a-chip over conventional chemical or biological laboratories. One of the important advantages lies in its low cost. Many reagents and chemicals used in biological and chemical reaction are expensive, so the prospect

**Figure 4.** An example of immunospecific cell separation.

of using very small amounts (in micro- to nanoliter range) of reagents and chemicals for an application is very appealing. Another advantage is that lab-on-a-chip requires very small amounts of reagents/chemicals, which enables rapid mixing and reaction because biochemical reaction is mainly

**Figure 5.** Magnetic carriers to deliver anticancer drugs to tumors. Reprinted courtesy of Dr. U. O. Hafeli, The Cleveland Clinic Foundation, USA.

involved in diffusion of two chemical or biological reagents and microscale fluidics reduces diffusion time as reaction probabilities increase. In practical terms, reaction products can be produced in a matter of seconds/minutes compared with laboratory scale taking hours or even days. In addition, lab-on-a-chip systems minimize harmful by-products since their volume is so small.

Complex reactions of many reagents could happen on lab-on-a-chip that has ultimate potential in DNA analysis, biochemical warfare agent detection, biological cell/molecule sorting, blood analysis, drug screening/development, combinatorial chemistry, and protein analysis.

One of the accomplishments was made for biosampling of antigen for on-chip immunoassay systems using nanomagnetic particles [30]. The limited goal was to develop a generic MEMS-based microfluidic system and to apply the fluidic system to detect biomolecules such as specific proteins and/or antigens in liquid samples. Figure 6 illustrates the schematic diagram of a generic microfluidic system for biochemical detection using a magnetic bead approach for both sampling and manipulating the target biomolecules [31]. The analytical concept is based on sandwich immunoassay and electrochemical detection [32] as illustrated in Figure 7.

Nanomagnetic particles are used as the solid phase for the capture of antibodies and as carriers of captured target antigens. A simple concept of magnetic bead-based biosampling with a microfabricated electromagnet for the application of selective biosampling is shown in Figure 8. Antibody coated nanomagnetic particles are introduced to the electromagnet and separated by applying a magnetic field. While holding the antibody-coated beads, antigens are injected into the channel. Only target antigens are immobilized and thus separated onto the magnetic bead surface due to antibody/antigen reaction. Other antigens get washed out with the flow. Since only the target antigens are collected by the magnetic beads, target antigens are also "filtered." Next, enzyme-labeled secondary antibodies are introduced and incubated with the immobilized antigens. The chamber is then rinsed to remove all unbound secondary antibodies. Substrate solution, which will react with enzyme, is injected into the channel and the electrochemical detection is performed. Finally the magnetic beads are released to the waste chamber and the bioseparator is ready for another immunoassay. The lab-on-a-chip system was microfabricated and integrated for nanomagnetic particle-based immunoassay. With the system, full immunoassays were performed following the sequence stated

**Figure 6.** A generic microfluidic system for electrochemical immunoassay-based remote biochemical sensors.

**Figure 7.** Analytical concept based on sandwich immunoassay and electrochemical detection. Reprinted with permission from [30], J.-W. Choi et al., *Lab on a Chip* 2, 27 (2002). © 2002, Royal Society of Chemistry.

for different antigen (mouse IgG) concentrations: 50, 75, 100, 250, and 500 ng/ml. Concentrations of primary antibody (antimouse IgG) coated magnetic beads and conjugated secondary antibody (rat antimouse IgG conjugated alkaline phosphatase) were  $1.02 \times 10^7$  beads/ml and 0.7  $\mu\text{g/ml}$ , respectively. Immunoreactant consumed during one immunoassay was 10  $\mu\text{l}$  and total assay time was less than 20 minutes including all incubation and detection steps.

The methodology and lab-on-a-chip system described has great potential in developing generic biomolecule detection and analysis systems by replacing antibody/antigen with appropriate bioreceptors/reagents such as DNA fragments or oligonucleotides for the application to DNA analysis and/or protein analysis.

## 6. CONCLUSION

A brief review on nanomagnetic particles in biomedical applications was given in this chapter. Nanomagnetic particles are advantageous in separation and manipulation of biomolecules such as cells, proteins, and DNA fragments by immobilizing the biomolecules on the surface of magnetic particles. In addition, nanomagnetic particles have large surface area of immobilization substrate that results in high population of target biological molecules due to large binding site. Furthermore, the magnetic separation and manipulation techniques do not cause electrical disturbance during the analysis process, which may result in damage to biomolecules or electrolyzing of sample solutions.

In regards to the nanomagnetic particles in biomedical application, further investigation on behavior of magnetic particles in terms of microfluidics and thermal energy of magnetic particles is needed. One of the main characteristics in nanomagnetic particle separation arising from physical laws is that magnetic forces on superparamagnetic particles are always attractive. That means only one directional control is possible. Although the superparamagnetic particles have relatively large thermal energy due to small size so they have Brownian motion in fluid, quick restoration of the separated magnetic particles to suspension would be required in some applications.

Another challenge will be high throughput two-dimensional magnetic separation. Accurate positioning, in two-dimensional arrays, of magnetic beads with specific biological molecules is strongly required for high throughput DNA and protein analysis. Although the technology using nanomagnetic particles can give several advantages in soaring biotechnology areas such as genomics, proteomics, or drug discovery, as yet very few articles have reported high throughput protein analysis in two-dimensional arrays due to a couple of technical difficulties—there have been heat problems in long operation times with integrated electromagnets as magnetic particle separator or inaccuracies in positioning magnetic particles with conventional rare earth magnets. Ongoing research efforts on separation and purification using nanomagnetic particles in micro- and nanoscale would overcome such difficulties for a better tool for biomedical applications.

Nevertheless, it seems an undoubted trend that magnetic separation using nanomagnetic particles in biomedical applications including lab-on-a-chip systems is becoming one of the revolutionary tools for various applications in biotechnology due to its fascinating aspects over conventional chemical or biological laboratories.

## GLOSSARY

**Complementary DNA (cDNA)** A DNA copy of an mRNA or complex sample of mRNAs, made using reverse transcriptase.

**Deoxyribonucleic acid (DNA)** A naturally occurring polymer composed of deoxy ribonucleotides. Although commonly found as a double-stranded, right-handed helix it can adopt one-, three-, and four-stranded forms having a variety of shapes.

**Diamagnetism** Phenomenon exhibited by materials like copper or bismuth that become magnetized in a magnetic field with a polarity opposite to the magnetic force; unlike iron they are slightly repelled by a magnet.

**Ferromagnetism** Phenomenon exhibited by materials like iron (nickel or cobalt) that become magnetized in a magnetic field and retain their magnetism when the field is removed.

**Immunoassay** A technique for identifying a substance by using antibodies specific to that substance to separate the substance or identify it with a marker.

**Immunomagnetic separation** A biological cell- or molecule-separation technique where magnetic microparticles are first coated with monoclonal antibody, allowed to search and bind to target cells or biomolecules, and are then selectively removed when passed through a magnetic field.

**Lab-on-a-chip** A chip-size device that performs biological and chemical laboratory functions on a microchip platform dealing with smaller amount than a few microliters. Lab-on-a-chip can be used not only to synthesize chemicals efficiently and economically but also to carry out biological and clinical analyses, to perform combinatorial chemistry, and to carry out full-scale analyses from sample introduction to chemical separation and detection, on a single, miniaturized device.

**Messenger RNA (mRNA)** Arises in the process of transcription from the DNA and includes information on the synthesis of a protein.

**Microelectromechanical systems (MEMS)** Refers to technology used to integrate various electro-mechanical functions onto integrated circuits. A typical MEMS device combines a sensor and logic to perform a monitoring function. Examples include sensing devices used to control the deployment of airbags in cars and switching devices used in optical telecommunications cables. MEMS developers will be able to exploit nanotechnologies in fabricating new integrated circuits.

**Microfluidics** The science of designing, manufacturing, and formulating devices and processes that deal with volumes of fluid on the order of nanoliters or picoliters.

**Paramagnetism** Phenomenon exhibited by materials like aluminum or platinum become magnetized in a magnetic field but it disappears when the field is removed. Attraction toward a magnetic field, stronger than diamagnetism, but still weak compared to ferromagnetism.

**Ribonucleic acid (RNA)** A naturally occurring polymer composed of ribonucleotides. Although commonly found in its single-stranded form, it can adopt two-, three-, and fourstranded forms having a variety of shapes.

**Streptavidin** A small bacterial protein that binds with high affinity to the vitamin biotin. This streptavidin-biotin combination can be used to link molecules such as radioisotopes and monoclonal antibodies together. These bound products have the property of being attracted to, and attaching to, cancer cells, rather than normal cells. The radiolabeled products are more easily removed from the body, thus decreasing their toxicity.

**Superparamagnetism** Property of a material that, when placed in a magnetic field, is magnetized to the field to an

extent proportional to the field showing lack of hysteresis in the magnetization curve, particularly for extremely fine ferromagnetic particles of single domain or smaller than a domain size.

## 1. INTRODUCTION

The biotechnology and materials science fields have developed over recent decades to allow the engineering of advanced technical devices and the industrial production of active substances for biomedical applications [1]. This review is mainly focused on emerging approaches to the use of magnetic nanocrystals in biomedicine. This novel and highly interdisciplinary field is closely associated with the interesting properties that materials containing crystallites or particles of nanometer dimensions have shown related to their extremely small size.

Nanostructures are intermediate in size between molecular and microscopic (micrometer-sized) structures. Viewed as molecules, they are so large that they provide access to realms of quantum behavior that are not otherwise accessible; viewed as materials, they are so small that they exhibit characteristics that are not observed in larger (even  $0.1 \mu\text{m}$ ) structures [2]. They combine small size, complex organizational patterns, a potential for very high packing densities and strong lateral interactions, and high ratios of surface area to volume.

For example, when we reduce the physical size of a semiconductor material so that becomes comparable to or smaller than the Bohr radius, the space in which the charge carriers move decreases, and thus additional quantum confinement is imposed on their motion. This leads to an

increase in the bandgap energy, the electron and hole kinetic energy, and the density of the charge carriers within and at the nanoparticle surface [3]. Because of this, as well as the fact that the surface-to-volume ratio greatly increases, new properties not possessed by the macroscopic semiconductor material or by the individual entity that makes the semiconductor are observed [4–9]. In a metal, as we decrease its size and confine its electronic motion, the separation between the valence and the conduction bands becomes comparable to or larger than  $k_{\text{B}}T$ , and the metal becomes a semiconductor. More confinement increases the energy separation further, and the material becomes an insulator. In the size domain at which the metal-to-insulator transition occurs, new properties are expected to be observed that are possessed neither by the metal nor by the molecules or atoms forming the metal [10–14].

Finite-size effects dominate the magnetic behavior of individual nanoparticles, increasing their relevance as the particle size decreases. Surface phenomena also dictate the magnetic behavior of nanomagnets. In general, the magnetic behavior of the particle surface differs from that corresponding to the core because of the different atomic coordination, compositional gradients, and concentration and nature of defects present in both regions. The core usually displays a spin arrangement similar to that of the bulk, whereas the surface presents a much higher magnetic disorder. Finite-sized effects along with surface effects, collective phenomena arising from interparticle interactions and unusual transport properties, cause nanomagnets to exhibit a number of outstanding physical properties such as superparamagnetism, giant magnetoresistance, quantum tunneling of the magnetization, and large coercivities [15–20].

## 2. NANOPARTICLES IN BIOMEDICINE

Nanotechnology is beginning to allow scientists, engineers, and physicians to work at the cellular and molecular levels to produce major benefits to the life sciences and health care. Real applications of nanostructured materials are still rare at the present time. However, the excellent properties of these materials, when compared with those of their bulk counterparts, foreshadow a very promising future for their use in

the field of biomedicine. Logically, we have to assume that when we deal with biomedical applications, unlike what is happening in other fields of nanotechnology, the severe but necessary regulatory laws that rule the use of many biomedical products will generate a long delay until the product is suitable for the market.

Gold nanoparticles that are functionalized with proteins have long been used in the biosciences [21]. For instance, antibody molecules adsorbed on colloidal gold (10–40 nm) are routinely used in histology, thus allowing the biospecific labeling of particular regions of tissue samples and subsequent TEM analysis. More advanced small gold clusters with a diameter of 0.8 or 1.4 nm can be used for the site-specific labeling of biological macromolecules [22–24]. These labels have a number of advantages over colloidal probes, including better resolution, stability, and uniformity. Moreover, their small size improves the penetration and more quantitative labeling of antigenic sites [1].

Gold particles are well-established carriers for the delivery of dsDNA in the so-called gene-gun technology [25]. In this method, plasmid DNA with a typical length of several thousand base pairs is adsorbed to Au or tungsten colloids with a typical size of about 500 nm to several micrometers. The DNA- or RNA-coated particles are loaded into a gun-like device in which a low-pressure helium pulse delivers the particles into virtually any target cell or tissue. An advantage of this technique is that it is not necessary to remove cells from tissue to transform them. The particles penetrate the cells and release the DNA, which is diffused into the nucleus and, for example, incorporated into the chromosomes of the organism.

Chemotherapy with small-sized nanoparticles was performed in tumor-bearing animals. Taxol incorporated into polyvinylpyrrolidone nanospheres with a diameter of 50–60 nm was assayed on a B16F10 murine melanoma transplanted subcutaneously in mice. Mice treated with repeated intravenous injections of taxol-loaded nanospheres showed a significant tumor regression and higher survival rates than mice treated with free taxol [26]. Similarly, the use in a murine tumor model (subcutaneously implanted J774A.1 macrophages) of a dextran-doxorubicin conjugate incorporated into small chitosan nanospheres (100 nm in diameter) was reported to outperform the free conjugate, especially in relation to life expectancy [27]. In both cases, a higher tumor uptake, thanks to the small size and the hydrophilicity of the carrier device, as well as the sustained release of the drug, were supposed to be the key factors in improving the efficacy of the chemotherapy [26, 27].

Nanoparticles can be used for qualitative or quantitative *in vitro* detection of tumor cells. They help the detection process by concentrating and protecting a marker from degradation, to render the analysis more sensitive. For example, streptavidin-coated fluorescent polystyrene nanospheres (Fluospheres (green fluorescence) and Trans-Fluospheres (red fluorescence)) were used in single-color flow cytometry to detect epidermal growth factor receptor (EGFR) on A431 cells (human epidermoid carcinoma cells) [28]. The results showed that the fluorescent nanospheres provided a sensitivity 25 times that of the conjugate streptavidin-fluorescein. The encapsulation of fluorescent markers resulted in objects that were brighter and

more concentrated than when simple conjugates of single dyes were used. Moreover, the fluorescent nanoparticles were used in combination with R-phycoerythrin (R-PE) (reagent for flow cytometry) in multicolor flow cytometry, enabling the concomitant detection of the CD3 and CD4 receptors on Jurkat cells (human acute T-cell leukemia cells) [28].

Another approach was the encapsulation of inorganic biomarkers, rather than fluorescent organic markers. These compounds are more photostable and are not hampered by the intrinsic fluorescence (background signal) emitted by cells and tissues, which makes them more suitable and sensitive for qualitative and, especially, quantitative detection. For example, streptavidin-coated nanoparticles containing lanthanide chelates were used in quantitative immunohistochemistry analysis with time-resolved fluorescence (TRF) imaging [29]. Both the amount of nanoparticles detected and the specific signal measured from a TRF image correlated linearly with the amount of antigen (prostate-specific antigen) used. Quantitative measurement is thus possible.

Cancer researchers have spent years working to starve tumors by blocking blood vessel growth, or angiogenesis, with mixed success [30, 31]. Recently, a study reported in the journal *Science* and led by vascular biologist David Cheresh have used lipid-based nanoparticles that target new blood vessels [32]. The nanoparticle's surface was studded with molecules that bind to  $\alpha v \beta 3$  and embedded with copies of a mutant form of the *Raf-1* gene that disrupts Raf's normal activity. In the mid-1990s, Cheresh and others found signatures specific for different types of blood vessels that they used as target "zip codes." One of these, belonging to a class of membrane proteins called integrins, is apparently always present on angiogenic, or newly growing, blood vessels but rarely on established ones ( $\alpha v \beta 3$ ) [31]. Meanwhile, various teams had become intrigued by cascades of molecular signals that seem critical to new blood vessel growth. One molecule central to several of these cascades is known as Raf. Inhibiting the *Raf-1* gene in mice prevents blood vessels from forming and halts embryonic development [31].

The researchers infused a dose of these particles into the tails of mice that had been injected earlier with malignant cells. A single treatment erased tumors 400 cubic millimeters in size—one-fortieth the size of the mouse, or the equivalent of a 2-kg tumor in an 80-kg person—in about 6 days. Most of the tumors in animals with metastases to the lungs or liver also disappeared. Examining the tumors under a microscope, the researchers saw the expected dead blood vessel cells, which self-destructed after the Raf mutant shuttled inside them.

### 3. BIOMEDICAL APPLICATIONS OF MAGNETIC NANOPARTICLES

By far the most employed material in biomedical applications is magnetite ( $\text{Fe}_3\text{O}_4$ ) or its oxidized form, maghemite ( $\gamma\text{-Fe}_2\text{O}_3$ ). Highly magnetic materials such as cobalt and nickel, toxic and susceptible to oxidation, remain of little interest [33]. Magnetite is a common magnetic iron oxide that has a cubic inverse spinel structure with oxygen forming a fcc closed packing and Fe cations occupying interstitial tetrahedral sites and octahedral sites [34]. Maghemite

(magnetite-hematite) has a structure similar to that of magnetite. It differs from magnetite in that all or most of the Fe is in the trivalent state. Cation vacancies compensate for the oxidation of Fe (II) cations [34]. Maghemite has a cubic unit cell in which each cell contains 32 O ions,  $21\frac{1}{3}$  iron (III) ions, and  $2\frac{1}{3}$  vacancies. The cations are distributed randomly over the 8 tetrahedral and 16 octahedral sites, whereas the vacancies (which are also randomly distributed) are confined to the octahedral sites. Synthetic maghemite often displays superstructure forms, which arise as a result of the cation and the vacancy ordering. The extent of vacancy ordering is related to both the crystallite size of the precursor and the amount of iron (II) in the structure [35]. All of these possible arrangements in the maghemite are partially responsible for the different magnetic behaviors manifested by maghemite nanoparticles prepared by different synthetic routes [36].

Biomedical applications require particles with magnetism that turns “active” upon application of a strong magnetic field and turns “inactive” upon removal of the field. Superparamagnetic particles fulfill this requirement, but superparamagnetism at room temperature only occurs for iron ferrites smaller than about 10–15 nm [36]. Below some critical size, each ferromagnetic nanoparticle can support only a single magnetic domain and so can be viewed as a single large spin with moment of roughly  $10^3$ – $10^5 \mu_B$ . At low temperatures, this moment points along one of the energetically favorable (easy) axes of the particle, giving the particle a nonzero magnetization on laboratory time scales. Above some temperature (the so-called blocking temperature), however, thermal fluctuations can overcome the anisotropy barrier, so the moments can rotate among different easy directions, whereupon the magnetization of each particle vanishes. These materials exhibit superparamagnetic behavior [37].

For most technological applications, magnetic nanoparticles have to be dispersed in liquids, forming the so-called ferrofluids. Ferrofluids, often described as magnetic liquids or stable magnetic colloids, were discovered by Elmore more than 60 years ago [38]. Ferrofluids have several unusual properties that depend on the applied magnetic field gradient, such as apparent density or viscosity. These suspensions have been widely used in, for example, rotary shaft sealing, oscillation damping, and position sensing [39, 40]. The term “ferrofluids” as normally found in bibliographies refers to the use of magnetic nanoparticles for biomedical applications, because on many occasions the particles have been supplied as dispersions in liquid media.

Magnetic nanoparticles useful for biomedical applications can be grouped into two main categories, depending on whether the nanoparticles have to be injected into the body (*in vivo* or *in vitro* applications). *In vivo* applications (Fig. 1) could be further grouped into two different applications: (a) therapeutic applications (mainly hyperthermia and drug targeting); (b) diagnostic applications (mainly NMR imaging). For *in vitro* applications (Fig. 2) the main use of the magnetic nanoparticles is diagnostic (mainly separation and selection, and magnetorelaxometry).

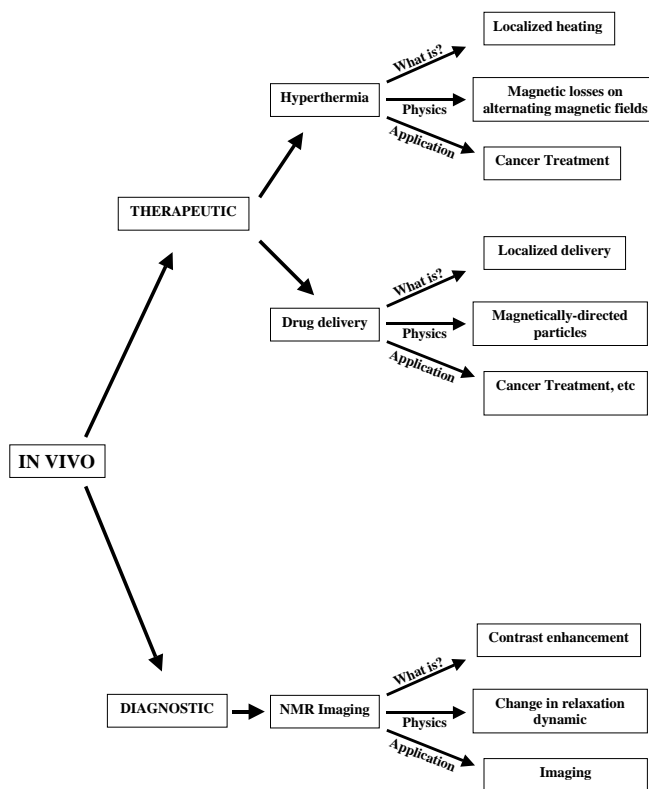

Figure 1. *In vivo* applications of nanomagnets.

### 3.1. *In vivo* Applications

#### 3.1.1. Therapeutic Applications

**Hyperthermia** More than 40 years ago, Gilchrist et al. [41] investigated localized magnetic hyperthermia with the use of fine magnetic particles. Exposed to an alternating magnetic field, these particles might act as localized heat sources at certain target regions inside the human body. The published results raised the hope of realizing a powerful method of cancer treatment within a few years. During the following decades many investigations were carried out, and *in vivo* experiments with animals in particular confirmed the general applicability to human patients. In 1981 Rand et al. [42] considered the method to be “ready for limited clinical application.”

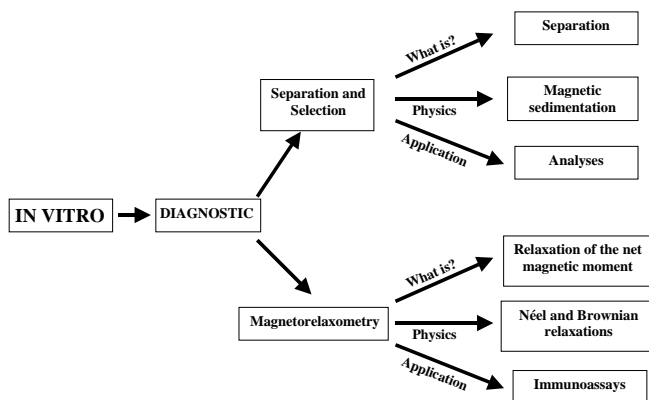

Figure 2. *In vitro* applications of nanomagnets.

Heating of certain organs or tissues to temperatures between 41 °C and 46 °C preferentially for cancer therapy is called hyperthermia [43]. The use of higher temperatures up to 56 °C, which yield widespread necrosis, coagulation, or carbonization (depending on the temperature), is called thermoablation [44, 45]. The two mechanisms act completely differently with respect to biological response and application technique. Classical hyperthermia induces almost reversible damage to cells and tissues, but it enhances radiation injury of tumor cells and chemotherapeutic efficacy. Modern clinical hyperthermia trials focus mainly on the optimization of thermal homogeneity at moderate temperatures (42–43 °C) in the target volume, a problem that requires extensive technical effort and advanced therapy and thermometry systems.

The heating of oxide magnetic materials with low electrical conductivity in an external alternating magnetic field is due to loss processes during the reorientation of the magnetization [46]. If the thermal energy  $k_B T$  is too low to facilitate reorientation, hysteresis losses dominate, which depend on the type of remagnetization process (wall displacement or several types of rotational processes). With decreasing particle size, thermal activation of reorientation processes leads, depending on temperature and measurement frequency, to superparamagnetic behavior of the particle ensemble and the occurrence of the so-called Néel losses [47]. In the case of ferrofluids losses related to the rotational Brownian motion of magnetic particles [48] may also act. Based on the Brown and Néel relaxivity, it was shown that subdomain particles (nanometer in size) absorb much more power at tolerable AC magnetic fields than is obtained by well-known hysteresis heating of multidomain (microns in size) particles [45, 49, 50].

Heating to the target temperatures causes moderate cellular inactivation in a dose-dependent manner. Although thermal dose–response curves look quite similar to radiation or drug dose–response curves, the critical target of thermal inactivation in the cell is not known yet. The most probable reason for this situation is that there is no individual cellular target of hyperthermia, in contrast to the well-known DNA damage after irradiation [51]. Most of the biomolecules, especially regulatory proteins involved in cell growth and differentiation and the expression of certain receptor molecules (involved in signal transduction pathways), are therefore largely influenced by hyperthermia.

Today, many cellular effects are known to be important for thermal inactivation. New insights from molecular biology have shown that a few minutes after hyperthermia, a special class of proteins is expressed in the cell, the so-called heat shock proteins. They protect the cell from further heating or subsequent thermal treatments and lead to an increase of cell survival after preheating, an effect called thermotolerance [52]. Additionally, the activity of certain regulatory proteins, kinases, or cyclins is influenced by hyperthermia, causes alterations in the cell cycle, and can even induce apoptosis, cell death driven by the cell regulatory system itself [53, 54]. Current research is also trying to characterize the interactions of thermal tolerance and multidrug resistance. The combined effect of radiation and hyperthermia takes place at the cellular level and is mainly due to the heat-induced malfunction of repair processes

after radiation-induced DNA damage. They are less effective when heat is given either before or after irradiation, and a well-defined time interval has been described for the two modalities [55]. Further effects were observed on the tissue level, such as changes in microvasculature, blood flow, energy, and oxygen status. Interestingly, heat-treated cancer cells may be better recognized by the host immune system because of alterations of some cell surface receptor molecules, which are then recognized by natural killer cells and inactivate the cancer cells, as has recently been demonstrated *in vitro* [56]. The joint action of all of the molecular mechanisms involved in hyperthermia is still under investigation.

**Magnetic Drug Targeting (Drug Delivery)** Since the pioneering concept proposed by Freeman et al. in 1960 [57] that fine iron particles could be transported through the vascular system and concentrated at a particular point in the body with the aid of magnetic fields, the use of magnetic particles for the delivery of drugs or antibodies to the organs or tissues altered by diseases has become a very attractive field of research [58].

The use of magnetic targeted carriers for drug delivery is intended to target drug to specific sites through the selective application of a magnetic field and to achieve prolonged release of high, localized concentrations of drug by retention of the carriers in the region of interest [59]. The process of drug localization with magnetic delivery systems is based on the competition between forces exerted on the particles by the blood compartment and magnetic forces generated by an applied magnet. When the magnetic forces exceed the linear blood flow rates in arteries ( $10 \text{ cm} \cdot \text{s}^{-1}$ ) or capillaries ( $0.05 \text{ cm} \cdot \text{s}^{-1}$ ), the magnetic particles are retained at the target site and may be internalized by the endothelial cells of the target tissue [58]. Drug delivery, of course, can be significantly improved with the use of drugs with functional groups that are able to specifically recognize the target.

The use of magnetic carriers for drug delivery of chemotherapeutic agents has evolved since the 1970s, when Widder et al. [60] developed albumin microspheres encasing the chemotherapeutic agent adriamycin and used magnetite as the magnetically susceptible component. In their research, Widder and his associates first demonstrated in animals the potential therapeutic benefit of magnetically directing microspheres, containing adsorbed drugs, into the capillary beds of tumors. Further development was not pursued because of the inadequate magnetic susceptibility of microspheres, which restricted the application of the technology to surface tumors. In the mid-1990s, Devineni et al. [61] compared the tissue distribution of methotrexate following intraarterial administration as a solution or as a magnetic microsphere conjugate to the brain. The authors concluded that once the magnetic field is turned off, the microsphere conjugates exit the brain and redistribute to other systemic organs, particularly lung. More recently, Lübke et al. used magnetic nanoparticles combined with epirubicin in preclinical and early clinical work [62].

The treatment of solid tumors with chemotherapy has been limited by systemic toxicity, resulting in suboptimal dosing, and by several other mechanisms (e.g., multiple drug resistance of the tumor cells, tumor architecture limiting

access of the drug to the tumor cells, volume of distribution for the drug), resulting in limited efficacy [59]. Regional therapy achieved through targeted drug delivery could improve efficacy by increasing the drug concentration at the tumor while limiting systemic drug concentrations. Higher drug concentrations at the tumor may be able to overcome the multiple drug-resistant phenotypes by overcoming the P-glycoprotein pump, which functions to pump drug out of cells. Magnetic particles carrying drugs may also achieve wide dispersion throughout the tumor through the action of the magnetic force on the particles. Regional drug delivery, however, will not be effective at treating distant sites of tumor metastases unless the drug is targeted to each known site. If systemic concentrations of drug remain low after regional delivery, it may be possible to systemically administer chemotherapy coincident with regional therapy to optimize efficacy.

The use of magnetic nanoparticles for drug delivery is not limited to cancer therapy. Another application is in the treatment of diseases of hollow organs (heart, stomach, intestine, vesicle, etc.) or joint disease (intraarticular injection in the case of rheumatism or osteoarthritis) [58].

### 3.1.2. Diagnostic Applications

**Nuclear Magnetic Resonance Imaging** The nucleus of an atom is built up of a number of protons and neutrons. Because the atomic particles are grouped in pairs that rotate in different directions, atoms with an even number of protons and neutrons display no external rotation. Nuclei in  $^1\text{H}$ ,  $^{19}\text{F}$ , or  $^{31}\text{P}$  display a weak external rotation or spin. Such nuclei also display a vibration effect or precession. Every object that can be made to vibrate will do so more strongly under the influence of a force applied at the same frequency as the natural resonant frequency of the object. A similar resonance effect occurs when atomic nuclei are subjected to electromagnetic waves at their own vibration frequency.

Among the substances in the human body that are important for nuclear magnetic resonance (NMR) image construction,  $^1\text{H}$ ,  $^{31}\text{P}$ , and  $^{23}\text{Na}$ , the first one ( $^1\text{H}$ ) gives by far the strongest signal, since it is present in almost all tissues and organs. When nuclei of elements with a weak external spin are placed in a strong homogeneous magnetic field, they align themselves with the direction of the field. When a force is applied to spinning atomic nuclei by a radio frequency (RF) at the so-called Larmor frequency, perpendicular to the direction of the magnetic field, the nuclei are tilted away from the aligned equilibrium direction and will perform a precession around the direction of the magnetic field. During this displacement from the equilibrium orientation the nuclei absorb energy. As soon as the RF or excitation is removed, the nuclei will reorient in the direction of the homogeneous field. The time constant describing the return movement of a group of nuclei to the field direction, or longitudinal direction, is known as the longitudinal or spin-lattice relaxation time,  $T_1$ . Since the local magnetic field strength is not homogeneous because of the presence of neighboring atoms, the nuclei precess at slightly different frequencies. As a result, the various nuclei fall out of phase with each other so that, although still rotating, they rapidly adopt different orientations in space; the resonance signals

emitted from the nuclei interfere with each other, resulting in a rapid decay of the received signal. The time constant describing this process is known as the spin-spin relaxation time or transverse relaxation time,  $T_2$ .  $T_1$  and  $T_2$  are dependent on temperature, magnetic field strength, and the chemical compound in which the atom is bound. In liquids, nuclei are relatively free, so that  $T_2$  is almost as long as  $T_1$ . In solids, the interaction between nuclei is much greater, so  $T_2$  is much shorter than  $T_1$ .

NMR imaging is essentially a form of emission tomography; the data required for the production of the image are generated from the electromagnetic signal originating within the body itself. The basis for this signal is, of course, the presence of protons; so the more protons there are in a particular volume, the larger the signal is. However, although proton density is important, it is the variation of signal strength due to the influence of relaxation times ( $T_1$  and  $T_2$ ) that makes proton imaging so flexible and attractive as a diagnostic imaging.

In the last decade the spatially resolved NMR, so-called NMR tomography, has become an important method in the field of biomedical and biophysical research [63]. The development of the NMR imaging technique as a clinical diagnostic modality has prompted the need for a new class of pharmaceuticals (magnetopharmaceuticals). These drugs must be administered to a patient to (1) enhance the image contrast between normal and diseased tissue and/or (2) indicate the status of organ functions or blood flow [64]. A number of different agents have been suggested as potential NMR contrast agents. Most contrast agents used in NMR imaging studies to date have been paramagnetic [65]. Superparamagnetic particles represent an alternative class of NMR contrast agents that are usually referred to as  $T_2$  or  $T_2^*$  contrast agents, as opposed to  $T_1$  agents such as paramagnetic chelates. Because of their large permanent dipole moments these agents are able to relax neighboring nuclei faster than paramagnetic ions. The contrast agents are useful in cases where differences between the  $T_1$  and  $T_2$  values of neighboring tissues are so small that they cannot be distinguished from the variations in these parameters.

The relaxation rate increase produced by magnetic particles is a contribution of several complex mechanisms. The size and the composition of these particles represent the essential parameters. The particles possess very large magnetic moments in the presence of a static magnetic field, and dipolar interactions between the superparamagnetic cores and surrounding solvent protons result in increases in both longitudinal and transverse relaxation rates, especially for small size domain particles (below 10 nm) [66–68].

Superparamagnetic particles have been used as contrast agents in NMR imaging for location and diagnosis of brain and cardiac infarcts, liver lesions, or tumors, where the magnetic nanoparticles tend to accumulate at higher levels because of the differences in tissue composition and/or endocytotic uptake processes [69]. Especially promising results have been detected in the improvement of the sensitivity of detection and delineation of pathological structures, such as primary and metastatic brain tumors, inflammation, and ischemia [70]. One of the potential applications of magnetic nanoparticles is to enhance the sensitivity to image

tissue microcirculation with the goal of direct quantitative measurement of blood flow and blood volume [71].

Lumirem (silica-coated iron oxide particles with a diameter of 300 nm) and Endorem (magnetite nanoparticles 150 nm in diameter, coated with dextran) are commercial names of superparamagnetic iron oxides (SPIOs) available on the market [72]. These nanoparticulate contrast agents are used, respectively, for gastrointestinal tract imaging and for liver and spleen disease detection. In the case of Endorem, the massive uptake of nanoparticles by Kupffer cells has led to an increase in the contrast between healthy and diseased tissue, like tumors or metastases, devoid of Kupffer cells [72].

Sinerem (magnetite nanoparticles 30 nm in diameter, coated with dextran) is an example of USPIO (ultrasmall superparamagnetic iron oxide) on the market [72]. Because of their long-circulating properties, USPIOs can be used for blood pool and tumor imaging (experimental imaging), based upon the detection and characterization of the lesions by their vascular appearance.

Sinerem has been used for lymphography of hyperplastic or metastatic (metastasis of a nickel-induced rhabdomyosarcoma) lymph nodes in rats, after intravenous administration [73]. Another USPIO device consisting of monocrystalline iron oxide nanoparticles (MION-46, a nanoparticulate contrast agent designed specially for lymphography, coated by an extended dextran layer, with a hydrodynamic diameter of 20 nm) was also tested in rats and rabbits to detect lymph node metastases (metastasis of VX2 carcinoma) and tumor-associated lymph node hyperplasia, by different administration routes (subcutaneous, intravenous, and intraarterial). [74] In both assays, hyperplastic lymph nodes showed NMR images consistent with active uptake and clustering of the nanoparticles inside the macrophages of lymphatic sinuses [74, 75]. The differentiation of malignant and normal lymph nodes was sometimes hindered by the following two problems: first, Sinerem nanoparticles showed a slight tumor accumulation, due to diffusive extravasation across the tumoral hyperpermeable vasculature [75]. This effect was so pronounced that in some extreme cases, the tumors could not be differentiated from the healthy lymphatics, as they both take up (even though by different mechanisms) the contrast agent. Second, when the MION-46 formulation was used, there was a lack of contrast agent accumulation in marginal follicles of normal lymph nodes, which, on occasion, rendered them indistinguishable from nodes with micrometastases [74]. Despite these two problems, which should be kept in mind during diagnosis, USPIOs appear to be very efficient tools for NMR imaging.

## 3.2. *In vitro* Applications

### 3.2.1. Diagnostic Applications

**Separation and Selection** Analysis of biologically active compounds or xenobiotics often requires preconcentration of the substance from large volumes of solutions and/or suspensions. This process is often accompanied by partial purification of the substance to be analyzed [76]. Sample preparation is often the most time-consuming step in chemical analysis, accounting on average for 61% of the time

typically required to perform analytical tasks [77]. Sample preparation is also a source of much imprecision and inaccuracy of the overall analysis [78].

At present, considerable attention is being paid to solid-phase extraction (SPE) as a way to isolate and preconcentrate desired components from a sample matrix. SPE offers an excellent alternative to conventional sample preparation methods, such as liquid-liquid extraction (LLE) [78]. The separation and preconcentration of the substance to be analyzed from large volumes of solution can take a lot of time by standard column SPE, and it is in this field that the method using magnetic or magnetizable adsorbents, called magnetic solid-phase extraction (MSPE), gains importance. In this procedure a magnetic adsorbent is added to a solution or suspension containing the target. This is adsorbed to the magnetic adsorbent, and then the adsorbent with the adsorbed target is recovered from the suspension with an appropriate magnetic separator [76].

In protein purification the protein can be precipitated via cross-linked antibodies to a suitable magnetic bead [79, 80] or other particle, which can then be detached from the protein-linked magnetic particle complex by, for instance, changing the pH of the medium [81]. Magnetic nanoparticles coated with dextran are also used for the fractionation of biomolecule (enzyme) systems, for analytical as well as for large-scale purification. These materials increase the kinetics of the process by a factor ranging from 35 to more than 70 [82]. In microbiology, several reports have described the use of magnetic nanocrystals for the separation and accumulation of bacterial and cell suspension of *Mycobacterium tuberculosis* [83], the identification of which in diagnostic specimens (sputum, urine) is the most reliable evidence of the active tuberculosis process.

Effective cell separation is a primary and most important step in many clinical and immunological applications [84, 85]. One of these applications is the separation of red blood cells (RBCs) from whole blood for photopheresis treatment of white cells. In the photopheresis treatment of white blood cells, light is used to activate a compound that binds to the DNA and may cause an increase in immunogeneity and thus stimulate the patient's own immune system [86]. Haik et al. [87] developed a magnetic separation device to isolate the RBCs from whole blood while the photopheresis treatment is administered to the patient's leukocytes.

Most of the tumor diseases and mortality of tumor patients are caused by epithelial tumors. The highest risk for patients is the spread of disseminated tumor cells after resection of the solid tumor [88]. Therefore, it is important to detect these disseminated cells. In the case of a minimal residual tumor disease the determination of the number of circulating tumor cells is of great importance. This and the possibility of characterizing these isolated cells would be an important step in the development of an optimized individual therapy. Conventional histopathological methods are not sensitive enough to detect the small number of circulating tumor cells in peripheral blood [89]. This is a reason why in the last few years cell isolation systems based on magnetic nanocrystals encapsulated in microspheres (e.g., Dynal A.S.) have become increasingly important for research and diagnostics [88].

**Magnetorelaxometry** Recently, magnetorelaxometry was introduced as a method for the evaluation of immunoassays [90]. Magnetorelaxometry measures the magnetic viscosity, that is, the relaxation of the net magnetic moment of a system of magnetic nanoparticles after the removal of a magnetic field [91]. There are two different relaxation mechanisms. First, the internal magnetization vector of a nanoparticle relaxes in the direction of the easy axis inside the core; this is called Néel relaxation [92]. The time constant of this process is

$$\tau_{\text{Néel}} = \tau_0 \exp(KV_{\text{core}}/k_B T)$$

where  $\tau_0$  is usually approximated as  $10^{-9}$  s. The Néel relaxation time depends exponentially on the energy barrier yielded by the product of the core volume  $V_{\text{core}}$  and the magnetic anisotropy constant  $K$ . In real systems of magnetic nanoparticles, the common distribution of the core volume and anisotropy constant leads, by the Néel mechanism, to a modified logarithmic decrease in magnetization as a function of time [93].

Second, particles accomplish rotational diffusion in a carrier liquid, called Brownian relaxation [94]. The corresponding relaxation time is often calculated according to [95]

$$\tau_{\text{Brown}} = 4\pi r^3 \eta / k_B T$$

assuming noninteracting spherical particles with a hydrodynamic radius  $r$ , where  $\eta$  is the dynamic viscosity of the carrier liquid. For an ideal system of monodispersed particles, the time dependence of the Brownian relaxation is a single-exponential decay. For polydisperse nanoparticles with different particle sizes it can be described as a superposition of exponential decays. This relaxation signal still looks like an exponential decay. Therefore, Néel and Brownian relaxation can be distinguished by their different time dependences [96]. Furthermore, Brownian relaxation can take place only in liquids, whereas Néel relaxation does not depend on the state of the nanoparticles.

The fact that magnetorelaxometry depends on the core size, the hydrodynamic size, and the anisotropy allows this technique to distinguish between free and bound conjugates by their different magnetic behaviors and therefore can be used as an analytical tool for the evaluation of immunoassays [91].

## 4. NANOMAGNET PRODUCTION

Biomedical applications impose strict requirements on the particles' physical, chemical, and pharmacological properties, including chemical composition, granulometric uniformity, crystal structure, stability of magnetic properties, surface structure, adsorption properties, solubility, and low own toxicity [97–103]. For example, for magnetic drug targeting to be safe and effective (with the least amount of magnetic particles a maximum of drug should be easily administered and transported to the site of choice), the following parameters of the nanomagnets are critical: (a) particle size (small as possible to improve tissular diffusion, with long sedimentation times and high effective surface areas), (b) surface characteristics (easy encapsulation of the

magnetic nanoparticles protects them from degradation and endows them with biocompatibility), and (c) good magnetic response (possibility of decreasing the nanomagnet concentration in the blood and therefore diminishing the associated side effects). On the other hand, magnetically active particles applicable in separation processes (*in vitro* applications) should be stable units composed of a high concentration of superparamagnetic nanoparticles, with each of the larger entities monodisperse in size and uniform in magnetic particle concentration.

The major difficulty in the synthesis of ultrafine particles is to control the particle size at the nanometric scale. This difficulty arises as a result of the high surface energy in these ultradivided systems. The interfacial tension acts as the driving force for spontaneously reducing the surface area by growth during the initial steps of the precipitation (nucleation and growth) and during aging (Ostwald ripening) [104, 105]. Therefore, the search for facile and flexible synthetic routes able to produce magnetic nanoparticles with the desired size and acceptable size distribution without particle aggregation is of extreme importance to realizing the full potential of these materials in biomedicine.

### 4.1. Synthetic Routes for the Production of Nanomagnets

#### 4.1.1. Coprecipitation

By far the method most employed for the synthesis of magnetic nanoparticles is the Massart method [106, 107]. It essentially consists of the coprecipitation of deaerated aqueous solutions containing iron (II) and iron (III) cations by the addition of a base. Changing the amount or nature of either the iron salt or the base added leads to solids containing magnetic nanoparticles of different sizes and degrees of polydispersity [108].

Modifications of this method are mainly in the direction of the synthesis in the presence of dextran or any other substance that renders the magnetic nanoparticles biocompatible [109]. For example, nanoparticulate magnetic particles are obtained by transferring an acidic iron (II)/iron (III) salt solution into iron (II,III) carbonate by adding equivalent amounts of alkaline carbonate, followed by thermal oxidation to iron (II,III) hydroxide [110]. The size of the particles can be controlled by the thermal reaction velocity and concentration of the iron salts. Thus, small diameters of 20–100 nm can be reached by timely separated building of iron (II,III) carbonate at temperatures of 5–10 °C and subsequent heating. After surplus salts have been removed, the particles can be stabilized with water-soluble polysaccharide or synthetic polymer derivatives. Nanoparticles coated with a starch derivative have a molecular mass of 10 kDa. As a result of the starch matrix, the magnetic particles can retain their dispersion stability in the pH range of 3–12 and in high salt concentrations [111].

#### 4.1.2. Microemulsions

Organized surfactant assemblies such as microemulsions, micelles, hexagonal phases, cubic phases, monolayers, and vesicles are unique reaction media. Indeed, they can solubilize, concentrate, localize, and even organize the reactants. Many naturally occurring biological reactions such as

photosynthesis [112] take place in organized media, and the self-organization obtained with surfactants in solution has opened a systematic exploration of their use to control chemical reactions [113]. Among all of these methods, water-in-oil microemulsions (also called reverse micelles) have recently been shown to be an adequate and simple method of preparing nanosized particles [114–119].

A microemulsion may be defined as a thermodynamically stable isotropic dispersion of two immiscible liquids consisting of nanosized domains of one or both liquids in the other, stabilized by an interfacial film of surface active molecules [115]. Microemulsions may be classified as water-in-oil (w/o) or oil-in-water (o/w), depending on the dispersed and continuous phases. The surfactant-stabilized microcavities (typically in the range of 10 nm) provide a confinement effect that limits particle nucleation, growth, and agglomeration [120].

In w/o microemulsions, the aqueous droplets continuously collide, coalesce, and break apart, resulting in a continuous exchange of solute content [115]. The collision process depends upon the diffusion of the aqueous droplets in the continuous medium (the oil), while the exchange process depends on the attractive interaction between the surfactant tails and the rigidity of the interface, as the aqueous droplets approach each other. The basics of nanoparticle formation can be summarized as follows: if we take two identical w/o microemulsions and dissolve two reactants in each of the respective aqueous phases, upon mixing, because of collision and coalescence of the droplets, the reactants come in contact with each other and form a precipitate. This precipitate is confined to the interior of the microemulsion droplets, and the size and shape of the particle reflect the interior of the droplet.

Magnetite nanoparticles around 4 nm in diameter were prepared by controlled hydrolysis with ammonium hydroxide of  $\text{FeCl}_2$  and  $\text{FeCl}_3$  aqueous solutions within reverse micelle nanocavities generated with the anionic surfactant AOT (sodium bis(2-ethylhexyl)sulfosuccinate) and heptane as the continuous oil phase [121]. Superparamagnetic maghemite nanoparticles have also been prepared by the controlled hydrolysis of  $\text{FeSO}_4$  with tetraethylamine (TEA) within the aqueous pools of the microemulsions [115]. To do this, a microemulsion containing a 0.15 M solution of  $\text{FeSO}_4$  was mixed with a 2 M solution of TEA in octane. Diffusion of TEA through the surfactant monolayer into the aqueous droplets resulted in the hydrolysis of  $\text{Fe}^{2+}$  ions. A second microemulsion, containing sodium nitrite as the dispersed aqueous phase, was added to this suspension, and then the system was kept at 45 °C for 1 h under constant stirring.

Pileni and co-workers prepared nanosized magnetic particles with average sizes from 3.7 to 11.6 nm and a standard deviation ranging from 0.22 to 0.34, also by using microemulsions [122]. A ferrous dodecyl sulfate,  $\text{Fe}(\text{DS})_2$ , micellar solution was used to make nanosized magnetic particles, the size of which is controlled by the surfactant concentration and by temperature. In contrast to what is obtained in a homogeneous solution, iron ferrite particles can be obtained when the synthesis is performed at very low reactant concentrations and room temperature. Furthermore, nanoparticles are obtained when the syntheses are performed with iron (II) as the reactant, whereas in a

homogeneous solution particles in the micrometric range are formed.

The work of Carpenter's group, which prepared metallic iron particles coated by a thin layer of gold by microemulsions [123], deserves special mention. The gold shell protects the iron core against oxidation and provides functionality, making these composites potentially adequate for their use in biomedical applications. The reverse micelle reaction is carried out with cetyltrimethylammonium bromide (CTAB) as the surfactant, octane as the oil phase, and aqueous reactants as the water phase [124]. Varying the water-to-surfactant ratio can cause the formation of micelles ranging in size from 5 to 30 nm, thus leading to careful control over the particle size. A cosurfactant of *n*-butanol is used to help decrease the fraction of the micellar head group that is neutralized and thereby increase the stability of the micelle [125]. Without the addition of the cosurfactant, the amount of free water available to carry on the reactions is greatly reduced, as most of the water is bound in the head group of the CTAB [126].

The metal particles are formed inside the reverse micelle by the reduction of a metal salt with the use of sodium borohydride. The sequential synthesis offered by reverse micelles is utilized to first prepare an iron core by the reduction of ferrous sulfate by sodium borohydride. After the reaction has been allowed to go to completion, the micelles within the reaction mixture are expanded to accommodate the shell, with the use of a larger micelle containing additional sodium borohydride. The shell is formed with the use of an aqueous hydrogen tetrachloroaurate solution. The particles are then washed, collected in a magnetic field, and dried under vacuum.

#### 4.1.3. Bionanoreactors

Nature has developed a variety of protein components that function as carriers or storage devices for metal components. Of these systems, the iron-storage protein ferritin is probably the most intensively studied and best understood [127]. Ferritin consists of a central core of hydrated iron (III) oxide encapsulated by a multisubunit protein shell. During formation, the protein shell self-assembles in the first step to form a hollow cage about 8 nm in diameter. As a consequence, subsequent inorganic mineralization leads to spatially confined nanoparticles of an antiferromagnetic iron oxide similar to the mineral ferrihydrite [128]. Mann and co-workers began to explore the use of ferritin as a nanometer-sized bioreactor for producing metal particles other than the natural ferrihydrite. Horse spleen apoferritin was used as a nanometer-sized reaction vessel to generate manganese oxide and uranyl oxyhydroxide crystals [129]. Later work concerned the production of magnetic proteins by reconstituting apoferritin with the ferrimagnetic minerals magnetite [130] and magnetite/maghemite [131]. As a result of the inner diameter of the nanoreactors, crystalline inorganic particles with a diameter of about 6–7 nm were formed, as determined by transmission electron microscopy. The magnetite/maghemite particles were generated by oxidation of apoferritin with trimethylamino-*N*-oxide, which was loaded with various amounts of iron (II) ions. The magnetic properties were studied by SQUID magnetometry, and

an approximately linear dependence of the superparamagnetic blocking temperature on iron loading was found [130].

#### 4.1.4. Nonhydrolytic Synthetic Methods

Alivisatos and co-workers [132] have demonstrated that injecting solutions of  $\text{FeCup}_3$  (Cup: *N*-nitrosophenylhydroxylamine) in octylamine into long-chain amines at 250–300 °C yields nanocrystals of maghemite. These nanocrystals range from 4 to 10 nm in diameter, are crystalline, and are dispersible in organic solvents. Hyeon and co-workers [133] have also been able to prepare monodisperse maghemite nanoparticles by a nonhydrolytic synthetic method (Fig. 3). For example, to prepare maghemite nanoparticles of 13 nm,  $\text{Fe}(\text{CO})_5$  (0.2 ml, 1.52 mmol) was injected into a solution containing 0.91 g of lauric acid (4.56 mmol), 7 ml of octyl ether, and 0.57 g of  $(\text{CH}_3)_3\text{NO}$  (7.60 mmol) at 100 °C in an argon atmosphere, with vigorous stirring. As soon as  $\text{Fe}(\text{CO})_5$  was injected into the mixture, the temperature rose to 120 °C and the solution became dark red, which indicated the successful oxidation of  $\text{Fe}(\text{CO})_5$ . The reaction mixture was then stirred for 1 h at 120 °C, and the solution was slowly heated to reflux. The solution color gradually became black, indicating that nanoparticles were being formed. After refluxing for 1 h, the solution was cooled to room temperature, and a black precipitate was obtained with the addition of excess ethanol and centrifuging. The precipitate can easily be redispersed in octane or toluene.

Very recently, Shen and Zeng [134] have been able to prepare monodisperse magnetite nanoparticles with sizes from 3 to 20 nm by the high-temperature (265 °C) reaction of iron (III) acetylacetonate in phenyl ether in the presence of alcohol, oleic acid, and oleylamine. In particular, magnetite nanoparticles of about 3 nm were obtained by the thermal

**Figure 3.** TEM image of monodisperse 11-nm  $\gamma\text{-Fe}_2\text{O}_3$  nanocrystallites prepared by thermal decomposition of  $\text{Fe}(\text{CO})_5$ . Reprinted with permission from [133], T. Hyeon et al., *J. Am. Chem. Soc.* 123, 12798 (2001). © 2001, American Chemical Society.

decomposition of the iron precursor, but to obtain diameters up to 20 nm a seed-mediated growth method using 4-nm-diameter magnetite particles was needed.

#### 4.1.5. Other Synthetic Routes

Dendritic macromolecules, or dendrimers, are synthetic three-dimensional macromolecules that are prepared in a stepwise fashion from simple branched monomer units, the nature and functionality of which can be easily controlled and varied. Their unique architecture and monodisperse structure have been shown to result in numerous previously unknown or significantly improved physical and chemical properties when compared with traditional linear polymers. As a consequence, dendrimers are now considered to be one of the prime nanometer-scale building blocks for the construction of nanoscale objects, molecular devices and molecular “machines,” advanced drug-delivery systems, etc [135–139].

Recently, iron ferrite nanoparticles have been prepared with dendrimers as templating hosts [140]. Carboxylated poly(amidoamine) PAMAM dendrimers (generation 4.5) were utilized for the synthesis and stabilization of ferrimagnetic iron oxide nanoparticles. Oxidation of Fe(II) at slightly elevated pH and temperature resulted in the formation of highly soluble nanocomposites of iron oxides and dendrimer, which are stable under a wide range of temperatures and pH. Size exclusion chromatography indicated aggregates in the nanometer size regime, consistent with the oligomeric nature of the composite material. Transmission electron microscopy revealed small assemblies of mineral cores with electron diffraction and high-resolution transmission electron microscopy data indicative of the mineral maghemite. SQUID magnetometry demonstrated that this crystalline composition exhibited superparamagnetism at room temperature. NMR relaxation studies of solvent (water) protons revealed unusually high  $T_1$  and  $T_2$  relaxivities, which make these materials excellent candidates as contrast agents for NMR imaging.

Rajamathi et al. [141] have reported very recently the synthesis of magnetic nanoparticles by the reaction of  $\text{FeCl}_3$  in propylene glycol under reflux. Maghemite nanoparticles were prepared under reflux in 50 cm<sup>3</sup> of 1,2-propanediol, starting with 4.0 g (0.015 moles) of  $\text{FeCl}_3 \cdot 6\text{H}_2\text{O}$ , 3.7 g (0.045 mol) of sodium acetate as the hydrolyzing agent, 3 cm<sup>3</sup> of water, and 5.5 cm<sup>3</sup> of the capping agent *n*-octylamine. Reflux was carried out in a 250 cm<sup>3</sup> round-bottomed flask that was fitted with a water condenser held at 283 K. After refluxing for 5 h, the material was precipitated with the help of a permanent magnet and the addition of a large volume (approximately threefold excess) of 2-propanol. The material was washed with ether to remove excess amine and glycol and then dried in air at 50 °C to obtain the crude product.

Electrochemical methods have also been used for the production of maghemite nanoparticles [142]. The electrochemical synthesis of nanoparticles of  $\gamma\text{-Fe}_2\text{O}_3$  was performed in an organic medium. The size was directly controlled by the imposed current density, and the resulting particles were stabilized as a colloidal suspension with the use of cationic surfactants. The size distributions of the particles were narrow, with the average sizes varying from 3 to 8 nm. <sup>57</sup>Fe

Mössbauer spectroscopy and magnetization measurements indicated that the dry powders exhibit superparamagnetic behavior at room temperature.

A number of other techniques have been developed to synthesize magnetic nanoparticles. Some of these are inert gas condensation [143], mechanical attrition [144], solvated-metal-atom dispersion [145], laser pyrolysis [146], and aerosol pyrolysis [147].

#### 4.1.6. Size Selection Methods

Biomedical applications like magnetic resonance imaging, magnetic cell separation, or magnetorelaxometry utilize magnetic properties of the nanoparticles in magnetic fluids such as their magnetic moment. Furthermore, these applications also depend on the hydrodynamic size. All of the parameters mentioned exhibit a broad distribution in common magnetic fluids. Therefore, in many cases only a small portion of particles contribute to the desired effect. The relative amount of the particles with the desired properties can be increased by the fractionation of magnetic fluids [91, 148].

Common methods currently used for the fractionation of magnetic fluids are centrifugation [149] and size-exclusion chromatography [150, 151]. Centrifugation separates on the basis of the particle size and density difference between the liquid and solid phases. Sedimentation of material in a centrifugal field may be described by

$$v = d^2(\rho_s - \rho_l)\omega^2 r F_s / 18\eta\theta$$

where  $v$  is the rate of sedimentation,  $d$  is the particle diameter,  $\rho_s$  is the particle density,  $\rho_l$  is the solution density,  $\omega$  is the angular velocity in radians  $s^{-1}$ ,  $r$  is the radius of rotation,  $\eta$  is the kinematic viscosity,  $F_s$  is a correction factor for particle interaction during hindered settling, and  $\theta$  is a shape factor ( $=1$  for spherical particles).  $F_s$  depends on the volume fraction of the solids present, approximately equaling 1, 0.5, 0.1, and 0.05 for 1%, 3%, 12%, and 20% solid volume fraction, respectively.

Size-exclusion chromatography (SEC), also called gel-filtration or gel-permeation chromatography (GPC), uses porous particles to separate molecules or particles of different sizes. It is generally used to separate biological molecules and to determine molecular weights and molecular weight distributions of polymers. Molecules that are smaller than the pore size can enter the particles and therefore have a longer path and longer transit time than larger molecules that cannot enter the particles. Nunes and Yu [150] were able to prepare seven different magnetic fractions (sizes between 7 and 17 nm), starting from a commercial ferrofluid EMG805 from Ferrofluids Corporation, by using size-exclusion chromatography. To do this, the authors placed 1  $cm^3$  of this fluid at the top of a 50-cm Sepharose Cl-4B200 column eluted with distilled water to which a small Dowdite-1 (*O*-phenylphenol) had been added to retard spilage. The elution rate was approximately 0.5  $ml \cdot min^{-1}$ . All of these methods separate in accordance with nonmagnetic properties like density or size.

Massart and co-workers have proposed an original size-sorting procedure based on the thermodynamic properties of aqueous dispersions of nanoparticles [152]. The

positive charges of the maghemite surface allow their dispersion in aqueous acidic solutions and make it possible to obtain dispersions stabilized through electrostatic repulsions. With increasing acid concentration (in the range of 0.1 to 0.5  $mol \cdot liter^{-1}$ ), the interparticle repulsions are screened and phase transitions are induced. Using this phenomenon, these authors describe a two-step size-sorting process, to get significant amounts of nanometric monosized particles (with typical diameters monitored between 6 and 13 nm). As the surface of the latter is not modified by the size-sorting process, common procedures are used to disperse them in several aqueous or oily media.

Preference should be given, however, to partitions based on the properties of interest, in this case the magnetic properties. So far, magnetic methods have been used only for the separation of magnetic fluids, for example, to remove aggregates (magnetic filtration) [153], weakly magnetic or nonmagnetic materials like synthesis by-products [154], or unlabeled material on the basis of magnetic labeling [155]. Recently, the fractionation of magnetic nanoparticles by flow field-flow fractionation was reported [156]. Field-flow fractionation is a family of analytical separation techniques [157]. The separation is carried out in a flow with a parabolic profile running through a thin channel. An external field is applied at a right angle to force the particles toward the so-called accumulation wall. In flow field-flow fractionation the external field is generated by a secondary transverse flow, the so-called cross-flow [148].

## 4.2. Synthetic Routes for the Production of Superparamagnetic Composites

The main problem when dealing with magnetic fluids is the presence of anisotropic magnetic dipolar attraction [158], which renders the suspensions unstable, even in the absence of an external magnetic field. Strategies for preventing this attraction are mainly based on the coating of magnetic particles in such a way that, in a zero magnetic field, magnetic fluids behave as an isotropic magnetic dispersion, whereas in the presence of an external magnetic field the particles reversibly form anisotropic structures [159].

For separation processes (*in vitro* applications) the size restrictions are not as severe (particles below the micrometer size can be used) as in *in vivo* applications (as mentioned above, the smaller the size the better the tissular diffusion). Therefore the microstructure for *in vitro* applications could consist of superparamagnetic nanocrystals dispersed in sub-micrometer diamagnetic particles that are expected to have long sedimentation times in the absence of a magnetic field (screening of the anisotropic magnetic dipolar attraction). Moreover, by the adequate selection of the diamagnetic matrixes, the superparamagnetic composite could be provided with functionality and biocompatibility. For example, superparamagnetic polysaccharide nanoparticles with a size range below 300 nm have some advantages over synthetic magnetic microparticles for applications in biomedicine, diagnostics, and molecular biology. They are biocompatible and nontoxic and have higher effective surface areas and lower sedimentation rates. The hydrophilic surface of polysaccharide particles decreases nonspecific adsorption processes for proteins and antibodies [160].

### 4.2.1. Deposition of Nanomagnets on Colloidal Templates

One of the most promising techniques for the production of superparamagnetic composites is the layer-by-layer (LBL) self-assembly method. This method was first developed for the construction of ultrathin films [161, 162]. It consists of the stepwise adsorption of charged polymers or nanocolloids and oppositely charged polyelectrolytes to flat surfaces, exploiting primarily electrostatic interactions for layer buildup. Notably, it allows the controlled formation of multilayers of various materials (and combinations thereof) on selected substrates in a straightforward and versatile manner and uniquely permits nanoscale control over the multilayer thickness.

Caruso, Möhwald, and co-workers have used the LBL method for the controlled synthesis of novel nanocomposite core-shell materials and hollow capsules [163, 164]. The significant modification is that they use colloidal templates instead of flat surfaces (Fig. 4). With this strategy, colloidal particles have been coated with alternating layers of polyelectrolytes [165, 166], nanoparticles [163, 167–169], and proteins [170]. Furthermore, the same authors have demonstrated that submicrometer-sized hollow silica spheres [163] or polymer capsules [166] could be obtained after removal of the template from solid-core multilayered-shell particles either by calcination or by chemical extraction.

Using this approach, these authors have been able to produce monodisperse magnetic dense and hollow spheres [171, 172] that in principle could be used in biomedical applications. For the preparation of superparamagnetic dense polystyrene spherical particles, magnetite nanoparticles with an average diameter of 10–15 nm were alternately deposited with either poly(diallyldimethylammonium chloride) (PDADMAC) or poly(allylamine hydrochloride) (PAH) on 640-nm diameter PS lattices. Multilayer shells of  $\text{Fe}_3\text{O}_4$  and polyelectrolyte (PDADMAC or PAH) were prepared on PS lattices precoated with a precursor three-layer polyelectrolyte film: the outermost layer was PDADMAC or PAH, therefore providing a positively charged surface for  $\text{Fe}_3\text{O}_4$  deposition. Alternate depositions of  $\text{Fe}_3\text{O}_4$  and PAH or PDADMAC on precoated PS lattices, under conditions where the nanoparticles and polyelectrolyte are oppositely charged (pH  $\sim$  5–6), produce magnetic nanoparticle/polyelectrolyte multilayer shells. Qualitative proof of multilayer magnetic shell buildup was obtained from electrophoretic mobility measurements: the zeta potential of the coated particles alternates in magnitude from +25 mV when the polycation is the outermost layer to +5 mV when  $\text{Fe}_3\text{O}_4$  is the outer layer. Formation of the magnetite shell

**Figure 4.** Schematic illustration of the layer-by-layer electrostatic assembly of nanoparticles on spherical colloidal templates (nanoparticles are adsorbed to the polyelectrolyte because of their opposite charge density).

covering the PS core can be directly visualized by transmission electron microscopy (TEM). A similar methodology was used for the production of hollow spheres, though in this case once the deposition process was finished, the polystyrene template was removed by heating at 500 °C. It is interesting that the researchers prepared hollow spheres with the inner and outermost layers composed of silica, which render these particles particularly useful for separation applications.

Inorganic and hybrid coating (or shells) on colloidal templates have also been commonly prepared by precipitation and surface reactions [173–178]. By the adequate selection of experimental conditions (mainly the nature of the precursors, temperature, and pH) this method can be used to create uniform and smooth coatings and therefore monodisperse spherical composites. With this technique sub-micrometer-sized anionic polystyrene lattices have been coated with uniform layers of iron compounds by aging, at elevated temperature, dispersions of the polymer colloid in the presence of aqueous solutions of ferric chloride, urea, hydrochloric acid, and polyvinylpyrrolidone (Fig. 5). The thickness of the deposited layers could be altered by suitable adjustment of the reactant concentrations, and they could also be increased by further aging of the coated particles in the presence of aqueous solutions of ferric chloride. Hollow colloidal spheres of iron compounds were obtained by calcinations of the polystyrene matrix at elevated temperature in air. Different chemical compositions of hollow colloidal spheres were obtained by heating them in hydrogen [179–180].

### 4.2.2. Polymer Encapsulation of Nanomagnets

Encapsulation of inorganic pigments in organic polymers endows pigments with important properties that bare pigments lack. Polymer coatings on pigments enhance

**Figure 5.** TEM micrographs of hollow iron oxide particles. Adapted with permission from [180], H. Shiho and K. Kawahashi, *J. Colloid Interface Sci.* 226, 91 (2000). © 2000, Academic Press.

compatibility with organic ingredients, reduce susceptibility to leaching, and protect pigment surfaces from oxidation. Consequently, encapsulation improves dispersibility, improves chemical stability, and reduces toxicity. Therefore it is not surprising that there is great interest in polymer-coated pigments for the preparation of paint, ink, pharmaceutical, and cosmetic formulations [181]. Rather than depositing magnetic particles on the surface of latex particles, uniformly dispersing the magnetic nanoparticles throughout the entire ensemble of latex particles should theoretically allow higher concentrations of nanoparticles per latex particle.

Polymer-coated magnetite nanoparticles were synthesized by seed precipitation polymerization of methacrylic acid and hydroxyethyl methacrylate in the presence of magnetite nanoparticles [182]. Cross-linking of polymers has also been reported to be an adequate method for the encapsulation of magnetic nanoparticles. To prepare composites by this method, mechanical energy must first be supplied to create a dispersion of magnetite in the presence of aqueous albumin [183], chitosan [184], or polyvinylalcohol [185] polymers. More energy creates an emulsion of the magnetic particle sol in cottonseed [183], mineral [184], or vegetable oil [185]. Depending upon the composition and reaction conditions, the addition of a cross-linker and heat results in magnetic latex, 0.3 to 30 micrometers in average diameter, polydisperse in size, with up to 24 wt% magnetite content [183]. Superparamagnetic, monodisperse (~135 nm), and charged polystyrene spheres (17.1 wt% iron oxide content) have also been synthesized by emulsion polymerization of styrene, methyl methacrylate, and sodium styrene sulfonate in the presence of iron oxide nanoparticles with a surface modified with oleic acid [186]. The reaction temperature was set to 70 °C, and ammonium persulfate was added to initiate the polymerization.

Recently the preparation of superparamagnetic latex via inverse emulsion polymerization has been reported [33]. The structure-directing nature of block copolymers, combined with the “mini-emulsion” polymerization process, facilitate the synthesis of superparamagnetic latex loaded with nanometric magnetic iron oxide. A “double-hydrophilic” diblock copolymer (polyethylene oxide block-co-polymethacrylic acid), present during the precipitation of magnetic iron oxide, directs nucleation, controls growth, and sterically stabilizes the resulting 5 nm of superparamagnetic iron oxide. After drying, the coated particles spontaneously reprecipitate into a mixture of hydroxyethylmethacrylate and methacrylic acid monomers, creating a ferrofluid-like dispersion. Inverse emulsification of the ferrofluid (magnetic particles plus monomer) into decane, aided by small amounts of diblock copolymer emulsifier along with ultrasonication, creates minidroplets (180 nm) filled with magnetic particles and monomer. Subsequent polymerization generates magnetic latex.

A novel approach to preparing magnetic polymeric nanoparticles by synthesis of the magnetite core and polymeric shell in a single inverse microemulsion was reported by Chu and co-workers [187]. Stable colloid dispersions of magnetic nanoparticles with a narrow size distribution were thus produced. The microemulsion seed copolymerization of methacrylic acid, hydroxyethyl methacrylate,

and cross-linker resulted in a stable hydrophilic polymeric shell of nanoparticles. The preparation of the nanoparticles was also carried out by the two-stage microemulsion process and seed precipitation polymerization. The particle size was varied in the range of 80–320 nm by changing the monomer concentration and water/surfactant ratio. The magnetic properties and the size distribution of the nanoparticles synthesized by these three methods were compared. The polymeric nanoparticles synthesized in a single microemulsion have superparamagnetic properties and the narrowest size distribution.

#### 4.2.3. Inorganic Encapsulation of Nanomagnets

An appropriate tuning of the magnetic properties is essential for the potential use of the superparamagnetic composites. In this way, the use of inorganic matrixes and, in particular of silica, as dispersion media of superparamagnetic nanocrystals has been reported to be an effective way to modulate magnetic properties by a simple heating process [188–190].

Another advantage of having a surface enriched in silica that is especially appropriate for separation applications is the presence of surface silanol groups that can easily react with alcohols and silane coupling agents [191], not only to produce dispersions that are stable in nonaqueous solvents, but also to provide the ideal anchorage for the covalent binding of specific ligands. The strong binding makes desorption of these ligands a difficult task. In addition, the silica surface confers high stability on suspensions of particles at high volume fractions, during changes in pH, or at high electrolyte concentration [192].

For separation applications a high loading of magnetic material is essential to generate the response of the material to a magnetic field gradient, precluding the use of some methods described earlier [193]. By combining the Lorentz equation for the force on a magnetic particle of radius  $R$  with the Stokes law for viscous drag for spheres, the sedimentation velocity,  $V$ , of a ferrofluid particle in a magnetic field gradient  $\nabla H$  is given by [194]

$$V = 2\mu_0 M_S R^2 \nabla H / 9\eta$$

where  $\mu_0$ ,  $M_S$ , and  $\eta$  are the permeability of vacuum, magnetic saturation, and viscosity, respectively. From the equation we can infer that the highest  $M_S$  (i.e., the highest the amount of magnetic material) generates the fastest sedimentation velocity,  $V$ .

Very recently, our group has been successful in preparing submicronic silica-coated magnetic hollow and dense spheres [195–196] by aerosol pyrolysis. The thermal decomposition of liquid aerosols (aerosol pyrolysis) represents a convenient procedure for obtaining finely dispersed particles of predictable shape, size, and variable composition. The resulting powders generally consist of spherical particles, the final diameter of which can be predetermined from that of the original droplets. The method offers certain advantages over other, more commonly used techniques (such as precipitation from homogeneous solution), as it is simple, rapid, and continuous [197].

Silica-coated  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> hollow spherical particles with an average size of 150 nm (Fig. 6) were prepared by the aerosol pyrolysis of methanol solutions containing iron ammonium citrate and tetraethoxysilane (TEOS) at a total salt concentration of 0.25 M [195]. An illustration of the possible formation mechanism of the silica-coated magnetic hollow spheres is shown in Figure 7. During the first stage the rapid evaporation of the methanol solvent favors the surface precipitation (i.e., formation of hollow spheres) of components [197]. The low solubility of the iron ammonium citrate in methanol when compared with that of TEOS promotes the initial precipitation of the iron salt solid shell. During the second stage the probable continuous shrinkage of this iron salt solid shell facilitates the enrichment at the surface of the silicon oxide precursor (TEOS). In the third stage, the thermal decomposition of precursors produces the silica-coated  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> hollow spheres. The formation of the  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> is associated with the presence of carbonaceous species coming from the methanol solvent and from the iron ammonium citrate and TEOS.

On the other hand, the aerosol pyrolysis of iron nitrate and TEOS at a total salt concentration of 1 M produced silica-coated dense  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> spherical particles of an average size of 250 nm (Fig. 8). The increase in salt concentration to a value of 1 M favored the formation of dense spherical particles instead of hollow ones.

A water-in-oil microemulsion method has also been applied for the preparation of silica-coated iron oxide nanoparticles [198]. Three different nonionic surfactants (Triton X-100, Igepal CO-520, and Brij-97) have been used for the preparation of microemulsions, and their effects on particle size, crystallinity, and magnetic properties have been studied. The iron oxide nanoparticles are formed by a coprecipitation reaction of ferrous and ferric salts with inorganic bases. A strong base, NaOH, and a comparatively mild base, NH<sub>4</sub>OH, have been used in each surfactant to observe whether the basicity has some influence on the crystallization process during particle formation. Transmission electron microscopy, X-ray electron diffraction, and superconducting quantum interference device magnetometry have been employed to study both uncoated and silica-coated iron oxide nanoparticles. All of these particles show magnetic behavior close to that of superparamagnetic materials. With this method, magnetic nanoparticles as small as 1–2 nm and of very uniform size (percentage standard deviation is less than 10%) have been synthesized. A uniform silica coating as thin as 1 nm encapsulating the bare nanoparticles is

**Figure 6.** TEM picture of the silica/iron oxide composites prepared by aerosol pyrolysis of a mixture of iron ammonium citrate and TEOS. Details of a hollow spherical particle showing an outer particle layer mainly constituted (according to TEM microanalyses) by SiO<sub>2</sub>.

**Figure 7.** Illustration of the formation mechanism of the silica coated magnetite hollow particles.

formed by base-catalyzed hydrolysis and the polymerization reaction of TEOS in microemulsion.

## 5. SURFACE MODIFICATION OF NANOMAGNETS

### 5.1. Biocompatibility

The biocompatibility of biomaterials in direct contact with the blood depends closely on the ability of these materials not to be recognized by the coagulation, the complement, and the platelet systems [199]. This is true for massive biomaterials like endovascular prosthesis, but also for nanosized suspensions injected intravenously, like superparamagnetic iron oxide nanoparticles [200]. For *in vivo* applications, the internalization of nanoparticles into specific cells is the critical step and is severely limited by three

**Figure 8.** TEM micrographs of silica/iron oxide composites prepared by aerosol pyrolysis of a mixture of iron nitrate (20 mol%) and TEOS (A) and further heated in a conventional furnace for 2 h at 900 (B), 1050 (C), and 1200 °C (D). Note in the sample heated at 1050 °C the presence of  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> (dark regions) nanoparticles smaller than 20 nm dispersed in a microspherical silica particle (lighter regions). At this temperature, the enrichment of silica on particle outerlayers is clearly observed. It is important to note that microstructures similar to that displayed in micrographs (B) and (C) were observed for smaller and bigger particles. Note also the high stability of the spherical magnetic composites (the particles lost their spherical shape only at a temperature of 1200 °C as a consequence of sintering). Reprinted with permission from [196], P. Tartaj et al., *Langmuir* 18, 4556 (2002). © 2002, American Chemical Society.

factors: (a) a short blood half-life of the particles, (b) non-specific targeting, and (c) low efficiency of internalization to endocytosed ligands grafted to the nanoparticles [201].

The rapid elimination of nanoparticles from the bloodstream after their injection is due to their recognition by macrophages of the mononuclear phagocyte system [202]. Nanoparticles have a large surface area/volume ratio and tend to agglomerate and absorb plasma proteins. When the nanoparticles agglomerate, or are covered with adsorbed plasma proteins, they are quickly cleared by macrophages before they can reach target cells. Two types of coating yielding “stealth” particles have been successfully developed: high-density layered polymeric brushes (e.g., PEG, polysaccharides as dextran, poloxamines, and poloxamers) [203–205] and ganglioside-containing liposomes [206]. In the first case, the low proteic adsorption and complement activation seem to be linked to the entropic repulsion of free proteins by mobile polymeric chains [203, 207, 208]; in the second case, the polar head group of neuraminic acid inhibits the autocatalytic activation of the complement system [206], allowing the adsorption of only one proteic layer.

As mentioned above, one possible approach to increasing the circulation time of nanoparticles in the bloodstream is to modify the particles with poly(ethylene glycol) (PEG) films to disperse them and minimize or eliminate protein adsorption. Surfaces covered with PEG are biocompatible (i.e., nonimmunogenic, nonantigenic, and protein-resistant) [209]. This is due to the fact that PEG has uncharged hydrophilic residues and very high surface mobility, leading to high steric exclusion [210, 211]. Therefore, covalently immobilizing PEG on the surfaces of superparamagnetic magnetite nanoparticles is expected to effectively improve the biocompatibility of the nanoparticles. In addition, it has been demonstrated that particles with PEG-modified surfaces cross cell membranes, in nonspecific cellular uptake [212]. The possible mechanism for this uptake is that PEG can dissolve in both polar and nonpolar solvents and have high solubility in cell membranes [213, 214]. For the past decades, significant effort has been devoted to surface modification of various polymer drug carriers with PEG to improve their biocompatibility, to resist protein adsorption, and to increase their circulation time and internalization efficiency [215]. Little work has been done on the surface modification of magnetic nanoparticles for the same purpose. Zhang et al. [216] have shown that the surface modification of nanoparticles with PEG could be used to resist the protein adsorption and thus avoid the particle recognition by macrophage cells, and to facilitate the nanoparticle uptake to specific cancer cells for cancer therapy and diagnosis.

Once the magnetic nanoparticles are modified to provide them with biocompatibility, the effective hydrodynamic radius of the plasma-located nanoparticles grows well above their core radius [199, 217]. Therefore, another limiting factor is that the overall dimensions of the antibodies and their inherent immunogenicity cause nanoparticles to diffuse poorly through biological barriers [218]. The development of thin coating layers would thus allow major impacts in the particulate targeting of tissular recognition sites. Low-molecular-weight targeting agents such as folic acid have been demonstrated to preferentially target cancer cells, because the folate receptor is frequently overexpressed on

the surface of cancer cells [219]. The folate receptor is not only a tumor marker, but also has been shown to efficiently internalize molecules coupled to folate [220, 221]. Furthermore, folic acid itself is stable and generally poorly immunogenic. Despite the well-known ability of folate receptor to facilitate the internalization of polymeric particles [221, 222], little effort has been expended on the delivery of magnetic nanoparticles modified with PEG and folic acid into cells. Zhang et al. [210] have shown that the surface modification of nanoparticles with folic acid could be used to resist protein adsorption and thus avoid particle recognition by macrophage cells, and to facilitate nanoparticle uptake to specific cancer cells for cancer therapy and diagnosis.

Denizot and co-workers checked different organic biocompatible molecules that in principle could generate thin coatings on the surface of magnetic nanoparticles and therefore reduce the hydrodynamic size [199, 217, 223]. These authors first tried with phosphorylcholine-derived polymers that are known to protect prostheses against protein contamination [224, 225]. But pure phosphorylcholine coatings do not allowed colloidal stability at physiological pH [199]. Because of this relative failure, they tried to improve adsorption stability by systematic modifications of the fixation site on the iron oxides with functions such as phosphonates, phosphates, sulfonates, and carboxylic acids, all known for their adsorption properties on metallic surfaces. Coating with bisphosphonates, the more interesting fixation moiety, leads to small (less than 15 nm) and stable objects in a wide range of pH, including neutrality. From stability data, the coating density was evaluated at around 1.6 molecules per nm<sup>2</sup>. Including a quaternary ammonium salt in the coating molecule lowers the electrophoretic mobility. Moreover, this type of coating protects steel plates against contamination without significant desorption. All of these properties allow further developments of these nanoparticles for biomedical applications [217].

## 5.2. Specificity

*In vitro* applications such as separation, purification, and immunoassay methods rely on coating of magnetic particles with proteins or monoclonal antibodies, which endow the particles with the ability to bind the specific cancer cell, DNA fragment, or enzyme of interest and remove that entity from the fluid upon the application of a magnetic field [226–228]. For example, albumin-based magnetic particles have been used for the magnetic separation of red blood cells [229]. The same authors also checked the efficiency of polystyrene magnetic microspheres and showed that albumin-based magnetic particles have a higher coupling efficiency [230].

Koneracká et al. [231] have shown that enzymes such as chymotrypsin and streptokinase can be immobilized as fine magnetic particles. One of the important applications the authors are considering and exploring is in the treatment of coronary thrombosis and in peripheral arterial occlusions. In coronary arterial occlusions during a heart attack, plasminogen tissue is an ideal drug for lysing a clot because of its specific targeting capacity.

Safarikova and Safarik [76] immobilized copper phthalocyanine dye on fine silanized magnetite particles. This

reactive was used as a specific adsorbent for the preconcentration of organic compounds with planar molecular structures (polyaromatic hydrocarbons and their derivatives [232–234] and triphenylmethane dyes [76]). Magnetic particles are often sensitized with streptavidin to take advantage of its extremely high-affinity interaction with biotin. Because biotin can be easily conjugated with many different diagnostic reagents, a variety of assays for different analytes in several formats can be developed [235, 236].

## 6. SUMMARY

Drug and gene delivery will continue to have a significant impact on the practice of biomedicine. Magnetic drug-targeting will undoubtedly dramatically improve the therapeutic potential of many water-insoluble and unstable drugs. The new development of drugs able to target selected cells or organs within the body will also deeply improve the benefits of some of the *in vivo* biomedical applications of nanomagnets.

One of the topics of importance is the controlled release of therapeutic agents. For example, cells that make up tumors are a nonsynchronous population. Since chemotherapeutic drugs are active during specific phases of the cell cycle (e.g., DNA synthesis), a short burst of drug may not kill a substantial portion of tumor cells [59]. Retention of magnetic carriers within the tumor may act as a drug reservoir. As drug desorbs from the particles over time, effective concentrations of drug may be maintained as more tumor cells cycle through the S phase.

The main applications of magnetic carriers have been derived from the fact that specific ligands (e.g., streptavidin, antibodies) can be covalently bound to the polymer matrix, permitting binding to diverse target substances/organs such as cells, proteins, or nucleic acids. The strong binding makes the desorption of these ligands a difficult task. In contrast, ionically bound ligands can easily be eluted from the matrix simply by a change in either ionic strength or the pH. Bergemann and co-workers [111] have succeeded in developing novel nano- and microsized magnetic particles and beads to which ion-exchange groups were attached, thereby enabling simple and reversible binding of ligands. The remarkable feature of pharmaceutical drugs ionically bound to the surface of particulate drug delivery systems is that the active low-molecular-weight substances can desorb from the carriers after a defined time span and hence can diffuse from the vascular wall into the tissue.

Application of magnetic liposomes (lipid vesicles, containing submicron-sized magnetic nanoparticles in their structure, either in the lipid bilayer or in the aqueous compartment) as “vehicles” for targeted drug delivery appears to be a promising technique [237]. Liposomes can be used for encapsulation of many biologically active substances and can prolong their therapeutic action by gradual release of the drug [238–240]. Magnetic components of the liposomes allow concentration of the liposomes in the desired area of the patient’s organs by magnetic forces, often augmented by magnetic agglomeration. Special mention deserves the work of Bulte and co-workers [241]. These authors have developed magnetic liposomes derivatized with the hydrophilic

polymer polyethylene glycol (PEG) that may escape rapid uptake by cells of the reticuloendothelial system.

Similar promising methods rely on the preparation of micro- and nanocapsules as containers of magnetic carriers by a layer-by-layer approach. In particular, the preparation of polyelectrolyte (PEM) capsules is of significant interest [242]. One of the advantages of PEM capsules is their versatility of physical and chemical properties, created by variation of composition and fabrication as well as application conditions. Several dozen natural and synthetic polyelectrolytes or other charged substances are suitable as layer components, including chitosan, chitosansulfate, poly(L-lysine), poly(acrylic acid), poly(diallyldimethylammonium chloride), dextran sulfate, and proteins. Many of them can be functionalized to provide special surface structures of biological or technical relevance. They are applied as containers for inorganic and organic matter, such as drugs or macromolecules [243].

Magnetically directed microspheres containing radionuclides have been used for internal radiotherapy [58]. However, little work has been done on the use of magnetic nanoparticles in radiotherapy. One strategy under active investigation to improve dose localization is that of administration of drugs, metabolites, and so forth that have been labeled with radioactive isotopes in a quantity sufficient to inactivate tumor cells [244]. In this way, the use of surface-activated magnetic nanoparticles could have a tremendous impact on improving the efficiency of the cancer treatments.

Extensive application of hyperthermic cancer treatment presents serious problems that have not been sufficiently cleared up [44]. In particular, the temperature distribution inside as well as outside the target region must be known as a function of the exposure time to provide a level of therapeutic temperature and, on the other hand, to avoid overheating of and damage to the surrounding normal tissue. Several theoretical studies are being carried out to check the possibility of determining the spatial temperature distribution by means of mathematical simulation on the basis of known physical parameters [44, 245–247].

Efficient drug targeting is vital for the medical treatment of various diseases, among them cardiovascular episodes, like stenosis and thrombosis. Ferrofluids, magnetoliposomes, and magnetic micro- and nanospheres are promising candidates for delivering drugs to specific locations within the body, with high accuracy and little or no surgical intervention, and at maximum concentration. However, the hydrodynamics of these materials after injection in blood remains little known. The ternary phase structure of blood (white cells, red cells, and plasma), as well as the plethora of particles that are present in the blood flow, makes hemodynamics an exceedingly complex research field. Moreover, the response of blood to magnetic fields is not yet completely known, though there are some indications of the diamagnetic, paramagnetic, or ferromagnetic character of its various constituents [248–251]. In this way, the theoretical studies carried out by Voltairas et al. [252] could help to increase the understanding of the physics of magnetic drug targeting. In particular, these authors have developed a general theory for treating magnetic drug targeting. With minor corrections, the theory can also be applied when the carrier

is not a typical ferrofluid, but rather a lipid vessel (magnetoliposome). All necessary physical parameters, like the strength and the orientation of the magnetic field, the magnetic composition of the drug, the blood composition and velocity, are introduced in a model case.

Another important goal to achieve in the future is to better understand the magnetic behavior of nanocrystals. This topic is extremely important if magnetic nanoparticles are to be widely used in biomedical applications. Magnetic behavior can vary widely, depending on the size and distribution of the nanocrystalline particles. For example, an enhancement of the effective magnetic anisotropy with respect to the bulk material coming fundamentally from surface anisotropy has been reported [147, 190, 253, 254]. Furthermore, for nanoparticles a reduction in  $M_s$  values associated with spin canting at the surface and/or the interior of the particles is normally observed [36]. In addition to the particle size, the magnetic behavior also depends on the volume fraction and on the interaction of the nanomagnets with the matrix [255–257]. Interparticle interactions (usually of a dipolar nature) will affect the effective anisotropy energy and change the temperature at which a particle becomes superparamagnetic [18, 258].

Another important field under continuous development is the search for new synthetic routes or the improvement of established ones to produce reliable magnetic nanoparticles with adequate characteristics (improved tissular diffusion, colloidal stability, biocompatibility, and specificity) [217]. If we can gain sufficient understanding and control of biological reactions with magnetic nanoparticles, we may be able to control the rejection of nanomagnets. Ultimately, better materials and understanding of their interaction with the body may lead to biocompatible nanomagnets.

We can even envisage a future in which nanomagnets could be used for the repair of the human body with prosthetics or artificial replacement parts. In this field special mention must be made of the pioneering work of Dailey et al., who have reported the synthesis of silicon magnetic fluid for use in eye surgery [259]. Retinal detachment is a major cause of vision loss in adults. It occurs when the retina separates from the choroid, resulting in the eventual death of the retina and a subsequent loss of vision. As a normal part of aging, the vitreous gel normally undergoes liquefaction, collapse, and separation from the retina. The goal of surgery is to close the holes in the retina, preventing further fluid flow into the subretinal space, allowing for reattachment of the retina.

Present techniques for treating retinal detachment consist of a silicon band sewn to the outside of the eye to compress the wall of the eye inward to close the holes in the retina. Other methods employ halogenated gas ( $\text{SF}_6$ ,  $\text{C}_3\text{F}_8$ ) or silicon oil as internal tamponades. These materials can be placed inside the vitreous cavity and block the hole from within. Currently used internal tamponades ( $\text{SF}_6$ ,  $\text{C}_3\text{F}_8$ , or silicon fluid) float upward, leaving the inferior retina unprotected. Other materials sink (fluorosilicon), leaving the superior retina unprotected. Moreover, current tamponades fill the vitreous cavity, decreasing vision, and contact anterior chamber structures, causing cataracts and glaucoma. Dailey et al. [259] have developed an internal tamponade from modified silicon fluid containing sterically stabilized

4–10-nm metal particles, which will be held in place with an external magnetized scleral buckle. Magnetization procedures for the solid silicon band currently used for the scleral buckle were well preceded. With an appropriate magnetic fluid inside the vitreous cavity, they can produce a stable, 360° internal tamponade. The encircling magnetized scleral buckle and magnetic fluid would produce a ring of silicon oil in apposition to the retinal periphery. The central vitreous cavity would be free of the magnetic fluid, and there would be no contact between the magnetic fluid and the lens, anterior chamber structures, or macula, thus avoiding the complications of currently available treatment modalities.

## GLOSSARY

**Apoferitin** Empty ferritin. Ferritin in which the iron hydroxide central core has been extracted.

**Bohr radius** In semiconductors, excitation involves the separation of electrons and holes (the charge carriers) by distances that encompass a number of the molecules or ions making up the lattice. Such a distance, known as the Bohr radius, is on the nanometer length scale.

**Deoxyribonucleic acid (DNA)** It is the primary chemical component of chromosomes and the material of which genes are made. Each strand of DNA, is a chemically linked chain of nucleotides, which each consists of a deoxyribose sugar, a phosphate, and one of four varieties of “aromatic” bases. Because DNA strands are composed of these nucleotide subunits, they are polymers.

**Diamagnetism** A weak repulsion in a magnetic field generated by the current of the orbiting electron. All materials are naturally diamagnetic, although paramagnetism is stronger in materials with unpaired electrons.

**Ferromagnetism** The development of extremely strong magnetic properties in certain materials which occurs when magnetic domains become aligned in the absence of an applied field, below a temperature known as the Curie temperature. Ferromagnetism is believed to be caused by magnetic fields generated by the electrons' spins in combination with a mechanism known as exchange coupling, which aligns all the spins in each magnetic domain.

**Fluorescence** The emission of visible light from a substance under the stimulation of radiation of a shorter wavelength.

**Gene** The word “gene” is shared by many disciplines, including whole organism-based or “classical” genetics, molecular genetics, evolutionary biology and population genetics. It has multiple uses within each of these contexts. But in the primary sense “genes” are material things that parents pass to offspring during reproduction and through which they propagate their biological traits or characteristics. This sense, which is common to all of the above disciplines, is also the original historical meaning of “gene.”

**$H_c$  Coercivity** The magnetic field needed to reverse a given magnetization.

**$k_B$  Boltzmann constant** The product  $k_B T$  is the thermal energy. In magnetic materials the thermal energy acts to randomize magnetic moments. In particular, when this term is similar to the magnetic anisotropy energy (defined as the

product of the magnetic anisotropy constant and the volume of particles), magnetic materials become superparamagnetic. Superparamagnetism, thus, occurs when the material is composed of very small crystallites (1–10 nm). In this case even though the temperature is below the Curie or Neel temperature and the thermal energy is not sufficient to overcome the coupling forces between neighboring atoms, the thermal energy is sufficient to change the direction of magnetization of the entire crystallite. The resulting fluctuations in the direction of magnetization cause the magnetic field to average to zero. The material behaves in a manner similar to paramagnetism, except that instead of each individual atom being independently influenced by an external magnetic field, the magnetic moment of the entire crystallite tends to align with the magnetic field.

**Magnetic anisotropy** The dependence of magnetic properties on a preferred direction is called magnetic anisotropy. There are several different types of anisotropy such as magnetocrystalline anisotropy, shape anisotropy or surface anisotropy.

**Magnetic dipolar energy** Interaction energy between two magnetic moments.

**$M_s$  saturation magnetization** The magnetization attained when all magnetic moments in the sample are aligned (maximum magnetization).

**Ribonucleic acid (RNA)** It is structurally distinguished from DNA by the presence of an additional hydroxyl group attached to each pentose ring and functionally distinguished by its role in the transmission of genetic information from DNA (by transcription) and into protein (by translation).

**Superconducting quantum interference device (SQUID)** Experimental technique used to determine the magnetic behavior of a material.

## 1. INTRODUCTION

Bulk nanostructured materials can be defined as solids with nanoscale (typically 1–100 nm) substructures in at least one dimension [1–4]. Siegel [3] has classified nanostructured materials into four categories according to their dimensionality: 0D—nanoclusters (particles); 1D—multilayers; 2D—nanograined layers; and 3D—equiaxed bulk solids. In short, he has described the 3D nanostructured materials as “. . . three-dimensionally modulated, synthetic materials with average grain, phase, or other structural domain sizes below 100 nm.” In this review, we are primarily concerned with 3D nanostructured materials.

Two complementary approaches have been developed to synthesize nanostructured materials. The first one is a “bottom-up” approach, in which bulk nanostructured materials are assembled from individual atoms or nanoscale building blocks such as nanoparticles [5]. Gleiter’s pioneering work [6] is a typical example of a “bottom-up” approach. Various chemical and physical methods have been developed to synthesize nanopowders for small-scale laboratory

investigations as well as for large-scale commercial use. Such methods include inert gas condensation (IGC) [6], high-energy ball milling [7], spray conversion processing [8], sputtering [9], physical vapor deposition [10], chemical vapor deposition [11], sol-gel processing [12], sliding wear [13], and spray forming [14]. The bottom-up approach has a number of applications such as films, coatings, electronic devices, drug deliveries, cosmetics, paints, lubricants, rocket fuels, catalysts, and reinforcements for nanocomposites.

Most bottom-up approaches produce nanopowders. For structural applications, the nanopowders need to be consolidated into bulk nanomaterials. However, consolidation of nanopowders has been a challenge. Gleiter [6] and Nieman et al. [15] cold-compacted IGC-produced nanopowders *in-situ* in ultrahigh vacuum and obtained nanostructured discs typically a few hundred micrometers in thickness and less than 10 mm in diameter. Their as-produced samples contained many flaws that masked the intrinsic mechanical properties [16]. Flaws included gas filled pores, cracks, poorly bonded grains, etc. These flaws render the material brittle, especially under tension. More recently, Sanders et al. [17] used warm compaction to reduce the density and size of such flaws and found improvement in the mechanical properties. However, flaws such as porosity and trapped gas still exist in the consolidated nanomaterials. A series of other conventional and new techniques, such as hot pressing, hot isostatic pressing (HIP) [18], rapid hot forging [19, 20], and plasma activated sintering [21], have been used to consolidate nanopowders. Most of these techniques involve the applications of heat and pressure. Grain growth usually occurs during consolidation, although nanopowder oxidation and contaminants may help impede grain growth. However, it should be noted that the existence of some degree of porosity is not always undesirable. For instance, the existence of small amounts of porosity may be responsible, in part, for the increase of short-range diffusional deformation

in certain ceramics. This, in turn, renders them more strain rate sensitive and more ductile [3], which could be useful in their forming and applications.

The second approach for producing nanostructured materials is a “top-down” approach, in which existing coarse-grained materials are refined into nanostructured materials. The most successful “top-down” approach has been via severe plastic deformation (SPD) techniques, among which the most developed are equal channel angular pressing (ECAP) and high-pressure torsion (HPT) [22]. The latter has also been referred to as severe plastic torsion straining (SPTS) [23], but was redefined as HPT for a more accurate description of the process at a NATO workshop on SPD in 1999 [24]. The ECAP technique was first invented by Segal in 1972 [25], and was later used to produce nanostructured materials [26]. Recently, new SPD techniques have been developed, such as accumulative roll bonding [27], multipass coin-forging (MCF) [28], and repetitive corrugation and straightening (RCS) [29, 30]. SPD-produced materials such as Cu, Fe, and Ti typically have an average grain size of 60–200 nm [23], somewhat above 100 nm, the upper bound often used to define the nanostructured materials. However, subgrains with low misorientation angles, dislocation cell structures [29], and the coherent crystallite domains as measured by X-ray analysis are usually smaller than 100 nm. It was agreed at the NATO workshop that the materials produced by SPD can be indeed classified as nanostructured materials.

Nanostructured materials produced by SPD techniques are free of porosity and contaminants, and can be used to study their intrinsic deformation mechanisms. These materials have unique micro- and nanostructures such as high dislocation density, nonequilibrium grain (subgrain) boundaries, and dislocation cells [23]. Recently, it was discovered that SPD-processed Cu and Ti have an extraordinary combination of both high strength and high ductility [31]. In addition, both strength and ductility were observed to increase with increasing SPD strain, which is contrary to the usual behavior of materials processed by conventional forming methods such as rolling and drawing, where plastic deformation increases the strength but usually decreases the ductility. SPD is also at present the only approach that can produce large, bulk nanostructured materials for structural applications, such as medical implants and aerospace components.

This review first describes recent developments in severe plastic deformation (SPD) techniques, followed by the unique structures and properties of nanostructured materials processed by SPD and the potential applications of these materials.

## 2. SEVERE PLASTIC DEFORMATION TECHNIQUES

The practice of shaping and forming metals and alloys through plastic deformation is several thousand years old. It was a primary method that blacksmiths used to make metal objects such as swords and horse shoes. Modern shaping and forming technologies include rolling, extrusion, drawing,

etc. Although these industrial practices can refine grains and improve mechanical properties of metals and alloys, they usually cannot produce nanostructured materials. They usually produce dislocation cell structures instead of grains with high angle grain boundaries [23]. Very high plastic strains are required to produce nanostructures in metals and alloys. The industrial shaping and forming technologies mentioned above reduce the cross section of a work piece that is deformed. As a result, the work piece is usually reduced to a geometry of thin foil or wire before nanostructures are formed inside it, which makes further plastic deformation difficult and the work piece unsuitable for most structural applications.

A common feature of SPD techniques for producing nanostructured materials is their capability of imparting large plastic deformation into a work piece without significantly changing its geometry. This makes it possible to repeatedly deform the work piece so that severe plastic strains can be introduced into it to create nanostructures.

Bridgman [32] first studied aspects of SPD processing of materials in the 1940s and 1950s, and established basic knowledge of material responses to severe deformation [33]. However, it was the work of Segal et al. [34] on equal channel angular extrusion (ECAE) in 1981 that gave birth to SPD processing of nanostructured materials. As discussed later, ECAE is also referred to as ECAP. Segal demonstrated the concept of subjecting a work piece to simple shear in order to modify its microstructure and enhance its properties. The work of Valiev et al. [35–37] significantly advanced the ECAE technique and created a momentum in the research and development of various aspects of the ECAE process and ECAE-processed materials. Recently, several new SPD techniques have been developed for processing nanostructured metals and alloys. This chapter focuses on SPD research and developments since Segal published his first work in international archival literature in 1981.

### 2.1. Principle of Grain Refinement through Plastic Deformation

It is not clear how the nanostructures are formed during the SPD processes. To make the matter more complex, each SPD technique generates a unique deformation mode, which refines grains in its own unique way. Hansen and co-workers [38] have done extensive work on the grain refinement mechanism during rolling. Their work primarily focuses on the early microstructural evolution at low to medium strains, for example, less than 100%. Although their work focuses on the microstructural evolution during rolling, we found that the general concept also applies to other deformation modes [39]. However, the detailed microstructural evolution may vary with deformation mode. In this section, we will discuss the microstructural evolution at low to medium strains, following the work of Hansen et al. Grain refinement processes at higher strains has not been well studied, and will only be discussed briefly.

Plastic deformation refines grains by a combination of several mechanisms, including dislocation glide, accumulation, interaction, tangling, and spatial rearrangement. Several polycrystalline deformation models have been helpful in

understanding the grain refinement process, including Sach's zero constraint model [40], Taylor's full constraint model [41], and the relaxed constraint model [42]. For equiaxed grains, it is generally agreed that Taylor's model is most appropriate [42, 43]. According to Taylor's model, slip is uniform within each grain and strain compatibility is achieved by simultaneous operation of at least five slip systems. However, it was found that the deformation within each grain is often not uniform in real materials. Consequently, the Taylor model has been modified.

It has been observed that in coarse-grained fcc materials, such as copper, each grain is divided into many volume elements during plastic deformation [44–60] and there are differences in the number and selection of active slip systems among neighboring volume elements [48, 49]. Each volume element deforms under a reduced number (less than 5) of slip systems, but a group of adjacent volumes act collectively to fulfill the Taylor criterion. Each volume element is usually subdivided into cells with dislocations forming cell boundaries. For this reason, the volume elements are referred to as cell blocks (CBs). Dislocations from neighboring CBs meet at their boundaries and interact to form CB boundaries. This type of boundaries is called geometrically necessary boundaries (GNB) since they are needed to accommodate the misorientation in neighboring CBs. The dislocation cell boundaries are called incidental boundaries since they are generated by statistical mutual trapping of glide dislocations [48], often supplemented by “forest” dislocations [61].

The misorientations are very small across cell boundaries but are much larger across cell-block boundaries. With increasing strain, the misorientations across cell and CB boundaries increase, and the sizes of cell blocks become smaller due to further division. At a certain strain, the misorientation between neighboring cells becomes so high that additional slip system may be triggered in the cells, which converts incidental boundaries into GNBs and makes the dislocation cells act like CBs. Domains surrounded by GNBs, such as CBs and CB-like dislocation cells, are called subgrain structures, and the GNBs are also called subgrain boundaries [48]. With further strain, large subgrains may further divide into smaller subgrains, and the misorientation between subgrains may increase to form low-angle GBs and high-angle ( $>15^\circ$ ) GBs. The above theory reasonably explains rolling-induced microstructures in metals with a medium to high stacking fault energy such as Cu and Al [45–47, 54], although the formation of subgrain structure from dislocation cells has not been experimentally observed.

Once the grains and subgrains reach a minimum size, they cannot be further divided into smaller grains/subgrains under a certain set of deformation parameters such as strain rate and temperature. We believe that when sufficiently small, each grain/subgrain can only sustain one set of slip systems, and therefore will deform uniformly. However, each grain may not have five active slip systems as hypothesized in Taylor's model. Instead, these small grains may deform in a coordinated way. Also, when the grains are very small, grain boundary sliding and grain rotation may also play a role in the deformation, assisting the coordinated deformation. Further experimental and theoretical studies are needed to clarify these issues.

## 2.2. Severe Plastic Deformation Techniques

### 2.2.1. Equal Channel Angular Pressing

ECAP is the most developed among all SPD techniques. It is also referred to as ECAE and equal channel angular (ECA) processing. We use the term ECAP in this review because it most precisely describes the physical process.

As shown in Figure 1, an ECAP die contains two channels, which are equal in cross section and intersect each other at an angle of  $\Phi$ . An outer arc, with an angle,  $\Psi$ , connects the two channels [62]. As a work piece is pushed through the channel, the shear strain imposed on the work piece from each ECAP pass is [63]

$$\gamma = 2 \cot\left(\frac{\Phi}{2} + \frac{\Psi}{2}\right) + \Psi \operatorname{cosec}\left(\frac{\Phi}{2} + \frac{\Psi}{2}\right) \quad (1)$$

When the outer arc angle  $\Psi = 0$ , the shear strain becomes

$$\gamma = 2 \cot\left(\frac{\Phi}{2}\right) \quad (2)$$

The most widely used ECAP geometry is a channel intersection angle of  $90^\circ$  and an outer arc angle of  $0^\circ$ , that is,  $\Phi = 90^\circ$  and  $\Psi = 0^\circ$ , which results in a shear strain of 2.

To compare the strains introduced by different deformation mode, we need to use von Mises equivalent strain, which is defined as

$$\varepsilon = \sqrt{\frac{2}{3} \left( \varepsilon_x^2 + \varepsilon_y^2 + \varepsilon_z^2 + \frac{\gamma_{xy}^2 + \gamma_{yz}^2 + \gamma_{zx}^2}{2} \right)} \quad (3)$$

The von Mises equivalent strain after one ECAP pass is

$$\varepsilon = \left[ \frac{2 \cot\left(\frac{\Phi}{2} + \frac{\Psi}{2}\right) + \Psi \operatorname{cosec}\left(\frac{\Phi}{2} + \frac{\Psi}{2}\right)}{\sqrt{3}} \right] \quad (4)$$

**Figure 1.** An ECAP die with a channel intersection angle  $\Phi$  and an outer arc angle  $\Psi$ .

For the special case of  $\Phi = 90^\circ$  and  $\Psi = 0^\circ$  (see Fig. 2), the equivalent strain is 1.15. Because of its simplicity, this is the die geometry most researchers have used to study fundamental issues in ECAP processing [22, 64–89]. As shown, a work piece is subjected to a simple shear at the shear plane.

Since the ECAP process does not change the sample cross section after each pass, it is possible to process a work piece for many passes, provided that the work piece does not fracture during the ECAP process. The multiple ECAP passes make it possible to rotate the billet around its longitudinal axis between adjacent passes, creating different ECAP routes [68, 71, 73, 90–94]. Four rotation routes have been used to study the microstructural development during the ECAP [68, 71, 73, 90–94]. They are defined by the rotation scheme of the billet around its axis (see Fig. 3) between two consecutive passes: route A: the billet is not rotated; route B<sub>C</sub>: the billet is rotated 90° clockwise; route B<sub>A</sub>: the billet is rotated 90° clockwise and counterclockwise alternately; route C: the billet is rotated 180°. Although both round and square channel cross sections have been reported, the square cross-section channel is preferred for fundamental studies because it allows accurate rotation of the work piece in different ECAP routes.

It has been found that the efficiency in refining grains and forming nanostructures varies with ECAP route [65, 67–69, 71, 77, 92, 94, 95]. For a  $\Phi = 90^\circ$  die, route B<sub>C</sub> has been found most effective in refining grains [67–69, 71, 77]. For a  $\Phi = 120^\circ$  die, route A is found most effective [92]. The effectiveness in grain refinement by different ECAP routes may be related to the unique shear strain plane/path of each ECAP route [77] (Fig. 4). We shall only discuss the special case of  $\Phi = 90^\circ$  in this review. Readers are referred to [77, 92] for more details for the  $\Phi = 120^\circ$  case.

As shown in Figure 4, in route A the odd-numbered passes shear along a plane that is perpendicular to the shear plane of even-numbered passes. In route B<sub>C</sub>, the odd-numbered passes shear along a plane that is 60° to the shear plane of even-numbered passes. In route B<sub>A</sub>, the shear plane orientations are a mixture of those in routes A and B<sub>C</sub>. In route C, the shear plane does not change, but the shear direction in odd-numbered passes is opposite to those in even-numbered passes. Therefore, the shear strain produced in even-numbered passes reverses the strain in odd-numbered passes.

**Figure 2.** Schematics of an ECAP die with  $\Phi = 90^\circ$  and  $\Psi = 0^\circ$ . The sample is subjected to a shear strain of 2 at the shear plane.

**Figure 3.** Rotation schemes of four ECAP routes. Reprinted with permission from [77], Y. T. Zhu and T. C. Lowe, *Mater. Sci. Eng. A291*, 46 (2000). © 2000, Elsevier Science.

Not surprisingly, the unique shear planes (or paths) of an ECAP route affect how the work piece is deformed during the ECAP. Assuming a cubic element is pressed through an ECAP die, it will be sheared into different shapes by different ECAP routes [62]. After the first ECAP pass, the cubic element is elongated (see Fig. 5). Obviously, the first pass is the same for all ECAP routes. The second ECAP pass by route A elongates the element further (see Fig. 6). The element will be continuously elongated with more ECAP passes by route A [62].

The second ECAP pass in route B<sub>A</sub> and route B<sub>C</sub> deform the element in the same way (see Fig. 7). In route B<sub>C</sub>, the element will be restored to cubic shape after the fourth pass, and every 4 $n$ th pass thereafter, where  $n$  is an integer. Route B<sub>A</sub> will continue to elongate the element into filamentary shapes. The second ECAP pass in route C restores the element to the cubic geometry (see Fig. 8). Route C restores the element to the cubic shape at every even-numbered pass. Readers are referred to [62, 69] for more details.

The grains in a sample are deformed in a way similar to the way a cubic element is, at least in the first few ECAP passes. For example, after the second ECAP pass in route C, the grains were found restored to the initial equiaxed shape [68], as a cubic element would. However, subgrain structures

**Figure 4.** Shear-strain planes for each ECAP route for a die with  $\Phi = 90^\circ$ . The number on the shear plane indicates the sequence of an ECAP pass. Reprinted with permission from [77], Y. T. Zhu and T. C. Lowe, *Mater. Sci. Eng. A291*, 46 (2000). © 2000, Elsevier Science.

**Figure 5.** The deformation of a cubic element through the first ECAP pass.

were developed within initial coarse grains, although the shapes of initial coarse grains were not changed. For an ECAP die with  $\Phi = 90^\circ$ , substantial grain refinement is obtained after only one pass and the grain size usually reaches a minimum value after four passes. However, the fraction of high-angle grain boundaries continues to increase with further ECAP passes. It has also been found that ECAP route  $B_C$  is most effective in increasing the grain boundary angles [78] and produces most equiaxed grains, indicating that ECAP route affects the efficiency of grain refinement as well as nanostructural evolution.

ECAP has been used to process various metals and alloys, including Cu and Cu alloy [73, 96, 97], Al and Al alloys [65, 68, 71, 73, 91–94], Ni [90, 98], iron and steel [99–102], Ti and Ti alloy [74, 78], and W [103]. It has also been combined with other deformation techniques to obtain the best mechanical properties [104–106].

**2.2.2. High Pressure Torsion**

High-pressure torsion (HPT) is perhaps the most effective technique in grain refinement. It subjects a work piece to shear strain under high pressure. Two types of HPT processes have been reported [107]. One is unconstrained HPT (see Fig. 9), in which the sample is not contained on the side. This allows the sample to flow sideways during the HPT

**Figure 6.** The element is further elongated after the second ECAP pass by route A.

**Figure 7.** The deformation of an initially cubic element after the second ECAP pass in routes  $B_A$  and  $B_C$ .

processing. As a result, the sample thickness after HPT is not uniform, with the center of the sample thicker than the edge [108]. The nonuniform sample thickness also results in nonuniform pressure, with the highest pressure at the center of the sample.

Another type of HPT is constrained HPT, as shown in Figure 10 [31]. In constrained HPT, the sample is completely contained and a uniform sample thickness and pressure is maintained during the HPT process. Obviously, the constrained HPT is an improvement over the unconstrained HPT.

One major feature of the HPT process is the nonuniform deformation from the center of a sample to its edge [108]. The shear strain in an HPT-processed sample can be calculated as

$$\gamma = \frac{2\pi rn}{t} \tag{5}$$

where  $t$  is the sample thickness,  $r$  is the distance from the center of a sample disk, and  $n$  is the number of rotations in turns. Equation (5) can be easily applied to the constrained HPT (Fig. 10) because the thickness  $t$  remains constant. However, there could be slippage between the sample surface and the plunger and the lower die surface, making it difficult to know the real shear strain in the sample.

**Figure 8.** The second pass in route C restores the element to cubic geometry.

**Figure 9.** The schematics of an unconstrained HPT. Sample 3 is processed between heads 1 and 2.

As discussed earlier, for unconstrained HPT, due to the lack of side constraint, the sample flows in the radius direction during the process, resulting in a reduction of thickness. Moreover, the samples do not have a uniform thickness along the radius. The center of the sample is thicker than the edge. There may also be slippage between the sample and die surfaces (parts 1 and 5 in Fig. 9). These factors make it impossible to rigorously apply Eq. (5) to calculate the shear strain.

The microstructural evolution in Cu processed by unconstrained HPT has been studied by Jiang et al. [108]. Although Eq. (5) predicts a zero shear strain at the center of the sample disc, it is found that the grains are nevertheless refined and the microhardness increased at the center (see Fig. 11). Not surprisingly, the microstructure and hardness are not uniform from the center of the sample disc to its edge. Figure 11 shows the radial distributions of microhardness in copper discs processed by unconstrained HPT for varying turns. One can easily observe three salient features: (i) for all samples, the microhardness in the center is lower than that in the outer region, (ii) the microhardness increases with increasing number of HPT turns (strain), and (iii) near the outer edge, the microhardness does not

**Figure 10.** The schematics of a constrained HPT.

**Figure 11.** Radial distribution of the microhardness in Cu discs processed by HPT for varying turns.

change significantly with radial distance from the center. The microhardness saturation near the sample disc edge is attributed to the lower axial pressure and slippage, because the sample edge was thinner than the center.

No systematic studies on constrained HPT have been reported in the literature. It would be interesting to compare the evolution of microstructures and microhardness in materials processed by constrained HPT with that by unconstrained HPT.

In addition to being used for processing solid metals and alloys, HPT has also been used to consolidate powders and simultaneously produce nanostructures [23, 107, 109]. HPT generally can produce smaller nanograins than ECAP because of its high pressure as well as high strain.

### 2.2.3. Accumulative Roll Bonding

Accumulative roll bonding was developed in Japan in 1998 [27, 110–113]. Its principle is shown in Figure 12. As discussed before, the key to obtaining nanostructures through deformation is to keep the cross section of a work piece nearing constant. However, although rolling is one of the most efficient deformation techniques, it reduces the thickness of the work piece. The ARB technique solves this problem by stacking two sample sheets together. As shown in Figure 12, the process starts with cleaning the surface of metal sheets, stacking two sheets together, rolling the stacked sheets into the thickness of one sheet to bond them together, cutting the rolled sheet, and repeating the above cycle. This process cycle can be repeated many times until nanostructures are obtained. A critical step of the ARB process is the surface cleaning, which ensures that the two sheets bond well.

Figure 12. The principle of the ARB process.

### 2.2.4. Multipass Coin-Forging

Multipass coin-forging (MCF) is a new technique developed for producing nanostructured metals [28]. In the MCF process, a sample plate is deformed between two die platens with sine-wave-shaped grooves. The grooves indent the surface of the sample, producing a wavy surface, similar to coin-forging. The workpiece is then rotated and pressed again. The process can be repeated many times, thus the term multipass coin-forging.

MCF is a surface deformation technique, since the shallow grooves only deform the surface layer of a workpiece. However, as the surface layer is work hardened with increasing MCF passes, the workpiece is deformed progressively toward its center. Correspondingly, the grain refinement starts at the surface layer and progressively moves to the center of a work piece with increasing MCF passes.

### 2.2.5. Repetitive Corrugation and Straightening

Repetitive corrugation and straightening (RCS) was recently invented by Zhu et al. [29, 114]. Its principle is illustrated in Figure 13. One RCS processing cycle consists of two steps. The first step is carried out by deforming the work piece to a corrugated shape (Fig. 13), and the second step is accomplished by straightening the corrugated work piece between two flat platens. The processing cycle can be repeated many times. RCS has been used to process Cu, and effectively produced nanostructures in a Cu sample with an initial average grain size of  $760 \mu\text{m}$  [29, 39].

The RCS setup was initially designed to provide only bending deformation to the work piece. However, the setup in Figure 13 subjects the work piece to both bending and shear strain, which turns out to promote the grain refinement. Our recent results show that bending alone is not effective in refining grains because the bending strain is limited during each RCS cycle [115]. Recently, Shin et al. [116, 117] used a setup similar to Figure 13 to refine the grains of Al, and also found that the grains can be refined effectively.

The advantage of RCS is that it can be adapted easily to current industrial rolling facilities. It is not difficult to machine corrugating teeth onto the rollers of a conventional

Figure 13. Die and work-piece setup for discontinuous RCS process.

rolling machine, which creates a continuous RCS process. Such a process has the potential to produce nanostructured materials in a continuous, economic way. The RCS technique is currently in its infancy and further R&D is needed to develop it into a mature SPD technique for producing nanostructured materials.

## 3. NANOSTRUCTURES

Nanomaterials synthesized by SPD techniques have unique nanostructures. The grain size distribution usually follows a lognormal statistical function [23]. ECAP, especially route  $B_C$ , in which the work piece is rotated  $90^\circ$  clockwise between adjacent passes, can produce equiaxed grains (see Fig. 14) [31]. In small grains, very few lattice dislocations are observed; in grains of intermediate size, a high density of lattice dislocations exists; and in large grains, subgrains are observed [22]. The nanostructures of metals and alloys processed by ECAP and HPT techniques have been reported by many research groups [22, 65, 73, 118]. In the following section, the nanostructures in a copper sample processed by RCS is presented. Although nanostructures generated by different SPD techniques are expected to be different,

Figure 14. TEM micrographs of Cu after ECAP for 16 passes. Reprinted with permission from [31], R. Z. Valiev et al., *J. Mater. Res.* 17, 7 (2002). © 2002, Materials Research Society.

they are all produced by plastic deformation and therefore have some common features. We believe that most of the nanostructures discussed below are general structural features generated by SPD.

A pure Cu bar was processed by discontinuous RCS (see the setup shown in Fig. 13) [29]. The average grain size of the copper before RCS processing is  $760\ \mu\text{m}$ . The copper bar was immersed in liquid nitrogen for 3 minutes before each RCS cycle. The RCS cycle was repeated 14 times with  $90^\circ$  rotations between consecutive cycles along the longitudinal axis of the Cu bar.

The nanostructure of the RCS-processed copper observed under TEM is shown in Figure 15. It is seen that the grain size ranges from twenty to a few hundred nanometers. Most of the crystallites are separated by low-angle grain boundaries that consist of dislocation arrays, as pointed out by the black arrowheads. Boundaries separating grains with a misorientation less than  $15^\circ$  are defined as low-angle grain boundaries. High-angle grain boundaries also exist in many places, as marked by the long white arrows. Figure 15 also shows high dislocation densities in most of the new grains. In some of the larger grains, the distribution of dislocations is fairly homogeneous in the grain interior (see the grain marked H), while in other large grains dislocations form cell walls (see the grain marked C).

Subgrains exist in RCS-processed nanostructured copper [39]. As shown in Figure 16a, dense dislocation walls (DDWs) [44], which are almost parallel to the two sets of  $\{111\}$  planes, delineate a subgrain with a size of about  $250\ \text{nm}$ . High-density dislocations exist inside the subgrain and are forming cell structures. Figure 16b is a high-resolution TEM (HRTEM) image of the DDW subgrain boundary at the point marked by an arrowhead in Figure 16a. The dislocation density is estimated as  $3 \times 10^{17}\ \text{m}^{-2}$  at

**Figure 15.** TEM micrograph shows nanostructures in copper processed by RCS.

**Figure 16.** (a) A TEM micrograph of a subgrain; (b) an HRTEM image from the DDW as pointed out by an arrowhead in (a). The dislocations are glissile type. The longer arrow points out the grain boundary orientation. The black and white circles mark interstitial and vacancy loops, respectively. Reprinted with permission from [39], J. Huang et al., *Acta Mater.* 49, 1497 (2001). © 2001, Elsevier Science.

the DDW. Interstitial loops (marked by black circles) and vacancy loops (marked by white circles) also exist. The dislocations are mostly glissile type. In addition, the lattice planes near the cell walls are heavily distorted. The misorientation across the subgrain boundary is measured as about  $5^\circ$ . There are significantly more dislocations than required to accommodate the misorientation. Thus, this subgrain boundary is in a nonequilibrium state.

Both equilibrium and nonequilibrium grain boundaries (GBs) exist in nanostructured materials synthesized by SPD. Shown in Figure 17a is a low-angle GB with a misorientation of  $9^\circ$  in RCS-processed Cu [39]. HRTEM images from the upper-left frame are shown in Figure 17b. Figure 17c is a structural model for the low-angle GB in Figure 17b. It is seen from Figure 17c that two types of dislocations, marked with T and  $\bar{T}$  respectively, are needed to accommodate the geometrical misorientation. In other words, these are geometrically necessary, or intrinsic, dislocations [22]. Figure 17b clearly shows three more T-type dislocations than Figure 17c does, which indicates that three extrinsic (or non-geometrically necessary) dislocations exist at the GB shown in Figure 17b. Therefore, this segment of low-angle GB is in a high-energy configuration and should be called nonequilibrium GB. On the other hand, Figure 17d shows that the GB in the lower-right frame is in an equilibrium state with no extrinsic dislocations.

**Figure 17.** (a) A TEM micrograph of a low-angle GB; (b) and (c) an HRTEM image and a structural model of the GB in the upper-left frame in (a); (d) an HRTEM image of the GB in the lower-right frame. Figure 18 shows a TEM micrograph of a grain with a diameter of about 500 nm in RCS-processed Cu [39]. A number of fine structures were observed in the interior of the grain. As pointed out by two arrowheads, an array of dislocations piled up along the (111) plane. Consequently, two subgrains (denoted by 1 and 2) with a misorientation of about  $1^\circ$  were produced. A low-angle GB was also found in this grain, as marked by four stars. The low-angle GB was formed by the accumulation of a number of glissile dislocations. It is not edge-on but overlapped, as revealed by the periodic Moiré fringes. The misorientation of the two grains as measured from an HREM image is about  $5^\circ$ .

Dislocation cell structure was also observed in subgrain 3 in Figure 18. These cells may form individual subgrains upon further plastic straining. Dislocation tangling was frequently observed in the interior of grains, as marked by a white circle, where the grain is heavily strained. Such a region was referred to as dislocation-tangle zone (DTZ). In the area marked by a white square, dislocation cells are forming from tangled dislocations.

## 4. PROPERTIES

### 4.1. Mechanical Properties

It is well known that plastic deformation induced by conventional forming methods such as rolling, drawing, or extrusion can significantly increase the strength of metals [119, 120]. However, this increase is usually accompanied by a loss of ductility. For example, as shown in Figure 19, with increasing

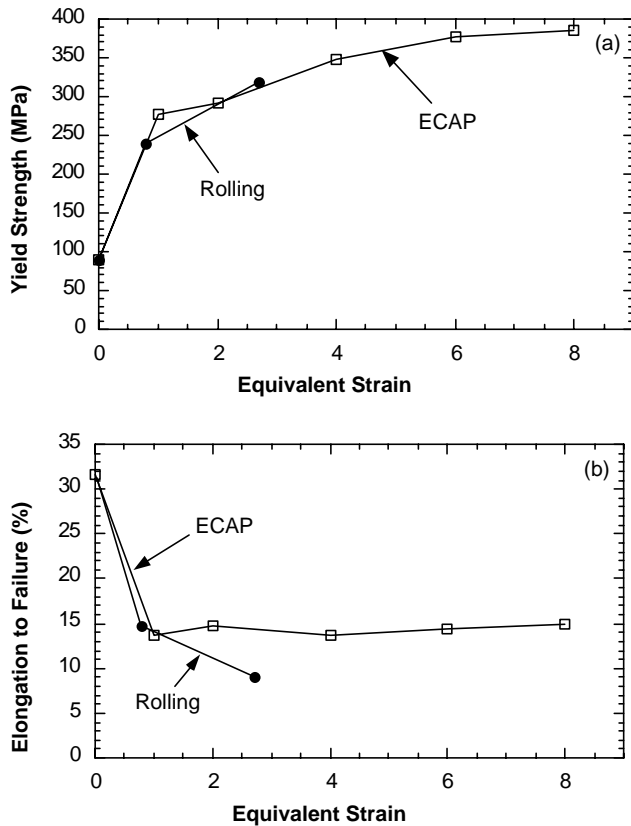

**Figure 18.** A TEM micrograph showing fine deformation structures in a grain. The numbers 1, 2, and 3 denote three subgrains; the two arrowheads point out an array of dislocations; the four stars mark a low-angle GB; the white circle marks a dislocation tangle zone (DTZ); the white square marks a transition from DTZ to dislocation cells. **Figure 19.** With increasing rolling strain, the yield strengths of Al, Cu, and a Cu alloy increase but their ductilities decrease.

rolling strain, the yield strengths of Al, Cu, and Cu-0.32Ag alloy monotonically increase, accompanied by a monotonic decrease in ductility (elongation to failure). The same trend is also true for other metals and alloys. Note that for heavily rolled metals, the ductility could slightly increase with increasing rolling strain. However, this increase is very limited and the overall ductility is usually very low. For example, elongation to failure of pure Ni and Al increased from 1.2% to 4% and from 6% to 8%, respectively, when the rolling strain increased from 4 to 6 for Ni and 2 to 4 for Al [121].

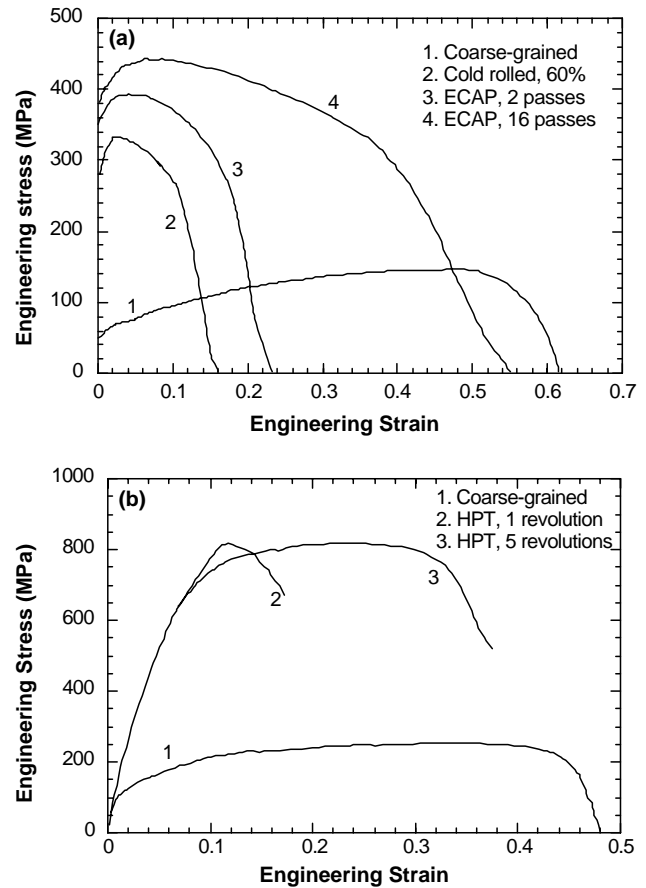

In contrast, nanostructured metals and alloys processed by SPD techniques such as ECAP and HPT have demonstrated high strength, while retaining high ductility. Horita et al. [122] compared the strength and ductility of 3004 aluminum alloy processed by ECAP and cold rolling. As shown in Figure 20, for both cold-rolled and ECAPed 3004 alloy, the yield strength increased monotonically with increasing equivalent strain imparted into the alloy by cold rolling or ECAP. However, the ductility of the alloy demonstrated different trends for the two different processing methods. Note that in Figure 20, each ECAP pass imparts an equivalent strain of 1. After one ECAP pass (a strain of 1), the elongation to failure (ductility) of the 3004 alloy decreased from 32% to about 14%. Further ECAP passes (or larger ECAP strains) did not decrease the ductility further. In contrast, the cold rolling decreased the ductility of the 3004 alloy in a similar magnitude initially, but further decreases the ductility with increasing rolling strain, although at a slower rate. This demonstrates that the deformation mode (or strain path) has a significant effect on the ductility of the metals. Cold rolling introduces plastic strain into the work piece with one deformation mode (strain path), while ECAP changes the strain path by rotating the work piece  $90^\circ$  clockwise between two adjacent passes (ECAP route B<sub>C</sub>) [77, 122]. Consequently, the ECAP processing resulted in equiaxed grains, in contrast to the elongated grains typically produced by cold rolling. The different microstructure as well as texture rendered remarkably different ductilities.

**Figure 20.** Comparison of yield strength and ductility of the 3004 Al alloy processed by cold rolling and ECAP [122].

The high ductility of the ECAP-processed metals is highly desired for structural applications.

Recently, even higher ductility was found in copper and titanium processed by ECAP and HPT to a higher strain [31]. Pure Cu (99.996%) was processed using ECAP with 90° clockwise rotations along the billet axis between consecutive passes, while pure Ti (99.98%) was processed using HPT. All processes were performed at room temperature. Strength and ductility were measured by uniaxial tensile tests performed using samples with gauge dimensions of  $5 \times 2 \times 1$  mm. Resulting engineering stress-strain curves are shown in Figure 21. Results for Cu tested at room temperature in its initial and three processed states are shown in Figure 21a. The initial coarse-grained Cu, with a grain size of about  $30 \mu\text{m}$ , has a low yield stress but exhibits significant strain hardening and a large elongation to failure. This behavior is typical of coarse-grained metals. The elongation to failure is a quantitative measure of ductility, and is taken as the engineering strain at which the sample broke. Cold rolling of the copper to a thickness reduction of 60% significantly increased the strength (curve 2 in Fig. 21a), but dramatically decreased the elongation to failure. This is consistent with the classical mechanical behaviour of metals that are deformed plastically [123, 124]. This tendency is also true for Cu subjected to two passes of ECAP (curve 3 in Fig. 21a). However, further deforming the Cu to 16 ECAP passes simultaneously increased both the strength and the ductility (curve 4 in Fig. 21a). Furthermore, the increase in ductility is much more significant than the increase in

**Figure 21.** Tensile engineering stress-strain curves of (a) Cu tested at 22 °C and (b) Ti tested at 250 °C. Both were tested at a strain rate of  $10^{-3} \text{ s}^{-1}$ . The processing conditions for each curve are listed on the figure. Reprinted with permission from [31], R. Z. Valiev et al., *J. Mater. Res.* 17, 7 (2002). © 2002, Materials Research Society.

strength. Such results have never been observed before and challenge our current understanding of mechanical properties of metals processed by plastic deformation.

Similar results were also observed in Ti samples subjected to HPT, which were tested in tension at 250 °C. The coarse-grained Ti with a grain size of  $20 \mu\text{m}$  exhibits a low strength and a large elongation to failure (curve 1 in Fig. 21b). After being processed by HPT for 1 revolution, the Ti material had a very high strength but significantly decreased ductility. Further HPT processing to 5 revolutions dramatically increased the ductility and slightly increased the strength (curve 3 in Fig. 21b).

Figure 21 shows that small SPD strains (2 ECAP passes or 1 HPT revolution) significantly increase the strength at the expense of the ductility, which is consistent with the results shown in Figure 20, while very large SPD strains (16 ECAP passes or 5 HPT revolutions) dramatically increase the ductility and at the same time further increase the strength. This is contrary to our classical understanding of the mechanical behavior of metals that were deformed plastically. Greater plastic deformation by conventional techniques such as rolling, drawing, or extrusion introduces greater strain hardening, which in turn increases the strength, but decreases the ductility of the metal. The extraordinary mechanical

behavior in metals processed by SPD at high strains suggests a fundamental change in deformation mechanisms. It also suggests the possibility of tailoring the microstructures through SPD to obtain superior mechanical properties.

It is not clear what nanostructures are responsible for the excellent ductility shown in Figure 21. In most SPD-processed nanomaterials, good ductility is maintained with high strength. The mechanical behavior of nanostructured Ti processed through warm ECAP + cold rolling was studied by Jia et al. [125]. It has a high yield strength of  $\sim 900$  MPa and a good ductility of about 9% (much higher than that for typical cold-rolled Ti). There was no strain hardening in the compressive stress-strain curve except at the beginning when the strain is less than 0.05. Early necking was observed in the tensile stress-strain curve. The strain rate sensitivity was found to be lower than that of coarse-grained Ti. The good ductility was observed despite the lack of strain hardening and low strain rate sensitivity. Significant post-necking strain was observed, indicating excellent resistance to fracture during the necking process. SEM micrographs of fracture surfaces show that the nanostructured Ti formed much finer voids than the coarse-grained Ti, which explains the high fracture resistance of nanostructured Ti [126].

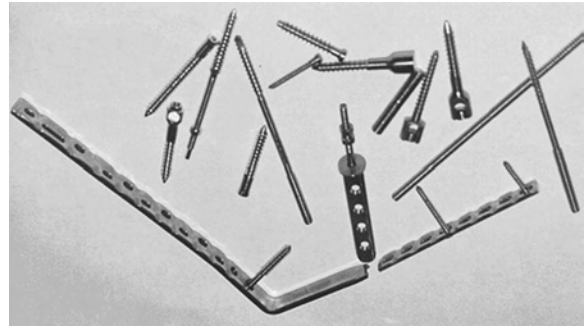

## 4.2. Superplasticity

Superplasticity is a material behavior in which a material sustains a tensile strain of hundreds to thousands percent without failure. Such behavior is usually observed in materials with micrometer-sized grains at a relatively high temperature ( $0.5\text{--}0.6 T_m$ ) and low strain rate ( $10^{-3}$  to  $10^{-4}$ ), where  $T_m$  is the melting temperature of the material [22]. Due to their fine grain size, nanostructured materials processed by SPD exhibit superior superplasticity at higher strain rate and lower temperature [22, 67, 72, 97, 127–132].

Pure nanostructured metals have low thermal stability, and therefore are not suitable for superplastic deformation [22]. It is critical to maintain a stable grain structure during the superplastic deformation, which will be destroyed by excess grain growth. McFadden et al. observed superplasticity in nanostructured Ni, intermetallic  $\text{Ni}_3\text{Al}$ , and Al alloys processed by SPD at low temperatures [131]. They also observed moderate grain growth during the superplastic deformation of nanostructured materials, due to the unstable nature of nanostructures in these materials.

**Figure 22.** Plate-implants for bone osteosynthesis made of nanostructured Ti.

**Figure 23.** Various medical implants and devices made of nanostructured Ti.

Horita et al. [127] observed superplasticity with a maximum elongation of 2280% in an Al-3%Mg-0.2%Sc at  $400^\circ\text{C}$  and a high strain rate of  $3.3 \times 10^{-2} \text{ S}^{-1}$ . An Al-3%Mg-0.2%Sc-0.12%Zr alloy processed by ECAP exhibited excellent thermal stability at  $500^\circ\text{C}$  and was superplastically deformed to an elongation of 1680% at  $500^\circ\text{C}$  and a strain rate of  $\times 10^{-2} \text{ S}^{-1}$  [128]. Nanostructured Cu-based alloys processed by ECAP also showed superplasticity [133].

## 5. APPLICATIONS

SPD can produce nanostructured materials in bulk form large enough for structural applications. With their superior mechanical properties, nanostructured materials produced by SPD are very attractive in applications such as medical devices and implants such as stents, prosthetics, bone screws and dental implants, sport goods such as golf clubs and bicycle frames, as well as aerospace structures. Due to their high production costs, the realistic applications of SPD-processed nanostructured materials will be in the high-valued medical market in the near term. ECAP is so far the most developed SPD technique and produces relatively large bulk nanostructured materials (see Fig. 24).

As more economical SPD techniques are developed, such as continuous ECAP and RCS, nanostructured materials will be cost competitive in other lower-valued markets. Pilot medical implants and devices have already been developed in a joint project between Los Alamos National Laboratory

**Figure 24.** An ECAP processed Ti rod, which is about 50 mm in diameter and 170 mm in length.

and Russian institutes (see Figs. 22 and 23) [134]. These medical implants, made of nanostructured Ti, are already on medical trials in Russia.

## 6. CONCLUDING REMARKS

Severe plastic deformation has great commercial potential for producing nanostructured materials for structural applications. Among all the SPD techniques, ECAP is the most developed and can so far produce the largest bulk nanostructured materials. However, ECAP is a discontinuous technique, which makes it a labor-intensive and relatively expensive process. Continuous ECAP and other continuous SPD techniques such as RCS are currently being developed, which may pave the way for large-scale applications of nanostructured materials.

Nanostructured materials show a combination of high strength and good ductility. However, the relationship between nanostructures and the mechanical properties is not well understood. It is possible to obtain both high strength and high ductility in nanostructured materials processed by SPD by tailoring their nanostructures. However, better understanding of structural-property relationship is needed before it is possible to optimize the nanostructures for optimum mechanical properties.

## GLOSSARY

**Accumulative roll bonding (ARB)** An SPD technique with each process cycle consisting of roll-bonding metal sheets and then restacking them for the next roll bonding.

**Bottom-up approach** An approach that builds bulk nanostructured materials from individual atoms or nanoscale building blocks.

**Constrained HPT** An HPT technique with the work piece fully constrained on all sides.

**Equal channel angular pressing (ECAP)** An SPD technique in which a work piece is pressed through two channels that are equal in cross section and intersect each other at an angle. It is also referred to as equal channel angular extrusion (ECAE).

**ECAP route A** A route that does not rotate the work-piece billet between adjacent ECAP passes.

**ECAP route B<sub>A</sub>** A route that rotates the work-piece billet 90° clockwise and counterclockwise alternately.

**ECAP route B<sub>C</sub>** A route that rotates the work-piece billet 90° clockwise.

**ECAP route C** A route that rotates the work-piece billet 180°.

**Equilibrium grain boundary** A grain boundary that contains only crystalline defects, such as dislocations, that are necessary for accommodating the grain misorientation across the boundary.

**Extrinsic dislocations** Dislocations that are at or near a grain boundary but are not needed for accommodating the grain misorientation across the boundary.

**Geometrically necessary boundary (GNB)** A boundary that separates two subgrains with two different sets of active slip systems.

**High-angle grain boundary** A boundary with the two grains across it having a misorientation higher than 15°.

**High-pressure torsion (HPT)** An SPD technique that refines metal and alloys into nanostructured materials by torsion under high pressure.

**Intrinsic dislocations** Dislocations that are required for forming a grain boundary.

**Multipass coin-forging (MCF)** An SPD technique that repetitively deforms the surface layer of a work piece so that grains are refined progressively from the surface of a work piece to its center.

**Nanostructured materials** Solids with nanoscale (1–100 nm) structural domains in at least one dimension.

**Nonequilibrium grain boundary** A grain boundary that has higher energy than minimum energy required by the grain misorientation across it.

**Repetitive corrugation and straightening (RCS)** An SPD technique that refines the grains of metals and alloys by repetitively corrugating and straightening them.

**Severe plastic deformation (SPD)** Techniques that refine coarse-grained metals and alloys into nanostructured materials by imparting extremely large plastic deformation into them.

**Subgrains** Volumes formed inside a grain by plastic deformation, with each volume (subgrain) containing one set of active slip systems. Subgrain boundaries are geometrically necessary boundaries.

**Top-down approach** An approach that refines existing coarse-grained materials into nanostructured materials.

**Unconstrained HPT** An HPT technique with the side of the work piece unconstrained.

# Nanomaterials for Cell Engineering

Xiaoyue Zhu, Tommaso F. Bersano-Begey, Shuichi Takayama

University of Michigan, Ann Arbor, Michigan, USA

## CONTENTS

1. Introduction
  2. Nanoscale Biological Recognition and the Cellular Nanoenvironments
  3. Materials with Controlled Nanogeometry
  4. Materials with Controlled Nanochemistry
  5. Materials with Controlled Nanomechanics
  6. Conclusion and Future Prospects
- Glossary  
References

## 1. INTRODUCTION

If we were to look from a sufficient distance, we would not be able to distinguish between a plain gray surface and the blurring of black texts and white background on a page of a book. However, it is exactly these minute features (the letters and their precise arrangement into words and sentences) that give meaning to a book. The same is true for cells and the materials they secrete or interact with. Any attempt to engineer cells for tissue reconstruction, biomedical research, and applications has to start from recognizing the role played by the nanoscale elements around the cells, because the cells “read” and interact with surrounding surfaces, materials, and other cells at this scale.

Nowhere else is nanotechnology more at work than in living organisms. The genetic information of living organisms is encoded on a 2 nm wide nucleic acid “tape” called deoxyribonucleic acid (DNA) [1]. This information is translated into machineries called proteins, which have average dimensions ranging from 3 to 150 nm [2]. Proteins can function individually as chemical factories (enzymes) [3], molecular motors (kinesins) [4], and docking modules (receptors and adaptor molecules) [3]. Multiple proteins, nucleic acids, and other molecules can assemble into larger complexes (tens to hundreds of nanometers in size) to fulfill more complicated functions such as supporting cell structure and movement, functioning as railroad tracks to transport cellular cargos (microtubules) [5], serving as pipes and valves (ion channels) [6], generating power or pumping ions (adenosine

triphosphatases) [7], acting as sources and sensors for light (rhodopsins) [8], heat transient receptor potential cation channel, subfamily M, member 8 (TRPM8s) [9], electricity [10], tension [11], and chemicals [3], and translating messenger RNA information into amino acid sequences to produce proteins (ribosomes) [12]. Electron tomography, which allows visualization of intact cell organelles and the dynamic reorganization of cell architecture in three dimensions [13], reveals that the 80 S ribosomes are ~27 nm in size and 26 S proteasomes are ~45 nm in length in *Dictyostelium* cells [14].

Many cellular activities require nanoscale machineries. For example, the cell membrane has nanometer scale channels that only allow ions and molecules of a certain size, charge, and polarity to pass through [15, 16]. The channels can achieve such selectivity because their pore sizes are on the same order as those of the molecules that pass through them [17]. The selectivity helps to maintain a steady intracellular environment in terms of pH and concentrations of ions and molecules. The concentration gradients of potassium, sodium, and calcium ions maintain a constant electric potential across the membrane that regulate many cellular phenomena including the function of neuronal cells [18]. In another example, molecular motors and cytoskeletal movements minimize energy requirements by taking advantage of Brownian motion. These molecular devices are nanoscale ratchets—structures that only allow movement in one direction. The molecular ratchets use random molecular vibration of Brownian motion to generate directed movement of cellular machineries with minimal energy cost [19].

The extracellular environment is highly controlled and is as dependent on nanoscale features and structures as the internal cellular components are. With the exception of single cell organisms such as bacteria, cells are “designed” to live in an ordered architecture to form tissues, in which cells interact with each other and communicate with the extracellular environment. Cells maintain their structures and perform coherent functions inside tissues under the guidance of nanoscale materials outside the cells, which are collectively termed the extracellular matrix (ECM) [20]. The ECM is a matrix composed of a variety of proteins and carbohydrates that have nanoscale structures and organizations that can be recognized by cells [2]. The ECM directs complex,

cooperative events such as embryogenesis [21] and organogenesis [22]. Cells respond to cues presented by topographical features [23], chemical patterns [24], and mechanical characteristics [25] of the ECM [26].

Cells constantly monitor their environments to decide their behavior [3, 27]. A large majority of cells are adherent and cell-ECM interactions are crucial in determining cell functions such as growth [28], development [29], and wound healing [30]. Abnormal cell-ECM interactions can cause diseases such as cancer and other functional defects [31]. Because the basic features of cells and the ECM lie in their nanoscale composition, it is necessary to understand, match, and manipulate these nanoscale features to control and induce certain desired cell behaviors. The development of nanoscale materials is crucial for engineering cells in applications such as tissue engineering, cell-based assays for drug delivery, and studies of basic cell biology and mechanisms of disease [24, 32–34].

This chapter describes recent work in developing nanoscale materials for engineering cells and is organized as follows. Section 2 gives an overview of the cellular nanoenvironment and the cell-ECM interactions in more detail. Sections 3, 4, and 5 address efforts to synthesize materials with nanoscale topography, nanoscale chemical patterns, and nanoscale mechanical properties that mimic the natural ECM. Section 6 discusses future prospects for nanomaterials in engineering cellular functions.

## 2. NANOSCALE BIOLOGICAL RECOGNITION AND THE CELLULAR NANOENVIRONMENTS

The majority of the cells in our body need to attach to appropriate substrates, such as the ECM, to survive and function properly [20, 35]. The ECM surrounds anchorage-dependent cells, connects them into tissue structures [36], and influences tissue development [2], cell migration [37], proliferation [35, 38, 39], and morphology [40]. Figure 1 shows some of the important nanoscale interactions between cells and the ECM.

Reflecting its complex regulatory function, the ECM has a correspondingly diverse composition [41] and a three-dimensional (3D) structural organization [26, 42, 43]. *In vivo* (that is, within a living organism), the ECM is made and oriented mainly by fibroblasts or other cells that produce ECM precursor molecules. The precursor molecules are chemically processed (enzymatically cleaved, sulfated, oxidized, and cross-linked) as they assemble with other components of the ECM [41]. After initial assembly, cells further rearrange the ECM molecules through physical interactions. For example, even *in vitro* (that is, in an artificial environment outside the living organism), fibroblasts mixed with a meshwork of randomly oriented collagen fibrils will tug on the collagen and cause the fibers to align into nanolines [44–47] (Fig. 1E). The assembly of this matrix is thus a highly regulated and dynamic process that results in distinct structures at the molecular, nanometer, and micrometer length scales. The relative amounts of the different matrix components and the ways they are organized into the extracellular matrix

**Figure 1.** Interactions between cell and substrate. The large image in the center (A) shows a conceptual view of the interaction interface between a cell and the extracellular matrix. Both surfaces have unique nanogeometry, nanochemistry, and nanomechanics and are patterned with proteins. The matrix of basal lamina is composed of type IV collagen proteins shown in (B), assembled together through lateral (lines) and C-term (circles) interactions to form a rigid 2D network similar to a grid. (Other matrix configurations found in the skin, tendon, bone, and other tissues use fibrillar collagen forms instead, which is not shown). Once a 2D grid plane is assembled, the N-term domain (arrows) from each monomer induces the formation of multiple 2D grid layers. The nanoscale mesh formed by collagen and other matrix proteins is essential for many of the nanomechanical and nanochemical mechanisms exhibited by cells. The relative rigidity of the grid-like nanostructures, for example, allows cells to migrate or crawl by forming and releasing new bonds with the matrix and pulling on them (F). In addition, since the junctions of the grid can be more easily pivoted than stretched, cells can also remodel the matrix by pulling on parts of it so that these distortions propagate through it (E). Migration is involved in many important cellular processes such as wound healing and organ formation. The density and arrangement of receptor binding between cells and matrix or between cells themselves (G) can also act as signals for apoptosis (programmed cell death), contact inhibition of growth, differentiation into different cell types, and cell polarization, in which cells form different structures on different sides of the cell, as determined by their arrangement with respect to substrates such as basal lamina and other surrounding cells. The connection between matrix proteins such as collagen and the cell interior is formed by cell surface receptor proteins such as integrin (C). Integrins connect through adaptor proteins to a complex 3D mesh inside the cell, called the cytoskeleton (D). The cytoskeleton is essential for maintaining cell shape and anchoring cell surface receptors such as integrins on the membrane surface. The cell can rearrange its cytoskeleton by inducing polymerization or depolymerization of the filamentous actin (F-actin) to lengthen or shorten them. The resulting changes in the cytoskeleton can be used to push or pull on the integrins and on the matrix and substrate connected to it and thus allow the cell to crawl or rearrange the substrate.

give rise to an amazing diversity of forms, each adapted to the functional requirements of particular tissues [41].

Cells “read” these ECM cues through cell surface receptors. One of the critical adhesion receptors is integrin (Fig. 1C). It is named based on its function as an integrator of the ECM and the cytoskeleton (“cell bones,” Fig. 1D) [47, 48]. Integrins are a family of heterodimeric receptors. They extend across the cell membrane and mediate communication between the cells and the ECM by translating features of extracellular materials into intracellular signals [47–49]. There are three levels of integrin signaling: (i) molecular recognition of specific ligands at the single integrin level [50], (ii) nanometer scale recognition of clusters of ligands that leads to aggregation of integrins [51], and (iii) mechanical signaling where clusters of integrins separated by micrometers serve to transmit forces through the cell [49].

The ECM must display appropriate ligands for receptors such as integrins to bind to them [52]. Having the right ligand available, however, does not guarantee desired responses from cells. Even with the same total number of ligands, the response of a cell can be totally different depending on the nanometer scale organization of the ligands (Fig. 3). For example, Griffith et al. [53] studied cell proliferation and migration on dendrimers with different numbers of ligands per dendrimer. Compared with solitary integrins, the integrin clusters that assembled around dendrimers presenting multiple RGD (Arg-Gly-Asp peptides) ligands differed in their ability to recruit adaptor proteins and cytoskeleton components to the intracellular portion of integrins. In another study, RGD ligand density at a substrate surface was shown to be critical for inducing C2C12 skeletal myoblast (muscle precursor cell) differentiation (Fig. 1G) [51, 54–56]. The ECM also regulates cells through mechanical signaling. Ingber et al. [57–59] performed a number of elegant studies that correlated cell growth, death, and differentiation with mechanical signaling on artificially engineered substrates, focusing particularly on cell shape. Results showed that micropatterns of cell-adhesive proteins on a material can regulate cell growth, apoptosis, and differentiation through control of cell shape and cytoskeleton tension.

In humans and other animals, abnormal ECM can influence embryonic development, cell polarity, migration, differentiation, growth, tissue organization, and wound regeneration [28–30, 60]. Invasiveness of tumor cells also depends critically on the nature of the ECM material surrounding the cells. The loss of ECM binding in epithelial cells is often a sign of tumor aggression [61–63].

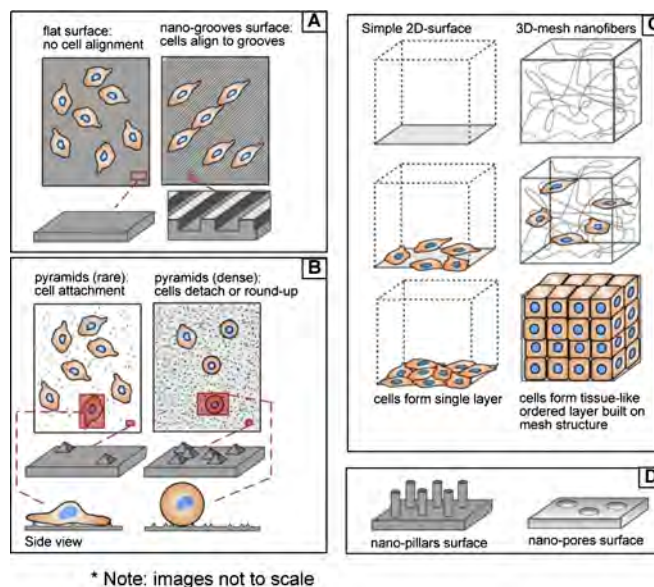

The importance of understanding nanoscale environments and the corresponding cellular behaviors has led to the development of man-made materials that mimic certain aspects of the ECM. These materials allow controlled, systematic perturbation and analysis of the crucial environmental cues to elicit specific cellular responses. Such efforts can be divided into three categories; study of nanometer-sized (i) structural features, (ii) chemical and molecular patterns, and (iii) mechanical properties. There are major challenges in engineering such materials due to the small size scale and high spatial resolution that are prerequisites for mimicking the ECM. In contrast to the highly regulated and

complex nanoscale organization of the ECM *in vivo*, conventional biomaterials commonly present unorganized micro- and nanoenvironments to cells.

The following three sections and Table 1 summarize the current knowledge on man-made nanomaterials used for cell engineering. The sections focus on the nanoscale geometrical structures, chemical patterns, and mechanical properties of the materials. They also summarize the techniques used to fabricate the nanomaterials.

### 3. MATERIALS WITH CONTROLLED NANOGOMETRY

One of the steps necessary to mimic physiological cellular environments is to study the nanogeometry of the ECM. Topographical features of the ECM have been explored with scanning electron microscopy, transmission electron microscopy, and atomic force microscopy. These studies have revealed that the ECM is a mesh of various fibrils that create topographical features such as pores, ridges, and grooves at nanometer scale [64] (Fig. 2). For example, in the porcine carotid artery, the surface topography of the ECM has feature heights of approximately  $1\ \mu\text{m}$  [65] whereas the ECM of the primate corneal epithelia has average feature

**Figure 2.** Nanofabricated synthetic features can affect cells by mimicking topography present on biological surfaces. Structures with different geometries affect cellular processes such as attachment and focal adhesion generation, cell alignment, and tissue formation. For example, a surface with embedded nanogrooves (A) causes cells to align and grow in the direction of the grooves similar to how certain cells align based on structural cues in biological tissues. (Nanowaves have a similar effect on cells even though they only possess rounded corners unlike the sharp corners on grooves). Pyramids (B) can interfere with focal adhesion formation and if present in sufficient density can cause cells to detach. (Rough surfaces and nanopillars (D) can have similar effects by presenting a surface that does not have sufficient contiguous space for cells to make functional focal adhesion point.) Three-dimensional meshes of ECM or polymer-based fibers (C) can act as scaffolds and allow cells to form tissue-like 3D constructs.

heights of 147–191 nm [66, 67]. In general, the average diameters of ECM fibers range from 3 to 500 nm in different species and tissues [2].

The bulk of nanomaterials research that is aimed at engineering cell function has been focused on controlling nanogeometry. These efforts are aided in large part by fabrication technology developed in the semiconductor industry. Commonly used techniques include photolithography, laser holography, chemical vapor deposition, various etching procedures [8, 68], and soft lithography [69]. In addition, isolation techniques (extracting ECM from tissues) allow incorporation of natural ECM components into artificial materials [66, 67].

A range of different nanoscale geometries have been engineered to mimic those of the ECM [70–72]. These surfaces include features such as fibers, groove/ridges, cliffs, pores, pillars, and pits. Some features, such as pillars, are seldom observed in physiological environments [73, 74]. Nonetheless, such artificial features are still useful in studying and engineering cellular behavior and in inducing or preventing cell attachment [75].

Collagen, one of the most abundant ECM components, plays a major role in determining the nanogeometrical features of ECM. Collagen forms fibrils and bundles of fibrils, which are three to hundreds of nanometers in diameter [41]. A variety of 3D architectures of collagen fibers are seen in different tissues, such as parallel bundles (in muscle, tendons, and ligaments), basket-weaves (in skins and bones), and orthogonal lattices (in corneas) [41, 76] [Fig. 1B shows an example of how collagen IV monomers assemble into stacked two-dimensional (2D) grids in basal laminae]. Fibrils of collagen are known to cause myoblasts, endothelial cells, and other types of cells to align [77]. Other components that comprise the ECM are proteins such as fibronectin and laminin and heavily glycosylated macromolecules such as glycosaminoglycans and peptidoglycans. Different features resulting from diverse combinations of these components give rise to specific cellular responses such as adhesion, orientation, proliferation, and differentiation.

The following paragraphs describe studies in which engineered nanogeometrical features were used to elicit specific responses from cells. Our definition of nanogeometry is material features that have at least one dimension that is equal to or less than 1  $\mu\text{m}$  (1000 nm). There are many studies that use larger, microscale structures to control cell behavior, but these are not included in this chapter because of space limitations and also because they have been reviewed extensively elsewhere [8, 64, 78].

### 3.1. Effect of Nanogeometry on Cells

#### 3.1.1. Nanofibers

One of the most direct ways to mimic the ECM architecture is to construct nanofibrous materials (Table 1). The cellular response to a number of nanofibers features has been investigated. For example, a meshwork of poly(lactic-co-glycolic acid) (PLGA) fibers guides cell spreading and motility as 3D tissue engineering scaffolds [72]. Osteoblasts increase proliferation with the decreasing diameters of the carbon fibers [32]. Further correlation between cellular responses

and reconstructed ECM-like nanofiber features are under investigation by multiple groups.

#### 3.1.2. Nanogrooves

Grooves are another type of engineered surface features that are commonly used to study the effect of surface topography on cell behavior (Fig. 2A). Many cell types elongate and orient in the direction of the grooves, whereas some align perpendicular to the grooves and others do not align at all (Table 1). Cellular response to nanoscale grooves can be used to study the mechanism of tissue formation. Clark et al. used groove features to investigate myogenesis (formation of muscle). It was discovered that myoblasts had a strong tendency to orient and elongate themselves along ultrafine grooved surfaces. Although such topographical features restrict the movement of myoblasts in one direction and inhibit lateral contact between cells, the linear aggregation of myoblasts still occurred and led to the fusion of mononucleated myoblasts into myotubes. Combined with results from a different experiment in which myoblasts were observed to form myotubes of constant diameter independent of the degree of lateral contact with other cells [167], studies using ultrafine grooves suggested that end-to-end interaction between myoblasts is the critical aspect for myotube formation [101]. Nanoscale grooved features have also been used for investigating the alignment of other cell types such as fibroblasts and adhesion and phagocytic activity of macrophages [75].

#### 3.1.3. Rough Surfaces

Surface roughness is another type of surface geometry. Rough surface features include waves, hills with round edges, and other features that are less well defined with respect to shape and uniformity (in comparison to fibers and grooves). The features are often created by molding or by less-controlled fabrication methods such as grinding, polishing, or etching (Table 1).

Roughness may sometimes be unintentionally produced during fabrication due to the techniques used. Even “smooth” surfaces used for control experiments are likely to have some topographical roughness on the order of a few nanometers, if they are not “derived by cleaving a perfect crystal or obtained by cooling a melt under vibration-free conditions” [168]. Although some cells are indifferent to such imperfections [112], many show significant differences in behavioral response to nanoscale roughness [65]. For example, human gingival osteoblasts change their morphology based on the amount and type of roughness they were exposed to [124]. Endothelial cells spread and proliferate more rapidly on substrates that replicate the topographical roughness of the natural ECM.

#### 3.1.4. Pores, Pillars, Pyramids, and Pits

The geometry of a substrate can be composed of numerous discontinuous and more pronounced structures such as pores, pillars, pyramids, and pits of various sizes and densities (Fig. 2B, and D). A variety of such features affect the behavior of single and even multicellular epithelial tissue sheets. For example, surfaces with 0.1–0.8  $\mu\text{m}$  pores

**Table 1.** Materials with engineered geometrical, chemical, and mechanical cues and their effect on cells.<sup>a</sup>

Features	Materials	Feature sizes	Cell or biomolecule types	Effect on cells	Fabrication technique	Ref.
<i>Materials with Controlled Nanogeometry</i>						
Fibers	PLGA	500–800 nm	BALB/c C7 and hMSC	Cells spread, maintained phenotype, and grew into 3D multicellular network along nanofibers	Ejection of polymer solution by electrostatic force between a syringe needle and a collecting plate	[72]
	Carbon with or without pyrolytic outer layer	60–200 nm	HOB	Osteoblast proliferation increased with decreasing fiber diameters; more alkaline phosphatase synthesis and extracellular calcium deposition on small diameter fibers	Chemical vapor deposition	[32]
Grooves	PDMS	0.5 $\mu\text{m}$ depth, 2.0–10.0 $\mu\text{m}$ wide ridge/groove	RDF	Orientation of intercellular and extracellular proteins on grooves	PDMS was cast against the silicon oxide mold fabricated by photolithography	[79]
		1.0–10.0 $\mu\text{m}$ wide ridge/groove with 0.45–1.0 $\mu\text{m}$ depth	RDF	Cells highly oriented on ridge <4.0 $\mu\text{m}$ ; ridge width instead of groove width and depth affects cell size, shape or orientation		[80]
		2.0–10.0 $\mu\text{m}$ ridge/groove with 0.5 $\mu\text{m}$ depth	Fibroblasts, erythrocytes, lymphocytes, macrophages	Lower number of inflammatory cells and higher number of blood vessels formed on grooved implants		[81]
		2.0–10.0 $\mu\text{m}$ ridge/groove with 0.5 $\mu\text{m}$ depth	RDF	Cell proliferation not affected by the presence of grooves; RDF oriented and elongated on 2.0 and 5.0 $\mu\text{m}$ grooves; Cells able to span the grooves		[82]
	PDMS (with or without precoated fibronectin)	0.5 $\mu\text{m}$ deep, 2, 5, 10 $\mu\text{m}$ wide	Human skin fibroblasts and HUVEC cells	Texture affects fibronectin deposition and focal contact assembly, attachment	PDMS was cast against a silicon oxide mold fabricated by photolithography	[83]
	PS	1 $\mu\text{m}$ deep, 1–10 $\mu\text{m}$ ridge/groove	RDF	Focal adhesion and cytoskeleton were oriented; position of the cell depended on the width of the groove	Mold against photoetched silicon wafer	[84]
		0.5–5.4 $\mu\text{m}$ deep, 1–20 $\mu\text{m}$ wide ridge/groove	RDF	Cell orientation increased with increasing depth, but narrowest and deepest grooves have less cell proliferation because cells bridge over the groove without attaching to the bottom to form focal adhesions	Mold against photoetched silicon wafer	[85]
		0.5 $\mu\text{m}$ deep, 1–10 $\mu\text{m}$ wide ridge/groove	RDF	F-actin in lamellipodia determines orientation; F-actin in the cell body not the reason but the result of orientation	Mold against photoetched silicon wafer	[86]

continued

Table 1. Continued

Features	Materials	Feature sizes	Cell or biomolecule types	Effect on cells	Fabrication technique	Ref.
	PS, Ti-coated Si, PLA	1–10 $\mu\text{m}$ wide ridge/groove with 0.5 $\mu\text{m}$ depth	RDF	Same topography but different chemistry affects cell contact guidance, morphology, orientation, proliferation	Mold against photoetched silicon wafer	[87]
	Titanium	1.0–10.0 $\mu\text{m}$ ridge/groove	RDF	Cells and stress fibers oriented along the 1.0 and 2.0 $\mu\text{m}$ wide groove; cell and FAP localization depends on the width of groove	Titanium wafer etched by plasma chemistry with photolithographically defined mask	[88]
	Glass covered by collagen and poly-L-lysine, or a layer of fixed aligned HSF	0.1–2 $\mu\text{m}$ depth and diameter	Neurons from CEB and DRG	Growth cone aligned along scratches and along the long axes of fibroblasts; crowded cultures of neurons ignore the guidance cues	Single scratch on coverslips	[89]
	Nitinol	1, 3, 15, 22 $\mu\text{m}$ ridge/groove	Endothelial cells	Alignment, elongation, increased migration, and proliferation on grooved surfaces		[90]
	PLA and PS	1–10 $\mu\text{m}$ ridge/groove, 0.5–1.5 $\mu\text{m}$ groove depth	RBM	No effect on cell proliferation; actin filaments and focal adhesion points aligned with the groove, but pattern different on different surfaces	Cast polymer against photolithographically produced silicon mold, followed by radiofrequent glow-discharge treatment	[91]
		1–10 $\mu\text{m}$ gratings, 0.5–1.5 $\mu\text{m}$ groove depth		On PLA surface, cell and matrix aligned to the groove; More mineralized ECM on 1 and 2 $\mu\text{m}$ wide, 1 $\mu\text{m}$ deep groove; increased alkaline phosphatase activity on grooved PLA surfaces		[92]
	Silica	30–282 nm depth	P338D1 cells and normal rat peritoneal macrophages	Increased adhesion, spreading, number of membrane protrusions, F-actin, and phagocytotic activity; F-actin and vinculin were colocalized along the edges of the steps and grooves, accompanied by phosphorylation of tyrosine	Reactive ion etching the silica sample through patterned photoresist mask	[75]
		5, 10, 25 $\mu\text{m}$ wide and 0.5, 1, 2, 5 $\mu\text{m}$ depth	Baby hamster kidney fibroblasts	Actin aggregation at the discontinuity (edge of ridge/groove) is prerequisite for cell orientation		[93]
	Silicon and PS	0.03–2.0 $\mu\text{m}$ depth, 0.5–100 $\mu\text{m}$ ridge	<i>Uromyces appendiculatus</i>	The fungus differentiated on ridge of 0.5–6.7 $\mu\text{m}$ , a step size that mimics topographical features on leaves of plants the fungus naturally grow on	Electron beam lithography	[68]

Silicon coated with titanium	125° interior corner V shape grooves: 3 $\mu\text{m}$ deep, 30 $\mu\text{m}$ pitch, 15 $\mu\text{m}$ wide; 3 $\mu\text{m}$ deep, 6–9 $\mu\text{m}$ pitch; 0.5 $\mu\text{m}$ deep, 1 $\mu\text{m}$ pitch	HGF	Microscale grooves align cells with either intact micro-tubule or actin filament; nanoscale grooves fail to align microtubule-deficient cells, but able to align actin-deficient cells	Photolithography and etching	[23]
6FDA-6FAP	100–150 nm wide, 4–5 nm unevenness	HeLa cells	HeLa cells aligned strongly on the rubbed surfaces	Rubbing the surface with a cylinder wrapped with cotton velour cloth	[94]
		Rat fibroblasts, platelets	Rubbed surfaces affect IgG absorption, platelets adhesion, fibroblasts adhesion proliferation, aggregation and collagen production		[95]
Quartz	260 nm ridge/groove of various depths (100, 210, and 400 nm)	BHK cells, MDCK cells, and chick embryo cerebral neurons	Alignment of BHK cells and elongation of MDCK cells depends on depth; chick embryo neurons do not respond.	Laser holography and micro-electronic fabrication	[96]
Quartz with or without pre-coated poly-L-lysine and laminin	1–8 $\mu\text{m}$ gratings, 0.08–0.8 $\mu\text{m}$ depth grooves and steps	Various CNS neuroblasts	Neuroblasts either align perpendicular or parallel to the grooves; Perpendicular alignment was observed on grooves with 0.3–0.8 $\mu\text{m}$ depth, 1 $\mu\text{m}$ width	Laser holography and photolithography	[97]
Quartz	14–1100 nm depth, 1–4 $\mu\text{m}$ wide	<i>Xenopus</i> spinal cord neurons and rat hippocampal neurons	Neuron extended and aligned parallel or perpendicular to the grooves, depending on cell age and type	Electron beam lithography and etching	[98]
	14–1100 nm depth, 1–4 $\mu\text{m}$ wide	<i>Xenopus</i> spinal cord neurons and rat hippocampal neurons	Topography affected filopodia and microtubule patterning; $\text{Ca}^{2+}$ channel and protein kinase C were involved in perpendicular contact guidance; Filopodia and cytoskeleton were not required for orientation		[99]
Quartz coated with poly-D-lysine	0.13–1.0 $\mu\text{m}$ wide ridge/groove, 0.10–1.17 $\mu\text{m}$ depth	Various neurons	Content of actin and cell alignment depends on cell type and topography; glial cells most sensitive to topographical guidance	Etching and laser holography	[100]
Quartz pre-coated with poly-L-lysine and laminin	130 nm wide groove/ridge, 210 nm depth	Myoblasts	Myotube formation was in end-to-end manner	Laser holography	[101]
PMMA	Groove 0.5–1.0 $\mu\text{m}$ wide, 1 $\mu\text{m}$ deep	WI38 cells	Oriented along the groove	Electron beam lithography	[102]

continued

Table 1. Continued

Features	Materials	Feature sizes	Cell or biomolecule types	Effect on cells	Fabrication technique	Ref.
Smooth groove and rough surfaces	Titanium coated with TiO <sub>2</sub> and carbonaceous layer	1–10 μm ridge/groove	Leukocytes	Leukocytes on rough surfaces had higher numbers of normal receptors; topography had larger impact than oxide thickness	Annealing commercially available titanium to generate oxide	[103]
Waves	PDMS precoated with fibronectin	0.1–10 μm wavelength, 0.01–1 μm depth	BCE cells	Cell alignment in the direction of grooves; Sharp edge of the groove is not necessary for contact guidance	Relaxing oxidized PDMS from stretching position creates continuous wavy features	[104]
Rough surfaces	PS	Feature size not mentioned	P338D1, WI38, VA13, VA13, L929, H615, and ts3T3 cells	Attachment depends on cell type	Untreated, sulfuric acid- and palladium-treated PS	[105]
	PET	R <sub>a</sub> of sinuous hills of treated surface is 19.04 nm, untreated surface 3.46 nm	3T3-L1, JEG-3, and MCF-7 cells	Cytoskeletal proteins, cell morphology, and proliferation not affected by the roughness; differentiation and apoptosis are more on plasma-treated surfaces, although the effects are moderate	Plasma treatment	[106]
	Biomer (polyurethane)	Typical height difference 1 μm; many features on the order of 100 nm	BAEC	Cells maintain physiological phenotype, spread rapidly, and become confluent	Replica molding of natural ECM	[65]
	Ti <sub>6</sub> Al <sub>4</sub> V	Various surface average roughness 160, 300, 430, 610 nm, 2.19 and 3.4 μm. R <sub>a</sub> = 0.32–0.874 μm	MC3T3-E1 cells and human osteoblastic cells Human bone marrow stromal cells	Negative correlation between roughness and cell proliferation and adhesion; for all surfaces, human osteoblast adhesion increase with time Cell attachment and proliferation increase with surface roughness; human serum albumin preferentially adsorb onto smooth surface; rough surface binds higher total protein and fibronectin	Polishing mechanically or manually to generate parallel orientation of residual grooves Polishing Ti alloy disks with SiC metallographic paper	[107, 108] [109]
	Ti <sub>6</sub> Al <sub>4</sub> V and titanium	R <sub>a</sub> = 0.22–4.2 μm	MG63 cells	Cell proliferation, differentiation, protein synthesis and local factor production depend on roughness and composition	Polishing or grinding	[110]
	Cp-titanium, Ti <sub>6</sub> Al <sub>4</sub> V and Ti <sub>30</sub> Ta	R <sub>a</sub> = 0.04–1.36 μm	HGF	Cell orientation increases with increasing roughness; round shape cells on Ti <sub>6</sub> Al <sub>4</sub> V due to release of vanadium	Grinding or polishing	[111]

Ti <sub>6</sub> Al <sub>4</sub> V, pure titanium	$R_a = 0.07\text{--}3.5 \mu\text{m}$	HOB	EE surface favors cell proliferation and adhesion; when substrate topography is comparable with cell size, cells prefer rough surfaces; when below cell size (nanoscale), cells prefer smooth surfaces	Machine-tooling, EE, polishing	[112]
NiTi alloy and titanium	Nano to microscale roughness	HGF	Highest orientation and lowest proliferation on the highest surface roughness	Polishing	[113]
Porous Si, polycrystalline Si, bulk Si wafers	Porous Si: 40 nm core size; polycrystalline Si: 10 nm; nanocrystallite size	B50 cells	Viability greatest on porous Si, much less on PECVD Si and bulk Si	Etch with HF for porous Si, PECVD for polycrystalline Si	[114]
Porous Si and Ge, crystalline Si and Ge, amorphous Si		CHO cells	Calcium phosphate deposited on nanoporous surfaces; cells attached to all porous substrates and were confluent; cell number greatest on low-porous Si	Electrochemically etched or chemically etched	[115]
Porous Si, polycrystalline Si, bulk Si wafers and glass	Feature size not mentioned in detail	CHO and B50 cells	CHO cells prefer polycrystalline Si and B50 cells prefer porous Si	Porous Si fabricated by stimulated plasma etching; polycrystalline Si fabricated by plasma-enhanced chemical vapor deposition	[116]
Bulk, porous, and polycrystalline Si	$\sim 10$ nm pore size for the porous Si	CHO, B50, and A431 cells	CHO cells grow best on polycrystalline silicon surface; B50 and A431 cells grow best on porous silicon	HF etching	[117]
Si	$R_a = 20\text{--}70$ nm	Substantia nigra cells	Surface roughness affects cell viability and attachment; cells form networks of neuron, with evidence of pathfinding by the axon	Etching	[118]
Oxidized crystalline Si and porous Si precoated with FBS and collagen	70% porosity with average pore size 2–5 nm	Primary rat hepatocytes	Cell increase adhesion on FBS and collagen precoated substrate	Etching	[119]
Alumina and titania	23 nm grain size alumina and 32 nm grain size titania	Osteoblasts	In the presence of 10% FBS, osteoblast adhesion on nanophase alumina and titania significantly greater than on borosilicate glass; the critical grain size for osteoblast adhesion is between 49 and 67 nm for alumina and 32 and 56 nm for titania	Mold/compact nanophase grains into disks	[120]

continued

Table 1. Continued

Features	Materials	Feature sizes	Cell or biomolecule types	Effect on cells	Fabrication technique	Ref.
	Alumina and HA	Grain size less than 100 nm	Rat bone marrow cells	Cells increased synthesis of TRAP and formation of resorption pits on nanophase alumina and HA	Compacting alumina powders in a die then sintering; HA was fabricated via wet chemistry	[121]
	Titanium	$R_a = 0.3\text{--}0.9 \mu\text{m}$	Saos-2 cells	Cells spread in the presence of serum, fibronectin, or vitronectin, increase roughness increase cell proliferation	Titanium discs were acid etched or sand blasted	[122]
	Epoxy resin coated with titanium coating	$R_a = 0.54$ and $4.92 \mu\text{m}$ $R_a = 0.58\text{--}5.55 \mu\text{m}$	MG63 cells HGF	Protein kinase A and phospholipase A <sub>2</sub> mediate cell adhesion Cell morphology and thickness are different, but volume remains the same when cells attach to different surfaces	Commercially available	[123]
	HAPEX	$R_a = 0.03 \pm 0.01$ for polished samples; $0.25 \pm 0.05$ for machined samples	HOB	Faster and larger numbers of cells attach to the rough surfaces and cells maintain more developed cytoskeleton than on micromachined surfaces	Titanium coating was generated on top of replicas that were molded against surfaces of different roughness HAPEX was created by incorporating 40% HA into PE via extrusion and compression molding; discs of HAPEX were machined or polished followed by sonication roughening with alumina particles	[124]
Pores	Polycarbonate and polyester coated with various polymer films	$0.1 \mu\text{m}$ pore size, $4 \times 10^8$ pores/cm <sup>2</sup> , $0.3 \mu\text{m}$ pore size, $2 \times 10^6$ pores/cm <sup>2</sup>	Cornea epithelial tissues	Migration on nonporous surface increased with surface contact angle and hydrophilicity, decreased with surface mobile chemistry; combination of $0.1 \mu\text{m}$ pore and hydrophilicity resulted in maximum migration speed	Track-etched	[126]
	Polycarbonate	$0.1, 0.4, 0.8, 1.0, 2.0$ , or $3.0 \mu\text{m}$ diameter pores	Cornea epithelial cells/tissues	Surfaces with $0.1\text{--}0.8 \mu\text{m}$ pores support assembly and maintenance of tissue stratification and protein deposition	Track-etched	[127]
		$0.1, 0.4$ , and $0.8 \mu\text{m}$ diameter pores	Cornea epithelial cells and tissues	Surfaces with $0.1$ or $0.4 \mu\text{m}$ pores stimulated epithelial tissue sheet and individual epithelial cell migration	Track-etched	[128]
		$0.1\text{--}3.0 \mu\text{m}$ pore diameter	Cornea epithelial tissues	Basement membrane and hemidesmosomal plaque deposition is related to the pore size of the substrates; tissue attachment affected by pore size and polymer surface	Commercially available, track-etched	[129]

Polycarbonate and cellulose acetate/nitrate coated with collagen or fibronectin	0.1–3 $\mu\text{m}$ columnar pores on polycarbonate membrane; 0.22–3 $\mu\text{m}$ tortuous pores on cellulose acetate/nitrate membrane	Cornea epithelial cells/tissues	Tissue migration was inhibited with increasing pore size and completely halted on 0.9 $\mu\text{m}$ pore membrane; coatings facilitated tissue outgrowth; cells reduce migration with pore sizes larger than 0.9 $\mu\text{m}$ , resume at 2.3 $\mu\text{m}$ pore membrane; single cell migration more sensitive to porous surface than that of tissues	Commercial cellulose acetate/nitrate membrane. Track-etched polycarbonate membrane either pretreated with PVP or PVP-free.	[130]
PIPAAm grafted porous membrane	Surface roughness 4.40 nm, pore size 0.45 $\mu\text{m}$	BAEC single cells and confluent cell sheet	Quicker detachment from porous surface than nonporous surface	Electron beam irradiation grafts PIPAAm onto porous membrane (Cell Culture Insert) or tissue culture polystyrene dish	[131]
Cellulose acetate and polyethersulfone	0.1–0.2 $\mu\text{m}$ and 0.8 $\mu\text{m}$ in diameter	Platelets and leukocytes	Higher platelet adhesion and leukocyte viability on 0.8 $\mu\text{m}$ pore size membrane	Commercially available	[132]
PLGA	Foam pore size: 150–300, 300–500, 710 $\mu\text{m}$	Stromal osteoblasts	The foams support proliferation, alkaline phosphatase activities, and bone formation	Solvent-casting particulate-leaching technique	[133]
Pillars and grooves	PS 5 $\mu\text{m}$ blazed ridge/groove, 850 nm ridge/groove, and 60 nm diameter pillars with 300 nm center to center spacing 80 nm base, 300 nm center-to-center spacing	Epitenon cells Rat tendon cells	Much fewer cells on pillar surfaces than on planar ones No attachment on nanopillars	Embossing into PS with an electron beam patterned perspex die	[73]
Pillars or pits or cliffs	Polycaprolactone Pillars or pits were 50 nm in diameter with center-to-center spacing of 75, 150, or 300 nm; cliffs were 200 nm high and 10 $\mu\text{m}$ apart Pillar: 0.5–2.0 $\mu\text{m}$ width, 0.5–5.0 $\mu\text{m}$ gap, 1.0 $\mu\text{m}$ height; well: 1.0 $\mu\text{m}$ deep, 0.5 $\mu\text{m}$ diameter, 0.5–2.0 $\mu\text{m}$ gap	HGTFN cells and rat epitenon fibroblasts LRM55 cells	Cell adhesion enhanced at cliff edge (asymmetric features); symmetrical arrays of pits or pillars inhibit adhesion 70% of cells prefer attachment to pillars and 40% prefer wells (compared with smooth surfaces); polarized distribution of actin and vinculin on pillars	Replica molding of electron beam defined patterns Replica molding of patterned surfaces generated by electron beam lithography and etching	[74, 134] [135]
Pillars and wells	Silicon	LRM55 cells	70% of cells prefer attachment to pillars and 40% prefer wells (compared with smooth surfaces); polarized distribution of actin and vinculin on pillars	Photolithography and etching	[136]

continued

Table 1. Continued

Features	Materials	Feature sizes	Cell or biomolecule types	Effect on cells	Fabrication technique	Ref.
		Randomly distributed pillars with average diameter 57 nm, 230 nm heights; wells 100–250 nm in width, $\leq 115$ nm in roughness	LRM55 cells and primary cortical astrocytes	LRM55 cells prefer to attach to wells; primary astrocytes prefer to attach to pillars	Photolithography and wet etching	[137]
Particles	Titania and alumina	430 and 620 nm	Human osteoblasts and chondrocytes	Cells increase proliferation in the presence of nanophaser particles but not with micrometer size particles	Aggregation	[33]
Pyramids	Germanium islands on silicon	15 nm high, 60 nm $\times$ 60 nm base	U937 cells	Pyramid density strongly affects cell viability and protein release	Chemical vapor deposition	[138]
Islands	PS and poly(4-bromostyrene)	Microscale wide, 13, 35 and 95 nm height islands	HGTFN cells	Cells spread and contain more developed cytoskeleton on topographical substrates than on flat ones; responses were related to the heights of the islands	Dimixing PS and poly(4-bromostyrene) to produce nanometer height islands	[139]
Fibers	PLLA, PLGA, PDLLA/THF PLLA/THF	Nanoscale fibrous matrix			Cross-linking	[71]
		Nanofibrillar matrices with particulate macropores $R_p = 0.3\text{--}4.9$ nm			Cross-linking	[70]
Rough Surfaces	Cuprophane, AN69, PS, and glass surfaces		Fibronectin, fibrinogen, and albumin	Membrane topography affects protein adsorption	Commercially available	[140]
	Silicon surface coated with Ti and Au	Nanodots 15 nm high and 60 nm in diameter separated by a distance of 50–150 nm	Collagen adsorption	Collagen forms layers, aggregates and no aggregates on smooth hydrophilic, smooth hydrophobic, and rough hydrophobic surfaces	Rough surface made by colloidal lithography, then coated with Ti and Au, followed by SAM to add functional chemical groups	[141]
	Titanium	Lines of 1–2 nm and 3–4 nm depths; Full width at half maximum 40 nm.	F-actin	Low adsorption and random orientation on 4 nm height structures; High adsorption and orientation on 1–2 nm height structures	Local anodic oxidation with AFM	[142]
	Titanium	$R_p = 8$ to 1200 nm	Human plasma fibrinogen	Different surface result in different protein adsorption	Mechanical polishing, grinding, sand blasting, and etching	[143]

		<i>Materials with Controlled Nanochemistry</i>		
Dots	Clusters of RGD on PMMA surfaces	Clusters separated by 1, 2, and 5 $\mu\text{m}$	WTNR6 fibroblasts	Increasing cell attachment and spreading with increased RGD cluster density [144]
	RGD peptide on protein-resistant PMMA-PEO substrate	Clusters at nanoscale with 32 nm spacing	WTNR6 fibroblasts	Tethered RGD to P(MMA- $\gamma$ -POEM) comb polymers [55]
	RGD clusters on PLA		WTNR6 fibroblasts	Surface segregation of the P(MMA- $\gamma$ -POEM) comb polymers blended in PLA [56]
	RGD peptide on protein-resistant PMMA-PEO substrate	Average cluster spacing varying from 6–300 nm	WTNR6 fibroblasts	Tethered RGD to P(MMA- $\gamma$ -POEM) comb polymers [53]
	RGD	32 nm clusters, separated by 14–25 nm	WTNR6 fibroblasts	Tethered RGD to P(MMA- $\gamma$ -POEM) comb thin films [37]
Lines	Varying RGD density and alginate type		C2C12 cells	Different alginate monomeric ratio [54]
	Fibronectin	0.7–5 $\mu\text{m}$	Myoblasts	Urea crystals were washed away after drying with fibronectin [145]
	SAM coated with HS(CH <sub>2</sub> ) <sub>5</sub> CO <sub>2</sub> H	1 $\mu\text{m}$	P19 cells	Gold surface was coated with EG <sub>6</sub> OH-terminated SAM; the groove was scalpel blade scratched and coated with HS(CH <sub>2</sub> ) <sub>5</sub> CO <sub>2</sub> H [146]
Other patterns	IgG, lysozyme, retromectin protein patterns PDDA(PAA/TiO <sub>2</sub> ) <sub>5</sub>	100–350 nm	3T3 Swiss fibroblasts	Dip-pen nanolithography [24]
	Thiolated ssDNA on alkanethiol SAM surfaces	External diameter 10–30 nm; wall thickness 3–5 nm 10–25 nm wide lines, nanoscale squares	PCI2 cells Enzyme	Assemble Ag/TiO <sub>2</sub> nanoparticles with PAA [147]
Dots				AFM nanografting [148]

Table 1. Continued

Features	Materials	Feature sizes	Cell or biomolecule types	Effect on cells	Fabrication technique	Ref.
	Single or multiple types of oligonucleotides on gold or silicon oxide surfaces	Many microns to less than 100 nm	Sequence-specific DNA	Sequence-specific DNA could bind to the patterned DNA	DPN	[149]
	Streptavidin-coated glass and positively charged glass	Micrometer scale	Biotinylated DNA, protein G		Nanopipette delivering	[150]
	Au with SAM monolayer	Resolution down to individual molecules	LYZ, BSA, IgG		Nanografting and SAM	[151, 152]
	Au coated with glycol monolayer	Nanometric scale	Rabbit IgG antigen patterns; goat anti-rabbit IgG Fab'-SH fragment patterns		SPL	[153]
Lines	<i>Sporosarcina ureae</i> S-layer	1.9 nm diameter	Platinum		Reduce $K_2PtCl_4$ to Pt and deposit it onto the S-layer	[154]
	Glass	3–4 nm high, 300 nm wide stripes	IgG		Microcontact printing with PDMS stamps	[155]
	Single or multiple layers of patterns	30–50 nm wide	Collagen fibers and collagen-like peptide		Using AFM tip to write directly	[156]
	Si with oxide layer	Various nanometric scale	Thiol and protein patterns		Nanografting and NPRW	[157]
Other patterns		600 nm × 250 nm (ridge × groove), 5–10 nm thick	S-layer of <i>Bacillus sphaericus</i> CCM 2177		Deep UV radiation	[158]
	Au	3.0 nm height, 289 nm periodicity	Cyclic peptides, porphyrin thiols, silane coupling reagents		Templating-assisted protein nanopatterning	[159]
3D matrices	Collagen		BSA		Particle nanolithography	[160]
	ECM and fibrinogen		Mouse and human fibroblasts	Local and long-distance matrix movements induced by fibroblasts	Polymerizing collagen	[47]
			Fibroblasts	Adhesion on 3D substrates different from 2D in the content of integrin, paxillin, cytoskeletal components, and FAK; mechanical stress and chemical composition of the substrate also affect cell adhesion	Isolating tissue-derived 3D matrix, cell-derived 2D matrix, 3D fibrinogen	[26]

Collagen	Human dermal fibroblasts	TGF- $\beta$ 1 and $\beta$ 3 function as mechanoregulatory GFs; alteration of cell stress stimulated integrin expression	Mixing collagen with DMEM	[161]
Collagen-chitosan	K562 cells	Cell proliferation decreased, cytokine release increased with increasing ratio of chitosan	Mixing at different ratios	[162]
Agarose	E9 chick DRG neurites	Increasing gel concentrations decreased elongation rate	Dissolving agarose powder in saline	[25]
Agarose and type I collagen gels	Rat cortical neurons	Collagen gel supported cell viability, normal neuronal polarity and extension of neurites; low-density agarose gels resulted in cell apoptosis	Cross-linking/gelation	[163]
Agarose-alginate coupled gel	E9 chick DRG neurites	Sensory ganglia extension of neurites depends on 3D gels, pore size, and charge of the polymer	Mixing	[164]
Corneal epithelium basement membrane cross-linked ECM fibers	Different pore size and charge 149 $\pm$ 60, 191 $\pm$ 72, 147 $\pm$ 73 nm, mean fiber diameter 77 $\pm$ 44 nm and pore diameter 72 $\pm$ 40 nm		EDTA soaking then remove epithelium or endothelium	[66, 67]
Clusters	32 nm clusters, separated by 14–25 nm	RGD cluster density and clustering affect cell response; mechanical stimuli enhance cell response for higher ligand densities; Fibronectin-coated surfaces do not affect adhesion reinforcement	Tethered RGD to P(MMA- $\gamma$ -POEM) comb thin films	[37]
Pillars	0.8 $\times$ 0.8 $\times$ 0.3, 0.4 $\times$ 0.4 $\times$ 0.3 $\mu$ m pillar with 2–30 $\mu$ m spacing	Focal adhesion is force dependent; local forces related to the orientation and area of focal adhesions	Soft-lithography	[165]
Modify adhesiveness	Varying cell surface receptor and substrate material	Cell aggregation is equilibrium of force between cell–cell cohesivity and cell–substrate adhesiveness	Cell transfection	[166]

<sup>a</sup> Some of the nanofeatured materials are promising but have not yet been utilized for cell engineering. Such kinds of nanomaterials are listed at the end of each category.  
 Note: 2D, 2-dimensional; 3D, 3-dimensional; **6FDA-6FAP**, fluorinated polyimide; **AFM**, atomic force microscopy; **BAEC**, bovine aortic endothelial cells; **BCE**, bovine capillary endothelial; **BHK**, baby hamster kidney; **BSA**, bovine serum albumin; **CEB**, chick embryo brains; **CHO**, Chinese hamster ovary; **CNS**, central nervous system; **DMEM**, Dulbeccos modified Eagle's medium; **DPN**, dip-pen nanolithography; **DRG**, dorsal root ganglions; **ECM**, extracellular matrix; **EDTA**, ethylenediamine tetraacetic acid; **EE**, electroerosion; **F-actin**, actin filament; **FBS**, fetal bovine serum; **GF**, growth factor; **HA**, hydroxyapatite, i.e., Ca<sub>5</sub>(PO<sub>4</sub>)<sub>3</sub>(OH); **HGF**, human gingival fibroblasts; **HGTEN**, human granulosoma tendon **hMSC**, human bone-marrow-derived mesenchymal stem cells; **HOB**, human osteoblasts; **HSF**, human skin fibroblasts; **HUVEC**, human umbilical vein endothelial cells; **IgG**, immunoglobulin G; **LYZ**, lysozyme; **MDCK**, Madin-Darby canine kidney; **NPRW**, nanopen reader and writer; **PAA**, poly(acrylic acid); **PDDA**, poly(dimethyl diallyl ammonium chloride); **PDLLA**, poly(DL-lactic acid); **PDMS**, polydimethylsiloxane; **PE**, polyethylene; **PECVD**, physically etched chemical vapour deposited; **PEO**, poly(ethylene oxide); **PET**, polyethylene terephthalate; **PtPAAm**, poly(*N*-isopropylacrylamide); **PLA**, poly-L-lactic acid; **PLGA**, poly(DL-lactide-co-glycolide); **PLLA**, poly(L-lactic acid); **PMMA**, poly(methyl methacrylate); **POEM**, poly(oxethylene); **PS**, polystyrene; **PVP**, poly(vinylpyrrolidone); **R<sub>g</sub>**, average roughness; **RBM**, rabbit bone marrow; **RDF**, rat dermal fibroblasts; **RGD**, Arg-Gly-Asp peptides; **SAM**, self-assembled monolayers; **Si**, silicon; **S-layer**, surface layer; **ssDNA**, single-stranded DNA; **TGF**, transforming growth factor; **THF**, tetrahydrofuran; **TRAP**, tartrate-resistant acid phosphatase; **UV**, ultraviolet.

stimulate epithelial tissue sheet migration [127–129]. The migration of this stratified tissue decreases with increasing pore sizes and halts completely for pore sizes larger than  $0.9\ \mu\text{m}$  [130]. Lymphocytes, leukocytes, and platelets display increased adhesion and viability on  $0.8\ \mu\text{m}$  pore substrates [132].

Cellular behavior depends on the cell type and can be significantly affected by the size of surface elements found on the substrate that the cell is adhered to. Epitendon, tendon, and fibroblast cells are unable to attach to surfaces with nanopillar arrays of 50-nm diameter [73, 74, 135], whereas primary astrocytes show preferential attachment to similar sized pillars [136, 137]. It is hypothesized that pillars that are only tens of nanometers in diameter are not large enough for many cell types to form focal contacts on [74]. In contrast, pillars with diameters of 500 nm and larger are able to support attachment of a larger variety of cell types [136]. When pillar diameters are of sufficient size to support cell attachment, the height of the pillars also becomes an important factor. For example, endothelial cell response differs greatly, depending on pillar height [125, 139]. Studies of U937 cells on nanoscale pyramid structures show a negative correlation between pyramid densities and cell viability and protein production. The cells showed decreased production of inflammatory cytokines such as interleukin- $1\beta$  and tumor necrosis factor, and less proliferation on substrates with higher pyramid densities [138] (Fig. 2B).

### 3.1.5. Three-Dimensional Architectures

Most artificial nanostructures are created on flat surfaces, mainly because of limitations in nanomanufacturing methods. The physiological cellular environment, however, is 3D in that cells contact materials on multiple planes, not just on the horizontal ones. It is well known that 3D environments are crucial for the tissue formation and function of a variety of cell types including endothelial cells [26], neurons [169], and fibroblasts [72]. The current technology for providing cells with a 3D environment is to use scaffolds made of polymer foams or gels that contain microscale pores and ill-defined nanogeometries (Fig. 2C). The development of new 3D nanofabrication technologies and their application in cell studies are areas of great potential for further research. The effect of 3D substrates on cell behavior is closely associated with the mechanical stress that is induced by the substrate on cells (see also Section 5).

## 3.2. Mechanism of Cellular Response to Nanogeometries

Although the exact mechanism is still unclear, certain cellular components have been shown to be crucial for cellular response to nanogeometries. The morphological response of cells, such as alignment to geometrical features, requires proper spatial arrangement of cytoskeletal components such as actin filaments and microtubules. Thin actin filaments in the cell periphery support membrane extension, whereas the large, axial bundles of actin stress fibers in the main cell body enable contractile movements. Cells cultured on grooved substrates will often show orientation of the actin

cytoskeleton in the direction of the grooves [75, 91]. Microtubules are another cytoskeletal component involved in cellular response to geometrical features. The intracellular alignment of both actin filaments and microtubules in the direction of the grooves is critical in determining overall alignment of the whole cell [23].

It is important to understand that cellular response to surfaces can be completely different depending on the type of cell and even the state of that cell, even when the nanogeometry of the substrate is the same. Cell type, cell density, and cell age are three main parameters that affect cellular response to nanogeometrical features. Endothelial cells [90], myoblasts, and fibroblasts align parallel to groove features [79–82, 85–88, 102, 170]. Neuronal cells, however, align either parallel [89] or perpendicular to nanofeatures [97–99], depending on the width of the groove and density of the cells. The orientation and spatial distribution of neurons also depends on their age and origin [98–100]. Cellular response to nanoscale geometry is not limited to mammalian cells. The *Uromyces appendiculatus* fungus responds strongly to engineered nanoscale steps that mimic the features of their host plant in nature by orienting their direction of growth and differentiation along the step features [68]. These fungi are amazingly selective in what size step features they respond to. Germ tubes of the fungus are highly oriented by ridges of 500–600 nm that mimic the host environment but not by features with sizes larger than  $1\ \mu\text{m}$  or less than 250 nm. It is also proposed that cell–cell contact sometimes has a higher priority than cell–substratum contact [96, 171]. Evidence can be seen from the experiment of Fitton et al. [130]: the migration of dissociated single cells is more sensitive to polymer topography than that of tissue.

The mechanism by which nanogeometrical features affect cell behaviors can be indirect. For example, Denis et al. [141] found that collagen deposited onto smooth/hydrophilic substrates formed 6 nm thick protein layers, whereas deposition onto smooth/hydrophobic substrates resulted in 20 nm thick protein layers that contained elongated protein aggregates. Deposition of collagen onto a rough/hydrophobic substrate resulted in a 20 nm thick layer that contained no aggregates. In this case, the response of cells to different nanogeometries could be due not to the direct effect of surface topography but rather to the indirect effect of differences in the proteins adsorbed onto it. Adsorption of fibrinogen (an abundant blood protein that can be proteolytically activated to form fibrin clots that stop bleeding) can be affected by nanostructured titanium with different roughnesses [143]. Bovine serum albumin, fibronectin, and vitronectin orient along grooves on silicon surfaces [79, 88]. Serum albumin prefers to attach to smooth substrates whereas fibronectin and total proteins adsorb more on rough surfaces [109]. Nanometer topographical features can render a material more biocompatible by changing adsorption of proteins and attachment of cells [118, 138].

The material composition and mechanical properties of the substrate also have a large influence on cell behaviors. Materials used for fabrication of nanogeometrical features include metals (titanium, silicon, and germanium) [68, 122, 138], alloys (Nitinol and  $\text{Ti}_6\text{Al}_4\text{V}$ ) [90, 107], inorganic materials (quartz, glass, carbon, silica, and hydroxyapatite (HA)) [32, 75, 89, 96, 121], polymers [polystyrene, poly(ethylene

terephthalate)(PET), polyurethane, polycarbonate, poly(*N*-isopropylacrylamide)(PIPAAm), polyethersulfone, agarose, polycaprolacton, poly(dimethylsiloxane)(PDMS), PLGA, poly(lactic acid) (PLA), fluorinated polyimide (6FDA-6FAP), hydroxyapatite reinforced polyethylene composite (HAPEX), poly(methylmethacrylate), and poly(L-lactic acid)] [65, 71, 72, 79, 84, 87, 92, 94, 101, 106, 125, 129, 131, 132], and other biologically derived materials (cellulose acetate/nitrate, corneal epithelium basement membrane, and collagen–chitosan matrices) [66, 67, 130, 162]. An individual cell will exhibit different behaviors on different materials, even in the presence of the same nanogeometries. For example, rat dermal fibroblasts cultured on very similar groove features showed differences in contact guidance, morphology, orientation, and proliferation on porous silicon, PLA, silicon, and titanium substrates [85, 87]. Materials can be altered during processing. Roughening of  $Ti_6Al_4V$  surfaces, for example, not only changes the material geometry but also increases aluminum oxides presented on the surface compared with untreated controls. Both the geometry and the materials properties contribute to the differences in protein adsorption between smooth and rough surfaces [102].

#### 4. MATERIALS WITH CONTROLLED NANO-CHEMISTRY

To enable materials to elicit specific and desired cellular response, it is necessary to generate chemical patterns that mimic those in the ECM. The cell membrane is covered with numerous nanoscale sensors such as receptors and structural microdomains such as lipid rafts, which probe the environment and send signals to cytoskeletal structures and organelles within the cell [3, 172] (Fig. 1A). The spatial distribution of receptors on the cell surface as well as their degree of clustering depends critically on what type of ligands are present as well as on the nanoscale arrangement of those ligands on the ECM (Fig. 3). The clustering of receptors generates a cascade of signals inside the cell to regulate cell function and behavior.

The basic molecular components of the natural ECM are collagens, laminins, fibronectins, proteoglycans, and hyaluronic acids, with collagens being the most abundant [3, 64]. Each of these molecules presents unique binding sites with distinct binding specificities to various cell surface receptors [173]. The complexity of cell–ECM interactions lies not only in these variations in molecular specificities of binding, but also in the diversity of spatial arrangements of the binding sites. Different types of collagens polymerize differently and form an assortment of fibrous structures. For example, type IV collagen forms intricate meshes of collagen fibers (Fig. 1B) whereas type I collagen forms long fibers. Further mechanical and chemical processing of collagen by cells defines its nanoscale spatial organization (Fig. 1E). Other proteins and carbohydrate molecules bind to specific regions of the collagen to create distinct ECM architectures. Cross-shaped laminin molecules and type IV collagen, for example, form a thin sheet-like ECM called the basal lamina, which is approximately 60–100 nm in thickness [3] (Fig. 1A, and B). Fibronectin is another common multiadhesive protein that facilitates cell attachment and migration.

**Figure 3.** Examples of different nanochemistries—that is, how the same number of adhesion ligands can be organized into different nanoscale patterns on a materials surface. Each black dot represents a chemical entity, such as an RGD motif, that binds to receptors. The dots can be grouped into clusters containing different numbers of ligands separated by different distances (local ligand density, A–C). The clusters can be arranged to have different intercluster distances and positions (intercluster arrangement, B–D). In the examples shown, the local ligand density and the intercluster arrangements are different, but the total number of ligands per surface area (bulk ligand density) is constant. The intercluster arrangements can be such that the clusters are evenly distributed (A–C) or arranged in lines or other geometries (D). Appropriate local ligand densities produce synergistic binding through multivalent interactions. In multivalent interactions the total binding strength is more than the sum of the individual bonds. Intercluster arrangements are also important as they determines the spatial organization of subcellular components and overall cell shape. For example, the shape of cell–material adhesion complexes observed inside the body (3D matrix adhesions) are often longer and thinner compared with adhesions formed on man-made materials (focal adhesions).

The spatial arrangement of the adhesive ligands presented on a substrate will determine the extent of receptor clustering, binding strength, organization of adaptor proteins and cytoskeleton, and shape of the attached cell (Fig. 1C and G). These changes will ultimately affect gene expression within the cell and determine its fate.

Although chemical patterning at the microscale is well established and commonly used to engineer cell function, methods for manufacturing nanoscale chemical patterns are rare. The use of man-made chemical nanopatterns to engineer cells is even rarer.

Two major categories of chemical nanopatterning technologies are microcontact printing and surface probe microscope mediated methods. Microcontact printing ( $\mu$ CP) transfers molecular inks, such as alkane thiols or biologically active proteins, from a stamp to a substrate [155, 174].  $\mu$ CP has the advantage of being able to pattern delicate molecules, such as proteins, because it does not require the use of harsh conditions such as the acids or bases that are necessary in photolithographic patterning [175]. Furthermore,  $\mu$ CP can be used for patterning large areas and

is also simple, quick, and inexpensive. By using small and well-defined features on the stamp, proteins are patterned onto substrates with high resolution and contrast. Images of nanopatterns created by microcontact printing have been taken with scanning probe microscopy techniques [24, 149, 151, 176]. The feature sizes are generally larger than 100 nm.

Scanning probe microscopy can be used to both image and generate features on a surface. There are two major methods of generating chemical patterns using the probe tips. One method, represented by dip-pen nanolithography (DPN), uses the probe tips of atomic force microscopes in a manner similar to that of a fountain pen where ink is transferred from the probe tip to the substrate. For example, DPN has been used to write collagen lines with widths of 30–50 nm [156]. The other method, known as nanografting, uses the probe tips to generate scratches on self-assembled monolayers (SAMs) after which the scratches are backfilled or grafted with desired biomolecules [153]. Another related method is the use of nanopipettes. This technique has been used to print biotinylated DNA onto streptavidin-coated glass substrate with submicrometer resolution [150].

Other techniques used to generate biochemical nanopatterns include particle lithography [160] and the use of ligand-bearing nanoparticles. Griffith et al. [37, 55, 56, 177, 178] used star polymers and branched polymers with different densities of RGD peptides to create biochemical nanoclusters. The RGD peptides, which are amino acid sequences that are integrin specific, mediate cell adhesion and are vital for cell survival, differentiation, and motility. Different spatial distributions of RGD peptides strongly influence integrin signaling. Rowley and Mooney [54] also observed that myogenesis depends critically on densities of RGD ligands in the ECM and showed that higher densities of ligands promote differentiation. Turner et al. [145] generated 0.7–5  $\mu\text{m}$  wide, parallel fibronectin lines via evaporation of a protein solution and used the resulting substrate to assay myoblast adhesion, migration, and contact guidance. Myoblasts plated onto these patterned substrates were found to orient and fuse into long, aligned myotubes. The features observed on the fibronectin nanolines were distinct from those of the circular clones seen in most conventional cultures.

The impact of protein patterning in the field of biomaterials is not limited to engineering cells. Microarrays of proteins as well as DNAs can be used as diagnostic tools and sensors to rapidly analyze large numbers of proteins and genes [152, 160]. In comparison to nanogeometry, nanochemistry is not as well developed. There is a lack of efficient methods to generate desired protein nanopatterns on biomaterials. It is an area that presents many challenges and opportunities for future nanoscale research.

## 5. MATERIALS WITH CONTROLLED NANOMECHANICS

In addition to topographical and chemical cues, mechanical stimuli, such as stretching and compression, also play a significant role in modulating cell behaviors. Mechanical interactions between the ECM and cells affect signal transduction, gene expression and protein synthesis [49].

As a result, mechanical stimuli can alter cell viability [49], development, motility [179], and morphology [180]. Mechanotransduction is also involved in biological functions such as touch sensation, hearing, maintenance of cardiovascular tone, and sensing gravity [181–183]. Researchers have identified a number of mechanotransducers on the cell membrane (such as stress-sensitive ion channels [184, 185]), which mediate the conversion of extracellular mechanical stimuli into intercellular chemical signals. For example, in bacteria such as *Escherichia coli*, there are ion channels of small conductance that are activated by stretching and is involved in sensing osmotic changes [11]. In eukaryotes such as mammals and yeast, stretch-activated channels regulate the influx of extracellular calcium. Calcium regulates production of actomyosin-based contractile forces [186–189], the structure and dynamics of the actin cytoskeleton [186, 190, 191], and the formation and disassembly of cell–substratum adhesions [192, 193]. Calcium also serves as a second messenger in many biochemical signal transduction pathways [157].

Other cellular components crucial for mechanotransduction include integrins and the cytoskeleton [35, 49, 194, 195]. Integrins link the internal actin cytoskeleton to the ECM through a group of adaptor proteins (Fig. 1C). They also form focal adhesions where integrins, adaptor proteins, growth factor receptors, ion channels, and various signaling enzymes are clustered together within a small region of the cell. When forces are applied to integrins or to cytoskeletal elements, the mechanical signals are converted to biochemical signals, in large part through the various molecular machineries localized to focal adhesions.

A challenge in the study of mechanotransduction lies in designing biomaterials with well-defined mechanical properties at the nanometer length scale. Biodegradable PLGA has been used widely as scaffolding material for bone regeneration because of its tensile properties, which are comparable to those of human cartilage and skin [72]. Collagen or agarose gels have also been used to investigate the effect of mechanotransduction on cells. Because gel stiffness varies with chemical composition, researchers have used different mixing ratios to investigate the relationship between the mechanical properties of the substrate and cell behavior [25]. Tan et al. [162] found that when the chitosan to collagen ratio in the gel was greater than three, cell proliferation decreased with increased chitosan concentration in the gel.

An example of how cellular responses can differ depending on presence or lack of tension even with the same geometry and chemistry has been demonstrated using collagen gels [196]. Gels attached to the surface of the container in which they were polymerized develop an intrinsic tension whereas gels detached from the surface releases any such tension within the gel. Myoblasts proliferated when plated on “stressed” gels but were quiescent when plated in gels that were relaxed.

An important component of cellular nanomechanics research is the measurement of mechanical forces generated by single cells or parts of cells. Forces exerted by cells on flexible substrates micropatterned with varying sizes of adhesive spots have been reported [165, 197]. Sheetz et al. [198, 199] used microcantilevers to measure traction forces generated by cells during migration. Taylor et al. [200] measured forces generated by single cells during cell division by

observing wrinkles formed on flexible silicone substrates by the cell tugging, and centrifugal detachment has been used to quantify the adhesive strengths of cells attached to substrates presenting similar overall ligand densities but with different size RGD ligand nanoclusters [37].

## 6. CONCLUSION AND FUTURE PROSPECTS

Biological nanomaterials research, which is at the crossroads between biology and nanotechnology, presents an exciting area with many challenges and opportunities. This chapter has focused on nanogeometry, nanochemistry, and nanomechanics to categorize biomaterials and their ability to engineer cell behavior. A number of intriguing examples show how nanoscale material properties can be used to elicit certain behaviors from cells. These results are promising for improvements and developments in tissue engineering, cell-based therapy and diagnosis, drug discovery, cell-based biosensors, and machine–cell hybrids.

To truly optimize cellular behavior using biomaterials, however, simultaneous control of multiple materials properties—preferably in real time—is necessary. Currently, the majority of research on the effect of different nanoproperties on cell behavior is opportunistic and nonsystematic, and often the mechanism for how the material properties are translated into cellular response is unclear. One of the most significant challenges at hand is the development of nanofabrication techniques that are able to pattern nanoscale features over large areas on three-dimensional biomaterials via inexpensive, quick, and reliable methods.

Although much work lies ahead before we can freely “write” nanoscale information to elicit specific desired functions from cells, we are well on our way in learning the basic “abc’s” necessary to develop biological nanomaterials that can guide cellular responses. The rapid progression of nanotechnology ensures that our nanoscale “vocabulary” for developing materials that can control cellular functions will continue to increase rapidly.

## GLOSSARY

**Cellular microenvironment/nanoenvironment** The local environment that surrounds and exerts influences on cells by set of microscale or nanoscale structures, molecules, and interactions.

**Clustering** The process of aggregation or grouping of molecules. For example, receptors diffusing freely in a cell membrane may bind to closely grouped ligand molecules on a surface to form closely grouped clusters of receptors. Receptor clustering is important for cell signaling.

**Cytoskeleton** The internal three-dimensional mesh-like network of proteins (including actin filaments, microtubules, and intermediate filaments) that gives shape and structural support to eucaryotic cells and also supports functions such as cell movement and transport of materials within the cell.

**Extracellular matrix (ECM)** Network of proteins (such as collagen) and carbohydrates that are secreted by cells to form a matrix with nanoscale structures and organization.

The ECM is recognized by cells and used for functions such as structural support in tissue formation and cell migration.

**Integrin** Heterodimeric receptors that extend across the cell membrane and mediate communication between the cells and the extracellular matrix by translating extracellular materials features into intracellular signals.

**Mechanotransduction** The conversion of extracellular mechanical stimuli into intracellular chemical signals.

**Micro-contact printing ( $\mu$ CP)** A micro- and nanopatterning fabrication technology that transfers molecular inks, such as alkane thiols or biologically active proteins, from a stamp to a substrate.

**Nanochemistry** The nanoscale spatial arrangement of chemicals such as ligands on a surface. For example, the same number of ligands (same bulk density) can be arranged into (separate/more distant) groups of two or more nearby ligands to more effectively match complex receptors structure and arrangement on cells (see Fig. 3).

**Nanogeometry** The nanoscale topographical features, shape, and patterns of a material (such as the pyramids, pores, grooves, or pillars of Fig. 2 or the collagen mesh of Fig. 1).

**Nanomechanics** Mechanical interactions and forces induced by nanoscale features of a material.

**Signal transduction** The process used by cells to transfer an extracellular signal or environmental stimulus to the cell or cell nucleus, usually through a relay of proteins and ligands.

**Soft lithography** A collection of microfabrication and micropatterning techniques that generates features and patterns by using soft, elastomeric polymers.

## 1. INTRODUCTION

Disk-shaped organic molecules form the basis for an exciting variety of new and emerging materials, including molecular wires, polarizing filters, compensation films, and advanced carbon materials such as fibers, foams, and microbeads. Of special interest are those discotics that form liquid crystals—orientationally ordered liquid phases [1]. The high molecular mobility and long-range order in liquid crystalline phases allow material structures to be created through equilibrium self-assembly processes driven by soft intermolecular interactions. Most of the current discotic applications are best classified as “nanostructured” materials since they have supramicron overall dimensions but derive their unique properties from the self-organized structures involving their constituent molecular disks of diameter 1–5 nm. In addition, however, there is an emerging class of true nanomaterials, formed by confining discotic liquid crystals within nanometric templates.

Interestingly, most discotics are not used in the dynamic liquid crystalline (LC) state, which typically exists only above room temperature. Rather the liquid crystalline phases serve as intermediates in the synthesis of ordered materials that perform their desired function in the solid state. In this respect they differ from calamitic, or rodlike liquid crystals as used in display technology and other photonic devices.

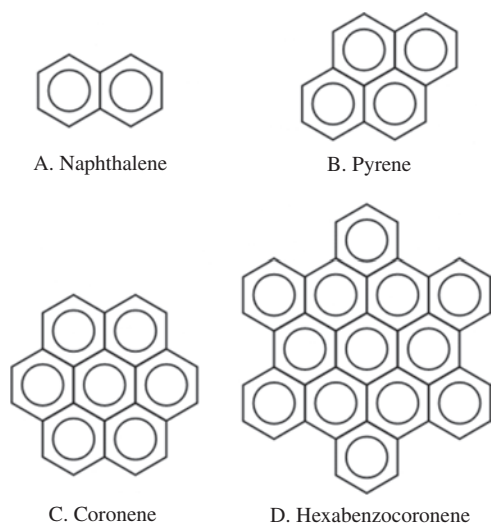

For discotics, the order developed in the liquid crystalline state is preserved either by quenching or by polymerization of reactive mesogens. The largest class of discotic-based solids is carbon materials, in which high-temperature polymerization is used to convert the discotic supramolecular assemblies into an arrangement of “graphene” (graphite-like) layers which preserve the liquid-phase orientational order.

This chapter gives an overview of discotic molecules (Section 1), their liquid crystalline behavior (Sections 2 and 3), and their applications as nanostructured materials (Sections 4 and 5) and emerging carbon nanomaterials (Section 6). The chapter covers both the science and technology aspects of discotics, but emphasizes practical synthesis routes for new material structures and their potential technological uses.

### 1.1. Discotic Molecular Structures

Carbon in  $sp^2$ -hybridization forms a set of three equivalent bonds lying in a single plane separated by  $120^\circ$ . Six-membered rings of  $sp^2$ -hybridized carbon are particularly common due to their enhanced stability arising from structural resonance. These aromatic and polyaromatic (multiple ring) compounds are nature’s intrinsically planar organic building blocks (see Fig. 1). Organic molecules containing a preponderance of  $sp^2$ -hybridized bonds begin to fill two-dimensional space as their molecular weights increase to form extended planar structures that can be plate- or disklike (see Fig. 1C, D).

Discotic structures can also include  $sp$ -hybridized carbon (with carbon/carbon triple bonds) that form linear segments bridging the  $sp^2$ -hybridized carbon as shown by the unique ring discotic molecule in Figure 2, or can include other bonding types in flexible groups that decorate a rigid ring (Fig. 2) or a rigid core (Fig. 3), which is most typically a polyaromatic rigid core (Fig. 4). Other discotic structures include synthetic dendrimers [2] and natural porphyrins [3].

**Figure 1.** Common planar polyaromatic compounds of increasing molecular weight. (A) Naphthalene; (B) pyrene; (C) coronene; (D) hexabenzocoronene.

**Figure 2.** Unusual discotic molecule with rigid ring and flexible core from [45]. Most discotic molecules are polyaromatics (Fig. 1) or contain a polyaromatic core with one or more peripheral side chains.

**Figure 3.** Discotic liquid crystalline compound with a rigid aromatic core and flexible aliphatic side chains.

**Figure 4.** The first reported synthetic discotic liquid crystalline compound [13], and basic model for most discotic liquid crystals today. It consists of polyaromatic core (here based on triphenylene) with multiple flexible aliphatic side chains.

### 1.1.1. Polycyclic Aromatic Hydrocarbons

The polycyclic aromatic hydrocarbons (PAHs) that are the basis for most discotics are common products of high-temperature organic reactions, as they lie along the minimum free energy pathway in C/H space between organic matter and the atmospheric-pressure thermodynamic end-state, graphite. The sp<sup>2</sup>-hybridized bonding leads to intrinsically planar molecules, in which each carbon is covalently bonded to three other carbons or two carbons and a hydrogen at the periphery. Curvature can be introduced with five-membered rings, or through steric hindrances in oligomers of smaller polyaromatic clusters connected by aryl linkages (C-C single bonds) or other cross-linking groups.

PAHs are ubiquitous in nature where they are of special interest as pollutants in the atmosphere and soil [4, 5], as biologically active compounds that form carcinogen-DNA adducts [6, 7] and exert complex effects on the immune system [8], as components in the interstellar medium [9], and as components in petroleum that cause harmful deposits in processing equipment [10]. In technology PAHs find use as liquid crystalline cores [11–14]; as optoelectronic devices including diodes and organic molecular thin films [15–19]; as organic superconductors; as feedstocks for advanced carbon material [20, 21]; and as enabling elements of nanotechnology used for molecular recognition [22], as molecular wires [18], or as coupling agents for sidewall functionalization of nanotubes [23].

The largest commercially available PAH is coronene (see Fig. 1), which melts at 440 °C into an isotropic liquid phase. The even larger PAH, hexabenzocoronene with six-fold rotational symmetry (see Fig. 1), can be readily synthesized [18, 24–26], and has been used as a sublimation source to form epitaxial molecular thin films [18]. Larger PAHs are seldom the subject of liquid-phase studies in pure form, as they typically decompose before melting. An even larger planar C<sub>60</sub> has been reported [27].

## 1.2. Discotic Liquid Crystals

Most discotic liquid crystals are based on polyaromatic compounds, but require some modification to avoid the very high melting crystalline solid phases. The following sections describe the two major classes of discotic liquid crystals: polyaromatic hydrocarbon *mixtures* (“pitches”) and synthetic polyaromatics with substituent side chains to promote liquid crystallinity (“synthetic discotic mesogens”).

### 1.2.1. Pitches

Among the naturally occurring polyaromatics are those of high molecular weight (300–2000 Daltons), which can be disklike or platelike (see Fig. 5). Most very large PAHs (>700 Daltons) are available only as complex mixtures referred to as “pitches,” and this has limited our fundamental understanding of their behavior. Interestingly, it is the multicomponent nature of pitches that is responsible for liquid crystalline behavior [28], since large, regular, unsubstituted polyaromatics are insoluble [27, 28], nonvolatile [10], and form high-melting solid phases that prevent discotic liquid crystalline formation [28].

Pitches are derived from heat soaking and/or extraction of petroleum fractions [29], coal tar, or from the polymerization of smaller organic compounds (see Fig. 5) [20, 30, 31]. Pitches are technologically important precursors for advanced carbon materials and the only source of liquid crystalline PAH. Synthetic pitches from catalytic polymerization of naphthalene were developed by Mochida and co-workers [20, 30] and are now commercially available through Mitsubishi Gas Chemical under the trade name of AR resins. They are brittle solids at room temperature, but soften near 280 °C to form a 100% anisotropic discotic liquid (bulk mesophase). The ready availability of homogeneous bulk mesophases should greatly accelerate the development of mesophase-based materials and nanomaterials in the coming years.

Pitches are complex materials, regardless of whether they are of natural origin (fossil-fuel derived) or synthetic, and a large literature has accumulated on the characterization [25, 26, 32–35] formation chemistry and kinetics [25, 36–38] of pitches, as well as on processing methods including solvent interactions [25, 29, 39], rheological aspects [40], blending [41], and air blowing [25] to improve or optimize pitch properties.

**Figure 5.** Examples of large, irregular PAHs found in pitches of different origin.

### 1.2.2. Synthetic Discotic Mesogens

Synthetic, single-component discotic liquid crystals are commonly based on polyaromatics, but require the addition of substituent groups to the core which disrupt packing in the solid phase (see Fig. 4). The ordered liquid phase is typically observed only when the length of the side chains falls within a certain range; for example, the nematic phase in hexa-*N*-alkoxybenzoates of triphenylene occurs only in the presence of substituent chains on the benzoate side groups of formula  $R = C_nH_{2n+1}O$ , with  $n$  from 8 to 12. It is currently believed that the side chains of an appropriate number and length are critical to the achievement of discotic mesophases. The importance of the length of the side chains suggests that the stability of columnar phases requires some kind of amphiphilic interaction [42] (in which the cores and side chains have different interaction potentials leading to preferential core/core attraction and chain/chain attraction). The cores and chains tend to segregate, producing a columnar structure in which the chains also provide lubrication between the columns to promote liquid-like behavior.

The first synthetic discotic was reported 12 years after the discovery of the carbonaceous discotic phase by Brooks and Taylor in 1965 [1]. Since then a wide variety of discotic liquid crystals have been synthesized and new discotic liquid crystals continue to be announced each year [43–46].

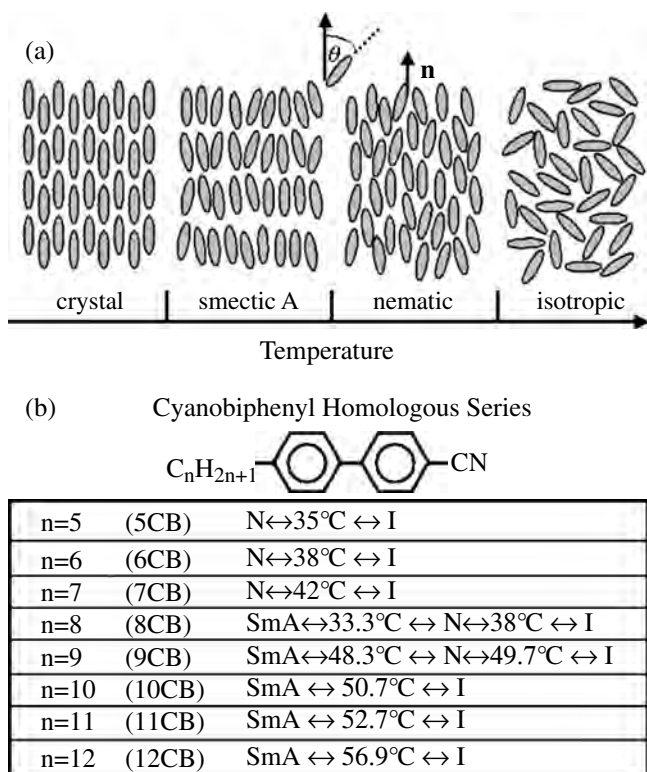

## 2. LIQUID CRYSTALLINE PHASES

### 2.1. Introduction

The term liquid crystal describes a state of matter that is intermediate between an isotropic liquid and a crystalline solid. Since their discovery in the late nineteenth century by Renitzer [47] and Lehmann [48], there have been thousands of compounds identified to exhibit a liquid crystalline phase. The essential prerequisite for liquid crystallinity is that the molecule must exhibit a high degree of shape anisotropy (e.g., rodlike or disklike). Depending on the nature of the molecular structure, a compound may pass through one or many different liquid crystal phases, characterized by order and symmetry, before transforming into a truly isotropic liquid. There are two generic classes of liquid crystals, those whose transitions are driven by thermal processes, known as thermotropic, and those strongly influenced by solvents, known as lyotropics. Liquid crystals are cataloged as either rodlike (calamitic) or disklike (discotic). In this section we briefly review their structure and ordering properties.

### 2.2. Calamitic Liquid Crystals

The majority of thermotropic liquid crystals are composed of rodlike molecules, which can be broadly classified as nematic, cholesteric, and smectic. Figure 6 illustrates a particular phase sequence as the temperature is increased: crystal, smectic A, nematic, and isotropic liquid. The conventional crystal structure possesses both positional and orientational order. The smectic A phase (the simplest smectic phase) possesses orientational order and a density modulation due to the arrangement of molecules in “bookshelf-type” layers. The orientational order is characterized by the nematic director,  $\mathbf{n}$ , which defines the average direction of

**Figure 6.** A typical phase sequence of a thermotropic liquid crystal (a) and transition temperatures of a typical cyanobiphenyl homologous series known as nCB (b).

an ensemble of molecules. The molecules within the smectic planes do not exhibit any correlation between their centers of mass (i.e., fluidity within layers). The nematic phase also possesses long-range orientational order, but no positional order. The nematic phase, the simplest of all the liquid crystal phases, differs from a truly isotropic liquid in that the molecules are approximately oriented with their long axis parallel to one another much like the smectic A phase with the absence of layers. The preferred direction of molecules in the nematic phase usually varies from point to point; however, an aligned specimen is optically uniaxial and birefringent.

An example of a family of rodlike liquid crystal compounds is shown in Figure 6b; these compounds are known as cyanobiphenyls. This particular family can have a rich variety of phase behavior depending on the length of the aliphatic chain. For example, the phase sequence of 5CB is crystal-nematic-isotropic, 8CB is crystal-smectic A-nematic-isotropic, and 12CB is crystal-smectic A-isotropic. There are also an intriguing variety of other smectic phases which are classified by order and symmetry but are not pertinent to this review [49]. In addition, the nematic phase can exhibit chirality and the molecules can exhibit a helical structure [50].

The Maier-Saupe theory has been phenomenally successful at quantifying the degree of orientational order in liquid crystals. Based on a mean-field approximation (i.e., each molecule is subject to an average internal field which is independent of any local variations or short-range ordering), the

temperature dependence of an orientational order parameter,  $S$ , can be determined [51]. The order parameter is defined as

$$Q = P_2 \langle (\cos \theta) \rangle = \frac{1}{2} (3 \langle \cos^2 \theta \rangle - 1) \quad (1)$$

where  $\theta$  is the angle which the long molecular axis makes with the nematic director,  $\mathbf{n}$ , and denotes an ensemble average. For perfect crystalline order,  $\langle \cos^2 \theta \rangle = 1$  and  $Q = 1$ . For complete disorder in the isotropic phase,  $\langle \cos^2 \theta \rangle = \frac{1}{3}$  and  $Q = 0$ . For the nematic phase,  $Q \sim 0.3-0.4$  near the nematic-isotropic transition and  $Q \sim 0.7-0.8$  deep in the nematic phase.

McMillan [52] extended the Maier-Saupe theory (based on Kirkwood-Monroe melting) [53] to describe the one-dimensional [translational periodically] at the layered smectic A phase. The orientational order parameter,  $S$ , is identical to the Maier-Saupe theory (Eq. (1)). A new parameter,  $\sigma$ , expressed as

$$\sigma = \left\langle \cos \left( \frac{2\pi z}{d} \right) \left( \frac{3 \cos^2 \theta - 1}{2} \right) \right\rangle \quad (2)$$

is a measure of the amplitude of the density modulation characteristic of the layer structure and defines the degree of smectic ordering. In the smectic A phase,  $\sigma \neq 0$  and  $S \neq 0$ ; in the nematic phase,  $\sigma = 0$  and  $S \neq 0$ ; and in the isotropic phase,  $\sigma = 0$  and  $S = 0$ .

We have briefly described the basic principles of calamitic (rodlike) liquid crystals. There is a vast amount of literature in this area, because of the rich fundamental physical phenomenon and application in optical devices (e.g., liquid crystal displays) [54]. The shape anisotropy of calamitic liquid crystals manifests itself in two often very important properties: (1) birefringence and (2) dielectric constant. Because of the anisotropy in the dielectric constant, the molecules can align parallel or perpendicular to applied fields depending on the sign of their dielectric anisotropy. The most common are compounds that exhibit a positive dielectric anisotropy ( $\Delta\epsilon > 0$ ) that align parallel to applied electric fields. The ability to align liquid crystals to a new orientation with an applied electric field enables one to manipulate the index of refraction, which is the basis for most liquid crystal-based optical technology.

### 2.3. Discotic Liquid Crystals

The general thought that a material must be composed of rodlike molecules in order for liquid crystallinity or mesomorphism to occur was defeated when it was demonstrated that compounds with disklike constituents also exhibit mesophases. They were first discovered in carbon precursor materials with a transient existence by Brooks and Taylor [1] in stable low molecular weight systems [55]. Discotic liquid crystals are generally classified into various categories depending on the nature of their ordering. The simplest configuration is the columnar phase (often denoted by D) consisting of stacks of disklike molecules forming columns as shown in Figure 7. The columns can organize in a variety of ways, such as hexagonal  $D_h$ , rectangular  $D_r$ , and even

**Figure 7.** A typical phase sequence of a thermotropic discotic liquid crystal phase (a). A discotic liquid crystal molecule that possesses a columnar rectangular phase, discotic nematic phase, and isotropic phase (b). A phase diagram based on an extended McMillan framework where  $\alpha$  is a parameter that is proportional to the chain length on the discotic molecule.

tilted. A hexagonal phase is shown in Figure 7a. The discotic nematic phase (often denoted as  $N_D$ ) is also shown in Figure 7a where the disks order along the nematic director  $\mathbf{n}$  (orthogonal to plane of molecule) but they do not organize into columns.

Transitions between the columnar and the discotic nematic phases occur in certain compounds. An example compound is shown in Figure 7b, known as 2,3,6,7,10,11-(triphenylene hexaocetylloxy benzoate), exhibits a rectangular hexatic phase and discotic nematic [56]. Like low molecular weight rodlike molecules, transitions can occur between  $N_D$  and the isotropic or between D and the isotropic phase as well, depending on the molecular configuration. To develop a quantitative description of the D- $N_D$ -isotropic transitions, an extended McMillan mean-field model can be employed; such a model is analogous to smectic A phase model where the density wave is now periodic in two dimensions [57–59].

The D phase can be described by a superposition of three density waves with wavevectors:

$$\begin{aligned} \mathbf{A} &= \frac{4\pi}{\sqrt{3}d} \mathbf{j} \\ \mathbf{B} &= \frac{4\pi}{\sqrt{3}d} \left( \frac{\sqrt{3}}{2} \mathbf{i} - \frac{1}{2} \mathbf{j} \right) \\ \mathbf{C} &= \mathbf{A} + \mathbf{B} \end{aligned} \quad (3)$$

where  $\mathbf{i}$  and  $\mathbf{j}$  are conventional unit vectors and  $d$  is the lattice constant. The orientational order parameter is identical to that of a rodlike nematic  $Q = \langle P_2(\cos \theta) \rangle$  and the

order parameter coupling the orientational and the transitional order is given by

$$\sigma = \frac{1}{3} \langle [\cos(\mathbf{A} \cdot \mathbf{r}) + \cos(\mathbf{B} \cdot \mathbf{r}) + \cos(\mathbf{i} \cdot \mathbf{r})] P_2(\cos \theta) \rangle$$

In the development of this model, the form of the potential ensures that the energy of the molecule is minimum when the disk is centered in the column with its plane normal to the z-axis. There are three possible minimum solutions to the energy, where  $Q = 0$  and  $\sigma = 0$  in the isotropic phase,  $Q \neq 0$  and  $\sigma = 0$  in the  $N_D$  phase, and  $Q \neq 0$  and  $\sigma \neq 0$  in the D phase. The phase diagram is shown in Figure 7c as a function of  $\alpha$ , which is a measure of the chain length in the McMillan model.

Discotic mesogens can also be of high molecular weight when attached to a backbone or as side groups as shown in Figure 8. When rod-shaped molecules form repeating units, conventional mesophases are observed as in low molecular weight compounds. Disk shape moieties can also repeat to form a side chain and main chain polymers as shown in Figure 8a and b, respectively. A polyester with disk-shaped triphenylene as the repeating unit in the main chain separated by flexible spacers forms a hexagonal column structure with intercolumn binding and intracolumn backfolding as shown in Figure 8c [60]. Rigid aromatic polyamides and polyesters with discotic units in the main chain exhibit a new type of mesophase known as sanidic (i.e., boardlike). In the sanidic nematic phase, the boards organize parallel to one another as shown in Figure 8d [61]. The incorporation of an electron acceptor molecule to discotic polymer certain non-mesogenic materials have been shown to induce mesophases—called the column nematic.

### 3. REACTIVE MESOGENS

These materials form liquid crystal phases whose order can be captured indefinitely by polymerization, often photocentrized. For completeness, we have also included the work on calamitic materials since there is significant synergy with mesophase-derived carbons in Sections 6 and 7.

**Figure 8.** Examples of polymeric discotic liquid crystals where liquid crystalline moieties are attached to the backbone as side chains (a) and main chain (b). A diagram illustrating intercolumnar binding and intracolumnar backfolding of the main chain (c) and the sanidic nematic phase composed of boards stacked parallel to one another (d).

### 3.1. Synthetic

Tailoring the molecular ordering profile of polymers in three dimensions is a highly desired property with many practical implications. The methods used in creating these ordering arrangements are limited in number and no generic algorithm exists, which enables complete and unrestricted control over the orientation of molecules in all directions. A method that approaches this ambitious goal focuses on photopolymerization of reactive monomers, which possess an intrinsic liquid crystal phase (these materials are often referred to as reactive mesogens). The well-known techniques to establish monolithic order in low molecular weight liquid crystals, based on their susceptibility to external fields and sensitivity to surface interactions, can be used to capture sophisticated ordered molecular architectures in thin polymer films. Tailored planar films created from reactive mesogens have recently become an inconspicuous passive optical element in liquid crystal displays to resolve their long-standing viewing angle problem (example given in Section 5.2). When reactive mesogens are polymerized in nonreactive liquid crystals, many other exciting applications are possible including bistable displays and switchable mirrors.

In addition to planar films, novel microstructures can also be created from reactive mesogen compounds. A typical reactive mesogen calamitic liquid crystal is shown in Figure 9 (known as RM257, available from EM Industries).

**Figure 9.** A reactive liquid crystal (mesogen) with a stable nematic liquid crystal phase. This material is known as RM257 and is commercially available from EM Industries (a). Scanning electron microscope photographs of microstructures created from reactive mesogens (b): yarn-ball, tube, and toroid (top) and sphere, rod, and ellipsoid particles (bottom). An example of a reactive discotic, epoxy-based discotic liquid crystal (c).

It is a diacrylate monomer with a stable nematic liquid crystal phase between 70 °C and 126 °C, and can be photopolymerized with UV light. Figure 9b shows scanning electron microscope photographs of a variety of novel microstructures, such as yarn-balls, hollow tubes, toroids, solid spherical balls, solid cylindrical rods, and ellipsoid-shaped particles.

The yarn-balls, tubes, and toroids are actually created through a self-assembly process. The reactive mesogen material (e.g., RM257) is dissolved in solvent and capillary filled into the channels (0.2  $\mu\text{m}$  in diameter) of Anopore membranes. Anopore membranes are porous alumina matrix ( $\text{Al}_2\text{O}_3$ ). The solvent is evaporated after the fill, and the sample is then subjected to UV light to polymerize the reactive mesogen while the material is held at constant temperature to stabilize the liquid crystal phase. It is believed that the reactive mesogen is ordered on the surface of the channels after evaporation, forming a thin ordered layer. The Anopore membrane is then etched away with a NaOH solution, leaving behind the polymerized reactive mesogen. Depending on the concentration of reactive mesogen in the solvent and the boundary conditions induced by the channel walls, various self-assembled microstructures have been reported: yarn-balls, hollow tubes, and toroids. It is also interesting to note that these microstructures (e.g., yarn-balls) will transition into a planar structure when subjected to an applied external field.

In order to create ordered solid microstructures using reactive mesogens, the material is filled into templates, heated to a temperature where the nematic phase is stable, and then photopolymerized with UV light. Figure 9b shows solid spherical balls created in a glycerin binder, solid rods created in an Anopore template, and ellipsoidal particles created in a stretched polyvinyl alcohol (PVA) binder. The spherical balls have also been shown to rotate with the application of electric fields since they have a captured dielectric anisotropy.

Up to this point we have discussed calamitic reactive mesogens, but there also exist reactive mesogens with stable discotic phases as shown in Figure 9c. These have tremendous application in flat panel displays as will be discussed in Section 5.2. Many of the process steps described in this section have also been applied to carbonaceous materials to form intriguing nanoforms.

### 3.2. Carbonaceous Mesophase

The class of reactive discotic mesogens includes carbonaceous mesophase, the naturally occurring discotic liquid crystal mixture that forms spontaneously during high-temperature treatment (>300 °C) of certain organic starting materials [28]. It is arguably the most important of all discotics, reactive or stable, due to its many technological uses, and a number of review articles have been dedicated to carbonian mesophase [23, 62–68]. It is classified here as a reactive mesogen since its main use is not in the liquid state or as a quenched mesophasic glassy solid, but as a precursor for ordered carbon materials, in which the order is established in the liquid phase and then “captured” by heating at temperatures in excess of 500 °C. This heating process captures order through loss of the lower molecular weight components that give mobility to the liquid crystalline phase as

well as through chemical coalescence of polyaromatic compounds accompanied by hydrogen evolution.

Remarkably, the discovery of carbonaceous mesophase predates the discovery of synthetic discotics in the late 1970s. Prior to the discovery of fullerenes, the discovery of carbonaceous mesophase in 1965 was the most celebrated advance in carbon science [28]. Despite its early discovery, carbonaceous mesophase is not as well understood as most other liquid crystalline systems. Its complex composition and chemical instability have discouraged systematic investigation of its key fundamental properties. Because of its importance in carbon materials, however, there has been a great deal of work over the last several decades to overcome these challenges and develop a deeper understanding of this unique liquid crystal and the practical carbons and nanocarbons derived from it.

### 3.2.1. Synthesis and Forms

Carbonaceous mesophase is formed by heating lower molecular weight organic material, typically in the absence of oxygen at temperatures from 300–500 °C. Chemical pathways in this thermal process have been reviewed by Lewis [69]. Carbonaceous mesophase first forms by precipitation of an ordered second liquid phase from the original isotropic liquid, and in some applications grows during further heating to eventually form a homogeneous, single-phase liquid crystal. As discussed in the introduction, it is often formed *in-situ* as an intermediate in the conversion of isotropic organic matter into carbon, but increasingly is manufactured as a bulk liquid crystal phase and marketed as “mesophase pitch” for further processing or applications.

### 3.2.2. Phase Behavior

Although carbonaceous mesophase shares many features with conventional (synthetic) liquid crystal systems, there are some notable differences. First, carbonaceous mesophase typically forms upon *heating*, in contrast to most liquid crystal systems which adopt ordered configurations upon cooling. Heating induces chemical reactions, a form of two-dimensional polymerization that increases the mean size and aspect ratio of the disk-like molecules and thus increases their liquid crystal forming tendency. Second, heating causes vaporization of smaller molecules in the mixture (which have weak LC-forming tendencies) and thus increases the concentration and mutual interaction of the larger molecules (mesogens), favoring order development as in lyotropic liquid crystals.

Further, the formation of carbonaceous mesophase is typically irreversible. At high temperature, mesogen cross-linking and evaporative loss of lower molecular weight fractions typically trap the liquid crystalline order in a permanent solid phase. Only when chemical growth and vaporization are limited, such as in the experiments of Lewis [70] on pitches of high chemical stability, is it possible to observe a reversible phase transition upon temperature cycling. In this particular case, temperature cycling between 650 and 770 K led to mesophase appearance on cooling and the appearance of an isotropic liquid phase (a “clearing” event) upon heating. This demonstrates the thermotropic nature of

the phase transition and implies the importance of attractive forces in the formation of liquid crystal order. Overall, it appears that carbonaceous mesophase has a dual thermotropic and lyotropic nature [28]. Liquid crystal formation is caused by a combination of intermolecular attractive forces between disks (thermotropic nature) and the loss of low molecular weight non-mesogenic material upon heating (lyotropic nature).

The quantitative treatment of phase equilibrium in mesophase-containing pitches is a major challenge due to the complex chemical makeup of pitch materials and their chemical reactivity. To date there have been only three attempts to quantitatively describe the liquid crystal phase behavior of pitches: one by Shishido et al. [71] and a series of two more recent papers [72, 73]. Shishido et al. [71] applied a statistical theory of liquid crystalline mixtures developed by Luckhurst and co-worker [74] to an experimental phase diagram reported previously by Mochida and Korai [75]. In the original experiments, Mochida and Korai separated a petroleum pitch into benzene soluble (BS) and benzene insoluble (BI) fractions and recombined them in various weight ratios and at various temperatures to obtain the partial phase diagram reproduced in the top panel of Figure 1. Shishido et al. [71] treated both fractions (BS, BI) as pseudo single components (rather than mixtures), thus reducing the complex phase equilibrium problem to a tractable binary problem. They further assumed the benzene soluble fraction to be non-mesogenic, that is, to have no liquid crystal forming tendency. This pioneering attempt at the quantitative treatment of mesophase formation involved no adjustable parameters and gave an impressive, if imperfect, description of the observed phase behavior.

Hurt and Hu [72] subsequently proposed a simple multicomponent model based on virtual clearing temperatures for pseudo-components of differing molecular weight. Both of the early modeling attempts are based on ideal solution behavior, that is, on the assumption that orientational molecular order is the main variable governing free energy. In fact, there is evidence that the various molecular weight fractions in pitches are chemically different, and the corresponding differences in intermolecular interactions, even in the absence of molecular order, strongly influence phase behavior. The most recent treatment of phase behavior combines statistical theories of the liquid crystalline state with nonideal mixing submodels based on the solubility parameter approach coupled with combinatorial contributions to the excess mixing entropy [73]. This model has been applied to several literature data sets, including the phase diagram of Mochida and Korai [75], the detailed fractionation data of Greinke and Singer [76], and the visual observations of phase behavior in naphthalene pitch from the hot stage microscope experiments of Lewis [70].

Sensitivity studies with the model indicate the importance of two distinct driving forces for mesophase formation: (a) poor solubility of high molecular weight aromatic molecules in the lower molecular weight fractions (the nonideal mixing effect), and (b) reduction in the system free energy by molecular orientation of the larger, disklike molecules (orientational ordering effect), the latter being enhanced by expulsion of some of the smaller, less oriented

molecules to a separate isotropic phase. For the cases examined in that study [72], both contributions are significant and must be considered.

### 3.2.3. Other Ordering Mechanisms

In common with other liquid crystals, carbonaceous mesophase can be aligned using fields [77–79], flows [21, 80], and surfaces [81, 82]. Surface and confinement effects are of particular importance and are treated in the following section.

## 4. ANCHORING AND CONFINEMENT

Liquid crystals constrained to confining geometries are currently a subject of intense research stimulated by fundamental interest and potential in electro-optic devices. Confined liquid crystals exhibit a rich variety of different structures, which strongly depend on the delicate balance between elastic, surface, and external field forces. Varying the temperature, field, surface conditions, and geometry can induce transitions among these structures. The focus of our article is on carbon materials processed through an intermediate discotic liquid crystal phase. There is a tremendous wealth of work on low molar mass liquid crystals confined to various geometrical shapes that can be leveraged to predict and better understand new carbon forms. We believe that this background is important for the future of carbon materials formed from discotic liquid crystal intermediates. Here we are interested in phenomena which occur on distances much longer than the nematic correlation length so that Frank elastic theory [83] can be employed.

### 4.1. Phenomenology of Nematic Ordering

We briefly review the phenomenology of bulk nematic liquid crystals and then focus our attention on the influence of the confinement. Although we will deal with elastic theory based on the director field description of nematic liquid crystals, we will try to see its limitations by first examining a more general tensorial description. Such a phenomenological approach, known as Landau–de Gennes theory, is based on the tensor order parameter  $\underline{Q}$  with components  $Q_{ij}$ . In the eigenframe defined by the nematic director,  $\mathbf{n}$ , the corresponding degrees of order are measured by eigenvalues  $Q$  (nematic order parameter) and  $P$  (biaxial order parameter), respectively. In this approach the free energy is expanded in terms of symmetry allowed powers of the order parameter and its derivatives. In zero external field, the expansion of the free energy density  $f_n$  must have second-, third-, and fourth-order terms in  $\underline{Q}$  to describe the nematic-isotropic transition, and terms quadratic in the first derivatives of  $\underline{Q}$  and linear in the second derivative to describe the weakly nonuniform states [84, 85]:

$$\begin{aligned} f_n = & f_0(T) + a(T - T^*)Q_{kj}Q_{kj}/2 - bQ_{ki}Q_{ij}Q_{jk}/3 \\ & + c_1(Q_{kj}Q_{kj})^2/4 + c_2Q_{jk}Q_{ki}Q_{ij}Q_{jk}/4 + L_1^{(1)}Q_{ij,ij} \\ & + L_1^{(2)}Q_{jk,i}Q_{jk,i} + L_2^{(2)}Q_{ij,i}Q_{kj,k} + L_3^{(2)}Q_{jk,i}Q_{ik,j} \\ & + L_1^{(2)}e_{ijk}Q_{il}Q_{jl,k} + L_5^{(2)}Q_{ik,ij}Q_{jk} + L_6^{(2)}Q_{jk,ii}Q_{jk} \end{aligned}$$

$$\begin{aligned} & + L_1^{(3)}Q_{ij}Q_{ij,k}Q_{kl,l} + L_2^{(3)}Q_{ij}Q_{ij,k}Q_{jk,l} \\ & + L_3^{(3)}Q_{ij}Q_{jk,k}Q_{jl,l} + L_4^{(3)}Q_{i,j}Q_{ik,l}Q_{jk,l} \\ & + L_5^{(3)}Q_{ij}Q_{ik,l}Q_{jl,k} + L_6^{(3)}Q_{ij}Q_{jk,l}Q_{kl,j} + \dots \end{aligned} \quad (4)$$

Here  $a(T - T^*)$ ,  $b$ ,  $c_1$ , and  $c_2$  are expansion coefficients of the homogeneous nematic phase and we use the  $L_i^{(j)}$  coefficients of the expansion in the non-uniformly ordered phase. We choose the standard notation where two equal indices indicate summation and the indices preceding the comma represent the derivatives.

The application of an external magnetic (or similarly electric) field  $\mathbf{H}$  adds to the free energy density in the following anisotropic contribution [86]:

$$f_f = 1/2\mu_0\Delta\chi_0\mathbf{H}\underline{Q}\mathbf{H} \quad (5)$$

where  $\Delta\chi_0$  is the difference between the principal values of the susceptibility tensor in a completely ordered nematic phase. The addition of this term “smooths” the first-order nature of the nematic-isotropic phase transition and may possibly result in its disappearance with increasing external field [87].

The combined free energy density  $f = f_n + f_f$  can qualitatively describe all features of a bulk nematic liquid crystal system. Taking into account the basic thermodynamic principle that the free energy of a system approaching equilibrium state at constant temperature and volume tends towards its minimum value, one can develop a formal procedure for the determination of the stable structures. Comparison of the theoretical predictions with experimental data for the order parameter, susceptibility, and specific heat, yields the values of expansion coefficients [20]. It is noted that fluctuations are neglected, and therefore the formalism cannot describe all details of the critical behavior.

### 4.2. Frank Elastic Theory

The free energy function (Eq. (4)) indicates that variations of the eigenvalues  $\underline{Q}$  and the director  $\mathbf{n}$  contribute in different ways. Spatial variations in the eigenvalues  $Q$  or  $P$  are characterized by the nematic correlation length [86]  $\xi = \xi_0|T/T^* - 1|^{-1/2}$  with  $\xi_0 = [(L_1^{(2)})/(aT^*)]^{1/2}$ , which does not exceed a few molecular lengths even close to the  $T_{NI}$ . Variations in  $\mathbf{n}$  tend to spread over the entire available space to reduce the contribution to the free energy of the deformation of the orientation field [86]. Therefore, on scales large compared to  $\xi$ , the degree of order ( $Q$ ) is nearly constant and the director slowly varies through the space. For a uniaxial nematic phase, such a constant order parameter approximation leads to the following:

$$Q_{ij}(r) = \frac{1}{2}Q[3n_i(r)n_j(r) - \delta_{ij}] \quad (6)$$

and consequently the nematic structure can only be described by the director field  $\mathbf{n}(\mathbf{r})$  with the  $\mathbf{n} = -\mathbf{n}$  symmetry [86].

The field contributing to the free energy density transforms into the following:

$$f_f = \frac{1}{2} \mu_0 \Delta \chi (nH)^2 \quad (7)$$

with  $\Delta \chi = \mathbf{Q} \Delta \chi_0$ , where  $\chi_0$  is the magnetic susceptibility of the perfectly ordered nematic phase. To measure the relative strength of the external field  $\mathbf{H}$ , the inverse magnetic coherence length  $\xi_M^{-1} = (\Delta \chi \mu_0 / K)^{1/2} H$  is employed, where  $K$  represents a specific elastic constant or an appropriate combination. Similarly for the electric field case, the inverse electric correlation length is  $\xi_E^{-1} = (\Delta \varepsilon \varepsilon_0 / K)^{1/2} E$ , where  $\Delta \varepsilon$  is the dielectric susceptibility.

The nematic free energy thus reduces to the Frank elastic free energy [88–90]:

$$f_d = \frac{1}{2} \{ K_{11} (\nabla \cdot \mathbf{n})^2 + K_{22} (\mathbf{n} \cdot \nabla \times \mathbf{n})^2 + K_{33} (\mathbf{n} \times \nabla \times \mathbf{n})^2 \} - \frac{1}{2} \{ K_{24} \nabla \cdot (\mathbf{n} \times \nabla \times \mathbf{n} + \mathbf{n} \nabla \cdot \mathbf{n}) + K_{13} \nabla \cdot (\mathbf{n} \nabla \cdot \mathbf{n}) \} \quad (8)$$

where the Frank elastic constants are related in the following way to the  $L_{ij}$  constants [22]:

$$\begin{aligned} K_{11} &= 9Q^2 \frac{(2L_1^{(2)} + L_2^{(2)} + L_3^{(2)} - L_5^{(2)} - 2L_6^{(2)})}{2} \\ &\quad + 9Q^3 \frac{(-L_2^{(3)} + 2L_3^{(3)} + L_4^{(3)} + 2L_5^{(3)} - L_6^{(3)})}{4} \\ K_{22} &= 9Q^2 (L_1^{(2)} - L_6^{(2)}) + \frac{9Q^3}{4L_4^{(3)}} \\ K_{33} &= 9Q^3 \frac{(2L_1^{(2)} + L_2^{(2)} + L_3^{(2)} - L_5^{(2)} - 2L_6^{(2)})}{2} \\ &\quad + 9Q^3 \frac{(2L_2^{(3)} - L_3^{(3)} + L_4^{(3)} - L_5^{(3)} + 2L_6^{(3)})}{4} \\ K_{24} &= 3QL_1^{(1)} + \frac{9Q^{(2)}}{2(2L_1^{(2)} + L_3^{(2)} - L_5^{(2)} - 2L_6^{(2)})} \\ &\quad + 9Q^{(3)} (L_4^{(3)} + 2L_5^{(3)} - L_6^{(3)}) \\ K_{13} &= 3QL_1^{(1)} + 3Q^{(2)} \frac{L_5^{(2)}}{4} \end{aligned} \quad (9)$$

The constants  $K_{11}$ ,  $K_{22}$ , and  $K_{33}$  correspond to splay, twist, and bend elastic deformations, respectively. Further,  $K_{24}$  and  $K_{13}$  are the saddle-splay and mixed splay-bend elastic constants [86–90]. The volume integral of terms describing the corresponding deformations in Eq. (8) can be readily reduced to a surface integral because of the divergence in the volume integral. Therefore, they are often called surface elastic constants, a misleading term because they have nothing to do with surface properties of the material. Recently the name divergence elastic constants was introduced by Lavrentovich and Pergamenschik.

### 4.2.1. Deformed States

In a bulk nematic system, which does not exhibit a spontaneous deformation, a nonuniform director field is unstable or metastable. One can distinguish between the following situations:

1. Weak inhomogeneities caused by thermal fluctuations.
2. Large-scale inhomogeneities that can relax to the stable by a continuous transformation of the director field.
3. Large inhomogeneities/singularities (defects) which cannot relax by a continuous transformation of the director field.

In real systems, deformations with or without singularities can be stabilized by external constraints (surface or fields). Here we will briefly review some aspects of the defects in the director field.

The points or lines in space where the director field is singular or not defined are called disclinations. Although they have been known since the observations of Lehman [91] and Fridel [92] many years ago, the attempt of a qualitative description was performed by Frank [17] much later. Disclinations are usually categorized by their defect strength  $s = \Phi / (2\pi)$ . The rotation angle of the director  $\Phi$  caused by encircling the defect is usually determined by polarization microscopy. Possible defects that occur in uniaxial nematic phases are shown in Figure 10a. For more details consult the literature [86, 93–95].

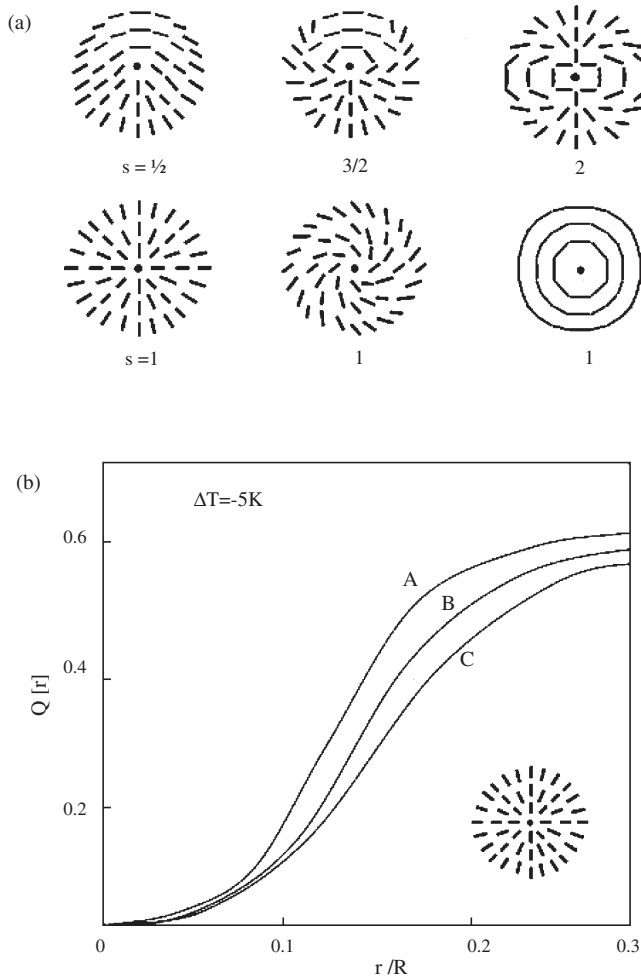

The phenomenology of point and line defects is well explained with a topological theory using homotopic groups [96–98] and supplemented by a free energy analysis.

Defects are in the same homeotropy class if their director field can be continuously deformed into another. This simply explains the transformation of a singular  $s = 1$  disclination line in a uniaxial nematic phase into a structure with a nonsingular director field with an escape into the third dimension [99–102]. One can find comprehensive reviews in this field [103], analogies with helium [104], and even arguments on how they are related to cosmological systems [105]. Since the elastic energy density in the defects cannot exceed the difference between the free energy of the nematic and isotropic phase, the order there is partially depressed (partial melting of the nematic phase) or it becomes biaxial. “Pushing” beyond the constant order parameter description and solving equations for either scalar or tensorial order parameters, one finds that solutions for  $Q$  or eigenvalues of the tensor  $\mathbf{Q}$  change continuously. The size of the area where they substantially deviate from bulk values, usually referred to as the defect core, is comparable to the nematic correlation length  $\xi$ . Order parameter variations close to an  $s = 1$  point defect are shown in Figure 10b.

### 4.2.2. Confining Surfaces

Perturbation of the orientational direction caused by the structure and interactions with the confining surface usually propagates through the entire confined liquid crystal sample. This enables the assessability of interesting phenomena not available in simple solids or liquids.

The coupling between surface and liquid crystal molecules depends on their structure. Excluding chemical bonding, the

**Figure 10.** Director fields of six different types of defects with their corresponding strengths (a). Variation of the order parameter  $Q$  in the vicinity of an  $s = 1$  point defect (b). The material parameters  $a$ ,  $T^*$ ,  $b$ ,  $c_1$ ,  $c_2$ , and  $L_1^{(2)}$  are particular to 5CB. Curve A corresponds to  $L_2^{(2)} = -L_1^{(2)}$ , curve B to  $L_2^{(2)} = 0$ , and curve C to  $L_2^{(2)} = L_1^{(2)}$ . The value of  $R$  is chosen to be 100 nm.

main contributions to the ordering “field” in the interfacial region are sterical repulsion, van der Waals interactions, and dipolar coupling. The non-polar coupling induced nematic ordering can also persist far away from the surface. The dipolar part is relevant for establishing polar order in the surface layer when molecules are amphiphilic and the surface is either polar or aliphatic [106]. The description of surface effects using the microscopic approach is limited to simple models describing the effective aligning interactions [107–109].

A direct prediction of nematic ordering has been performed using the Monte Carlo method; but this approach is limited to very small droplets [110]. The main value of these microscopic approaches is that they enable a prediction of the coefficients of the phenomenological Landau–de Gennes description of surface phenomena [111]. In recent years, Zumer and co-workers have significantly pushed Monte Carlo simulations to new levels to better understand confined liquid crystals.

It is instructive to examine possible symmetry breaking of the orientational ordering caused by surfaces:

**Translational symmetry** is directly broken by the presence of boundaries and indirectly by the nonuniform positional and orientational ordering caused by confinement. This can lead to layering.

**Oriental symmetry** is broken on surfaces because of restricted molecular orientations. This results in preferred anchoring direction.

**Rotational symmetry** (around the axis along the director) is lost on the surface and in the rest of the volume where the liquid crystalline ordering is distorted. This leads to biaxial ordering and flexoelectric polarization [20].

**Inversion symmetry** (rotation around the short molecular axis) can be lost in the surface layer if the molecular interaction is such that the head, tail, or other parts, of the liquid crystal molecule have a preferred position relative to the surface. This usually manifests in nonzero surface polarization.

Macroscopic description of surface effects is based on the contribution to the free energy given by an integral of the surface free energy density (fs)–surface tension–over the entire confining surface. For a review of this field see the paper by Jerome [112].

If the surface is not planar, it is convenient to distinguish a supramolecular scale (comparable to the nematic correlation length  $\xi$ ) where the surface is characterized by its roughness, and the macroscopic scale (distances  $\gg \xi$ ) where shape of the surface is characterized by its radii of curvature.

#### 4.2.3. Anchoring Energy

The term anchoring energy was introduced to describe the part of surface tension associated with the deviation of the nematic ordering direction at the surface from its preferred value at the surface, caused by elastic torques in the constrained liquid crystal. The omission of the variation of the degree of orientational order can be justified on similar grounds as in the case of the Frank elastic theory. For many systems, orientational anchoring can be broadly classified as homeotropic, tilted, or planar anchoring depending on whether the preferred direction is perpendicular, tilted, or parallel to the surface. Additionally, the last two cases can be monostable, bistable, multistable, or degenerate depending on the nature of the surface.

In our discussion we are going to deal with homeotropic and monostable (usually called homogeneous) planar anchoring when the lowest order terms in the surface free energy density expansion are retained. This well-known Rapini–Paupolar form of the anchoring free energy is given by

$$f_s = f_{s0} + \frac{1}{2} W_\theta \sin^2 \theta \quad (10)$$

for homeotropic anchoring and has a similar form [60]

$$f_s = f_{s0} + \frac{1}{2} (W_\theta \cos^2 \phi + W_\theta \sin^2 \phi) \sin^2 \theta \quad (11)$$

for monostable planar anchoring. Here  $\theta$  is the angle between the director  $\mathbf{n}_s$  and preferred anchoring direction  $\mathbf{m}_s$  and  $\Phi$  is the angle measuring the azimuthal direction of  $\mathbf{n}_s$ , as presented in Figure 11. The parameter  $W_\theta$  represents the polar anchoring strength associated with any variation of the angle  $\theta$  in the homeotropic case and with out-of-plane variations in the planar case, while  $W_\phi$  represents the azimuthal anchoring strength associated with in-plane director deviations in the planar case. Anchoring transitions, sometimes called alignment transitions, can be driven by the temperature [113], the concentration of adsorbed aligning molecules at the surface [114], or the chain length of the surface aligning molecules. Discrete [110, 114] and continuous changes in the tilt angle [115, 116] have been observed. Theoretical considerations based on a microscopic model [46] and Landau–de Gennes theory [117, 118] are in agreement with observations.

#### 4.2.4. Total Free Energy

Within the limitations of the director field approach, which combines bulk and surface contributions of the free energy, it is possible to predict all stable and even metastable structures of a confined nematic liquid crystal. For instructive purposes, let us choose a relatively large spherical cavity where the director field does not deviate much from the case of infinitely strong anchoring and make an order of magnitude estimate of both contributions. It is instructive to compare the elastic deformation in the bulk and surface anchoring contributions. The surface contribution to the free energy (Eq. (10)) is thus  $W_\theta(\Delta\Theta)^2R^2$ , where  $\Delta\Theta$  is the average deviation of the director angle from the preferred surface anchoring angle. The bulk contribution estimated from Eq. (8) is  $\sim KR$  and the reduction from this value is  $\sim K\Delta\Theta R$  because the anchoring angle is not perfect. The minimization of total free energy indicates that  $\Delta\Theta \sim K/(W_\theta R)$ . A similar estimate can be made also for cylindrical cavities. The parameter  $K/(W_\theta R)$  will be further used to distinguish between (1) weak anchoring regime  $K/(W_\theta R)I$ , usually realized in cavities of micrometer size; (2) strong anchoring regime  $K/(W_\theta R) \gg I$ , usually realized in supramicrometer-size cavities.

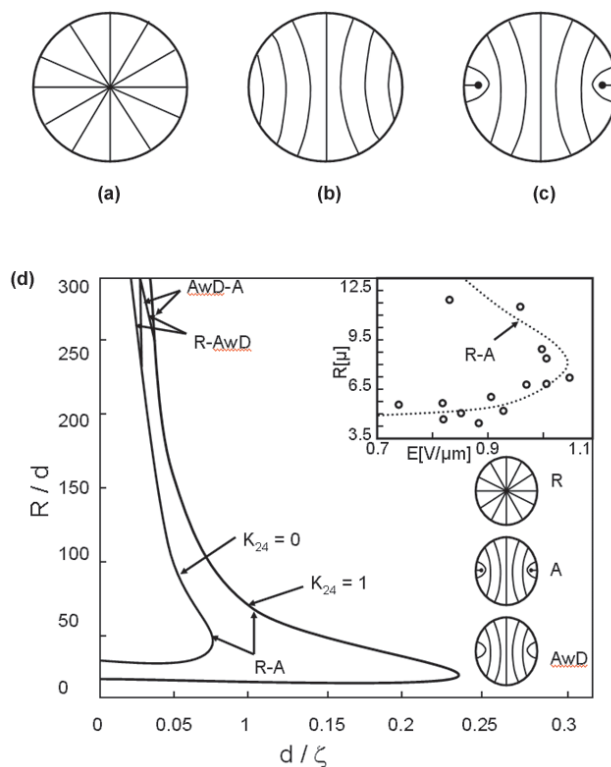

**Figure 11.** Schematic presentation of the anchoring geometry with the symbols used in the text.

### 4.3. Calamitic Nematic Structures and Structural Transitions in Confined Liquid Crystals

We will briefly review some simple systems reported in the literature for low molar mass systems. We focus on spherical and cylindrical systems. For simplicity we limit our discussion to surfaces, which support either homeotropic or planar anchoring and materials.

#### 4.3.1. Calamitic Nematic Microdroplets

Let us first consider a transition in micrometer-size droplets which can be studied with optical polarizing microforms and reasonably well described by Frank elastic energy, but is still small enough to be in a relatively weak anchoring regime. The first, more quantitative study of transitions in nematic liquid droplets, as shown in Figure 12, dispersed in a polyurethane matrix, was performed by Erdmann and co-workers [119]. The first-order transition from a radial to an axial director field (see Fig. 12d) in droplets with homeotropic anchoring was induced by either temperature (Fig. 10a) or applied electric fields. The inset in Figure 12d shows the applied external electric field data. A single elastic constant  $K_{11} = K_{22} = K_{33} = K$  free energy without surface elastic terms supplemented by Rapini–Papoular surface coupling (Eq. (10)) was used. The dimensionless variables  $R/d$ ,

**Figure 12.** Stable nematic director fields in spherical geometries: (a) radial, (b) axial in the weak anchoring regime, and (c) axial in the strong anchoring regime, with an equatorial line disclination. The calculated stability diagram of droplets with homeotropic anchoring in the external field for two values of  $K_{24}$  constant (d). The experimental phase diagram is shown as an inset.

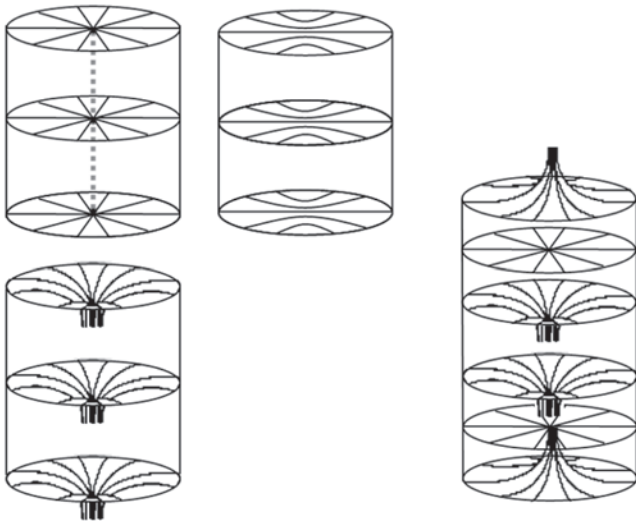

where  $d$  is the extrapolation length [86] and  $d/\xi_E$ , where  $\xi_E^{-1}$  is the inverse electric coherence length, are employed. The comparison with experiments was used to determine anchoring energy  $W_\theta$  as a function of temperature and to estimate the effective internal electric field whose small values (five to seven times smaller than applied field) were attributed to the dielectric properties of liquid crystal and polymer. A more detailed calculation taking into account  $K_{24} \neq 0$  shows that besides the axial structures without a defect (see Fig. 12b), there is in the strong anchoring regime ( $W_\theta R/K \gg 1$ ) a stable region where an axial structure with a  $s = \frac{1}{2}$  ring defect in the diametrical plane (Fig. 12c) is stable. The stability area of this structure terminates in a triple point (see Fig. 12d). One must be aware that in this strong anchoring limit the transitions exhibit a large hysteresis because of the high energy barrier between the two structures [120]. The lines of coexistence have two other interesting points: the zero transition point  $(0(R/d)_0)$  and the inversion point  $((d/\xi_E)_i, (R/d)_i)$  corresponding to the largest  $d/\xi_E$  (field) where radial structure is still stable. The nonzero  $K_{24}$  value broadens the stability range of the radial structure (see Fig. 12d), which is the basis of the two methods for simultaneous determination of  $K_{24}$  and  $W_\theta$ .

### 4.3.2. Calamitic Nematic Liquid Crystals in Cylindrical Cavities With Homeotropic Anchoring

The structures considered in this section are stable in case of homeotropic surface anchoring conditions. The four structures to be reviewed are schematically presented in Figure 13.

**Planar-Radial Structure** The planar-radial (PR) configuration has been treated in detail by Dzyaloshinskii [121], Cladis and Kleman [100], Meyer [101], and Saupe [89], and is illustrated in Figure 13. Since  $\mathbf{n}$  is normal to surface,

**Figure 13.** Stable nematic direction fields in cylindrical geometries when homeotropic anchoring is enforced at the cylindrical walls.

the free energy per unit length of the cylinder (pure splay energy) is expressed by

$$F_{PR} = \pi K_{11} \ln(R/\rho) \quad (12)$$

where  $\rho$  is the radius of the line disclination which is of the order of molecular dimensions where elastic theory breaks down. This configuration is independent of the surface anchoring energy since  $\mathbf{n} \parallel \mathbf{r}$ .

**Planar-Polar Structure** The planar-polar structure (PP) can be specified by  $\mathbf{n} = \cos \psi(r, \theta) \mathbf{i}_r + \sin \psi(r, \theta) \mathbf{i}_\theta$ , where  $\psi$  is the angle between the local nematic director and the direction of the symmetry axis as illustrated in Figure 13 [122]. The exact solution to the director field in the  $K_{11} = K_{33} = K$  approximation is given by

$$\psi(r, \theta) = \frac{\pi}{2} = \tan^{-1}\{(R^2 + \gamma r^2) \tan \theta / (R^2 - \gamma r^2)\} \quad (13)$$

where  $\gamma = (\varsigma^2 + 1)^{1/2} - \varsigma$  and  $\varsigma = 2K/RW_\theta$ . The PP director field is therefore a strong function of the effective anchoring strength  $RW_\theta/K$  and independent of  $K_{24}$ . The free energy per unit length is given by

$$F_{PP} = \pi K \{1 \ln(2\gamma\varsigma) + (1 - \gamma)/\varsigma\} \quad (14)$$

The calculation for the PP structure becomes more involved for  $K_{11} \neq K_{33}$  since no analytical solution exists and one must resort to numerical methods.

**Escaped-Radial Structure** The escaped-radial (ER) structure, illustrated in Figure 13, was studied in the strong anchoring limit by Cladis and Kleman [100], Meyer [101], and Saupe [89], and later researchers [122], included  $K_{24}$  and  $W_\theta$ . The nematic director field can be completely specified by  $\mathbf{n} = \cos \Omega(r) \mathbf{i}_r + \sin \Omega(r) \mathbf{i}_z$ , where  $\Omega$  is the angle between  $\mathbf{n}$  and the cylinder axis  $\mathbf{i}_z$ , and only depends on the radial coordinate  $\mathbf{n}$ . Employing the one-constant approximation  $K_{11} = K_{33} = K$ , the nematic director field has the following analytical form:

$$\Omega(r) = 2 \tan^{-1}\{r \tan(\alpha/2)/R\} \quad (15)$$

where the molecular anchoring angle is  $\alpha = \Omega(r = R) = \cos^{-1}(1/\sigma)$  and  $\sigma = RW_\theta/K + K_{24}/K - 1$  is the dimensionless surface parameter. Equation (13) is valid for  $\sigma > 1$ . If the physical constants are such that  $\sigma < 1$ , then the director field is aligned along the cylinder axis ( $\Omega = 0$ ). The free energy per unit length in the one-constant approximation is

$$F_{ER} = \pi K (3 - K_{24}/K - 1/\sigma) \quad (16)$$

where  $\sigma = RW_\theta/K + K_{24}/K - 1$  is the dimensionless surface parameter. Equation (14) is valid for  $\sigma > 1$ , and for  $\sigma < 1$  the free energy becomes  $\pi K (RW_\theta/K)$ . There also exists an analytical form for the situation when  $K_{11} \neq K_{33}$  [84]. It should be emphasized that the  $K_{11}$  contribution, because of the cylindrical symmetry, only renormalizes the anchoring strength.

**Escaped-Radial Structure with Point Defects** In practice, the ER structure is seldom realized. Fluctuations that are intrinsic near the nematic-isotropic transitions and irregularities of the cavity walls often lead to an ER structure with alternating radial and hyperbolic defects along the cylinder axis. This director field is called the escaped-radial structure with point defects (ERPD) and is schematically shown in Figure 13. In cylindrical cavities of finite length, it is stabilized by the boundary conditions on both ends [123]. The structure has the lowest free energy when it is periodic in the  $z$  direction. The period  $2L$  is the distance between two defects of the same type.

The ERPD structure does not have an analytical solution even in the one-constant approximation. There have been two methods employed to treat this structure [124]. The simpler is to construct a trial function that satisfies all necessary boundary conditions, the case where defects are equally spaced. Restricting our interest to the region  $L/R > 2$  and  $0 \rightarrow 1$ , an appropriate trial function is given by

$$\Omega(r, z) = \tan^{-1} \left\{ \frac{\sigma r}{z(1 - z/L)[\sigma - (\sigma - 1)r/R]} \right\} \quad (17)$$

for  $r < R$  and  $0 < z < L$ . Points in the region  $-L < z < 0$ , which make up the half of the unit cell, have angle  $\Omega$  that is the supplement of angle  $\Omega$  at the corresponding point in the region  $0 < z < L$  ( $\Omega(-z) = \pi - \Omega(z)$ ). Periodic repetition of this cell produces a lattice of alternating radial and hyperbolic defects of spacing  $L$  that is consistent with observations. The trial function (Eq. (17)) of the director field for the ERPD structure satisfies the director field near the radial point defect at  $r = z = 0$ , given by  $\Omega(r, z) = \tan^{-1}(r/z)$ , and the director near the hyperbolic defect given by  $\Omega(r, z) = \tan^{-1}(r/[1 - zL])$ , and simplifies to  $\mathbf{n} = \mathbf{i}_r$  at the surface in the strong anchoring limit; therefore, it is a reasonable approximation of the true director field. The resulting free energy per unit length for the ERPD trial function is given by

$$F_{\text{ERPD}} = \pi K \{ -4 \ln(L/R)/3 + 3 - K_{24}/K + 8/9 + (3\sigma)^{-1} + (6\sigma^2)^{-1} + \pi L(\sigma - 1)/5\sigma R \dots \} \quad (18)$$

A more precise way to model the ERPD director field is to pursue numerical solutions of the Euler–Lagrange equations for this case as was performed by Vilfan et al. [125]. In these numerical studies they discovered that in the case of very weak anchoring, the radial defect can be substituted by an aligned defectless structure similar to the axial structure in droplets illustrated in Figure 12b.

### 4.3.3. Calamitic Nematic Liquid Crystals in Cylindrical Cavities With Parallel Anchoring

The structures considered in this section are stable for parallel surface anchoring conditions. The four structures are schematically presented in Figure 14.

**Figure 14.** Stable nematic director fields in cylindrical geometries when parallel anchoring is enforced.

**Planar-Concentric Structure** The planar-concentric (PC) structure is a planar director field with a pure deformation and a line disclination along the cylinder axis as illustrated in Figure 14. This structure was first predicted by Dzyaloshinskii [121] and Cladis and Kleman [100]. The free energy per unit length is given by

$$F_{\text{PC}} = \pi K_{33} \ln(R/4\rho) \quad (19)$$

where  $\rho$  is the radius of the line disclination.

**Planar-Bipolar Structure** The planar-bipolar (PB) structure is a splay-bend director field with two surface disclinations running parallel to the symmetry axis of the cylinder connecting the poles of the planar director field (see Fig. 14) [126]. It is completely specified by  $n = \cos \psi(r, \varphi) \mathbf{i}_r - \sin \psi(r, \varphi) \mathbf{i}_\phi$ , where  $\Phi$  is the angle between the radial vector and the symmetry axis of the structure. The nematic director field has an analytic solution given by the expression

$$\psi(r/\varphi) = \tan^{-1} \{ \cot \phi (R^2 + \gamma r^2)/(R^2 - \gamma r^2) \} \quad (20)$$

where  $\gamma = (s^2 + 1)^{1/2} - s$  and  $s = 2K/RW_\theta$ . It depends only on the polar anchoring strength  $W_\theta$ . The finite anchoring conditions prohibit the presence of both surface disclination lines of the structure. The free energy per unit length of the PC structure is given by the expression

$$F_{\text{PC}} = \pi K \{ -\ln(2\gamma s) + (1 - \gamma)/s \} \quad (21)$$

There is no analytical solution for the  $K_{11} \neq K_{33}$  structure.

**Escaped-Twisted Structure** The escaped-twisted (ET) structure is a defectless director field illustrated in Figure 14 where the director is everywhere parallel to the surface and stabilized by the presence of the azimuthal anchoring  $W$  [126]. We consider the case where the preferred parallel anchoring direction on the surface is everywhere perpendicular to the cylinder axis. The bend-twist deformation of such a structure is specified by the cylindrical coordinates  $n = \sin \alpha(r) \mathbf{i}_r + \cos \alpha(r) \mathbf{i}_z$ , where  $\alpha$  is the angle between

the local nematic director and the cylinder axis. The equilibrium configuration for  $k = K_{33}/K_{11} > 1$  is given by the expression [61]

$$\left[ \frac{[1 + (k-1)\sin^2\alpha]^{1/2} - \cos\alpha}{[1 + (k-1)\sin^2\alpha]^{1/2} + \cos\alpha} \left( \frac{\sigma+1}{\sigma-1} \right) \right]^{1/2} \quad (22)$$

where  $\sigma = RW_\theta/K + K_{24}/K - 1$  is the dimensionless surface parameter. The free energy per unit length in the one-constant approximation is given by

$$F_{ET} = \pi K(3 - K_{24}/K - 1/\sigma) \quad (23)$$

The ET structure has no analytical solutions for the situation when  $K_{11} \neq K_{33}$  [126].

**Parallel Axial Structure** The parallel axial (PA) structure has a director field everywhere parallel to the cylinder axis ( $\alpha = 0$ ). The free energy per unit length is given by  $\pi K(RW_\theta/K)$  [126].

#### 4.3.4. Confined Discotic Liquid Crystals

The tracing and modeling in this section has focused on studies performed on low molar mass calamitic liquid crystal systems. However, it is equally applicable to discotic liquid crystals. Figure 15 illustrates possible director configurations for discotic liquid crystals with face-on and edge-on anchoring. Since the director of a discotic liquid crystal is orthogonal to the molecule, the director profile and molecular ordering are orthogonal. For calamitic liquid crystals, the director field is parallel to the long axis of the liquid crystal.

**Experimental Studies of Discotic Anchoring and Confinement** For discotics and calamitics, surface anchoring states are determined by a complex interplay of the molecular structure of the liquid crystal molecules, the substrate chemistry, the substrate topology, and possible surface texture induced by directional rubbing [127–131].

**Figure 15.** Possible direction-field configurations of discotic liquid crystals in cylindrical geometries for homeotropic or face-on anchoring (top) and planar and edge-on anchoring (bottom). Reprinted with permission from [141], K. Jian et al., *Adv. Mater.* (2003). © 2003, Wiley-VCH.

Because of this complexity, anchoring behavior and confinement effects must be investigated experimentally for the liquid crystal/substrate pair of interest. To our knowledge there have been two studies of confined discotics [132, 133]. The phase transitions of hexa-n-octanoate of rufigallol were probed within the fibrous pores of a millipore filter [132] and calorimetry showed the phase transitions to be modified relative to the bulk liquid crystal. The study did not report specific anchoring states or detailed director fields in confinement. In the second study, a columnar discotic phase has been dispersed in a solid polymer matrix, which is reported to modify its phase behavior, optical properties, and electron transport properties [133].

There have been only a few systematic studies of discotic surface anchoring [12, 14, 129]. Vauchier et al. [129] report planar (edge-on) orientation on a lamellar silicate and on muscovite mica. In addition, Furumi et al. [134] demonstrate the alignment of spin-coated discotic thin films on silica using oblique illumination of nonpolarized 436-nm light, and the exploitation of this effect to achieve micropatterning. Anchoring of the discotic HPT has been observed to be planar (edge-on) heterogeneous on Si, and  $\text{CaF}_2$ , and planar homogeneous on ZnSe, and ZnS [12], with a transition occurring to homeotropic (face-on) with time and temperature under some conditions. Anchoring is partly determined by the competition between intermolecular and molecular/substrate forces, and it can be expected that planar (edge-on) anchoring would be the most common state [12], as it preserves the favorable intermolecular face-to-face interaction between discs. The lack of order in the anchoring plane (heterogeneous cases) is an indicator of weak interaction with the substrate. Nylon coating of the same substrates favored homeotropic (face-on) anchoring, which has been attributed to favorable interactions of the side chains with the nylon polymer chains achievable for face-on disks [14]. Generally, research on surface anchoring and alignment techniques for discotics lags behind that for rodlike liquid crystals due to their intrinsic high viscosity and high mesophase temperatures [134]. These are in turn a consequence of strong intermolecular forces as cited previously.

#### Experimental Studies of Anchoring in Mesophase Pitch

Recent anchoring studies have targeted the carbonaceous mesophase, the discotic nematic mixture, due to its importance as a carbon materials precursor. Anchoring at the free surface is reported to be planar heterogeneous (edge-on) for the naphthalene-derived AR mesophase [81, 135], as apparent from the strong anisotropy of these surfaces in polarized reflected light (Fig. 16). Planar free surface anchoring was reported earlier for a petroleum-derived mesophase by White and co-workers [136]. Edge-on anchoring at the free surface is believed to be favored because it preserves internal  $\pi$ - $\pi$  bonds, which require face-to-face interactions among the polyaromatics [3]. Indeed  $\pi$ - $\pi$  bonding, a geometrically favored van der Waals interaction, is strong enough in these planar molecules to cause their early aggregation into short columnar segments (2–4 layers) even in disordered aromatic-rich liquids.

Anchoring on solids is found to be edge-on or face-on depending on the choice of substrate. Table 1 provides the

**Figure 16.** Polarized light micrograph of unpolished free surface of mesophase pitch: crossed polars. Edge-on anchoring makes these free surfaces highly anisotropic. Note that mesophase pitch is opaque to visible light, so the standard analytical technique uses polarized reflection microscopy. Here we see concentric circular features ( $s = 1$  defects) in the nematic disclination pattern.

anchoring data on 20 solid substrates, all obtained by this technique. Most surfaces are edge-on, but important exceptions are carbons (especially sphere-based surfaces [66, 77, 81]), mica, and the metals, silver, platinum, and nickel.

There have been only two measurements of elastic constants for carbonaceous mesophase: a value of  $10^{-5}$  dynes

**Table 1.** Anchoring states on various substrates determined by direct microscopic observation of the interfacial plane [135].

Pitch	Substrate	Observed anchoring <sup>a</sup>
AR-HP	Gas phase	edge-on

<sup>a</sup> All face-on cases were strictly optically isotropic upon direct examination of the interfacial plane. This anchoring state is referred to as “homeotropic” in liquid crystal nomenclature. All edge-on states were optically active with random in-plane orientations, referred to as “planar heterogeneous” in liquid crystal nomenclature.

<sup>b</sup> In these samples, examples of both anchoring states were found in different regions of the substrate. The state listed was the more prevalent of the two.

for the bend-splay elastic constant [77] and  $3 \times 10^{-5}$  dynes for the bend elastic constant  $K_{33}$  [137].

Zimmer and Weitz [77] determined this bend-splay elastic constant from optical measurement of the magnetic coherence length ( $7 \mu\text{m}$ , for a field strength of 5500 G) in the vicinity of carbon fiber acting as cracking surfaces, together with a repeated value for the diamagnetic anisotropy of  $-0.69 \times 10^{-6}$  emu/g [138] for carbon mesophase. The face-on anchoring on carbon fibers in that study was strong enough to resist the 5500 G field which favored the opposite alignment [77].

A complete quantitative theory of anchoring state selection is not yet available for these materials, but the data do show a number of trends. The preferred anchoring state is the one that minimizes the interfacial energy,  $\gamma$ , composed of both entropic and energetic terms. Entropic effects are believed to favor face-on anchoring, since this state reduces the excluded volume at the interface [130]. The magnitude of this entropic contribution on flat surfaces is significant, but is expected to decrease with increasing surface roughness.

Attractive forces, however, also play a role in anchoring, and indeed many aspects of molecular orientation are discussed in terms of a balance between intermolecular forces *within* the film and *between* the film and substrate [127]. A theory has been proposed [135], that pitch interacts primarily through dispersive forces (rather than polar interactions), and that the liquid/substrate dispersion was inhibited by a geometric mismatch between the large planar mesogens and most surfaces. Only surfaces of lamellar materials that are atomically flat (graphene layers, mica) are capable of dispersive interactions with large pitch mesogens that are sufficiently strong to overcome internal  $\pi$ - $\pi$  bonds and produce face-on anchoring. To achieve the face-on state, the pitch mesogens must give up one set of internal  $\pi$ - $\pi$  bonds in order to form a  $\pi$ -surface bond, and therefore this is the less common state, as it requires strong interaction and/or very good geometric accommodation between the planar mesogens and the substrate. For this reason, there is a strong (but imperfect) correlation between wetting behavior and anchoring, with face-on orientation often associated with a small contact angle [135].

These basic considerations can be used to interpret the larger anchoring data set in Table 1. First, the anchoring is edge-on on the very low energy surfaces (gas phase, PTFE) as expected, as these surfaces offer little or no energetic interaction to overcome internal  $\pi$ - $\pi$  bonds. Edge-on anchoring is also seen for all glasses/oxides with the exception of mica. The oxides can be expected to offer modest dispersive interactions, and these are inhibited by the non-atomically-planar nature of these surfaces. The polar contribution that raises the total surface energy of the oxides does not interact with the pitch to promote either wetting or face-on anchoring [135]. The natural lamellar materials graphite and mica have a high entropic contribution for face-on anchoring coupled with good geometric accommodation to the flat polyaromatic molecules which increases the effective dispersion interaction.

The metals provide an interesting data subset with both edge-on and face-on cases. No complete theory has been offered, but a correlation has been noted with oxidation

potential (well-developed surface oxide films favoring edge-on anchoring [135]) and with the ability of metal surfaces to form  $\pi$ -d or other electron transfer complexes with aromatic rings [135, 139, 140], which requires face-on orientation.

There have been very few studies of carbonaceous mesophase in confinement [77, 141], and these viscous materials often exhibit persistent disclinations (defects) in all but the smallest spaces. The disclination structures in carbonaceous mesophase have been reviewed by Zimmer and White [142].

**Behavior of Single-Component Polyaromatic Compounds** Single-component polyaromatics do not form liquid crystals, but the interfacial behavior of these disklike compounds is nevertheless of great interest in nanotechnology. Reports from the molecular thin-film literature indicate face-on configuration for single pentacene molecules on silicon(001), but edge-on orientation for multimolecular islands, suggesting the greater importance of intermolecular interactions among pentacene molecules relative to pentacene/substrate interactions [15]. Face-on orientation on HOPG has been reported for coronene [17] and hexa-peri-benzocoronene [16], at least for monolayer and submonolayer coverage.

The largest PAH studied, hexa-peri-hexabenzocoronene, adsorbs face-on on two atomically flat layered materials (HOPG,  $\text{MoS}_2$ ), and edge-on on the atomically rough oxidized silicon(001) and polycrystalline gold, similar to the trends reported here [18]. The film structure of hexa-peri-hexabenzocoronene on HOPG was not stable during annealing at 425 K, however, and converted to edge-on needle-like domains, which has been attributed to intermolecular interactions that favor tilted herringbone structures, which are mismatched to the atomically flat HOPG surface [18].

In general, surface molecular orientation in pitch anchoring, pure discotic anchoring, and PAH epitaxial deposition are all governed by a balance of soft interactions—a competition between intrafilm intermolecular forces and substrate/overlayer forces, the same considerations that apply to molecular thin films [19]. As a result, the effect of substrate on surface orientation is similar in the three types of interfacial systems, but exhibits some differences. Most notable is the tendency of the regular PAH in thin-film studies to pack in edge-on herringbone patterns in multilayer films where the molecules do not lie in any single plane and are thus poorly compatible with face-on orientation on lamellar substrates.

## 5. APPLICATIONS OF SYNTHETIC DISCOTICS

The flat panel display industry has been engaged in nanoscience and nanotechnology for years. There are several application examples of discotic liquid crystals used in or being considered for flat panel displays: (1) thin-film polarizers, (2) compensation films, (3) electroluminescent discotics, (4) photovoltaics, and (5) molecular wires [143]. In this section we will focus on a few potential applications for discotic liquid crystals.

### 5.1. Thin-Film Polarizers

Molecular engineering of discotic textile dyes has produced unique materials that can be used to manufacture thermally stable thin-film polarizers. One of the most intriguing applications is thin-film polarizers for flat panel displays. These compositions of organic dye material possess a lyotropic liquid crystal phase when dissolved in water. The dye molecules are flat and therefore form liquid crystalline phases (molecules stack on top of each other). Several dyes that have been investigated for thin-film polarizer applications are shown in Figure 17a [144–146]. They are very attractive for liquid crystal display applications because of low light leakage at oblique viewing angles [147] and an overall improvement of the viewing angle for certain applications [148–150].

Water-soluble dyes of flat molecular architecture are oriented in two steps as shown in Figure 17b. The first step is the formation of a lyotropic liquid crystal and the second step is the crystallization of pre-aligned complexes on the surfaces by evaporating off the water. Using a Meyer bar, the lyotropic liquid crystal molecular complexes are ordered along the direction that the Meyer rod is rolled as shown in Figure 17b.

The polarizers that are created by this process are e-type and therefore transmit the polarization component with the e-vector parallel to the direction of alignment and absorb if

**Figure 17.** Examples of textile ink molecules that when dissolved in water form lyotropic liquid crystal phases (a). When these materials are distributed over a substrate surface with a Meyer Bar, a thin-film e-type polarizer is created (b). it is perpendicular, as shown in the inset of Figure 17b. The iso-transmittance curves of a conventional polarizer (known as o-type) are compared to an e-type polarizer formed with the discotic-like materials. There has been a great deal of work on the applied front with these materials because of their potential as polarizers in displays. There have been a few more basic studies on these lyotropic liquid discotic materials to better understand their structure [151, 152] and rheological properties [153]. Optiva is currently pursuing commercialization of these materials.

## 5.2. Compensation Films

Liquid crystal displays are known to have an inferior viewing angle due to the anisotropic nature of the liquid crystal alignment. This effect is most noticeable when gray scale images are displayed. The poor viewing angle can be compensated by a passive film created out of reactive discotic liquid crystals. Sample reactive discotic compounds are shown in Figure 18a. They are low molecular weight and therefore can be ordered with surfaces of external fields. This ordered configuration is then captured indefinitely with photopolymerization [154].

The concept of optical compensation is shown in Figure 18b. The viewing angle problem in liquid crystal displays is due to the optical retardation of the liquid crystal, which in most cases is positive uniaxial. This results in light

**Figure 18.** An example of reactive discotic material that can be photopolymerized (a) and the configuration of a photoreactive discotic film used to compensate a p-cell liquid crystal display (b). leakage through crossed polarizers at wide angles since the display is typically optimized for normal incidence. By suppressing the amount of light leakage at oblique angles in the optically dark state, the viewing angle of the display can be compensated to achieve better performance (i.e., better optical contrast at all incident angles). The underlying concept of viewing angle compensation using a reactive discotic liquid crystal film is as follows. The viewing angle dependence of the positive birefringence of the liquid crystal can be compensated by a negative birefringence whose optic axis is parallel to that of the positive birefringence.

Compensation films based on reactive discotic mesogens can be used in many types of liquid crystal display configurations [155–157]. One example is shown in Figure 18b where the discotic film is used to compensate a  $\pi$ -cell liquid crystal display. A  $\pi$ -cell is a homogeneous liquid crystal display configuration with opposing pretilt angles of the liquid crystal molecule at the surfaces as shown in Figure 18b. To achieve a dark state, an electric field is applied to align the liquid crystal molecules. To compensate such a complicated structure, the compensation film must have a mirror image of the director configuration so that each liquid crystal pairs up with a corresponding discotic molecule with a negative birefringence. When the liquid crystal is sandwiched between two compensating films as shown in Figure 5c and viewed between cross polarizers, the viewing angle becomes broader and more symmetric. These materials are now being commercialized by Fuji Film Corporation and are utilized by many display manufacturers.

## 5.3. Electrofluorescent Columnar Liquid Crystals

Discotic liquid crystals offer unique properties which can be exploited in organic light-emitting diode (O-LED) applications [158–162]. Characteristic features of light-emitting liquid crystals are the anisotropy of the electric properties, a strong coupling to external fields, and a tendency to form spontaneously monodomain films. It is well known that discotic columnar liquid crystals have great potential as hole transporting layers. In the columnar phase, the charge carrying mobility is  $\mu = 10^{-1} \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$  (this is greater than values for amorphous organic materials and slightly smaller than values for molecular single crystals) [163]. One very attractive feature of columnar liquid crystals is their ability to expel defects upon the annealing process.

Benning and co-workers [162] studied the homologous series of 3,4,9,10-tetra-(n-alkoxycarbonyl) perylenes  $\text{C}_{20}\text{H}_8(\text{CO}_2(\text{CH}_2)_{n-2}\text{CH}_3)_4$  [164]. They demonstrated red shift in dilute solutions of the compounds and the columnar phase of pure compounds. Additionally, they demonstrated long fluorescent lifetimes. This intriguing behavior was explained by the formation of excimers in the liquid crystal phase. These materials may have potential in LED applications.

## 5.4. Photovoltaic Discotic Liquid Crystals

The self-organization feature of discotic liquid crystals and crystalline-conjugated materials has been used to create thin-film photovoltaic devices. Schmidt-Mende and co-workers [165] demonstrated that the discotic liquid

crystal hexa-perihexabenzocoronene could be implemented with perylene dye to produce thin films with vertically segmented perylene and hexabenzocoronene. By implementing these materials into a diode configuration, the device has a photovoltaic response with quantum efficiencies of >24% at 490 nm. The mechanism of these efficiencies is photoinduced charge transfer between hexabenzocoronene  $\pi$  systems. These systems, along with their simple processing cast from solution, have the potential to create low-cost, high-performance thin-film photovoltaic technology.

### 5.5. Electron Transport in Discotic Liquid Crystals

One-dimensional molecular electronic conductors are of interest because of their potential as molecular wires. Most conducting and semiconducting organic materials that have been reported in the literature, such as charge-transfer complexes [166], metallo-organic complexes [167], and doper polymers, tend to exhibit anisotropic (or quasi-1D) electrical conductivity. There has been a considerable amount of interest in discotic liquid crystals as an alternative class of conducting one-dimensional materials.

Conductivity has been investigated in a broad class of discotics, such as metalomesogens [168, 169] and polynuclear aromatic mesogens, and by modifying organic charge-transfer complex [168, 169]. For example, peripherally substituted metallophthalocyanines display stable columnar mesophases over an extended temperature range [170]. Another example is copper octa-*n*-octyloxyphthalocyanine, which in its columnar mesophase state has a conductivity of  $\sigma = 3 \times 10^{-3} \text{ S m}^{-1}$ . Charge-transfer salts of highly oriented fibers of crystalline 2,3,4,6,7,10,11-hexapentyloxytriphenylene have been processed by drawing strands from the columnar phase followed by oxidation with bromine [171]. The conductivity of these samples is more than three orders of magnitude greater ( $\sigma \sim 10^{-2} \text{ S m}^{-1}$ ) than powdered samples ( $\sigma \sim 10^{-5} \text{ S m}^{-1}$ ).

Boden and Lowerkens [172] have shown a new class of quasi-one-dimensional p-type semiconducting materials, formed by doping the hydrocarbon chain matrix of discotic liquid crystals. They studied the discotic liquid crystal material 2,3,4,7,10,11-hexahexyloxytriphenylene (HAT6) doped with the Lewis acid  $\text{AlCl}_3$ , and discovered many new phenomena: (1) HAT6 when doped with  $\text{AlCl}_3$  is converted from an insulated to a quasi-one-dimensional semiconductor, with conduction along the column being three orders of magnitude greater than perpendicular to it; (2) the frequency dependence of the conductivity along the column axis can be modeled as a single charge-transfer process in which charge carriers hop between localized sites, which [suggest charge transport ones macroscopic distances] (100 nm); and (3) charge transport proceeds stochastically by phonon-assisted tunneling between neighboring states.

## 6. APPLICATIONS OF MESOPHASE-DERIVED CARBONS

This section deals with discotic-based nanostructured carbon materials, some of which are rather advanced in their development and are already incorporated in commercial

products. Nanomaterials based on discotics (nanofibers, nanotubes, nanophase particulate) are an emerging materials class and are covered in the subsequent section.

The almost exclusive use of carbonaceous mesophase is as an intermediate in the synthesis of carbons, especially highly crystalline graphitic forms that are formed upon heat treatment near 3000 °C. The spontaneous formation of long-range (>1  $\mu\text{m}$ ) molecular order in mesophase establishes the basic layer structure early, so that the high-temperature annealing process must only “flatten” the meandering structure and remove local defects. If long-range orientational order is not established in a low-temperature carbon, it cannot typically be produced after the fact by high-temperature annealing, even at 3000 °C. Traditionally, mesophase was formed *in-situ* during carbonization of nonmesogenic precursors, but increasingly, a single-phase liquid crystalline pitch is selected as the starting material. Pitches derived from petroleum, coal-tar, or the polymerization of small PAH all find use as precursors for different carbon products. The recent commercial availability of AR-mesophase, a naphthalene homopolymer manufactured by Mitsubishi Gas Chemical, provides a homogeneous liquid crystalline mixture in a consistent formulation for research on advanced materials. The advantages of mesophase pitch as a carbon precursor include:

1. Spontaneous development of long-range order (>1  $\mu\text{m}$  and often much larger) in the liquid phase, which is used to impart similar long-range crystallographic order in carbons.
2. High solids yield upon carbonization. For an organic liquid it has a low H/C ratio and low volatile content, and thus produces a large increase in density in a single infiltration step when used as a matrix material in composites.
3. Ability to obtain very-long-range anisotropy in material properties through flow ordering of the discotic molecules (extrusion, fiber spinning) or through surface anchoring phenomena (e.g., in interfiber spaces in C/C composites).

To understand the significance of mesophase in carbon synthesis, some background on carbon materials and their structure/property relations is necessary. Carbons are a diverse class of materials ranging from the high-temperature structural materials used in rocket nozzles and aerospace applications (C/C composites) to disordered porous materials used as environmental sorbents (activated carbon). Most are crystallographically related to graphite, but consist of finite snippets of the graphite lattice of “graphene layers” that adopt a variety of spatial configurations. The graphite lattice is highly anisotropic in its bonding and properties, with strength, modulus, electrical conductivity, and thermal conductivity are much higher within the covalently bonded planes than across them. For example, the elastic constants of single-crystal graphite are 1060 GPa within the covalently bonded planes and only 36 GPa between planes. The opposite trend is observed for the coefficient of thermal expansion, which is about  $30 \times 10^{-6} \text{ K}^{-1}$  across the primary planes, but less than  $1 \times 10^{-6} \text{ K}^{-1}$  within the planes. As a result of the anisotropy in the graphite lattice, the arrangement of the

graphite snippets in real carbon materials, that is, the carbon nanostructure, strongly influences the bulk properties of practical materials and their directional dependencies. For example, the stiffness of carbon fibers may be 30 GPa if the graphene layers are oriented randomly, but can reach 800 GPa if the layers have a high degree of alignment along the fiber axis [28]. Nanostructure also determines the space filling properties of the solid phase and thus the ultrafine pore structure that governs the accessibility of internal surface sites by small probe molecules. This accessibility is key to the high adsorptivity of activated carbons, which have total internal surface areas as high as 1500 m<sup>2</sup>/gm.

A key to designing carbon materials, therefore, is the ability to create desired configurations of graphene layers. For example, ordered configurations are desired where high stiffness, strength, or conductivity along a specified axis is desired, such as is the case for carbon nanotubes, or high modulus carbon fibers. The ability to manipulate the discotic molecules in the mobile yet ordered mesophase becomes a critical advantage. With this background, some of the most important mesophase-derived carbon products are summarized in the following.

### 6.1. High Modulus Carbon Fibers

Mesophase pitch can be used to manufacture carbon fibers with superior stiffness, relatively high strength, and electrical and thermal conductivities along the fiber axis. The favorable properties arise from the preferential ordering of the graphene layer planes parallel to the fiber axis, which in turn arises from molecular flow ordering in the fiber spinning process [21, 79, 173]. Fibers are typically melt spun above the softening point, then quenched and stabilized by low-temperature oxidation, which cross-links and thermosets the structure to preserve the flow-induced discotic molecular order. Fibers are then carbonized ( $T \sim 1000$  °C) or graphitized ( $T \sim 3000$  °C) as required by the particular application.

Discotic liquid crystalline flow is a complex process most often described by the Leslie–Erickson continuum theory [21]. The theory makes a simple prediction that the extensional flow accompanying fluid acceleration into the narrow spinning nozzle orients the discotic molecules with their planes parallel (directors perpendicular) to the extensional flow axis [174], in agreement with observation. The perpendicular director field is not a unique structure, however, and there are a variety of possible director configurations in the plane perpendicular to the fiber axis—so-called transverse textures, that provide a challenge for prediction [174, 175]. There is a significant literature on fiber transverse textures, including experimental studies [21] and theoretical treatments motivated by a desire to understand the origin of carbon fiber textures and develop methods of tailoring them for specific fiber applications [21, 174, 176]. Experiments have observed radial, concentric, and “zig-zag” structure in the transverse sections [174]. A significant barrier to the decisive application of theory is the lack of liquid crystal material constants for mesophase pitch, including as a minimum set, the elastic constants for bend, splay, and twist, and the directional or Miesowicz viscosities. Theoretical treatments have often been restricted to solution forms

and trends, but have nevertheless provided insight into real fiber textures.

Recent R&D efforts on advanced pitch-based carbon fibers have focused on the new pitch formulation, on the spinning of elongated fibers or “tapes” with radial or laminar transverse textures that depend on flow conditions [177], on the origin and theoretical prediction of transverse textures [21, 174, 176, 178], mesoscale structures [179, 180], and of course fiber properties and applications [21, 181, 182].

### 6.2. C/C Composites

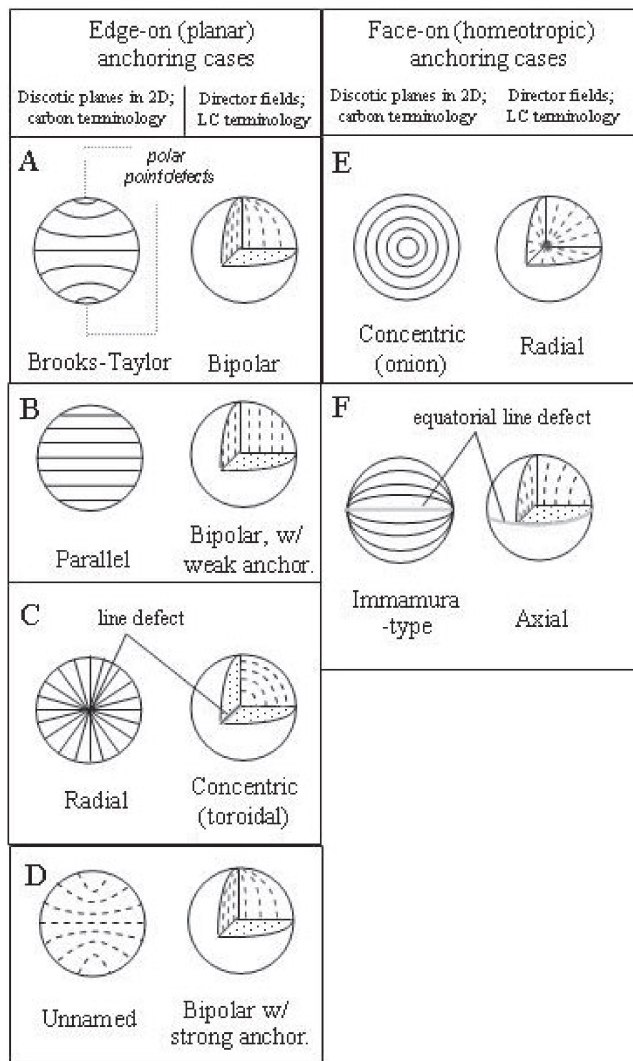

Mesophase pitches find use as binder phases in carbon fiber composites to make all-carbon (C/C) materials of special use in very-high-temperature applications. The discotic molecules enter the interfiber spaces driven by pressure or capillary forces and are converted to carbon matrices by further heating. Fibers act as anchoring surfaces for the discotic mesogens and the 1- to 10- $\mu$ m interfiber spaces provide the confined geometry that leads to distinct liquid crystal patterns as described in Section 4. Most or all studies report face-on (homeotropic) anchoring on the fiber surfaces, which causes the graphene layers to align parallel to the fiber axis and enhances the tensile strength and stiffness of the composite [77]. The interfiber spaces are small enough to produce primarily homogeneous (defect-free) liquid crystal domains, and the influence of the surface is sufficient to resist the reorienting effects of a Gauss magnetic field [77]. In the absence of the confining surfaces, this or similar magnetic fields have been shown to successfully orient carbonaceous mesophase.

### 6.3. Mesocarbon Microbeads

The anisotropic spherical droplets that led to the original discovery of carbonaceous mesophase in 1965 are now produced commercially under the name “mesocarbon microbeads.” The microbeads are formed by slow heat soaking of aromatic-rich hydrocarbon phases and are typically separated from the surrounding material by solvent extraction, and then used/marketted in green form, or in carbonized form after heat treatment above 700 °C. A variety of laboratories synthesize and characterize mesocarbon microbeads [183, 184], while an important commercial source is Osaka Gas Chemicals Co., LTD. A number of studies have been carried out focused on formation, structure, and applications.

#### 6.3.1. Structure and Formation Mechanism

Mesocarbon microbeads are most commonly found to have the bipolar (Brooks–Taylor) structure shown [184–186], but a variety of other liquid crystal structures have also been reported (see Fig. 19). The carbon literature contains a variety of casual terms for these structures that differ from the terms used for nematic droplets in the generic liquid crystal literature. In this chapter, structures are named from the symmetry of their director configuration. For example, the bipolar configuration in discotics is a result of edge-on anchoring, as compared to the bipolar structure in low molar mass compounds, which has planar anchoring. Independent of the anchoring regimes, the director profile is analogous. The origins of the different molecular configurations are

**Figure 19.** Molecular configurations in carbonaceous mesophase droplets; all but (C) have been experimentally observed. The 2D spheres on the left show the orientations of the discotic planes, as is the convention in the mesophase and carbon literature, and give the corresponding names in that literature if any. The 3D spheres at the right show the director fields, as is the convention in the liquid crystal literature, and the structure name common in that literature. Note the directors run perpendicular to the discotic molecular planes. Structures are as follows: (A) Brooks–Taylor (bipolar) [1, 66, 184, 185]; (B) Parallel (bipolar with very weak anchoring) [119, 184, 192]; (C) Radial (concentric or toroidal); (D) Unnamed variant of a report under very low temperature formation conditions (bipolar with strong anchoring) [78]; (E) Concentric (radial) [184]; (F) Bipolar with planar anchoring (axial) in presence of carbon black [78]; and in presence of isotropic coke (carbon) particles [184]. Note that (F) is not bipolar, but rather has a circumferential line defect at the equator. Other types reported include an asymmetrical version of the concentric structure (E) and a version of the bipolar homeotropic structure (F) but containing defects when made in the presence of anisotropic coke [184].

poorly understood, but generally believed to arise from the interplay of anchoring at the mesophase/isotropic interface and elastic director strain, and thus to be governed by the science of confined liquid crystals as discussed in general terms in Section 4.

Studies of discotic surface anchoring find edge-on anchoring to be the most common form and especially prevalent at the pitch/gas interface and on low-energy surfaces. Since organic liquid surfaces have lower energies than most solid surfaces, the preference for edge-on anchoring in these forms (A–D in Fig. 19) is expected. A likely explanation for at least some of the observed homeotropic cases (E, F in Fig. 19) is the presence of impurities that can serve as nucleation centers or accumulate at the surfaces of the mesophase droplets where they may affect anchoring. Especially common are carbon solids as impurities in pitches (“quinoline insolubles”) or additives such as coke or carbon black used in some studies [184]. Since anchoring is face-on (homeotropic) on carbon, mesophase spheres assembled under these conditions are likely to exhibit structures E or F in Figure 19, as generally borne out by experiment. Structure E is reported to be a stable form in the presence of face-on (homeotropic) anchoring [187], while F occurs in the presence of fields or if anchoring is weaker [188]. The asymmetrical form of E [184] has also been seen in other liquid crystals, when an external field shifts the point defect from the center toward the surface [189].

Considering the more common edge-on (planar anchoring) cases, A–D in Figure 19, the bipolar or Brooks–Taylor structure is predicted by Zumer and co-workers [188] to be the most stable when elastic constants,  $K_{11}$ ,  $K_{22}$ ,  $K_{33}$ , are similar. Indeed, it was the first structure found and is the most commonly reported for carbonaceous mesophase. Only for very low bend/splay ratio ( $K_{33}/K_{11}$ ) is the radial (toroidal) structure, C, predicted to have the lowest free energy [190, 191] propose that  $K_{33} > K_{11}$  for the high molecular weight carbonaceous mesophases, which would make the radial (toroidal) structure unlikely, and indeed this structure has not to our knowledge been reported in mesocarbon microbeads.

Structure B in Figure 19 apparently represents weak anchoring, although it is easy to imagine this simple structure arising in the early stages of growth to bipolar spheres, perhaps as a metastable intermediate. One of the reports of the laminar structure is for very small ( $<1 \mu\text{m}$ ) droplets [192], and indeed there are theoretical reasons to expect a transition to weak anchoring as size decreases, as is the case in low molecular weight liquid crystal systems [99]. The overall free energy is composed of an anchoring contribution (of order  $W_0$  in  $\text{mJ}/\text{m}^2$ ) and an elastic contribution of order  $K/L$ , where  $K$  is an elastic constant and  $L$  is the length scale of curvature. As droplet size decreases ( $L \rightarrow 0$ ), the elastic term increases in importance and the molecules deviate from the preferred anchoring state to minimize the dominant elastic strain contribution. A similar argument has been put forth by Yang [193] to explain the homogeneously ordered liquid crystal domains of approximately 100 nm in a mesophase-derived porous carbon (see Section 6). This weak anchoring condition may be common in carbonaceous mesophase droplets or grains of submicron size.

In general, more work is needed to fully understand the origin of all the sphere types in Figure 19. Some structures may represent metastable, nonequilibrium states, a distinct possibility for these viscous materials with high cohesive energy density and high rotational barriers. Nevertheless,

the major trends in Figure 19 are those expected from liquid crystal theory and from the anchoring rules derived from simple experiments on planar substrates.

### 6.3.2. Microbead Applications

Mesocarbon microbeads are of interest primarily as precursors for advanced carbon materials, including anodes for Li-ion batteries [184, 194]. An advantage of mesocarbon microbeads is their active surface populated preferentially by graphene edge sites. Compared to carbon black particles with concentric structure, mesophase spherules have been shown to be more amenable to electroless metal plating following surface oxidation by nitric acid. The nitric acid treatment introduced 3.5 mmol/g of acid sites to the mesophase spherules (material M6G) compared to 0.76 mmol/g for carbon black, despite a total physical surface area of the carbon black over 150 times as great. Mesocarbon microbeads are also self-sintering [195]—an advantage for binderless applications.

The properties/performance of the different sphere types have not been systematically compared for most applications. In one exception [184], Chang et al. report on the suitability of various mesocarbon microbeads as anodes for Li-ion batteries. The discharge capacity and cyclability show a modest variation with structure. The lamellar and BT forms show generally highest initial capacities, consistent with the expected higher mobility for Li ions into the interlayer spaces. Differences become less pronounced upon cycling, possibly indicating structural rearrangements in the less “open” forms to accommodate Li exchange [184]. All types show increase in capacity with increases in heat treatment temperature from 2400 to 3000 °C.

### 6.4. Other Applications

Mesophase pitches are used in the production of graphite foams for lightweight thermal management applications [196, 197]. Vapor bubbles produced by volatilization of the lower molecular weight fractions cause volume expansion of the liquid and following high-temperature heat treatment lead to low-density, high-conductivity foams. The biaxial extensional flow caused by bubble growth leads to parallel alignment in the bulk of the stretched bubble cavity membranes, so that the dominant alignment of the graphene layers is parallel to the bubble surfaces. The overall result is a foam with desirable *isotropic* thermal conductivity, reflecting the distribution of orientational vectors around the spheres. Pitch has been at least evaluated as a precursor for other carbon products, including gas membranes [198], conducting additives in electronic cells [199], and activated carbons [200].

## 7. NEW CARBON NANOMATERIALS

There is tremendous excitement surrounding new structural forms of carbon, both as components in emerging nanotechnologies and as subjects of scientific inquiry. This section begins with a brief review of carbon nanoforms, then proceeds to demonstrate a new, flexible concept for nanocarbon synthesis based on discotic liquid crystals.

### 7.1. Brief Overview of Carbon Nanoforms

In recent years the classical picture of  $sp^2$ -hybridized carbon as flat sheets has given way to a host of structural possibilities based on closed spheres (fullerenes [201], onions generated in electron beams [202] and in immersed arcs [203]), multi- and single-walled nanotubes [204], nanotubes that are Y-shaped [205], bent or helical [206], graphite fibrils with scroll-like structure [207], and single-atomic-width monolayer graphite films on metal surfaces [208].

A variety of synthetic routes have been demonstrated including arc evaporation of carbon, catalytic decomposition of hydrocarbons on metal particles [209–211], and templating methods using nanochannel membranes [212–214]. Most of these new carbon forms are assembled at high temperature from vapor-phase precursors, including nanotubes by arc evaporation, CVD, PECVD, or thermal deposition on templates; fullerenes from flames or arcs; and graphite whiskers grown by catalytic decomposition of hydrocarbon gases [210, 215, 216]. These catalytic, “vapor-grown” carbon nanofibers exhibit a variety of sphere layer structures that depend on the crystal facets of the catalyst particle. Forms include concentric, “platelet,” “herringbone,” and cup-shaped nanofibers [166, 177, 217–219].

Some condensed-phase routes to nanocarbons have also been demonstrated. These include the impregnation of nanochannel alumina membranes with polyacrylonitrile [220] or furfuryl alcohol [221], the latter giving tubes with internal cell structures similar to natural bamboo. Templated nanocarbons include layered forms made by carbonizing furfuryl alcohol in clay templates [222], the thermal carbonization of polymer thin films, and nanostructured porous carbons made using templates in the form of silica nanoparticles [223], mesoporous silica materials [224], zeolites [225], silica gel or porous glass [226, 227], or from etching nanocomposites made by sol-gel processing [228]. These studies include double templating methods, in which the interior of the carbon nanotubes provides the geometric constraints for growth of second phases, such as nanorods, plates, or particles of Pt, Ag, Fe, or NiO [229–231]. Further nanostructured porous carbon forms have been produced from sucrose pyrolysis within mesoporous silica molecular sieves as templates [232], or from pyrolysis of recorcinol/formaldehyde in the presence of a silica solution [233]. Zakhidov et al. [234] have produced “inverse opal” carbons using partially fused silica sphere templates with three-dimensional periodicity. By filling the 3D sphere arrays with phenolic resin followed by carbonization, or by chemical vapor deposition with propylene, a porous templated carbon material is formed that is capable of Bragg reflection of visible light [234]. For the plasma-enhanced CVD variant of this procedure, the graphene layer orientations were probed by high-resolution TEM and found to lie parallel to the former sphere surfaces, producing onion-like structures [235]. Templated nanocarbons show promise in a variety of application fields, where they may serve as conductive catalyst supports for fuel cell electrodes, anodes for lithium ion batteries, components in nanocomposites [236], ultracapacitors, and chemical filters, with many of the applications requiring ordered arrays [237].

As with other carbon materials, these new nanoforms possess the basic  $sp^2$ -hybridized bonding of graphite, but

differ in the spatial arrangement of their graphene layer. As discussed earlier in the chapter, graphene layers, like the graphite lattice itself, are highly anisotropic in their electrical, thermal, and chemical properties [28], and thus their orientational patterns are key to most carbon and nanocarbon properties. Most of the reported nanocarbon forms are assembled at high temperature under reactive conditions, where thermodynamic driving forces attempt to minimize the number of high-energy edge sites having unsatisfied valencies. The result is an edge-to-edge assembly process that produces closed structures (tubes, spheres, shells, parallel films), in which the exposed surfaces consist primarily of graphene basal planes. For example, multi-wall nanotubes are concentric structures in which the curved graphene planes lie parallel to the tube axis and face outward at the tube periphery; as a result, they have high axial conductivities, stiffness, and strength but are inert to many chemical processes, leading to weak bonding in assemblies and difficulties with sidewall functionalization [21]. The templated nanotubes of Kyotani et al. [214] and Martin and co-workers [238] formed by vapor-phase deposition also show preferential alignment of the graphene layers parallel to the channel walls, and thus have basal-plane-rich surfaces, similar to other pyrolytic carbon films. The next section describes alternative carbon nanoforms with edge-rich surfaces produced by a new route based on discotic mesogenic precursors.

## 7.2. Templated Carbon Forms from Discotic Precursors

The phenomenon of discotic surface anchoring discussed earlier in this chapter opens new possibilities for the molecular design of carbon and nanocarbon materials, including the synthesis of nanocarbons with active edge-rich surfaces. Table 1 can be used as a guideline for selecting templates to produce films of orientationally ordered discotics that can be converted to carbon materials by polymerization about 400 °C.

### 7.2.1. Patterned Surfaces

This concept of surface anchoring templates was first exploited to make periodic microarrays of edge-on and face-on surfaces in solidified discotic mesophase using a Cu/HOPG two-component anchoring template [135]. Figure 20 shows an example micropatterned surface in quenched AR-mesophase. When these ordered polyaromatic thin films are thin ( $<50 \mu\text{m}$ ), oxidative stabilization at around 200 °C followed by heat treatment above 700 °C can convert them to carbon surfaces possessing the same spatial pattern of graphene edge and basal sites [135].

### 7.2.2. Orthogonal Carbon Nanofibers

Using anchoring templates, the surface-induced order typically propagates only micrometer or submicrometer distances into the bulk discotic phase, after which it gives way to flow-induced domains in the interior of these viscous materials [193]. Therefore, for macroscopic carbon bodies, anchoring templates can determine *surface* orientational patterns, but not bulk structure. If, however, the

**Figure 20.** Optical micrograph (crossed polars) showing polyaromatic solid surface with microscale molecular orientational pattern established with a two-component surface anchoring template. The template was a Cu TEM grid (imparting edge-on anchoring) on a cleaved HOPG graphite basal surface (imparting face-on anchoring). After physical removal of the template, the grid pattern is clearly evident as bright anisotropic (edge-on) regions at former Cu interface and dark isotropic (face-on) regions at the former graphite interface. It is anticipated that a variety of new carbon forms with programmed graphene layer orientations can be synthesized by this principle. Reprinted with permission from [81], R. H. Hurt et al., *Chem. Mater.* 14, 4558 (2002). © 2002, American Chemical Society.

idea is extended to three-dimensional templating in confined nanospaces, the surface-induced order can propagate fully across the nanoform to produce wholly new carbon forms. A first example of this approach was carbon nanofibers (see Fig. 21) produced by capillary impregnation of mesophase pitch (AR) into nanochannel alumina templates [193]. Except for the liquid crystalline precursor, this method is similar to previous templating methods used to create conducting polymers [213, 239, 240], mesogenic polymers [241, 242], metals [243], and semiconductors [244].

The remarkable feature of these nanofibers is the “orthogonal” arrangement of the graphene layers. The high-resolution TEM fringe image in Figure 21 shows the layers to lie perpendicular to the fiber axis with a statistical meandering about the mean orientational vector, which is characteristic of a solidified discotic nematic phase. Digital processing of image using the technique of Shim et al. [245] yields an estimated two-dimensional order parameter of 0.88, which translates to a three-dimensional order parameter of about 0.45 for a HRTEM Bragg tolerance of 10° using the projection mapping function derived in the same study [245]. The very edge of the nanofiber appears to show an atomic-scale parallel film of one or two layers, which is an adsorbed contaminant (commonly seen on surface at atomic resolution) or the result of layer rearrangement or deposition during carbonization or etching. The orthogonal arrangement is significant as it is the opposite of normal flow-induced order. Both elongational flow (into the channels) and shear stress (across the diameter) during in-channel flow align the discotic molecular planes parallel to the channel long axis [246], which is the same essential phenomenon that gives rise to axial alignment in conventional (supermicron) mesophase-pitch-based fibers.

The origin of the observed orthogonal structure likely lies in static equilibrium states for confined liquid crystals. Figure 15 previously illustrated the possible configurations for discotics, which depend on the delicate interplay of

**Figure 21.** Example of nanomaterial synthesis using confined liquid crystals. Here is the synthesis route for “orthogonal” carbon nanofibers from mesophase pitch confined in commercial nanochannel alumina templates. Reprinted with permission from [141], K. Jian et al., *Adv. Mater.* (2003). © 2003, Wiley-VCH.

surface anchoring and energies and the various modes of elastic strain energy (splay, bend, twist). For edge-on anchoring (the known favored state on alumina), the concentric configuration exhibits a line disclination along the cylindrical axis; planar-bipolar exhibits two line defects, and the homogeneous configuration is defect free. There also exists a twisted-concentric structure [247], which is improbable in discotic systems. The observed orthogonal structure corresponds to the “homogeneous” configuration in Figure 15, which is the lowest free energy state available, since it is the only configuration that preserves the favored edge-on anchoring and has no elastic strain or defects.

The homogeneous “orthogonal” configuration of our nanofibers distinguishes itself from the graphene layer configuration in classical nanotubes (concentric), in vapor-deposited alumina templated nanotubes (concentric with imperfect order [214]), and in conventional isotropic carbon fibers (random orientation) or conventional high-modulus fibers based on pitch or PAN (axial alignment with a variety of transverse textures [21, 80]). The most similar documented structures are the herringbone and platelet fibers produced by catalytic decomposition of vapor-phase hydrocarbons under certain conditions [210], but these forms do not exhibit mesophasic order, that is, small graphene layers with meandering, long-range orientational order. It is also noteworthy that continuous, dense fibers can

be produced here without the usual bubble formation and foaming, which would cause expulsion of a majority of the liquid from the channels. Most mesophase-derived materials require an extra synthesis step: low-temperature ( $\sim 200^\circ\text{C}$ ) oxidative stabilization to thermoset their molecular structure and physical form prior to carbonization to prevent resoftening and swelling. The fact that the current nanofibers can be produced by a one-step process (omitting oxidative stabilization) is likely due to the suppression of bubble nucleation by nanoconfinement or to early formation of carbonized caps that prevent swelling.

There are a variety of potential applications for such nanofibers as electrodes, catalyst supports, sorbents, thermal protection materials, and chemical sensor components, driven by their high density of surface active sites, easy access to interlayer spaces, and low axial conductivities. Further, they can be produced from a low-cost precursor (mesophase pitch rather than synthetic discotics), using simple one-step processing, and in the form of dispersed fibers, large arrays, or alumina-matrix composites. As yet these application possibilities remain unexplored.

### 7.2.3. Nanophase Mesocarbon

A similar carbon nanomaterial with all-edge surfaces can be produced using porous inorganic templates [193]. Figure 22 shows a porous carbon material with nanometric grains ( $\sim 100\text{ nm}$ ) created by capillary infiltration of AR mesophase pitch into controlled pore glass. After carbonization at  $700^\circ\text{C}$  and template removal with NaOH, the resulting carbon has a high concentration of edge-sites on the internal surfaces that were originally in contact with the glass

**Figure 22.** “Nanophase mesocarbon,” a monolithic porous carbon with nanometric internal grains having a high concentration of active graphitic edge sites. Material produced by capillary infiltration of mesophase pitch into nanoporous glass templates followed by heating and NaOH etching. (A) glass template, SEM; (B) nanophase mesocarbon, SEM; (C) nanophase mesocarbon, high-resolution TEM showing internal crystal structure, in which most graphene layers lie perpendicular to the concave inner surfaces that mark the original glass/pitch interface.

template (see high-resolution TEM in Fig. 22). This crystal structure is expected based on the known edge-on (planar) anchoring on glass (Table 1). This configuration of graphene layers is in contrast to that produced by plasma-enhanced CVD of carbon on silica opal templates [248] and most other known carbon forms, which are dominated by “closed” structures in which the accessible surfaces are rich in graphene basal planes.

This new nanostructured carbon form can be made as coarse particles similar in size to the original porous glass template particles (0.3  $\mu\text{m}$ ), or as a type of nanophase particulate carbon after grinding to liberate the 100-nm grains [193]. The classical carbon nanoparticulate is carbon black or soot, a high-temperature form that consists of partially fused 10–100 nm diameter primary particles that consist of spherically concentric graphene layers (onion structure). The new material with edge-rich outer surfaces has a similar graphene layer arrangement to mesocarbon microbeads (see Section 6) but has overall nanometric dimensions. For this reason the material might be referred to as “nanophase mesocarbon,” or to pursue the analogy with classical carbon particulate, “inverse soot.”

#### 7.2.4. Nanocarbons from Isotropic Phases

Additional materials can be made by varying the discotic precursor and/or introducing solvents. Infiltrating a dilute solution of polyaromatics into nanochannels yields tubes whose inner hollow space is created by the volume loss associated with solvent evaporation. As an example, Figure 23 shows carbon nanotubes made by capillary uptake of a pyridine extract of AR-mesophase pitch into nanochannel alumina, followed by carbonization and template removal. The heating and etching procedures are the same as for orthogonal nanofibers.

In summary, the infiltration of discotic precursors into nanometric templates is a new and powerful synthesis route for a variety of novel carbon materials. In the case of liquid crystalline discotics, the graphene layer arrangements can be systematically engineered by intelligent template selection using anchoring rules derived from simple experiments on planar substrates. Table 1 in this chapter can serve as a guide for selecting templates to achieve the desired anchoring state. Discotic nanocarbon materials have just been introduced, and this topic is fertile ground for research and development in the coming years.

**Figure 23.** Carbon nanotubes made by capillary infiltration of solvated discotic mesophase pitch into nanochannel alumina.

## GLOSSARY

**Discotic** Disklike molecules, as opposed to the more common rodlike or “calamitic” liquid crystalline systems.

**Graphene layers** Carbon sheets of single-atom thickness that are the building block of many carbon and nanocarbon materials.

**Liquid crystal** A fluid phase with one or more degrees of orientational molecular order.

**Lyotropic** A liquid crystal that undergoes order/disorder phase transitions with change in concentration in solution.

**Mesophase** A liquid crystalline phase (“meso-” signifying intermediate between the liquid and solid phases).

**$\pi$  bonding** Molecular interactions involving  $\pi$  electron orbitals such as those found in planar aromatic organic molecules.

**Pitch** Multicomponent mixtures of high molecular weight organic compounds formed by thermal or catalytic polymerization of low molecular weight precursors. Pitches are solid at ambient temperature and soften upon heating to viscous liquid or liquid crystalline phases.

**Surface anchoring** The phenomenon in liquid crystalline phases of preferred molecular orientation at a foreign surface or phase boundary.

**Thermotropic** A liquid crystal that undergoes order/disorder phase transitions with change in temperature.
