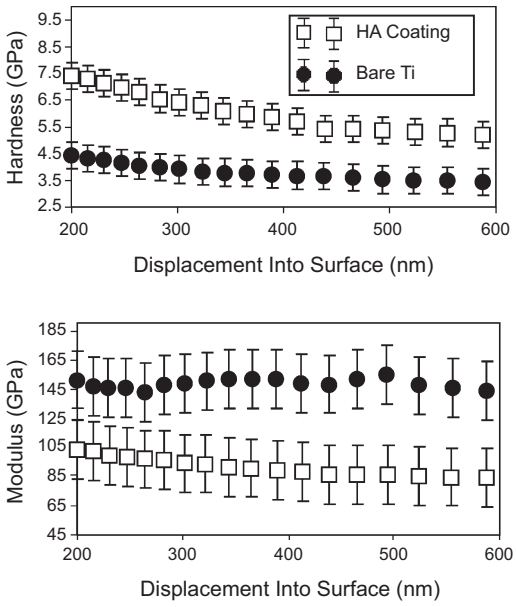

Figure 17. Nanoindentation hardness and Young's modulus vs indentation depth for the plasma sprayed hydroxyapatite coating deposited on the titanium implant screw shown in Figure 17. For comparison, similar measurements were also obtained from the uncoated titanium surface. Reprinted with permission from [148], S. A. Catledge et al., *J. Nanosci. Nanotechnol.* 2, 293 (2002). © 2002, American Scientific Publishers.

Young's modulus for the HA screw coating as well as that obtained from the uncoated titanium surface; each data set is plotted with error bars. This error represents the standard deviation from 12 indents at that depth. The average values of hardness and modulus (6.1 ± 0.4 and 89 ± 6 GPa, respectively, at 400 nm depth) represent critical mechanical property measurements for HA coatings that must withstand large abrasion forces during implant insertion.

Concerns about the lack of control of microstructure and the relatively low bond strength with the metallic implant substrate cause some scientists and clinicians alike to reject the use of plasma sprayed HA-coated implants, in spite of the apparent benefits of these coatings. The average grain size of HA crystals in these coatings is 15–25 μm, and each grain is surrounded by amorphous regions resulting from the rapid cooling of the semimolten ceramic material [115]. The generation of unwanted calcium oxide and other more dissolvable calcium phosphate crystalline phases (such as tricalcium phosphate) is also quite common with the plasma spray process. The size of the grains and the percent of amorphous material and non-HA crystalline phases influence the dissolution rate. Studies have indicated that a 46% crystalline HA plasma sprayed coating dissolves three times as rapidly as a 75% crystalline HA coating [116, 117].

The size of the grains for plasma sprayed coatings is based on the initial size of the starting powder, which is typically in the range of 20 to 40 μm (average about 35 μm). It is not possible to use smaller particles as feedstock in the plasma spray process because they will volatilize and result in significant compositional changes. The grains or crystals in the deposited coating are the remaining cores of the starting powder that did not dissolve in the argon gas plasma. The

rapid cooling of the semimolten powder leaves little opportunity for microstructural control during the plasma spraying process, and postdeposition heat treatment has been found to be of little value in optimizing the microstructure of the coatings. Because of this lack of control of the coatings on either the micro- or nanostructural level, a coating with optimal dissolution properties has not been achieved using plasma spraying or thermal spray processes in general. Incremental advances in HA coatings require that a different coating method be used that will allow control of the crystalline structure on a nanostructural level.

Previous studies at the University of Alabama at Birmingham (UAB) have demonstrated that several alternative coating techniques have the potential for producing calcium phosphate coatings that are superior to the existing commercial plasma sprayed coatings. The two methods shown to be most successful in producing HA coatings with controlled chemistry and structure are ion beam sputtering and pulsed laser deposition, both of which are described in previous publications [118, 119]. Ion beam sputter deposited coatings were shown to possess superior bond strength and density as compared to plasma sprayed coatings [120, 121]. Figure 18 shows the crystalline structure of a sputter deposited calcium phosphate coating. Sputtering can produce nanocrystalline coatings when followed by an appropriate heat treatment [122]. The primary value of both of these vacuum chamber processes is that nanosize grains can be formed because the coatings are essentially built up in small increments, or on an atom-by-atom basis if desired. In both of these coating techniques, material is removed from a pressed/sintered HA target by bombardment with a beam. This is usually an argon ion beam in the case of ion beam sputtering, or by a laser in the pulsed laser deposition (PLD) process. In both techniques the coatings can be built up slowly, thus permitting the precise tailoring of deposition conditions to grow nanosize crystals rather than the microsize grains inherent in the plasma spray process.

Desirable aspects of thin, HA coatings are high density, high abrasion resistance (important during implant insertion), the ability to release a small amount of calcium and phosphate ions to stimulate bone growth, and sufficient durability to remain on the metallic implant until bone apposition has taken place [123]. Of course, the ability to enhance bone formation around the implant is the primary reason for using any type of calcium phosphate coating, and thin film coatings must accomplish this objective in the human body prior to dissolution. Initial results using nanocrystalline bioceramic coatings are encouraging, as thin calcium phosphate coatings deposited by radio frequency sputtering were shown to possess sufficient durability and to provide stronger implant attachment to bone as compared to uncoated titanium implants [124].

When comparing the various coating methods, laboratory studies at UAB have indicated that the PLD technique is overall the most promising means of placing nanocrystalline HA coatings on titanium and other metallic implant materials. For calcium phosphate coatings deposited by ion beam sputtering, control of the composition and grain size was found to be slightly more difficult as compared to PLD, and microstructural analyses showed that the sputtered coatings were less dense and less crystalline on deposition than those obtained by PLD [125].

Typically, either of the vacuum deposition processes, sputter coating or PLD, produces amorphous calcium phosphate films (when using HA targets) that do not possess sufficient resistance to dissolution. Crystallization is necessary for these coatings to stay on the implant long enough to provide a useful benefit, and that can be accomplished by either closely controlling conditions in the vacuum chamber during deposition or by the use of a postdeposition heat treatment. Typical processing conditions for PLD include the use of a starting vacuum in the range of 2×10^{-5} Torr, a laser energy of about 5 J/cm^2, the introduction of a water vapor/argon mixture during deposition (to replace lost OH ions from the structure), and the use of a substrate heater to provide the thermal energy necessary to grow crystals [126]. Microstructural analyses showed that the PLD coatings produced at UAB using these parameters were very dense and of a much higher quality than those obtained by plasma sprayed HA coatings. The ability to bind specific proteins was demonstrated to be higher than uncoated specimens, thus indicating the potential for more rapid bone attachment to the implant [127]. Further research will be necessary to determine the precise role of nanostructure in influencing properties such as dissolution, abrasion resistance, bond strength, and *in vivo* performance of bioceramic HA coatings for dental and orthopedic implants.

4. NANOSTRUCTURED METALLOCERAMIC COATINGS

Total joint replacements have provided a viable option for restoring function to individuals whose joints have been afflicted by arthritis, joint fractures, bone tumors, and even trauma. Presently, total hip joint replacements consist of an ultrahigh molecular weight polyethylene (UHMWPE) acetabular cup in contact with a metallic femoral head, commonly fabricated from a wrought Co–Cr–Mo alloy. A metallic-plastic combination has been used for the past

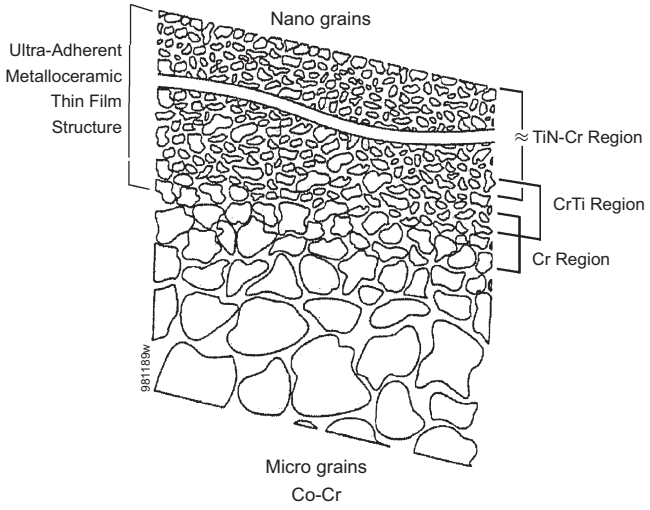

Figure 19. Schematic of functionally graded, nanocrystalline metalloceramic coating deposited by ion-beam assisted deposition. Adapted with permission from [101], S. Woodward, A Novel Metalloceramic Coating for Reduced UHMWPE Wear in Biomedical Devices, Master's Thesis, University of Alabama at Birmingham, 2002.

30 years; however, it is not without clinical shortcomings. Wear of the UHMWPE has been cited as a dominant factor limiting the long-term success of these devices [128–130]. To increase longevity of orthopedic implants, researchers have evaluated potential alternative materials for the articulating surfaces.

The wear process has been shown to be dependent upon the hardness and the roughness of the counterface. Slight changes in roughness can produce a large increase in UHMWPE wear rate [131–133]. A harder, more scratch-resistant surface will improve the resistance to third body wear [134]. Noting the importance of a hard surface layer for tribological purposes, various surface hardening processes have been evaluated for orthopedic devices. These include nitrogen ion implantation [135, 136], plasma ion nitriding, and physical vapor deposition (PVD) of various coatings [137]. All have met with limited success. One of the most detrimental problems in coating applications is inadequate adhesion to the substrate. Adhesion is defined as the joining of superficial layers of two different bodies brought into contact through the presence of attractive forces [138]. There are three primary chemical bonds that materials possess: metallic, ionic, and covalent. Materials with covalent bonding are hard, are strong, and have high wear resistance. Metallic materials are tough and ductile, while ionic materials are hard and stable. Ceramic materials typically have a combination of covalent and ionic bonding. This difference in bonding leads to adhesion problems when depositing a ceramic coating on a metallic substrate. Intermediate layers are often used to increase adhesion. For example, for the deposition of diamondlike carbon (DLC) on titanium, a Ti–TiN–TiC–DLC multilayer structure was used to improve adhesion [139]. Hubler et al. [140] used a titanium intermediate layer to improve adhesion of TiN coating on a silicon substrate. The idea is to gradually move from metallic bonding at the substrate to primarily covalent bonding at the surface.

A novel, functionally graded nanocrystalline metalloceramic coating for Co–Cr–Mo components has been developed by Spire Corporation (Bedford, MA), which may potentially reduce UHMWPE wear in orthopedic devices without the common adhesion problems evident in coating applications. This multilayer coating deposited by ion beam assisted deposition (IBAD) has metallic initial layers and a hard, nanocrystalline ceramic outer coating (Cr/CrTi/CrTiN). A schematic of the graded coating structure is shown in Figure 19. A (Cr/CrTi) metallic layer at the interface will increase adhesion to the cobalt chrome substrate, while the surface layer (CrTiN) is primarily covalent in nature and will enhance scratch and wear resistance of the coating. The chromium metal layer increases adhesion between layers and increases strength of the coating by serving as a barrier to crack formation and propagation. These coatings have three primary advantages over conventionally deposited ceramic films: nanocrystalline structure with grain size about 10 nm, functionally graded layer whose bonding gradually changes from metallic to covalent with increasing ceramic material toward the surface, and inclusion of nanocrystalline metal to enhance strength and toughness (as a barrier to crack formation and propagation). The coatings will have metallic adherence to metals, but with significantly better wear resistance and a lower friction coefficient. The benefits of the film in orthopedic applications will be substantially enhanced surface hardness and wear resistance, enhanced adhesion compared to ceramic coatings, conformal surface which maintains a smooth finish, and retention of surface finish *in vivo*, leading to lower UHMWPE wear. An example of the smooth surface exhibited by the metalloceramic coatings is illustrated in the atomic force microscopy (AFM) images in Figure 20 for both the coated and uncoated Co–Cr–Mo disks. The AFM images are very similar for both samples. The coated sample had an rms surface roughness value of 11.1 nm, while the uncoated sample had an rms value of 11.5 nm.

Figure 21 shows the thin film XRD pattern of the metalloceramic CrTiN coating with peaks indexed to a cubic sodium chloride structure. The coating shows a preferred (200) orientation with [200] direction being aligned perpendicular to the substrate surface. The diffraction peaks are broad as expected for a nanocrystalline material and the grain size was calculated from the Scherrer equation to be 12 nm.

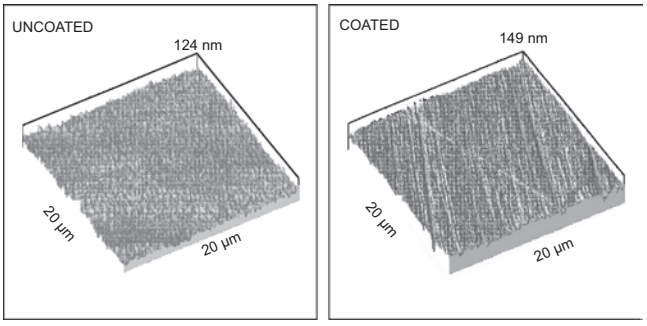

Figure 20. Atomic force microscope images of metalloceramic-coated and uncoated Co–Cr–Mo samples. Reprinted with permission from [148], S. A. Catledge et al., *J. Nanosci. Nanotechnol.* 2, 293 (2002). © 2002, American Scientific Publishers.

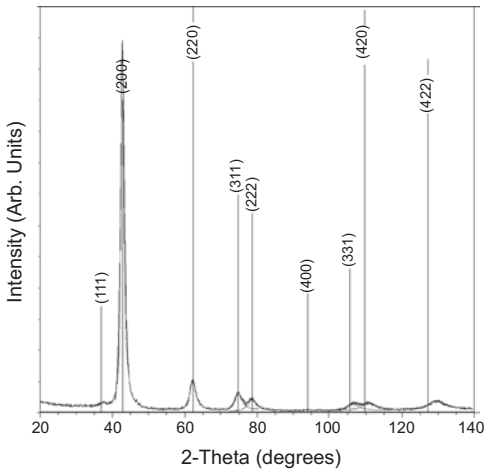

Figure 21. Thin film XRD pattern of the CrTiN metalloceramic coating. The miller indices (*hkl*) are indicated for the cubic sodium chloride structure. The fitted value for the lattice parameter is 4.2169 ± 0.0035 Å.

The bars indicate a least squares fit to the cubic structure resulting in a best fit lattice parameter of 4.2169 ± 0.0035 Å. Table 4 shows *d*-spacings of the fitted peaks with the percent error between observed and calculated values. It can be seen that the fit does not provide an excellent match to the weak (111) reflection or to the higher index peaks (331), (420), and (422). Table 5 shows the lattice parameter for bulk TiN as well as for experimentally determined TiN films prepared by different methods including PVD, N^+-IBAD, annealed N^+-IBAD, and Xe^+-IBAD. These values are all higher than our experimental lattice parameter for the metalloceramic film, which lies between that of CrN and TiN having lattice parameters of 4.140 and 4.244 Å, respectively. Therefore, since the XRD pattern provides a closer fit to TiN but with a lower lattice parameter than bulk TiN, we suggest that the surface layer is a tertiary Ti–N–Cr disordered solid solution which is predominantly TiN, but with some Cr atoms substituted for Ti.

Figure 22 shows nanoindentation hardness and Young's modulus vs indentation depth for the metalloceramic coating as well as for the uncoated Co–Cr–Mo substrate. The Young's modulus of the coating shows a drop from 325 GPa at 150 nm depth to 285 GPa at a depth of 600 nm. This drop

Table 4. Comparison of observed and calculated *d*-spacings for XRD peaks indexed for metalloceramic coating.

Miller index	Observed *d*-spacing (Å)	Calculated *d*-spacing (Å)	% Error
111 (very weak)	2.3957	2.4503	2.223
200	2.1128	2.1220	0.434
220	1.4930	1.5005	0.500
311	1.2695	1.2796	0.789
222	1.2171	1.2251	0.653
331	0.9618	0.9736	1.212
420	0.9361	0.9490	1.359
422	0.8518	0.8663	1.674

Note: The calculated *d*-spacings are based on a lattice parameter $a = 4.2169$ Å.

Table 5. Comparison of lattice parameters for TiN coatings prepared from different methods. The value for bulk TiN is also shown.

Preparation Method	PVD[a]	N^+-IBAD[a]	N^+-IBAD[a] treated at 850 °C	Xe^+-IBAD[a]	Bulk Tin
Lattice parameter (Å)	4.221	4.227	4.235	4.240	4.244

[a] From [147].

is likely due to interaction of the long-range elastic strain field with the underlying substrate having a lower modulus of 240 GPa. The hardness measurement is not as sensitive to this substrate effect since the region of plastic deformation is of shorter range. The measured average hardness of the metalloceramic coating is 27 GPa while that of the uncoated Co–Cr–Mo substrate is 10 GPa. The coating hardness is similar to values reported for TiN coatings [141]. For comparison, nanocomposite hard coatings such as those based on nanocrystalline TiC grains embedded in an amorphous carbon matrix have been engineered to have 32 GPa hardness and an extremely high plasticity of 40% (in nanoindentation deformation) [142]. As shown in the load vs displacement curve in Figure 23, the metalloceramic coating shows a remarkably high plasticity of 55%. Such plastic compliance is not typical of a hard ceramic coating and represents more than a fivefold increase over that observed for 60–70 GPa hard DLC coatings [143, 144]. The higher plasticity of the metalloceramic coating is attributed to the graded metallic-to-covalent bonding structure. The chromium subsurface metallic bonding promotes toughness within the coating while the outer primarily covalently bonded TiN–Cr layer enhances the surface hardness. The combination of a graded metallic–ceramic nanocrystalline film with metallic interfacial adhesion and ceramic surface hardness makes them unique and very attractive for implant applications.

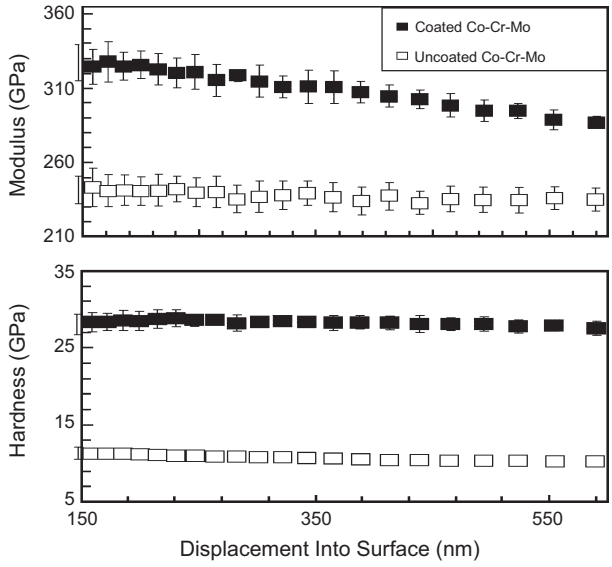

Figure 22. Nanoindentation measurements of Young's modulus and hardness for the metalloceramic coating and uncoated Co–Cr–Mo substrate.

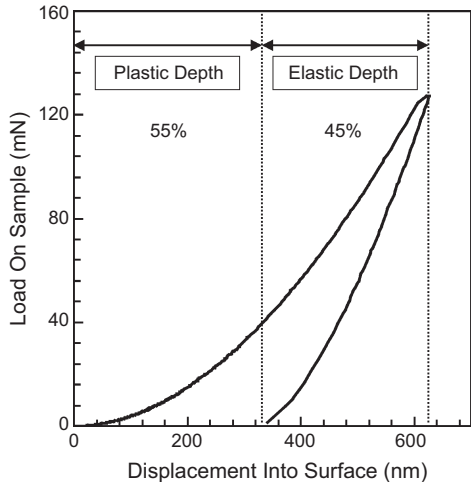

Figure 23. Nanoindentation load vs displacement curve for metalloceramic coating showing the large plasticity (55%).

The functionally graded and nanocrystalline nature of the metalloceramic coating is also expected to improve adhesion at the film/substrate interface. The bonding at this interface is completely metallic since a chromium layer was deposited as the first processing step. The chromium should serve as a barrier to crack formation and propagation. In addition, the nanosize grains should enhance the strength and toughness near the interface as compared to an interface having conventional grain size and/or having a more abrupt transition in bonding. In order to evaluate adhesion of the metalloceramic coating, scratch testing was performed. The scratch tip was a hemispherical diamond with 125 μm radius. Figure 24 shows the normal force and acoustic signal vs scratch distance produced during a 10 mm scratch while ramping the normal force up to 60 N. A critical force of 39 N was established, upon which abrupt changes in the acoustic signal indicated cracking/decohesion of the coating. This was confirmed by detailed microscopic investigation of the scratch. Several scratches were performed to obtain an average critical force of 44 ± 5 N. The inset in the figure shows an optical micrograph of the scratch segment corresponding to the time near the critical event. The coating shows only very localized spalling near the edge of the scratch. No catastrophic cracking or delamination occurred, indicating excellent interfacial adhesion.

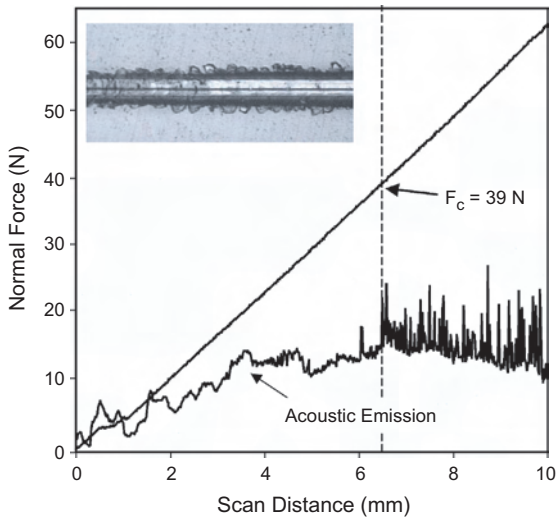

Figure 24. Plot from scratch adhesion test showing normal force and acoustic signal during a 10 mm scratch on metalloceramic coating. The inset shows an optical micrograph of the scratch segment corresponding to the time near the critical event.

The corrosion behavior of potential biomaterials must be addressed due to the corrosive environment of the human body. Being ceramic in nature one would expect a greater corrosion resistance with the metalloceramic coating (Cr/CrTi/CrTiN). This hypothesis has been affirmed through potentiodynamic polarization testing. Figure 25 shows polarization curves for metalloceramic-coated and uncoated control samples in deaerated neutral pH Hanks salt solution at 37 °C. The polarization curve for the coated sample is displaced a log decade to the left of the control sample, illustrating the order of magnitude lower corrosion rate of the coated sample. The breakdown potential (E_{bd}) of the coated sample (703 mV vs SCE) was significantly higher than the uncoated control sample (469 mV vs SCE). Also, on reversal of the polarization scan after breakdown, the coated sample exhibited a reduced current density (no hysterisis) while the uncoated sample exhibited a higher current density until open circuit potential was reached (large hysterisis). This indicates that pitting and crevice corrosion will propagate after breakdown on the uncoated substrate in comparison to the coated sample. Also, the coated sample may be able to repassivate any surface damage due to mechanical/electrochemical interactions. T-tests found that the corrosion rates and the breakdown potentials were significantly different between the coated and uncoated disks at $p < 0.05$.

Studies of the wear resistance of metalloceramic coatings are in progress. Previous investigators have demonstrated that a titanium nitride coating reduced UHMWPE wear. There was no delamination or penetration of the ceramic coating as found by Pappas et al. [145]. Likewise, in knee simulation studies conducted by Peterson et al. [146], titanium nitride coated Ti-6Al-4V femoral components showed

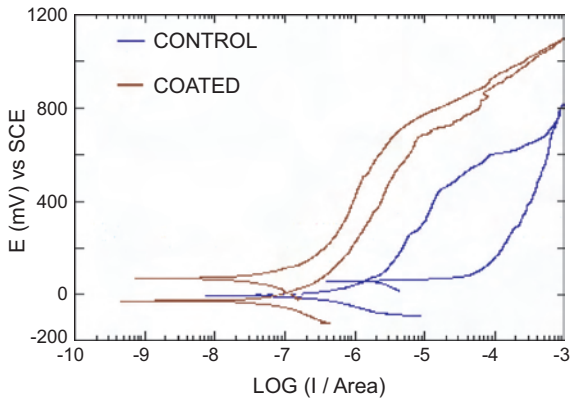

Figure 25. Overlaid representative polarization curves for control and metalloceramic-coated samples in deaerated neutral pH Hanks salt solution at 37 °C. Reprinted with permission from [148], S. A. Catledge et al., *J. Nanosci. Nanotechnol.* 2, 293 (2002). © 2002, American Scientific Publishers.

no scratches and retained a polished surface similar to that of cobalt–chromium–molybdenum components. There was no coating breakdown throughout testing. The metalloceramic coating reviewed here has exhibited promising characteristics. Ultimately, wear tests will predict if this coating should be further considered as a possible alternative in hip devices.

5. CONCLUSIONS

Although the wear and corrosion resistance of the ceramic coatings discussed in this chapter are promising for use in biomedical implant applications, further studies are needed to confirm their long-term safety, biocompatibility, and performance in use. Nevertheless, the benefits of nanostructured diamond, hydroxyapatite, and metalloceramic coatings are obvious.

Nanostructuring of diamond can occur via several processing routes and results in a dramatic improvement in fracture toughness and adhesion, reduced friction and wear rate, and higher corrosion resistance. The mechanical properties of diamond films can easily be tailored over a wide range by the appropriate manipulation of processing parameters. The nanostructured diamond coatings provide an ideal testing ground for the global hypothesis for wear studies that a particular "superhard" or "medium-hard" nanocrystalline diamond coated metal surface will perform better in laboratory wear tests and *in vivo* and may result in next generation of implant devices. The studies show that it is possible in the case of nanostructured diamond coatings to change the hardness and roughness parameter independently.

Nanostructuring of hydroxyapatite coatings by ion beam sputtering or pulsed laser deposition appears to allow for better control of chemistry and microstructure when compared to the more conventional plasma spray process. This, in turn, results in higher coating density and bond strength. The nanocrystalline coatings were shown to possess sufficient durability and to provide stronger implant attachment to bone as compared to uncoated titanium implants on metals. They promote better attachment to the bone while optimizing abrasion resistance, bond strength, and the dissolution rate. The nanometer-sized grains and high volume fraction of grain boundaries in nanostructured hydroxyapatite have been found to increase osteoblast adhesion, proliferation, and mineralization. Further research will be necessary to determine the precise role of nanostructure in influencing properties such as dissolution, abrasion resistance, bond strength, and *in vivo* performance of bioceramic hydroxyapatite coatings for dental and orthopedic implants.

Nanostructured metalloceramic coatings with a functionally graded structure from metallic (at the coating/substrate interface) to ceramic at the surface provide improved adhesion over conventional ceramic coatings on metals. The (Cr/CrTi) metallic layer at the interface will increase adhesion to the cobalt chrome substrate, while the surface layer (CrTiN) is primarily covalent in nature and will enhance scratch and wear resistance of the coating. The benefits of the film in orthopedic applications will be substantially enhanced surface hardness and wear resistance, enhanced adhesion compared to ceramic coatings, conformal surface which maintains a smooth finish, and retention of surface finish *in vivo*, leading to lower UHMWPE wear. These coatings show good corrosion resistance but further tests are needed to evaluate their wear-resistance potential for biomedical implants. Tables 6 and 7 provide a comparison summary of the properties and advantages/disadvantages for each NS coating described in this chapter.

Table 6. Summary of properties for each of the nanostructured diamond, hydroxyapatite, and metalloceramic coatings discussed in this chapter.

	NS diamond	NS hydroxyapatite	NS metalloceramic
Hardness (GPa)	85	6	27
Young's modulus (GPa)	700	89	305
Surface roughness (nm)	15	not measured	11

Table 7. Summary of the advantages and disadvantages for each of the nanostructured diamond, hydroxyapatite, and metalloceramic coatings discussed in this chapter.

	NS diamond	NS hydroxyapatite	NS metalloceramic
Advantages	• combination of extreme hardness, low surface roughness, and good fracture toughness	• promotes bone formation around implant • increases osteoblast adhesion, proliferation, and mineralization	• Combination of high hardness, very low surface roughness, and extremely good adhesion
	• good adhesion to titanium alloys • good corrosion resistance		• good corrosion resistance
			• conformal coatings
	• easily tailored mechanical properties		
Disadvantages	• poor adhesion to cobalt chrome and steel substrates • conformal coatings not well developed yet	• low toughness and flexural strength; not useful for load-bearing applications	• still in early state of development and testing; many properties remain unknown
		• control of chemistry and microstructure remains a challenge

GLOSSARY

Chemical vapor deposition (CVD) Deposited species are formed as a result of chemical reaction between gaseous reactants at elevated temperature in the vicinity of the substrate. The solid product of the reaction is deposited on the surface of the substrate and is used to deposit films of semiconductors (crystalline and noncrystalline), insulators, as well as metals. Variations of CVD processes include atmospheric pressure CVD, low pressure CVD, and plasma enhanced CVD.

Hydroxyapatite A compound that is chemically similar to the mineral component of bones and hard tissues in mammals. It is one of few materials that are classed as bioactive, meaning that it will support bone ingrowth and osteointegration when used in orthopedic, dental and maxillofacial applications.

Metalloceramic coating A graded coating with a gradual transition from metallic bonding to ionic/covalent bonding typical of ceramics. The coatings will have metallic adherence to metals, but with significantly better wear resistance and a lower friction coefficient. The benefits of the film in orthopedic applications will be: substantially enhanced surface hardness and wear resistance, enhanced adhesion compared to ceramic coatings, conformal surface which maintains a smooth finish and retention of surface finish *in vivo*, leading to lower UHMWPE wear.

Orthopedics Orthopedics is the branch of medicine concerned with diseases, injuries, and conditions of the musculoskeletal system—relating to the body's muscles and skeleton, and including the joints, ligaments, tendons, and nerves.

Osteoblasts Cells which aid the growth and development of teeth and bones.

Tribology The branch of engineering that deals with the interaction of surfaces in relative motion (as in bearings or gears): their design and friction and wear and lubrication.

ACKNOWLEDGMENTS

We acknowledge support from the National Institute of Dental and Craniofacial Research, National Institutes of Health under grant 5R01D013952-02. We thank Spire Corporation (Bedford, MA) for the nanocrystalline metalloceramic samples for some of the studies described in this chapter. In addition, we thank Dr. Dieter Gruen of Argonne National Laboratory, USA and Dr. T. Soga of Nagoya Institute of Technology, Japan for allowing us to use results from their publications in this chapter. Finally, we thank Dr. Bill Lacefield, Dr. Jack Lemons, Dr. Krishna Venugopalan, Dr. Jones Papo, Dr. Camillo Machado, and Shanna Woodard for their useful discussions and contributions.

Nanostructured Zeolite Films

Yushan Yan, Huanting Wang

University of California, Riverside, California, USA

CONTENTS

1. INTRODUCTION

1.1. Zeolites

Zeolites and zeolite-type materials (hereafter referred to as zeolites for simplicity) are a class of crystalline oxides with uniform channels and/or cages ranging from 0.3 to 2 nanometers (nm). Structurally, a zeolite consists of three dimensionally linked tetrahedra and each tetrahedron has one tetrahedrally coordinated atom (hereafter referred to as T-atom) (e.g., Si, Al, P, B, Ga, Ge, Zn, Be, etc.) at the center and four oxygen atoms at the corners. Every corner oxygen in the zeolite structure is shared by two neighboring tetrahedra [1, 2]. Depending on the T-atom, the zeolite framework could be charged or neutral. When the framework is charged, balancing ions are needed, and this is the origin of ion exchange capability of zeolites. According to their structural symmetry and topology, zeolites are classified into different framework types. More than 130 framework types with numerous compositional variations are known [2, 3]. Each framework type is assigned with a unique three-letter code by the International Zeolite Association (www.izc-online.org). For example, zeolite ZSM-5 is designated as MFI. The three-letter codes will be followed whenever appropriate in this review.

At present, zeolite materials are commercially used as shape/size selective catalysts in petrochemical industry and molecular sieving separation media for fixed gases and hydrocarbons. For both applications, zeolites are used in powder composite form such as pellets and granules. Zeolite catalysis has been an important and expanding field and several recent reviews are available [4–6]. Zeolites are good acid catalysts. Zeolites have also found use in base and oxidation catalysis. Immobilization of catalytically active guests such as ship-in-the-bottle complexes, chiral guests, and enzymes has also been studied [4]. One key benefit of zeolite catalysts is their shape-selectivity. For example, zeolites are good catalysts for conversion of two-ring and three-ring polycyclic hydrocarbons into value-added intermediates for making specialty chemicals and monomers of new polymer materials such as advanced engineering plastics, polyester fibers and films, and liquid crystal polymers. New developments in this area were discussed in a recent review covering reactions over large-pore zeolite catalysts [5]. Another recent review focused on heterogeneous chiral catalysis and the use of zeolites containing chelate complexes was discussed [6].

Separation and purification of gases or liquids by selective adsorption into zeolite adsorbents are well established commercially. For example, air separation by pressure swing adsorption (PSA) has been practiced for many years. Zeolites have also been used for separation of xylene isomers. Another important use of zeolites is as detergent builders. Little discussion of this application has appeared in the open literature although numerous patents have been pursued or issued [7–14]. The use of zeolite LTA as detergent builders is very well documented [7–10].

1.2. Related Recent Reviews

Several reviews related to zeolite films and their synthesis and applications have been published [15–25]. This section is intended to provide a brief analysis of emphases of these reviews. Applications of zeolite films as membranes and catalytic coatings have been discussed in several short reviews [15–17]. In 1996, Bein published a comprehensive review on zeolite membrane and layers [18]. This review had very

ISBN: 1-58883-063-2/$35.00

Encyclopedia of Nanoscience and Nanotechnology
Edited by H. S. Nalwa
Volume 7: Pages (763–781)

extensive coverage on sensor applications and strategies for fabrication of oriented crystal layers. In 1999, Tavolaro and Drioli published a review on zeolite membranes which provided a comprehensive list in convenient table format of various zeolite membranes (zeolite and support) and their separation performances [20]. Polymer-zeolite composite membranes were also included. In 2000, Caro et al. published a review on zeolite membranes which provided critical analyses on important issues such as how crystal orientation and grain boundaries in a zeolite membrane affect its thermal stability and diffusion resistance [23]. In 2000, Tsapatsis et al. published a review that focused on the relationship between microstructure and permeability of MFI membranes [21]. This review had extensive discussion of the three hydrothermal synthesis methods, especially seeded growth. Another two reviews were published recently [24, 25]. Although these two did not focus on zeolite films, they, however, provided discussions on new applications of zeolite materials and many of these new applications require zeolite to be in a film form.

All currently available reviews on polycrystalline zeolite films focused on membrane and membrane reactor applications. The goal of this review is to take an integrated approach that includes zeolite films with different configurations (e.g., polycrystalline, matrix composite, and layers), provide an introduction and analyses of film preparation methods and film applications, and provide a comprehensive list of zeolite films published up to 2002 in a format that can be easily referenced and expanded.

1.3. Structure of This Review

This review begins with a brief introduction of zeolite materials and their structures. Current commercial applications of zeolites are briefly discussed (Section 1.1). Recent reviews related to zeolite films are analyzed (Section 1.2). Section 2 provides a brief discussion of types of zeolite-based films followed by Section 3 on demonstrated synthesis methods. Section 4 documents applications for zeolite films, including membrane, membrane reactor, adsorption, catalysis, sensor, low-k dielectrics, corrosion-resistant coating, hydrophilic coating, heat pump, and thermoelectrics. To keep Sections 3 and 4 brief, only significant examples that are most familiar to the authors were selected to illustrate the concepts. A comprehensive collection of all reported zeolite films are provided in Section 5. Most of the films covered in Section 5 are not discussed in previous sections and are organized according to their three-letter codes (except MFI, FAU, and LTA) for easy reference. Some recent developments are discussed in Section 6. Concluding remarks and future perspectives are provided in Section 7 followed by acknowledgments, and references.

2. TYPES OF NANOSTRUCTURED ZEOLITE FILMS

2.1. Polycrystalline Zeolite Film

Polycrystalline zeolite films consist of intergrown zeolite crystals with no apparent significant cracks or pinholes (e.g., [26]) (Fig. 1). These films are made of zeolite only, without any nonzeolite components (e.g., amorphous silica or polymer). They are normally supported on a substrate although free-standing films have also been synthesized [27]. Polycrystalline films are primarily prepared by hydrothermal synthesis methods including *in-situ* crystallization [26], seeded growth [28], and vapor transport [29] (see Section 3 for details) and have potential use in all of the applications discussed in this review (see Section 4 for details).

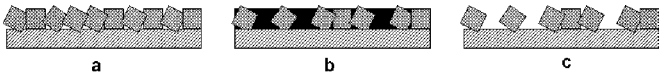

Figure 1. Schematic of the three types of nanostructured zeolite films. (a) a polycrystalline zeolite film, (b) a zeolite matrix composite film, and (c) a zeolite crystal layer.

2.2. Zeolite Matrix Composite Film

A zeolite matrix composite film is defined as a film in which isolated zeolite crystals are imbedded in a solid matrix that is either inorganic (e.g., silica and carbon) [30, 31, 32] organic (e.g., polymer [33]) (Fig. 1). For an inorganic matrix, these films are often supported while for an organic polymer matrix they normally are free-standing. The selection between an inorganic and an organic phase as the imbedding matrix depends strongly on the intended application. For example, a silica matrix would be ideal for applications where thermal stability is required [30], whereas a polymer matrix is a natural choice when flexibility is desired [33]. These composite films are usually prepared by wash-coating, sol–gel processing, and polymer film casting (see Section 3 for details).

2.3. Zeolite Crystal Layer

Another form of zeolite films is zeolite crystal layer which consists of isolated crystals deposited on a solid substrate [18] (Fig. 1). The substrate could be a variety of materials such as metal, ceramic, or silicon wafer. Although polycrystalline and matrix composite films could be prepared as a free-standing film, crystal layers have to be supported. There has been exciting fundamental research carried out in this area [34, 35]. However, demonstrated applications have been limited to sensors. Organic linker approach appears very promising for preparation of this type of film [36–39].

3. DEMONSTRATED SYNTHESIS STRATEGIES OF ZEOLITE FILMS

3.1. Hydrothermal Synthesis

Zeolites are normally synthesized hydrothermally in a sealed reactor under autogeneous pressure. The synthesis temperature is normally below 200 °C and the pressure inside the reactor is about several atmospheric pressures depending on synthesis temperature and the chemical composition of the synthesis mixture. The term "hydrothermal" by definition means that water is the solvent of choice in the synthesis. Zeolite synthesis has also been successfully carried out in nonaqueous solvent. When a nonaqueous solvent is

used, the process is sometimes called solvothermal synthesis. So far, all known syntheses of zeolite films used hydrothermal synthesis although solvothermal process may offer distinctive advantages. A common feature of the hydrothermal methods is that they produce pure polycrystalline "binderless" zeolite films while "binders" are needed in the nonhydrothermal techniques.

3.1.1. *In-situ* Crystallization

In-situ crystallization refers to a film deposition process where the substrate to be coated is directly submerged in the synthesis mixture and the zeolite crystals are formed "*in-situ*" on the substrate surface [26, 40]. The term "*in-situ* crystallization" originates from the fact that no preformed zeolite crystals are used in the synthesis. *In-situ* crystallization could be considered as a natural extension of the normal hydrothermal synthesis of zeolite powders. However, it is important to recognize that synthesis of a continuous zeolite film on a substrate could be fundamentally different from that of loose zeolite powder [26] (Fig. 2). To form high quality zeolite films, the synthesis composition and crystallization conditions have to be conducive to good intergrowth between the zeolite crystals and good adhesion of the zeolite film to the substrate. This requirement makes composition optimization very often essential [26, 41]. Many of the unsuccessful preparations for a functional zeolite membrane in the early days could be attributed to direct adaptation of a documented recipe for powder synthesis.

The *in-situ* crystallization process has several important advantages over other deposition processes. It is a simple one-step process while all other methods that will be presented in this review involve multisteps. Furthermore, *in-situ* crystallization has been clearly demonstrated to be able to coat surfaces of complex shape and in confined spaces [42]. This capability is important and very often essential for many practical applications. Corrosion-resistant coatings [42] and hydrophilic coatings on heat exchangers [43] are clearly such examples. For adsorption, catalysis, and heat pump applications, zeolite coatings on a structured monolithic support are needed. Many of these monolithic supports possess tiny and sometimes wavy channels whose internal surface has to be coated. Wash-coating, sol–gel processing, assembly with organic linkers, seeded-growth, and the vapor-phase transport method either have clear significant difficulties in coating these surfaces or have not been clearly demonstrated.

The most favorable situation for *in-situ* crystallization is that the film formation proceeds through a heterogeneous nucleation process that produces a dense layer of nuclei/gel on the surface and the bulk crystallization of loose crystals is minimized or avoided. Minimization of the production of zeolite crystals in the bulk avoids clogging of small channels in a structured support such as a heat exchanger. This is clearly the case for some of the ZSM-5 (MFI) films and this could be the major reason that they have been successfully demonstrated for a number of applications including membranes [26], corrosion-resistant coatings [42], and hydrophilic coatings [43]. The presence of a small amount of aluminum in the synthesis mixture is essential for the heterogeneous mechanism to dominate because the formation of pure-silica MFI film appears to proceed via a significantly different mechanism [41, 44]. However, a heterogeneous nucleation/growth process and a suitable synthesis composition may not be available for all zeolites and this could be a limitation for *in-situ* crystallization.

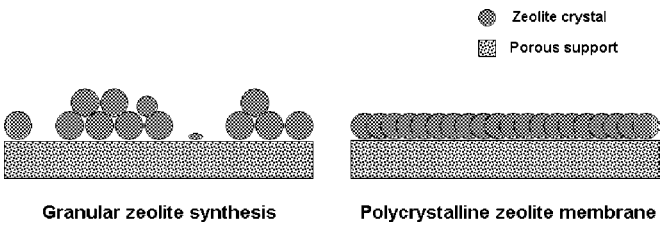

Figure 2. Schematic illustration of synthesis of normal zeolite granules versus a polycrystalline zeolite film.

3.1.2. Seeded Growth

Seeded growth refers to a film deposition process where a layer of preformed zeolite crystals is deposited on the substrate prior to its subsequent hydrothermal treatment [28]. Several methods for introducing the seed layer onto the substrate have been developed and these include rubbing the substrate surface with zeolite crystals [45], laser ablation of zeolite powders [46], and colloidal zeolite particle seeding through dip-coating [28]. The advantages and disadvantages of each seeding method have been thoroughly discussed in a recent review [21]. Colloidal particle seeding appears to be a frequent choice for seeded growth method.

The main advantage of seeded growth is the possibility of decoupling of nucleation and crystal growth. Since the film formation begins with a dense layer of zeolite colloidal particles, and if an appropriate synthesis mixture is developed for the secondary growth, secondary nucleation can be minimized or avoided. Another advantage of the seeded growth is that the growth process can be carried out at a temperature lower than *in-situ* crystallization if desired, although the deposition rate can be low.

The limitation of the seeded growth method is the need to synthesize small dispersible zeolite particles. This often requires sophisticated synthesis engineering, and at present appropriate synthesis composition and crystallization conditions are still not available for some zeolites [21]. In principle, zeolite particles with a small diameter are preferred for seeded growth. However, the yield of zeolite nanoparticles is often low for small diameter particles (e.g., 50 nm) [47]. Although possible in principle, it has not been clearly demonstrated that seeded growth can coat surfaces of complex shape and in confined spaces.

3.1.3. Vapor Phase Transport

Vapor phase transport refers to a film deposition process where a reactive gel layer is deposited on the substrate prior to its subsequent hydrothermal/solvothermal treatment [29]. The vapor introduced in the second step could be the organic structure-directing agent (SDA) or water depending on the zeolite system. Such an approach has been used to prepare supported or free-standing zeolite films. Since SDA molecules are either already concentrated in the gel layer or only needed to treat a minimized amount of gel on the

substrate, vapor phase transport has the benefit of minimized use of SDA, which is often the cost driver for zeolite synthesis.

Similar to seeded growth, vapor phase transport method is a two-step process. For vapor phase transport to work, a reactive gel has to be prepared. So far, a reactive gel is still not available for some zeolites. Another major concern for vapor phase transport is that the gel density is usually much lower than that of zeolite crystals, and thus the crystallization of the gel layer tends to produce intercrystal voids. Consequently, to produce a continuous film, the voids must be filled through the dissolution-recrystallization process.

3.2. Nonhydrothermal Synthesis

One common feature of the nonhydrothermal techniques is that they all use preformed zeolite crystals. In addition, they all use some form of "binder."

3.2.1. Wash-Coating, Sol–Gel Processing, and Polymer Film Casting

Wash-coating is a well-established industrial process for deposition of high-surface-area catalyst support on a structured monolith (e.g., ceramic cordierite honeycomb). Manufacturing of automotive three-way catalysts involves the use of wash-coating of γ-alumina. Typically, fine alumina particles that could be produced by ball milling are blended with an inorganic binder to form a slurry. The slurry is then flown through the channels of the monolith to leave behind a layer of slurry on the channel surface. Air-knifing is usually employed to blow away the extra slurry before the coated monolith is dried and then sintered to establish binding within the film and between the film and the monolith support. This method can be extended straightforwardly to zeolite coatings with silica or alumina-based binder [48]. The key benefit of the wash-coating method is that it is a well-established method and a large amount of know-how is available. However, it has several drawbacks. First, a binder has to be used and this occupies valuable space in the film and also tends to clog zeolite pores at high concentration. Second, high-temperature sintering is needed for binding and this could be incompatible with metallic substrates. Third, this method also has difficulty in handling very small and nonstraight channels (e.g., wavy channels).

Sol–gel processing is also well established [49]. After blending zeolite crystals (usually micrometer-sized) in an appropriate sol (e.g., hydrolyzed tetraethylorthosilicate (TEOS)), a standard sol–gel film formation process such as spin-coating and dip-coating can be used. For this strategy to work, zeolite crystals have to be synthesized first. One simple, but significant extension of this technique to zeolite nanocrystals, was recently developed [30, 31]. Zeolite nanocrystals are usually synthesized hydrothermally and the synthesis solution contains both nanocrystals and amorphous silica components. To retrieve the nanocrystals, a long period of high-speed centrifugation has to be performed. If a sol–gel matrix composite film is the desired product, however, the film can be simply formed by spin-coating or dip-coating by using the nascent synthesis solution without going through centrifugation separation. This has proven to be very promising for preparation of zeolite low-k dielectric films. Another recent study of zeolite composite films has shown that they could be used for photovoltaics [50].

Polymer film casting again is a well-established industrial process. It can produce polymeric membranes for gas and liquid separations. Once zeolite particles are incorporated into the polymer solution, this process could be readily extended for the preparation of polymer-zeolite mixed matrix membranes [51–54]. The main motivation for this composite approach is to combine high selectivity of the zeolite and the excellent processability of the polymer into one membrane.

3.2.2. Assembly of Micron-Sized Crystals Through Organic Linkers

A newly developed method for depositing zeolite layers is the assembly of micrometer-sized zeolite crystals using organic linkers [36, 39, 55–57]. In this method, the substrate and the zeolite crystals are both functionalized in such a way that a covalent bond could be formed between them but not among the zeolite crystals. This favors the formation of a monocrystal layer on the substrate [58]. A wide variety of well-known chemistry could be exploited in this method [59]. This strategy can be used for different zeolites and different substrates [38]. Patterning can also be readily achieved with this synthesis strategy [37, 60]. However, this method produces isolated crystal layers whose application may be limited. The adhesion of the crystals to the substrate is also weak. Nonetheless, this layer could be used as a seed layer for subsequent hydrothermal treatment.

4. APPLICATIONS OF ZEOLITE FILMS

4.1. Membrane

Zeolite membranes can be used for separations of gases, vapors, and liquids. This section focuses on polycrystalline zeolite films and polymer-zeolite mixed matrix films, which are also useful as membranes, and will be briefly discussed in the section of recent developments. Single crystal membranes have been studied. They are important tools for the fundamental study of mass transport through membranes, but are not suitable for large-scale applications [61]. For polycrystalline zeolite membranes, these films are required to be continuous and free from intercrystal porosity. They are also normally deposited on porous substrates for mechanical stability [62–66], although free-standing zeolite membranes have also been synthesized [67, 68]. Because of their extremely uniform pore size, zeolite membranes could have exceptionally high selectivity. Furthermore, due to their inorganic nature, zeolite membranes are more stable than polymeric membranes at high temperatures and in aggressive chemical environments. The high thermal and chemical stability make zeolite membranes suitable for membrane reactor applications. A large fraction of the reports on zeolite membranes are on MFI (ZSM-5 or silicalite) membranes because MFI membranes are relatively easy to prepare and have important practical use. Thus, MFI membranes are used exclusively in this section to illustrate the important developments of zeolite membranes. However, many of the techniques developed for MFI membrane are directly applicable to other zeolite membranes.

MFI membranes have been commonly prepared on porous alumina and stainless steel supports. The butane isomers have slightly different kinetic diameters (n-butane = 4.3 Å, i-butane = 5.0 Å) and both diameters are very close to the pore size of MFI (5.5 Å). Thus n-butane/i-butane selectivity is often used as a measure of the quality of MFI membranes. A high n-butane/i-butane selectivity indicates a MFI membrane of high quality (Fig. 3). Using *in-situ* crystallization, polycrystalline MFI membranes prepared on α-alumina showed n-butane/i-butane selectivity of 31 at 185 °C [26]. Seeded growth [69] was also successfully used for MFI membranes with n-butane/i-butane selectivity of 28–62 at room temperature. Very recently, vapor phase transport method [70] was used to prepare MFI films but permeations results were not reported.

The two key performance parameters for a membrane are permeation rate and selectivity. It was shown that under *in-situ* crystallization conditions for ZSM-5 membranes, there was significant penetration of siliceous material into the pore of the substrate. This penetration was believed to decrease the permeation rate and selectivity. To reduce this penetration, a temporary carbon barrier was introduced into the substrate pores before *in-situ* crystallization (Fig. 4). The carbon barrier was removed by calcination after membrane synthesis. Both flux and selectivity were improved by the use of the temporary carbon barrier [71].

It was also realized that ZSM-5 membranes by *in-situ* crystallization may have micro-defects (i.e., defect diameter < 2 nm). Clearly, if these defects could be removed, the membrane selectivity could be improved. With this goal in mind, a selective coking method was developed and n-butane/i-butane selectivity was improved from 45 to 322 at 185 °C. Triisopropylbenzene (TIPB) was chosen as the coking precursor because it is (kinetic diameter = 8.4 Å) too large to enter the MFI pores (pore diameter = 5.5 Å), so that coking selectively occurs in the microdefects while the MFI pores are intact [72] (Fig. 5). Chemical vapor deposition (CVD) was also used for modification of zeolite membranes to improve shape-selectivity of MFI membranes through counter-diffusion of tetramethylorthosilicate (TMOS)/O_3 [73, 74].

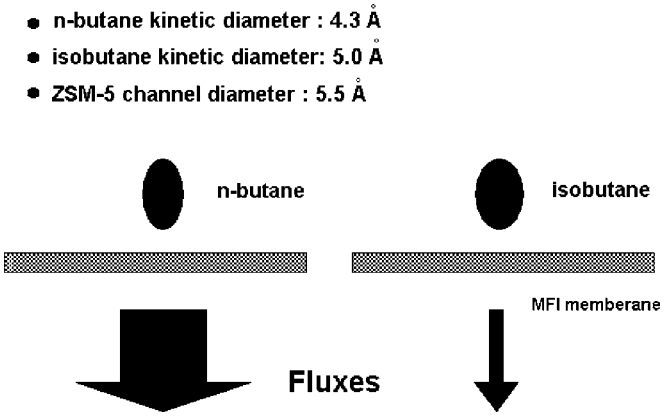

Figure 3. Schematic illustration of molecular sieving effect of a MFI membrane toward butane isomers. Small difference in kinetic diameters results in large difference in fluxes.

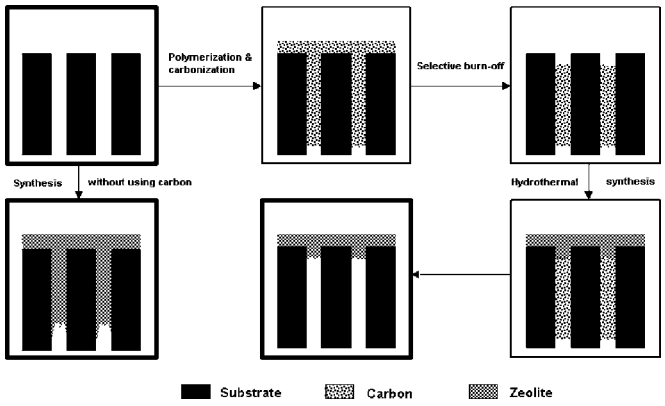

Figure 4. Schematic illustration of the use of a temporary carbon barrier to improve membrane flux.

It is well known that zeolite pore size can be finely modulated by ion exchange [1]. Perhaps the best known example for pore size modulation is zeolite LTA (A). When the cation in LTA (Si/Al ratio of 1) changes from sodium to calcium, the pore size increases from 4 Å to 5 Å. In an attempt to take advantage of this phenomenon, ZSM-5 membranes with Si/Al ratio of 25 were ion exchanged with H^+, Na^+, K^+, Cs^+, Ca^{2+}, and Ba^{2+}. The membranes were stable after exchange and single-gas permeances increased in the order: $K^+ < Ba^{2+} \approx Ca^{2+} < Cs^+ < Na^+ \approx H^+$, which coincided with the decrease in ion size and only the Cs ion did not fit this trend [75]. Another flexibility of a zeolite membrane is isomorphous substitution which could impact the surface hydrophilicity/hydrophobicity. ZSM-5 zeolite membranes with Al, Fe, B, or Ge substituted for Si in the framework were prepared by *in-situ* crystallization onto porous stainless steel supports. Their single-gas and mixture separation properties were compared to silicalite membranes [76].

The synthesis of high-silica zeolite membranes often requires the use of an organic structure directing agent (SDA). These molecules are eventually trapped in the zeolite pores blocking mass transport. Therefore, these molecules have to be removed. Calcination at a high temperature is often used to remove these organic molecules. However, calcination tends to generate cracks in the membrane and reduce selectivity [77]. To understand crack formation, calcination of large SDA-containing MFI crystals was studied [78]. The interesting finding was that there was

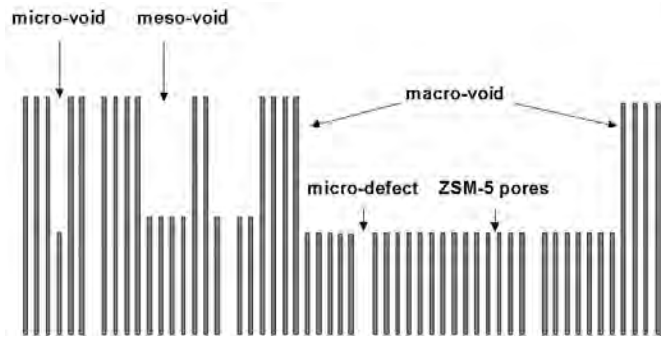

Figure 5. Schematic illustration of a MFI membrane with microdefects that could be selectively filled by coking of triisopropylbezene (TIPB) (after [72]).

positive thermal expansion in a- and c-direction while there was negative expansion in b-direction. This study was later extended to MFI films using *in-situ* X-ray diffraction [79].

To bypass the calcination process, efforts have been made to synthesize MFI membranes without using SDA so that the calcination process is not needed [80]. Hedlund et al. used the seeded growth method. They used SDA-containing crystals as the seed and calcination was performed before the coated substrate was exposed to a synthesis solution that did not contain SDA. The membranes obtained were considered of high quality, but nonzeolitic pathways were evident [81]. *In-situ* crystallization was also used for SDA-free membrane synthesis using a special synthesis composition [82].

To characterize defects, an interesting fluorescence confocal optical microscopy (FCOM) was developed. Fluorescence confocal optical microscopy is a nondestructive tool for the evaluation of zeolite membranes. This technique can provide two-dimensional, optical sections of the membranes with submicron resolution without physical damage to the sample [83]. Another technique for defects characterization is transient permeation which offers much more information than the normal steady state studies [84, 85].

4.2. Membrane Reactor

The high selectivity and high thermal and chemical stability of zeolite membranes make them extremely attractive for membrane reactor applications [86]. The benefits of a membrane reactor are improved selectivity and yield. Selective removal of a product and controlled admission of a reactant are the two commonly used themes. Most membrane reactor applications involve catalysis. The zeolite membrane could actively participate in catalysis. In this configuration, the catalyst is located within the zeolite film [87, 88]. Alternatively, the zeolite membrane could be used passively only as a separation membrane and the catalysts are packed outside the zeolite film [89].

For an active membrane, examples include V-MFI zeolite membrane reactor on alumina tubes for oxidative dehydrogenation of propane. Both MFI and V-MFI membranes were found to produce propene with about 40% selectivity but with higher O_2 and C_3H_8 conversions for the V-MFI [87]. Si-MFI, Ti-MFI, and V-MFI were also prepared by the seeded growth method on porous stainless steel for membrane reactor applications. Transport properties were studied but catalytic performance was not given [88].

For a passive zeolite membrane, the Si-MFI membrane reactor on a porous stainless steel support by the seeded growth method was used for the liquid-phase oligomerization of isobutene. Isooctene was selectively removed from the reaction environment, thus reducing the formation of unwanted C_{12} and C_{16} hydrocarbons. An acid resin catalyst bed was located on the membrane tube side. The membrane reactor produced a very significant increase in the selectivity and yield of isooctenes compared to a conventional fixed bed reactor [89]. zeolite membrane reactors have also been used for selective water removal from gas phase synthesis of methyl-tert-butyl ether (MTBE) from tert-butanol and methanol [90], and for selective hydrogen removal from dehydrogenation of isobutene using Pt-In catalyst [91].

A thermodynamic analysis has also been carried out for CO_2 hydrogenation to methanol in a zeolite membrane reactor where methanol was selectively removed. An increased methanol yield led to reduced consumption of reactant and also allowed the reactor to operate at low pressure and high temperature, which favors the kinetics that reduce the residence time and the reactor volume [92]. ZSM-5 membranes were prepared by seeded growth on porous alumina. After ion-exchanging from Na^+ to the H^+, alkylation of toluene with methanol was carried out and a maximum p-xylene selectivity of 80% was achieved at 450–500 °C [93].

4.3. Sensor

Chemical sensors are important for industrial process control and environmental monitoring. They could also find critical use in medical and defense applications. Two of the critical performance parameters of a sensor are selectivity and sensitivity. It has been shown that when an appropriate zeolite film is used, both of these parameters can be improved [94–96]. A large number of publications [97–124] have appeared in this area, and a comprehensive review on this topic is beyond the scope of this chapter. An in-depth review on zeolite films for chemical sensor applications up to 1996 was provided as a section in a recent review by Bein [18].

The two most commonly used sensor platforms that have been coupled with zeolite films are surface acoustic wave (SAW) and quartz crystal microbalance (QCM) sensors. Using a sol–gel matrix composite film and a SAW sensor platform, Bein et al. formed thin coating of zeolite with pores from 0.4 and 0.8 nm (e.g., zeolite Y, chabazite, and ZSM-5) in hydrolyzed TEOS. High discrimination ratios were observed between molecules entering the zeolite pore system and those excluded from the molecular sieving sensor [94]. In another example, silicalite was grown by *in-situ* crystallization in an oriented way on a quartz substrate to form a well-defined SAW-sensor chemical interface for CO_2 detection. The SAW-sensor device responded well to CO_2, while the sensitivity to water seemed not to be severe [102].

Using an organic linker approach, and a QCM sensor platform, Yan and Bein attached zeolite crystals to the gold electrodes. Thiol-alkoxysilanes on the gold surface served as interfacial layers for the subsequent adhesion of the zeolite crystals to the QCM. The resonance frequency response of zeolite-coated QCM to vapor pulses could be increased up to 500-fold compared to the bare sensor. The regular micropores (0.3–0.75 nm) of the QCM-attached zeolite crystals were found to efficiently control molecular access into the film. Selectivity of the frequency response in excess of 100:1 toward molecules of different size and/or shape could be demonstrated [98]. A seeded growth method has also been used to deposit silicalite film on a QCM sensor for hydrocarbons detection. The seed layer was introduced by electrostatic interaction by modifying the substrate with a cationic polymer. The sensor was evaluated as chemical sensors by exposing it to highly dilute hydrocarbon vapors [109].

4.4. Adsorption

Zeolites in powdery form (e.g., pellets and granules with binders) have been commercially used as effective adsorbents for separation and purification. For example, air

separation can be achieved by using a pressure/temperature swing adsorption process using zeolite adsorbents. The primary motivation for moving from powder to a film configuration is to reduce pressure drop. Other benefits of a film versus packed column include no attrition and potentially better mass transfer and heat management. When hydrothermal synthesis is used, zeolite coating also involves no binder and this could be important because binder tends to clog zeolite pores. Usually for this application, a structured support such as a monolith honeycomb is needed. Literature on this technology dates back to the 1960's when a zeolite coating was used on cryopumping surfaces [125].

In the early 1990's, Davis et al. published a study on the formation of zeolite Y coatings on flat metal surfaces and the use of this kind of coating for adsorption was suggested [126]. The method used was *in-situ* crystallization. It was shown that zeolite crystals were selectively bonded to one side of the metal foil substrate due to gravitational effects during the zeolite crystallization. Dunne and Taqvi et al. [127, 128] have used slurry wash-coating to deposit zeolite coatings on flat metal panels for adsorption applications including moisture and volatile organic compounds (VOC) removal from air. A unique configuration was developed involving a rotating wheel so that adsorption and regeneration can be achieved simultaneously. As mentioned before, the wash-coating deposition process requires a high temperature sintering step (e.g., 650 °C). Monolithic supports have also been used for coatings of ZSM-5 deposited by *in-situ* crystallization and by vapor phase transport [129–131].

4.5. Catalysis

Similar to adsorption, the choice of zeolite coatings on a structured support over a packed bed of zeolite particles (e.g., granules and pellets) is motivated by the desire to lower the pressure drop [132]. Zeolite-coating reactors also could have high catalyst utilization because of facile mass transfer. The use of zeolite coatings dates back to the early 1970's [133, 134]. Wash-coating was used on simple supports such as glass fibers. In a later patent, more complex support was claimed [135]. *In-situ* crystallization that could produce binderless zeolitic coatings is very attractive, and has been used to deposit ZSM-5 coating on monolithic stainless steel structures [132]. Synthesis composition was optimized, and homogeneous zeolitic coatings with a Si/Al ratio of 34 and with coverage of up to 25 g/m^2 were obtained in a single synthesis run of 24 h at 150 to 170 °C. Neither the state of the silicon source nor the curvature of the support surface (monoliths constructed from foil or 35-μm wire gauze) had a significant effect on these figures.

More recent developments on zeolite coatings seem to focus on microreactors [136, 137]. Hydrothermal formation of ZSM-5 zeolitic coatings on stainless steel plates with a microchannel structure has been investigated at different synthesis mixture compositions. The procedures of coating and thermal treatment were optimized. Obtaining a uniform thickness of the coating within 0.5 μm-wide microchannels required a careful control of various synthesis variables. The prepared samples proved to be active in the selective catalytic reduction (SCR) of NO with ammonia. The microreactor showed no mass transfer limitations and a larger SCR reaction rate was observed in comparison with pelletized Ce-ZSM-5 catalysts [136].

4.6. Low-k Dielectrics

Low-k (k for dielectric constant) dielectric materials have been identified as one of the most difficult challenges for interconnects of the future generation integrated circuits (ICs). Many materials have been proposed, studied, or under commercial development as potential candidates for low-k dielectrics. Among these materials, two major classes are dense organic polymers and porous inorganic-based materials. It has been shown that some dense, organic polymers could easily have k between 2 to 3, but there are concerns about their low thermal stability and low heat conductivity. Also, due to their low mechanical strength, polymeric materials may have potential problems with the chemical and mechanical polishing (CMP) process.

Current dielectric material is dense silica that has a $k = 4$. Porous silica has lower k because of the incorporation of air. Sol–gel silica and mesoporous silica have been studied as possible low-k materials. However, these materials have concerns of low mechanical strength and low heat conductivity. Sol–gel silica also has randomly occurring large pores that can cause electrical breakdown. High mechanical strength is needed for the new low-k materials to be compatible with CMP process.

Very recently, zeolites have been studied and demonstrated to be a promising low-k material. Zeolites have very uniform pores and their pore size (<2 nm) is significantly smaller than IC feature size. Therefore, the problem of electrical breakdown should be mitigated. Zeolites have high heat conductivity and mechanical strength due to their dense crystalline structure [30, 138, 139]. Pure-silica MFI films were first developed by using *in-situ* crystallization. These films had a k value of 2.7 and were highly hydrophobic. The elastic modulus was 30–40 GPa by nanoindentation using a film of 0.43 μm thick. This value is much higher than sol–gel silica or mesoporous silica films. Mechanical polishing experiments showed that the film was strongly adhered to the silicon wafer and there was no cracking or delamination during the polishing. Low resistivity, high resistivity, oxide-covered, and nitride-covered wafers have been successfully coated using *in-situ* crystallization method.

Although the films formed by *in-situ* crystallization are strong mechanically, the k value is still high. The solution phase deposition is also of concern to the semiconductor industry. Another process was recently developed by a simple spin-on process of zeolite nanoparticle suspension [30]. The spin-on process is simple and preferred by the semiconductor manufacturers. Therefore, it represents a significant step forward toward the integration of zeolite materials into microelectronic devices. Nanoindentation was performed on a 0.42-μm thick film and the elastic modulus was 16–18 GPa. It is worth mentioning that a modulus of 6 GPa is usually considered to be a threshold value for industrially viable low-k dielectrics.

4.7. Corrosion-Resistant Coating

Aluminum alloys are widely used in aerospace because they are light and mechanically strong. However, some of the aerospace aluminum alloys (e.g., 2024-T3) are very prone

to corrosion. For combating corrosion of aluminum alloys, chromic acid anodization and chromate conversion have thus far proved most effective. Both processes, however, use and release hexavalent chromium, a proven human carcinogen, causing serious environmental and worker health and safety concerns. A chromium-free alternative with equivalent or superior corrosion performance has long been desired. Sol–gel coatings have been shown to be a promising alternative and are cited for their superior adhesion, good barrier properties, and high thermal and chemical stability. However, sol–gel coatings usually require high temperature curing that is not compatible with many metal alloys. It is also difficult to coat surfaces of complex shape and in confined spaces. Electrochemical deposition of conductive polymer coatings is another developing technique for combating corrosion of metal and metal alloys. Thermal stability and adhesion are concerns for pure polymer coatings.

The idea of corrosion-resistant zeolite coatings takes advantage of several well-known facts about zeolites. First, high-silica and pure-silica zeolites are stable thermally and chemically. For example, many high-silica zeolites are thermally stable to 1000 °C, and pure-silica zeolites are stable in all mineral acids except hydrofluoric acid [140]. Thus, the framework of zeolites has the needed corrosion resistance. Second, most of the high-silica zeolite syntheses use SDA molecules, and these molecules are eventually trapped inside the zeolite pores. Normally, for separation and catalysis applications, these molecules have to be removed by high temperature calcination. It was recognized very early on that as-synthesized zeolite membranes could be gastight if they were defect-free. This suggested that as-synthesized zeolite films could be corrosion resistant.

It has been shown recently that as-synthesized SDA-containing high-silica MFI coatings on aluminum alloys have superior corrosion resistance to chromate conversion coatings in strong acids, bases, as well as pitting aggressive media [42]. It was also demonstrated that the *in-situ* crystallization coating deposition process can coat surfaces of complex shape and in confined spaces. In addition, the thermal and mechanical properties of the high-silica MFI coatings were shown to be satisfactory [143]. It was also shown that corrosion resistance is general for all high-silica zeolite coatings such as MFI, BEA, and MTW [141–143], and high-silica MFI coatings can be extended to other aluminum alloys such as 6061-T6.

4.8. Hydrophilic Coating

An environmental control system for a manned spacecraft typically includes a condenser for controlling cabin temperature and humidity. As the moisture-laden air is cooled in the small channels of the condenser, water normally condenses out as water droplets. Under a microgravity environment, these water droplets tend to become entrained in the air stream and carried back into the cabin, failing to achieve water separation. In such an instance, rain could quite literally fall inside the cabin. To effectively remove water from the air, heat exchanger surfaces could be coated with a hydrophilic zeolite coating [43] so that the condensation mode changes from drop-wise to film-wise (Fig. 6). The water film can be removed by vacuum sipping. Zeolite

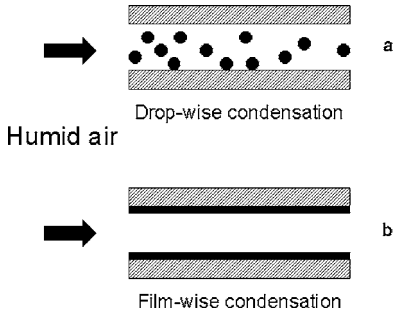

Figure 6. Schematic illustration of the use of a hydrophilic zeolite coating on a heat exchanger surface to change condensation mode from drop-wise without zeolite film (a) to film-wise with zeolite film (b).

coatings were shown to be highly hydrophilic with advancing contact angle of 0–15 degrees and a receding contact angle of 0 degrees. The adhesion was 5 B under ASTM method 3395.

In-situ crystallization was used and clearly preferred as it can coat surfaces of complex shape and in confined spaces. In addition, it was a low temperature process (e.g., 165 °C) and compatible with most metal alloys. Another significant advantage for a zeolite coating is that an antimicrobial characteristic can be added readily through ion exchange of metal ions such as silver. Antimicrobial function is desirable for hydrophilic coatings as damp surfaces tend to grow bacteria and fungi. Furthermore, once depleted, the antimicrobial capability of zeolite coatings can be easily regenerated by another ion-exchange without the need of a potentially costly recoating.

4.9. Heat Pump

It is well known that water adsorption in zeolites releases heat while its desorption absorbs heat. This phenomenon has been exploited for the design of a heat pump for cooling applications using waste heat or solar energy. At present, zeolite pellets are used and the heat and mass transfer are inefficient, leading to bulky pumps. The utilization of zeolite coatings could eliminate these limitations. Zeolite coatings on metal substrates have been claimed for enhancing transport of sensible and latent heat from warm air to cool air. Moisture adsorption/desorption was exploited. The coatings were required to be capable of adsorbing/releasing moisture from/to an air stream, but not capable of adsorbing contaminants from the air stream [144]. There have been renewed interests in zeolite coating heat pumps recently [145, 146]. A new *in-situ* crystallization method for zeolite coatings was developed which suppresses the reaction in the bulk and promotes it on the substrate by applying a temperature difference between the reaction mixture and the substrate. The substrate was heated directly, while the reaction mixture was kept at a lower temperature by means of a water bath. The method was tested for zeolite 4A coatings on stainless steel plates from a clear aluminosilicate synthesis solution. Impurity seemed to be a concern, and a final treatment that involved an increase in the temperature of the water bath could be applied to the coatings at the end of their preparation in order to remove the impurities [145].

In another study by the same group, the thermal and mechanical stabilities of the coatings were determined by the application of consecutive heating and cooling cycles and ultrasonic treatments. Although ultrasonic treatments resulted in relatively higher mass losses, the stabilities of the zeolite coatings synthesized on stainless steel plates were observed to be only moderately affected by the very rapid and consecutive heating and cooling cycles applied. No difficulty was observed for desorption of water vapor out of the zeolite layer [146].

4.10. Thermoelectrics

Thermoelectrics are all solid-state devices that can directly convert heat to electricity (power generation) or use electricity to pump heat from cold to hot (refrigeration), both without using any moving parts and hazardous compressed fluids. Thermoelectric devices are lightweight, compact, and with extremely fast response, and therefore are particularly useful for applications such as microelectronics and semiconductor lasers where conventional compression-based cooling is very difficult or impossible. At present, applications of thermoelectric devices are limited because of their low efficiency. The efficiency of a thermoelectric device is usually characterized by a dimensionless figure of merit, ZT. Current thermoelectric materials have a $ZT = 1$. A thermoelectric cooler with a $ZT = 1$ operates at only 10% of Carnot efficiency, whereas a thermoelectric cooler with a $ZT = 4$ would achieve 30% of Carnot efficiency, which is comparable to the efficiency of a home refrigerator.

Very recently, theoretical calculation for isolated single nanowires predicts over a 10-fold increase in the figure-of-merit. In order to realize these size effects, wires must be synthesized with diameters less than the thermal de Broglie wavelength (typically less than 10 nm), which is smaller than is currently accessible by lithography techniques. Also, in order to transfer meaningful amounts of thermal energy, a practical device must consist of an array of a large number of nanowires in parallel. One way to potentially synthesize these nanowire arrays is to use the pores of microporous and mesoporous materials as a mold to template the diameter and orientation of wires of suitable thermoelectric materials. A recent review has been published discussing the relevant physics and derived a model to assess the feasibility of using microporous and mesoporous frameworks in the fabrication of thermoelectric devices [147]. The model accounted for the possible deleterious effects of thermal conduction through the microporous or mesoporous framework and the presence of bulk thermoelectric material (that may result from defects in the microporous or mesoporous framework) in parallel with the wires on the thermoelectric figure-of-merit. Simulation results were reported for SBA-15, MCM-41, and zeolites VFI, LTL, and LTA embedded with Bi_2Te_3 nanowires. The results showed that the microporous zeolite frameworks may yield figures-of-merit much larger than one, while thermal conduction through most mesoporous frameworks reduces the figure-of-merit below the level currently available using traditional thermoelectric materials.

5. COLLECTIONS OF ZEOLITE FILMS

A large number of articles have been published on zeolite films. This section was intended to be a comprehensive collection of these reports up to 2002 although accidental omission is inevitable. To avoid duplication, papers that were used as examples to illustrate the synthesis strategies and applications in previous sections are not included in this section except in some special cases. This section begins with three most widely studied zeolite films: MFI, FAU, and LTA. The rest is in alphabetical order according to their three-letter codes. This format makes it easy for future expansion of this review as the field of zeolite films evolves.

5.1. MFI (ZSM-5 and Silicalite)

5.1.1. Separation Membranes

Membrane Preparations. MFI membranes have been prepared by *in-situ* crystallization on a variety of supports including porous alumina and sol–gel derived mesoporous yttria doped zirconia [148], a TiO_2-coated porous stainless steel support [149], porous sintered glass tube [150], porous alumina and other substrates [151, 152], porous stainless steel and alumina tubes using an alkali-free synthesis mixture [153]. The *in-situ* crystallization method could be assisted by an electrophoretic technique to attract zeolite/gel particles to the substrate surface [154]. The surface properties of the porous stainless steel support is very important and the effects of surface functional groups (-SiO_2, -OH, and -COOH) were simulated using adsorbed surfactants [155]. In an effort to have a separation module without dealing with the sealing problem, MFI membranes were grown within stainless steel membrane modules and the MFI layers remained thermomechanically stable upon calcination at 400 °C in air [156].

MFI membranes have also been prepared by seeded growth methods on a variety of supports, including inside the pores of porous alumina support tubes [157], porous alumina tubes with seeding under ultrasonication [158, 159], porous alumina disks and nonporous substrates with preferential orientation [160]. MFI membranes prepared by seeded growth on mesoporous alumina support were compared with those by *in-situ* crystallization for their performance in pervaporation and steam permeation of water/iso-propanol and water/methanol mixtures [161]. The seeded growth process of polycrystalline MFI films was simulated in two spatial dimensions using a front tracking technique [162].

An interesting combination of seeded growth and a vapor phase transport method was used to prepare silicalite membranes. A silica layer was first deposited on the porous support and followed by a silicalite nanocrystal layer. Then the coated substrate was treated with steam in a closed reactor [163, 164].

Membrane Separations. MFI membranes have been demonstrated for several classes of separations based on adsorption, diffusion, molecular sieving, or a combination of these. The first major class is separation of organic/water mixtures through pervaporation. Selectivity

for pervaporation is mainly determined by the hydrophobicity/hydrophilicity of the membrane. Demonstrated pervaporations include separation of mixtures of methanol/MTBE [165], 1,3-propanediol/glycerol and glucose/water [166], ethanol/water [167, 168], methyl ethyl ketone/water, methanol, ethanol, and acetone/water [169].

The second major class is separation of hydrocarbons such as xylene isomers and linear/branched hydrocarbons. Examples include pervaporation of pure xylene isomers and their binary mixture through alumina-supported MFI membranes [170], separation of C_4, C_6, and xylene isomers through a MFI membrane prepared by seeded growth [171], permeation of n-octane, isooctane, and n-hexane vapors through silicalite membranes on porous alumina [172], n-hexane/2,2-dimethylbutane [173, 174]. One interesting development is the use of an MFI composite tubular membrane to improve the stability of liquid membranes [175].

The third one is separation of fixed gases and hydrogen. Examples here include separation of CO_2 and CH_4 [176], binary mixtures of CH_4-N_2, CO_2-N_2, and CO_2-CH_4 [177], a CO/air mixture at very low CO concentration (160 ppbv) [178], hydrogen in a Town gas mixture [179], and hydrogen in a refinery gas mixture [180].

Many separation experiments were carried out aiming to understand the permeation behavior. Studied were effects of operating conditions on the flux such as temperature, feed pressure, sweep gas flow rate, and orientation of the membrane [181, 182], pressure drop and sweep gas versus vacuum on the permeate side [183], influence of membrane microstructure [184], chemical nature of the sweep gas and orientation of the composite membrane [185–187].

Membrane Transport Theory. Transport in zeolite membrane is a rather complex process involving adsorption and diffusion. The presence of defects adds extra complexity to the problem. Significant amount of theoretical work has been carried out aiming to understand and perhaps eventually predict the permeation of molecules. Maxwell–Stefan formulation appears to be widely used either alone or together with other techniques [188–190]. Diffusion of methane, n-butane, n-hexane, isobutane, and 3-methylpentane was studied, and Maxwell–Stefan equations were used for the interpretation of the results [191]. Models based on Maxwell–Stefan formulation were also used to describe transport of supercritical fluids in zeolite materials [189].

A combination of adsorbed solution theory to describe the mixture sorption, and Maxwell–Stefan equations for diffusion have been used for modeling transport through zeolite membranes [192]. Similarly, a combination of configurational bias Monte Carlo simulations for pure component and mixture isotherms and Maxwell–Stefan theory for diffusion provided a nearly quantitative explanation of the experimental data on separation of n-hexane from 2,2-dimethylbutane (DMB) [193].

Other techniques included simple models based on surface diffusion, activated gaseous diffusion and viscous flow [194, 195], molecular simulation [196], dual control volume grand canonical molecular dynamics [197], and dual ensemble Monte Carlo simulation for pervaporation of a Lennard–Jones (LJ) fluid mixture [198, 199]. Models addressing nanoscopic defects were also developed [200].

5.1.2. Nonseparation Films

MFI films were formed by *in-situ* crystallization on a variety of substrates such as cordierite modules [201], activated carbon with suitable nucleation sites introduced by adding hydrophilic montmorillonite clay [202]. The change in morphology of ZSM-5 films during steaming at 443 K was studied [203]. Large differences were observed in morphology and an Si/Al ratio between outer and inner sides of the films on a nonporous substrate [204]. The effects of aging of source materials were studied for films on quartz surfaces [205]. A model for nucleation and growth of silicalite crystals was proposed [206]. Free-standing films were synthesized under elevated gravity (16 G) [207].

Seeded growth methods were also widely used for forming MFI films on polymer and glasses [208], carbon, ZrO_2, Al_2O_3, mullite, ceramic and pyrex glass fibers [209], gold [210, 211]. The out-of-plane grain orientation could be manipulated [212]. Micrometer-sized zeolite particles were found to form relatively stable particle monolayers at the air-water interface when spread from a chloroform dispersion. The transfer of the floating thin film onto a solid substrate via the Langmuir–Blodgett (LB) technique proved to be possible [213].

5.2. FAU (X, Y, Faujasite)

Zeolite X films were formed by seeded growth method on TiN-coated silicon wafers and porous stainless steel disks using laser ablation for seed layer deposition [214], and on porous alumina tubes showing permselectivity of CO_2 to N_2 of 20–100 [45]. Na-X membranes by *in-situ* crystallization contain adsorbed azobenzene (AZB) were shown to have photoswitchable permeation properties due to the trans-cis photoisomerization of AZB [215].

Zeolite Y membranes were synthesized by *in-situ* crystallization on the outer surface of a porous alumina tube and ion-exchanged with KCl, RbCl, or CsCl. The CO_2/N_2 selectivity for the equimolar mixture was in the order of Rb = K > Cs > Na [216]. In another study by the same group, zeolite Y membranes were ion-exchanged using Pt, Ru, Rh, Co, Ni, Cu, or Ag. The metal-loaded Y membranes were shown to have activity for CO oxidation with PtY membrane being the most active [217]. The effects of cations of alkaline and alkaline earth elements were studied and K-Y membranes gave the highest CO_2/N_2 selectivity [218].

Permeation through Y membranes was calculated by density function theory. The results successfully predict the experimental observation of selective permeation of gaseous molecules in the order $C_2H_6 < CH_4 < SF_6 < CO_2 < N_2$ [219]. The separation of carbon dioxide from the carbon dioxide and nitrogen mixture was calculated by molecular dynamics (MD) method [220]. Zeolite Y coatings on stainless steel were achieved. The bonding with the support and thus the coverage are improved by an oxide layer on the surface formed upon calcination at high temperature [221].

FAU membranes with an Si/Al ratio of 1.3–1.8 were prepared by seeded growth on porous alumina disks. The selectivity for N_2/CO_2 and CH_4/CO_2 were 8.4 and 3.5, respectively [222]. FAU membranes with Si/Al about 1–1.5 were synthesized on porous alumina by *in-situ* crystallization and seeded growth, and the mixtures examined (and

the corresponding equimolar mixture separation factors) were benzene/cyclohexane (160), benzene/n-hexane (144), toluene/n-heptane (45), propylene/propane (6.2), and ethylene/methane (8.4) [223]. Oriented FAU films were achieved on compositionally different, micrometer-sized EMT zeolite crystals [224, 225].

5.3. LTA (A)

The preparation of zeolite A films began with a report on free-standing film [226]. Thereafter, zeolite A membranes were commonly prepared by seeded growth method and used for pervaporation of water/organic mixtures [227–230]. It was shown that surface seeding could accelerate the formation of NaA on the support and inhibit the transformation of NaA into other zeolites. In addition good selectivities for H_2/n-C_4H_{10} and O_2/N_2 were achieved [231, 232]. Preferred orientation was demonstrated [233–236].

Zeolite A membranes have also been prepared by *in-situ* crystallization using a local heating method [145] intended for heat pump applications. Several other interesting applications have been demonstrated for A membranes including sensors [119, 237], and reverse osmosis [238]. A molecular simulation scheme was also developed for osmosis and reverse osmosis [239].

5.4. AFI (SAPO-5 and ALPO-5)

5.4.1. AFI (SAPO-5)

SAPO-5 films and membranes were prepared on a variety of substrates such as steel and Cu [240], Teflon slab [241], filter paper [242], and anodic alumina [243]. Separation of aromatics has been studied [244] and preferred orientation has been achieved [243].

5.4.2. AFI (ALPO-5)

There are many studies on $ALPO_4$-5 films and membranes. Some of these are pure, supported zeolite membranes and others are polymer-zeolite composite membranes [245, 246] and zeolite imbedded in nonporous metals [247]. For supported zeolite films and membranes, both *in-situ* crystallization [248] and seeded growth using laser ablation for seed deposition [46, 249] were used. Several applications were demonstrated including separation [245, 246], and sensors [250, 251]. There are also reports on oriented films on Au [251] and oriented membranes on anodized alumina substrate [252–254], oriented crystals embedded into a metallic grid and fixed by galvanic Ni deposition [255, 256].

$ALPO_4$-5 membrane reactors have also been studied and the membranes were evaluated as O_2 distributors in a passive membrane reactor for the partial oxidation of alkanes [257]. $ALPO_4$-5 films could also have applications in nonlinear optics [258]. A simplified lattice gas model was used to describe adsorbate passage inside $ALPO_4$-5 pores [259], and an atomistic model was developed for single gas permeation in $ALPO_4$-5 membranes [260].

5.5. ANA (Analcime)

Polycrystalline ANA films were prepared by *in-situ* crystallization. The films were about 200 μm thick and were deposited on a porous alumina support at temperatures above 160 °C. The films were thermally stable at temperatures up to 700 °C, and no structural changes were observed after treatment in nitric acid solution below 0.01 M. An ion-sieve capability was demonstrated [261], and treatment of radioactive waste using these films was suggested [262].

ANA films were also prepared by vapor phase transport method on porous alumina substrate. Dissolution of aluminum was suggested to be responsible for the formation of high aluminum zeolites like ANA. When the support was coated with silica, high-silica zeolites such as FER and MFI were formed [263].

5.6. BEA (Beta)

Zeolite BEA membranes were prepared by *in-situ* crystallization on porous stainless steel [264] and ceramic filter [265]. Separations of gases (H_2, N_2, n-, and i-butane) and liquids THF/H_2O, iPrOH/H_2O, tBuOH/H_2O, 1,3-propanediol/H_2O, glycerol/H_2O, and 1,3-propanediol/glycerol/H_2O [264], and PhOH/H_2O and C_6H_6/H_2O [265] were studied.

Zeolite BEA thin films were grown on a Ta-substrate using colloidal crystals as seeds [266]. Zeolite BEA coatings on structured packings were used for catalytic distillation to prepare octane booster t-BuOEt (ETBE) [267] and to improve the etherification of methanol and isobutene [268]. Zeolite BEA coatings were also prepared on polystyrene beads and then the polymer beads were removed to generate zeolite hollow spheres [269].

5.7. CHA (Chabazite and SAPO-34)

5.7.1. CHA (Chabazite)

Free-standing chabasite films were prepared on walls of polypropylene reaction bottles. Relatively large pieces can be readily peeled off from the walls of the polypropylene bottle [270]. Supported pure-phase chabasite membranes have not been reported. A mixed-phase zeolite membrane (mordenite/ZSM5/chabazite) was prepared on alumina tubular supports by *in-situ* crystallization. This membrane was used for study of permeation of single gases (N_2 and n-butane), ternary mixtures containing water, alcohol (methanol, ethanol, or propanol), and a permanent gas (O_2) [271, 272], and a binary mixture of n-butane/H_2 and n/i-butane [273]. Fuel cell membranes containing chabasite were also proposed and studied [274]. Heteroepitaxial growth of chabazite on sodalite was also achieved [275].

5.7.2. CHA (SAPO-34)

SAPO-34 membranes have been primarily prepared by *in-situ* crystallization [276] on alumina supports [277] and ceramic monolith [278]. Several separations were attempted and these included single gases and mixtures of H_2/CH_4, CO_2/CH_4, H_2/N_2, and CO_2/N_2 [277, 279]. The effects of humidity on these membranes were studied [280].

5.8. DON (UTD-1)

Highly oriented films of high-silica DON were prepared using the seeded growth method. The seed layer was deposited by pulsed laser ablation of as-synthesized DON

crystals onto polished Si wafers. Densely packed aggregates of elongated DON crystals grew from the ablated surface with the zeolite channels oriented perpendicular to the substrate [281]. This technique was later extended to small three-dimensional objects. Specifically, oriented DON zeolite films were prepared on the surface of glass and steel beads by first vibrating the spheres in a laser-generated plume [282].

5.9. ERI/OFF (T)

Zeolite T membranes were used for pervaporation-aided esterification of acetic acid with ethanol to prepare ethyl acetate. Almost complete conversion was reached within 8 h when initial molar ratios of alcohol to acetic acid were 1.5 and 2 [283, 284].

5.10. FER (Ferrierite)

FER membranes were prepared on porous alumina by vapor-phase transport method using ethylenediamine (EDA), triethylamine (TEA), and H_2O as vapor sources [285]. The formation mechanism was studied and pervaporation of bezene/xylene, and m-xylene/1,3,5-triisopropylbenzene mixtures was performed [286–288].

5.11. KFI (P)

Zeolite KFI membranes were synthesized by *in-situ* crystallization on porous alumina supports. Permselectivity as high as 102 was obtained for H_2/SF_6. At room temperature, the permselectivities for H_2/Ar and CH_4/Ar were 5.29 and 2.36, respectively. The apparent activation energies for permeation of H_2, CH_4, and Ar in 25–65 °C were estimated to be 11.1, 9.1, and 15.2 kJ/mol, respectively. In a dry atmosphere, the crystal structure gradually transformed from a cubic to a tetragonal phase at temperatures higher than 65 °C. The transformation did not result in drastic changes in gas permeance and permselectivity, indicating that KFI films were still continuous. KFI membranes were more stable in a humid atmosphere [289].

5.12. MOR (Mordenite)

in-situ crystallization was used to prepare MOR membranes on porous alumina and stainless steel [290] for separations of several mixtures such as water from water/He, water/HC, water/HC/He mixtures (HC for methane, propane, or n-butane) [291], and water/iso-propyl alcohol [292]. In another study, a mixed-phase zeolite membrane containing MOR/MFI/CHA was prepared on alumina tubes and used to separate ternary mixtures containing water, alcohol (methanol, ethanol, or propanol), and O_2 [271]. The membrane formation mechanism has been studied [293] and separation of aromatics (p-xylene, o-xylene, and benzene) was demonstrated [244]. Free-standing membranes were prepared [294].

The seeded growth method was used to prepare MOR membranes on porous alumina supports for pervaporation of a water/iso-propanol mixture [295]. The vapor phase transport method was demonstrated on porous alumina for separations of benzene over p-xylene [263]. Parallel diffusion models were proposed for permeation of H_2, He, CH_4, N_2, O_2, and CO_2 [296]. Preferred orientation was also achieved [297].

Pulsed laser deposition was used to deposit MOR films for gas sensor applications. These films were comprised of small crystallites embedded in an amorphous matrix. The amorphous material was microporous having pore sizes on the order of those in the parent zeolites. These pores were oriented perpendicular to the substrate. Quartz crystal microbalances coated with the material have been tested for gas uptake and were shown to discriminate between isomers of small molecules [107, 298].

MOR layers were grown on a metallic Cr surface by vapor phase transport for catalytic applications [299]. Honeycomb supports were coated with a mixture of zeolites ion-exchanged with rare earth elements and zeolites ion-exchanged with Cu or Co for improved catalytic NOx removal. The use of MOR was suggested [300]. Structured packings coated with BEA and MOR were used to prepare octane booster t-BuOEt (ETBE) in a liquid phase batch system [267].

Electrochemical applications of MOR films were demonstrated. For example, Cs-selective electrodes were prepared from MOR crystals embedded in an epoxy resin [301]. MOR composite films were also suggested as proton conductors for proton exchange membrane (PEM) fuel cell applications [302, 303].

5.13. MTW (ZSM-12)

High-silica MTW coatings were synthesized by *in-situ* crystallization using a new two-silica method [142] on Al-alloys (Al-2024-T3 and Al-6061-T4) and stainless steel (SS-304). All coatings were continuous and had excellent adhesion. The as-synthesized zeolite coatings were tested by a dc polarization technique and found to be highly corrosion-resistant in severely corrosive acidic (0.5 M H_2SO_4) and alkaline (0.1 M NaOH) media [141].

5.14. MWW (MCM-22)

MWW films were grown on glass substrates by *in-situ* crystallization [304, 305]. The thin disk-like MWW crystals were found to be perpendicular to the substrate surface in the early stage of crystallization and then grew thicker to form a continuous film. It was suggested that the fast growth rate in the layer direction was responsible for the observed orientation.

MWW films were prepared on TiN-coated silicon wafers, polished graphite, and porous stainless steel frits by seeded growth. The seed layer was introduced by pulsed laser ablation of as-synthesized layered MWW. The films were partially oriented with a-direction largely normal to the substrate surface. The oriented MWW membrane grown on porous stainless steel was evaluated for room temperature separation of an alcohol/water mixture and a selective permeation of water was observed [306].

5.15. ETS-4

Since Engelhard titanium silicates have octahedral coordination in addition to tetrahedral coordination, they are officially non zeolite-type materials. Nonetheless, ETS films could have interesting membrane and film properties, and therefore are included in this review. A combination of *in-situ* crystallization and a seeded growth method was used to prepare ETS-4 supported films and membranes. It involved formation of a seed layer on a support by *in-situ* crystallization followed by seeded growth. The synthesized films and membranes exhibited b-out-of-plane preferred orientation that corresponded to the eight-member ring channels of ETS-4 oriented perpendicular to the substrate. Membranes consisting of thin intergrown films of Na-ETS-4 on porous TiO_2 supports were highly H_2O permselective for 1:1 H_2O/ethanol mixtures. The selectivity of the ETS-4 membranes was similar to the highest reported for Na-X and Na-Y membranes, and approximately 10 times lower than the selectivities of zeolite Na-A prepared in the same lab and up to 100 times lower than the highest selectivities reported in the literature for zeolite Na-A membranes. The flux of H_2O through Na-ETS-4 membranes was comparable or higher than that through zeolite A, X, and Y membranes [307].

6. RECENT DEVELOPMENTS

6.1. Oriented Zeolite Films

Almost all applications for zeolite films could benefit from a preferred orientation. This is especially critical for zeolites with anisotropic pore systems. Noncontinuous zeolite layers with preferred orientation have been prepared [34, 57, 254, 308, 309], but this section focuses on continuous oriented polycrystalline films. Examples include b-oriented MFI by *in-situ* crystallization on MFI [41, 44], c-oriented MFI [28] and LTA [233] by seeded growth [310], and MFI [70] and MOR [295] by vapor phase transport.

One particularly interesting b-oriented MFI film is shown in Figure 7. It is a continuous monolayer film (0.4–0.5 μm thick) by *in-situ* crystallization on metal substrates (stainless steel and Al alloy) [41, 44] or on silicon wafer [138]. Since MFI has straight channels in the b-direction, this film is well suited for membrane application. It has been found that there is positive thermal expansion in a- and c-direction and negative expansion in b-direction, thus a b-oriented MFI film helps to relieve thermal stress. The thinness of the film is also important for relieving thermal stress. Also because this is a monolayer film, it does not have any grain boundaries in the direction perpendicular to the substrate, leading to minimized resistance for mass transport. This film could also be useful for sensor, magnetic, optical, thermoelectric applications as the template for nanowire arrays.

6.2. Zeolite Nanocrystals as Building Blocks

Zeolite nanocrystals have been demonstrated to be versatile building blocks for constructing hierarchical porous structures [311–317]. The use of nanoparticles as building blocks allows mild processing conditions and innovative strategies to be used that would have been difficult or impossible otherwise with the conventional hydrothermal

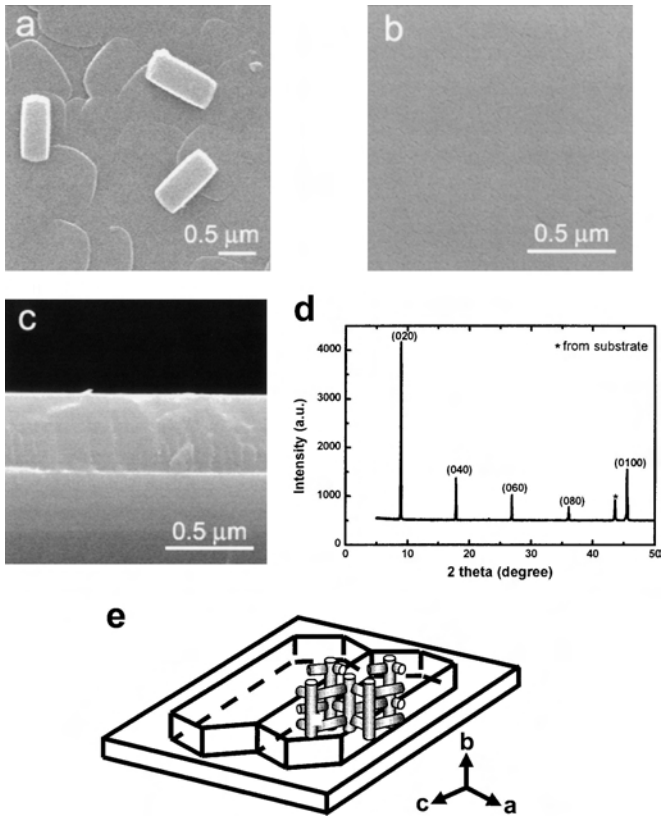

Figure 7. (a, b, c) SEM micrographs of silicalite films on silicon wafer by *in-situ* crystallization, (a) before polishing, top view, (b) after polishing, top view, (c) after polishing, cross-sectional view; (d) XRD pattern of the silicalite film showing that all the straight channels are vertical to the silicon substrate; (e) a schematic showing the orientation of the crystals versus the substrate (after [41, 44, 138]).

synthesis methods such as *in-situ* crystallization, seeded growth, and vapor phase transport. The fabrication of three-dimensional structures with designed shapes via gel-casting [315] and transparent zeolite films [312] (Fig. 8) are examples that clearly illustrate the utilities and versatility of this approach.

Specifically for the preparation of zeolite films, zeolite nanoparticles could be used directly to form zeolite films by self-assembly [311]. They could also be combined nicely

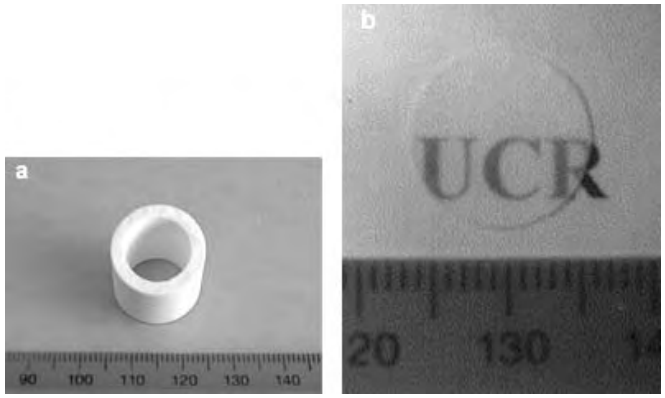

Figure 8. Zeolite structures constructed by using zeolite nanocrystals as building blocks (after [312, 315]).

with seeded growth and the vapor phase transport method to produce high-quality polycrystalline zeolite films [28, 163]. There is clear evidence that small zeolite nanoparticles are preferred for producing compact continuous films.

Another important application for zeolite nanaoparticles is the preparation of zeolite matrix composite films. Micrometer-sized crystals have been used in these types of film using techniques such as wash-coating and sol–gel processing. However, the use of nanoparticles in these films appears to offer unparalleled advantages in terms of achievable film thickness and uniformity and processability. The low-k dielectric films [30, 139] and polymer-zeolite nanocomposite membranes [33, 318] are two examples. The efforts for polymer-zeolite nanocomposite films were primarily driven by gas separation applications. Zeolite membranes have high selectivity and high thermal and chemical stability. But it is difficult to develop a high density module such as hollow fibers that are commonly used by polymer membranes. On the other hand, polymer membranes can be easily processed but have relatively low selectivity. Therefore, it has been an outstanding goal to combine the excellent properties of these two materials.

Another interesting application is microreactors. Zeolite adsorbents and catalysts have been an important part for the conventional reaction-separation system. As the efforts to miniaturize reactors evolve, using zeolite nanocrystals as building blocks could be an ideal way to introduce zeolites into these microreactor systems.

6.3. Patterned Zeolite Films

The ability to pattern zeolite films is critical for many of their potential applications, especially optical, magnetic, and electronic applications that have not been adequately explored. The first patterned zeolite film was achieved by using zeolite nanocrystals as building blocks combined with soft lithography [311] (Fig. 9). Convection-assisted assembly was also demonstrated for a generation of surface-patterned zeolite films although the patterns were not very regular [31] (Figure 9). Recently, using organic linkers, Yoon et al. have demonstrated that microcrystals can also be patterned and oriented. Although these films have very sophisticated patterns, they are not continuous and adhesion is not very strong. There is a critical need to fabricate oriented continuous films on a variety of substrates.

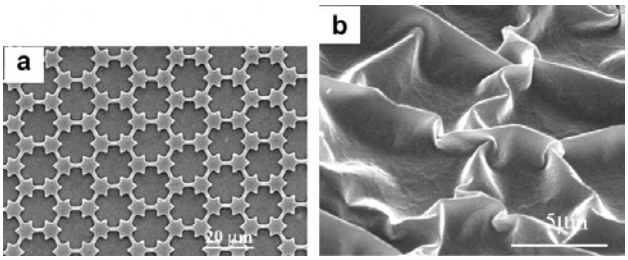

Figure 9. Patterned zeolite films by using (a) soft-lithography and (b) convection-assisted assembly of zeolite nanoparticles (after [31, 311]).

7. CONCLUDING REMARKS

The field of nanostructured zeolite films has come a long way during the last decade from almost nonexistence in the early 1990's to a vibrant field today with many applications demonstrated to be promising, and one commercial application already realized. Although scattered activities can be traced back to the 1960's, the key to this success has been the persistent work of a large number of researchers around the world during the last 10 years. The single biggest driver behind this collective effort so far appears to be the potential application of zeolite films as membranes and membrane reactors. But nonconventional applications (i.e., nonseparation and noncatalysis) have been quickly added and these new applications promise to offer even more exciting opportunities. Table 1 shows some of the properties of nanostructured zeolite films. As shown in this review, zeolite based-nanostructured films could take on several different configurations and be prepared by a number of synthesis methods. Current strategies for oriented films are highly specific for a particular zeolite or a particular orientation. More general methods for preparing oriented films are still critically needed. The use of nanoparticles as building blocks has broadened our capability significantly and will continue to bring exciting opportunities to the field. Although not covered in this review, additional new applications such as optical, magnetic and electric devices are being and will continue to be explored. For these device applications, the ability of patterning by simple techniques will be crucial.

Table 1. Physical properties of nanostructured zeolite films.

Nanostructured zeolite films	Dielectric constant	Elastic modulus (GPa)	Corrosion current (A/cm^2)	Contact angle (Degree)	Micropore size (nm)	Mesopore size (nm)	Ref.
MFI (silicalite) by *in-situ* crystallization	2.7	30–40	10^{-8}	—	0.55	N/A	[138]
MFI (silicalite) from nanocrystals	1.8	—	—	—	0.55	17	[138, 311]
MFI (silicalite) from nanoparticles	2.1	16–18	—	—	0.55	2.6–2.8	[30, 31]
MFI (ZSM-5) by *in-situ* crystallization	—	—	10^{-8}–10^{-12}	0–15 advancing 0 receding	—	N/A	[42]
BEA (pure-silica) by *in-situ* crystallization	—	—	10^{-8}	—	—	N/A	[141]

GLOSSARY

Calcination A process where a sample is heated in an oxidizing environment.

Chemical mechanical polishing (CMP) A semiconductor processing step that is used to level the interconnect layers.

Chemical vapor deposition (CVD) A commonly used semiconductor process for deposition of thin films.

Low dielectric constant material (Low-k material) Dielectric material is used in computer chips to insulate the wirings among the transistors.

Pressure swing adsorption (PSA) This is a process that separates gases by selective adsorption of a component in a mixture to an adsorbent such as zeolites.

Structure directing agent (SDA) These are organic molecules that are used to direct the synthesis to a desired structure.

Tetrahedrally coordinated atom (T-atom) In zeolites T-atoms refer to atoms such silicon and aluminum that are coordinated by four oxygen atoms in the crystal structure.

Tetraethylorthosilicate (TEOS) This is a commonly used silica source for zeolite synthesis.

Thermoelectric Thermoelectric materials can provide solid state refrigeration using electricity or generate electricity from a temperature difference.

Zeolite A class of porous crystals with uniform molecular-sized pores. Zeolites can be found in nature and can also be synthesized in laboratory.

ACKNOWLEDGMENTS

The authors wish to thank their sponsors for providing financial support and their colleagues in the Yan Group at UC-Riverside for contributing to their work which is included in this article.

The sponsors are as follows: AlliedSignal/Honeywell International, Advanced Micro Devices, Asahi Kasei Corporation, Pacific Fuel Cells Corporation, The Technology for Sustainable Environment (TSE) program of the U.S. Environmental Protection Agency, The Strategic Environmental Research and Development Program (SERDP) of the U.S. Department of Defense, University of California—Semiconductor Manufacturing Alliance Research and Teaching (UC-SMART), University of California—Toxic Substance Research & Teaching Program (UC-TSR&TP), University of California—Energy Institute (UC-EI), California Energy Commission, and Riverside Public Utilities.

The authors' colleagues include: Dr. Z. Wang, Dr. X. Cheng, Dr. A. Mitra, Dr. L. Huang, Dr. S. Li, Dr. C. Wang, Dr. H. Luo, T. Cao, D. Beving, B. Holmberg, Z. Li, A. Avila, J. Zhao, M. Waje, and C. Demmelmaier.

CONTENTS

1. INTRODUCTION

Tiny edifices with a size of around 1–10 nm (1 nm $= 10^{-9}$ m) are called nanocrystals or nanoclusters. These structures are aggregates of atoms or molecules containing from a few atoms to a few thousands atoms. The novelty of these systems relates to the fact that they have an atomic arrangement and material properties drastically different from the same material in bulk. Nanoscience aims at the study of electronic, material, optical, and structural properties of tiny clusters and their composites. The goal of nanotechnology is the production of new and different things—smaller and with new properties. It is emerging as the next technological revolution, promising great advances in many fields, from information technology and medicine to artificial intelligence and environmental restoration.

Richard Feynman in his prophetic lecture "Plenty of Room at the Bottom" in 1959 expressed a strong belief that someday we would be able to manipulate matter on the atomic scale: "The principles of physics, as far as I can see, do not speak against the possibility of maneuvering things atom by atom. It is not an attempt to violate any laws; it is something, in principle, that can be done ...." Thus, the core idea and the ultimate goal of nanotechnology is a realization of "the possibility of manoeuvring things atom by atom": constructing a new nanomaterial by placing atom by atom at the proper construction site at a proper time. We are still far from realization of this idea in practice; however, many important steps in this direction have been made.

The major problem in nanotechnology lies in the development of efficient methods for the formation of nanoclusters with predictable and controlled size and properties that can then be scaled to industrial production. The primary goal in any method for nanocluster formation is to decompose the initial material into a preferably atomic state via evaporation or ablation and form a beam (or cloud) of hot atoms. The interaction of this beam with the flow of another gas (a noble gas or a reactive one) in a proper temperature-controlled environment creates the temperature and density conditions for the formation of a new structure. The hot atoms from the beam collide with the ambient gas atoms, cool down, and attach to each other, binding and forming a new structure in a self-assembly mode. The newly created material should then be annealed appropriately in order to transform it into a phase state which is stable at room temperature and atmospheric pressure.

The formation of different structures in a self-assembly fashion occurs in a variety of natural systems. In the methods for nanocluster formation, self-assembly is achieved by the proper choice of reacting materials so that they naturally bond with each other in the desired configuration. In theory, one can prepare an atomic mixture in an experimental chamber under carefully controlled conditions and allow the components to assemble themselves. This is the so-called bottom-up approach, or atom-to-atom attachment. In reality the processes of atomic beam formation, cluster creation, and annealing are fast and transient. These processes are very difficult to control and register *in-situ* even with modern diagnostic methods.

A variety of methods have already been proposed and employed for the production of nanoclusters in the past 2

decades, including the use of supersonic nozzle sources, ion beam implantation, methods of colloid chemistry, chemical vapor deposition (CVD), arc discharge, ion sputtering, laser ablation, and others [1–3]. Methods for the creation of supersonic molecular and atomic beams have allowed one the production of clusters in the gas phase from different materials, including the most refractory and complex systems (fullerenes, carbon and boron nitride nanotubes, metallic and covalent clusters, complex clusters). Nanofilms of different materials and thin layers of matrix-embedded cluster composites have also been successfully deposited and characterized [1–3].

In fact, all methods for nanocluster formation stem from the original experiment for the preparation of so-called "blacks," the historical predecessor of nanocrystal networks, conceived and implemented by the American physicist Pfund in 1930 [4, 5]. He evaporated bismuth in an imperfect vacuum. The low-density gas fill acts as a confinement and a heat sink for evaporated the atoms. The hot atoms from the evaporation source cool down through collisions with the gas fill and then form tiny droplets when the supersaturated state is achieved. The process comprises three stages: nucleation, growth, and cluster network formation on a substrate [5]. The differences between all of the modern methods for nanocluster formation relate mainly to how the atomic beam is prepared. In this chapter we describe the laser ablation method for the formation and control of an atomic plume which is then used for the formation of various nanostructures under different experimental conditions.

The laser ablation process has a number of remarkable features. First, laser ablation has the highest instantaneous ablation and deposition rate among all known deposition methods, such as electron-beam deposition, magnetron sputtering, and chemical vapor deposition. Second, a laser beam is a "clean" tool: it provides direct energy transfer into the ablated material, and thus there is no source of contamination in the process. Consequently, the laser deposition process maintains the same stoichiometry in the deposited film or in a nanocluster as that in the ablated target. Third, the laser ablation process can operate over a wide range of gas pressures. Finally, it is possible to manipulate the atomic beam created by a short laser pulse at a time scale of picoseconds and a space scale of micrometers.

During the past decade, a number of complicated structures have been successfully produced by laser ablation and deposition. Examples include high-temperature superconducting films [6], various types of nitrides [7–9], complex multicomponent oxides [10, 11], nanocrystalline quantum dots [12], ferroelectric thin films [13], planar lasers, and nonlinear waveguides [14, 15]. Throughout these studies lasers of various wavelengths (from 193 nm to 10.6 μm), pulse durations (from tens of picoseconds to hundreds of nanoseconds), and intensities have been used.

Laser vaporization has been used for the production of nanocluster production since the early seventies, when commercial lasers became available [1, 2, 6]. Metal clusters [16–18], fullerenes [19], carbon and boron nitride nanotubes [20–22], silicon clusters, and many other structures have been produced with laser ablation. In all these studies, commercially available lasers were used as a heating source rather than exploring all the opportunities that a laser offers for controlling beam composition and properties. Extensive studies of laser–matter interaction, including ablation and the properties of a laser-created plume, were performed within laser fusion projects in major laser laboratories around the world starting in the early sixties [23–26]. Recently it has been understood that many results obtained in laser fusion programs can be usefully employed in laser-assisted methods for nanocluster formation in materials science research.

Laser-assisted nanostructure formation is conventionally performed in a special chamber in which an intense laser beam is focused onto a target from which the desired nanostructure should be formed. Initially, commercial Nd:YAG (neodymium doped yttrium–aluminium garnet) lasers and excimer lasers with pulse durations of 10–30 ns, repetition rates of 10–30 Hz, and average intensities per pulse of $2–4 \times 10^9$ W/cm^2 have been employed for target evaporation [16–18]. Laser evaporation generates a plume with a rather high ion temperature of a few electron volts during the pulse time. However, due to the large time gap between successive pulses, the laser plume cools down below the temperature which is necessary for cluster formation. Therefore, additional heating of the ambient gas was necessary in order to maintain the proper conditions for cluster formation. The target was placed into a furnace with a controlled temperature and with a continuous noble gas flow. With a long (nanoseconds)-pulse, low repetition rate (several Hertz) laser, it is possible to produce a pulsed flow of evaporated vapors with low time-averaged flux intensity.

The use of dual-pulsed Nd:YAG laser vaporization has proved to increase the efficiency of carbon nanotube formation [27]. Furthermore, the use of continuous-wave CO_2 lasers at an intensity level $\sim 10^5$ W/cm^2 [28] or an almost continuous 20-ms pulse [29, 30] for evaporation of carbon targets made it possible to obtain a continuous supply of hot carbon atoms into an argon-filled experimental chamber. The collision of hot carbon atoms with cold argon atoms maintains a temperature sufficient for carbon nanotube formation without additional heating in a furnace.

The next step in improving the average vapor beam intensity and control over the density and temperature of the laser-ablated vapor relates to the use of short (a few femtoseconds), intense (average intensity per pulse, $\sim 10^{13}$–10^{14} W/cm^2), low-energy (μJ) pulses delivered at high repetition rates (100 kHz–100 MHz) [31–33]. The high average intensity per pulse allows a significant number of particles, $\sim 10^{11}$ atoms per 100-fs pulse, to be removed during the short pulse time, while the high repetition rate maintains the average atomic beam intensity at a sufficiently high level of 10^{19} atoms/s.

Self-consistent choice of the optimum combination of laser parameters (pulse duration, energy, wavelength, and intensity distribution during the pulse time and in space over the focal spot) along with the target parameters allows one to produce an atomized flow of ablated vapors from any material. The temperature, density, atomic content, and degree of ionization in a cloud of vapors depend on the above combination and therefore can also be controlled.

Ablation with high repetition rate lasers also increases the average temperature of the ablated atomic beam up to

20 times compared with conventional long-pulse low repetition rate lasers. Thus additional heating during cluster formation can be eliminated and the experimental setup is simplified. The laser beam is continuously scanned over the target surface in order to prevent crater formation and to maintain a constant ablation rate for successive pulses. Fast scanning across a complex target makes possible the coevaporation of different materials. As a result, combinatorial material synthesis in the plume can be implemented. Vapor composition can be varied continuously by adjusting the dwell time on different parts of a composite target.

The laser-ablated atomic beam can be used for the formation of new structures in two fundamentally different experimental situations. In the first operation mode, the ablated plume is used for the deposition of thin films on different substrates in an evacuated chamber. The substrate to be coated is placed in the path of the laser-produced plume; the vapor adheres to the surface to form a nanofilm. In the second operation mode the ablated atomic flow interacts with a different gas fill in a chamber at different pressures, creating nanoclusters and nanocluster networks. The characteristics of the ablated plume are sensitive to a combination of laser and target parameters. Therefore, this combination should be different for the two operation modes mentioned above.

Let us consider thin film deposition by laser ablation. The main drawback to widespread industrial application of lasers for deposition of homogeneous thin films has been the formation of droplets (0.1–1 μm) in the laser plume, which spoil the surface finish of the deposited film. Many applications require the density of micrometer-sized particles to be less than one particle per cm^2 on the surface of the deposited film. The origin of these particles (droplets) relates to inhomogeneities in the target, spatial and time distribution and fluctuations of laser intensity, and the level of absorbed laser energy. While there have been attempts to prevent particles from the target from reaching the substrate using some form of mechanical filtering, there does not appear to have been any satisfactory or universal solution to the problem.

A solution to this problem has been found through deeper insight into the physics of the laser ablation process. It was proposed to use for ablation picosecond or femtosecond laser pulses delivered on a target with a repetition rate of several tens of megaHertz [31, 32]. The method was coined "ultrafast laser ablation" due to the combination of short laser pulses with a very high repetition rate. A single short low-energy pulse evaporates very few hot atoms per pulse, thereby inhibiting the condensation of droplets during fast nonequilibrium expansion. To compensate for the reduced ablated mass per pulse, high pulse repetition rates are then used to achieve a high averaged deposition rate. The application of the ultrafast laser ablation (UFLA) method for deposition of thin films has resulted in atomic surface quality films of diamondlike carbon [31, 32], with the total elimination of macroscopic particles from the film surface. Recently As_2S_3 chalcogenide optical films [34] have been produced with similar surface quality and high-volume homogeneity.

Complex nanoclustered networks of carbons were formed by evaporating a glassy carbon target in an argon-filled chamber. It was discovered that with the appropriate adjustment of the parameters of ablated flow and pressure of the ambient gas, the formation of new structures of a known material with unexpected properties results. For example, a new form of carbon, a cluster-assembled paramagnetic carbon nanofoam, was produced at an argon pressure above 0.1 Torr [37]. Conversely, at an argon pressure of 300–500 Torr, carbon nanotubes can be formed [28–30].

Recent developments clearly showed that a better understanding of basic physics and chemistry at all stages of the nanocluster formation process allowed the implementation of new methods for the prediction and control of this process. Using laser ablation, an atomized flow of any material with a controlled and predictable ablation rate, density, and temperature can be produced. The minimum number of particles ablated by a short-pulse (100 fs) laser is now reduced to $\sim 10^{11}$ atoms. This is comparable to the number of atoms in a cubic micrometer of a conventional solid. This is an important step toward the ultimate atom-to-atom attachment mode of nanocluster formation.

The research field of nanoscience and nanotechnology is a multidisciplinary one, in which the different areas of physics and chemistry overlap. In this review, we try to present a unified view of nanocluster formation by lasers, combining experimental results, theory, and simple models. The references were carefully selected to be guides in a vast sea of published papers, with emphasis on the most important topics and achievements. Therefore, the reference list is by no means exhaustive and reflects the views of the authors.

The review is organized as follows. First, we describe the lasers available for the ablation of different materials, the types of experimental installations for nanocluster production, and *in-situ* and *ex situ* diagnostic methods for observing cluster formation conditions and their structural and electronic properties (Section 2). Then we give a brief account of laser–matter interaction physics, with emphasis on the simple scaling that allows the prediction and interpretation of the experimentally observed ablation rate and plume parameters (Section 3). The processes of thin amorphous film formation and composite formation on a substrate are considered in Section 4. Laser plume–ambient gas interaction, the conditions for the formation of different nanostructures, and mechanisms for cluster formation are the topics of Section 5. In Section 6, the formation of cluster-assembled films and cluster networks is considered. Finally, we discuss the perspectives of laser ablation for the controlled production of nanostructures and the possibilities for scaling this method for industrial applications.

2. CLUSTER FORMATION BY LASER ABLATION: EXPERIMENTAL INSTALLATIONS AND DIAGNOSTIC METHODS

In this section, we describe the experimental installations for the formation of different nanoclusters in which a laser is used for ablation of a target to produce a flow of hot atoms. The general principles for the design of these installations are the same. The laser hits a target, ablates it, and produces a hot atomic flow in an expanding plume. This flow then interacts with atoms of noble gas in the chamber where the nanoclusters are formed. Depending on the laser parameters and on the kind of nanocluster to be formed, additional

components, such as a furnace, diagnostic tools, etc., complement the major parts of the installation.

First, we briefly describe the lasers available for material ablation and nanocluster formation. Then we present the typical experimental installations used for different nanocluster formation. Finally, the experimental techniques for the *in-situ* diagnostics of cluster formation conditions and for the *ex-situ* characterization of the final product are described.

2.1. Lasers

For ablation of materials, a variety of lasers is now available, with wavelengths ranging from 0.15 to 10 μm and with pulse durations spanning from several tens of femtoseconds up to continuous wave mode operation (cw lasers). The pulse repetition rate ranges from several Hertz to 100 MHz. With these lasers, the evaporation and atomization of any material is possible. Commercially available solid state Nd:YAG (fundamental wavelength, $1\omega = 1064$ nm; second harmonic, $2\omega = 532$ nm), Ti:sapphire lasers ($1\omega = 800$ nm; $2\omega = 400$ nm), along with XeF (353 nm), XeCl (308 nm), KrF (248 nm), ArF (193 nm), and F_2 (153 nm) excimer gas lasers with pulse durations of 10–30 ns, energy per pulse 0.5–0.3 J, and repetition rates of 10–30 Hz, are conventionally used in many experimental installations [15, 18, 26]. Recently subpicosecond lasers (pulse duration, 50 fs to tens of picoseconds) with high repetition rates of 10 kHz–100 MHz have been demonstrated to be very efficient for target ablation and nanocluster production [31–33].

The "state of the art" powerful Nd:YVO laser, newly developed at the Australian National University, can operate over a wide range of wavelengths, intensities, and repetition rates in the megaHertz range. This laser provides a flexible tool for producing an ablated flow of hot atoms of any material with a controlled temperature and ablation rate. It can be used for high repetition rate laser ablation and for the formation and deposition of different nanostructures. The laser generates 12-ps pulses with variable repetition rates of 1.5, 2.6, 4.1, and 75 MHz in the first (1.064 μm) and second (532 nm) harmonics at an average power of 50 W [38]. Further updating to generate in the third (355 nm) and forth (266 nm) harmonics is in progress. A variable repetition rate was achieved by extension of the laser cavity using a multipass cell to increase the cavity length up to 100 m. The time gap between consecutive pulses is from 15 to 750 ns. The laser produces a continuous flow of hot atoms with an ablation rate of $\sim 10^{20}$ atoms/s. This means that the mixture of the ablation plume and the ambient gas (usually argon) cools down slowly between the pulses, and the temperature of the mixture oscillates around the equilibrium level during the formation process [39].

Therefore, the temperature and atomic density in the nanocluster formation zone are controlled entirely by the tunable laser parameters: pulse duration, energy per pulse, and repetition rate. The principal scheme of this laser is presented in Figure 1.

Several important parameters, such as pulse duration, wavelength, pulse repetition rate, and laser fluence (J/cm^2) and intensity (W/cm^2), should be defined in order to choose

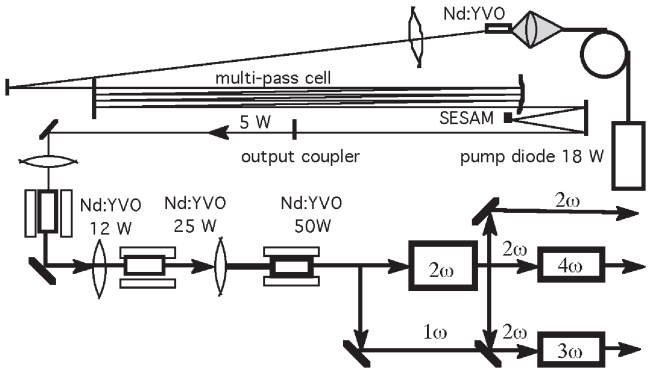

Figure 1. Principal scheme of a new powerful Nd:YVO laser installation at the Australian National University. The laser generates 12-ps pulses with variable repetition rates of 1.5, 2.6, and 4.1 MHz in the first (1.064 μm), second (532 nm), third (355 nm), and forth (266 nm) harmonics. It can be used for high repetition rate laser ablation and deposition of any material for the formation of different nanostructures under conditions controlled by flexible laser parameters.

an optimum laser for the ablation of a particular target and for cluster formation. First, the absorbed energy density delivered to the target should exceed the ablation threshold, which is in the range of 1–2 J/cm^2 for the majority of materials, and it can be defined for any material, as explained below in Section 3 [31]. The laser intensity and wavelength should be chosen appropriately to ensure efficient absorption of the laser radiation. Second, the molecular content and ionization state of the plume depend on the laser intensity distribution in time during the laser pulse and in space across the focal spot on the target surface.

2.2. Experimental Installations

2.2.1. Installation for the Production of Carbon Nanotubes

The use of laser ablation for nanocluster production was proposed by R. Smalley in 1983 [18]. The first installation used a commercial solid state low repetition rate laser with a noble gas flow through a tube placed in a furnace ($\sim$1200 K) where single-walled carbon nanotubes were produced. Later Smalley and co-workers [27] proposed the use of two lasers for enhancing the mass production of carbon nanotubes. Their current installation [40] uses two Nd:YAG lasers for ablation of a graphite target containing the catalysts cobalt and nickel (1 at.% each). The target is maintained at 1473 K in a tube furnace in an argon atmosphere (100-sccm flow, 66.7-kPa pressure, 500 Torr). The lasers produce 8-ns, 300-mJ pulses, with a repetition rate of 10 Hz. The first laser operates at the fundamental wavelength of 1064 nm, while the second laser operates at the second harmonic of 532 nm and hits the target 50 ns after the first laser shot. The laser beams are adjusted to travel colinearly such that they overlap on the target. The weblike deposit contains the nanoclusters that were produced in the laser plume and in argon gas. The deposit is collected either on the brass water-cooled collector that is positioned at the end of a quartz tube just outside the furnace or on the

quartz tube walls. The scheme of the installation is shown in Figure 2.

2.2.2. Experimental Setup for Formation of Metal and Covalent Clusters

The second typical installation is the so-called "laser vaporization cluster source" [1–3] that is used for production of metal and covalent clusters. In these devices, the clusters are also produced by the interaction of an ablated plume with the flow of a noble gas in the interaction chamber. The cluster flow is then released through a nozzle into a channel where mass (size) selection of clusters is performed. The flow of size-selected clusters is then deposited on a substrate. The scheme of a typical laser vaporization cluster source is shown in Figure 3.

2.2.3. Experimental Setup with High Repetition Rate Short-Pulse or Continuous-Wave Lasers: Formation of Cluster-Assembled Foams and Carbon and BN Nanotubes

The third type of installation is based upon commercially available powerful short-pulse high repetition rate lasers (see Fig. 4) [32, 33]. Short time intervals of 10–100 ns between the laser pulses lead to the overlapping of plumes produced by consecutive pulses. Proper tuning of both the laser intensity on the target surface and the pulse repetition rate allows one to control the temperature of the laser plume and noble gas mixture in the nanocluster formation zone, and a furnace for temperature control is not required. In installations described below, the laser parameters and scanning speed of the laser beam over the target surface are chosen to optimize the ablation rate, the temperature, and the molecular and ion states in the ablated plume.

Two high average power, high repetition rate Nd:YAG lasers ($\lambda = 1.064\ \mu$m) were used for laser ablation of a carbon target and for deposition experiments [32]. One laser

produced 42 W in 120-ns-long pulses with a variable repetition rate in the range of 2–25 kHz. This laser created an average intensity of $\sim 2 \times 10^9$ W/cm^2 at the focal spot $S_{foc} = 1.6 \times 10^{-5}$ cm^2 on the target, or an energy density

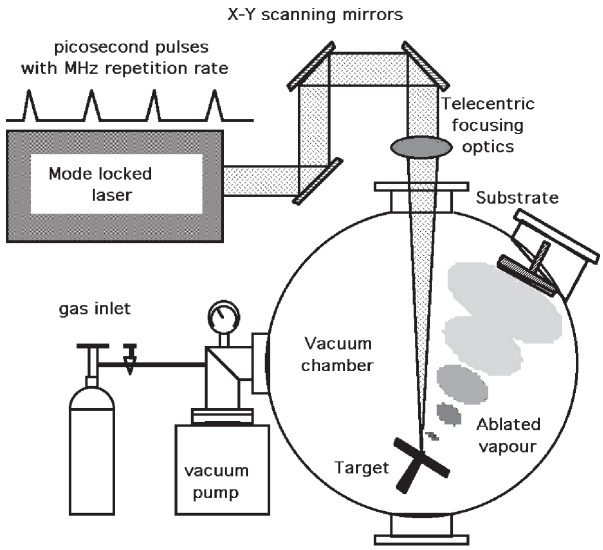

Figure 4. Schematic of the installation used for the formation of nanoclusters (carbon and boron nitride nanotubes) and nanoclustered materials (magnetic carbon nanofoam) in Ar at constant pressure with the use of high repetition rate short-pulse lasers. This installation is equipped with a powerful new laser [38] which allows the choice of all laser parameters: intensity, repetition rate, wavelength, etc., in order to obtain optimal conditions for the formation of the desired nanocluster.

in excess of 100 J/cm^2. The second one was a 25-W 60-ps mode-locked laser with a repetition rate of 76 MHz. Note that the period between the consequent pulses in this laser comprises only 13.2 ns. An intensity of $\sim 3 \times 10^9$ W/cm^2 was produced at the focal spot $S_{foc} = 1.8 \times 10^{-6}$ cm^2 with this laser [32].

2.3. *In-Situ* Characterization of Cluster Formation Conditions

2.3.1. Ablation Rate: The Feedstock for Cluster Formation

The rate of supply of hot atoms in the cluster formation zone depends on the laser ablation rate. This rate is conventionally measured by the target mass loss averaged over many laser pulses. This measurement provides an immediate check on how close the laser parameters are to those required for optimum evaporation. Indeed, the mass evaporated per single pulse can be estimated as the absorbed laser energy divided by the energy of evaporation per unit mass for a particular material. For example, if all the absorbed laser energy could be spent in evaporation, that is, spent only on breaking bonds, then 0.5 J of laser energy absorbed in a carbon target with the energy of vaporization at 30.4 kJ/g would result in ablation of 1.64×10^{-5} g of the target mass. However, the absorbed energy also goes into heat and shock waves in the target and in the kinetic and thermal energy of the ablated species.

Given optimum laser parameters, the ablation rate was found and measured in experiments with an Nd:YAG laser ($\lambda = 1.064$ μm; pulse duration, $t_p = 120$ ns; energy per pulse, $\sim$3 mJ at 10 kHz) [32]. The evaporation rate by Rode et al. [32] was deduced from the volume V_{evap} of the evaporated conelike crater on the target surface, measured with both an optical microscope and a scanning electron microscope for a given number of pulses. For a single laser pulse the measured rate comprises 5.6×10^{14} particles/pulse (or 0.01 μg/pulse). Note that the measured differential rate $R_{evap} = (1.4 \pm 0.2) \times 10^{26}$ atoms/(cm^2/s) qualitatively complies with the theoretical estimate of 10^{27} atoms/(cm^2/s) [31]. One can easily note the importance of the high repetition rate laser. For the 10-kHz repetition rate by Rode et al. [32], the ablation rate comprises 10^{-4} g/s. In this case, the carbon feedstock into the nanocluster formation zone amounts to 5.6×10^{18} particles/s.

A similar evaporation rate per pulse was observed in experiments where an XeCl excimer laser ($\lambda = 308$ nm; repetition rate, 10 Hz; $t_p = 17$ ns) was used for the ablation of graphite [41]. The ablation rate decreased after 100 laser pulses per single spot on the target surface.

A C–Ni–Co target was ablated by a single CO_2 laser pulse (20 ms; average intensity, 1.3×10^5 W/cm^2) in an argon atmosphere with the goal of carbon nanotube production [29]. The ablation rate was measured by the target weight loss of 0.1 mg after 10 laser shots, thus amounting to 10^{-5} g/pulse.

The influence of the scanning speed of a laser beam over the target surface on the evaporation rate also has to be considered. If the laser focal spot is kept at the same position on the target for several consecutive pulses, a crater is produced in the target, and its depth increases with each successive pulse. At very high repetition rates, this leads to an increase in the density of the vapor in the crater. As a result, the laser light is likely to be absorbed in the vapor away from the solid target surface and consequently, the interaction regime changes to a less favorable one in terms of evaporation efficiency [42]. When the crater depth becomes comparable with the diameter of the focal spot, the ablation rate drops in comparison to the single pulse regime. In a deep crater, the thermal losses from the vapor into the crater walls dominate the laser–target interaction process.

2.3.2. Emission Spectra of the Plume and Ambient Gas Mixture

Transient Temperature The emission spectrum of the target surface and the laser plume consists of two easily distinguished parts: one is continuous radiation, and another is line radiation. The average temperature of the mixture of the ablated plume with ambient gas can be found by fitting the continuous radiation spectrum with Plank's radiation law. Line radiation allows one to identify the molecular and ion content in the plume and to estimate the temperature and the level of ionization.

For example, time-integrated, space-resolved, target surface and plume temperatures were measured by Rode et al. [32] for a carbon target ablated by 10-kHz 120-ns laser pulses in a vacuum. The continuous radiation in the 600- to 800-nm range fits well with the Planck spectrum, with the temperature in the range of 2500 to 3500 K.

Single-wall carbon nanotubes were grown by ablation of a carbon–cobalt–nickel target with a Nd:YAG laser (1.064 μm, 300 mJ/pulse, 8 ns pulse width) in argon gas in an oven heated to 760–1100 °C [43]. The transient temperature of the carbon plume diffusing through the argon was estimated by Puretzky et al. [43] by fitting the measured blackbody radiation spectrum to Planck's law. The temperature of the carbon–argon gas mixture changes from 3500 °C at 0.1 ms to 1488 °C at 1 ms after ablation. It decreases to the oven temperature during the next 4 ms.

A similar procedure of fitting the continuous emission spectra to the Planck function by Kokai et al. [29] gives the temperatures for a carbon cluster–argon mixture in the range 3410–3540 K. Note that in this case, the single-wall carbon nanotubes were synthesized by ablation of a C–Ni–Co target by a 20-ms CO_2 laser single pulse ($\lambda = 10.6$ μm; peak power, $\sim$1 kW; average intensity, 1.3×10^5 W/cm^2) in an argon atmosphere. Thus, under all seemingly different conditions, the temperature in the formation zone for carbon nanotube formation is around $\sim$3000 K.

Molecular Content of a Plume Determined by Spectroscopic Measurements The carbon target was ablated by relatively long 120-ns laser pulses at a 10-kHz repetition rate at an intensity of $1–3 \times 10^9$ W/cm^2 [32]. The analysis of the line radiation spectrum of a carbon plume in a spectral range below 400 nm by Rode et al. [32] revealed that there is rather weak radiation from neutral carbon at 248 nm (the first excitation line for carbon) along with the intense lines corresponding to singly ionized and doubly ionized carbon. The temperature estimates led to high values of 1.5–6 eV in the plume.

The emission spectrum of a carbon–argon mixture was recorded by Arepalli et al. [40] in the spectral range of 300–650 nm. The spectral features were identified as emission of a Swan system from C_2 and a Comet Head system relevant to the presence of C_3. Comparison of the computed spectra to the measured excitation spectra allowed estimation of the vibration temperature in the range of 2500 to 4000 K. The temperature measurement results clearly demonstrate that the ionization time in the plume should be considered along with the intensity of the laser radiation on the target surface for predicting the plume temperature in the cluster formation zone [44].

2.4. *In-Situ* Characterization of the Cluster Size (Mass)

2.4.1. Cluster Mass Abundance Spectra

Clusters are formed as a result of interaction of the laser plume with noble gas in a cluster nucleation chamber (Fig. 3). The clusters then flow through a nozzle to the channel leading to the deposition chamber, where a substrate is located [2, 3, 45].

Cluster size (mass) distribution is conventionally determined by a time-of-flight method in a double-field configuration (see, for example [1–3] and references therein). In this method, the ionized clusters are deflected in the applied electric field and then separated in accordance with the charge/mass ratio. When neutral clusters are produced, a separate short-wave laser is used to ionize the neutral clusters, and then they are deviated by an applied electric field and analyzed with a spectrometer. The photon energy of the short-wave laser is chosen to be slightly larger than the first ionization potential of cluster material to assure that only single charged clusters will be produced. The mass abundance spectra have characteristic maxima at "magic numbers" which correspond to the most stable remarkable atomic structures, such as fullerene (C_{60}), cobalt and nickel icosahedra, aluminium octahedra, or metal clusters with closed electronic shells.

The most spectacular mass distribution (or, distribution of number of atoms per cluster) of carbon clusters produced by laser ablation of graphite was obtained by Rohlfing et al. [45] (see Fig. 5). The distribution is bimodal and the highest cluster intensity in the second peak corresponds to the famous fullerene, C_{60}, cluster. A typical mass resolution in this method, $M/\Delta M$, commonly stands between 100 and 1000, but it can be improved up to 30,000 [1].

2.4.2. In-Situ Absorption Spectroscopy of Carbon Nanoparticles: Average Cluster Size

In order to estimate the size of carbon clusters in the plume–ambient gas mixture absorption spectroscopy was used by Puretzky et al. [46]. The short (35–77 nm) single-wall carbon nanotubes were formed using nanosecond Nd:YAG laser ablation of a C–Ni–Co target inside a high-temperature (760–1100 °C) argon-filled oven. The light from a pulsed Xe lamp passed through the ablated plume in the oven, and then the extinction spectrum was measured. The set of extinction spectra was also calculated on the basis of Mie theory for the scattering and absorption of light on spherical particles of a relatively large size (diameter $d > 0.05\lambda$ where λ is the wavelength of the scattered radiation) [47]. For such particles, the extinction spectra are sensitive to the particle size. Comparison of calculated and measured spectra has shown that good fit of the experiment to the theory is obtained for the cluster diameter of 80 nm. This means that 1 ms after the ablation, when the spectra were measured, the carbon atoms have already aggregated into large clusters.

2.4.3. Imaging of a Plume Diffusion Through the Ambient Gas: Onset of and Time for Cluster Formation

Carbon nanotubes are conventionally formed through interaction of a Laser-ablated plume of a carbon–cobalt–nickel target with a noble gas, which fills the experimental chamber. However, it is still unclear how long it takes for nanotube formation, when the growth process starts and ends, and what the conditions (temperature and density) in the formation zone are. Recently several experimental groups published results clarifying some of the stages in the cluster building process.

Single-wall carbon nanotubes were synthesized by ablation of a C–Ni–Co target with 20-ms pulses from a CO_2 laser (1 kW peak power; average intensity, 1.3×10^5 W/cm^2) in an argon atmosphere [29]. A high-speed video imaging technique was applied to record the expansion of the ablating plume. The authors observed that the moment when the carbonaceous material in the expanding plume became visible was 3 ms after the beginning of the laser pulse. This moment can be qualitatively identified as the moment when the number of big clusters became sufficient to make the absorption in the plume visible. The expansion velocity of

the plume in the argon atmosphere (the velocity of propagation of the diffusion front) was measured to be $\sim 10^3$ cm/s as estimated from the plume images at 1.7 and 3.3 ms.

Puretzky et al. [43] suggested that the time of nanotube growth is related to the time dwelt by the plume in the region of the furnace where the temperature is almost uniform. In order to measure this time dwell, the propagation of the laser-ablated C–Co–Ni plume diffusing through an Ar atmosphere at 500 Torr was registered *in-situ* by measuring the scattered light from a time-delayed probe laser beam (XeCl laser, 308 nm, 30 ns, 6 mJ/cm^2) [43]. By measuring the velocity of plume diffusion, the above dwelling time or formation time can be estimated. This time ranges from 15 to 120 ms. The authors [43] also measured the length distribution among nanotubes created under slightly different temperature conditions. The maximum length distribution of the nanotubes formed ranges from 35 to 77 nm. One can relate the above growth time to the corresponding nanotube length and obtain the growth rate for the nanotubes, which ranges from 0.6 to 5.1 μm/s. The growth rate measurements are in agreement with simple kinetic estimates of the single-walled nanotube formation rate under different thermal conditions and similar Ar pressure, which are in the range of 0.5–100 μm/s [48].

It is interesting to note that the measured velocity of the leading (sharp) edge of the diffusing plume in [43] changes abruptly at $\sim$3 ms, decreasing from $\nu_D = 8$ to 0.76×10^3 cm/s. This velocity is directly related to the average diffusion velocity, $D = l\nu/3$, of carbon atoms in the argon atmosphere (here $l = (n\sigma^{-1})$ is the cluster mean free path; n is the number density of particles in the formation zone (mainly argon atoms); $\sigma \sim r_{\text{cluster}}^2 \sim N^{2/3}$ is the cross section for cluster–argon collision, where r_{cluster} is the cluster radius and N is the number of atoms in the cluster). The velocity of a cluster decreases as the cluster mass increases since $\nu \sim (T/Nm)^{1/2} \sim N^{-1/2}$. Therefore, the diffusion velocity depends on the cluster size according to $D \sim N^{-7/6}$ [48]. The distance traveled by the diffusion front as it was measured in the experiment can be expressed as $R = (Dt)^{1/2} = \nu_{\text{D}} t$. Therefore $D \sim (\nu_{\text{D}})^2 t$. The cluster size grows as the diffusing front propagates through the cluster formation zone. Thus, in accordance with the plume propagation measurements in [43] after 3 ms, the number of particles in an average cluster increases $\sim$100-fold.

2.5. *Ex-Situ* Characterization of Individual Clusters and Cluster-Assembled Films (Foams): Structural and Electronic Properties

In this section we describe the diagnostic methods for *ex-situ* characterization of structural and electronic properties of individual nanoclusters and cluster-assembled materials.

2.5.1. Electron Microscopy

A very powerful tool for studying the electronic and structural features of nanoclusters is electron microscopy, with which imaging of the electron beam scattering on and transmission through the studied structure as well as the interference and diffraction patterns can be investigated. Electron microscopy allows the identification of subtle structural features of complicated individual nanoclusters and nanocluster networks. The images of single-wall carbon nanotubes were obtained by using scanning tunneling microscopy [49, 50]. This technique gives atomically resolved lattice images of relatively high contrast. However, there are difficulties in observing such delicate features as the chirality of nanotubes by using this technique. Recently, high-resolution transmission electron microscopy, operating in the imaging mode, was used for characterization of single-walled carbon nanotubes and nanotube bundles produced by the laser ablation technique [51]. A high-resolution transmission analytical electron microscope, the JEM-300F (JEOL) equipped with a 300-keV field emission gun (NIRIM Tsukuba, Japan), was used for these observations. The microscope has a theoretical spatial resolution limit of 0.17 nm. In reality, lattice fringes of 0.21 nm were resolved in the "core" region of a single-walled nanotube, as is seen in Figure 6. Considering the orientation and contrast of these fringes, a researcher is able to observe and estimate such subtle nanotube characteristics as chirality (or helicity) [51].

2.5.2. Raman Spectroscopy

The Raman scattering technique is a powerful tool for determining the structural features of different crystalline structures, nanoclusters, and nanomaterials. Comparison of the known Raman spectra of a bulk crystalline material to that of the nanoclustered one allows the determination of a transition to a nanostate where quantum confinement effects can be observed. The Raman spectra of carbon nanoclustered materials are usually compared to crystalline diamond and graphite lines. Diamond has a very sharp peak at 1330 cm^{-1}, and graphite is characterized by two broad peaks at 1400 cm^{-1} (D-peak) and 1600 cm^{-1} (G-peak) [52]. Amorphous carbon (a-C), regardless of the way it is produced, tends to have a broad single asymmetric peak with a maximum around 1500–1550 cm^{-1} [52, 53].

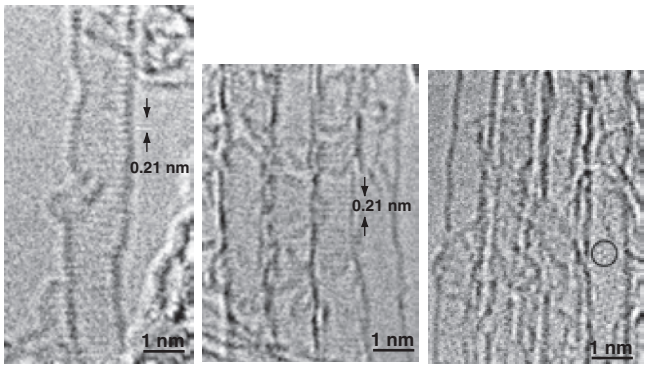

Figure 6. High-resolution transmission electron microscope (HRTEM) images of an individual single-wall carbon nanotube isolated (left) and in a bundle (center) exhibiting 0.21-nm fringes in the core region in agreement with a "zigzag" arrangement of atoms. A 2D dot contrast in the core region, in agreement with the armchair arrangement of the atoms in a tubular shell, is shown in the right image. Reprinted with permission from [51], D. Goldberg et al., *Carbon* 37, 1858 (1999). © 1999, Elsevier Science.

Raman spectra of the carbon nanofoam measured with an excitation wavelength of 632.8 nm showed two separated broad peaks centered at 1341–1353 and at 1569–1579 cm^{-1}, which were attributed to graphitic sp^2 bonding [54]. The detected peaks at 1350 and 1580 cm^{-1} were assigned to disordered and ordered carbon phases, respectively, and the samples were described as glassy carbon with very little order.

A resonant Raman scattering process on single-wall carbon nanotubes was observed with the laser excitation wavelength varying from 514.5 to 1320 nm [55]. The resonance results from the one-dimensional quantum confinement of the electrons in the nanotube. It was shown theoretically and later confirmed experimentally [56] that depending on the symmetry and diameter of the carbon nanotubes, they can be either metallic or semiconducting. These quantum size effects manifest themselves in the Raman scattering signal from the nanotube vibrational modes. In [55] carbonaceous structures were produced by laser ablation. These nanotubes with a very narrow diameter distribution were separated through a long purification procedure, including a microfiltration technique to remove most of the carbon nanoparticles which were also produced in the process.

According to theory [56], nanotubes are described by two indices (n, m). These indices (n, m) define the atomic coordinates for the one-dimensional unit cell of the nanotube. The tube with $n \neq m \neq 0$ has a chiral symmetry. The achiral tubes ($m = 0$, or $m = n$) are divided into two subclasses: tubes with $(n, 0)$ are referred to as "zigzag" tubes and tubes with (n, n) are referred to as "armchair" tubes. The Raman data were analyzed assuming only the armchair symmetry for the studied tubes because the previous calculations have shown that chiral tubes exhibit very few Raman-active modes in the range 400–1500 cm^{-1}.

The theory predicts a strong diameter-dependent Raman line: 206 cm^{-1} for (8, 8) nanotubes with diameter $d =$ 10.85 Å and 150 cm^{-1} for (11, 11) nanotubes with diameter $d = 14.927$ Å. Using 514.5-nm laser excitation, a strong broad line was observed at 186 cm^{-1}. This line associated with a randomly oriented mixture of nanotubes with diameters corresponding to (n, n) tubes with n ranging from 8 to 11. Thus, the Raman observation allows a reasonable estimation of the average diameter of nanotubes in the sample.

It was also observed [55] that the Raman spectrum (intensity and positions of the peaks) strongly depends on the laser excitation frequency. The redistribution of the spectral intensity as a function of the excitation wavelength is an indication of unusual resonant Raman scattering. Resonant scattering occurs when the energy of the incident photon matches the energy difference in an electronic transition due to optical absorption. It is now well known that starting from some small dimension on the nanometer scale (a certain diameter of nanotube or nanocluster), the energy difference between the electronic states responsible for the optical absorption increases when the nanocluster diameter decreases. This effect is often referred to as the quantum size effect or as a one-dimensional quantum confinement phenomenon. For a large diameter, the character of the electronic states is essentially independent of the tube diameter, so the Raman spectrum should be very close to that for a flat graphene sheet and should be independent of the excitation frequency. The experimental observations and calculations of a Raman spectrum presented by Rao et al. [55] provide strong evidence of a diameter-dependent Raman effect that is a consequence of quantum confinement in single-wall carbon nanotubes with diameters of 10–15 A.

2.5.3. Electron Energy Loss Spectroscopy

The character of the bonding in an individual nanocluster or in a nanocluster-assembled material can be investigated using the electron energy-loss spectra (EELS) technique [57]. For example, in carbonaceous materials the important characteristic of the electronic structure is the ratio of sp^2 hybridized bonds (signature of graphite) to sp^3 bonds (signature of diamond). This ratio $sp^2/(sp^2 + sp^3)$ in carbon nanofoam was investigated by the EELS technique [37]. The EELS spectra were analyzed using a GATAN 666 parallel electron energy-loss spectrometer (PEELS). PEELS spectra were collected by two methods. First, a number of different regions of laser-produced carbon nanoclusters were chosen and five different spectra were collected from around each region. In the second method, in-house software was used to collect a number of spectra along a chosen straight line across the nanocluster. This method allowed one mapping of the variation of sp^2 bonding across a single cluster with 1-nm spatial resolution [58]. The mapping of a 6-nm carbon cluster, which is a typical structural unit of the nanofoam, revealed that the carbon atoms inside the clusters have predominantly sp^2 bonding, while at the cluster boundaries sp^3 "diamond-like" bonding prevails.

2.5.4. Surface Area Measurements for Nanocluster-Assembled Materials

Nanocluster-assembled materials usually have a porous, sponge-like or foam-like structure. One of the characteristics for such materials is the characteristic surface area, that is, the area of the inner pores for the unit weight of material. The multipoint Brunauer–Emmett–Teller (BET) method [59] for surface area measurements is commonly used to measure this parameter.

Using this method, the surface area measurements for carbon nanofoam produced by the ultrafast laser ablation of graphite were performed using a surface-area analyzer [37]. About 100 mg of nanomaterial was placed into a sample holder and first outgassed at 120 °C under a nitrogen flow and immersed in liquid nitrogen. The measurements showed that the surface area of the nanofoam is in the range of 300–400 m^2/g. Detailed studies of the desorption of the nitrogen from the foam can be made using the BJH method [60], which calculates the pore volume distribution. The analysis of nanofoams formed at different argon pressures demonstrated that all foam samples have essentially constant pore volume, with no evidence of a preferred pore size.

2.5.5. Small-Angle X-Ray Scattering

Small-angle X-ray scattering data have been found useful for analysis of the fractal dimensions of aerogels, carbon nanofoam [37], and nanoclusters [1–3]. X-rays from a conventional Cu X-ray source were collimated with standard

Guinier optics onto a carbon nanofoam sample to reveal its structural features. The scattered radiation has been collected on a home-built camera [37]. According to Schmidt [61], fractal structures of fractal dimension d give rise to a power law decay of the scattered intensity $I(q) \sim q^{-d}$, where q is the scattering vector. The exact location of this power law regime on the q scale is in practice delicate. However, it is possible in some cases to identify this functional form over a reasonable q range. Rode et al. [37] found the power law to be valid in a range of 0.1–0.4 Å^{-1}, leading to an estimation of the fractal dimension of 2.4. This means that the atomic arrangement in space lies somewhere in between homogeneous two-dimensional sheets and three-dimensional (3D) volumes.

2.5.6. Measurement of the Bulk Density of Cluster-Assembled Materials

A convenient method for determining of the bulk density of cluster-assembled materials (foams, aerogels, sponges, etc.) is Rutherford backscattering [62]. The bulk density of the carbon nanofoam deposited on a silicon substrate [37] was determined from 2-MeV He^+ ion backscattering measurements. The area density of the sample was deduced from the energy width of the carbon peak and the energy shift of the silicon edge, and the thickness of the foam sample was obtained from the scanning electron microscope images (see Fig. 7), giving the density of the foam as $2–10 \times 10^{-3}$ g/cm^3.

3. HOT VAPOR (PLASMA) PRODUCED BY LASER ABLATION

In this section we underline the main physical features of laser–matter interaction and formation of an evaporated plume of hot vapor and plasma. The simple and self-consistent procedure allows the choice of the proper combination of laser and material parameters to design an experiment for producing a plume with the desired parameters, for example, to produce an atomic flow by laser ablation.

3.1. Laser–Matter Interaction: Light Absorption and Ablation Threshold

In order to remove an atom from a solid by means of a laser pulse one should deliver energy in excess of the binding energy ε_b of that atom (the energy of evaporation per atom).

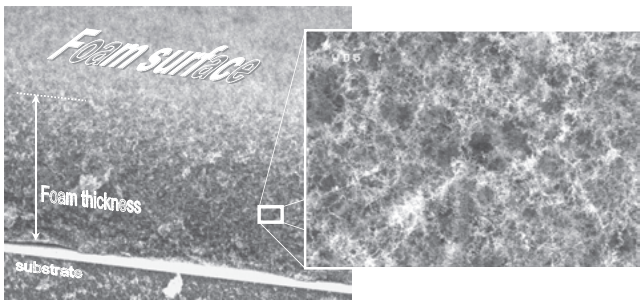

Figure 7. Scanning electron microscope images of a 100-μm-thick nanofoam assembled from carbon nanoclusters and deposited on a silicon substrate.

Therefore, to begin with, efficient absorption of the laser energy is necessary. The ratio of the absorbed energy flux to the incident laser flux, or the absorption coefficient, depends on the material properties and on the intensity and wavelength of the laser.

Absorption coefficients for different materials and for various wavelengths can be found in the literature [31, 63, 64]. To illustrate spectral dependencies we present simple estimates for the absorption coefficient for metals. The laser field penetrates into a solid at the skin depth, l_s, which in metals is much smaller than the wavelength of the laser, $l_s \ll \lambda$. The skin depth, $l_s = \frac{c}{\omega k}$, is conventionally expressed through the imaginary part of the refractive index, k, and the laser frequency, ω [63]. One can show that the absorption coefficient is given by $A \approx \frac{4\pi l_s}{\lambda}$ [65]. As can be seen, the use of short wavelength lasers is preferable for good absorption. Electrons absorb the laser energy at a distance comparable to the skin depth. Suppose that the laser intensity distribution, I_0 (W/cm^2), over the focal spot diameter and during the pulse time, t_p, has a "tophat" profile. The absorbed laser energy per unit area F (J/cm^2) is expressed as $F = AI_0t_p$. This quantity is called the absorbed fluence.

The absorbed energy is confined in the electrons, and therefore, the maximum electron temperature at the end of the laser pulse is proportional to the absorbed laser fluence as

$$T_e = \frac{4F}{3n_e l_s}$$

where n_e is the number density of free electrons in the metal. Finally the hot electrons transfer their energy to cold ions, and the electron and ion temperature T_i equilibrates, such that $T_e = T_i$. The ions can leave the solid (or to be ablated) if $T_i > \varepsilon_b$. Now one can immediately obtain a relation between the laser fluence and material parameters needed to reach the ablation threshold $F_{threshold} = \frac{3}{4} n_e l_s \varepsilon_b$. A typical binding energy for the majority of solids is a few electron volts and therefore, the typical absorbed laser fluence for ablation threshold is around 0.5 J/cm^2.

One can see that ablation by long or short laser pulses occurs under very different conditions. In order to ablate the same amount of material with a short pulse, one should apply a larger laser intensity approximately in inverse proportion to the pulse duration. For example, laser ablation with a 100-fs pulse requires the intensity to be above 10^{13} W/cm^2 [31–33, 65], while with 10-ns pulses, the same material is ablated at much lower intensities, $\sim 10^8$–10^9 W/cm^2 [31]. The depth of material ablated per single short laser pulse is proportional to the skin depth, whereas in the case of long pulse ablation, the characteristic ablation depth is proportional to the heat conduction length per pulse $\sim (at_p)^{1/2}$, where a is the thermal diffusivity (cm^2/s) of the target material. Correspondingly, the number of particles evaporated per pulse differs by several orders of magnitude.

It has been shown [33, 65] that at laser intensities in excess of 10^{13} W/cm^2, practically any target material is ionized during the subpicosecond pulse time. Following ionization, the laser energy is efficiently absorbed by free electrons due to

inverse Brehmsstrahlung and resonance absorption mechanisms and does not depend on the initial state of the target. Consequently, the interaction of a laser pulse with both metals and dielectrics proceeds in a similar way. The efficient evaporation of dielectrics and the formation of atomic beams of ablated atoms is now possible using short and intense laser pulses. Since additional energy, ~10 eV/atom, is required for ionization, it is obvious that the ablation threshold for dielectrics must be higher than that for metals. Indeed, the experiments show that the ablation threshold for dielectrics is typically ~2 J/cm^2 [33].

3.2. Ablation Rate and Deposition Rate

The most efficient ablation will be achieved if all the absorbed energy is used in ablation only, and any losses and overheating of the plume are avoided. In this case, the instantaneous ablation rate (the ablation rate during the pulse) can be easily estimated as the absorbed laser intensity divided by the binding energy

$$(n\nu)_{\text{abl}} \approx \frac{AI_0}{\varepsilon_{\text{b}}} \ (\text{atoms/cm}^2/\text{s})$$

In fact this ablation rate is close to the experimentally measured value for the optimum ablation mode. This is the highest rate from all available ablation methods. The values for the instantaneous ablation rate span from 10^{32} atoms/cm^2/s for short, ~100-fs pulses, to 10^{27} atoms/cm^2/s for the nanosecond pulses. The total number of atoms evaporated per single pulse with the total energy E_{las} is given by $AE_{\text{las}}/\varepsilon_{\text{b}}$. The laser energy per short pulse is in the order of ~μJ, while in the nanosecond pulses it reaches 1 J. Thus, the ablation rate per pulse, with the pulse duration ranging from nanoseconds to femtoseconds, is correspondingly ~10^{12}–10^{18} atoms/pulse. Taking into account the different pulse repetition rates (up to 100 MHz for the short pulses and 10–30 Hz for the long nanosecond pulses) one can see that the average flow of laser-ablated atoms is $N \sim 10^{19}$–10^{20} atoms/s near the ablation surface. This figure, along with the temperature and ionization state of the vapor, defines the initial conditions for the formation of new structures in a chamber.

Let us consider the use of the atomic flow for the deposition of thin films on a substrate placed at a distance d from the target in an evacuated chamber. The film growth rate for the formation of a film with a number density n_{a} is defined as $N/2\pi d^2 n_{\text{a}}$. Thus, taking the average target to substrate distance of 10 cm and the number density of solid 10^{23} atoms/cm^3 the deposition rate for the formation of amorphous films with laser ablation can reach several tens of nanometers per second.

3.3. Criterion for the Full Atomization of Ablated Vapor

The phase state of the ablated vapors is determined by the conditions of evaporation, that is, it depends on the amount of laser energy absorbed in the ablating material. The energy delivered by a laser is spent on the breaking of interatomic bonds and on the kinetic energy of atomic expansion. If this kinetic energy is low, the vapor expands slowly, and therefore it can be condensed back near the target shortly after the laser pulse termination. We shall determine the magnitude of the kinetic energy sufficient for keeping the plume expanding into a vacuum in a gas state of non-interacting atoms. One can estimate the energy threshold necessary to achieve full atomization of the ablated plume on the basis of thermodynamic arguments similar to those used for establishing the criterion for complete vaporization of a material in an unloading stage after the action of a strong shock wave [66]. In this case all the nonequilibrium processes related to the energy transfer to ions are assumed to be completed before the expansion begins. The target material after the termination of the pulse experiences adiabatic expansion.

The adiabatic expansion from a solid state to the gas state can be described by the conventional relation between the gas energy, pressure P, and gas volume, V, but with a volume-dependent exponent (so called the Gruneisen coefficient). In order to get the final stage of expansion as a gas state, the adiabatic curve in the PV plane must pass higher than the critical point, $P_{\text{cr}}, V_{\text{cr}}$, separating the states of a homogeneous phase (atomized vapor) from states with a mixture of phases (gas and condensed liquid droplets). Given these constraints, it can be determined that the energy delivered by the laser per ablated atom must be approximately three to four times larger than the binding energy. Therefore, the absorbed laser energy density necessary to transform the ablated material into an atomized vapor should exceed the ablation threshold in accordance with the condition $F > 4F_{\text{thr}}$.

3.4. Damage and Condensation Thresholds

If the total energy delivered by the laser is close to the binding energy, $\varepsilon_{\text{total}} \sim \varepsilon_{\text{b}}$, then a solid experiences only a small density decrease from the standard solid density of the target material. The pressure in the material is comparable to the bulk modulus. Therefore, the final state of the target affected by the laser at this energy level might be considered "damaged," having cracks, flakes, etc. in the laser focal spot depending on the initial state of the target (such as the presence of defects, impurities, etc.). If the deposited energy is in the range $\varepsilon_{\text{b}} < \varepsilon_{\text{total}} < (3\text{–}4)\varepsilon_b$, then the final state of the expanding vapors may lie in the region of the pressure–volume parameter space where the mixture of phases is energetically favorable. The condensation of vapor into liquid droplets in a course of expansion in a vacuum may occur when the absorbed laser energy is within $F_{\text{thr}} < F < (3\text{–}4)F_{\text{thr}}$.

3.5. Ionization State and Velocity Spectrum of Ablated Ions

Ionization of a solid target material during the ablation process and the ionization of ablated vapors occurs due to processes of photoionization, multiphoton ionization, and ionization by electron impact (avalanche ionization) [66]. As ionization proceeds, the vapor is converted into a high-density plasma whose properties can eventually dominate the physics of the laser–vapor interaction. If the laser–matter interaction occurs at a high intensity, which is typical in ablation by femtosecond laser pulses, the full first ionization is completed during the first few femtoseconds at the

beginning of the laser pulse [65–68]. Afterward the interaction proceeds with the plasma. The energy distribution of the ions in the ablated flow appears to be non-Maxwellian. It can be roughly approximated as a two-bump distribution composed of the slow and fast parts. Experimental and theoretical studies have demonstrated that the energy distribution of outflowing ions is highly dependent on the ratio of the maximum intensity in the main laser pulse to the intensity in the prepulse (the so-called contrast ratio) [69]. It has been observed that for 100-fs laser pulses in the laser intensity range of 10^{14}–10^{16} W/cm^2, the ion energies vary from 100 eV to 20 keV [69]. Therefore, the interaction of an ionized flow, either with an ambient gas in the chamber resulting in cluster formation or with a substrate leading to the formation of a nanofilm, proceeds in a different way, as has been confirmed by experiments which are discussed below. We should stress that all parameters of a hot atomic flow which affect the process of a nanocluster formation can be controlled and steered in a desirable manner.

4. FORMATION OF NANOCLUSTERS IN A VACUUM

The whole process of nanostructure formation can be separated tentatively into the following stages. First, laser-ablated atomic vapors (or plasma) are produced to form a plume. Then, the laser plume expands into a vacuum and cools in the experimental chamber. The nanostructure formation process (nucleation) is composed of vapor–vapor, vapor–filling gas, vapor–substrate, and cluster–substrate interactions. Finally, the resulting product is annealed and cooled. In this section, we concentrate on the processes of nanostructure formation, taking the parameters of ablated vapors (plasma) as the initial conditions. Then, we discuss the characterization of the structure produced and relate the structural and material features to the formation conditions resulting from vapor–gas–substrate coupling.

We start from the most studied process of thin film deposition in an evacuated chamber. Recently a huge variety of different structures were deposited by the laser ablation method including refractory and complex materials. The literature covering this topic comprises thousands of references [i.e., 70, 71]. Our goal in this review is to point out relations between the properties of the atomic beam, the ambient gas, and the conditions created in the chamber to the properties of the emerging nanostructure. Such relations, when properly understood, would allow the control and prediction of the formation process. Therefore, we concentrate on several structures where this relation has been at least partly revealed. We also mention recent achievements in the quality and in the efficiency of thin film deposition, which makes the pulsed laser deposition technique more attractive for industrial applications.

4.1. Deposition of Nanometric Films in a Vacuum

Laser ablation has been successfully used for thin film deposition during the last 3 decades with the use of conventional nanosecond, 10- to 30-Hz lasers [70–72]. However, due to poor control over the laser beam parameters in these lasers, the surface quality (abundance of droplets) and material properties (for example, the sp^2/sp^3 bond ratio in carbon films) would differ from one laser installation to another with seemingly similar parameters. In addition, the deposition rate with lasers running at a repetition rate of 10–30 Hz was too low for most industrial applications.

The recent advent of short-pulse, high average power, high repetition rate lasers resulted in the elimination of these drawbacks of laser deposition. Progress in the understanding of the ablation process led to control over the pulse time shape (elimination of the prepulse), over the spatial distribution of the intensity across the laser focal spot (top-hat distribution), and over the temperature of the ablated ions. Now full control of the ablated plume parameters, at least in principle, can be provided. Future developments will determine whether it will be possible to make this process cost effective and to scale it to the industrial level.

4.1.1. Interaction of Hot Atoms with a Substrate in a Vacuum

Let us describe the succession of processes accompanying thin film deposition in a vacuum. We consider, for example, the flow of carbon atoms forming diamond-like carbon films on a substrate (conventionally the substrate is a silicon or silica) in a high vacuum, $P = \sim 10^{-6}$–10^{-7} Torr, which corresponds to a density of air molecules of $\sim 2 \times 10^9$–10^{10} cm^{-3}. A short-pulse laser with a high repetition rate produces 10^{19}–10^{20} atoms/s, which destroys the vacuum after several seconds of operation [32, 73–75]. Therefore, continuous chamber evacuation is necessary in order to maintain constant conditions during the long, 30- to 120-min deposition process. Continuous chamber evacuation at a rate of 2×10^3 liters/s maintains the number density of particles in the chamber at an approximately constant level of $n_a \sim 2 \times 10^{10}$ cm^{-3} [73]. Under these conditions, the mean free path for the particles (carbon atoms and air molecules) is $l \sim 1/n_a\sigma = 5 \times 10^4$ cm, assuming that the cross section of atom–atom collisions is $\sigma \sim 10^{-15}$ cm^2. Hence, one can suggest that there is no influence from any collisions in the chamber on the film formation process at the substrate and no cooling of the carbon atoms under this vacuum condition. Thus, the films of any material are formed due to direct vapor–substrate interaction at the vapor's temperature, which approximately corresponds to the target surface temperature. Note that these conditions are appropriate for the formation of sp^3 carbon bonds assuming $T > 10^3$ K. However, not all of the collisions between the ablated atoms and the substrate lead to the sticky attachment of an atom to the substrate. Some atoms can rebound from the substrate or from the chamber walls, cool down, and flow around the vacuum chamber [3, 73, 76]. Some small deposition of the ablated material on the rear side of the substrate may serve as direct experimental evidence of this effect.

Another important factor for deposited film formation is the pressure on the substrate during the film building process. This pressure consists of two components: kinetic pressure, P_{kin}, and thermal pressure, P_{th}. The momentum transferred to the substrate by the incoming flux of atoms (ions) determines the kinetic pressure. However, the kinetic

pressure is small in comparison to the thermal pressure, which depends on the average temperature of the substrate. The average temperature on the substrate surface generated by the impact of the ablated flow can be calculated through the maximum temperature on the target surface, T_{max}, the laser repetition rate, and the pulse duration [73]. The thermal pressure and average temperature on the substrate were estimated as 20 kbar and 1600 K, respectively, for the 120-ns pulse laser and 40 kbar and 3000 K for the 60-ps laser by Gamaly et al. (1999, 2000) [31, 73]. These pressure and temperature values are close to the range of parameters most appropriate for the carbon-to-diamond phase transition to occur under equilibrium conditions.

One can see that an increase in laser intensity will increase the energy of the ablated ions and consequently will increase the temperature and pressure on the surface of the substrate, thus affecting the conditions for thin film formation.

4.1.2. Experiments: The Material Properties of the Films Produced

High average power, high repetition rate Nd:YAG lasers ($\lambda = 1.064\ \mu$m) were used for laser ablation of carbonaceous targets and deposition experiments [73, 75]. Laser radiation with parameters of 60 ps, 3×10^9 W/cm^2, and 76 MHz is absorbed well ($\sim$85%) by a graphite target and produces an almost fully ionized laser plume with a surface temperature (average over many pulses) in the range from 2500 to 3500 K [73]. Thin carbon film deposition was performed in a chamber evacuated to 10^{-7} Torr on a mica substrate. The surface morphology of carbon films with a thickness of 25–120 nm has been investigated with an atomic force microscope [73–75, 77]. Films with thicknesses of 20–25 nm appear to be almost atomically smooth with the surface root mean square (rms) roughness around 0.4–1 nm [73, 75]. The optical bandgap of 0.5–0.7 eV extracted from ellipsometry measurements and Raman spectra indicated that the deposited films had properties similar to the diamond-like amorphous carbon (a-C) films.

Studies of the influence of laser intensity in the range 10^{14}–10^{16} W/cm^2 and wavelength in a range of 400–1000 nm on the properties of deposited films unveiled several interesting phenomena [73–76]. The energy distribution of ions which were ablated with short (around 100 fs), intense (in excess of 10^{14} W/cm^2), and prepulse free laser pulses has a pronounced two-bump form composed of a main thermal part, E_{th}, and a fast part, with energy 3–5 E_{th} [74]. Studies of the deposited films revealed that the transmission of the films increases with increasing laser intensity, while the ratio of sp^3 to sp^2 bonds decreases, being evidence of a less diamond-like character. The bandgap for these films determined with ellipsometry measurements was 0.85 eV, which supports the assumption of the amorphous nature of the films. Experiments using an intense short-pulse, high repetition rate laser demonstrated, along with atomic surface quality, an extremely high deposition rate up to a few micrometers/hour [73, 75], exceeding that for all other available methods of thin film deposition. It is instructive to compare with a deposition rate using a long pulse ($\sim$17 ns), low repetition rate (10–20 Hz) KrF laser (248 nm, 5–125 J/cm^2), where the deposition rate for the production of amorphous carbon films with high surface quality (rms roughness of 0.6 nm) constitutes 0.3–0.6 micrometers/hour [77].

4.2. Deposition of Complex Films

Laser ablation can be used to produce films of complex materials with the same stoichiometry as the original target. Provided that the laser intensity is chosen such that the bonds with the highest binding energy can be destroyed, laser ablation can produce an atomized beam containing the whole mix of constituent atoms. As a result, the laser plume contains a mixture of atoms with exactly the same atomic content and with the same atomic ratio as in an original target. Therefore the deposition process maintains the same stoichiometry in the deposited film or in a nanocluster as in the ablated target. As an example of complex structures being successfully deposited, we mention chalcogenide glasses (As_2S_3) [34] and high-temperature superconducting ceramics [78–80].

5. NANOCLUSTERS PRODUCED THROUGH THE INTERACTION OF ABLATED VAPOR WITH NOBLE GAS

The ideal mode of formation for any nanostructure is bottom-up or atom-to-atom attachment in a proper place in space, and at the proper rate in time, in order to form clusters with desirable characteristics. To approach this mode, one should be able to control the formation process on a space scale of angstroms and on a time scale less than a picosecond.

An atomic beam for cluster formation can be created by laser ablation with short (picosecond and subpicosecond) successive laser pulses, with the repetition rate up to 100 MHz. In this case, the shortest controllable time scales are the laser pulse duration and a time gap between the pulses. The smallest controllable number of atoms is the number of atoms evaporated per single laser pulse. Of course, the decrease of a single pulse duration and increase of the repetition rate will lead to a smaller controllable time scale and number of particles per pulse. In principle, there is no upper (lower) limit: in the ultimate limit of extremely short pulses and the highest possible repetition rate, one has atom-by-atom evaporation with as short as necessary time control and consequently an atom-to-atom attachment process of cluster formation.

The process of nanocluster formation is composed of several stages, namely, the formation of a laser-produced flow of hot atomic vapors, plume propagation, diffusion, cooling/heating in a chamber, a cluster nucleation process, and a final stage of annealing, cooling, and stabilization. In what follows, we describe all the formation stages of individual clusters and compare with experimental data where available. We briefly discuss size-dependent cluster material properties and the internal structure of nanoclusters. We then discuss interactions with the substrate and the formation of cluster-assembled films.

5.1. Nucleation, Growth, and Annealing

It is instructive to consider the simplest case of the formation of clusters composed from one element. The most studied cases are those of carbon cluster and metal cluster formation. We consider, for example, the thoroughly studied carbon cluster formation process in a noble gas filling of the experimental chamber. There are also many studies of cluster formation in a reactive gas atmosphere [7–9, 81]. The processes of cluster formation in reactive gases are more complicated and less developed. Therefore, we restrict ourselves to interactions between atomic beams with noble gas. Many features of the formation process that we describe are common for the formation of clusters of different elements.

We should note that many essential details of cluster formation mechanisms have still not been uncovered, and some of the proposed mechanisms are questionable. There is no clear understanding or mutual agreement about the onset of the nucleation process, the progression toward cluster building, or growth termination. Many theoretical models have been proposed. But due to the lack of *in-situ* diagnostics, no experimental validation of the proposed mechanisms has been obtained to date. However, the general picture of cluster formation can be presented in a reasonable scenario. In the following we present a qualitative picture of cluster formation based on kinetic and thermodynamic arguments.

5.1.1. Nucleation and Growth

The cluster formation mechanism appears to be simple from first appearances. The hot vapor of ablated atoms rapidly expands in a cold gas. Thus, the thermodynamic approach of fast vapor condensation into minidroplets, that is, clusters, seems straightforward. Close examination, however, reveals that the process is too fast in comparison to the equilibration time. The vapor density is relatively low, and the atom-to-atom collision time is not negligibly small in comparison to the characteristic time of the process. Thus caution should be exercised in applying the thermodynamic approach for describing the cluster formation process. In the following, we discuss and compare the thermodynamic and kinetic descriptions of the cluster formation process.

Thermodynamic Approach—Condensation Nucleation is a process through which clusters of a new phase grow inside an initial phase, which has been heated above the phase transition temperature. In thermodynamics the nucleation process describes the early stages in phase transformation, such as condensation of gases during expansion or solidification of melts. The expanding vapor (plasma) of ablated atoms during interaction with a cold gas or substrate can be transformed into a supersaturated state. This state is thermodynamically unstable. Therefore, a vapor–liquid phase transition develops leading to the formation of nuclei of the new phase, minidroplets of liquid. If some fast annealing process can suddenly terminate further growth of these droplets, then nanoclusters can be formed.

The nuclei of the new phase are formed due to fluctuations in an unstable system. A nucleus can continue its growth only in cases where its radius exceeds a definite critical value. Classical condensation theory [82] predicts well the critical size of a nucleus when a liquid droplet forms, starting the fast process of the phase transformation under the conditions of local thermodynamic equilibrium.

The small seeds (nuclei) of a new phase are created in the overheated, initially homogeneous, vapor phase due to fluctuations [82]. Such seeds are unstable structures because the formation of an interface between two phases is energetically unfavorable: to create a seed, the work to overcome the surface tension for the formation of a nucleus needs to be spent. The seeds with a size less than the critical value decay into the initial phase. The seeds with a size exceeding the minimum critical radius start to grow up, rapidly becoming the centers of the fast transformation into a new phase. The critical radius of a seed can be obtained from the condition of minimization of the free energy of a seed assuming that it has the form of a spherical droplet. Physically, this condition is equivalent to the balance between the surface tension and the thermal pressure. The critical radius of the seed is expressed through the temperature of the overheated phase, T, as [82]

$$r_{\mathrm{cr}} = \frac{2\alpha}{P' - P} \approx \frac{2\alpha}{n_{\mathrm{a}}(T - T_{\mathrm{melt}})}$$

where α is the surface tension between the liquid and gas, P' is the transient pressure in a gas, and P is the pressure corresponding to the liquid–gas equilibrium: $P = n_{\mathrm{a}} T_{\mathrm{melt}}$. One can consider seed formation as the attachment of a single atom (or monomer) to the seed center, with a characteristic thermal velocity $\nu_{\mathrm{th}} \sim (2T/M)^{1/2}$. This approach allows the estimation of the cluster size under conditions close to those in equilibrium. There have been numerous attempts to improve a classical theory of cluster formation by molecular beams under nonequilibrium conditions without considerable success. Review and discussion of these theories by Milani and Iannotta (1999) is available [3].

The critical radius is directly proportional to the surface tension between the liquid and gas phases and inversely proportional to the pressure of the expanding vapor. Therefore, as one can easily estimate from the above formula, the nanometer size clusters can be formed via the condensation process only in a very dense vapor with a density a few times, 3 to 10 times, lower than the solid density. It means that the formation of nanoclusters by vapor condensation from the supersaturated state might occur in a region very close to the ablated target. Note that the above description of minidroplet formation applies to a monoatomic homogeneous vapor in thermal equilibrium.

Let us now compare the above model to the experimental data of cluster formation. Hot silicon vapor was produced by laser ablation (ArF laser, $\lambda = 193$ nm, 15 ns, 1–3.9 J/cm^2) of a monocrystalline silicon sample [83]. Silicon clusters with a diameter in the range of 1–4 nm were formed through interaction with a flow of pure helium (at pressure from 1 to 4 Torr). The silicon target was used as a substrate where the nanoclusters were collected. Patrone et al. and Marine et al. [83, 84] found that cluster size grows in direct proportion to the increase in laser fluence. However, the increase in laser fluence results in increases in the near surface temperature and pressure of vapors. Thus, in thermodynamics, it should result in a decrease in the critical radius of the nucleus of the new phase and therefore make easier the growth of large droplets. It was also demonstrated that the cluster size

decreases as the distance from the laser focal spot increases. The temperature at the substrate decreases as the distance from the focal spot increases. In accordance with the classical theory of expanding vapor condensation [66, 82], this must result in an increase in the number of critical nuclei for condensation, which is in contradiction to the experimental observation. The vapor condensation model has also been mentioned by Sattler [85], in relation to carbon nanotube formation, as a possibility for forming half-fullerene seeds for the further construction of nanotubes. One can note that condensation leads to the formation of a disordered (liquid) droplet. The complicated internal structure is a result of a microscopic atom-to-atom interaction. One can conclude that the direct application of the thermodynamic approach for explanation of the transient processes of nanocluster formation looks rather questionable. It allows an estimation of an approximate cluster size at best. Let's now consider the kinetic approach to the cluster building process.

Kinetics of Vapor–Gas Interaction The flow of atomic carbon is created by laser ablation near the surface of a target. The carbon cloud expands, carbon atoms collide with the filling gas atoms, exchanging energy, diffusing, and finally forming a mixture of carbon and filling gas with some average transient density and temperature. Thus, the conditions for the formation of clusters—"the primeval soup"—are created. The number density and temperature of this mixture change with the distance from the target. It is quite different near the target and near the substrate, several centimeters away. The processes of collision, diffusion, and atom-to-atom (atom-to-cluster, cluster-to-cluster) attachment can be described qualitatively on the basis of a simple kinetic theory [54, 86–87]. Depending on the masses of ablated atoms and the atoms of the filling gas, the processes of energy exchange will occur at different rates. If the masses of colliding atoms are comparable (for example, carbon flow with an argon fill), the carbon can loose a significant part of its energy even in a single collision. Hence, efficient energy equilibration occurs after several collisions: the carbon vapor is cooling down and the argon gas is heating up. The main processes which contribute to changes in the density of carbon atoms in the cluster formation zone are the following: delivery of atomic carbon by the target ablation, carbon losses due to diffusion out of the formation zone, and carbon consumption in the cluster formation process. On the basis of kinetic considerations, the scenario of carbon cluster formation in a carbon–argon mixture created by the high repetition laser has been suggested. We point out that the main features of this scenario are applicable to the cluster formation of any other element.

Kinetics: Nucleation by Monomer Addition Laser ablation creates an almost continuous inflow of hot carbon atoms and ions, with an average temperature of a few electron volts, into the experimental chamber. The shock wave generated by each pulse rapidly decelerates in the ambient gas atmosphere, and further propagation of hot atoms proceeds by diffusion. Initially the ambient gas is at room temperature (or the temperature of the furnace). The continuous inflow of hot carbons increases the partial density of carbons in the chamber, along with the temperature in the mixture. When the carbon vapor temperature and the number density reach the level where the probability of carbon–carbon attachment becomes significant, the formation of carbonaceous clusters begins. The carbon consumption rate during this formation process significantly exceeds the evaporation rate due to laser ablation. Therefore, the carbon number density rapidly decreases to the value at which the formation process terminates. Thus, the ablation rate, target parameters, pressure, and properties of the ambient gas determine *the formation time* and, accordingly, *the size* of the cluster formed. Continuing laser evaporation leads again to an increase in the carbon number density to a value sufficient to resume the next cycle of cluster formation.

It has been suggested by Gamaly et al. [87] that the cluster formation process is composed of periodic stages of heating and cluster formation, with the time period depending on the initial argon density, the evaporation rate, and on the carbon attachment reaction rate, which in turn is a function of the temperature and density of the atomic carbon. It is clear that the average temperature of the ambient gas depends on the laser repetition rate. For example, in the case of a high repetition rate laser [73], during the short period of cluster formation (in comparison to the heating period), the argon gas does not cool down but maintains a temperature approximately equal to that required for cluster formation. As a result, the average temperature in a carbon–argon mixture appears to be high enough for formation of sp^2 and sp^3 bonds, as experimentally observed.

The maximum number of atoms in a cluster (or the maximum cluster size) from the kinetic viewpoint is directly related to the cluster formation time defined above. The characteristic time for N atomic cluster assembly in an argon–carbon mixture can be estimated under the assumption that the main building process is dominated by single atom attachment to a bigger cluster, taking the attachment cross section to be equal to the geometrical cross section for elastic collisions. This time is directly proportional to the ambient gas density and inversely proportional to the square of the partial density of single carbon atoms. These predictions qualitatively comply with the experimental data that small clusters ($\sim$6 nm, 10^4 atoms) are preferably formed at a low gas pressure of 1 Torr [37, 73], while carbon nanotubes (10^6 atoms) are formed at pressures of 300–500 Torr [27–30, 87]. Therefore, the kinetic approach can qualitatively predict the formation time and the size of the nanocluster. However, kinetic theory, as well as thermodynamics, fails to explain fundamental issues relevant to the internal structure of the nanoclusters and their unusual material properties already observed experimentally, for example, why clusters having a particular number of particles (magic numbers) are more abundant, which features of the formation process are responsible for the intricate structure of a cluster, and what are the reasons for the formation of crystalline or amorphous clusters.

5.1.2. Cluster Annealing and Stabilization

Laser ablation creates a dense homogeneous mixture of hot ablated atoms and atoms of an ambient gas that proved to be the most appropriate medium for the formation of three-dimensional clusters. The homogeneous mixture has high

symmetry—it is almost isotropic. Kinetics and thermodynamics theories can qualitatively explain why the hot atoms can form a cluster of a definite size, like an amorphous snowball, during the many "sticky" collisions. However, it is well known that nanoclusters have different and sometimes very complicated structures. A fundamental question then arises, namely, how does the transition from such a disordered gas phase to the highly symmetric molecule of fullerene [19], or a carbon nanotube [20, 21], or even the more complicated structural unit of carbon nanofoam [37] take place? The most natural answer may be found in the general theory of phase transitions for condensed matter, in the breaking of the initial high symmetry of a homogeneous gas and in the formation of primary seed structures displaying the specific symmetry obtained in the final structure.

Formation of a three-dimensional cluster breaks the initial high symmetry in the cluster formation zone. In the genesis of fullerene, C_{60}, for example, a lower symmetry cluster, pentagon or hexagon, displaying an axis of rotation of a higher order (5 and 6) is created. From the chemical point of view, the substance in the nanocluster formation zone is a random mixture of different low-dimensional carbon clusters (monomers, dimers, trimers, five- and six-membered rings, etc.) formed in the process of stochastic "sticky" collisions of carbon atoms in the carbon-ambient gas mixture. All of these clusters have a lifetime strongly dependent on the temperature. Generally, this lifetime increases with decreasing temperature. Simultaneously, the spatial amplitude of fluctuations decreases when the temperature falls to the critical temperature and below. The critical temperature is the characteristic temperature at which the particular structure begins to stabilize and becomes rigid [88]. The jump in the order parameter (a singularity), which manifests the appearance of a new symmetry, also occurs at this temperature. The free energy of a newly formed cluster at $T < T_c$ must include, in addition to thermal energy, the internal (strain) energy which is absent from a totally disordered state. The configuration entropy of a cluster also characterizes its particular structure. The minimization of the free energy determines the critical temperature for the defect-mediated phase transition from a disordered gas phase [89, 90] or, for the case considered here, the optimum temperature for nanocluster formation. This critical temperature, or rather optimum temperature for nanostructure formation, was found experimentally: for carbon nanotube formation this temperature is approximately 1200–2000 K [29, 40, 43]. For fullerene formation this temperature as seen in molecular dynamics simulations [91] lies in the range of 2000–3000 K.

The formation of three-dimensional carbon clusters can be understood in terms of a phase transition from a disordered to an ordered phase by the introduction of a specific defect assembly or seed with a new structure. In the case of fullerene formation, it is associated with the appearance of pentagon-shaped, or five-wedge, disclinations. This is similar to the conventional scenario seen for disorder–order transition phenomena in the growth of crystalline structures [88, 89]. The appearance of a disclination—a singularity in order parameter—in a hot mixture of unassociated carbon atoms echoes arguments presented by Anderson that "the fluctuations do become of quasi macroscopic size and dimension at the critical point..." [88]. The defect in this context is a means for replacing the symmetry of an initial phase with that of a new one.

We should note that most of the studied three-dimensional carbon clusters display very complicated internal structure. For example, fullerenes and fullerene-like structures are embedded with pentagons, which are units relevant only to surfaces of positive curvature. It is likely that carbon clusters, which include surfaces with negative curvature where heptagons are the responsible topographic elements, have also been identified experimentally [37].

5.2. Electronic and Structural Properties of Individual Nanoclusters

Many intrinsic properties of a particular bulk material, become dependent on the size of a system when the cluster size decreases to several nanometers. The thermodynamic and electrodynamic arguments which apply to the infinite system (when one can ignore boundary effects) become invalid for the description of the properties of very small particles.

The unique features of nanoclusters are directly related to their small size. That size lies between the atomic size and the macroscopic dimensions of many particles in a bulk structure. There are at least two main consequences for the physical and chemical properties resulting from size. First, a nanocluster is a system of many, but a limited, number of particles, say $10–10^4$, and behaves as a large atom with discrete energy levels. Second, accompanying a decrease in cluster size, the ratio of the surface to volume increases. In this case, the surface phenomena dominate the electronic and optical properties of a cluster. For example, in a cluster containing 1000 atoms, about a quarter of the atoms lie close to the surface, suggesting that these atoms may strongly influence the cluster properties.

5.2.1. Critical Cluster Size

It is crucial for understanding the properties of nanoclusters to know at what cluster size (or at what number of atoms in a cluster) the material properties of an atomic system approach those of the bulk structure. Moreover, it is important to understand if all the material properties are changing at the same critical "threshold" size or if different properties change at different cluster sizes.

It was theoretically predicted [92] that small metal clusters ($n < 10$) would have a face-centered cubic (fcc) structure, while in bulk, the structure is body-centered cubic (bcc). It was observed later on [93] that a structural evolution from amorphous to fcc, and subsequently to bcc, structure occurs in tungsten when the number of atoms in a cluster increases, in agreement with Tomanek et al. [92]. The critical cluster size for metallic chromium nanoclusters is determined to be 490 ± 100 atoms, and for Mo nanoclusters it is in the range of 1460–3900 atoms for the cluster–bulk transformation in a structural sense to be completed [94]. The surface-to-volume ratio is huge for small clusters and therefore the surface energy contribution dominates in the total cluster energy. The fcc structure is more compact than the bcc and thus provides a lower surface energy and overall lower total energy

of a cluster. As will be shown in the next section, the critical cluster size appears to be different for different materials and for different properties.

5.2.2. Size Effects

Quantum Size Effects A system of particles in a finite volume has discrete energy levels. In general the distances between energy levels decrease exponentially with increases in the number of particles. In bulk, the interference of electronic wave functions results in a band structure. However, at the opposite limit, when the size of the system decreases to the nanometer scale, the energy bands split again into energy levels. For example, the difference in energy between the electronic levels, $\Delta\varepsilon$, in a small metal cluster increases in inverse proportion to the size of the cluster, R, as $\Delta\varepsilon \sim \nu_F/R$, where ν_F is electron Fermi velocity [95]. If the applied electric field is small in comparison to the interatomic field $eER \ll \Delta\varepsilon$, and the frequency of the external field complies with condition $\omega \ll \nu_F/R$, then the small metallic particle behaves in such a field like an atom with a certain polarizability. A moderately small cluster possesses a larger polarizability than that following from the classical polarization of a metal sphere.

Size-dependent photoluminescence of silicon nanoclusters has been observed experimentally where the cluster size ranged from 1 to 3.5 nm [83, 84]. Analysis of the internal structure of the silicon clusters using high-resolution transmission electron microscopy (HRTEM) revealed that clusters had a crystalline structure and nearly spherical shape [84]. When the cluster sizes were decreased from 3.5 to 1 nm, the peak in the luminescence spectrum shifted from 750 to 300 nm.

Neutral silicon clusters ranging in diameter from 1 to 20 nm were produced by laser ablation of a silicon target in an ambient atmosphere of helium at a pressure of 8 Torr and extracted into a vacuum as a cluster beam. The cluster beam was then scattered by an argon beam flowing in a direction perpendicular to the cluster beam. Clusters of different sizes were deposited onto substrates positioned at different distances from the axis of the cluster beam. On the substrate placed directly on the beam axis, spherical isolated clusters with a mean diameter of 10 nm were deposited. The average size of the clusters decreases as the distance from the axis of the cluster beam increases.

The nanocluster films exhibit a strong red photoluminescence after being exposed to air. The energy of the photoluminescence peak changes between 1.42 eV (845 nm) and 1.72 eV (700 nm) depending on the substrate position: the farther from the cluster beam axis, the higher the energy. Wu et al. [96] relate the observed energy shift to the quantum confinement of carriers in surface-oxidized silicon nanocrystals. A blue shift in the energy of the photoluminescence peak, of up to 2.1 eV, in surface-oxidized porous silicon quantum dots was also observed by another research group when the size of the dot decreased from 3 to 2 nm [97].

These observations qualitatively comply with the effect of increasing the distance between the energy levels while the cluster size decreases. Note that such a luminescence has not been observed in bulk silicon.

Formation Energy It was experimentally determined that the energy for the formation of individual clusters depends on their size and shape. Tin nanoclusters containing from 95 to 975 atoms were formed by laser ablation of tin in a helium atmosphere [98]. For one type of tin clusters it was found that the formation energy was proportional to $(1.64 \pm 0.04 \text{ eV}) \times N^{-1/3}$, indicating compact spherical-like shapes. Another class of clusters had almost constant formation energy of 0.4 ± 0.05 eV. The theory developed for elongated neutral silicon clusters indicates [99, 100] that the surface-to-volume ratio of in these clusters is constant, which indicates that the formation energy was independent of size. It was suggested that the second type of cluster has a quasi-one-dimensional geometry. Thus, in the first type of cluster, the surface energy changes with the change in the number of atoms in the cluster, while in the second cluster type, the contribution of the surface energy to the total cluster energy is the same for clusters of different sizes. The experiments [98] clearly demonstrate the strong influence of surface energy on the formation energy of a cluster: the smaller the cluster is, the easier it is to form.

Melting Temperature: Solid-like to Liquid-like State Transition It has been demonstrated both experimentally and theoretically that the melting temperature of nanoparticles and nanorods is significantly lower than that for the bulk material (see, for example Wang et al., 2002 [101] and references therein). The melting point of platinum nanowire was found to be 400 °C [102] (the bulk value 1772 °C), while the melting temperature of 4.6-nm-thick palladium was 300 °C, which is drastically lower than the bulk value of 1552 °C [103]. Through molecular dynamic simulations [101], the melting temperature of gold helical cylindrical nanowires was found to be ~1100 K, that is, lower than the bulk value of 1357 K, but higher than that of gold nanoclusters.

Usually equilibrium melting starts from the surface and then propagates into the interior. Surface atoms have the fewer nearest neighbors and weaker binding, which may lead to a lower melting temperature at the surface than that for the bulk. Large surface-to-volume ratios and quantum size effects are the two major factors believed to be responsible for this dramatic decrease in the melting temperature of nanoclusters compared to the bulk value.

In contrast, it was found that the interior melting temperature in gold nanorods appeared to be lower than that of the atoms on the surface. Melting starts from the interior atoms, while surface melting occurs at relatively high temperature. This unique thermodynamic behavior, compared to the above description, is closely related to the helical structure of the nanorod. In this case, surface melting is responsible for the overall melting of the structure, and the effect of higher interior melting temperature entirely relates to the complicated internal structure of a rod [101].

The transition from a solid-like to a liquid-like state for finite systems, where the surface and boundary effects are dominant, is not as well defined as that for a bulk solid. The transition may exhibit the intermediate state of the coexistence of different structural phases (isomers) of the same cluster [104]. The solid–liquid phase transition in a system with a finite number of particles is described in terms

of a potential energy surface [105]. Stable clusters correspond to minima on the potential energy surface. If a cluster acquires sufficient energy, the transition from one isomeric form of a cluster to another corresponds to a "jump" over the saddle-like potential barrier separating the minima. The more liquid-like a cluster becomes (the higher the temperature and internal energy), the shorter the time for a transition from one isomeric form to another. One can define the transient state as a state when the lifetimes for the different isomeric forms of a particular cluster become comparable [104].

The lifetime of cesium halide clusters with different spatial arrangements of constituent atoms were observed using temperature-dependent photoelectron spectra and applying the pump-probe technique [104]. The clusters were produced in a laser vaporization source. A plume of laser-ablated cesium halide vapor was swept through a temperature-controlled nozzle by a flow of helium. The clusters were formed through helium–vapor interaction and then mass selected using time-of-flight mass spectrometry. The anions of desired mass were directed into a magnetic bottle, where the electrons were then detached by the action of 1- to 2-ps-long probe laser pulses, and the electron spectra were measured. Three different isomers of cesium halide consisting of four cesium atoms and three iodine atoms were identified: cube, flat ladder, and ring. The transition between these structures proceeds in the following succession: cube $\rightarrow$ ladder $\rightarrow$ ring. At a temperature $\sim$500 K, the lifetime for all three isomers become of the same order of magnitude of several tens of picoseconds. Therefore this temperature can be considered the cluster melting temperature: at this temperature all three isomers are continuously transforming to each other, thus making any particular structure indistinguishable, as in a liquid drop. From the measurements, the time for this phase transition to occur was estimated to be in the range of $\sim$100 ps. One may note that the melting temperature for the bulk cesium halide is 900 K.

Adsorption Energy Two other important microscopic parameters, which depend on the cluster size, are the adsorption energy and the bond distance of single atoms on surfaces. The adsorption energy, or energy of an interaction of an ad-atom and the surface, increases as the number of atoms decreases. Conversely, when the number of atoms in a system increases, this energy converges to the final constant value corresponding to the bulk solid [106]. For example, the adsorption energy for a copper atom on a four-atom copper cluster comprises 3.6 eV, whereas the adsorption energy saturates at 2.7 eV for clusters with a number of atoms larger than 56 [106].

5.2.3. Dielectric Function for a Single Metal Cluster

The qualitative dependence of the dielectric function of a single metal cluster on its size can be understood on the basis of simple arguments of general physics. Let us assume that the dielectric function for the metal cluster in an external electric field with frequency ω has the same form as the function for a conventional metal, for example, having the Drude form [63]:

$$\varepsilon = 1 - \frac{\omega_{\mathrm{pe}}^2}{\omega(\omega + i\nu_{\mathrm{eff}})}$$

here $\omega_{\mathrm{pe}} = (4\pi e^2 n_{\mathrm{e}}/m_{\mathrm{e}})^{1/2}$ is the characteristic electron plasma frequency, n_{e}, m_{e} are the electron number density and electron mass, respectively, and ν_{eff} is the effective frequency of electron collisions with the lattice, which is responsible for the energy dissipation. We assume that the cluster of radius R contains N atoms of a metal with one conductivity electron per atom. One can reasonably suggest that all conductivity electrons fill the whole volume of the cluster homogeneously like a jellium [2, 107, 108]. The electron number density can be expressed as $n_{\mathrm{e}} = Ne/(4/3\pi R^3)$, thus giving the dependence of the plasma frequency on the cluster size.

One can see that the energy dissipation of an external electric field imposed on a small cluster also depends on the size of the cluster. Indeed, in a nanometer size metallic sphere, the mean free path of an electron between collisions significantly exceeds the cluster diameter $l_{\mathrm{mfp}} \gg R$. Therefore, the electron can loose its energy only in collisions with the cluster. The characteristic frequency of this process is proportional to ν_{F}/R. Hence, the effective frequency of energy dissipation is $\nu_{\mathrm{eff}} \sim A\nu_{\mathrm{F}}/R$, where A is a dimensionless proportionality coefficient. It was shown that the classically derived $(1/R)$ law also follows from quantum mechanical calculations (see the thorough discussion of this problem and references by Krebig and Vollmer (1995) [107]). It appears that this law represents a fundamental quantum size effect; it also reflects the surface-to-volume ratio. These simple relations show how the optical properties of metal nanoclusters can be controlled by their size, which suggests many applications. We should note that the dielectric function of a single isolated cluster has not yet been determined experimentally.

5.2.4. Static Polarizability of a Single Metal Cluster

From the viewpoint of classical electrodynamics [63], a metal sphere in an external static electric field E acquires an induced dipole moment $P = R^3E$, which is proportional to the volume of the sphere. However, close consideration of the dipole moment even in frames of a simple jellium model shows that electrons are spilled out of the cluster boundary (defined as $R \sim N^{1/3}$) at a distance δ, depending on the nature of the metal. Usually, this distance is $\delta \sim 1.3$–1.5 Å. Thus, the nanocluster dipole moment is expressed as $P = (R + \delta)^3 E$. These estimations, in the frame of a simple jellium model, are well supported by quantum mechanical calculations [107]. The important conclusion follows that the small metal sphere possesses a polarizability larger than that predicted by classical electrodynamics due to the effective increase in the cluster radius caused by spilling out the electric charge. The change in polarization can be controlled by the size of the particle. This effect was observed experimentally [2] with reasonably good agreement with the theory.

5.2.5. Shell Model for a Simple Metal Cluster

The abundance mass spectra of alkali metal clusters produced and detected by Brack (1993) [108] revealed a striking feature: clusters with a particular mass value, containing a specific number of atoms—"magic numbers"—appeared to be much more abundant in comparison to the average mass of the clusters produced. It is established now that this characteristic abundance pattern holds up even for clusters containing several thousand atoms [2, 108]. It was recognized that the abundance pattern reflects the electronic structure of the cluster and is indicative of the most stable clusters. Clusters of metal atoms are considered a unified edifice having a common electronic structure, with all valence electrons belonging to all constituent atoms and filling corresponding shells that are characterized by specific quantum numbers for such an edifice as a whole. Therefore, maxima in the mass abundance spectra have been identified as clusters with closed electronic shells. Just as for atoms, the electronic system of a cluster with exactly the right number of electrons to complete a shell is very stable. If one more atom is added to a cluster with a closed shell, the valence electrons of this extra atom will occupy the higher energy state, and hence the stability of the new cluster is reduced. The reduced stability is reflected in reduced abundance, which explains the experimentally observed drops in the cluster abundance spectra after each shell-closing number [2]. The theory also predicts that closed-shell clusters have a spherical shape, while open-shell clusters are significantly distorted. Molecular dynamics and quantum chemical calculations later supported the initial simple theories, revealing fundamental physical features of the shell model. The theory of the cluster shell model is now well developed, with many predictions experimentally confirmed (for comprehensive review, see de Heer (1993) and Brack (1993) [2, 108] and references therein). While it is difficult to determine the cluster size and shape experimentally, through measurements of the optical properties of the clusters it is possible to make some conclusions about the influence of shape on the properties of the clusters.

5.2.6. The Affinity between the Internal Structure, Material Properties, and Formation Conditions of Nanoclusters

The discovery and studies of new nanostructured carbon phases, such as fullerenes [19, 51] and nanotubes [20, 21, 56], has opened a new era in materials science. It has been discovered that minute changes in the spatial arrangement of carbon atoms in the space scale of tens of angstroms can profoundly change the electronic properties of these systems from a semiconductor to a metal [110, 111], from a conductor to a superconductor [112, 113], and even from diamagnetic to ferromagnetic [114], with a drastic difference from the bulk properties of graphite, diamond, or amorphous carbon. One could expect that structural rearrangements at the nanometer scale might also change the properties of other materials in ways similar to those with the carbonaceous structures. To date thorough studies have been performed with carbon nanoclusters. Below we concentrate on structural and material properties in connection with the relevant formation conditions of carbonaceous clusters and clustered films.

Laser ablation was used to generate carbonaceous nanoclusters under different experimental conditions: in the ambient gas at different pressures; with additional gas heating; and with different catalysts. A broad variety of different nanostructures have been created which now form the family of "fullerenes." This family includes single-shell fullerenes, C_{60} and C_n [19], multiwalled hollow nanoparticles (fullerene onions), single-wall and multishell carbon nanotubes [20, 21, 29, 56], hypothetical carbonaceous structures with negative curvature [115–118], carbon nanohorns [119], and carbon nanocones [120]. Both the nanocluster formation energy and kinetic factors define the formation conditions and therefore the abundance of the particular nanocluster [118, 121]. The primary product of the interaction between the laser-produced plume and a noble gas is a complicated network of different nanostructures mixed together and interconnected. In order to study the individual nanotubes the meticulous processes of separation and purification of the primary material are used [21]. Another method of cluster selection and separation is to preionize the clusters using a special short-wavelength laser and then to selectively remove clusters with an applied electric field [2, 3, 45, 122].

Cage-like Structures A plume of carbon atoms and ions ejected during the laser ablation of a graphite target was made to interact with a noble gas buffer [45, 122]. Carbon clusters created in such an interaction were then detected by a mass spectrometer. The measured abundance spectra may be regarded as an accumulated "snapshot" of salient features in the nucleation and growth of carbon clusters in a time sequence. A typical mass spectrum of positively charged clusters is bimodal [45, 122]. The peaks in the mass abundance spectra correspond to clusters of enhanced stability. The maximum in the first group of clusters ($n < 30$) corresponds to clusters comprising 11 carbon atoms, while the maximum in the second group ($30 < n < 100$) relates to the famous fullerene, C_{60}, molecule consisting of 60 carbons [19, 122]. Any closed-shell-like exclusively carbon cage is referred to as a fullerene [123]. The fullerenes are viewed as graphitic sheets distorted by inclusions of topological defects, such as five-membered rings, or pentagons. The simplest ball is a pentagonal dodecahedron comprising 20 carbons. The appearance of a pentagon is the signature of a curved surface with positive Gaussian curvature. C_{60}, which is the most stable, and central to the fullerene family, consists of 12 pentagons and 20 hexagons.

The range of clusters is composed of one- and two-dimensional structures (linear and ring clusters, $n = 3$–20) along with three-dimensional clusters, like the closed cage of the fullerene molecule. Multiwalled hollow nanoparticles (nested fullerenes or onions) can be also formed under similar conditions [123]. All these clusters are formed in an almost homogeneous mixture of carbon and noble gas atoms at pressures of several hundred Torr and temperatures of 1000–2000 K. The estimates of the scale of the temperature for fullerene formation may be made from the self-energies of nanoclusters [118, 121]. The additional energy that it is necessary to spend for fullerene formation, in comparison

to the flat graphite sheet, ranges from 0.6 to 0.4 eV/atom [118, 121]. This means that the optimum temperature for the formation of such clusters can be in a range of several thousand degrees Kelvin. This estimate qualitatively complies with the experimental measurements.

The relative population of a particular cluster is governed by cluster growth kinetics. In turn these kinetics depend on the transient partial number density of carbon atoms in the carbon–noble gas mixture and the transient temperature in the cluster formation zone. Therefore, one can conclude that under isotropic conditions, no cluster of preferential symmetry can be formed but only the simple clusters, or clusters with a high symmetry of the order 5 and 6, like fullerenes.

Carbon Nanotubes Another carbon nanocluster, the nanotube, is also produced by laser ablation at high pressure in an almost homogeneous mixture of carbon atoms, noble gas atoms, and a metal catalyst at a temperature of around 1000–2000 K. The required optimal ambient gas pressure was found to be around 500 Torr for the formation of carbon nanotubes, while at 100 Torr the efficiency of carbon nanotube formation was drastically reduced. Carbon nanotube can be imagined as a graphitic sheet rolled up and stitched without seams. Therefore, nanotubes consist entirely of sixfold rings, hexagons. The straight nanotube possesses an axial symmetry, which is apparently absent in the zone of formation. However, it was observed that carbon nanotubes formed in a homogeneous carbon–noble gas mixture were only formed in the presence of metal catalysts at a concentration of ~1% of the total carbon content. These catalysts are usually transitional metals, such as cobalt, iron, or nickel or a mixture of them. Thus, there is strong experimental evidence that a catalyst is responsible for the formation of axially symmetric structures. It may be that catalytic particles are either atoms or metallic clusters containing many atoms; however, there is no thorough theoretical explanation of catalyst action in the formation process.

Nanotubes in general are helical, meaning that the tube is twisted around its axis. In the spirit of defects and energy arguments, one can assume that tubules grow helically with the introduction of a screw dislocation, as metal "whiskers" grow [113]. The theory shows [110, 111] that a chiral tube can be generated in such a way that no distortion of bond angles is introduced. This distortion relates only to the cylindrical curvature of a tube. Helicity is responsible for one of the most striking properties of nanotubes. Depending on chirality one third of the tubules will be metallic and two thirds semiconducting. The existence of metallic and semiconductor nanotubes has been observed experimentally [124]. Raito et al. [111] have suggested that a large fraction of metallic tubules might be formed if the initial seed for the tube cap is centered around a pentagon. However, the proper conditions for the preferential formation of such seeds needs to be formulated. These properties imply many important applications in the future. For example, one can imagine nanometric conducting wires, microscopic metal–semiconductor devices for nanoelectronics or photonics, and many other possibilities. Nanotubes also possess extraordinary strength, with the highest Young modulus of all known materials. This was deduced from the observation of temperature vibrations of freestanding tubes in a transmission electron microscope [125].

It follows from molecular dynamics calculations and a simple elasticity approach [118, 121] that the energy necessary for the formation of tubes consists entirely of the energy required to bend a graphite sheet into a tube, which is ~0.2 eV per carbon atom. Comparison to the fullerene self-energy implies that the tubes are more stable than fullerenes. Another conclusion is that the temperature required for nanotube formation may be somewhat lower than that for the creation of fullerenes and may be around 2000 K, which qualitatively complies with the experimental data presented in Section 2.

Structural Units of Carbon Nanofoam According to theoretical predictions [115–118], hypothetical carbonaceous structures with negative, or hyperbolic, Gaussian curvature, branded "schwarzite," are more complex than fullerenes (elliptic curvature) and buckytubes (parabolic curvature). Sevenfold rings (heptagons) are the topological elements (disclinations) responsible for the generation of schwarzite structures. The exact shape of a single negative disclination is not yet known; however, calculations show that heptagons, in terms of local structure, are energetically less costly (more stable) than pentagons, with the self-energy per carbon in a range of 0.1–0.15 eV/atom [118, 121]. This also means that the temperature conditions for hyperbolic structure formation may be close to those for carbon nanotubes. It has been suggested that the complicated spatial structure of schwarzites might result in unusual electronic properties.

Recently, low-density cluster-assembled carbon nanofoam was produced by laser ablation of glassy carbon in an argon-filled chamber at a pressure range of 0.3–1 Torr [37, 114]. Diffusion-limited aggregation of carbons in the carbon–argon mixture and the subsequent fast quench resulted in a unique, fractal, all-carbon foam deposited on a substrate. Preliminary studies revealed the presence of a hyperbolic schwarzite structure, rather than the expected nanotube-like structures. The foam structure was characterized by scanning electron microscopy, transmission electron microscopy, HRTEM, small-angle X-ray scattering, Raman spectroscopy, EELS, Rutherford backscattering, and surface-area measurements [37, 54, 114]. These studies revealed that the foam is made of a web-like fractal network of randomly interconnected clusters, 6–9 nm in diameter, as can be seen in Figure 8. HRTEM images demonstrated that individual clusters possess an internal periodic structure with a period of ~5.6 Å. The spatial variation of sp^2/sp^3 bonding across a single cluster was mapped using a PEELS with a spatial resolution of 1 nm [37]. These results indicate that sp^2-bonded carbons prevail in the core region of clusters, whereas sp^3-bonded carbons dominate near the cluster boundary. The measured high dc resistivity of the foam suggests that these sp^3-bonded carbon atoms are responsible for sticking the clusters together.

The most salient property of the foam is its unusual magnetic behavior. The freshly produced foam is strongly attracted to a permanent magnet, just like a metallic dust, which demonstrates the existence of an intrinsic positive magnetic moment. Only the structural rearrangement of carbon atoms in the foam can be a reason for the dramatic change in the magnetic properties of this all-carbon system. Electron spin resonance measurements gave the density

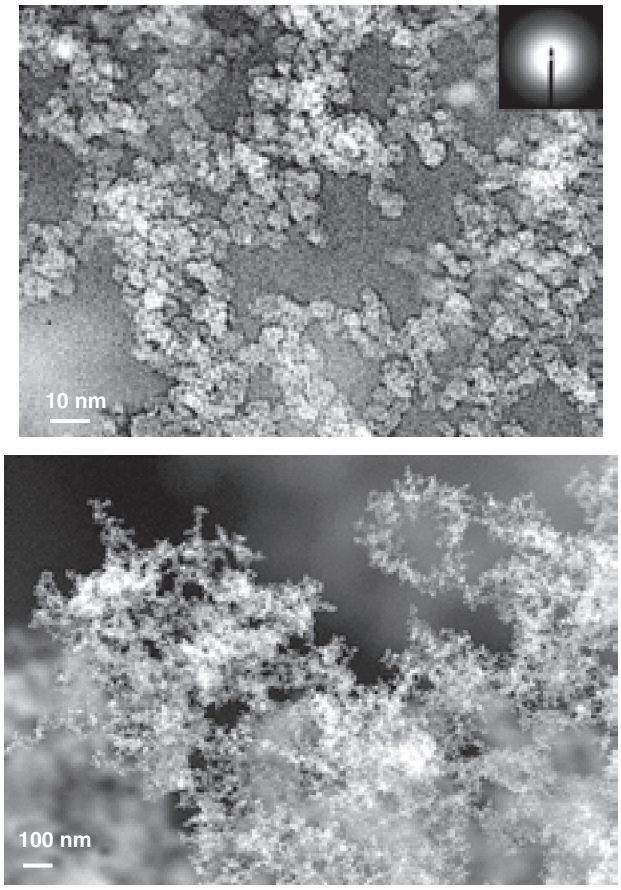

Figure 8. Transmission electron micrograph of carbon nanofoam (left) showing that the foam is assembled from 6-nm clusters. The SEM image (right) shows the web-like structure at lower magnification.

of unpaired spins up to 1.5×10^{20} spins per gram, or one unpaired spin per several hundred carbon atoms.

The ferromagnetic behavior exhibited by the new phase of carbon is extremely unusual in comparison to all known allotropes of carbon. Graphite, diamond, fullerenes, multiwalled carbon nanotubes, and single-walled carbon nanohorns possess a diamagnetic susceptibility in the range of -10^{-5}–10^{-6} emu/g. It seems natural to suggest that the observed ferromagnetic behavior can be traced to the complex microstructure of the foam.

The origin of magnetism in cluster-assembled carbon foam has been theoretically studied using a geometry which contains hyperbolic, negatively curved surfaces [114]. The basic structural unit is a tetrapod that exhibits many of the structural features observed in experiments. The core structure consists of warped sp^2-bonded carbon segments terminated by sp^3 carbon atoms at the hydrogen-passivated edges of the four extremities. In a tetrapod, like in other schwarzite-related structures, tubular segments of 0 Gaussian curvature coexist with convex segments of hyperbolic, saddle-like regions of negative Gaussian curvature. The radius of curvature in this basic unit is close to 6 Å, which is consistent with the superstructure found in the diffraction pattern. The tetrapod-like building blocks can be assembled into a rigid foam structure with a very low density that compares to the measured density of 2–20 $\mu g/cm^3$. The threefold coordinated carbon atoms in the sp^2 regions form a network of hexagons and heptagons only. These trivalent carbons are sterically protected within the system of single and double bonds imposed by the sp^3-terminated tetrapod and occur in groups of three. The number of unpaired spins was found to be robust with respect to size and boundary shape variations within the tetrapod. However, this number depends sensitively on the bonding topology in the regions of the negative Gaussian curvature. Subclusters (tetrapods) containing 264 and 336 carbon atoms have been considered, and the predicted magnetic moment in a C_{264} tetrapod agrees well with the experimental observation.

This is the first time to our knowledge that trivalent carbon radicals embedded into hyperbolic surfaces have been identified in an undoped all-carbon nanocluster prepared under specific conditions by laser ablation. Stabilization of carbon radicals by steric protection has been known since the synthesis of triphenylmethyl by Gomberg in 1900 [126].

The ferromagnetism found in these complex nanoclusters occurs as a consequence of nanometer-sized conducting segments containing atoms with different electronic configurations. It appears that a careful preparation of conditions for nanocluster formation by laser ablation may lead to similar changes in the structural and electronic properties of different materials.

Fractal Nanoclusters Nucleation of a new phase is one of the processes where the fractal nature of the object often manifests itself. The generally accepted models for cluster growth include diffusion-limited aggregation, cluster–cluster assembling, homogeneous nucleation by monomer addition, and others. All the models assume that the nucleus, the seed of the new phase, has a spherical shape on which the further assembling of the structure occurs. Experimental evidence has been presented by Zenkevich et al. [127] which shows that gold clusters of ~5 nm in diameter have a fractal structure with fractal dimension of $D = 1.33 \pm 0.08$. These clusters were deposited on the surface of highly oriented pyrolitic graphite by laser ablation using an Nd:YAG laser with the following parameters of ablation: $\lambda = 1.06$ μm; 15-ns pulse duration; 25-Hz repetition rate; average intensity $\sim 10^9$ W/cm. The authors [127] suggested that the shape and dimension of the clusters are determined by the rate at which atoms arrive at the surface where the formation occurs and by the symmetry of this surface. It was proposed that the formation of clusters proceeds under highly nonequilibrium conditions by the attachment of an ad-atom to the fractal nucleus.

6. CLUSTER-ASSEMBLED MATERIALS

With the laser technology that is currently available, it is possible to ablate any existing material—refractory metals, complex composites, and dielectrics—if the laser parameters are chosen according to the properties of the material. The proper choice of laser parameters and conditions in the experimental chamber (pressure of the ambient gas or vacuum) defines the mass distribution in a cluster flow. The size of the clusters produced ranges from several atoms to tens of thousands of atoms per cluster. Clusters then can be deposited on a substrate to form a cluster-assembled film [3].

Films of clusters embedded in various codeposited matrices have been produced [128]. Very often such a film possesses material properties drastically different from those in the bulk of the initial material.

Cluster networks can be classified into two categories [5]. The first one comprises clusters embedded in a host matrix and well separated from each other. The properties of such structures depend on the properties of the individual clusters and that of the host matrix. The dielectric properties of the cluster-embedded composites depend on low and easy-to-change filling factors (~0.01 vol fraction of clusters) and on cluster-to-cluster contacts and connections. The second category includes cluster networks—sponge, froth, or foam-like structures—with properties which are drastically different from those of isolated clusters and which strongly depend on intercluster connections and interactions.

6.1. Cluster-Assembled Films

The flow of nanoclusters hits a substrate and starts building a deposit. First of all we shall distinguish between cases when the cluster-assembled film grows on a substrate in a vacuum [3, 32, 33] and in a noble gas-filled chamber [37, 83, 84, 114].

Molecular dynamics simulations of film growth by energetic cluster impact in a vacuum have shown the influence of cluster energy on the morphology of the film [129]. It is now widely accepted that the energy of a cluster must be sufficiently low in order to prevent the splitting of a cluster during cluster–substrate impact. The straightforward idea of "random paving" on a substrate seems to be in contradiction to experiments: it appears that film morphology depends on the cluster size [128]. Indeed, gold, antimony, and silver clusters, comprising 250–300 atoms, 2 nm in diameter, form large branched and well-separated islands with definite long-range order when deposited on a graphite surface.

The presence of an evaporation cell in the deposition chamber allows the production of films with clusters embedded into different matrices. Harbich et al. [130, 131] produced films of mass-selected metal clusters (Ag_n and Au_n) embedded in various solid matrices of Ar and Kr using this technique.

Gold clusters, comprising 250–300 atoms, embedded in various matrices (SiO_x, LiF, and MgF_2) are randomly distributed over a film surface. It was demonstrated that the cluster volume fraction of Au clusters embedded into a SiO_x matrix can be easily changed from 2 to 11% [128]. Therefore, films with variable dielectric function can be produced for a range of optical applications.

Another interesting application relates to the deposition of transitional metal clusters onto different substrates to produce magnetic films for high-density memory devices and spin electronics. Films with the size-controlled clusters of iron, cobalt, and nickel have recently been produced [128]. The incident free cluster size distributions were centered on Fe_{150}, Co_{300}, and Ni_{300}. Cluster-assembled films with thicknesses up to 100 nm were produced. These films have a granular structure with a grain size of 3–5 nm, slightly larger than the size of the incident cluster size resulting from the diffusion and coalescence of clusters.

Cluster-assembled films about 100 nm thick were produced with carbon cluster beams. The mass distribution in the beams was centered on C_{20}, C_{60}, and C_{900}. These films have a highly porous nanostructured morphology resulting from a random stacking of incident clusters. The density of the films is around 1 g/cm^3, which is much lower than that of conventional carbonaceous structures. The most interesting structure appears to be C_{20} "amorphous" film with a short-range order of 15 nm, with pure sp^3 hybridization and the absence of any long-range order.

Similar films were produced with silicon cluster beams with the size distribution centered on Si_{50}. It is suggested that the presence of a large number of pentagons may significantly change the electronic structure of the clusters. These silicon films also have a granular structure and they are highly porous. The most unusual feature of these films is a strong visible luminescence at ~750 nm comparable to that seen in porous silicon and recently observed in 3.5-nm silicon clusters [83, 84].

6.2. Magnetic Properties of Cluster-Assembled Films

Monodispersed cobalt nanoclusters, with cluster sizes varying from 300 to 9000 atoms, were produced by the cluster-beam technique [132]. These clusters were embedded in Cu and SiO_2 substrates, where the cobalt volume concentration varied from 10 to 50%. The magnetization of cobalt in such structures is always lower than the bulk value. This magnetization increases with increasing cluster size and decreases with increasing Co concentration for a given cluster size. Calculations of intercluster exchange interactions are used to qualitatively explain the magnetization data as a function of Co concentration in good agreement with the experimental results [132].

6.3. Nonlinear Optical Properties of Cluster-Assembled Films

It was found [133] that Si films deposited by laser ablation exhibit a nonlinear refractive index change, as high as $\Delta n = -0.5$ at a wavelength of $\lambda = 532$ nm for films with an average thickness of 200 nm. These films consist of large droplets composed of crystallites with hexagonal wurtzite symmetry and with nanoclusters interspersed between them. The crystallographic symmetry of these droplets was observed with Raman spectroscopy, as well as linear and nonlinear optical measurements, when the films were annealed under various conditions. The authors attribute the large nonlinear refraction coefficient to the hexagonal wurtzite symmetry of the crystallites, which raises the possibility of developing very efficient nonlinear optical devices [133]. However, the origin of this nonlinearity is not fully understood.

6.4. Electrical Conductivity of Nanoclusters and Cluster-Assembled Materials: Quantum Charge Transport and Localization

Another interesting property of the nanocluster-assembled system relates to electrical conductivity. It appears that the "conductivity quantum," or conductivity scale of $2e^2/h$, plays

an important role in the electric conductance through the "bottle necks" connecting the nanoclusters in the cluster-assembled systems. Simple scaling illustrates the appearance of the "conductivity quantum" or "resistance quantum," h/e^2, when one considers the charge transport at the atomic space and time scales. The motion of electrons with charge e, mass m, and number density n in an applied electric field E of high-frequency ω generates the current density

$$j = en\nu \approx \frac{e^2 n}{m(v + i\omega)} E \equiv \sigma E$$

This is Ohm's law, where v stands for the electron collision frequency responsible for the energy dissipation (or resistance $1/\sigma$). The full current, $I = jS$, flowing through the sample with a cross section S, and length L, and containing a total number of electrons $N = nSL$, can be presented in the form

$$I \approx \frac{e^2 N}{mvL} E \approx \frac{e^2 N}{mvL^2} V$$

We assume $\omega \ll v$, which always holds for metals, and $E \propto V/L$ (where V is a potential). The resistance R, can be expressed as

$$R \approx \frac{NV}{I} = \frac{mvL^2}{e^2}$$

Considering all parameters at atomic scales, that is, taking the collision frequency as the same order of magnitude as the atomic frequency, $\nu \cong e^2/a_B$, and $L \cong a_B$, where $a_B = \hbar^2/me^2$ is the Bohr radius, one obtains the quantum unit of resistance as

$$R_0 \approx \frac{\hbar}{e^2}$$

This unit comprises 2.5812×10^4 ohm. Most probably this value of conductance (resistance) separates two different regimes of high and poor conductivity, giving the percolation and localization regimes [134].

The conductivity in nanowires of atomic dimension behaves in the jump-like manner of quantum charge transport. The electrical conductivity of small silicon clusters ($n =$ 1–10, 13, 20) placed between atomistic aluminium and gold leads has been investigated using the *ab initio* nonequilibrium Green's function formalism [135]. All clusters display metallic conductance ranging between one and two quantum units, $2e^2/h$. The transport properties of these cluster junctions may be understood in terms of both the band structure of electrodes and the electronic states of the cluster, modified by the lead environment and size effects. The resistance in this system is $R \sim R_0$.

Carbon nanofoam composed from well-defined carbon clusters of 6–9 nm in diameter, randomly interconnected in a web-like fractal structure, demonstrates a different limit case for conductivity [49]. The resistivity of the as-deposited foam, measured in the voltage range ± 100 V, demonstrates nonlinear current–voltage characteristics with strong hysteresis. The resistivity of the foam after annealing is equal to $1–3 \times 10^9$ Ω/cm at room temperature and $1–10 \times 10^{13}$ Ω/cm at 80 K, which is similar to that of amorphous diamond-like films. Thus, resistance of the foam exceeds R_0 by many orders of magnitude. One can assume that the electrons in a foam are strongly localized in nanoclusters, and the electron conductivity has a tunneling character.

6.5. Photoluminescence in GaAs Nanoaggregates

Laser ablation of a single crystal GaAs target in a vacuum or Ar gas has produced nanoclusters of GaAs [136]. Atomic force and transmission electron microscopy have shown that most of the clusters were spherical, with diameters in the range of 1 to 50 nm, with a peak size distribution between 5 and 9 nm, depending on the Ar gas pressure or laser fluence. X-ray diffraction, solid state nuclear magnetic resonance, Auger electron spectroscopy, electron energy-loss spectroscopy, and high-resolution transmission electron microscopy revealed that these nanoclusters were randomly oriented GaAs crystallites. An oxide outer shell of $\sim$2 nm subsequently developed on the surfaces of the nanocrystals as a result of transportation of the cluster in air. Unpassivated GaAs nanoclusters exhibited no detectable photoluminescence. After surface passivation, these nanoclusters displayed photoluminescence energies less than that of the bulk GaAs from which they were made. These experiments suggest an abundance of sub-bandgap surface states in GaAs nanocrystals. Thus, this kind of nanocluster with a surface layer demonstrates that a decrease as well as an increase can be achieved with transition from the bulk to the nanoscale level. Such changes in the photoluminescence energy were similar to that observed with silicon clusters [83, 84].

7. PERSPECTIVES ON LASER ABLATION FOR CONTROLLABLE PRODUCTION OF NANOCLUSTERS

Laser ablation has proven to be an efficient and flexible tool for the production of a large variety of novel nanoclusters with remarkable properties. These novel nanostructures include fullerenes, carbon and boron nitride nanotubes, magnetic nanofoam, metal clusters, silicon clusters, and a variety of cluster-assembled films and nanofilms. It is clear that this is only the beginning; many different and complex clusters can be created and tested for future applications. Generation of nanoclusters by laser ablation is already a well-controlled process where the ablation rate, temperature and ionization states of the ablated atomic flux, and the conditions of the laser plume and ambient gas interaction can be controlled with high precision. Moreover, it is now clear that control over these processes in time and space can be significantly improved by the use of short laser pulses, as short as a few femtoseconds, and high repetition rate (up to hundreds of megaHertz) lasers. There are also some obvious extensions for the use of laser ablation for simultaneous coevaporation of several different targets for deposition of complex films or preparation of unusual composites and alloys. The same technique can be used for the preparation of multilayered systems consisting of nanometer-thick layers of different materials, which may be regarded as a one-dimensional analog of cluster-assembled films.

Nanoscience and nanotechnology are still in their infancy. However, one can easily foresee many short-term and long-term applications for nanoclusters and cluster-assembled structures.

The obvious short-term applications for cluster networks are in catalytic devices, systems with unusual and variable dielectric properties, and layers with controllable heat conduction. However, there will be also many long-term applications for nanoclusters, for example, as part of future nanodevices for nanoelectronics, nanophotonics, and spintronics. We may also mention nanowires of carbon nanotubes, nanometric metal–dielectric junctions, and ultra-low-capacitance devices comprising one or several nanoclusters, Coulomb-blockade structures where one-by-one passage of a single electric charge between two neighboring particles can be regulated.

The pulse duration, the intensity on the target surface, and the repetition rate can be precisely controlled in laser ablation, so precise and improved control over the ablated vapor can be achieved. Using lasers one can control heating and annealing rates on a space scale of micrometers and a time scale of femtoseconds. This improvement in the control of cluster formation conditions leads to realization of the atom-to-atom attachment mode of nanocluster building, increasing the possibilities for control over the cluster size and the internal structure of a cluster. Laser ablation is also a route for creating metastable allotropes of known materials where the unusual internal structure determines new material properties such as were seen in conducting carbon nanotubes or paramagnetic all-carbon nanofoam.

Laser ablation has demonstrated the highest deposition rate in the production of thin films, of $\sim$10 μm/h [73, 75], and the highest rate of production of a nanofoam of 1 cm^3/min. If lasers can be made cost effective and manageable under industrial conditions, then the industrial production of nanostructures with the use of lasers is a distinct possibility in the near future.

Indeed, there is still a "plenty of room at the bottom" and lasers will help to fill it with new and amazing nanostructures.

GLOSSARY

Ad-atom An additional atom attached to a nanocluster.

Adsorption Process of attachment of ad-atom to a structure.

Atomized flow Plume or cloud of atoms created by laser ablation.

Binding energy The energy necessary to separate atoms from a molecule. It equals to the energy of vaporisation per atom.

Critical cluster size The cluster size (or critical number of atoms in a cluster) at which the material properties of a nanocluster approach to those for the bulk structure.

Femtosecond, picosecond, nanosecond Time units, respectively, 10^{-15} s, 10^{-12} s, 10^{-9} s, used to characterise fast laser-matter interaction processes such as laser ablation and nanocluster formation.

Laser Abbreviation of the "light amplification by stimulated emission of radiation." Modern lasers are capable of transformation of any of existing materials to atomic state.

Laser ablation Removal of material from a surface by means of laser irradiation. The term 'laser ablation' is used to emphasize the non-equilibrium vapour/plasma conditions created at the surface by intense laser pulse, to distinguish from 'laser evaporation,' which is heating and evaporation of material in conditions of thermodynamic equilibrium.

Nanoclusters, or Nanoparticles Aggregates of atoms or molecules containing between a few and a few thousand atoms that have properties drastically different from those in bulk. The size of nanoclusters is in the range of 1–100 nm (1 nanometer = 10^{-9} m). Nanoparticle behaves as a large atom with discrete energy levels. With a decrease in cluster size the ratio of the surface to volume increases, and the surface phenomena dominate the electronic and optical properties of a cluster.

Nanocluster-assembled film Films formed by clusters of desirable size and mass deposited on a substrate, or film of clusters embedded in various co-deposited matrices.

Nucleation An initial process of cluster growth (formation of nucleus or seed) inside an atomic mixture by aggregation of atoms and clusters.

Quantum charge transport The jump-like behaviour of charge transport between the nanoclusters connected by a "bottle neck" that contains a few atoms. It can be associated with a motion of a few single charges.

Quantum-size effects, quantum confinement The changes in electronic and structural properties as the size of the system decreases to the nanometer scale where quantum effects become dominant—the energy bands split into energy levels.

Self-assembly Formation of nanostructures from an atomic mixture where atoms bond due to inherent tendency of molecules and molecular clusters to interact and organize themselves into structures.

Shell model for cluster electronic structure The cluster is a unified edifice (somewhat similar to a big "atom") having electronic structure with all valence electrons filling the common "shells." Filled shells correspond to most stable clusters. Maximums in the mass abundance spectra correspond to the clusters having the closed electronic shells.

"Sticky" collision Inelastic atomic collision resulting in bonding of atoms.

ACKNOWLEDGMENT

The authors acknowledge Dr. D. Golberg for providing HRTEM photographs of single wall carbon nanotubes for the present review. The authors are grateful to S. T. Hyde, A. G. Christy, and D. Tomanek for many useful discussions, and to K. Gamaly for careful proofreading of the manuscript. E. G. G. acknowledges the assistance of the Australian Research Council under the ARC Centers of Excellence program through the Centre for Ultrahigh bandwidth Devices for Optical Systems (CUDOS).

Nanostructures Within Porous Materials

Y. Kumzerov, S. Vakhrushev

Ioffe Physico-Technical Institute, St. Petersburg, Russia

CONTENTS

1. INTRODUCTION

The experimental implementation of new effects in the physics of nanostructures relies upon our ability to create new types of structures and devices. Our understanding of material processing in the pursuit of ultrasmall structures is steadily advancing. Epitaxial growth and lateral microstructuring techniques have made it possible to create low-dimensional electronic systems with quantum-confined structures, that is, quantum wells, quantum wires, and quantum dots. Nanostructures can also be obtained by confining a solid or a liquid within nanometer-sized pores of various porous materials. There are a lot of materials that incorporate into their structure systems of voids (nanometer pores), and, what is more, we may say that virtually all materials have some porous structure if they are not single crystals. When we fill such a porous material with some substances, we may prepare some types of nanostructures. Systems with nanoparticles embedded in a porous matrix via chemical coating have received some attention in recent years. In this case, the confined liquid materials penetrate into the pores by means of wetting processes. In the case of nonwetting there is a possibility of using a mechanical coating of inner surfaces of porous materials by forcing a nonwetting liquid into the pores by external pressure. The material coating the inner surfaces of the pores in different porous matrices may be of interest as a physical object with characteristic nanometer sizes, that is, some new types of nanostructures. We emphasize some advantages of such nanostructures:

1. It is possible to prepare nanostructures with a large range of characteristic sizes (from approximately 1 nm to approximately 200 nm).
2. It is possible to prepare nanostructures with various geometries (two-dimensional (2D) film-like structures, 1D wire-like structures, 0D small particle-like structures).
3. It is possible to prepare nanostructures from various substances (metals, semiconductors, insulators, etc.).
4. It is possible to prepare nanostructures with a very large amount of nanomaterial (up to several cubic centimeters). This situation permits the use of some experimental methods (e.g., neutron scattering, heat capacity measurements, etc.) that require a large amount of nanostructures.

It seems that such nanoobjects are similar to the well-known nanocomposite materials, used very widely nowadays, and in some situations it is not so simple to distinguish them. We mean that nanocomposites are rather 3D objects demonstrating new special properties owing to some interaction or combination of properties intrinsic to the nanoporous matrix and to a substance introduced into nanopores. In the case of nanostructures within nanoporous matrices, we are mainly interested in the properties of a substance in nanovoids and take into account the porous matrix virtually only as some external support for such a nanostructure.

Recently there have been a lot of investigations (more than 500 in the past 10 years) that can be considered to be concerned with nanostructures of this kind. At the same time, there are no reviews describing various aspects of the physics of nanostructures within porous materials. The objective of this chapter is to fill the gap in the existing literature.

This chapter is organized as follows. Examples of nanoporous matrices are presented in Section 2 with some descriptions of their porous structures, including characteristic sizes of nanopores, distributions of characteristic sizes of nanopores, relative volumes of nanopores, etc. Section 3

Edited by H. S. Nalwa
Volume 7: Pages (811–849)

describes some methods for the preparation of nanostructures within nanoporous matrices, including mechanical methods for which such a characteristic as wetting is very important, and some chemical methods, electrochemical methods, etc. Section 4 is devoted to various nanostructures based on nanoporous matrices and to physical properties of such nanostructures and possible applications.

2. POROUS STRUCTURES

2.1. Porosity

The "porosity" of a solid material means the existence of some free volume inside its structure that is not occupied by structural elements of this material. Such a porous volume can be divided ambiguously into elementary porous structures—pores, which may differ in their characteristic sizes, types of shape, and types of connections. They may be organized as an open porous system as to be isolated. The possibility of having different chemical compositions, different structural units, and different origins of porosity leads to a very large diversity of porous structures. The porous structures can be conventionally divided, according to their genesis, into two large groups: systems based on a composition of some solid elements with porous space situated between these elements and those based on extraction of some part of structural elements due to decomposition, dissolution, or leaching from a bulk nonporous material. Examples of the first group are tissues, paper, granules of sorbents and catalysts, porous ceramics, crystals of zeolites and chrysotile asbestos, etc. Examples of the second group are dry hydrates of metals, carbonized and activated coals, porous glasses, porous membranes, etc. The general characterization of a porous system is determined by the characteristic sizes of its pores and by geometrical factors. There are porous systems with strongly regular alternation of identical pores connected through identical channels and those in which the characteristic sizes of pores, their arrangement, and connections are stochastic.

The quantitative characterization of porous materials can be based on:

1. The porosity of a porous system ϕ, which can be defined as the relative volume of the porous space, that is, the volume of the porous space, V_0, divided by the total volume V: $\phi = V_0/V$. The relative volume of the nonporous skeleton is in this case $1 - \phi$. Occasionally, such a parameter as $\phi/(1 - \phi)$ is used to estimate the porosity. For the existing porous materials the value of ϕ may vary between virtually 0 to approximately 0.9.
2. The characteristic sizes of pores, which reflect the typical effective sizes of cross sections of the empty porous space and are the most important parameters controlling the main processes in a porous medium. To have a simple parameter, the complicated form of the porous space can be reduced to the simplest geometrical figures with some equivalent parameters (spheres or cylinders with characteristic diameters, etc.). According to the regulations of the International Union of Pure and Applied Chemistry (UIPAC) porous materials are named according to their characteristic pore sizes: submicroporous (diameter less than 0.4 nm), microporous (diameter in the range 0.4–2 nm), mesoporous (diameter in the range 2–50 nm), and macroporous (diameter exceeding 50 nm).
3. The size distribution of pores. This characteristic is often stochastic and can be determined through such a function as the density of diameter distribution $f(D)$, where $f(D)\,dD$ is the probability of finding pores with diameters in the range of D to $D + dD$ in the unit volume of a porous material. Naturally, $\int f(D)\,dD = 1$. There is a more practically interesting function $V(D)$—the distribution of the porous volume over diameters. $V(D) = \int (D^2/D^2) f(D)\,dD$, where $D^2 = \int D^2 f(D)\,dD$.
4. The inner surface of a porous material, which corresponds to the area of the interface between the porous space and the skeleton of the matrix. It can be defined as the relative surface S, that is, the internal surface area per unit mass or unit volume of a porous material (measured in m^2/g or m^2/cm^3). For different porous materials, S may vary between about 10^{-2} and about 10^3 m^2/g.

Naturally, real porous objects mainly have irregular and stochastic systems of nonidentical voids with parameters that are very difficult to calculate. In this case, a usual way to describe them is associated with attempts to reduce the porous system to various geometrical models. A simple variant is to reduce porous materials to systems of spheres, modeling the skeleton of a porous matrix, in which the empty space between these spheres is modeling the real porous space. In the simplest case of identical spheres with regular packing, the needed parameters are only the sphere radius R and the coordination number n, characterizing the density of packing. In this case, the main parameters for a porous medium can be found as [1]

$$\phi = \frac{2.62}{n}; \qquad S = 3(1 - \phi)R^{-1} \tag{1}$$

Unfortunately, the simplest geometrical models cannot describe the topologically complex space of real, irregular porous matrices. A stronger description of porous systems of this kind was given in [2], where it the porosity itself was regarded as a fundamental random variable, because the value of porosity ϕ or the pore size distribution is not sufficient to characterize the complex pore-space geometry. The characterization is based on analyzing the local geometry on a mesoscopic scale, and the local geometry around a lattice point $\mathbf{R}$ is defined as the intersection of the pore space and the primitive cell at $\mathbf{R}$. To define the local porosity, the characteristic function of an arbitrary set A is introduced as $\chi_A(\mathbf{r}) = 0$ if $\mathbf{r}$ lies outside the set A and 1 if $\mathbf{r}$ lies inside the set A.

The local porosity $\phi(\mathbf{R}, L)$ at the lattice position $\mathbf{R}$ is defined for length scale L as

$$\phi(\mathbf{R}, L) = \rho \int \chi_{\mathrm{MC}}(\mathbf{r}; \mathbf{R}, L)\chi_{\mathrm{PS}}(\mathbf{r})\,d\mathbf{r} \tag{2}$$

where ρ is the density of Bravais lattice points; $\chi_{\mathrm{MC}}(\mathbf{r}; \mathbf{R}, L)$ is the characteristic function of the measurement cell at $\mathbf{R}$, having size L; and $\chi_{\mathrm{PS}}(\mathbf{r})$ is the characteristic function of

the porous space. The integration is done over the porous medium. To define the local porosity distribution function, let $\mu(\phi, \mathbf{R}; L)$ measure the probability of finding the local porosity ϕ in the range from ϕ to $\phi + d\phi$ in a cell of linear dimension L at a point $\mathbf{R}$. If the porous medium is homogeneous, μ must be independent of $\mathbf{R}$, and $\mu(\phi, \mathbf{R}; L) = \mu(\phi; L)$ can be named the local porosity density at scale L. The bulk porosity ϕ^* can be determined as an integral over the entire volume or as an average over a statistical ensemble of measurement cells, and, assuming "ergodicity," we have $\phi = \phi(\mathbf{R}, L \to \infty) = \int_0^1 \phi_\mu(\phi; L)\, d\phi$, independent of $\mathbf{R}$ and L.

Higher-order distribution functions $\mu_n(\phi_1, \mathbf{R}_1; \phi_2, \mathbf{R}_2; ; \phi_n, \mathbf{R}_n; L)$ measure the probability density of finding ϕ_1 in the cell at $\mathbf{R}_1$, ϕ_2 in the cell at $\mathbf{R}_2$, etc. at scale L. A set of such functions gives full information about the statistical properties of a porous medium at scale L. The local porosity distribution $\mu(\phi; L)$ depends on L. There is an intermediate length scale ξ, the porosity correlation length, at which the local geometries are relatively simple, but, on the other hand, the single-cell distribution function has sufficient nontrivial geometric content to be a good approximation. More precisely, ξ is determined by a two-cell distribution function, $\mu_2(\phi_1, \mathbf{R}_1; \phi_2, \mathbf{R}_2; L)$, which depends only on the distance R in the isotropic case, that is, $\mu_2 = \mu_2(\phi_1, \phi_2; R; L)$. Namely, $\xi^2 = \{\int R^2 C(R, 0) d^3R\} / \{\int C(R, 0) d^3R\}$, where $C(R, L)$ is the porosity autocorrelation function at scale L:

$$C(R,L) = \left\{ \int_0^1 \int_0^1 (\phi_1 - \phi^*)(\phi_2 - \phi^*) \mu_2(\phi_1, \phi_2; R; L) d\phi_1 d\phi_2 \right\} \Bigg/ \left\{ \int_0^1 (\phi - \phi^*)^{2\mu} (\phi; R; L) d\phi \right\}. \quad (3)$$

The local porosity distribution can be defined as $\mu(\phi) = \mu(\phi; \xi)$, the single-cell porosity at scale ξ. The important aspect of $\mu(\phi) = \mu(\phi; \xi)$ is that it is measurable with modern image-processing equipment. The procedure for observing $\mu(\phi)$ in homogeneous and isotropic media measures this function on photographic images of thin 2D sections across the porous space. The local porosity distribution contains a good deal of geometrical information about the pore-space geometry, and it is optimal in the sense that it contains the maximum amount of information based purely on the porosity concept. The second geometric property to characterize local geometries is whether or not the pore space percolates. Let $\lambda(\phi)$ denote the fraction of percolating cells with local porosity ϕ. $\lambda(\phi)$ can be called the local percolation probability. The two functions $\mu(\phi)$ and $\lambda(\phi)$ constitute only a partial and approximate geometric characterization of the pore space, but they have rich geometrical content.

2.2. Characterization of Porous Media

For the pore sizes of the nanometer scale there is no unique method yielding full information about the porous structure. We need to use various methods to extract the whole body of information of interest [1, 3, 4]. The most essential of these are listed in Table 1.

2.2.1. Electron Microscopy

This is the well-known method for the study of porous structures (see [3, 4]), frequently used as an additional method because of the laborious procedure of sample preparation, especially in the case of transmission electron microscopy. This method gives in its simplest form direct information about the sizes and shapes of pores, and about their connections, but only in some local positions. For more complete information, several measurements are needed for varying and averaging the positions on a sample, as are the feature-counting measurements on electron micrographs. As an example of a study of this kind, mention can be made of the fact that the fractal geometry was confirmed for the porous space in sandstone with the use of scanning electron microscopy (SEM) with manual feature-counting in SEM images [5]. For the same purposes, an automated technique

Table 1. Information about methods for porous media characterization.

Method	Information that can be obtained	Minimum characteristic size
1. Electron microscopy	Amount, volume, and distribution of pores. Internal surface area. The possibility to determine the closed pores. There is only local information.	≈0.5 nm
2. Methods based on porous structure filling with wetting materials		
a. Pycnometry	Total porosity	≈0.5 nm
b. Monolayer and multilayer adsorption	Internal surface area	≈0.5 nm
c. Capillary condensation	Volume and distribution of pores, internal surface area	≈1 nm
3. Methods based on porous structure filling with nonwetting materials (mercury porosimetry)	Volume and distribution of pores, internal surface area	≈1 nm
4. Small-angle scattering of X-rays and neutrons	Pore sizes, internal surface area. The possibility to determine the closed pores. Nondestructive method	≈0.5 nm
5. Methods based on NMR		
a. Relaxation time measurement for confined liquids	Volume and distribution of pores, internal surface area	≈2 nm
b. Pulsed field gradient NMR	Pore sizes, internal surface area	

has also been developed for making SEM measurements [6] with image digitizing, filtering, counting of geometrical features as a function of feature sizes, and fitting feature histograms.

2.2.2. Methods Based on Filling of Porous Structures with Wetting Materials

Pycnometry This method for studying porous structures [3, 4] is based on a comparison of the densities of porous materials with empty and filled porous space. The pores in this method may be very easily filled with a liquid that wets the internal surface of the porous space (in the simplest case this may be water) and thereby can penetrate all open pores. The difference between the densities of a sample with empty pores and the same sample with filled pores gives the total porous volume for this sample if the density of the wetting liquid is known. Thus this method permits one to determine the total porosity of porous materials.

Monolayer and Multilayer Adsorption A study of adsorption of various gases by porous materials is a source of important information about the internal surface of a porous space (see [3, 4, 7–12]). This process can be described by isotherms of adsorption, that is, by the dependences of the volume of adsorbed substance on the relative pressure at a given temperature. The substance most frequently used for adsorption in nanoporous materials is nitrogen at 77 K.

A theoretical description of monolayer adsorption is based on a model developed by Langmuir [13], in which the isotherm looks like

$$V/V_{\mathrm{m}} = (Bp/(1 + Bp)) \tag{4}$$

Here V is the volume of condensed sorbate, V_{m} is the maximum volume corresponding to the inner surface covered with a monolayer of sorbate, $p = P/P_0$ is the relative pressure, P_0 is the saturated vapor pressure, and B is a constant. From experimental data, $V = V(p)$, it is very easy to determine first V_{m} and then S, the internal surface area of the porous space, if we know the characteristic sizes of molecules for the sorbate used. Brunauer et al. [14] developed this model for multiple-layer adsorption. The isotherm of adsorption corresponds in this case to the equation (the so-called BET equation)

$$V/V_{\mathrm{m}} = \{Cp/(1 - p)[1 + (C - 1)p]\}, \tag{5}$$

where $C \approx \exp(Q/RT)$, Q is the heat of adsorption, R is the gas constant, and T is temperature. This equation, when written in the form $p/V(1-p) = 1/V_{\mathrm{m}}C + p(C-1)/CV_{\mathrm{m}}$, is very convenient for the approximation of experimental data, because the dependence of $p/V(1 - p)$ on p, which can be obtained in experiment, is a straight line, which permits one to determine the coefficients $1/V_{\mathrm{m}}C$ and $(C - 1)/CV_{\mathrm{m}}$ and then to calculate V_{m} and C. It was established that experimental data are frequently in agreement with the BET equation, especially at relative pressures p in the range from approximately 0.05 to approximately 0.35.

Capillary Condensation When $p = P/P_0$ is more than approximately 0.75, the pore space is filled by sorbate not through multilayer adsorption but through capillary condensation. This results from a decrease in the saturated vapor pressure over the curved surface of the wetting liquid in a capillary in comparison with the saturated vapor pressure over the planar surface of the same liquid, which leads to condensation of wetting liquids in the pores at $p < 1$. The condensed liquid volume can be calculated with the Kelvin equation (see [8, 9])

$$\ln(P/P_0) = -4\sigma V \cos\theta/DRT \tag{6}$$

where σ is the surface tension of the liquid, V is the molar volume of condensed liquid, θ is the wetting angle (at full wetting $\theta = 0$ and $\cos\theta = 1$), D is the pore diameter, R is the gas constant, and T is the temperature. The experimental dependence $V = V(P)$ can be used to calculate, with the Kelvin equation, the dependence of the characteristic porous volume on pore diameter. A more exact description of capillary condensation needs to take into account the thickness of adsorption layers and the dependence of the surface tension on the curvature of the liquid meniscus (see [9]). The adsorption and desorption processes also exhibit a hysteresis depending on the geometry of the porous space. Commonly, practical calculations use the simplest form of the Kelvin equation and the desorption branch of the capillary condensation hysteresis. Some examples of such a study are the following: [15] for xenon adsorption on silica gel; [16, 17] for adsorption of Ar, N_2, O_2, C_2H_4, and CO_2 on model mesoporous adsorbents MCM-41; and [18] for the adsorption of xenon on Vycor porous glass. Some models have been proposed for describing the adsorption hysteresis on the basis of Monte Carlo [19] and molecular dynamic computer simulation [19, 20], the density functional approach [21], the lattice gas model [22], and percolation theory [23].

2.2.3. Mercury Porosimetry

This method is based on the possibility of filling porous materials under high pressure with liquids that do not wet the surface of the porous space (see, e.g., [3, 4, 24]). Owing to the property of mercury that it will not wet most porous materials, it has frequently been used for these purposes, and this method has been named "mercury porosimetry" (some other materials can also be used, see, e.g., [25], where the Wood alloy was employed). The pressure needed for filling is the well-known Laplace pressure. In the simplest case (for full nonwetting, when the wetting angle θ is 180°) it can be written as $P = 4\sigma/D$ (σ, surface tension; D, pore diameter). At this pressure the entire porous volume of pores with diameters exceeding D is filled with nonwetting liquid. From the experimental dependences of filled porous volume on external pressure it is possible to calculate the distribution of porous volume over diameters. $P = 4\sigma/D$ can be written as $4F/\pi D^2 = 4\sigma/D$ (F strength). For a cylindrical pore with length L this expression can be rewritten as $4FL/\pi D^2 = 4\sigma L/D$ or $FL = \sigma(\pi DL) \approx \sigma S$, where FL is

the mechanical work done by the piston pressing liquid into the pore and S is the total surface area of the cylinder. In this form the above equation reflects the process of mechanical energy transformation during the process of filling into the surface energy σS of dispersed liquid and permits one to determine the total surface area of the porous space. When there is some distribution of pore diameters, the surface area of the pore space can be determined from the experimental dependence of filled volume on the external pressure $V(P)$

$$S = (-1/\sigma)\int_0^{V\max} P\,dV \tag{7}$$

2.2.4. Small-Angle Scattering of X-Rays and Neutrons

X-ray and neutron scattering is a powerful technique for studying crystalline materials. For a given wavelength λ, the scattering angles φ for a lattice constant d are determined by the Bragg condition $n\lambda = 2d\sin\varphi$, where n is an integer. In porous materials, the characteristic lengths $L \gg d$, and the scattering features are observed at small angles. For example, for $\lambda \approx 0.15$ nm and 2 nm $< L <$ 100 nm the typical angles φ are in the range from 5° to 7°. A theory has been developed for describing the X-ray and neutron scattering at small angles (see [26, 27]), and such a study is very informative regarding porous structures at the nanometer scale (see [3, 4, 28–30]). According to a theory for scatterers bounded by a smooth surface, the limiting form of the scattered intensity must be proportional to q^{-4}, where $q = 4\pi\lambda^{-1}\sin(\varphi/2)$. Some deviations from this dependence have been observed for various porous materials (sedimentary rocks, lignite coals, silica aerogels, porous glasses) and attributed to the existence of fractals (for fractals, see [31]) in the porous structure of these materials (see [32–38]). A difference between volume and surface fractals was established. In the former case, the scattering intensity $I(q) \sim q^{-D_v}$, where D_v is the fractal dimension relating the mass M to the characteristic length L as $M(L) \sim L^{D_v}$ for a sphere of radius L. In the latter case, the scattering intensity $I(q) \sim q^{D_s-6}$, where D_s is the surface fractal dimension which relates the surface area S to length as $S \sim L^{D_s}$ for a sphere of radius L. The conventional dependence $I(q) \sim q^{-4}$ corresponds to $D_s = 2$, that is, to a 2D geometry of porous surface space.

2.2.5. Methods Based on Nuclear Magnetic Resonance

Measurement of Relaxation Time for Confined Liquids

Relaxation time measurements can probe the local surface-to-volume ratio for a porous space and thus can determine the average pore sizes and pore distributions [39–41] (see, also [42]). In this method, the relaxation of magnetization with time is measured after the application of an appropriate pulse sequence to a porous sample filled with some suitable liquid. An increased relaxation rate (either transverse or longitudinal) caused by the interaction of the solid surface with fluid molecules near the surface is assumed for molecules within a certain distance λ from the surface. For the liquid within a single pore, there is a single relaxation time $1/T = 1/T_B + (s/v)(\lambda/T_S)$, where $1/T$ is the longitudinal or transverse relaxation rate; $1/T_B$ and $1/T_S$ are, respectively, the corresponding relaxation rates in the bulk or within λ from the surface; s and v are the surface area and volume of the pore. For the entire sample the contribution of relaxation rates from different pores to magnetization decay can be written in the continuum form,

$$A(t) = \int_0^\infty P(D)\exp[-t(1/T_B + (\lambda/T_S)(m/D))]\,dD \tag{8}$$

where $A(t)$ is reduced magnetization which depends on the NMR signal $E(t)$: $A(t) = (1/2)[1 - E(t)/E(\infty)]$ for a longitudinal inversion recovery sequence and $A(t) = E(t)/E(0)$ for a transverse pulse sequence ($E(\infty)$ is the echo signal upon full recovery and $E(0)$ is that at zero delay time), $P(D)$ is the pore size distribution function, D is the pore diameter, $s/v = m/D$ (the constant m depends on the pore geometry). Inversion of the experimental magnetization data for practical purposes may permit calculation of the function $P(D)$. In [41], the experimental $P(D)$ data determined in relaxation time measurements with various porous glasses were compared with the experimental results obtained with measurements by the adsorption method and mercury porosimetry.

Pulsed-Field-Gradient NMR Pulsed-field-gradient (PFG) nuclear magnetic resonance (NMR) is a versatile tool for studying the transport of fluids in porous media [43–47]. The PFG NMR technique can reveal structural properties of the porous medium by measuring the molecular transport, that is, by monitoring the restricted self-diffusion of the molecules. NMR, combined with an additional space- and time-dependent magnetic field, so-called pulsed field gradients (PFGs), offers an opportunity to generate labeled molecules and to detect their mean displacements related to any transport process (the labeling is due to the Larmor precession ω of nuclear spins associated with the molecules). The Larmor frequency $\omega(z, t)$ can be written as $\omega(z, t) = -\gamma(B_0 + g(t)z)$, where B_0 is time-independent uniform magnetic field parallel to the z coordinate, $g(t)$ is an additional time-dependent magnetic field with a field gradient oriented parallel to the z direction, and γ is the gyromagnetic ratio of the nuclei under investigation. In such a magnetic field, the complex magnetization density $m(\mathbf{r}, t)$ gets an additional z dependence,

$$m'(\mathbf{r}, t) = m(\mathbf{r}, t)\exp\left(-i\gamma z\int_0^t g(t')\,dt'\right) \tag{9}$$

If the magnetic field gradient $g(t)$ is turned off after a time δ, the magnetization density is found to be embossed with a z-dependent factor

$$m'(\mathbf{r}, t) = m(\mathbf{r}, t)\exp(-i\gamma g\delta z) \tag{10}$$

This phase factor represents the labeling of the molecules observed in PFG NMR diffusion studies. A length scale $l_{PFG} = (2k)^{-1}$ ($k = \gamma\delta g$) can be introduced, over which a significant change in the phase factor and, hence, the labeling of the diffusing molecules are achieved. The self-diffusion process of the molecules observed smears out the

originally present spatial distribution of phases. Measurement of this phase distribution after an observation time Δ allows evaluation of the self-diffusion of the molecules. This process is caused by a second magnetic field gradient pulse after a time Δ, which has to refocus the special phase distribution introduced by the first pulse. Owing to the displacements of the molecules, caused by self-diffusion, the refocusing is not complete. The NMR signal observed, which follows from integration of the magnetization density over the sample volume, is reduced by the factor

$$\psi(k, \Delta) = \int P(z - z, \Delta) \exp[ik(z - z')]d(z - z')$$

in comparison with the signal measured without a pulsed field gradient ($P(z - z', \Delta)$ denotes the probability density that a molecule is displaced by $z - z'$ within a time interval Δ). $P(z - z', \Delta)$ is given by the inverse Fourier transform of the NMR signal attenuation [48] and contains information about the geometrical features of the pore space, which affect the molecular motion of the pore fluids [49–53]. The power of PFG NMR as a tool for the investigation of porous systems is based on the fact that l_{PFG} and k can easily be controlled by choosing the appropriate values for the pulsed field gradient intensity g and width δ. l_{PFG} values of less then 0.1 μm (required, e.g., for ^{1}H NMR with $\delta \geq 1$ ms and $g \geq 20$ T/m) can be achieved with the current state-of-the-art PFG NMR spectrometers [54].

2.3. Porous Matrices

2.3.1. Matrices with Irregular Porous Structure

Porous Glass A porous silica glass can be defined as a bicontinuous random structure of two interpenetrating percolating phases, namely the solid and the pore networks. The pores in the glasses are connected to each other, and the pore size distribution is narrow (see Fig. 1). Porous glass is available in standard forms such as tubing, rods, and sheets. It is mechanically hard and strong, nondusting, nonflaking, and chemically inert (for its physical and chemical properties, see [55–62]). The preparation methods and properties of various types of porous glasses are summarized in [63] (see also [64–77]). Porous glass is often used for the filtration and separation of compounds. The open-cell network allows permeability on a selective basis—the species must be smaller than the microscopic pores to pass through a porous glass. A porous glass matrix can also be used in nuclear waste storage [78, 79] and optical applications [80]. The present status and future potential for porous glass applications are reviewed in [81]. The homogeneous pore diameters can be controlled to be, on the average, between 40 and 500 Å. A typical example of porous silica glasses is Vycor glass (Corning vycor brand 7930 [82]). Its standard chemical composition is as follows: 96% SiO_2, 3% B_2O_3, 0.40/a Na_2O, $R_2O_3 \pm RO_2 < 1\%$ (R = mostly Al_2O_3 and ZrO_2). Its physical characteristics are given in Table 2.

For Vycor porous structure, see also [29, 36, 37, 75, 83–89]. Such a structure is obtained as a result of spinodal decomposition of the following two phases: SiO_2 and $B_2O_3 + Na_2O$. Vycor porous glass is prepared in three steps [90]. A melt composed of 75% SiO_2, 20% B_2O_3, and 5% Na_2O is quenched near (but below) its consolute temperature, inside the immiscibility gap. During the heat treatment, a slow liquid-liquid diffusion occurs, resulting in separation into two phases, rich in B_2O_3 alkali oxide and in SiO_2. After the glass is heat-treated and annealed, the B_2O_3-rich phase is removed by leaching at about 100 °C with acid, leaving an almost pure SiO_2 skeleton. The resulting structure of the interconnected matrix has been interpreted in different ways. First the pore network was suggested to be a mass fractal, associated with 3D percolation clusters [91]. Next, Vycor glass was analyzed [85, 92] with the theory developed for the early stages of spinodal decomposition [93]. In this model, the phase separation occurs by growth of unstable long-wavelength concentration fluctuations. The acid leaching removes the regions "poor" in SiO_2, creating an interconnected solid skeleton. The third proposed separation process is suggested to be driven by nucleation and growth of an almost pure SiO_2 phase [37, 94, 95]. The Vycor glass must have a structure made up of a randomly packed assembly of spheroidal particles forming a connected and homogeneous solid network. The geometrical nature of the interfacial microstructure of the pore network has also been controversial. There have been discussions in the literature, regarding both the volume and surface fractal structures in Vycor glass [36, 37, 83–86, 91, 96, 97]. Most of the information

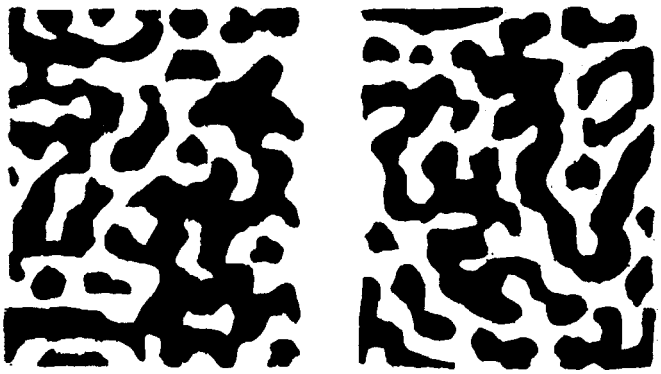

Figure 1. Model of porous structure for porous glass.

Table 2. Main physical characteristics of porous glasses.

Parameter	Value
Approx. specific gravity (dry)	1.5
Void space	28% of vol.
Internal surface area	250 M^2/g
Avg. pore diameter (standard)	40 Å
Appearance	Opalescent
Avg. modulus of rupture of abraded "A" rods, 25 °C	6000 psi
Young's elastic modulus, 25 °C	2.5×10^6 psi
Loss tangent at 25 °C, 100 Hz	0.007
Dielectric Constant at 25 °C, 100 Hz	3.1

Note: Loss tangent and dielectric constant are affected by water in porous glass.

related to the pore morphology has been obtained by means of transmission electron microscopy, adsorption methods, and small-angle scattering techniques. A study using a small-angle scattering technique [36] interpreted the power-law scattering at large q ($\sim q^{-4}$) to be a signature of scattering from a smooth interface [26]. However, some results [37] show an asymptotic behavior at large q, with power-law scattering of the form $q^{-3.7\pm0.1}$. This noninteger exponent may be due to scattering from a rough pore interface.

Xerogels and Aerogels Some other materials with an irregular porous structure are xerogels and aerogels. These materials are based on a gel that is on a suspension or polymer solution that behaves as an elastic solid or semisolid, rather than a liquid. A dried-out gel is termed a xerogel. A xerogel has an open porous structure at the nanometer scale. The porosity of this material is due to a random colloid aggregation process in the solution precursor. The classical models of their porosity-dependent properties are based on highly simplified geometrical structures like packed spheres or bottlenecked bubbles [7]. An aerogel is a special kind of xerogel in which the dried-out gel retains most of the original open structure. The most frequently used xerogels and aerogels are those based on SiO_2: silica gels and silica aerogels (for their production, see [98]). Their porous structure has been studied by various methods: gas/vapor adsorption (see [15]); mercury porosimetry (see [24], but this technique is generally not effective with aerogels); X-ray, neutron, and visible light scattering methods (see [99–108]); and numerical simulations [109–111]. Pores in various materials are either open or closed, depending on whether the pore walls are solid or porous themselves. A macroscopic example of an open-pore material is a common sponge. In a closed-pore material, gases or liquids cannot enter a pore without breaking it. This is not the case with an open-pore structure. In this instance, gases or liquids can flow from pore to pore with limited restriction, and eventually through the entire material. It is this property that makes aerogels effective materials for gas-phase catalysts, microfiltration membranes, and substances for chemical vapor infiltration. Physical properties of typical silica aerogels are listed in Table 3.

Table 3. Physical properties of silica aerogels.

Apparent density	0.003–0.35 g/cm^3	Most common density is about 0.1 g/cm^3.
Internal surface area	600–1000 m^2/g	As determined by nitrogen adsorption/desorption.
% solids	0.13–15%	Typically 5% (95% free space).
Mean pore diameter	≈20 nm	As determined by nitrogen adsorption/desorption.
Primary particle diameter	2–5 nm	Determined by electron microscopy.
Coefficient of thermal expansion	$(2–4)*10^{-6}$	Determined with ultrasonic methods.
Dielectric constant	≈1.1	For density 0.1 g/cm^3. Very low for solid material.
Sound velocity through the medium	100 m/s	For density 0.07 g/cm^3. One of the lowest velocities for a solid material.

Nanoporous Particle Track-Etched Membranes In 1962, Price and Walker [112, 113] made an interesting observation that the tracks in a material damaged by the passage of heavy charged particles through insulators can be revealed by chemical etching to form pores. The tracks that traverse the specimen are seen to be quite uniform and about 700 Å in diameter. Bean et al. [114] described an electrical method for subsequent pore growth during etching and a theory describing the rate of pore enlargement. They used clear muscovite that was cleaved to thicknesses between 3 and 8 μm. Irradiation was accomplished from a sample of spontaneously fissionable ^{252}Cf. About 10^5 tracks/cm^2 were formed in 16 h. The process of pore growth was monitored by measuring conductance across a thin sample. In summary, this study demonstrated that pores in mica, with radii from 30 Å to many micrometers can be created and monitored. A similar technology has been developed for polymeric track and other membranes [115–121]. The technology consists of irradiation of thin polymer foils with accelerated heavy ions, sensitization, and chemical treatment, resulting in the formation of uniform micro- or nanopores in the polymeric matrix. The pores are straight cylindrical channels with a clearly defined diameter. The surface pore density is also precisely predetermined by irradiation conditions. Special etching procedures give pore channels as small as 15–50 nm. The pore shape can also be changed at will. At the Joint Institute of Nuclear Research (Dubna, Russia) [115, 116] the irradiation of polymer foils is carried out on a U-400 cyclotron. It furnishes an opportunity to perform a homogeneous treatment of large sample areas. Accelerated Kr and Xe ions with energies of 4–6 MeV/amu are available.

2.3.2. Matrices with Regular Porous Structure

Zeolites Zeolites are nanoporous crystalline solids with well-defined structures [122–126]. Generally, they contain silicon, aluminum, and oxygen in their skeleton. Many zeolites occur naturally as minerals and are extensively mined in many parts of the world. Others are synthetic and are made commercially for specific uses [126–129]. Natural and synthetic zeolites are typically powders with a characteristic size less than 10^{-2} cm. Because of their unique porous properties, zeolites are used in a variety of applications with a global market of several million tons per annum. Their major applications in the world are in petrochemical cracking, ion exchange (water softening and purification), and separation and removal of gases and solvents. Other applications are in agriculture, animal husbandry, and construction. Zeolites are often also referred to as molecular sieves. A defining feature of zeolites is that their frameworks are made up of 4-connected networks of atoms. One way of thinking about this is in terms of tetrahedra, with a silicon atom at the center and oxygen atoms at the corners. These tetrahedra can then be linked together by their corners to form a rich variety of structures. The framework structure may contain linked cages, cavities, or channels, which are roughly between 3 and 15 Å in diameter (see Fig. 2). The centers of zeolite cages (or channel axis) are arranged in space with crystalline order, which allows preparation of ensembles with size-calibrated clusters and/or atomic diameter wires with long-scale macroscopic ordering [130]. In all,

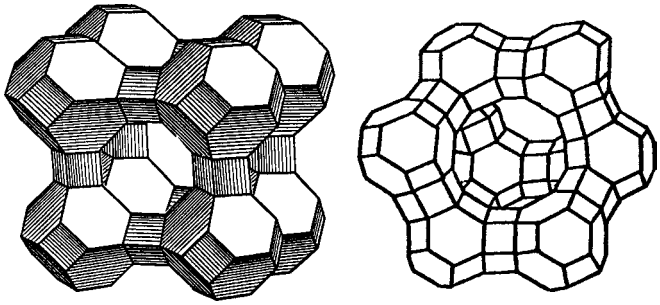

Figure 2. Zeolite cages for NaA (left) and NaX (right) matrices.

130 different framework structures are now known [131]. In addition to those having silicon or aluminum as the tetrahedral atom, other compositions have also been synthesized, including the growing category of nanoporous aluminophosphates known as ALPOs. The structural properties of some typical zeolites are listed in Table 4 [122, 130].

Mesoporous Molecular Sieves There are new kinds of nanoporous materials with regular systems of nanovoids, the so-called mesoporous molecular sieves, such as MCM-41 [132–137] and SBA-15 [138], which have many desirable properties for application as separation media (see also [139–145]). Members of this family of materials, designated MCM-41, were first observed in electron micrographs of products from hydrothermal reactions of aluminosilicate gels in the presence of quaternary ammonium surfactants. The material possesses a regular array of uniform, hexagonally shaped channels with narrow pore size distribution, the dimensions of whcih can be tailored in the range from 16 Å to 100 Å or more through the choice of surfactant, auxiliary chemicals, and reaction conditions. The pore walls are composed of amorphous silica, as indicated by X-ray diffraction measurements. MCM-41 has been used as a model system for sorption isotherms of various gases. The BET surface area is $\geq$1000 m^2/g with exceptionally high sorption capacities. The range of pore volumes for MCM-41 samples is 0.7–1.2 cm^3/g (porosity of up to 80%). The use of amphiphilic triblock copolymers to direct the organization of polymerizing silica species has resulted in the preparation of well-ordered hexagonal mesoporous silica structures, SBA-15, with uniform pore sizes up to approximately 30 nm. These materials are synthesized in acidic media to produce highly ordered, 2D hexagonal silica block-copolymer mesophases. Calcination at 500 °C gives porous structures with pore sizes from 4.6 nm to 30 nm, pore volume fractions up to 0.85, and silica wall thicknesses of 3.1 nm to 6.4 nm.

Artificial Opals Natural opal is known as a precious stone with beautiful colors due to its structure, which is really a natural diffraction grating for visible light [146–149]. It consists of identical silica spheres with a very narrow size distribution (for its structure, see also [150–153]). There are now artificial opals [147, 154, 155] that also consist of identical silica spheres with diameters (D) varying from 150 to 900 nm [156]. The size uniformity of these spheres allows their assembly in a close 3D lattice, usually with FCC symmetry (see Fig. 3). There are empty voids between neighboring spheres, which, in turn, form their own regular lattice. There are two types of interpenetrating voids in the opal lattice: 8-fold-coordinated large voids, each connected with eight 4-fold-coordinated small voids. The large void has the form of a truncated tetrahedron with four windows to four large voids. The diameters of spheres inscribed in the larger and smaller voids are $d_1 = 0.41D$ and $d_2 = 0.23D$, respectively. The diameter of a circle inscribed in the triangular window is $d_3 = 0.15D$. The density of voids in opal is typically 10^{14} cm^{-3}. The porosity of the ideal package of spheres is 26% of the whole volume. The main opal spheres consist of smaller spheres 30–40 nm in diameter, which in turn are composed of particles 5–10 nm in diameter. Thus, the total porosity of opals may approach 59%, constituted by the 26, 19, and 14% porosity corresponding to the lower hierarchy of size [157]. The actual porosity of the opal may be either above or below this value, depending on the synthesis history (sintering conditions, interstitial cement).

Chrysotile Asbestos Asbestos is a general term for a number of naturally occurring, fiber-rich minerals. The minerals are silicates, which means that the crystal structure is built up around SiO_4, frequently with a high concentration of magnesium, iron, or alkali metals [158, 159]. There are a number of health issues associated with exposure to asbestos [160, 161]. Chrysotile asbestos (chemical formula $Mg_3Si_2O_5(OH)_4$) is the only type of asbestos that can be

Table 4. Structural properties of typical zeolites.

Property	Zeolite NaX	Zeolite NaA	Zeolite NaM (mordenite)
Chemical formula	$Na_{86}[(AlO_2)_{86}(SiO_2)_{106}]32 \times 8H_2O$	$Na_{12}[(AlO_2)_{12}(SiO_2)_{12}]29H_2O$	$Na_{8.7}[(AlO_2)_{8.7}(SiO_2)_{39.3}]24H_2O$
Lattice of voids	Diamond-like with lattice constant 25.4 Å	Cubic with lattice constant 12.27 Å	Parallel channels with distance between their axes of 13–14Å
Diameter of voids	13 Å	11.4 Å	Diameters of channels 6.7–7 Å
Diameter of window between voids	7–8 Å	4.2 Å	
Relative volume of voids	42% of the total volume (there are some small voids with relative volume of 8%)	40% (there are some small voids with relative volume of 7%)	20%
Density with adsorbed water	1.91 g/cm^3	1.96 g/cm^3	2.13 g/cm^3
Density without water	1.41 g/cm^3	1.49 g/cm^3	

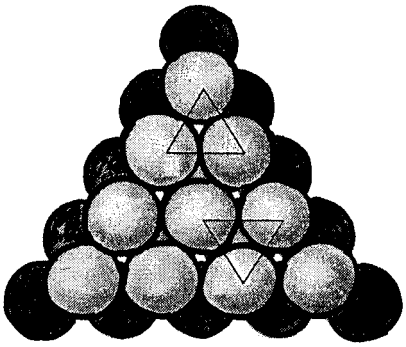

Figure 3. Packing of silica spheres in opal matrix.

decomposed by acids. It is a regular set of closely packed, parallel, ultrathin dielectric tubes with external diameters of about 20–25 nm. Its color may be white, gray, green, or yellowish. Currently chrysotile asbestos is the only type of asbestos mined on a large scale. The biggest deposit of asbestos mined now is located in the Urals (Russia) [162]. The mineral structure is described as a layer of partially hydrated MgO bound to a corresponding SiO_2. Since the MgO layer cannot adapt properly to the SiO_2 layer, being larger, the thin double layer rolls up into very thin tubes, with the magnesium oxide layer outermost. The fibers are therefore hollow cylindrical tubes with an outer diameter of 200–250 Å and an inner diameter of 20–50 Å [158, 159] that are convenient for nanowire preparation (see Fig. 4). The density of chrysotile is 2.4–2.6 g/cm^3. The surface area depends on the distribution of fibers and may vary within 4–50 m^2/g, which is more than the corresponding variation in other fibrous textile materials. The refractive index along the fibers is 1.531–1.541 [159, 163, 164]. The low-temperature magnetic susceptibility of Canadian chrysotile obeys the Curie law, and Rhodesian chrysotile has an antiferromagnetic Weiss constant of about 1 K. The apparent paramagnetism of chrysotile may be due to the presence of iron compounds, such as magnetite, as impurities [165]. The pH reaction of chrysotile corresponds to $Mg(OH)_2$ in water in that a 0.5% chrysotile suspension free of CO_2 has a pH of 10.33. The determination of the lattice parameters of chrysotile has been beset by unusual difficulties, as a result of the peculiarities of its diffraction pattern [166, 167].

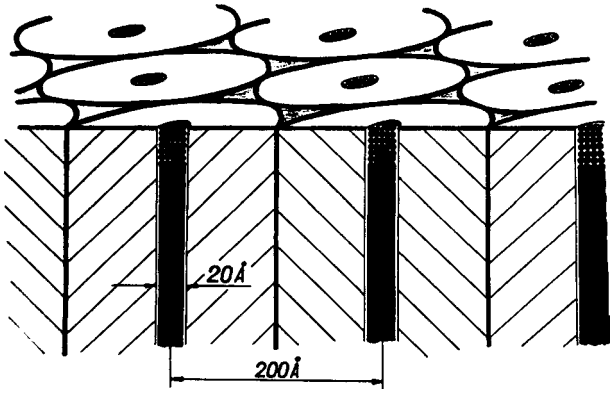

Figure 4. System of nanowires within the channels of chrysotile asbestos.

For example, no single crystals of the mineral are available, and the finest fiber specimen that can be examined gives a diffraction pattern with the full symmetry of a rotation photograph. Warren and Bragg [168] suggested a structure based on amphibole-like silicate chains. Warren and Herring [169] and Aruya [170] pointed out that the diffuse reflections of chrysotile are similar to cross-grating reflections and, therefore, assumed that the mineral has a disordered layered structure. Modern structural results were obtained by Whittaker [166] at a time when electron-microscopic results appeared to be well established, but before the theory of diffraction by cylindrically curved layers was worked out. The types of structure that can be formed by cylindrically curved layers have been classified, and their diffraction effects have been discussed systematically [171–175]. The typical specimen studied by Whittaker [176] was a fiber pencil (17 mm long and 0.14×0.07 mm in cross section) from Bell's mine, Thetford, Québec, Canada. All of the reflections from this specimen are in the positions expected for a monoclinic cylindrical lattice with parameters $a = 14.65 \pm 0.01$ Å, $b = 9.2$ Å, $c = 5.34 \pm 0.01$ Å, $\beta = 93°16' \pm 1'$. Some other types of chrysotile have also been studied by Whittaker [177–179] (for lattice parameters of chrysotile reported by different authors, see [180–184]. The porous structure of asbestos has been studied by Pundsak [185, 186]. The void fractions observed experimentally were on the order of 6%. The water vapor adsorption-desorption data demonstrated that, in all of the samples, more than 80% of the void volume is in pores with radii less than 30 Å. Similar experiments have been carried out by Naumann and Dresher [187] with the use of nitrogen adsorption-desorption. A direct observation of porous structure in asbestos with the use of high-resolution electron microscopy was done by Yada [180, 188]. It was found that the outer diameter of the microfibers ranges from about 150 to 1000 Å, and the average value is about 500 Å. Most of the fibers were actually found to be hollow tubes with central holes 50–80 Å in diameter. The most frequent values of the outer and inner diameters of the samples showing a sharp distribution are 220–270 Å and 50–80 Å, respectively. None the tubes observed are simple cylindrical ones, but consist of spirally wound layers. Perfect concentric cylindrical layers were also found. The proportion of chrysotile fibers that are not hollow is very small. It was demonstrated that short uniform fibers of chrysotile asbestos exhibit strong interparticle forces parallel to the fiber axis, which result in aggregation of the fibers into distinct geometrical shapes [189].

Carbon Nanotubes The discovery of fullerenes provided exciting insights into carbon nanostructures. Carbon nanotubes are the most striking example. Carbon nanotubes were discovered by Iijima in 1991 during a study of the surfaces of graphite electrodes used in electric arc discharge [190]. Numerous novel and exceptional properties have been observed or predicted for these systems [191–200]. The basic structural unit of a carbon nanotube is a graphitic sheet rolled into a cylinder, with the tube tips closed by hemispherical or polyhedral graphitic domes. The aspect ratios of nanotubes vary with diameter, but the average length may be several micrometers. Experimentally, carbon nanotubes can be classified into two types: single-walled carbon

nanotubes (SWCNTs) and multiwalled carbon nanotubes (MWCNTs). SWNTs consist of single graphene cylindrical walls with diameters ranging between 1 and 2 nm. MWNTs have thicker walls consisting of several coaxial graphene cylinders separated by a spacing of 0.34 nm, which is close to the interlayer distance in graphite. The outer diameters of MWCNTs range between 2 and 25 nm, and the inner hollows, between 1 and 8 nm. Individual SWCNTs have a uniform diameter, although, when formed, they also show a strong tendency to pack together in large bundles. The very long cavities of carbon nanotubes have a special potential due to their high aspect ratio, and they can be used as templates for the fabrication of elongated nanostructures [201–205]. It may be noticed that there are some artificial noncarbon nanotubes based on MoS_2, WS_2, $NiCl_2$, etc. (see [206–210]). Some properties and the main methods for the synthesis of noncarbon nanotubes, as the results of experimental and theoretical studies, are discussed in [211].

3. METHODS FOR THE PREPARATION OF NANOSTRUCTURES WITHIN NANOPOROUS MATRICES

3.1. Filling with Wetting Liquids

Filling of nanovoids in porous matrices with various substances can be done from the molten state. In this situation, the possibility of filling the nanovoids strongly depends on such a characteristic of a system formed by the molten substance and the nanoporous matrix as wettability (see [212, 213]). If a liquid substance wets the inner surface of nanovoids it penetrates into these nanovoids and can organize inside the nanoporous material nanostructures whose shapes and sizes reflect the geometry of the porous space. So, to prepare nanostructures of this kind, we need in the simplest case only to melt some substance wetting the nanoporous matrix and to put this nanoporous matrix into this melt. There are many examples of nanostructures prepared in this way. First of all it should noted that water very frequently wets porous materials (and may even condense inside the nanopores from air) and so can be studied as a nanostructure [214–222]. Simple liquids like N_2, O_2, H_2, Ar, Ne, and CO have been introduced into nanopores of mainly Vycor porous glass [223–229] as superfluid liquids ^{3}He and ^{4}He [230–242] (zeolites have long been used as molecular sieves for wetting liquids). Various liquid crystals have also been studied in the confined geometry of the nanoporous space (mainly in nanopores of Vycor porous glass) [243–253]. Nanostructures have been prepared from the wetting liquid state or wetting solutions from organic materials and polymers [254–262], ferroelectric materials $NaNO_2$ and KH_2PO_4 [263–265], and fullerenes [266–268]. Carbon nanotubes have also been filled under the action of capillary forces in molten media [201, 203, 269] (see also [204, 205]).

3.2. Filling with Nonwetting Liquids

To fill porous matrices with liquids that do not wet the inner surface of porous space, it is necessary to apply some external pressure, which depends on the surface tension of liquid material and on the effective diameter of nanopores and corresponds to the formula for the Laplace pressure, $P = 4\sigma/D$, where σ is the surface tension and D is the diameter. In preparation of nanostructures within porous matrices, we need to put a porous matrix into the melt of some substance and to compress this system up to the pressures corresponding to the Laplace pressure, when the liquid substance fills the pore space and forms a nanostructure reflecting the geometry of nanovoids (see Fig. 5). This method of nanostructure fabrication is similar to the process of mercury porosimetry and, in the case of mercury-based nanostructures, the fabrication process exactly coincides with such a porosimetry. The characteristic surface tensions and the needed pressures (P_c) are presented in Table 5 for some liquid substances introduced into nanoporous matrices.

When the external pressure is decreased after filling, the liquid nanostructures are unstable because of a nonwetting situation, and some breaks appear even within nanovoids with uniform shapes. The nanostructures are in this case similar to some sets of isolated nanopatricles. However, the probability of breaking is lower if the external pressure is decreased after the system is cooled to the temperatures below the melting point, and the nanostructures may be continuous in this case. Nanostructures may be fabricated by filling Vycor porous glass with various metals at low temperatures of melting. Nanostructures have been prepared from Hg and Ga metals [270–276], In metal [277–281], and BiPb alloy [282–284]. Regular systems of nanovoids in zeolites [130, 285–288] and opals [153, 289–292] have also been filled with metals and other materials. Nanotubes of chrysotile asbestos have been filled under high pressure with Hg [293–297], In [298], Sn [299], Bi [300], Te [301], and InSb [300–303].

For this type of nanostructure preparation, there is an interesting question: What is the minimum diameter of nanopores for which this method can be used? This question is associated with such fundamental problems of capillary phenomena as determination of the local structure and properties of interface layers (so-called Tolman length

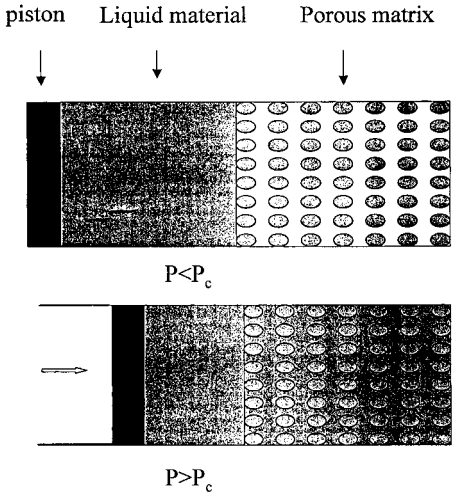

Figure 5. Process of porous matrix filling with molten material under high pressure.

Table 5. Surface tensions and typical needed pressures for filling of porous matrices with nonwetting liquids.

Liquid material (melt)	Surface tension (Erg/cm^2)	P_c (kbar, for $D = 100$ Å)	P_c (kbar, for $D = 20$ Å)
Bi	372	1.49	7.45
Hg	465	1.86	9.3
Pb	440	1.76	8.8
Se	105	0.42	2.1
Te	179	0.72	3.6
Sn	530	2.12	10.6
In	556	2.22	11.1
Ga	706	2.82	14.1

[213]), static and dynamic properties of the interphase interaction [212], capillary phenomena in extremely thin channels, or transition from capillary to diffusion phenomena. The experimental results from filling, with liquid metals, of channels of atomic-scale diameters in zeolites under high pressure [130, 286, 304–306] demonstrated that the interface transition layer has a thickness of about 1–1.5 Å, and the formula for the Laplace pressure can be used even for diameters of about 10 Å, in which this pressure approaches a value of $(20–30) \times 10^3$ atm. Capillary effects in this situation are a direct manifestation of the transformation of the mechanical energy (mechanical work done by a piston pressing some nonwetting liquid into a porous matrix) to the surface energy of a material highly dispersed in the pore space. Zeolites that contain liquid metals in their channels are heterogeneous systems with very high surface energy (one can estimate the energy capacity to be up to 200 kJ/liter) and can be used for simple direct storage of mechanical energy [305–309]. This high energy capacity (roughly 10^3 times greater than that of a spring) corresponds to that of an electrochemical storage unit, but, unlike the latter, it does not require an electric motor to produce mechanical work. Hydrocapillary storage units are sources of high-pressure liquid and can be used in transport, for example, with highly efficient hydraulic motors with high specific power (about 0.1 liter/kW) [307].

3.3. Chemical Methods for Filling of Nanoporous Materials

When some substance cannot be introduced into nanopores from a melt (such a situation is typical of materials with a high melting point), there are a lot of opportunities to prepare nanostructures through some chemical reactions inside the nanoporous space filled with various solutions (or vapors) of the components needed for such a reaction. Two main features characterize this method. First, it is not universal in comparison with the methods based on capillary phenomena and, therefore, requires in any particular case some special chemical approach that may be different from those employed. In the conventional bulk situation (a chemical reaction in the confined geometry of a nanoporous space may be not the same as in bulk). Second, such a method does not permit filling of the entire porous volume, because it is necessary to remove products of chemical reactions, and, as a result, the filling factor may be lower. A variety of chemical methods are based on electrolysis in an electrolyte introduced into the nanoporous system.

Metal-organic chemical vapor deposition (MOCVD) has been used to prepare GaAs and InAs nanoparticles from organogallium and organoindium compounds in Vycor porous glass [310, 311], InP nanoparticles in Vycor glass [312], and InP nanowires from trimethyl indium within asbestos nanotubes [313]. Other semiconducting compounds have been prepared in porous glass [314, 315]; CdS, CdSe, PbS, and PbSe compounds have been synthesized with the photochemical method [316]. The antiferromagnetic material MnO [317], like Fe compounds [310], has been introduced chemically into porous glass. Three-dimensional regular systems of Si and Si-Pt [318–322], GaN, InN, InGaN [323–326], and VO_2 [327] nanostructures have been fabricated in the void sublattice of a synthetic opal. The idea of using zeolites and mesoporous materials for the growth of quantum dots and wires has been proposed [328], and different nanostructures were synthesized within nanovoids of such porous materials as metals [329, 330], nanostructured metal sulfides [331], Ge [332], noble metal [333] nanowires, CdS nanorods [334], oxides [335], and organic materials and polymers [336–339]. Chemical reactions inside carbon nanotubes are described in [204, 205]; in particular, silver nitrate ($AgNO_3$) has been introduced (melting point 212 °C) into single-wall carbon nanotubes and decomposed into pure silver by thermal treatment at 400 °C, and the transformation of $AuCl_3$ in multiwalled carbon nanotubes into its base metal was described as an example of observation of reduction as a transformation of NiO to nickel metal. Similarly, encapsulated crystals of pure Pd [340, 341] have been prepared inside carbon nanotubes. Apart from hydrogen reductions, other kinds of reactions have been carried out inside carbon nanotubes. An example is the formation of cadmium sulfide crystals with hydrogen sulfide at 400 °C [342]. Electrodeposition has mainly been used for filling of some nanoporous membranes. Bi and Pt nanowires have been prepared in nanoporous anodic aluminum oxide [343–345] as Fe and Co nanowires [346] within nanoporous membranes and Ni nanowires in a porous Si matrix [347].

4. PROPERTIES OF NANOSTRUCTURES BASED ON NANOPOROUS MATRICES

4.1. Optical Properties

Artificially structured nanomaterials within porous matrices have attracted interest as objects of an optical study, because of the opportunity to observe quantum confinement, such as molecular-like discrete spectra, which exhibit strong size dependence, and some other effects, not associated with quantum confinement, which may be useful for different applications.

4.1.1. Quantum-Confinement Effects

Theoretical descriptions of the electronic structure of such nanostructures have advanced from considering a simple particle in box models to much more sophisticated approaches, including finite well effects, Coulomb interactions, nonparabolicity of the conduction band, confinement-induced mixing of valence subbands, etc. (see [348]). The simplest approach is based on the model of a spherical

quantum well with an infinite potential barrier, assuming a parabolic dispersion of electron and hole bands. The carrier energies are quantized and can be determined for semiconductors from the expression

$$E_{l,n}^{\mathrm{e,h}} = \left(\frac{h}{2\pi}\right)^2 \phi_{l,n}^2/(2m_{\mathrm{e,h}}a^2) \tag{11}$$

where $E_{l,n}^{\mathrm{e}}(E_{l,n}^{\mathrm{h}})$ is the electron (hole) energy reckoned from the bottom of the conduction (valence) band, $\phi_{l,n}$ is the nth root of the first-order spherical Bessel function, $m_{\mathrm{e}}(m_{\mathrm{h}})$ is the electron (hole) effective mass, and a is the nanoparticle radius. The absorption spectrum consists of narrow peaks with spectral positions

$$\left(\frac{h}{2\pi}\right)\omega_{l,n} = E_{\mathrm{g}} + \left(\frac{h}{2\pi}\right)^2 \phi_{l,n}^2/(2m_{\mathrm{r}}a^2) \tag{12}$$

where $m_{\mathrm{r}} = m_{\mathrm{e}}m_{\mathrm{h}}/(m_{\mathrm{e}} + m_{\mathrm{h}})$ and E_{g} is the energy gap for the bulk material. The absorption edge, which can be designated the energy gap for a nanoparticle, corresponds to the lowest transition and is shifted in comparison with the bulk situation. Because of quantum confinement, the gap increases as a^{-2} with decreasing nanoparticle size.

The first three roots $\phi_{l,n}$ are π $(l = 0,\ n = 1)$, 4.49 $(l = 1,\ n = 1)$, 5.76 $(l = 2,\ n = 1)$. So the absorption edge is given

$$by\left(\frac{h}{2\pi}\right)\omega_{01} = E_{\mathrm{g}} + \left(\frac{h}{2\pi}\right)^2 \pi^2/2m_{\mathrm{r}}a^2 \tag{13}$$

.

Because in semiconductors the hole mass is typically much greater than that of the electron, the electron levels are much more sparse than the hole levels. Estimation of the absorption edge shift gives a value of about 25 meV for $a = 5$ nm and $m_{\mathrm{e}} = m_{\mathrm{h}} = m_0$ (m_0 is the free electron mass). So the absorption edge shift due to quantum confinement can be observed in nanostructures within nanopores only a few nanometers in diameter or in semiconductors with sufficiently small effective mass of carriers. Luong and Borelli [349] have shown that III–V (GaAs, GaP) nanocrystallites in Vycor porous glass, introduced by metal-organic chemical vapor deposition, exhibit size-dependent shifts in the absorption and emission spectra, indicative of the quantum confinement. Optical properties of GaAs confined in mesoporous matrix MCM-41 also were studied [350]. Exciton absorption and luminescence spectra of PbI_2 nanocrystals [351] incorporated into porous glass by a low-temperature method (from solution) also demonstrated a short-wavelength shift due to quantum confinement. Indium phosphide has been deposited in 4-nm and 15-nm Vycor porous glass by the reaction of trimethylindium with excess PH_3 [312]. The absorption spectra of InP in a 4-nm porous glass have an onset at approximately 750 nm and reach a maximum at 500 nm. This sample is clearly blue-shifted with respect to the 15-nm sample, which displays a more broadened spectrum with an onset well before 1000 nm and a maximum at 700 nm. For comparison, bulk InP would show a sharp transition near 918 nm. Such a behavior of the absorption edge is consistent with quantum confinement. A broad absorption edge was attributed to a distribution of crystal sizes, since it has been observed that a 10% change in particle size results in broadened, featureless spectra.

A strong quantum confinement effect has been found for nanowires within chrysotile asbestos nanotubes, for GaAs [352–354], CdSe [354, 355], and InP [354]. The polarized absorption spectra of GaAs nanowires demonstrated bands at energies of 1.8 eV and 2.2 eV for both polarizations (the absorption is stronger for light polarized along the wire), the bandwidths being ~0.1 eV. Asbestos is transparent in the spectral region considered. Thus, all of the bands can be attributed to optical transitions in the GaAs nanowires. The energy of the first transition between the highest valence subband and the lowest conduction subband of a cylindrical quantum wire with infinite bandgap discontinuity can be estimated. If we take as a room-temperature energy gap $E_{\mathrm{g}} = 1.44$ eV for bulk GaAs, we obtain the quantum-wire energy gap and the first transition energy to be ~1.8 eV. This value correlates well with the spectral position of the 1.8-eV band. The band at 2.2 eV can be assigned to a transition between the valence band subbands split off by the spin-orbit coupling and the first conduction subband. The polarized absorption spectra of CdSe nanowires also display stronger absorption for light polarized parallel to the wires and weaker absorption for light polarized perpendicular to the wires. The broad band peaked at about 1.87 eV was observed and can be attributed to intersubband transitions in the cylindrical CdSe quantum wires. This band displays a blue shift of about 0.14 eV relative to the bulk CdSe absorption edge (the energy gap of the bulk CdSe is 1.73 eV at room temperature), which corresponds to the quantum-confinement energy shift of the first intersubband transition (for $m_{\mathrm{e}} = 0.12m_0$, $a = 3.5$ nm).

4.1.2. Metallic Composite Medium

The optical properties of metallic nanostructures within nanoporous matrices have been described mostly in the framework of the Maxwell-Garnett theory [356], which is a simple treatment of composite materials, addressing the shape but not the size of a particle. It provided the first theoretical basis to explain the resonant absorption (or dielectric anomaly), which is characteristic of systems of this kind. In the Maxwell-Garnett theory, the effective dielectric function $\varepsilon_{\mathrm{eff}}$ of a composite medium is related to the polarizability of a single metal particle via the Clausius-Mossotti equation [357], that is,

$$(\varepsilon_{\mathrm{eff}} - \varepsilon_{\mathrm{i}})/(\varepsilon_{\mathrm{eff}} + 2\varepsilon_{\mathrm{i}}) = (4/3)\pi N\alpha_0 \tag{14}$$

where N is the number density of metal particles, $\alpha_0 = R^3(\varepsilon_{\mathrm{m}} - \varepsilon_{\mathrm{i}})/(\varepsilon_{\mathrm{m}} + 2\varepsilon_{\mathrm{i}})$, ε_{i} is the dielectric function of the dielectric host, ε_{m} is the dielectric function of the metal, and R is the radius of the metal sphere. From this equation follows the relationship between the dielectric function of the metal-insulator composite and the dielectric functions of its constituents

$$(\varepsilon_{\mathrm{eff}} - \varepsilon_{\mathrm{i}})/(\varepsilon_{\mathrm{eff}} + 2\varepsilon_{\mathrm{i}}) = f(\varepsilon_{\mathrm{m}} - \varepsilon_{\mathrm{i}})/(\varepsilon_{\mathrm{m}} + 2\varepsilon_{\mathrm{i}}) \tag{15}$$

where $f = 4\pi^3 NR^3/3$ is the volume fraction of metal spheres.

In such a way the optical properties of a composite porous glass with Ag have been studied [358] by measuring the reflectance between 10,000 and 40,000 cm^{-1}. It was shown for samples with different sizes (mean radius from about 2.5 nm up to about 45 nm) that the red shift, broadening, and reduction of the peak in reflectance can be successfully compared with theoretical predictions. In a similar way nanoscopic gold cylinders of controlled radius (from 30 nm to 60 nm) and aspect ratio were studied; these were prepared via electrodeposition of the metal within the pores of anodically grown porous aluminum oxide membranes [359]. Maxwell-Garnett's original work addressed spherical inclusions, and it is for this specific geometry that the factor of 2 appears in the denominators. This factor is also called the screening parameter and, in general, is denoted by k (see, [360]). Hence, while $k = 2$ for spheres, long needlelike particles with their axes of revolution aligned with the direction of light incidence have a k value approaching unity. On the other hand, k tends to infinity for thin flat disks with an axis of revolution perpendicular to the direction of light incidence. The Maxwell-Garnett-calculated spectra are in qualitative agreement with experimental data for Ag in porous glass, which show dependence on both size and shape. Polarized optical spectra of long nanowires made of Hg, Bi, and InSb have been studied in the spectral range 0.5–3 eV [300]. These wires were prepared within channels of chrysotile asbestos by filling the channels with molten material under a pressure of up to 10 kbar. A high absorption anisotropy has been observed. This was explained in terms of the Maxwell-Garnett theory with depolarization factor k dependent on the nanowire orientation with respect to the electric field vector of incident light.

4.1.3. Interaction Between Filler and the Porous Matrix

In the case of nanostructures within porous materials, based on wetting liquids, the optical properties have attracted much attention because of the possibility of making some important conclusions about the phase state of encapsulated molecules and the possible mechanism of interaction between the filler and the active centers of the matrix, situated on the inner surface of pores, such as the molecular mobility of liquids within the nanopores. In such a way, the reorientational and vibrational dynamics of ethylene glycol and its homologous systems, possessing different numbers of OH groups per molecule, have been studied [257, 258] (see also [361]). The above systems have been studied in bulk and in the confined state within a porous glass matrix with pores 2.5 nm in diameter by means of light scattering (Raman and Rayleigh). By a comparison of the results obtained, evident influence of the chemical and physical traps on the molecular mobility was shown. The infrared absorption and Raman measurements, performed in the O-H stretching region, allowed identification of the intramolecular, H-bond subband and related various subbands to different intermolecular environments originating from the existence of the H-bond potential [362]. The optical properties of the 4-*n*-alkyl-4′-cyanobiphenils (*n*CBs, where n is the number of carbon atoms in the alkyl radical $n = 5, 8$) confined to porous glasses with four different mean pore sizes (2, 4, 54, and 90 nm), have been studied [255]. It has been shown that the interaction of *n*C8 molecules with the pore surface is accompanied by the formation of hydrogen bonds between the SiOH group on the glass pore surface and the cyano group of the *n*CB monomer. In contrast, in the case of benzophenone confined to porous glass, weak OH-Si hydrogen bonds are formed. Phosphorescence spectra of benzophenone encapsulated in the inner space of mesoporous aluminosilicate molecular sieves of the MCM-41 type (the channel diameter is about 4 nm) have been analyzed at 4.2–200 K [254]. A comparison of these spectra with the spectra of a bare MCM-41 matrix, pure benzophenone, and benzophenone incorporated into the porous glass led to conclusions about the phase state of encapsulated molecules and the possible mechanism of interaction between the filler and active centers (of the Si-OH type) on the inner surface of pores. The main influence exerted by the strong dipolar interactions on the dynamics of hydrogen-bonded liquids (propylene glycol) diffusing within 2.5-nm and 7.5-nm pores of a sol–gel porous glass has been demonstrated [363] by depolarized light-scattering spectroscopy. The experimental spectra measured as a function of temperature revealed unambiguously the slowing down of the collective reorientational processes triggered by the confinement effects. In addition to intermolecular interactions, an interaction mechanism of induced absorption has been identified in porous Vycor glass filled with liquid H_2 by measuring the infrared absorption [364]. Infrared spectra have been studied for pyridine adsorbed on porous glass [365], and it was established that physical adsorption occurs by hydrogen bonding of pyridine to SiOH and B-OH groups via a nitrogen atom. Absorption in the far infrared region has been used to investigate surface vibrations in NaCl crystals dispersed in porous glass [366]. The experimental results were in good agreement with the theory predicting a gap between the limiting frequencies of the longitudinal and transverse optical surface vibrations in very small ionic crystals. Optical methods have also been used to study the interaction between liquid crystals and the inner surface of porous matrices [250, 252, 367, 368]. Dynamic and static light-scattering measurements in a nematic liquid crystal, pentylcyanobiphenil (5CB), confined in silica porous glasses with an average pore size of 100 nm (volume fraction of pores 40%) and 10 nm (volume fraction of pores 27%), demonstrated significant changes in the physical properties of confined liquid crystals [252]. The nematic-isotropic phase transition temperature is depressed by 0.6 K in 100-nm pores, compared with the bulk value, and this phase transition is not detected at all in 10-nm pores. It was found that even at about 20° below the bulk melting point the relaxation processes in a confined liquid crystal are not frozen. The infrared absorption spectra of 5CB dispersed in porous glass and molecular sieves of the types Si, Al-MCM-41 and Cu-Si, Al-MCM-41 (pore diameter of about 4 nm) have been investigated in the region of fundamental and overtone vibrations [367]. The mechanism of interaction between a part of 5CB molecules and the active centers of the porous interface was estimated. In this case, a strong enough interaction occurs between the cyano groups of 5CB and the hydroxy groups of the channel surface. It was also shown that another part of the 5CB molecule exists in the liquid-crystal state, and its

amount depends on the size and nature of the pores. Photon correlation spectroscopy was used to investigate nematic liquid crystals dispersed in porous matrices with randomly oriented interconnected pores (porous glasses) and parallel cylindrical pores (Anopore membranes) [250]. Investigation of liquid crystals in cylindrical pores, together with studies in random porous matrices, made it possible to separate the effect of random structure and domain formation from the contributions due to the existence of a liquid crystal–solid pore wall interface and the effect of the finite pore size in relaxation of the order parameter or director fluctuations.

4.1.4. Luminescence, Phosphorescence, Spectral Kinetics

Interface phenomena in nanostructures formed within porous matrices have also been studied with the use of luminescence, phosphorescence, spectral-kinetic techniques, etc. (see [266, 267, 313, 369–376]). An enhanced and broadband photoluminescence behavior of fullerene (C_{60})-doped porous glasses has been observed [371]. By means of photoluminescence and photoluminescence-excitation spectroscopy of C_{60} dopant in surface-unpassivated and -passivated porous glasses, it was shown that the interaction of C_{60} with the silica surface is quite strong (see also [267]) and that the modified C_{60} molecules contribute only in the orange-red region (1.9 eV) of the observed photoluminescence spectrum. The luminescence spectra of a number of polypyridine ruthenium (II) complexes adsorbed on the surface of a porous glass have also been studied [372]. Experimental data on the decay of the excited state of adsorbates were adequately described within the framework of a two-exponential model. Special features of the spectral luminescence parameters measured were accounted for by inhomogeneous broadening of spectra of luminophores arranged under heterogeneous conditions on the glass surface. The revealed features of luminophore quenching in heterogeneous conditions [373] were explained within the framework of a model analyzing two subsystems of adsorbed luminophores. Different mechanisms of quenching were considered, and a conclusion about the dynamic character of luminophore quenching in a porous glass was made. A comparative study of Raman, optical absorption, and photoluminescence spectra in 3D regular ensembles of InP quantum wires [313, 369, 377] revealed the dependence of the optical properties of these quantum wires on interfacial effects, namely, atomic interactions in the wires, and wire-matrix and wire-wire interactions. InP quantum wires have been produced in channels of chrysotile asbestos (wire diameter $D = 8$ nm, distance between wires $A = 40$ nm), MCM-41 mesoporous framework silicate ($D \approx 3$ nm, $A \approx 3.4$ nm), and $AlPO_4$-5 zeolite ($D \approx$ nm, $A \approx 1$ nm) by a two-stage gas-phase substitution reaction of the metal-organic compound trimethylindium [378]. InP wires in chrysotile asbestos are virtually isolated from one another; in other words, there is no wire-wire interaction. The spacial separation between the channels in MCM-41 is small enough (channel wall thickness of 0.8 nm) to allow effective coupling between nanowires. Taking into account that only one InP molecule can fit to the diameter for $AlPO_4$-5 zeolite, it appears natural to assume that the interaction between the $AlPO_4$-5 matrix and InP is the strongest among all of the hosts considered. A comparison of optical data for these three matrices demonstrated that the wire-matrix interaction distorts the InP lattice, broadens the electronic density-of-states spectrum of the wire in the vicinity of the energy gap, and redistributes the relaxation of photoinduced excitations among states belonging to the wire itself and to defects in the matrix bound to the wire.

The migration of triplet excitations of complex molecules in a confined geometry was studied in [374–376]. The results of investigation of the decay kinetics of phosphorescence and delayed fluorescence of disordered chrysene and chrysene in porous matrices were presented. The study of triplet-triplet annihilation kinetics allows an understanding of transport in disordered films, polymers, and membranes and of paradigms of heterogeneous chemical kinetics. It is also a tool for studying the topology, morphology, and structure of molecular aggregates, strands, pores, and domain boundaries. Porous glasses represented as chaotically arranged spheres and natural mineral chrysotile asbestos represented as hollow cylinders packed parallel to one another were used as matrices. An investigation of delayed luminescence of disordered chrysene and chrysene in porous matrices has shown that the triplet excitation transport in these systems at $T = 77$ K is dispersive in nature. The annihilation kinetics of triplet excitations is described by a rate coefficient that depends on time according to a power law. The exponent is determined by the microscopic structure of a sample and its geometry. In the case of chrysene in porous matrices, the annihilation kinetics of triplet excitations is determined by the matrix geometry and varies slightly with increasing temperature. An analysis of the decay kinetics of delayed luminescence from chrysene in porous glasses in comparison with chrysotile asbestos has led to a conclusion that the topology of the porous network of porous glasses is similar to that of the 3D percolation cluster.

4.1.5. Structure of Clusters and Nanochains in Zeolites

Zeolites, which possess a regular system of cavities with a diameter of about 1 nm, are very appealing, in that they permit the preparation of arrays of unisized nanoclusters in the cavities. There are a lot of questions about the kind of structures that may be stabilized inside the zeolite pores. Some of these have been solved by applying optical spectroscopy methods to clusters of chalcogens (sulfur, selenium, tellurium) introduced into the pores of zeolites NaA and NaX (see [319, 379–387]). Chalcogens are good materials for the preparation of this kind of cluster, because they can easily be introduced from the melt or adsorbed into zeolite nanovoids, and their optical properties can be studied in the visible and near-UV spectral ranges, in which zeolites are transparent. For sulfur clusters it has been shown by Raman scattering and optical absorption spectra [382] that the main molecular unit of sulfur in the NaA zeolite is the most stable sulfur molecule, namely, the S_8 crown-like ring. NaA with selenium has been examined by Raman [380, 381, 383, 384, 386, 387] and optical absorption [379, 381, 385–387] spectroscopies. The whole body of data obtained

shows that some kind of Se ring molecules, rather than chain molecules, are stabilized. The NaA zeolite with Te has also been studied by Raman [380, 386] and optical absorption [386] spectroscopies. Similar to the case of Se clusters, the experimental data obtained indicate that, probably, Te ring molecules are stabilized. A more detailed study of Raman spectra [388] yielded evidence in favor of the stabilization of S_8, Se_8, Se_{12}, and Te_8 ring molecules in the NaA zeolite. S_8 and Se_8 molecules are well known to exist in the condensed state, but there has been no information about the stabilization of Se_{12} and Te_8 rings under conditions different from those in the zeolite NaA cavities. A possible reason for this stability is the good compatibility of the size and symmetry of Se_{12} and Te_8 with the size and symmetry of cavities in the NaA zeolite. Strong and broad low-frequency bands in the Raman spectra of a NaA zeolite with sulfur and selenium were attributed to librations of ring molecules in the cavities. To obtain information about the symmetry of the Raman-active vibrations and the orientation of clusters in zeolite cavities, Raman microprobe polarization measurements have been performed (usually microcrystalline powder samples were studied) [389]. The dependences obtained correspond to S_8 rings with the D_{4v} point group symmetry, with their fourfold axes aligned with the fourfold axes of zeolite NaA, and Se_{12} rings with the D_{3d} point group symmetry, with their threefold axes oriented along the threefold axes of the zeolite. The possibility of determining the ratios between the Raman tensor components of vibrations of zeolite-confined clusters was demonstrated.

There are zeolites, such as mordenite, cancrinite, and $AlPO_4$-5, which are very attractive for the preparation of 1D systems. The chalcogen guest materials (sulfur, selenium, tellurium) have been introduced into the cavities of these zeolites, and the structure of chain-like nanostructures within the pores has been studied by optical methods (see [381, 384–386, 390] for mordenite matrix, [391–393] for cancrinite matrix, and [394–396] for $AlPO_4$-5 matrix). Polarized Raman and optical absorption spectra of natural mordenite single crystals containing sulfur, selenium, or tellurium within 1D channels (channel diameter 0.7 nm) have been studied. The bands in the Raman and absorption spectra, which are polarized along the channel direction, are attributed to helical chains. The helical chains and ring molecules (S_6, S_8, Se_6, Te_6) coexist in the mordenite channels. The chains contribute to absorption spectra only for the E$\|$c polarization. Correspondingly, the resonance enhancement of Raman spectra of the chains is working for cc-polarization, and so Raman bands of the chains are active in this polarization. Ring molecules absorb light for all possible polarizations, and so the molecule vibrations are active for the aa-, bb-, and cc-polarizations. The ratio between the concentrations of chains and rings can be related to some kind of regular arrangement between chains and rings inside a channel.

Polarized Raman, optical absorption, and luminescence spectra of cancrinite crystals possessing parallel nanochannels with Se inside have been investigated. It was shown that Se is stabilized in the form of Se_2^{2-} and Se_2^- dimers situated at the center of the channel and oriented along the channel. When present in high concentration, the Se_2^{2-} dimers show a tendency to organize linear chains. At low temperatures, quite strong interdimer bonding for both Se_2^{2-} and Se_2^- was observed. The additional Raman bands were attributed to vibrations of linear Se_2^{2-} chains distorted by the incommensurate potential of cancrinite. Strong near-infrared polarized luminescence was observed. Photoionization of dimers was shown to be an important step in the mechanism of the luminescence.

From Raman spectra of selenium incorporated into the channels of $AlPO_4$-5 zeolite single crystals ($AlPO_4$-5 is a molecular sieve with nearly cylindrical channels with diameter of 0.73 nm) it has been concluded that single helical chains and Se_8 molecules are formed inside the channels. The temperature dependence of the Raman spectrum of single helical Se chains was studied. Dramatic changes in the spectra owing to structural transformations in this 1D system were observed. The chains are ordered at 77 K. One-dimensional Se shows transformations of the chains from the ordered state at low temperatures to weakly and strongly disordered states at higher temperatures. A phase transition from a weakly to a strongly disordered state is accompanied by structural relaxation of the chain. The structural transformations observed in single Se chains can be regarded as an example of how a nearly 1D system confined in a nanochannel behaves.

4.1.6. Nonlinear Optical Properties

The potential of quantum-confined semiconductor nanoparticles for nonlinear optical and electro-optical applications has been anticipated [397–399]. Experimentally, the nonlinear optical properties of nanoparticles in porous glass have been studied for GaAs [400, 401], InP [402], and Cu_2O [315]. Time-resolved pump/probe Z-scan experiments (for the Z-scan technique, see [403]) using 1064-nm 100-ps pulses have been performed to determine the temporal characteristics of the optical nonlinearities of GaAs nanocrystals. The buildup and decay of the nonlinearities were instantaneous, compared with the duration of the excitation pulses. Single-beam Z-scan experiments were also used to measure the two-photon absorption coefficient, β, and bound electronic nonlinear refractive index, γ, of the quantum-confined crystals. The ratio γ/β is greater by approximately a factor of 10, compared with bulk GaAs. In the case of InP nanocrystals, the magnitudes of nonlinearities in a 15-nm sample were found to be similar to those in bulk InP, whereas for a 4-nm sample the ratio γ/β was a factor of 14 greater, compared with that in bulk InP.

Carrier confinement to a single dimension must also lead to enhanced optical nonlinearities [397], and, therefore, the nonlinear optical properties of quantum wires have attracted much attention. Nanowires in channels of chrysotile asbestos (GaAs, CdSe, InP) have been intensively studied in this regard [354, 404–411]. The experiments used the pump and probe method to measure the differential transmission $\mathrm{DT}(\omega) = [T(\omega) - T_0(\omega)]/T_0(\omega)$, where $T(\omega)$ and $T_0(\omega)$ are the transmission spectra of the excited and unexcited samples. Nonlinear optical absorption at discrete frequencies (bleaching bands) has been observed for GaAs quantum wires with an average diameter of about 6 nm. The induced decrease in absorption was accounted for by filling of the quantum-well energy levels

of quantum wires with nonequilibrium carriers (saturation effect). Strong ($\chi^{(3)} \approx 10^{-8}$ e.s.u.) and fast (relaxation time $\leq$50 ps) third-order optical nonlinearity has been revealed. The nanowires within chrysotile asbestos demonstrate pronounced excitonic behavior with enhancement of excitons, with the binding energies ranging from 120 to 260 meV.

4.1.7. Photonic Crystals

The concept of a photonic crystal whose behavior with respect to photon waves is similar to that of a dielectric crystal with respect to electron waves has been advanced by Yablonovich [412] and John [413]. In periodic dielectric structures with a period close to the wavelength of electromagnetic waves, these waves undergo Bragg diffraction, and a stop band is formed for modes propagating in a given direction. If the stop bands for all propagation directions overlap in some frequency range, a photonic gap can be created, in which the density of photonic states is zero. It has been shown that synthetic opals [414–417], like opal-like films formed from polymethyl methacrylate beads [418], possess the properties of photonic crystals throughout the visible spectrum. Moreover, because of their regular porous structure, opals can be used as matrices for the fabrication of regular arrays of nanosized systems in the voids between the spheres constituting opal, which may also possess photonic stop bands. The voids between the silica spheres may comprise up to 26% of the total volume of the opal material. This makes it possible to change the optical contrast coefficient ($\eta = (\varepsilon\nu/\varepsilon_s)^{1/2}$, where $(\varepsilon_s)^{1/2}$ and $(\varepsilon\nu)^{1/2}$ are, respectively, the bulk refractive indices within the SiO_2 spheres and outside them [419]) by filling the voids with different substances. According to the theoretical estimations [419], a complete photonic bandgap may exist at $\eta \geq 2.8$. In pure opals, where η is considerably lower, the formation of the complete photonic bandgap is, apparently, impossible. Therefore, materials with a high dielectric constant should be used to fill the voids. In a similar way nanosystems of CdS particles [420] have been prepared: GaN, InN, and InGaN particles [323–326]; Si particles; VO_2 particles [327]; and photonic crystals made of nematic liquid crystals [421]. Moreover, after filling of the original opal matrix, SiO_2 can be removed chemically, and opal replicas can be prepared from different materials [422–424]. This operation yields a 3D semiconducting lattice, which occupies up to 26% of the total volume of the material and is surrounded by a "matrix" of air spheres that occupy the remaining 74% of the volume. The potential applications require control of the photonic gap structure in real time under external effects. It has been proposed [421, 425] that the opal pores be filled with liquid crystals, which allow tuning of characteristics of the photonic bandgap structure through an electro-optical effect in the liquid crystal, occurring when an electric field is applied. It has been demonstrated [327] that the photonic bandgap structure can be controlled via the metal-semiconductor phase transition in VO_2 embedded in opal. A controllable and reproducible variation of the photonic bandgap properties of the opal-VO_2 composite during heating and cooling in the temperature range 60–90 °C was achieved. This is due to the change in the dielectric constant of VO_2 upon the phase transition. It was suggested that a phase transition in this material and, hence, the photonic bandgap tuning in the opal-VO_2 composite can also be observed under ultrafast laser pulses.

4.1.8. Laser Media Based on Nanoporous Materials

New optical media have been developed on the basis of nanoporous materials, mainly porous glasses, for both optoelectronic applications [426] and laser elements [427]. New types of lasers have been fabricated by the incorporation of active dyes into porous glasses [428–434]. Molecular sieves can host some laser active dyes, too. Pyridine-2 molecules have been introduced into the channel pores of nanoporous $AlPO_4$-5 zeolite [435]. It was established that many effective dye molecules, such as rhodamines, do not fit into the pores, but the amount of encapsulated dyes can be raised by modifying the structure of the dyes so that they could match the host templates. The resulting microlasers have properties that depend on the size and shape of microcavities. For dyes that fit into the pores, partial regeneration of the photoinduced damage has been observed.

4.1.9. Materials for Optical Data Recording

Filling of porous media with photosensitive materials has been used to prepare new media for optical data recording (silver-containing porous holograms). With these materials, one can make a volume holographic record with high diffraction efficiency [436–442]. Deep 3D holograms with large physical thickness, allowing postexposure amplification and a posteriori alteration of the grating parameters, were obtained. The sol–gel technology for making glass has made it possible to synthesize a new class of porous materials, monolithic xerogels. Xerogels have a more uniform porosity, which is an important advantage in data recording. It has been shown that holograms with a diffraction efficiency of nearly 100% can be obtained upon an exposure of about 0.1 J/cm.

4.2. Electronic Transport

4.2.1. Superconductivity

Superconducting Properties of Metals in the Confined Geometry of Porous Glass The first studies of superconductivity in confined geometries of porous glass were concerned with the development of new artificial hard superconductors [443, 444]. New superconducting nanostructures were fabricated by pressing mercury into porous Vycor glass placed in mercury in a small balloon and compressed hydrostatically for 20 min at 3300 atmospheres, the pressure required to force the mercury into the Vycor glass. By measuring the weight gain, it was found that 10% of the total volume of the sample, whose interconnected pores were approximately 3 nm in radius, was filled with mercury. The superconductivity was measured with the magnetic induction technique. The measurements of magnetization and critical current demonstrated a large enhancement of the critical magnetic field and critical current in comparison with their bulk values. The critical current density was $\sim 10^4$ amps/cm^2, and the critical magnetic field, $\sim$40 kOe at 2.1 K (the critical magnetic field for bulk mercury at 2.1 K is 320 Oe).

This size effect may arise when the characteristic sample size is made comparable to, or less than, the bulk coherence length ξ_0 and the magnetic field penetration depth λ_0. For bulk mercury, $\xi_0 \approx 200$ nm and $\lambda_0 \approx 43$ nm, and, therefore, the observed enhancement is not surprising. Furthermore, the superconductivity of some other metals (In, Sn, Pb, Tl, Ga) within nanopores of porous glass was studied [445–447]. Measurements of the critical magnetic field and transition temperature of superconducting indium in porous glass have been made with a low-frequency mutual-inductance technique [446]. Pore diameters from 6.5 to 25 nm were used. It was found in these measurements that the critical magnetic field H_c depends strongly on D, the pore diameter of the glass. Below $t = 0.5$ ($t \equiv T/T_c$, T_c critical temperature) H_c can be represented as approximately $H_c = (3415 \pm 40)(1 - t^2)/D^{(1.00 \pm 0.14)}$, where H_c is measured in kOe and D in Angstroms. This is in agreement with the predictions of H_{c2} made by de Gennes and Maki [448, 449] for type II superconductors in the dirty limit under the assumption that the electron mean free path is proportional to D. According to the de Gennes-Maki theories,

$$H_{c2}(0) = (3/2\pi^2)(\Phi_0/\xi_0 l) \tag{16}$$

where Φ_0 is the flux quantum, ξ_0 is the coherence length of the pure metal, and l is the electron mean free path. Near $t = 0$, de Gennes and Maki obtained

$$H_{c2} \cong 0.87\lambda_L(0)H_c(0)(1 - t^2)/l \tag{17}$$

where $\lambda_L(0)$ is the London penetration depth in pure metal at $t = 0$. The dependence of T_c on D is conveniently represented as $T_c - T_{cbulk} = 1 - 0.028/D$, where D is in Angstroms. It was supposed that the change in T_c may be due to strain, mean free path, or surface effects. Experimental results on the transition temperature of indium, thallium, and lead grains of various sizes in porous glass, together with preliminary measurements on other metals [447], have been interpreted in terms of changes in the phonon spectrum, which alter the electron-phonon coupling constant. McMillan [450] has shown that the transition temperature of simple metals can be raised by reducing the Debye temperature. It has been suggested [451, 452] that, in small crystallites, the phonon spectrum is appreciably modified by a greater proportion of low-frequency surface phonons, and this is the reason for the shifts in T_c in granular or disordered materials. For these purposes the phonon spectra of gallium and tin embedded in porous glass have been studied with the Mössbauer technique [453, 454]. In [281], superconducting metals within porous glass were described as granular superconductors, that is, as superconductors consisting of small grains that are separated spatially but connected by electron tunneling. Abeles et al. [455] have carried out a calculation for a 1D model of a granular superconductor, with the grain boundaries represented by δ-function barriers. They found that the material behaves like a homogeneous dirty superconductor, with a critical field given by de Gennes-Maki theory, but with an effective mean free path $l = D\tau/(1 - \tau)$, where D is the grain size and τ is the transmission coefficient for electrons incident on a δ-function barrier. Some experimental results and results derived from this theory for metals in porous glass are given in Table 6.

Table 6. Parameters of superconductivity for metals in porous glass.

	D (Å)	T_c (K)	H_{c2} (kOe)	ξ_0 (10^5 cm)	τ	l (Å)
Indium	31	4.24	69	3.5	0.042	1.31
	60	4.05	39	3.7	0.036	2.17
	80	3.96	29	3.75	0.036	2.90
Lead	32	7.05	96	0.85	0.120	3.84
	58	7.15	55	0.83	0.120	6.90
Tin	31	4.97	54	1.72	0.11	3.42

It has been shown that Pb-Bi alloys embedded in a porous glass [282, 283, 456] can be used in some applications because of their very large critical magnetic field (for Pb-40%Bi H_{c2} was about 120–125 kOe at 4.2 K). The transition temperature was about 7.8 K for porous glass with a 6-nm pore diameter. Measurements of the critical current density for Pb-40%Bi alloy in porous glass with an average pore diameter of 3.5 nm have been made in a transverse magnetic field and demonstrated a typical critical current density of about 10^5 A/cm^2 in a zero magnetic field and 10^4 A/cm^2 at 90 kOe. For Pb-Bi alloy in porous glass with a 2-nm pore diameter [456], the critical temperature was found to be 6.2 K, and $H_{c2}(0)$ was 230 kOe (as estimated by extrapolating from 210 kOe, the highest field used in measurements). Interestingly, the last value is greater that the so-called paramagnetic limit introduced by Clogston [457] and Chandrasekhar [458]. They pointed out that the electron Zeeman energy in the normal state can make a significant contribution to H_{c2} determined at high enough fields. At magnetic fields stronger than $H_p = [\Delta_0/(2\mu_B)^{1/2}$ (where Δ_0 is the energy gap of the superconductor and μ_B is the Bohr magneton) superconductivity must be impossible, since the free energy of electrons in the normal state is equal at H_p to the superconducting condensation energy. For PbBi alloy, H_p is about 120 kOe, and so the experimental value of H_{c2} for this material in porous glass exceeds the paramagnetic limit. The explanation was found in the framework of the theory [459], including the effects of spin-flip scattering induced by spin-orbit coupling.

Gallium has been introduced under a pressure of 14 kbar from a melt into porous media, such as cellulose, corundum powder, synthetic zeolites (NaA, NaX), and porous glass [271]. In the temperature range studied (4.2–16 K), two superconducting transitions were observed in the range from 6.1 to 6.4 K and between 6.8 and 7.2 K. The first transition was ascribed to the metastable phase β-Ga, and the second, to another metastable phase, named δ-Ga. These phases were previously observed in thin films and in gallium emulsions [460, 461] (T_c of the ordinary phase of gallium is 1.08 K). The major part of gallium in porous glass was not superconducting above 4.2 K. At 4.2 K, a broadened signal was observed, which could hardly be suppressed with a magnetic field. This signal was identified with the "tail" of some low-temperature ($T_c < 4.2$ K) transition of gallium into the pores. Further study of the superconductivity of gallium embedded in nanoporous materials (various porous glasses and opal) was performed [462–466] to reveal how the size and configuration of pores influence the superconducting

features, because it was found previously that many general superconducting properties of porous glasses filled with metals occur because of the interplay of strong and weak links between metallic nanoparticles in pores. The superconductivity was studied with a superconducting quantum interference magnetometer with a 7-T solenoid in the temperature range 1.7–20 K. Single and double superconducting phase transitions were observed for different samples. Magnetization hysteresis loops were also measured and found to be dependent on the size and geometry of the pores. The changes in magnetization below about 6.4 K were analyzed in terms of models for granular superconductors, while the alterations in magnetization near 7.1 K were regarded as resulting from a superconducting phase transition in a coexistent structural modification of confined gallium. X-ray diffraction measurements confirmed the presence of such an additional gallium modification. The results obtained suggest that studies of magnetization at low temperatures can be used to get information about the geometry of the pore network and distribution of Josephson links in porous composite materials.

A double resistive superconducting transition has also been found for indium within 5.6-nm-pore Vycor glass [467] (see also [468, 469]). The interconnected network of pores occupied approximately 30% of the total sample volume. From the broadening of the X-ray diffraction lines, a characteristic crystalline size of about 35 nm is inferred, which is significantly larger than the pore size of the Vycor. Furthermore, the X-ray diffraction measurements do not reveal a second phase. At the same time, the zero-field resistive transition shows a two-step temperature dependence with maximums in the derivative dR/dT at 3.99 and 4.03 K (T_c of bulk indium is 3.40 K). In a magnetic field, two fundamentally different transitions were observed by means of electric transport and magnetic susceptibility measurements. It was concluded that the presence of two distinct transitions is an intrinsic effect associated with the microstructure of indium in the porous Vycor glass. The superconducting transition temperature of an In-impregnated porous glass with 3.8-nm pore diameter has also been measured as a function of a hydrostatic pressure of up to 3.74 kbar [280]. All measurements were performed with a sample inside a Be-Cu pressure cell. The mean T_c increased above the value characteristic of bulk In by 17%. Its pressure derivative dT_c/dp was determined to be $(-2.8 \pm 0.6) \times 10^{-5}$ K/bar less than the effect of pressure in bulk indium. It was concluded that the increase in the critical temperature and the smaller effect of pressure on the critical temperature for In-impregnated porous glass, compared with bulk indium, are both due to the softening of the phonon spectrum, resulting from the increased surface-to-volume ratio of the pores.

Superconducting Properties of 3D Arrays of Weakly Coupled Nanoparticles within Opal Arrays of nanosize superconducting metal particles have been prepared by impregnation of the opal matrix with molten metal (In, Pb, Sn, Ga, and PbBi alloy) under high hydrostatic pressure [153, 289–292, 470]. The shape of the metal grains is an exact copy of the void configuration, since the metal occupies the entire free volume of the matrix, and so a 3D replica of the matrix can be formed. In accordance with the matrix structure [150], each section consisting of two adjoined grains contains a constricted region that can be considered a weak link (in the sense of superconducting properties), that is, an element of the S-c-S (S, superconductor; c, constriction) type, and so the proposed material contains a regular array of identical Josephson junctions. Owing to the matrix, these elements are arranged in a crystalline manner and form a macrosystem. The density of weak links in this material is about 10^{14} cm^{-3}. The interest in systems with a large number of Josephson junctions has been growing because of the practical demand. Microwave generators, receivers, and other devices based on a single Josephson junction are limited in their application because of their inability to emit powerful radiation in the generator mode and their liability to saturation in a weak external field in the detector mode. In-series connected Josephson junctions are very promising for application as power sources of microwave radiation for space communications, wide-dynamic-range detectors, parametric Josephson amplifiers, voltage standards, etc. Their main advantage is the coherent addition to the output signal from each element of an array. Microwave generators using coherent oscillations of an array of 40 or 100 Josephson junctions have been fabricated with good performance: emitted power of up to 10^{-6} W and frequencies of up to 300 GHz; moreover, the phase-locked emission linewidth was less than 5 kHz [471, 472]. In addition, an increase in the dynamic range of detectors in proportion to N^2 is observed for N in-series connected junctions [473]. The results obtained with opal-based Josephson junction arrays show that the materials prepared behave like continuum Josephson media exhibiting mutual phase locking. The following dependences were measured: resistance versus temperature, $R(T)$; critical current versus temperature, $I_c(T)$; and current–voltage characteristics. The measured detector response to an external radiofrequency signal were compared with $R(T)$ and dR/dT dependences and current–voltage characteristics. The microwave sources in use covered the range from 0.5 to 10 GHz. To separate the amplitude- and frequency-dependent response components from the total detector signal, amplitude-modulated radiation and frequency-modulated radiation were used. Magnetic properties of the system in a weak magnetic field $H < 150$ Oe, namely, the dependences $I_c(H)$ in dc and ac magnetic fields, shift of the superconducting transition temperature, and distortions of the voltage–current characteristics and responses, were also studied. The resistive transition demonstrated a shift toward higher temperature. For the In-based system, the critical temperature was shifted to $T\ (R = 0) = 3.446$ K, compared with that in bulk In ($T_c = 3.40$ K). Taking into account the experimental dependences of T_c on the diameter of superconducting nanoparticles, one can estimate the related size of In grains to be 50 nm. This value corresponds to the void size. The critical current density of each bridge was on the order of 10^4 A/cm^2, which is about 10 times less than the characteristic bulk value, and the sample-average critical current density was about 10^2 A/cm^2. An oscillating dependence of the critical current on the external magnetic field has been observed. Conventionally, such a dependence corresponds to trapping of flux quanta in the lattice cells of a phase

coherent array of Josephson junctions. For a Sn-based system the periods of the observed oscillations, $\Delta H_1 = 3$ Oe in a weaker magnetic field and $\Delta H_2 = 22$ Oe in a stronger field, were smaller than the critical field in bulk Sn ($H_c(0) =$ 306 Oe) at $T = 3.42$ K, fixed in the experiment. Therefore, this effect can be regarded as resulting from quantum interference in a regular lattice of magnetic vortices. These data were fitted using the relation $\Delta H \pi D^2/4 = \Phi_0$ (Φ_0 is the flux quantum). The first period corresponds to a lattice of loops with effective diameter $D = 2500$ nm. When a state with 4 flux quanta per loop is achieved, the system jumps to a state with loops 1000 nm in diameter. Both periods correspond well to multiples of the silica sphere diameter (250 nm). The typical voltage–current characteristics of the samples under investigation look like the curves observed for bridge-type Josephson junctions, which obey the resistively shunted junctions model. Typically, the hysteresis loop of the voltage–current characteristic takes place at $T < T_c$. However, other specific features of the voltage–current curve were found: switching between some fixed states in the resistive branch of the voltage–current characteristics; irreversibility of voltage–current characteristics (that is, any shift of the operating point along the resistive branch forward and back results in a hysteresis loop); an "anomalous" hysteresis loop at temperatures that are low but close to T_c, that is, the downward branch of voltage–current characteristics branch passes above the upward branch [153, 289, 290]. As for the last phenomenon, upon cooling the magnitude of this hysteresis first reaches a maximum and then gradually decreases and turns into the "normal" one. Moreover, the stronger the current through the sample ($I > I_c$), the greater the "anomalous" difference between the upward and downward branches of the voltage–current characteristics. The response to microwave radiation shows no Shapiro steps in the voltage–current characteristics of a sample exposed to external radiation; that is, there is no selective detection typical of separate junctions. However, the origin of detection of the radiofrequency signal is Josephson-related rather than classical. The frequency-modulated response curve differs significantly from the amplitude-modulated one both in magnitude and in shape; that is, the sample exhibits frequency-dependent properties. So, a Josephson-like behavior of such a system was demonstrated, but, at the same time, some disadvantages were found: the indefiniteness of its structure, related to the polycrystalline nature of artificial opal-like matrices, and the uncertainty of the type of interjunction interaction due to the close displacement of Josephson junctions.

Superconductivity in Metallic Nanowires The nanochannels of chrysotile asbestos matrix have been filled under high pressure with superconducting metals (Hg, In, Sn, Ga, Pb), and the superconducting transitions of a complete series of such samples have been studied by the contact method [293–299, 474, 475]. Relieving the external pressure after filling of asbestos channels with liquid metals led to a loss of sample conductivity because of some oozing of liquid metals from the pores due to the nonwetting instability. It was, therefore, essential to study the system directly under high pressure, using autonomous chambers where the pressure was kept. Each sample contained about 10^6 parallel nanowires with the same diameter and length of about 0.5 cm, separated from one another by an insulator (asbestos) layer 30 nm thick. For such a system the temperature dependence of resistance in the region of the superconducting transition has a temperature spread ΔT, which is due to fluctuations significant for such thin elements (width of the critical region). It is known that fluctuations smear the superconducting transition, so that the resistance smoothly decreases from the normal-state value R_N to zero in some finite temperature region. In the low temperature region, the fluctuations destroy the superconductivity and result in the appearance of finite conductivity. In the high-temperature part of the superconducting transition, an additional conductivity correction associated with fluctuation electron pairing appears. For mercury nanowires of 8-nm diameter the temperature smearing of the transition is $\Delta T \sim 0.4$ K (from ~4.9 K to ~5.3 K). Measurements performed on mercury nanowires with diameters of 2 nm [294] have shown that their superconducting transition is smeared from ~2 K to ~6 K, that is, $\Delta T \sim 4$ K. Some attempts to describe theoretically the fluctuation-smeared superconducting transition have been reported [476–480]; they are reviewed in [481]. The dimensionless smearing of the superconducting transition due to fluctuations in the 1D case (for ultrathin wires) was estimated to be

$$\Delta t_1 \equiv \Delta T/T_c = (\varepsilon_F/kT_c)[k_F^3 \xi(0) D^2]^{-1} \qquad (18)$$

where ε_F is the Fermi energy, $(h/2\pi)k_F$ is the Fermi momentum, $\xi(0) = (\xi_0 l)^{1/2}$, ξ_0 is the coherence length, l is the mean free path for electrons, D is the diameter, and T_c is the critical temperature. For macroscopic D (~0.01 cm), the dimensionless smearing can be calculated as $\Delta t \sim 10^{-12}$, and so no influence of fluctuations can be observed. For $D =$ 6 nm, Δt is about 10^{-1}, and for $D = 2$ nm, $\Delta t \sim 1$, which is in agreement with experimental data for mercury nanowires for $T_c \approx 4$ K. It is not quite clear how to determine the critical temperature T_c for such a temperature-smeared superconducting transition. This parameter was determined for superconducting nanowires within chrysotile asbestos channels from the temperature dependence of resistance, using theoretical descriptions of the fluctuation-smeared superconducting transition. In the low-temperature range, the temperature dependence of resistance can be written as

$$R(T) = R_N(\varepsilon/\Delta t_1)^{9/4} \exp[-(-\varepsilon/\Delta t_1)^{3/2}] \qquad (19)$$

where $\varepsilon = (T - T_c)/T_c$ is dimensionless temperature. T_c can be obtained by comparing the above dependence with experimental data. The temperature dependence $[\ln(R(T)/R_N)]^{-2/3}$ in the low-temperature part of the superconducting transition is linear and equal to zero at T_c. A good agreement with such a dependence was observed for all of the samples studied, and the T_c values were determined for different superconductors. The critical temperature T_c can also be calculated from the high-temperature part of the superconducting transition, where the temperature dependence of the resistance corresponds to the theoretical dependence

$$(\sigma - \sigma_N)/\sigma_N = \varepsilon^{-3/2} \qquad (20)$$

where $\sigma(T) \equiv 1/R(T)$ and $\sigma_N \equiv 1/R_N$. In this case, the dependence $[(\sigma - \sigma_N)/\sigma_N]^{-2/3}$ vs. T is linear and equal to zero at T_c. There was also a good agreement of such a dependence with experimental data, and T_c parameters determined for the two sides (low- and high-temperature) of superconducting transitions were the same. This is an interesting experimental result, because the theoretical descriptions of the low- and high-temperature parts of the superconducting transition (and, therefore, the experimentally obtained T_c parameters) are independent. Such a result indicates that this T_c corresponds to a physical quantity that can be designated the critical temperature for a smeared superconducting transition. Dependences of T_c on diameter D have been measured for mercury, tin, and indium nanowires with diameters of 2 to 15 nm [152, 299]. The critical temperature of tin nanowires increases with decreasing diameter (up to 5.2 K), and the $T_c(D)$ dependences for mercury and indium nanowires show maximums. For mercury nanowires, $T_c^{max} = 4.6$ K at $D = 4$ nm; for indium nanowires, $T_c^{max} = 6.5$ K at $D = 2.5$ nm.

The current-induced breakdown of superconductivity in nanowires within asbestos nanotubes has been studied [293, 294], and some discrete steps in voltage–current characteristics were observed. It was suggested that they correspond to nonequilibrium processes in superconducting nanowires, associated with formation of the so-called phase-slip centers (see [482, 483]), studied for superconducting whiskers and nanobridges. The voltage–current characteristics of mercury nanowires are strongly nonlinear in the superconducting region, and further cooling ($T < 2.9$ K) gives rise to a falling region [295]. It was found that the distinguishing features of the characteristics observed are the N-type shape and the existence of an upper limit to the oscillation frequency. The frequency dependence of the characteristics was investigated with a relaxation oscillator in which the sample served as the active element. The N-type region of the characteristics was accounted for by the appearance of a thermal resistive domain associated with local heating of the sample by the current.

The heat capacity of mercury and indium nanowires in the temperature range of the superconducting transition has been measured [296]. Experiments have been carried out on mercury nanowires with different diameters (from 2 up to 15 nm) and indium nanowires with a diameter of 5 nm, obtained by forcing the metal into the channels of chrysotile asbestos. A nonstationary method has been used (similar to that in [484, 485]) from the variation of the nanowire resistance in the region of the superconducting transition under the influence of a thermal flux modulating the temperature of the sample at a frequency of 25 Hz. This method fails to give the absolute values of the heat capacity and yields only its temperature dependence in the region of the superconducting transition smeared, because of fluctuations, over a considerable temperature interval. Three heat capacity peaks were observed in the region of superconducting transition for nanowires, and only one jump, in the bulk metal. This splitting of the heat capacity peak grows with decreasing nanowire diameter and vanishes when the nanowires are thick. These distinctive features of the heat capacity of metal nanowires cannot be accounted for by the coexistence of different crystal modifications with different critical temperatures (for mercury, α-Hg with $T_c = 4.15$ K and β-Hg with $T_c = 3.95$ K are known), because, first of all, there are three of them, and, furthermore, the temperature dependence of the heat capacity of indium nanowires, which do not have any different crystal phases, also displays three peaks. To explain the observed effect, it was suggested that the heat capacity peaks result from the electron system splitting into a series of subbands associated with spatial quantization and having their own different critical temperatures. In such a system, both the superconducting and the Peierls phase transitions (exhibiting different heat capacity features) are also possible [297, 486].

Critical magnetic fields have been measured for superconducting mercury nanowires [474, 475]. For nanowires 6 nm in diameter, the critical magnetic field extrapolated to $T = 0$ was 65 kOe for a magnetic field aligned with the nanowires and 36 kOe for a field oriented in the perpendicular direction. For mercury nanowires with a 2-nm diameter the critical magnetic field along the nanowires for $T = 0$ was 220 kOe, which exceeds by approximately a factor of 500 the value for bulk mercury. What is more important, this value is approximately three times the paramagnetic limit [457, 458] (77 kOe at $T = 0$). Such a large enhancement of the critical magnetic field can be explained in the framework of the theory, taking into account the spin-orbit scattering on the inner surface of asbestos channels [487].

4.2.2. Weak Localization in Nanowires

The electronic transport properties of thin wires in the temperature and field regime have been the object of numerous studies, mainly because of localization effects that strongly depend on the spatial dimensionality. In a 3D system, localization of all of the electronic states does not occur until the randomness exceeds a certain nonzero level. However, it has been shown for 1D systems [488, 489] that any amount of disorder, no matter how small, would make all of the states localized, and this would lead to vanishing conductivity at $T = 0$. For not strictly 1D systems (i.e., wires) it has been shown [490, 491] that the electronic states will be localized with a localization length L_{loc} equal to a wire length corresponding to an impurity resistance of $h/e^2 \approx 25.8$ kOhm. Thus, any wire with a resistance greater than this value, which is longer than the localization length, will have a thermally activated conductance at low temperatures and be an insulator at absolute zero. At high temperatures, an electron will experience frequent inelastic collisions with phonons. Each of these collisions will cause the electron to jump from one localized state to another, and the localization will have no effect on the conductance. The effect of localization will be felt when the mean free path for inelastic scattering is comparable to the localization length. At finite temperatures the resistance will be given by $R = R_0 + \Delta R$, where $\Delta R/R = L_i/L_{loc}$, R_0 is the temperature-independent impurity resistance, L_i is the distance to which an electron diffuses between inelastic collisions ($L_i = (D\tau_i)^{1/2}$), D is the electron diffusion constant (due to elastic collisions), and τ_i is the inelastic scattering time. Experimentally, the localization effects in thin wires have been studied in metals for samples fabricated with a method based on the substrate

step technique, in which a wire is formed in the corner of a step ion-milled into a substrate (see [492–495]). As for nanostructures within porous matrices, localization effects have been observed for mercury nanowires with diameters of 2 to 10 nm within the channels of chrysotile asbestos [496]. In the temperature range 10–50 K, the experimental data for Hg nanowires are well described by a $\Delta R \sim T^{-3/2}$ dependence (for 25-Å nanowires $\Delta R_{max}/R_0 \approx 0.4$). Below 6 K, the superconducting fluctuations govern the conductivity. As for nanowires with larger diameters, their negative temperature derivative of resistivity also corresponds to the $\Delta R \sim T^{-3/2}$ dependence, but $\Delta R/R_0$ decreases with increasing diameter. From the $\Delta R/R_0 \sim T^{-3/2}$ dependence it follows that $\tau_i \sim T^{-3}$. According to [490], such a temperature dependence of the inelastic scattering time may be due to scattering on 3D phonons. This is not surprising, since the nanowires are embedded in the dielectric matrix and are, to some extent, in contact with it, so that part of the phonons in such a composite medium may be three-dimensional. At 10 K, $\Delta R/R_0 \sim 0.45$, $\rho \sim 3 * 10^{-5}$ Ωcm (this value is determined from the ratio R_{300}/R_{10} and the resistivity of liquid mercury, $\sim 10^{-4}$ Ωcm), $D = v_F l/3 * 10$ cm^{2}s^{-1} ($v_F \sim 10^8$ cm/s, l is the mean free path for elastic collisions, determined from the temperature dependence of resistance). From these data, it can be found that $\tau_i \sim^{-10}$ s at 10 K. The localization length ($D\tau_i^{1/2}$) at 10 K is about $3 * 10^{-5}$ cm, which satisfies the localization criterion for these nanowires. More recently, localization effects have also been studied in Bi nanowires. The semimetal Bi is often selected for such studies because the electron density is about five orders of magnitude smaller than that in the conventional metals. Furthermore, the very small effective mass of electrons in Bi results in a large spatial extension of the electron wave functions; the effects of reduced dimensionality can, therefore, be seen in samples with dimensions on the order of 100 nm. Bi nanowires have been electrodeposited into nanometer-size cylindrical pores in polycarbonate membranes [497], introduced by pressure injection of a liquid Bi melt [498, 499] (see also [500]) and by vacuum evaporation [501] into the nanochannels of an anodic alumina template, and injected into porous Vycor glass by the application of hydrostatic pressures of 5 kbar [502]. The anodic alumina templates, having an array of parallel nearly cylindrical channels, were produced by anodizing aluminum substrates in acid solutions (for nanowires within these templates, see also [503–505]). The diameters of the pores in alumina templates are uniform to within 10% over the channel length (40–64 μm) from approximately 30 nm up to approximately 200 nm for different samples with average spacing between nanochannels of about 100 nm. In pores of polycarbonate membranes, Bi nanowires with diameters of 2000, 1000, 400, and 200 nm were fabricated, with wire densities of, respectively, $2 * 10^4$, $2 * 10^5$, $1 * 10^6$, and $3 * 10^6$ wires/mm^2. In the Vycor porous glass, the average pore diameter was about 6 nm. Measurements of the resistance of Bi nanowire arrays with different wire diameters have been carried out over a wide range of temperatures and magnetic fields. An increase in resistivity and a large positive magnetoresistance were observed. The additional magnetoresistance was ascribed [501] to a transition from 1D localization at a low field to 3D localization at a high field, when the magnetic length becomes smaller than the wire diameter. Most of the experimental results obtained in [499] are in good agreement with the theory and are accounted for by the electronic subband structure of quasi-1D Bi nanowires. Evidence that localization effects occur at low temperatures ($T < 4.0$ K) was obtained, but it was established that the localization effects are not the dominant mechanism affecting either the resistivity or the magnetoresistance in the temperature range 2.0 K $< T <$ 300 K. In Bi nanowires, 6 nm in diameter, in Vycor glass [502], no strong localization was observed, and this composite was a basically a good conductor. The observed temperature rise at low temperature and the associated magnetoresistance were interpreted in terms of weak localization.

4.2.3. Thermoelectricity in Bi Nanowires

Bi nanowires are of special interest for thermoelectric applications owing to the unique properties of bulk Bi, such as its small electron effective mass components, high anisotropy of its Fermi surface, and low thermal conductivity of Bi. Theoretical calculations predict that nanowires of bismuth must have an enhanced thermoelectric figure of merit [506] (see also [507, 508]), defined by $ZT = S^2\sigma T/k$, where S is the thermoelectric power (Seebeck coefficient), σ is the electrical conductivity, and k is the thermal conductivity. For a material to be a good thermoelectric cooler, it must have a high figure of merit, ZT. With known conventional solids, a limit for the figure of merit is obtained, and modification of any one of the parameters adversely affects the other transport coefficients, so that the resulting ZT does not vary significantly. Currently, the highest $ZT \cong 1$ at 300 K is observed in the Bi_2Te_3 compounds. It has been demonstrated that quantum wires have a strongly different ZT, since the electrons are confined to a single dimension. This increase is due mainly to the change in the density of states. In addition, there is enhanced phonon scattering from the wire surfaces. This must reduce the lattice thermal conductivity and, hence, lead to higher ZT. According to calculations, an array of nanowires with diameters on the order of 7 nm, oriented along the trigonal direction, could have a figure of merit of ~ 2 at 300 K. Single-crystal bismuth nanowires 200 nm in diameter (embedded in porous anodic alumina) have been used to measure the thermoelectric power and longitudinal magneto-Seebeck coefficient, and the first data on thermoelectric power, taken on an array of bismuth nanowires, were presented [509]. The temperature-dependent thermopower data are consistent with the partial electron and hole thermopower values calculated using the carrier Fermi energies obtained from Shubnikov-de Haas oscillations on the same samples.

4.2.4. Luttinger Liquid-Like Behavior in Semiconductor Nanowires

InSb nanowires with a diameter of about 5 nm (a length of about 0.1 cm) have been prepared within the channels of chrysotile asbestos [300, 302] by filling with InSb melt at 550 °C under a high pressure of 15 kbar. These nanowires are stable at room temperature, even after the pressure is removed. The temperature dependence of their zero-field electric conductance $G(T)$ is a power function of temperature, $G(T) \sim T^{\alpha}$, in the temperature interval 1.5–300 K

[302], with the exponent α ranging from $\approx$2 to $\approx$7. Current–voltage characteristics of such nanowires are nonlinear and follow at low temperatures the power law $I \sim V^{\beta}$ [302]. A similar behavior has been observed for 5-nm Te nanowires [301]. For InSb nanowires with 5-nm diameter and carrier effective mass $m^* = (0.014\text{–}0.2)m_e$ (possible range of effective masses for bulk InSb), the energy spacing between the first and the second quantum levels was $\Delta E = (\pi h)^2/2m*d^2 = 800\text{–}20000$ K $\gg T$ for the temperature range examined. So the electron band structure is in this case essentially one-dimensional. Thus, the samples studied consist of long quantum wires with one or few quantum conduction channels. The electron–electron correlation, negligible in the 3D case, predominates in the 1D case [510]. As a result, the physical properties of a 1D metal are expected to be dramatically different from the properties of the conventional metals with a Fermi liquid of electrons. One of the most significant consequences of the correlation effect is the absence of quasi-particle excitations in 1D metals. Instead, collective excitations associated with separate spin and charge degrees of freedom develop in the 1D case [511]. In the absence of long-range interactions, a 1D liquid (so-called Luttinger liquid) is formed [510, 511], whereas the long-range Coulomb interaction leads to a 1D Wigner crystal [512]. Charge transport is of a collective nature in this case and cannot be described by the conventional kinetic equation. The following temperature dependence of conductance, $G \sim T^{\alpha}$, has been predicted for tunneling between two drops of a pure Luttinger liquid, and nonlinear current–voltage characteristics, $I \sim V^{\beta}$ [513], are similar to those observed in InSb nanowires. It was suggested that, in multiple InSb samples prepared within asbestos nanotubes, long-range interactions between electrons in each wire may be screened by the Coulomb interaction of these electrons with electrons of neighboring wires. This leads to short-range intrawire electron–electron interaction, which is a basic assumption of the Luttinger liquid theory. Transport properties of individual nanowires are determined by impurities and weak links (e.g., constrictions) appearing in the fabrication process. The number of such weak links can be estimated, and it corresponds to $\approx 10^3$ weak links/cm per nanowire. The magnetoresistance of InSb nanowires has been studied over the temperature range 2.3–300 K in magnetic fields of up to 10 T [303]. The magnetic field leads to a 20% increase in the exponents α and β at $H = 10$ T. The magnetoresistance is positive; current suppression by up to an order of magnitude was observed at $T < 5$ K and $H = 10$ T. This may result from breaking of spin-charge separation in the 1D electron system, which is a novel mechanism of magnetoresistance.

The results of an experimental investigation of the thermoelectric properties of InSb and Te nanowires (diameter 5 nm) [301] support the Luttinger liquid model. The thermopower S of InSb nanowires is characterized below $T \approx 250$ K by a linear temperature dependence $S(T)$ ($G(T) \sim T^{2.8}$). For Te nanowires, $S(T)$ exhibits a metallic behavior but is not linear in any temperature interval and changes sign at $T \approx 180$ K ($G(T)$ for Te nanowires is $\sim T^{3.3}$). Such a behavior of the transport properties is typical of neither semiconductors nor metals and corresponds, at least qualitatively, to the Luttinger liquid model [514], which predicts a metallic behavior for the temperature dependence of thermopower (see also [515]).

4.3. Magnetic Properties

The influence of reduced physical dimensions on magnetic entities is of both fundamental and technological interest. Mainly motivated by technological interests, techniques for fabrication and characterization of magnetic nanoscaled systems have been developed. Physical vapor deposition techniques, followed by lithography of ever-increasing resolution, are usually considered to represent the ultimate technique for producing nanoscale magnets. However, well-crystallized nanomagnets can also be fabricated by a different method. In this method, thin wires of magnetic metals with large aspect ratios are electrochemically synthesized within the voids of anodic oxide films on aluminum [516] (Co and Co-Ni alloy) and track-etched polymer membranes [517] (Co, Ni). Nickel nanowire arrays have been fabricated by electrodeposition into the nanopores with lateral dimensions as small as 30 nm [518, 519]. The porous templates were fabricated by nuclear track etching. Particle tracks were formed in 5-μm-thick mica wafers by exposure to $\sim$6 meV α particles from a 100 μCi Cf-252 source in a chamber at a pressure of about 10^{-3} Torr. Interesting properties are expected to appear when the geometrical dimensions of the wires become comparable to a characteristic length scale, such as domain wall width or exchange length, and to mesoscopic dimensions, such as domain width. In bulk magnetic systems, the correlation length ξ increases with temperature and diverges at the bulk transition temperature $T_c(\infty)$. When one or more dimensions in the system are small, the growth of ξ is eventually limited by the smallest dimension d, and the system displays a lowered transition temperature $T_c(d)$ owing to finite-size effects. For Ni nanowires with diameters of 500 to 30 nm [519], the measured $T_c(d)$ values obey the finite-size scaling relation $[T_c(\infty) - T_c(d)]/T_c(\infty) = (\xi_0/d)\lambda$, where $\lambda = 0.94$ and $\xi_0 = 22$ Å. The measured correlation length $\xi_0 = 22$ Å is close to the value of 20 Å reported for thin polycrystalline nickel films. Large coercive fields have been observed for assemblies of ferromagnetic Ni cylinders with diameters ranging from 35 to 250 nm, produced by electrodeposition in nanoporous membranes [520]. At low temperature these coercive fields could be attributed to the curling mode of magnetization reversal, with account taken of the distribution of wire diameters and orientations. The coercive field of the nanowires of smaller diameter decreases from 1500 Oe to 200 Oe at 300 K nearly linearly. The magnetoresistance of similar nanowires has been measured at room temperature [521, 522]. The full magnetoresistive hysteresis loop was studied as a function of the angle between the applied field and the wire direction. The anisotropic magnetoresistance and magnetic properties of arrays constituted by similar objects have also been studied by other authors [523–526]. A giant magnetoresistance of about 15% has been observed at room temperature in a nanostructured material consisting of multilayer magnetic nanowires (Co/Cu) formed by electrodeposition into nanometer-sized pores of a template polymer membrane [527].

The classical antiferromagnet MnO has been embedded in a porous glass with an average pore diameter of about 7 nm [317]. MnO was synthesized from manganese nitrate solution by the chemical bath deposition method. The temperature evolution of the crystal and the magnetic structure of MnO under the "confined geometry" conditions were examined by means of neutron diffraction. It was demonstrated that a magnetic order similar to that observed in the bulk appears in regions smaller than the average size of nanoparticles. However, the ordered magnetic moment of 3.84 μ_B/ion was noticeably smaller than that in the bulk. The magnetic phase transition was found to be second-order with elevated Néel temperature, in contrast to the discontinuous first-order transition in the bulk. The experimentally observed temperature dependence of the magnetic moment was $m(T) \sim (1 - T/T_N)\beta$ with $T_N = 122$ K and $\beta = 0.34$. The critical index β is close to those expected for phase transitions in the classical 3D Heisenberg model.

4.4. Freezing and Melting in Confinement: Structure of Solid Phases

The confinement effect on freezing and melting (f/m) has been of considerable theoretical and experimental interest for many years. As early as 1888, J. J. Thomson proposed that the freezing temperature of a final particle would depend on the properties of the surface [528]. The first experiments on f/m in confined geometry (CG) were reported in the beginning of the last century [529–536].

Confinement usually results in depression of the f/m phase transition. Considering the difference in the Helmholtz free energy between liquid and solid in the pore, one obtains [537]

$$\Delta G = A[\gamma_{li} - \gamma_{si} + V\Delta G_m] \tag{21}$$

where ΔG_m is the free energy of fusion, γ_{li} is the substrate-liquid energy, and γ_{si} is the substrate-solid interfacial energy. A is the total interfacial area between the material and substrate and V is the total value of the confined material. The energies of any other interfaces in the system are ignored. ΔG_m is given by

$$\Delta G_m = \frac{[T_m - T]\Delta S_m}{V_m} = \frac{\Delta T \Delta H_f}{V_m T_m} \tag{22}$$

where ΔS_m is the entropy of melting, T is the melting point of the confined material, ΔH_f is the heat of fusion, and v_m is the molar volume. The differences in molar volume and heat capacity between solid and liquid are ignored.

Analyzing Eq. (21), one can determine two different characteristic temperatures [537, 538],

$$T_1 = T_m - \frac{A}{V}\frac{V_m T_m[\gamma_{si} - \gamma_{li}]}{\Delta H_f} \tag{23}$$

where A/V is geometry dependent and can be written as $A/V = \alpha/r$, where $\alpha = 3$ for a sphere of radius r and $\alpha = 2$ for a cylinder of radius r. T_1 corresponds to the equilibrium condition, when the energy of the completely liquid particle is equal to the energy of the completely solid particle. So T_1 represents [538] a thermodynamic lower bound for the melting temperature. However, taking into account kinetic arguments, one can obtain a second characteristic temperature equal in the case of a cylindrical pore of radius r

$$T_2 = T_m - \frac{3V_m T_m[\gamma_{si} - \gamma_{li}]}{r\Delta H_f} \tag{24}$$

T_2 corresponds to the vanishing of the energy barriers between solid and liquid. It represents a thermodynamic upper bound for the melting temperature. It is most likely that the freezing will take place around T_2, and the melting around T_1.

Following [537], we should emphasize that the influence of the material of the pore on the confined substance was completely neglected in the treatment considered above. The situation in the case of f/m phase transition is more complicated than that in the case of liquid/vapor. Wall effects on solid structure are expected to have a long-range character. The structure of the solid in confinement can be different from that the bulk.

In the following paragraphs we will present a brief summary of experimental studies of the f/m in CG (for a more detailed review see, e.g., [537] and references therein).

The first experimental results for f/m in confinement were mostly related to the f/m of water adsorbed on different hydrogels [529, 530]. The essential freezing-point depression was found for several different liquids on silica gel [536], and in the case of water adsorbed on 1.1-nm silica gel no freezing was found down to 208 K [539]. Scientific activity in the field essentially increased with the appearance of porous glasses, xerogels, and more recently channel matrices like MCM-41. f/m was studied for different types of materials.

Properties of gases and some of liquids embedded by absorption from vapors strongly depend on the degree of filling, f. At low filling the pore condensate exists as an adsorbate on the pore walls [227]; at higher filling the pore center is filled. So a distinction should be made between the layers absorbed on the pore walls and the fluid or solid in the central part of the pore.

4.4.1. Inert Gases

Inert gases (IGs) except helium (see Section 4.7) are the simplest substances to be studied in CG. In [540] suppression of the T_m for Ne in Vycor ($d = 5.4$ nm) (as well as for H_2 and D_2) was found, and estimation of the solid-liquid surface energy was found to be 2.6 mJm^{-2}. The 1.8 K difference between $T_m = 22.5$ K and $T_f = 20.7$ K (freezing temperature) was found and was attributed to the nucleation effects. In [228] f/m of neon and argon (together with H_2 and O_2) in Vycor and a silica xerogel were studied by combined heat-capacity and ultrasonic methods. Depression of the f/m was confirmed, but essential irreversibility of the freezing was found. It was demonstrated that any solid that forms, even in very small amounts, remains frozen until warmed well above the onset of solidification. Melting, however, is complete at a well-defined temperature between the onset of freezing and the bulk T_m. This fact was used as an indication that freezing is controlled by the pore geometry and not by nucleation kinetics. The width of the freezing region was attributed to the distribution of the pore sizes. Adams et al. [541] saw such measurements as providing a "spectrometer

of pore size." Wallacher and Knorr [542] presented results of elaborate heat capacity and vapor pressure study of Ar in Vicor. Measurements were performed for various filling and sample histories. It was demonstrated that first and second monolayers on the pore walls do not participate in f/m, whereas for other layers, in particular for the third one, a delayering transition was observed in the case of incomplete filling. Structures of frozen IG in CG were studied by X-ray diffraction [543, 544]. In the case of complete filling for pores down to 6 nm, a crystalline structure was revealed. Ar 2.2-nm and 2.5-nm diffraction patterns were similar to those of amorphous solids. For Ar in 7.5-nm gelsil in the case of incomplete filling diffraction patterns changed from amorphous at low $f \leq 0.4$ to crystalline at $f > 0.4$ [544]. The structure of the solid phase of Ar and Kr in Vicor [545] was interpreted as a disordered hexagonal close packed with phase transition to the fcc one at $T/T_f \approx 0.5$. In [544] this result was argued, and the structure of confined solid Ar was described in terms of fcc structure similar to that of the bulk, but with numerous stacking faults.

4.4.2. Diatomic Compounds: N_2, O_2, CO

In general f/m of diatomic gases in confinement is similar to the IG [228, 537]. In [546] a picosecond optical technique was used to study f/m of O_2 in Vicor. For low filling (less than two monolayers) no freezing was found. For pore sizes 2.2 nm $\leq d \leq$ 5.2 nm, ΔT_f followed the $1/d$ law (see Eq. (23)). f/m hysteresis was especially well pronounced at 2.2 nm and 2.8 nm. A γ–β solid-solid phase transition was observed, and the transition temperature $T_{\gamma\beta}$ was also depressed as $1/d$. A neutron diffraction study [547] demonstrated that the crystallites were considerably larger than the pores (about 10 times). An expected suppression of the melting temperature was also observed for nitrogen and CO. The crystal structure of CO is identical to structure of the bulk, with a crystallite size twice that of the mean pore diameter. In the case of N_2 and CO in 2.5-nm MCM-41 [537], it was suggested that the structure was either amorphous or liquid.

4.4.3. Metals

Unlike the cryogenic and H-bonded fluids, liquid metals usually do not wet the pores, and so there are no layering processes. For liquid mercury in the porous glasses, which has a high surface tension, it was demonstrated that the size of the solid clusters was temperature independent and equal to the pore diameter [276]. The main features of f/m transitions in Hg are broadening of both transitions and the existence of large thermal hysteresis, as demonstrated by neutron diffraction, NMR, and acoustic [274] measurements. It was shown that the freezing process was irreversible, but melting consisted of reversible and irreversible temperature regions. Combined use of longitudinal and transverse acoustic waves made it possible [274] to come to a conclusion about the origin of different behavior on melting. The broadening of melting was explained by the formation of a liquid layer on the mercury solid surface, whereas freezing was shown to be driven by the pore geometry with no visible precursor effects.

Few papers were published that related to the study of liquid metals in zeolites (Hg and Ga) [287], with cavities about 12 Å in diameter, and mordenite (Hg and Bi), with an average channel diameter of about 6.6 Å [548]. In 12-Å zeolites, well-defined jumps in temperature dependences of electric conductivity and peaks in the temperature dependences of the specific heat were observed and were considered to be evidence of the melting/freezing phase transition, with strong depression of the melting point. This result, which was rather surprising for such small clusters, was interpreted as evidence of the strong suppression of the fluctuations near the melting point related to the possible interaction between individual drops. In the case of the mordenite channel, the main result was demonstration of the possibility of producing monatomic metallic chains in the channels of the dielectric matrix; m/f transition was not searched for in this case.

Bogomolov et al. [549] have reported the study of one-dimensional metallic filaments produced by embedding of liquid mercury in the channels of natural chrysotile asbestos with diameters of 20–100 Å. It was demonstrated that as the filament diameter is reduced the phase transition region shifts toward low temperatures (shifts value follows the $\sim 1/d$ law) and becomes diffuse over a large temperature interval (the width of the transition region follows the $\sim 1/d^2$ law). The hysteresis between the melting and the solidification decreases and vanishes at $d \approx 20$ Å. Data analysis based on the Imry-Scalapino theory of the fluctuation effect on the first-order phase transition has demonstrated that the contribution of the fluctuations to the transition broadening does not exceed 1 K for the smallest diameters.

Heat capacity measurements of In in PG demonstrated essentially different behavior on melting and freezing (the heat capacity peak is much stronger for melting than for cooling). Careful differential scanning calorimetry (DSC) study of In in porous silica glasses with mean pore diameters from 6 to 141 nm has demonstrated [538] that, in agreement with Eq. (23), the melting temperature is reduced in inverse proportion to the pore size. In the smallest pores (8.2 and 18.2 nm) the latent heat of fusion was found to be about one-third to one-half of the bulk value. In was crystallized in the tetragonal phase identical to the bulk phase, but with a uniform lattice expansion of 0.5%. Unlike mercury, in the case of indium the crystallite size in 5.6-nm Vycor was about 20 nm, which is considerably larger than the pore size.

Liquid gallium in porous glasses and opals was extensively studied by electrical resistance measurements [550], X-ray diffraction [275, 550, 551], NMR [552–554], and acoustical [555, 556] methods. In contrast with mercury in porous glass, the size of confined gallium crystallites was estimated to be 22 nm, which was significantly larger than the pore size ($\approx$4 nm) [275]. Within the limits of experimental accuracy this size was nearly temperature independent. Only a slight tendency to the peak narrowing (i.e., size increase) was observed on cooling. The authors concluded that since the size of crystallites was about constant during the melting, the broadening cannot be attributed to the particle size distribution. Nor can it be explained in terms of the pore size distribution, since the gallium crystallites were much larger than the pores. As in the case of mercury, it was proposed that the broadening is related to the formation of the

liquid around the particles. Information about the crystal structure of the solid gallium confined in the porous glasses is contradictory. In paper [551] several modification were found upon Ga solidification in the 4-nm porous glass, while in [275] only a single phase was found down to 20 K, and below this temperature the appearance of the second phase was reported. Both modifications reported in [275] were different from the known bulk gallium structures. In the case of Ga confined in opal, four different modifications were reported [550]. Two of them were similar to those observed in the porous glass and so were different from bulk, whereas two others were identified as β-Ga and disordered α-Ga. An interesting effect was reported for the f/m of disordered α-Ga. Melting-freezing hysteresis for this modification was found to depend on the temperature of prewarming.

4.4.4. Water

As mentioned above, water was the first material used to study the f/m transition in a confined geometry. A number of methods were used for its study, including DSC [557], neutron diffraction [557–559], and NMR [560, 561]. The studies of water freezing in the porous materials (silica gel, porous glasses, and activated charcoal) showed a freezing point depression consistent with two or three layers of nonfreezing water on the pore surfaces [537, 560]. In some cases freezing resulted in the formation of confined crystallites with a structure different from that of the bulk. In particular, cubic ice was shown to form in pores at 260 K. This modification was known before only at high pressure conditions. In samples with 2-nm pores, water remained liquid down to 251 K. On lowering of the pore size from 50 nm to 4 nm, the predominant ice modification changed from hexagonal to cubic [562]. NMR studies of water confined in glasses with different hydrophobicities (treated with hexamethyldisilazane) have demonstrated an increase in the melting point depression with increase of hydrophobicity. In the case of the most hydrophobic samples water was unable to penetrate the pores. Such behavior is consistent with the larger contact angle of the water-ice interface on the treated glass substrate [537]. In [562] the low-temperature (down to 173 K) structure of water in MCM-41 with $d = 3.3$- and 3.5-nm structure was found to be incompatible with neither cubic nor hexagonal ice. X-ray diffraction experiments performed on water confined in 2.4 nm and 4.2 nm MCM-41 demonstrated that water freezes abruptly in the middle of 4.2-nm channels and more gradually in 2.4-nm channels [563]. As in the porous glasses, a disordered liquid-like layer was found. In contrast to porous glasses, no hysteresis was found in MCM-41 materials. This results in the conclusion that large f/m hysteresis in other matrices can be attributed to a network effect [537].

4.4.5. Organic Liquids

For organic liquids confined in porous glasses, depression of the freezing temperature is typically observed. For cyclohexane in silica glass the temperatures of both f/m transition and the transition from the plastic to the brittle crystal are decreasing [564, 565]. Booth and Strange [566] demonstrated that for pores smaller than 5 nm, the plastic crystalline phase was replaced with a structurally disordered phase with high rates of diffusion. No freezing was observed in the case of 2,4,6-trinitrotoluene in 2.5-nm and 5-nm gelsil glasses and in 10-nm and 20-nm glasses a bulklike orthorhombic structure was formed [567]. Systematic studies of CCl_4 and nitrobenzene in silica glasses and silica gel (4–100 nm) [537, 568, 569] showed a good linear correlation between the melting-point depression and the inverse pore diameter. Takei et al. [569] found no changes in the transition temperature resulting from silanizing the pores with hexadimethylsilazane. The same linear dependence was observed in [570] for *cis*-decalin, *trans*-decalin, cyclohexane, benzene, chlorobenzene, naphthalene, and *n*-heptane in silanized silica glasses (4–73 nm). No freezing was observed for cyclohexane or *cis*-decalin in 4-nm pores [537, 570].

Essentially different behavior was observed in the case of f/m of organic liquids in MCM-41 materials. Morineau et al. reported differential scanning calorimetry measurements of cyclohexane, benzene, toluene, *o*-terphenyl, and *m*-toluidine confined in 4-nm MCM-41 [571]. Only a moderate decrease (not exceeding 6 K) of the f/m temperature was observed. In the presence of a few percent excess liquid, crystallization of the confined part was found to be sensitive to the presence of crystal outside the pores. The absence of supercooling of the confined part was explained by a freezing mechanism induced by the outside part. Glass transitions in confined toluene, *o*-terphenyl, and *m*-toluidine were nearly unaffected by confinement.

4.5. Dynamics

Confinement strongly affects dynamical properties of the embedded materials, especially liquids (for the solid phase the problem is much less studied). Especially well studied are water and H-bonded systems [572, 573]. For many H-bonded fluids crystallization is easily suppressed in confinement, and these systems are considered as glass-forming materials. In general there are several mechanisms that can influence the molecular dynamics:

- Structural effects due to (i) geometrical obstacles in the finite volume [574] and (ii) a reduced density resulting from the difficulty in packing molecules. In the case of diffusion the existence of dead-ended pores became important.
- Surface effects: Interaction of liquids with the surface results in the formation of two (interfacial and bulklike) [575] or even three [576] (consisting of molecules having solidlike, interfacial, and bulklike dynamics, respectively) layers.
- Finite-size effects due to spatial heterogeneity of the confined material–when the length scale of confinement becomes smaller than an intrinsic length scale related to the dynamics of bulk material. Such a situation is typical in glass formers when the glass transition temperature, is approached.

Dynamics of confined materials are studied by several methods: dielectric spectroscopy [574, 575, 577–579], nuclear magnetic resonance (NMR), optical spectroscopy (Raman and dynamic light scattering) [573], and neutron spectroscopy [573, 579] are most important.

4.5.1. Dielectric Properties in Confinement

Dielectric properties of confined systems are crucial for many applications. Dielectric spectroscopy is appropriate for the investigation of polar materials and covers a large dynamical range from dc to microwaves [574, 580]. The difficulty with the interpretation is that neither the permittivity of the filler, ε_p, nor that of the matrix, ε_m, but a volume-averaged value, ε_{eff}, is obtained. ε_{eff} can be presented as [574]

$$\varepsilon_{eff} = \frac{(1-f)\varepsilon_m + f\varepsilon_p \langle E\rangle_p / \langle E\rangle_m}{(1-f) + f\langle E\rangle_p / \langle E\rangle_m} \tag{25}$$

where $f = V_p/V_{total}$ is the volume filling factor, $\langle E\rangle_p$ is the electric field averaged over the filler volume, and $\langle E\rangle_m$ is the electric field averaged over the matrix volume. The ratio $\langle E\rangle_p/\langle E\rangle_m$ and thus the measured effective permittivity depend on the microstructure, that is, the topology, degree of order, and dimensionality. This problem is discussed in detail in [574]. In general we can formulate the following main results:

- 3D confinement (droplets): The values of ε_{eff} and the relaxation frequency ν_{relax} depend on the exact spatial distribution of the particles. In the case of dilute inclusions of strongly polar materials, relaxation strength $\Delta\varepsilon_{eff} \ll \Delta\epsilon_p$ becomes independent of $\Delta\epsilon_p$. With increasing disorder or filling factor F, $\Delta\varepsilon_{eff}$ increases, while the frequency shift of ν_{eff} decreases. Agglomeration gives rise to a broadening of the relaxation peak [581]. In the case of asymmetric relaxations described by the Havrilak-Negami (HN) formula,

$$\varepsilon_{HN} = \varepsilon_\infty + \frac{\Delta\varepsilon}{\{1 + [i(\nu/\nu_0)]^{1-\alpha}\}^\gamma} \tag{26}$$

  with shape parameters α and γ, the shift of the relaxation frequency increases with increasing asymmetry ($\gamma < 1$). Similar to the symmetric case, it decreases with increasing disorder or filling factor. The slopes of the low- and high-frequency sides of $\varepsilon''(\nu)$ are unchanged.
- 2D confinement (channel-like pores running through the whole sample; real porous systems with a high amount of dead ends and/or a fractally rough surface should be considered as an intermediate 2D-3D case): In the case of noncrossing pores, $\nu_{eff} \simeq \nu_p$; $\Delta\varepsilon_{eff} \propto \Delta\varepsilon_p$). The high-frequency side of $\varepsilon''(\nu)$ is slightly flattened. In the case of a network of interconnected pores the form of electric relaxation is hardly distinguishable from that of bulk material. In the most important case of real porous systems, the following basic features can be formulated [574]:
  - The effective relaxation strength increases linearly with $\Delta\varepsilon_p$ for large enough values: $\Delta\varepsilon_{eff} \simeq a\Delta\varepsilon_p + b$.
  - The effective relaxation frequency roughly equals that of the filler, $\nu_{eff}/\nu_p \simeq 1$.
  - The shape of the relaxation is preserved on the low-frequency side of the peak and is weakly modified on the high-frequency side.
- 1D confinement (films or multilayer structures): The situation depends on the orientation of the layer. In the case of layers oriented parallel to the film, the characteristics resemble those of a 2D confinement, and in the perpendicular case, the 3D confinement.

The molecular dynamics of confined liquids in the frequency range from 10^{-6} to 10^{12} Hz is characterized by the superposition of different relaxation processes that take place on a local scale (β-relaxation) and cooperative fluctuations (α-relaxation, dynamic glass transition). In most cases an additional relaxation peak appears, which is usually ascribed to the Maxwell-Wagner-Sillars (MWS) polarization appearing when a slightly conducting liquid is enclosed in an insulating material [577, 582]. Experimental dielectric results were obtained for several different confined systems. In nitrobenzene in CPG, Vycor, and MCM-41 [582], already mentioned above, two relaxation components were found in the liquid state at about $5 * 10^{-3}$ s and 10^{-4} s, both of simple Debye relaxator shape. The slow one has been attributed to the MWS polarization, and the fast to the relaxation of the contact layer. The response of the bulk fluid was out of the experimental range. Nitrobenzene is not a glass former, and neither component demonstrates essential temperature dependence. The dynamic behavior of glass formers is essentially different. Several glass-forming liquids were studied, among them *N*-methyl-ε-caprolactam (NMEC) (nonassociating liquid) [577, 583, 584], propylene glycol (PG) and its oligomers (PPG) [578, 579, 584], salol [575], pentylene glycol [575], and glycerol [575]. Experimental dielectric spectra typically contained a MW peak plus one or two relaxation peaks. Peaks are broadened as compared with a simple Debye relaxator and asymmetric; the shape is consistent with the HN formula. In the case of two relaxation peaks a slow process was unambiguously attributed to the interface dynamics. This fact was confirmed by modifying the porous glass surface (silanizing with trimethylchlorosilane) [577], which results in weakening of liquid (NMEC) to the surface and in the nearly complete suppression of the slow peak. Liquids with two (PG) or three (glycerol) hydroxy groups were shown to exhibit only one relaxation process [575]. This was interpreted in terms of a shell model of a bulklike phase and an interfacial layer including molecular exchange between the two subsystems. For all components relaxation times were temperature dependent [575, 577, 579], following the Vogel-Fulcher-Tammann (VFT) relation [585, 586]

$$\tau_m = \omega_m^{-1} = A\exp[DT_0/(T - T_0)] \tag{27}$$

where ω_m is the position of the maximum of the dielectric loss peak, A is the prefactor, D is the fragility parameter (higher values of D correspond to stronger glass formers), and T_0 is the Vogel temperature. A fit of dielectric data to the VFT equation is often used to determine the glass transition temperature T_g, based on $\tau_m(T_g) = 100$ s. In such a definition T_g is exactly dynamic, determined by the whole set of VFT variables. Some published results are summarized in Table 7. For interface components relaxation is always retarded; as clearly seen from a comparison of prefactors, T_g for the interface layer is essentially lower than that for bulk. However, there is no regular change of Vogel temperature, even for the interface layer. The α relaxation of the liquids

Table 7. Parameters of VFT equation for dielectric relaxation.

Note: $\Delta T_g = T_g^{conf} - T_g^{bulk}$, $\Delta T_0 = T_0^{conf} - T_0^{bulk}$.

in the inner pore space is much less affected by confinement and the results of different authors are controversial, as one can see from the data in Table 7.

Conducting Liquids in Porous Media In many natural inhomogeneous materials, such as brine-saturated sedimentary rocks, giant values (about 10^6) of low-frequency dielectric permittivity were observed ("dielectric anomaly of rocks"). A similar result was obtained for brine-saturated porous alumina ceramics [587], where $Re\varepsilon \approx 2 * 10^5$ was reported for the porosity 0.193. This anomaly was analyzed [587–589], and the best agreement was obtained for the model considering a system of pores separated by thin walls.

In [590] giant growth of ε was observed on heating of $NaNO_2$ ferroelectric confined in 7-nm porous glass (up to 10^8 at 100 Hz and $T > 550$ K). This effect was explained by an essentially broadened melting transition. In a very recent paper [591] the temperature evolution of structure in a restricted geometry was studied for the ferroelectric $NaNO_2$ embedded in a porous glass, and it was shown that this CM forms a kind of interconnected cluster, probably of the dendrite type, with a practically temperature-independent average size of about 45 nm. Above T_c the volume "premelted" state is formed, manifesting itself in a sharp growth of the thermal motion parameters, softening of lattice, and increase of lattice volume. In such a case the possible appearance of ionic current due to oxygen jumping diffusion is proposed as a reason for the observed giant growth of dielectric permittivity. On cooling below T_c macroscopic polarization and potential barriers suppress the lattice softening, and the normal ferroelectric phase exists.

There is very limited information on the behavior of *ferroelectric materials* in confinement. In [263, 265, 592] sodium nitrite and Rochelle salt embedded in 7-nm porous glass were studied. Only a very small negative shift of transition temperature was found in contrast to the dispersed $BaTiO_3$ and $PbTiO_3$ [593]. Substantial broadening of the transition was reported and interpreted as an effect of the fluctuations. In [263, 592] KDP embedded in artificial opal and porous glass was studied. A fast increase of the transition temperature with decrease of pores size was observed. The most plausible explanation is coupling of the embedded materials with the pore surface.

4.5.2. Diffusion

Hindered transport in restricted geometries is of theoretical and practical interest because of its relevance to many important processes, such as chromatographic separation of polymers, enhanced oil recovery, membrane separation, and polymerization in the presence of heterogeneous catalysts [594].

In an early paper on the study of molecular diffusion by forced Rayleigh scattering in porous media, published more than 15 years ago [595], the diffusion of an azobenzene molecule in Vycor was reported to be two orders of magnitude slower than in free unbound solution. The authors succeeded in separating chemical heterogeneity and geometrical disorder and developed a detailed fractal model relating pore size distribution to self-diffusion. In another paper [596] the diffusion of polystyrene in 74.5-nm porous silica glass was studied by dynamic light scattering. Adsorption of polymer was excluded by silanizing the surface. Decay of long-wavelength fluctuations was governed by a single "macroscopic" relaxation rate. It was found that the correlation length depends not only on the pore geometry but on the hydrodynamic radius R_H of the polystyrene molecule as well. Samples with number-averaged molecular weights of 35,000 and 93,000 corresponded to $R_H \approx 4$ nm and $R_H \approx 7.5$ nm, respectively. The following description was proposed for an effective macroscopic self-diffusion coefficient D_∞

$$D_\infty = \chi f(R_H/R_P) D_0 = \chi D_P \tag{28}$$

where χ is the intrinsic conductivity (hindrance factor) of the porous medium ($T = 1/\chi$ is called tortuosity), D_0 is the bulk diffusion coefficient, R_P is the average pore radius, and D_P is the diffusion coefficient within the pores for the

short times or distances. An intrapore short-distance translational diffusion coefficient can be effectively measured with incoherent quasi-elastic neutron scattering [597], though we do not know any paper in which coefficient f was analyzed on the basis of a comparison of D_∞ with D_P from neutron data. A rough estimate of $\chi \approx 0.75$ was given in [596] with estimations for f of 0.92 and 0.83, and 4 nm and 7.5 nm for R_H, respectively. Diffusion of polystyrene with molecular weights of 2500–13,000 in 2-nm Vycor glass with a porosity $\phi \approx 0.28$ (ratio of polymer free-solution radius to the glass pore radius from 0.017 to 1.4) was studied with dynamic light scattering [594]. Strong dependence of the D_∞/D_0 on R_H/R_P was confirmed, and an estimation of $\chi = 0.3$ to 0.7 was obtained. Such an estimation is in good agreement with calculations in the frames of model of medium composed of random structural elements (pores) chaotically connected with one another [598]

$$\chi = 1 - \tfrac{2}{3}(1+\phi)(1-\phi)^{3/2} \tag{29}$$

This yields $\chi = 0.48$ for $\phi = 0.28$. The extremely small χ value obtained in [595] was explained in [594] by incomplete suppression of the adsorption on the pore walls.

A limiting case of diffusion in the very narrow pores was considered in [599]. Diffusion of tetrafluoromethane (diameter of molecules 0.47 nm) in the $AlPO_4$-5 zeolite (channel diameter on the order of 0.73 nm) was studied by pulsed field gradient NMR. $AlPO_4$-5 zeolite is traversed by parallel channels. It was demonstrated that in this case the mean square displacement $\langle \zeta^2 \rangle$ increases in proportion with the square root of observation time, in contrast to the ordinary diffusion when $\langle \zeta^2 \rangle \propto t$. This observation corresponds to the regime of "single-file" diffusion, when the molecules are unable to pass each other. Measurements provide a diffusion coefficient D on the order of $5 * 10^{-7}$ $m^2 s^{-1}$, which is about 2 orders of magnitude larger than in other zeolites [600]. The observed phenomenon was explained in [599] as the effect of molecular guidance by the channels, resulting in the enhancement of molecular mobility in one-dimensional channels in comparison with higher-dimensional pore networks.

Self-diffusion properties of plastic formers succionitrile and cyclohexane confined in porous glasses [601, 602] and in MCM-41 [603] were studied. In the confined liquid, above freezing the diffusion coefficient is essentially lower than in the bulk, similar to the other confined substances considered above. However, on freezing, the diffusion coefficient in bulk drops down by about 4 orders of magnitude. In the confined material two phases develop, namely, a plastic phase in the center of the pore and a liquid-like component with D about 3 orders of magnitude higher than in the bulk.

4.6. Liquid Crystals

Liquid crystals (LCs) are often considered as ideal objects for the study the effects of confined geometry. Kralj et al. [249] have explicitly formulated the main advantages of LCs as model systems for such research: (i) LCs exhibit a variety of phases with different degrees of orientational or translational order; (ii) there exist different kinds of transitions between these phases; (iii) they are typical representatives of soft materials (their response to perturbations induced by the confining matrix is pronounced and long-ranged); (iv) LCs and the host materials do not interact chemically; and (v) both LCs and the host matrixes are in most cases transparent, and consequently samples can be studied by a variety of optical methods. Key to understanding the large part of confinement effects on LCs is an interaction of the LCs with surfaces [604]. In the case of the nematic LC this interaction is usually described in terms of the preferred orientation of the nematic director at the surface called the "easy direction" and the strength of the interaction. The easy direction is the direction of the director at which the surface energy is minimal. The strength of the interaction is determined by the so-called anchoring strength, which tells what torque is needed to move the orientation of the director from the easy direction. Anchoring properties of the surface strongly affect both static and dynamic characteristics of LCs.

The influence of the confinement on the LCs is related to the contribution of the LC/matrix surface to the free energy. This effect is usually described in the framework of the Landau-de Gennes theory [605, 606], with the surface term described as

$$F_s = \int (f_n + f_s) d^2 \vec{r} \tag{30}$$

with the nematic contribution f_n described as [607]

$$f_n = -W_1 S\left(\frac{3(\vec{n}\,\vec{e}^{\,2} - 1)}{2}\right) + W_2 S^2$$

where W_1 and W_2 are positive surface anchoring constants, $\vec{n}$ determines the nematic director field, S is the nematic orientational order parameter, and $\vec{e}$ is the easy direction. The linear term is concerned with the direct interaction between the surface and LC molecules, and the S^2 term is due to the fact that LC molecules have fewer neighbors at the surface [249]. The smectic contribution f_s is presented as [249]

$$f_s = -W_p \eta \cos(\Phi - \Phi_s)$$

where W_p is a positive constant.

We will follow [249] in describing possible LCs structure in the simplest case of the cylindrical cavities of radius R and length L_d or the cavities that can be presented as a space between two concentric cylinders of radii R_0 and $R_0 + 2R$, respectively. Two extreme cases can be considered: homeotropic anchoring (the LC molecules tend to be aligned along the surface normal) and planar anchoring (the molecules are forced to lie in the limiting plane, where all directors are equivalent). The case of planar anchoring corresponds to the homogeneous structure (Fig. 6(i)) or the homogeneous structure with point defects (Fig. 6(ii)). In the case of homeotropic ordering one expects formation of the escaped radial (Fig. 6(iii)) [249, 608] or escaped radial with point defects (Fig. 6(iv)) structures. In the limiting case of strong homeotropic anchoring, structures (iii) and (iv) are transformed into the planar radial structure (Fig. 6(v)) [249, 608, 609]. In this case the bend nematic deformation, characteristic for structures (v) and (iv), is absent and the director field radially streams from the center of the cylinder with a line defect along the cylinder axis.

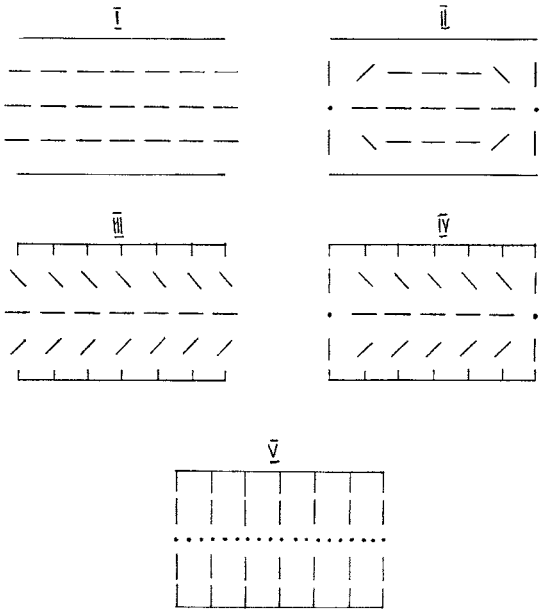

Figure 6. Model director structures. (i) Homogeneous. (ii) Homogeneous with point defects. (iii) Escaped radial. (iv) Escaped radial with point defects. (v) Planar radial structure. For the type (v) cavity the director field is either radially distributed or perpendicular to $\vec{R}$. (following [249]).

An important effect is related to the quenched disorder in the LC-matrix nanocomposites. The matrix in this case not only geometrically confines the LCs but also induces a random orienting field that fixes the direction of the order parameter near the surface of the matrix [610]. The randomness is determined by the geometry of a confining porous matrix. Maritan et al. [611] were the first to associate the effects of the porous media with that of a random field. Their theoretical considerations supported the early experimental results of [612, 613] reporting the light scattering and calorimetry measurements of confined LCs. It was demonstrated that the first-order phase transition observed in bulk LCs was replaced by a smooth evolution to a glassy state, with the correlation length not exceeding the characteristic pore size. More elaborate (renormalization group) theoretical treatment of the problem of confined nematics was recently reported by Feldman [610]. He has demonstrated that in the case of weak disorder a state with quasi-long-range order can be formed. However, in the case of strong disorder the topological defects drive the system into the glass state, in which the orientation of the director is determined only by the local random potential. Influence of randomness to a large extent is governed by the ratio between the average pore radius R and the nematic correlation length ξ_n. In [249] estimations were made for the controlled porous glass matrix, and it was shown that the effects of randomness become important for $R < \xi_n$, where the noncorrelated curvatures of cylindrical voids are the main origin of randomness.

Properties of the confined LCs have been extensively studied by different experimental techniques such as NMR [249, 614], light scattering [604], dielectric spectroscopy [615], X-ray diffraction [246], etc.

In particular it was shown that in small pores, as already mentioned, isotropic-nematic (I-N) phase transition is replaced by a gradual evolution of the nematic order [249, 612–614]. However, in the case of large enough pores ($R \geq$ 25 nm for pentylcyanobiphenil (5CB) in controlled porous glass [249]) the I-N phase transition is discontinuous. In this case $T_{\text{I-N}}$ can be shifted either upward or downward, depending on the size of the cavity and on the ordering properties of the cavity surface. In the mentioned example of 5CB in CPG, with a decrease of $T_{\text{I-N}}$ with $\Delta T_{\text{I-N}} = \mathcal{T}_{\text{I-N}}^{\text{bulk}} - \mathcal{T}_{\text{I-N}}^{\text{conf.}} \propto 1/R^{1.3\pm0.3}$ [249]. $\Delta T_{\text{I-N}} = \propto 1/L$ (L is the mean free path in the empty regions), scaling was observed for LCs in aerogel matrix [616]. It should be mentioned that in many cases the surface-induced paranematic order is observed in the isotropic phase [614]. The nematic-smectic-A phase transition is usually more affected than the I-N one [249]. It was demonstrated for the octylcyanobiphenyl (8CB) in controlled porous glass [246, 249] that 8CB was confined to anopores (200 nm in diameter) [617] and aerogels (mass densities $\rho = 0.080.60$ g $\cdot$ cm^{-3}) [616]. In the case of porous glasses, LC-surface interaction was modified by silanizing the surface. According to [249], silane-treated surface exhibits homeotropic anchoring and nontreated surface planar anchoring. In nontreated samples the smectic order parameter temperature dependence is similar to that in bulk LCs, with the order parameter reduced by a few percent [246]. In the case of nontreated surface pretranslation, smectic ordering is observed. Temperature dependence of the smectic correlation length ξ_{sm}, similar to that in magnetic systems with random fields, was observed for both treated and untreated samples [246]. ξ_{sm} was gradually increased by lowering the temperature from the nematic phase and saturated at $\xi_{\text{sm}} \approx R$. In the case of anopores the surface was either untreated or lecithin-treated. The rough untreated surface inhibited the smectic growth, whereas in the case of the lecithin-treated surface the smectic layers were initiated at the surface [617].

Dynamics of LCs is strongly affected by confinement. Broadband dielectric spectroscopy of 5CB and 8CB in porous glasses (10–100 nm) has revealed a number of differences between bulk and confined behavior [618]. Similar to those of confined liquids (see 4.5.1), all observed relaxation processes are of the non-Debye type but can be well described by the Havriliak-Negami equation, (26). The relaxation processes in confined LCs are not frozen, even at temperatures about 20° below bulk crystallization temperatures. Confinement resulted in the appearance of two new relaxation processes not observed in the bulk LCs. One of the processes is related to the presence of the surface layer; the origin of the other is not clear yet. Dynamics of the nematic-isotropic phase transition was studied with time-resolved transient grating optical Kerr effect measurements [619]. Nonexponential decay and drastic decrease in the relaxation time of the order parameter fluctuations were observed in the pretransitional temperature range. This result is in contrast with data of Wu et al. [612], who observed below bulk $T_{\text{I/N}}$ slowing down of the critical fluctuations described by the Vogel-Fulcher law.

Dielectric spectroscopy was also used to study the smectic-A to smectic-C* transition in W314 LCs confined in aerogels ($\rho = 0.08$ and 0.17 g $\cdot$ cm^{-3}) [615]. In addition to

the Goldstone collective mode, an additional relaxation process related to the surface layer was found with decreasing, strength while the strength of the Goldstone mode increased on cooling.

4.7. Helium in Confinement

The problem of quantum liquids (He and hydrogen) is too broad to be covered as a small part of a more general review, so we will indicate just some of the main topics related to this problem. As early as 1956, the first studies of Vycor glass as a superleak were reported in [620]. Later on, solidification [537, 541], superfluid transition [621–624], dynamics [625, 626], and other properties were studied in great detail. A paper by Adams et al. [541] remains the most detailed study of the P-T phase diagram of ^{4}He confined in the Vycor glass for 0.8 K $< T <$ 2.5 K and $P \leq 60$ bar. No solidification was found for $P < 36.3$ bar, and it was shown that at $T = 0.8$ K, solid and liquid may coexist for 36.3 bar $< P <$ 38.0 bar. The line of λ superfluid phase transitions was shifted to lower temperatures for about 0.2 K but remained parallel to that in bulk liquid He. In [623] the temperature dependence of the superfluid density ρ_S was examined in the critical region for ^{4}He in Vycor glass. It was shown that superfluid density follows a power law in reduced temperature, $\rho_S \propto \tau^{\zeta}$, with the exponent $\zeta \approx 0.67$, in numerical agreement with the bulk value. Later [624] $\rho_S(\tau)$ dependences were checked for He in Vycor (full filling and films) xerogel (full and film) and aerogel, and values of ζ from 0.63 to 0.91 were obtained. Different critical exponents indicate different universality classes. Moreover, Mulders et al. [627], analyzing earlier published data on ρ_S and specific heat temperature dependences, have demonstrated apparent violation of the hyperscaling relation $3\zeta = 2 - \alpha$. We are not aware of any reliable explanation of the described facts. Recently several papers were published that attempted to solve the puzzle of confined helium properties by microscopic measurements. In [626] Sokol et al. report the results on an inelastic neutron scattering study of roton excitations in two different porosity aerogels. Crossover in the temperature dependence of the roton energy gap was observed at $T \approx 1.9$ K, which was explained in terms of length scales of confinement and the roton mean free path. It was suggested that the roton mean free path determines the spatial scale above the crossover temperature, while below it the temperature dependence of the roton energy is suppressed. Some very recent inelastic neutron scattering results on He in xerogel glass were presented in [625]. In spite of the huge total number of publications, we believe that there is still no comprehensive understanding of the problem.

GLOSSARY

Confinement Restriction of some material to a given volume; can be one-dimensional (films), two-dimensional (filaments), or three-dimensional (isolated particles).

Phase transition Change of a substance from one phase (the type of a system, such as solid, liquid, gas, superconductor, ferromagnet, etc.) to another. Also known as phase transformation.

Porosity The existence of some free volume inside a solid material structure, which is not occupied by structural elements of this material.

Size effect The effect of size of a piece of material on its properties.

Wettability The ability of any solid surface to be wetted when in contact with a liquid; that is, the surface tension of the liquid is reduced so that the liquid spreads over the surface.

Nanostructuring at Surfaces Using Proteins

Michael Niederweis

Friedrich-Alexander Universität Erlangen-Nürnberg, Erlangen, Germany

Stefan H. Bossmann

Universität Karlsruhe, Karlsruhe, Germany

CONTENTS

1. INTRODUCTION

The information age can be characterized by its ever-increasing demand of ultrafast computer systems, which resulted in the expectation of an exponential success in miniaturization, which is known as Moore's "law" [1]. Although more conventional techniques, such as (deep) UV-patterning [2], X-ray proximity [3], or ion-beam projection lithography [4] are being optimized and installed in industrial development and production units, it is apparent that the successful design of nanoscale systems will require entirely new materials, processes, and device architectures.

In order to meet this challenge, a wide range of methods for the nanostructuring of (mostly metal-) surfaces [5] was developed during the last two decades. This research endeavor is particularly dedicated to the development of advanced hardware. However, other commercial applications of (bio-)nanosystems are of increasing importance as well; for instance bio- and medical sensing systems [6] and optical devices [7]. The most advanced technologies today are commonly described as electrochemical nanostructuring (by tip-induced metal deposition or oxidation) [8] and atomic force microscope (AFM) lithography [9]. Electrochemical methods are based on the technology of the scanning tunneling microscope (STM) [10]. However, until now the most significant disadvantage of electrochemical nanostructuring and AFM Lithography is that nanostructuring has to be performed atom-by-atom or fragment-by-fragment, respectively. Consequently, the defined nanostructuring of surfaces has been time-consuming and expensive. Therefore, the generation of well-defined nanostructures by protein or macromolecule deposition on two-dimensional surfaces would represent a considerable advantage compared to the technologies previously mentioned. Especially the use of proteins has many advantages [11]. Proteins are, in comparison to synthetic polymers, much more "intelligent" materials, because they are able to interact site-specific with each other as well as with possible ligand molecules or substrates [12]. Furthermore, proteins permit the harvest of the results from very many of years of evolution for nanotechnical purposes [13]. Even better, the genetic technology of site-directed mutagenesis permits the introduction of specific features for tailor-made nanotechnological application into the protein-based assemblies.

1.1. Design and Future Applications of Quantum Dots

Recent developments in nanotechnology offer applications in very different areas, such as electron tunneling (superconduction) at feasible temperatures [14], (photo) electro-catalysis [15], the development of quantum computers [16], as well as novel photoelectrochemical devices, using the effect called "plasmon-resonance" of an array of nanoparticles or -wires [7]. To date, the most developed nanosystems for quantum applications consisted of

ISBN: 1-58883-063-2/$35.00

Encyclopedia of Nanoscience and Nanotechnology
Edited by H. S. Nalwa
Volume 7: Pages (851–867)

doped carbon-nanotubes [17] and doped zeolites [18]. However, both template materials lead inevitably to at least some degree of electrical connection between the embedded nanoparticles. Therefore, possible quantum effects could be cloaked by unwanted electrical connection of the individual quantum dots. In this case, we cannot expect "real quantum effects" when these materials are used for advanced electrocatalysis.

The use of a stable protein as nanotemplate for the stabilization of nanoparticles and -wires would provide an electrically insulating matrix for the consequent electrosynthesis [19] of metal-nanoparticles or nanowires. Furthermore, at least some proteins possess the ability of self-organization under *in-vitro* conditions. A straightforward approach to the generation of stabilized nanoparticles consists of the use of nanotemplates, which act as "hosts" for the nanoparticles [20]. These nanoscopic particles are generated by reduction of metal salts by chemical processes [21].

Protein-stabilized nanoparticles represent an ideal quantum-dot system, having the big advantage that the exterior of the synthesized Au, Ni, or Pt-nanoparticles or -nanowires will be embedded by the protein, serving as an ideal insulator. Since only the openings of the metal-filled nanochannels or nanopores will be open to the supernatent buffer or the substrate, real quantum effects could occur. Besides quantum effects, protein-based nanodots may permit the observation of very large electrical field effects, since the electrical field at the top of a metal-doped protein channel will easily exceed 10^6 Vcm^{-1}.

1.2. S-Layer Proteins and Porins

Two groups of bacterial proteins are of a special interest for the design of future nanotechnology: the S-layer proteins and the porins. S-layer proteins form two-dimensional crystalline surface arrays and have been identified in hundreds of different species from nearly every taxonomic group of walled eubacteria and are also present in many archeabacteria [22]. S-layer proteins from numerous species were isolated and characterized and are, in principle, available for technical applications. Porins are channel proteins in bacterial outer membranes and allow the diffusion of small and hydrophilic compounds [23–26]. In contrast to the S-layer proteins, various porins have been intensively studied with respect to their biophysical properties [27–29]. The mechanisms and the triggering factors of the channel-opening are of especially great interest because of possible applications of ion- and diffusive channels [30–34]. Furthermore, the crystal structures of some porins of Gram-negative bacteria have been solved and the diffusion of ions through porin channels have been computer-simulated [35].

Channel porins from Gram-positive bacteria and especially from Mycobacteria [36] are of special interest with respect to their application in nanotechnology because of their unique channel lengths [37].

Since the structures (and especially also the functions) of bacterial porins have been optimized in evolution, we might as well use these highly versatile biological structures directly, instead of mimicking their structures and working principles in chemical membrane and surface models. Nevertheless, it must be noted that evolution was not directed toward any applications in nanotechnology, but rather headed for an optimized influx of nutrients while providing maximal protection at the same time. Therefore, we have to proceed with great care on this path. It is apparent that the chemical stability of bacterial proteins (S-layer subunits and porins) against thermal and photochemical decomposition reactions must be sufficient in order to permit a successful application in nanotechnology [38]. The porin MspA isolated from *Mycobacterium smegmatis* possesses a superior chemical stability and can, principally, be used as a chemically synthesized polymer [39]. It possesses very distinct properties and forms nanochannels (not open "pore" structures like those found within S-layer lattices) of approximately 2.5 nm in diameter and 10 nm in length [37]. Furthermore, MspA can be reconstituted in various environments just as lipid bilayers, polymers, and hydrophobic surfaces. Therefore, the formation of nanochannels cannot only be achieved within one defined environment, like in the case of pore formation within S-layer lattices, but can be achieved in virtually any hydrophobic environment. This approach is considerably more versatile with respect to nanotechnology applications. In this respect, it is very fortunate that MspA has a very high tendency to form pores in artificial environments and that these pores were, at least in the examples known to date, of comparable geometric extensions. MspA nanochannels are hydrophilic in their interior and strongly hydrophobic in their exterior. Due to the electrically insulating nature of the pore walls and their geometric dimensions, the pores formed by the MspA porin from *Mycobacterium smegmatis* represent a serious challenge to carbon nanotubes as host systems for nanotechnological applications.

This chapter is describing the most important developments in the field of nanotechnology on surfaces employing proteins. It consist of the following sections: (2) S-Layer Proteins; (3) Porins from Gram-Negative Bacteria; (4) The Porin MspA from *Mycobacterium smegmatis*.

In each section, a comprehensive description of the most striking biochemical and biophysical properties is provided, before we discuss the applications as well as the application potential of the proteins of interest in nanotechnology at surfaces and surface structures.

2. S-LAYER PROTEINS

The surface of many bacteria is covered by two-dimensional crystalline arrays of proteins or glycoprotein subunits, which are commonly referred to as "S-layers" [22, 40]. Consequently, S-layer proteins belong to the most abundant proteins in prokaryotes comprising up to 15% of the total cellular protein [22]. Although considerable knowledge has accumulated on the structure, assembly, biochemistry, and genetics of S-layers, relatively little information is available about their specific functions [41]. S-layers are thought to function as molecular sieves, protective or adhesive coatings or ion traps. Furthermore, in all bacteria that possess S-layers as exclusive cell wall components, the cell shape is determined by the (glyco)proteins [41]. Whereas the S-layer proteins from archaebacteria and Gram-negative eubacteria are not connected to their cytoplasmic or outer membranes, respectively, the S-layer

proteins of at least some Gram-positive eu- and archaebacteria are indeed chemically linked [42]. As it can be seen from the examples provided in Figure 1, considerable variations in structure, complexity, and lattice symmetry of S-layer proteins exist. However, many S-layers are similar with respect to their chemical composition, formation principles, biophysical properties, and molecular size distribution.

The thickness of S-layers ranges from 5–25 nm [40]. The outer surface appears often to be smooth, whereas the inner surface is more corrugated [43]. Structural investigations of S-layers *in vivo* and after recrystallization on various substrates were performed using a combination of very different techniques, such as metal-shadowing, negative staining, ultrathin-sectioning, freeze-etching, scanning probe microscopy experiments, and underwater atomic force microscopy [22]. Structural information was obtained down to the subnanometer range. Consequently, the formation principles of two-dimensional S-layer protein arrays and their self-repeating structures are known [44]. S-layer lattices, which form an array of protein or glycoprotein subunits, possess either oblique (p1, p2), square (p4), or hexagonal (p3, p6) symmetry (see Fig. 2). The symmetry class in which the S-layer proteins crystallize is strongly dependent on the bacterial species, but not on the experimental conditions of the crystallization process. The experimental conditions only determine whether the formation of well-ordered lattices at surfaces does occur or not. One of the results from the structure elucidation of S-layers is that they form highly porous mesh works with a porosity in the range between 30–70%. The assemblies of identical protein or glycoprotein subunits possess masses in the range of 35,000 to 230,000 Dalton and exhibit pores of identical size and morphology. Many S-layers feature two or even more distinct classes of pores in the range of 2–8 nm. The subunits of most S-layers interact with each other during the process of S-layer formation through noncovalent forces including hydrophobic interactions, hydrogen bonds, ionic bonds, and the interaction of polar groups [40].

The chemical composition of S-layer (glyco)proteins from all phylogenetic branches was found to be surprisingly similar [40]. The typical S-layer is composed of an acidic protein or glycoprotein, possessing an isoelectric point in the region from pH 3 to 5. Since the isoelectric point of a protein results from the superposition of the isoelectric points of those amino acids, which are exposed to the aqueous electrolyte, it is very interesting to take a look at the chemical composition. Typical S-layer proteins have high amounts of glutamic and aspartic acid. Together, they account for 15 mol%. The lysine content of S-layer proteins is in the range of approximately 10 mol%. Thus, ionic amino acids make up about a quarter of the total composition of S-layer proteins. This finding indicates clearly the importance of ionic interactions during the formation of the S-layer lattice structure. It is noteworthy that the content of sulfur-containing amino acids in the S-layer proteins is close to zero. Interestingly, the main fraction of amino acids of S-layer proteins is hydrophobic in nature. It is even more interesting that hydrophobic and hydrophilic amino acids do not form extended clusters, but alternating segments with a more hydrophilic region at the terminal N-end. Information regarding the secondary structures of S-layer

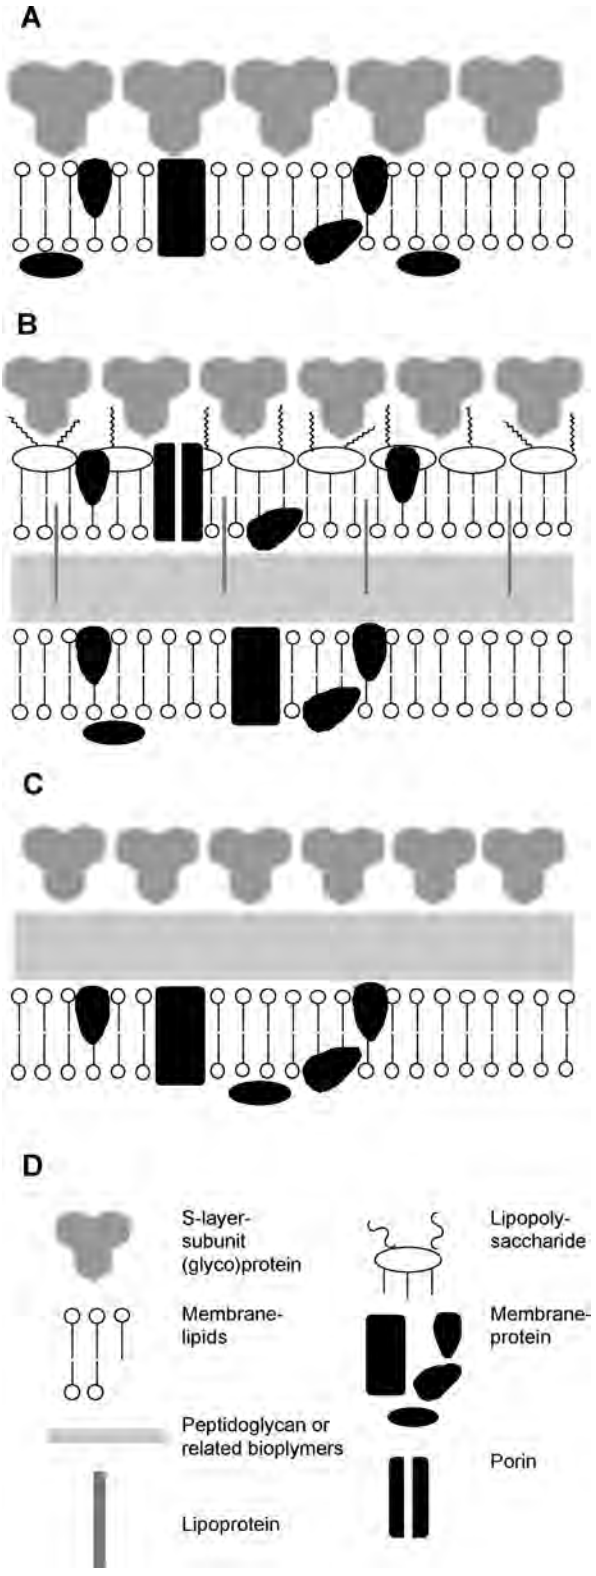

Figure 1. The structures of bacterial cell walls. (A) Archaebacteria; (B) gram-negative eubacteria; (C) gram-positive archae- and eubacteria [22]; and (D) legend.

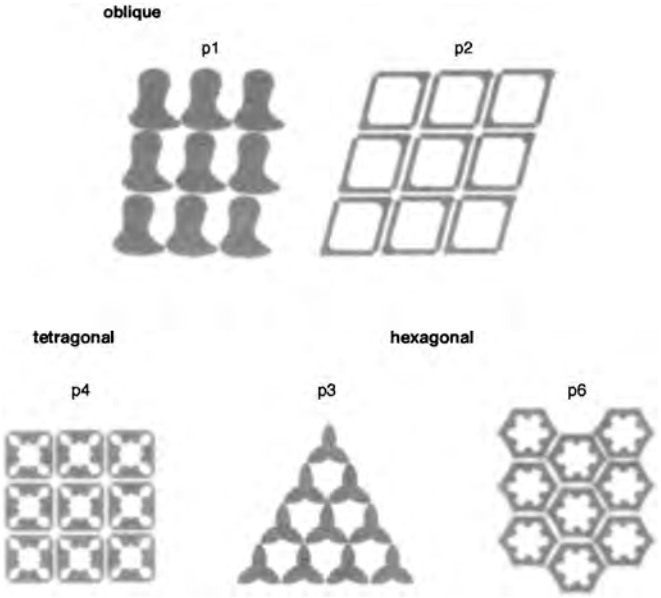

Figure 2. Symmetries of S-layer lattices (schematic representations).

proteins was obtained by using circular dichroism measurements, FT-IR-spectroscopy, and especially from secondary structure prediction based on the available protein sequence data [45]. In a typical S-layer, up to 70% of the proteins form α-helices and 20% form β-sheets. Aperiodic foldings and β-turn contents account for most of the missing fraction. In many of the S-layers, the N-terminal regions, which are among the parts of the protein-sequence self-organized as α-helices, are able to recognize distinct structures in the underlying cell envelope [46]. Because of the noncovalent nature of the bonds between the subunits, which are hydrophobic as well as ionic in nature, the growth of the S-layer, which is in most of the investigated cases surrounding the whole bacterium, proceeds very rapidly. One can approximate that a coherent S-layer at the surface region of an average cell is formed by the supramolecular interaction of approximately 5×10^5 protein or glycoprotein subunits. For S-layered bacteria with a generation time of 20 min, approximately 500 copies of the S-layer subunits have to be synthesized inside the cell, translocated and integrated into the S-layer per second [22] (Fig. 3). Because of their unusual building mechanisms and dynamics, S-layers can been described as "dynamic closed surface crystals," with the intrinsic capability to assume a structure of low free energy during cell growth and also during their growth and assembling processes at membranes and artificial surfaces.

2.1. Applications of S-Layer Proteins at Surfaces

The physicochemical properties and especially the permeability of S-layer cell envelopes are of a profound interest because they offer (a) an insight into the function principles of the bacterial transport mechanisms, and (b) the possibility of designing permeability filters for nano- and biotechnological applications [22, 47].

2.2. S-Layer Proteins as Permeability Barriers

S-layer proteins from mesophilic and thermophilic *Bacillaceae* were studied in detail. Opposite to the underlying peptidoglycan-containing "wall skeleton," no net negative surface charge was determined. The charge density found in the native S-layer from *B. sphaericus* was 1.6 carboxylic acid functions per nm^2. However, the free carboxylic acid functions are neutralized by free amino groups of lysine. The presence of an approximately equimolar amount of amino groups and carboxylic acid groups in the pore areas of many *Bacillaceae*, prevented the adsorption of charged macromolecules inside the pores. Therefore S-layers from *Bacillaceae* can be used as suitable antifouling coatings. Furthermore, permeability studies performed on the same S-layers, demonstrated that, in spite of the considerable differences in the lattice types, the molecular weight cut-off was 30,000–40,000 Da [48]. This data is in agreement with the assumption of a pore diameter of approximately 4–5 nm.

2.3. S-Layer Ultrafiltration Membrane

For the synthesis of S-layer ultrafiltration membranes (SUMs), [49] either cell wall fragments with adhering S-layer proteins or previously isolated self-assembling S-layer subunits are used. Also in this case, S-layers from *Bacillaceae* possess ideal physical and chemical properties. The fixation of S-layers at microfiltration membranes can be achieved using a pressure procedure. Then the S-layer lattices on top of either the microfiltration membrane or the cell fragment adhering to the microfiltration membrane are crosslinked with glutaraldehyde, and thereafter the Schiff bases are reduced employing sodium borohydride as reagent. Depending on the very defined structures of S-layer lattices on surfaces, the rejection curves of S-layer-SUMs are distinctly

steeper than of microfiltration membranes made of amorphous polymers. Again, a molecular weight cut-off of 30,000–40,000 was found. This is not surprising because the molecular weight rejection effect is achieved by the pore structure of the S-layer lattice.

2.4. Chemical Modification of S-Layers

The crosslinking procedure using glutaraldehyde produces eventually a net negative charge. Carbodiimide activation offers the opportunity to link carboxylic acids to a manifold of chemical reagents and groups [50]. Thus, either a strong net negative charge or a strong positive net charge can be achieved. Also the hydrophobicity of SUMs could be modulated following the same experimental approach. It is of special importance that the distinct geometry of the self-repeating S-layer lattice did not change noticeably when the free carboxylic acids are chemically modified. S-layer glycoproteins offer the same opportunities via the activation of their glycan chains either by periodate oxidation or cyanogens-bromide activation.

A recent example of this versatile strategy was the application of S-layer-coated liposomes for entrapping and binding of functional molecules: The S-layer protein from *Bacillus stearothermophilus* PV727P2 was recrystallized on positively charged unilamellar liposomes of an average diameter of 180 nm formed by dipalmitoyl phosphatidylcholine (DPPC), cholesterol, and hexadecylamine (HDA) (molar ratio: 10/5/4) [51]. The S-layer subunits possess the molecular weight of 97,000 and form a two-dimensional lattice of oblique symmetry. Crosslinking was achieved using glutaraldehyde. Then, the free carboxylic groups were activated with 1-ethyl-3-(dimethylaminopropyl)-carbodiimide (EDC). This reagent has the advantage that it can be successfully employed also in aqueous solutions. The crosslinking process could be observed employing S-layer–coated carbonic anhydrase containing liposomes (SCALs). Whereas the crosslinking reaction proceeded exclusively between adjacent S-layer subunits within the two-dimensional lattice at the outer surface of the liposomes, the enzyme carbonic anhydrase, located inside the liposomes, was not effected by the chemical treatment as it could be demonstrated using SDS-polyacrylamide gel electrophoresis (SDS-PAGE). When the crosslinking of the S-layer subunits was performed using Bis(sulfosuccinimidyl)suberate (BS), evidence for heterologous crosslinking between the S-layer protein and membrane incorporated HDA was found.

The supramolecular as well as the highly specific binding of molecules and polymers to S-layer lattices can also be achieved by using noncovalent forces. Important factors determining the nature and the selectivity of the binding are the S-layer lattice type, the geometric sizes (or the van-der-Waals radii, respectively) of the morphological units and the chemical nature, the physicochemical properties, and the distribution of binding sites on the array. An example for this binding type is the binding of polycationic ferritin (PCF) on the S-layer lattice of *B. coagulans* E38-66 [52].

The hexagonally ordered S-layer lattices from *B. stearothermophilus* PV72 and *Thermoanaerobacter thermohydrosulfuricus* L111-69 [53] and the square S-layer lattice from *B. sphaericus* CCM 2120 can bind anionic, cationic, zwitterionic, and noncharged macromolecules. Note that only the surface of *Thermoanaerobacter thermohydrosulfuricus* is glycosylated [22].

2.5. Semifluid Membranes

A simple and straightforward method for generating coherent S-layers on lipid films is the injection of isolated S-layer protein subunits in the subphase of the Langmuir–Blodgett (LB)-trough. The crystallization of the two-dimensional S-layer lattices begins at several nucleation points and proceeds underneath the preformed phospholipid or tetraether-lipid films until coalescence of the single crystal domains occurs. Generally, the orientation of S-layers, which can be crystallized on any kind of surfaces, is determined by the anisotropy of their physicochemical surface characteristics. The more hydrophilic surface, which possesses net negative charges, is usually directed towards the negatively charged or zwitterionic head groups of phospholipid or tetraether-lipid films. Since the direction is determined by the charged head groups embedded in the S-layer structure, the more hydrophobic "outer" face (with respect to its natural orientation adhering to the bacterial cell) is directed toward the water phase during its formation. However, ordered phases with adhering S-layers can be either turned or transferred onto organic, ceramic, or metal supports. It is noteworthy that the fluidity of the lipid films, which were previously used as self-assembled mono- or bilayers is a very critical parameter for generating coherent S-layer lattices. When the formation of S-layers adhering to lipid films is achieved, crosslinking can be performed using glutaraldehyde. The latter procedure increases the mechanical stability of the S-layers on lipid film remarkably.

In a very similar manner, so-called semifluid membranes can be generated [54]. In these cases, where free carboxylic or amine groups are left after the crosslinking procedure using glutaraldehyde, lipid molecules of the LB film can be chemically linked to the S-layer protein lattice. The linking of the S-layer protein subunits to individual lipid molecules, which interact nevertheless with all lipid molecules forming the lipid monolayer or bilayer, decreases the lateral diffusion (Fig. 4). Consequently, the fluidity of the whole membrane assembly decreases. Using standard procedures, a manifold of functional biomolecules (for instance, ion channels, molecular receptors, proton pumps, or porins) can be integrated in semifluid membranes. Depending on the structure and hydrophobicity of the biomolecules, the integration into the lipid film can be achieved either before the chemical fixation of the adhering S-layer lattice or after this procedure. Because of the flexibility of this experimental approach, this technology has a big potential to initiate a broad spectrum of developments in the fields of optical or electronic nanodevices, diagnostics in medicine, and life science engineering.

The application of S-layer–coated liposomes for entrapping and binding of functional molecules via the avidin- or streptavidin-biotin bridge demonstrated this potential [54]. Two biotin residues accessible to avidin binding were bound to every S-layer subunits within the crosslinked S-layer lattice. Using biotinylated ferritin, which serves as an excellent electron paramagnetic resonance (EPR) marker, it could

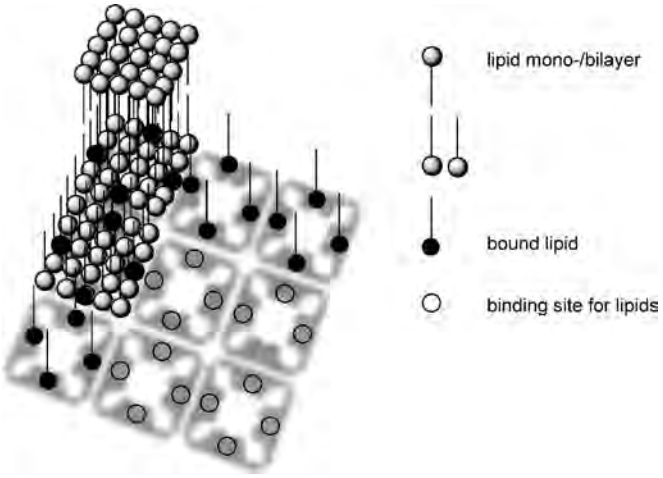

Figure 4. Schematic representation of a "semifluid" membrane, composed of an S-layer lattice possessing binding sites for lipid molecules and a lipid mono-/bilayer.

be demonstrated that a well-ordered layer of straptavidin formed on the accessible surface of the S-layer coated liposomes.

The same strategy also proved valuable when biotinylated antihuman IgG was attached via streptavidin to the biotinylated S-layer–coated liposomes (Fig. 5). The biological activity of the S-layer bound antihuman IgG was confirmed using the enzyme-linked immunosorbent assay technique (ELISA).

A similar strategy was used for the immobilization of the enzymes invertase (Mr 270,000) and glucose oxidase (Mr 150,0000) at the S-layers of *B. stearothermophilus* PV72 and *T. thermohydrosulfuricus* L111-69 [54]. The labeling density corresponded to 2–3 enzymes per hexametric unit cell of the S-layer lattice. This finding corresponded to the formation of a monomolecular enzyme layer on the surfaces of both L-layer lattices. Immobilized invertase retained approximately 70% of its enzymatic activity in the nonimmobilized state, glucose oxidase approximately 35%. When spacer molecules were used (4-amino butyric acid or 6-amino caprotic acid), the measured activity of glucose oxidase increased to about 60%. The use of spacers obviously prevented the binding of whole enzymes or partial enzyme structures within the S-layer pores and is especially advantageous for the generation of enzyme assays.

2.6. S-Layer Based Amperometric and Optical Biosensors

As already pointed out, a broad range of amperometric and optical bioanalytical sensors have been developed using suitable S-layer lattices as nanoscale immobilization matrix. The concepts of enzyme-immobilization and the manufacture of SUMs have already been discussed. For the fabrication of a single enzyme sensor, for instance a glucose sensor, glucose oxidase was bound to the surface of a S-layer ultrafiltration membrane. The electrical connection to the sensing layer was achieved by sputtering a nanoscopic gold or platinum layer onto the S-layer bound enzyme layer. The whole sensor assembly is then usually stabilized using a conventional gold or platinum electrode, by which the electrical contact to the nanolayer is achieved. In this configuration, the analyte reaches the immobilized enzyme through the pores of the S-layer (Fig. 6) [55, 56].

2.7. Molecular Nanotechnology Using S-Layers

One important and very successful approach towards the molecular nanotechnology of the future consists in the generation of so-called "self-assembled monolayers" (SAMs) at metal (especially gold)-, silicon-, or highly oriented pyrolithic graphite (HOPG) surfaces [57]. Self-assembled monolayers are formed by chemically attached lipids, which are bound to these surfaces in such a density that

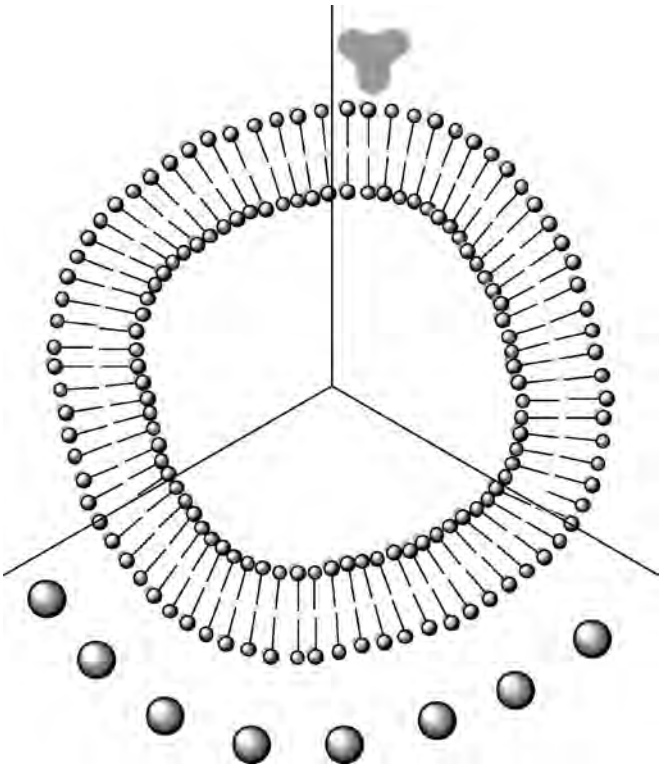

Figure 5. Schematic representation of a liposome, which is coated with an S-layer lattice. The S-layer subunits are chemically linked to functional macromolecules, such as enzymes.

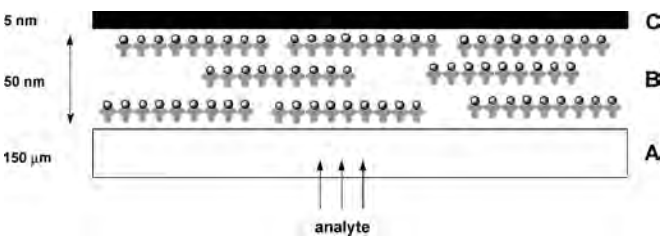

Figure 6. Schematic representation of an amperometric biosensor. (A) microfiltration membrane; (B) multiplayer, consisting of enzyme loaded S-layer fragments; (C) sputtered metal layer.

cooperative effects, just as two-dimensional condensation, occur. Therefore, SAMs are highly ordered and can serve as substrates for the binding and/or incorporation of hydrophobic substrates of all kinds. A very interesting alternative to the formation of SAMs is provided by the recrystallization of S-layer subunits of surfaces, which are suitable for nanofabrication. Silicon or gallium arsenide wafers are two examples for the successful creation of an ordered S-layer on a semiconductor material. S-layer lattices have a great potential for the development of molecular manufacturing procedures and biological nanoresists.

A first success using recrystallized S-layer lattices on semiconductor materials was achieved by the method of deep ultraviolet irradiation (DUV) [58] (Fig. 7). This method is principally related to the conventional negative photoresists, which will not be able to satisfy the hardware needs of the information age. However, it can be regarded as an example for the modern nanotechnology yet to be developed, because it uses the self-replication properties of S-layer lattices for lateral nanopatterning of wafer surfaces.

The method of deep ultraviolet irradiation employs the argon-fluorine (ArF) excimer- (or more correctly, exciplex-) laser system as a coherent light source. The current restriction in the availability of optimal mask systems only permits the generation of submicron structures. Exposure with deep ultraviolet photons, followed by the treatment with an aqueous buffer solution leads to the complete removal of the S-layer lattice located on top of the wafer material. It is very likely that the absorption of high energy photons causes chemical transformations of the amino acids, which are forming the S-layer subunit proteins. Possible photoreactions are Norrish I and II reactions [59], as well as photoinitiated oxidation reactions, which produce water-soluble groups such as carboxylic acids and alcohols. Because of this deep UV-induced chemical transformation, the ability of the S-layer subunits to form ordered lattices is greatly diminished. If the exposure time is optimized, the exposed S-layer surfaces can be completely removed by this procedure. It is noteworthy that the unexposed S-layer surface areas retain their structural and, therefore, their functional integrity.

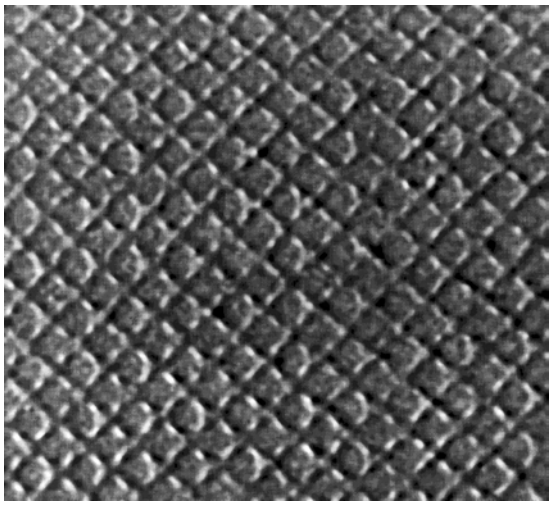

Figure 7. DUV (193 nm)-patterned S-layer coated surface (550 × 550 nm). (For the original images, see [58]).

2.8. Synthesis of Semiconductor and Metal Nanoparticles Using S-Layer Templates

As pointed out earlier, the use of organic and inorganic templates for the synthesis of semiconductor and metal nanoparticles is a very promising strategy. S-layer lattices represent ideal templates, because they represent highly ordered pore structures [57]. By choosing the right S-layer type, nanopores can be obtained. These nanopores can support either the crystallization of inorganic nanoparticles or their chemical or electrochemical reduction [54].

Inorganic superlattices of cadmium sulfide (CdS) with either oblique or square lattice symmetries were fabricated by exposing self-assembled S-layer lattices to Cd^{2+}-ion solutions. After cation-exchange, a slow reaction with hydrogen sulfide was carried out. Precipitation of CdS was confined to the nanopores only and, therefore, the resulting CdS-doped S-layer superlattices possessed the same symmetry as the S-layer lattices used as templates. Using this method, extended arrays of a very defined nanostructure, extending to 5×10^4 nm^2 could be fabricated [60].

A similar procedure resulted in the generation of a square superlattice of uniform 4–5 nm-sized gold particles with a 12.8 nm repeat distance [61]. The key steps of this procedure were the induction of thiol groups to the S-layer and the exposition of the resulting template to a tetrachloroauric acid ($H[AlCl_4]$) solution. Electron irradiation under transmission electron micrograph (TEM) conditions led to the initial formation of a grainy gold layer covering the whole surface of the S-layer. The shape of the gold particles resembled the morphology of the pore region of the S-layer. Crystalline Au(O)-particles were found. However, they did not follow a crystallographic pattern. This approach to nanopatterned metal-coated S-layers did not only work with $H[AlCl_4]$, but also employed $PdCl_2$, $NiSO_4$, $KPtCl_6$, $Pb(NO_3)_2$, and $K_3[Fe(CN)_6]$ [54]. Principally, any combination of S-layer lattice symmetries (oblique, square, or hexagonal), -lattice dimensions and pore sizes with a suitable nanomaterial (metal, metal oxide, or semiconductor particle) can be achieved.

3. PORINS FROM GRAM-NEGATIVE BACTERIA

Porins are channel proteins in bacterial outer membranes and allow the diffusion of small and hydrophilic compounds. Their properties are under intensive investigation [23–26]. Numerous biotechnological applications of porins from Gram-negative organisms were reported [62, 63] with respect to biochemical [64–66] and medicinal [67] applications. Porins from *E. coli* or other Gram-negative bacteria are stable channel-forming proteins, but they dissociate into inactive monomers above temperatures of 55–70 °C [68–70]. Therefore, their application in nanotechnology at surfaces are limited.

We want to describe one very promising application of a porin from a Gram-negative organism in more detail here, because of its prospects for future developments: Nanoreactors based on polymerized ABA-triblock copolymer vesicles have been successfully designed [71]. They

consisted of stable nanocapsules from an ambiphilic poly(2-methyloxazoline)-block-poly(dimethylsiloxane)-block-poly(2-methyloxazoline) triblock copolymer (PMOXA-PDMS-PMOXA) [72]. In perfect structural analogy to the S-layer proteins, these artificial block copolymers consist of separated hydrophilic and hydrophobic polymer segments.

Therefore, the PMOXA-PDMA-PMOXA-triblock copolymer aggregates spontaneously in dilute solutions into vesicular structures. Depending on the experimental conditions, the size of the polymer-triblock vesicles can be controlled in the range from 50–500 nm [73]. Again, in a further analogy of the S-layer lattices, the resulting nanocapsules can be further stabilized by subsequent crosslinking polymerization of the reactive end groups. The result is a "supermacromolecule," in which all the individual block copolymers are connected by covalent bonds. The polymer triblock vesicles were used to encapsulate a model enzyme β-lactamase in its interior [74]. To create a nanoreactor, the very thick triblock copolymer shell ($d = 10$ nm) has to be overcome in order to feed the enzyme with a suitable substrate. However, owing to their higher hydrophobic thickness, the triblock copolymer shells are even less permeable than conventional phospholipid bilayers. This situation is a typical case where the application of a suitable channel porin is requested, because the PMOXA-PDMA-PMOXA triblock copolymer behaves in aqueous buffer solutions principally like a higher molecular weight analogue of conventional lipids. However, the block copolymer membranes are approximately twice as thick as conventional bilayers.

The bacterial porin OmpF forms trimeric channels in the outer membrane of *E. coli* [75] and was chosen to provide a pathway through the block copolymer membrane. The high flexibility and the conformational freedom of the triblock-copolymer membrane permits its adaptation to the specific requirements of the bacterial porin [76]. If the OmpF porin can retain its specific geometric and dynamic conditions, it will retain its "natural" functions. After the spontaneous reconstitution of OmpF in the triblock copolymer shells, the encapsulated enzyme β-lactamase was successfully "fed" using the antibiotic ampillicin as model substrate, resulting in the "production" of ampicillinoic acid (Fig. 8). The latter, in contrast to ampillicin, is able to reduce iodine to iodide. This offers the opportunity to observe the reaction progress monitoring the Vis-absorption of the iodine/starch-complex. A high activity of β-lactamase was retained within the nanoreactors, which represent a perfect model for the nanoreactor technology of the future. Upscaling of a nanoreactor system is easily possible because of the very favorable diffusion conditions in the nanoscopic scale.

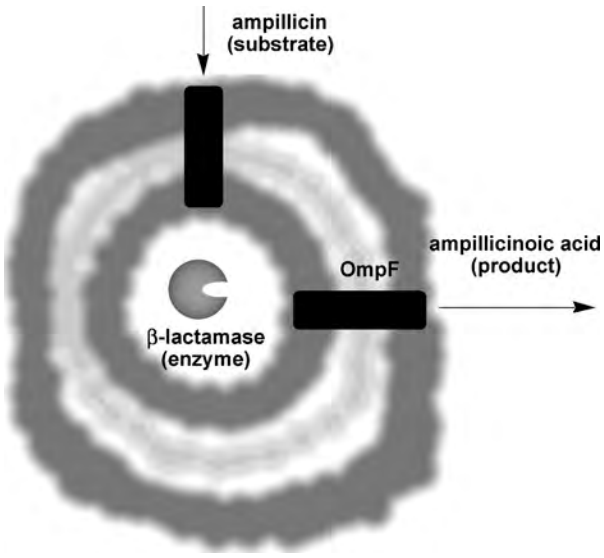

Figure 8. Scheme of a nanoreactor consisting of the crosslinked PMOXA-PDMA-PMOXA triblock copolymer, the bacterial porin OmpF, and the encapsulated enzyme β-lactamase [74].

4. THE PORIN MspA FROM *MYCOBACTERIUM SMEGMATIS*

4.1. The Mycobacterial Cell Envelope

The mycobacterial cell envelope forms an exceptionally strong permeability barrier rendering mycobacteria naturally resistant to a wide variety of antimicrobial agents. This is due to its unique structure [77]. The arrangement of the various layers of the mycobacterial cell wall is shown schematically in Figure 9. The innermost layer of the envelope is the cytoplasmic membrane of about 4 nm thickness. Outside this membrane is the so-called "cell wall skeleton," a giant macromolecule entirely surrounding the bacterial cell,

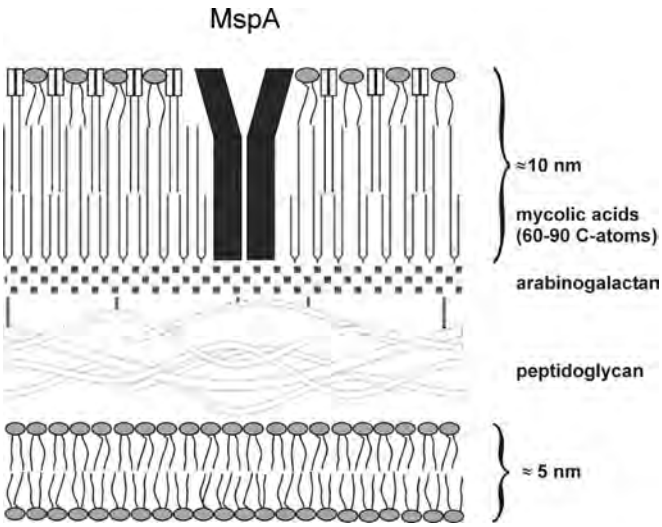

Figure 9. Structure of the mycobacterial cell envelope The inner leaflet of the outer membrane is composed of very long-chain fatty acids, the mycolic acids, which are covalently linked to the arabinogalactan-peptidoglycan copolymer The mycolic acids differ in length and modifications. The outer leaflet is formed by a great variety of extractable lipids such as trehalose-dimycolate ("cord factor"), lipooligosaccharides, sulfolipids, glycopeptidolipids, phenolic glycolipids and glycerophospholipids. It should be noted that bilayer formation of mycolic acids is only possible, when the cross-linked glycan strands and the arabinogalactan strands run in a direction perpendicular to the cytoplasmic membrane. The inner membrane is mainly is mainly composed of convential phospholipids. The thicknesses of the inner and outer membrances are derived from electron microscopic images of mycobacterial cell envelopes and are drawn to scale.

and consisting of peptidoglycan (a structure of oligosaccharides formed from disaccharide units of N-acetylglucosamine and N-glycolylmuramic acid crosslinked by short peptides), arabinogalactan (a complex branched polysaccharide), and mycolic acids (long-chain, 2-alkyl-3-hydroxy fatty acids). Associated with the cell-wall skeleton, but not covalently attached to it, are a large variety of other lipids. Substantial evidence for the organization of the mycolic acids in a second lipid bilayer in addition to the cytoplasma membrane was presented by Nikaido et al. [78]. X-ray diffraction measurements on purified mycobacterial envelopes, free of plasma membranes (<2% contamination or less), discovered a strong reflection at 4.2 Å and a weaker and more diffuse one at 4.5 Å. Such reflections are distinctive of ordered fatty acyl chains, and were interpreted as indicating the presence of highly ordered and less ordered regions, respectively. Measurements on a partly oriented sample of walls obtained by centrifuging onto a flat surface showed that the acyl chains were aligned perpendicular to the plane of the wall. By studying purified walls (walls with most of their associated lipids removed with the detergent Triton X-114 and whole cells) it has been clearly shown that the nature of the mycolic acids is the main determinant of the high-temperature phase change. Chain length is one important factor, since corynebacteria, whose mycolic acids are much shorter than those of mycobacteria, have a lower temperature phase change. Also important seems to be the configuration of the double bond or cyclopropyl group proximal to the carboxyl group of the mycolate, since a higher temperature phase change correlates with a higher proportion of *trans* configuration. It was shown for some environmental mycobacteria that they can adjust the composition of their mycolates according to temperature, presumably to achieve the required behavior of their outer permeability barrier. So *M. smegmatis* became less permeable to two lipophilic drugs when grown at higher temperatures [79, 80].

Measurements by continuous wave electron paramagnetic resonance (CW-EPR) of lipophilic probes (spin-labeled fatty acids) "dissolved" in purified cell walls or whole bacteria showed that these entered only a less ordered and more fluid region. This second region may either be interpreted as the alkyl chains of associated lipids that intercalate into that part of the mycolate monolayer where only the longer of the two alkyl chains of each mycolate is present or as the region occupied by the alkyl chains of the associated lipids forming the other (outer) half of a bilayer. The measured mobility varied with depth of insertion of the spin label into the layer (determined by the position of carbon atom in the fatty acids that was substituted with the spin label of the nitroxide type). This effect had already been observed with conventional bilayers, but the change of mobility with depth was different in the case of mycobacterial walls, underlining the unusual nature of the mycobacterial outer permeability barrier. Electron paramagnetic resonance spectra obtained with whole cells were similar to those obtained with highly purified walls, confirming that the nitroxide-labeled fatty acids entered only the outer part of the barrier [81, 82].

Detailed knowledge of the structure of the arabinogalactan of the mycobacterial envelope made it clear how a mycolate monolayer can be formed even though the mycolate residues are covalently attached to the polysaccharide. The mycolates occur as esters of terminal arabinose units on the polysaccharide, four mycolates attached to five arabinoses. The arabinosyl mycolate units are chemically bound to arabinan side chains, which are attached in turn to a galactan backbone, quite close to its attachment to the peptidoglycan. The whole polysaccharide is composed of sugars in their furanose form, which confers additional flexibility on the chain and so presumably allows the structure to accommodate itself to the close packing of the mycolate units [78, 81].

All these observations support the view of a mycobacterial outer permeability barrier as an asymmetric bilayer, with an inner leaflet of closely packed, essentially "frozen" mycolate residues and an outer leaflet of more mobile lipids. This outer membrane has unique properties: (i) it has a very low fluidity and does not melt up to 70 °C in contrast to cytoplasmic membranes of other mesophilic organisms, which begin to melt at 20 °C [82]; (ii) it is about 10 nm thick, exceeding the thickness of all other known membranes by about 2.5-fold [83]; (iii) it provides a very hydrophobic cell surface, which causes the bacteria to clump in an hydrophilic environment; and (iv) its fluidity decreases toward the periplasmatic side of the membrane in contrast to that of the outer membrane of Gram-negative bacteria [81].

4.2. MspA from *M. smegmatis* is the Prototype of a New Family of Bacterial Porins

Hydrophilic molecules enter the mycobacteria by diffusing through channel-forming proteins—the porins [82, 83]. MspA was recently identified as the first porin from *M. smegmatis* [36]. An MspA deletion mutant demonstrated that it provides the main hydrophilic pathway through the cell wall of *M. smegmatis* [84]. Electron microscopy and crosslinking experiments revealed that MspA is a tetrameric protein forming a central pore of 10 nm in length [37] (Fig. 10).

This is drastically different from the trimeric porins of Gram-negative bacteria, which have three pores per molecule and are 4 nm long [26]. These properties classify MspA as the prototype of a new family of pore proteins, since three other porins MspB, MspC, and MspD were identified in *M. smegmatis*, which differ only by a few amino acids from MspA [85].

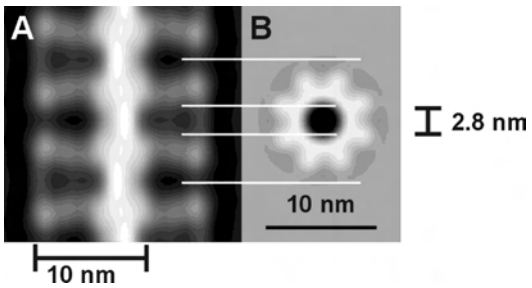

Figure 10. Structure of MspA by electron microscopy, resulting from single-molecule analysis: A. side view of an MspA aggregate; B. top view of an MspA pore. For the original images, see [37].

4.3. The Advantages of MspA in Nanotechnology Compared to Other Proteins

Proteins are macromolecules with dimensions in the nanometer range and can be tailored to specific needs by site-directed mutagenesis. However, their use in nanotechnology is severely hampered because most proteins lose their structural integrity in a nonnative environment and, therefore, cannot be used in technical processes. The MspA porin from *M. smegmatis* is an extremely stable protein, which retains its channel structure even after boiling in 3% SDS or extraction with organic solvents [32]. This should considerably stabilize nanoparticles synthesized inside the channel. The same argument holds true for specific sensor functions inside the MspA channel. Longer template channels also allow the synthesis of longer nanowires extending their application potential. The hydrophobic surface of MspA allows its assembly into biomimetic membranes. Thus, MspA is the most stable channel-forming protein known thus far. Furthermore, MspA has an astonishing tendency to self-assemble into ordered structures on surfaces [37]. This permits the synthesis of nanoarray lattices as well as nanoparticles- and rods in a statistic distribution, embedded by a suitable hydrophobic surface.

Furthermore, MspA is the only mycobacterial porin that can be purified in milligram quantities. It is selectively extracted by boiling entire cells of *M. smegmatis* for 30 min in a buffer containing detergents and purified by chromatography to apparent homogeneity [86] (see Fig. 11).

4.4. Nanostructuring by Deposition of the MspA Porin on HOPG Surfaces

The generation of well-defined nanostructures by protein or macromolecule deposition on two-dimensional surfaces (area up to 1.0×10^{-4} m^2) represents a considerable advantage compared to state-of-the-art technologies. However, most conventional proteins lose their structural integrity in a nonnative environment and, therefore, cannot be used in technical processes. Due to the extreme stability of MspA, it can be used in the following simple and straightforward procedure for the nanopatterning of extended surface areas: MspA, dissolved in a buffer solution can be dispersed into droplets employing a simple sonication procedure. The formed droplets are allowed to reach a HOPG surface. Depending on the exact deposition conditions (temperature, MspA concentration, sonication duration and intensity, and the length of the curing procedure after deposition), various nanostructures were obtained at HOPG. Therefore, these experimental results offer a simple and straightforward approach to the nano-structuring of surfaces by the deposition of protein containing buffer droplets. At deposition and curing temperature of 30 °C, the generation of regular nanostructures, which feature nanochannels, was proven unambiguously by electron microscopy in combination with computer-assisted image analysis [39]. The formation of these highly desired nanochannels within the deposited layer proceeded most likely by the reconstitution of biologically active MspA-nanopores ($M \approx 80{,}000$ Da) within the codeposited MspA protein layer, which was formed by interaction of MspA monomers ($M \approx 20{,}000$ Da) [87].

Three different kinds of layer structures were created by depositing protein/buffer droplets on HOPG surfaces and independently analyzed by REM and TEM. The results are summarized and compared with each other in Figure 12. It becomes immediately clear that the temperature during this deposition of droplets and during the curing process (the surface was allowed to (nano)structure for at least 1 h of the chosen temperature) after deposition of protein/buffer mixtures determined the formed nanostructures at HOPG.

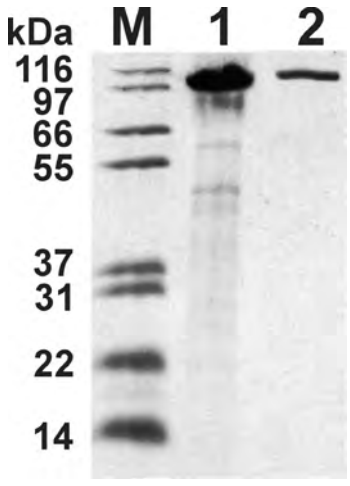

Figure 11. Protein samples were separated on a denaturing 10% polyacrylamide gel. Lanes: (M) molecular mass marker (200, 116.3, 97.4, 66.3, 55.4, 36.5, 31, 21.5, 14.4, 6 kDa); (1) 4 μg protein from MspA-containing fractions pooled after anion exchange chromatography. (2) 0.7 μg protein from MspA-containing fractions pooled after gel filtration chromatography. The proteins were stained with Commassie Blue.

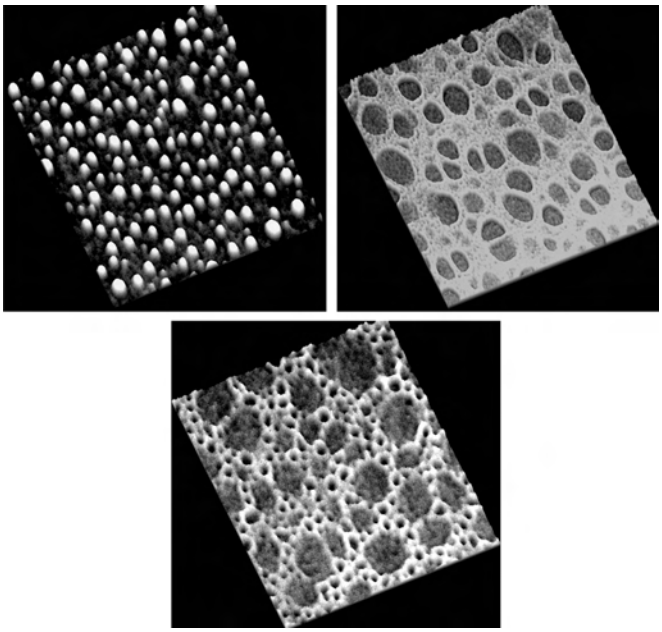

Figure 12. Three types of layer structures created by depositing protein/buffer droplets onto HOPG surfaces (surface plots created by IMAGE; further explanations are provided in the text.). The extension of each image is 110 nm × 110 nm.

After depositing MspA and curing at $T = 20$ °C, only isolated proteins and no channel structures were observed (Fig. 12, left image). The main diameter of the units in these images is 2.15 ± 0.40 nm. Deposition of the denatured MspA monomer resulted in similar structures (main diameter 2.14 ± 0.70 nm) indicating that MspA deposited mainly in the form of its monomer ($M = 20{,}000$ Da). Note that the denatured MspA monomer did not form any channels. This is in agreement with earlier findings, which demonstrated that the MspA-porin loses its ability to form nanochannels once it becomes the MspA monomer.

The raising of the deposition and the curing temperature to $T = 25$ °C, yielded in the formation of a supramolecular structure formed by MspA on the HOPG surface (Fig. 12, center image). The thickness of the protein layer was 4.5 ± 0.25 nm. Only indentations of the diameter of 9.2 ± 2.1 nm are found within the investigated structure. The residual thickness of the protein layer at the bottom of these dead-end channels was 1.4 ± 0.30 nm. This analysis revealed that no open channels were present in this supramolecular structure.

The dimensions of the MspA pore were determined by electron microscopy of negatively stained cell wall preparations of *M. smegmatis* and of purified MspA. The MspA pore has an inner and outer diameter of 2.5 and 10 nm, respectively, and a length of about 10 nm. Considering these dimensions of MspA, two interpretations of the supramolecular structure are possible: (i) The MspA pore might be intact, but is either completely perpendicular with respect to the HOPG surface or it is formed in an angle, which does not permit detection. (ii) The observed indentations might be formed by larger aggregates of interacting MspA monomers. Note that the TEM technique does not permit the elucidation of the exact structure of the filled bottom of these indentations. Only the integrated thickness of the carbon containing protein structure can be estimated.

After increasing the deposition and the curing temperature to $T = 30$ °C, real nanochannels possessing a regular diameter of 2.6 ± 0.50 nm are detectable as indicated by the appearance of the uncovered HOPG surface in the center region of the nanochannels (Fig. 12, right image). Considering the nonnative environment, the diameter of these channels is in excellent agreement with structure of MspA, demonstrating that the channel protein did not denature during the deposition procedure at $T = 30$ °C. It should be noted in this regard that the Tet repressor protein (TetR), which is a water-soluble DNA-binding protein and does not form channels [85], could not be deposited on a carbon surface using the sonication-deposition procedure described here. During sonication, a complete disruption of TetR was observed indicating that this nanostructuring method can only be applied to stable proteins. In Figure 13, a surface plot of the highly structured MspA layer on HOPG is shown using high-resolution TEM files as input. Geometric features down to a size of less than 2 nm are clearly discernible. MspA formed a layer of an average thickness of 5.8 ± 0.25 nm, which was attached to HOPG by means of hydrophobic interaction. Real nanochannels were formed by reconstitution of further MspA-monomers into this layer. Note that dead-end channels of a diameter of 7.2 ± 1.25 nm

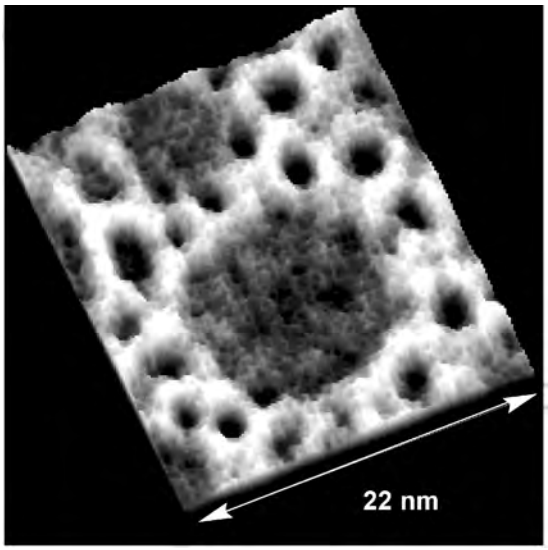

Figure 13. IMAGE surface plot a highly structured MspA layer on HOPG using high-resolution TEM as input.

were also detected within this highly complex layer structure. At the bottom of these indentations, the thickness of the MspA layer was reduced to 1.0 ± 0.2 nm.

In Figure 13, the TEM resolution is zoomed to its maximum limit. It can be clearly seen that the MspA nanochannels are open towards the HOPG surface at their lower ends. This permits an electrical contact between the interior of the porin channels, which are hydrophilic in nature, and the HOPG electrode. Due to the hydrophobic properties of the deposited MspA layer on HOPG, the protein structure proved to be stable for 24 h when immersed into H_2O.

The superposition of 50 nanopores is shown in Figure 14. A typical MspA pore featured a diameter of 3.1 ± 0.2 nm and a length of 9.5 ± 0.4 nm. The wall region surrounding the typical pore had an extension of 3.2 ± 0.4 nm. Whereas the average depth of the MspA layer was measured to be 5.8 ± 0.25 nm, the thickness of the wall region in close proximity to the MspA nanopores extended to 9.5 ± 1.0 nm.

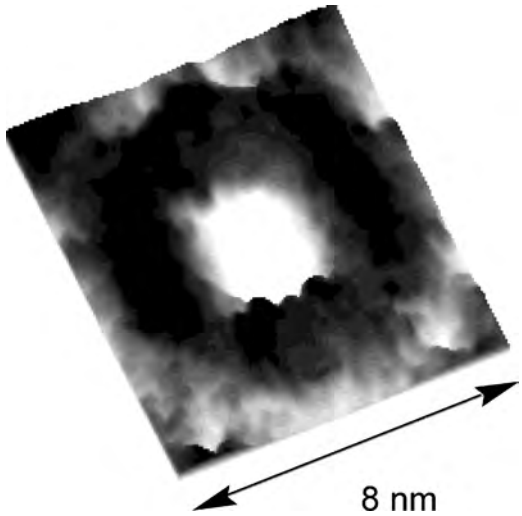

Figure 14. A typical MspA pore.

A more quantitative insight into the statistical size distribution of the nanochannels generated on HOPG was again provided by a detailed IMAGE analysis: For the calculation of Figure 15, the information from 10 different deposition experiments at $T = 30$ °C, was analyzed. As it is summarized in Figure 15, the statistic distribution of pore diameters deviates approximately by ± 0.50 nm from the mean value of 2.6 nm.

The generation of these highly ordered MspA nanostructures proceeded in a completely reproducible manner. In order to understand the remarkable process of MspA nanostructuring at hydrophobic surfaces, a look at the natural environment of this channel-forming protein might offer some additional information. The exceptionally thick (approximately 10 nm) and strongly hydrophobic membrane of *M. smegmatis* is the natural environment in which MspA nanochannels form. Based on the insight in the mycobacterial cell wall structure, the following interpretation of the observed channel-forming activity of MspA under technical conditions can be attempted: The biologically active form of the MspA is known to form nanochannels of a mass of approximately 80,000 Da. At $T = 20$ °C, the MspA monomer prevails at the HOPG surface indicating that no nanochannels survived the sonication procedure. The biologically inactive porin monomers, which are formed to various extents during the sonication process, possess hydrophobic as well as hydrophilic structure elements. Their amphiphilic nature permits various types of supramolecular interaction among originally identical protein monomers of the mass of 20,000 Da, as experienced by the formation of very different phases or layer structures, depending on the deposition and curing temperature.

At $T = 25$ °C, the MspA forms a highly complicated nanostructured layer at HOPG. It is still uncertain whether a fraction of the MspA nanochannels, which were present before sonication, are codeposited and therefore become a building element of this nanostructured layer. At $T = 30$ °C, a considerable fraction of the MspA nanochannels "survives" the sonication process most likely as a result from stronger hydrophobic interaction among the MspA subunits compared to lower temperatures. Presumably, the MspA oligomers reach the HOPG surface as nanochannels of an average diameter of 2.6 ± 0.50 nm and reconstitute in the supramolecular protein layer of codeposited MspA monomers at positions with the highest hydrophobicity. This hypothesis would explain the observation of enhanced thickness in the direct proximity of the MspA channel openings, because individual MspA pores reconstitute within an MspA protein layer of a different structure. Our future investigations will be aimed at a more detailed comprehension of the MspA deposition and channel-forming mechanisms in our biomimetic systems of high technical interest.

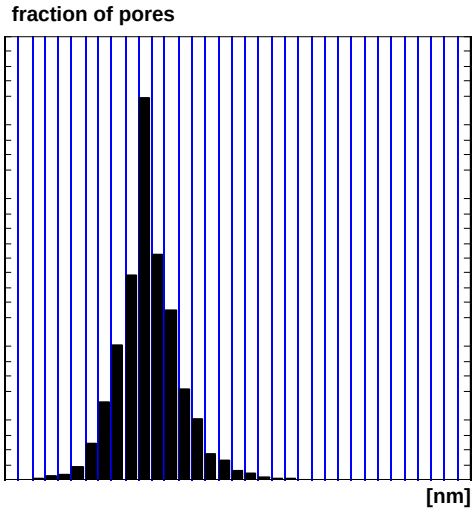

Figure 15. Quantitative analysis of the pore sizes formed by MspA on HOPG using IMAGE.

4.5. Nanostructuring of Carbon Surfaces By Deposition of a Channel-Forming Protein and Subsequent Polymerization of Methyl-Methacrylate-Prepolymers

As was previously pointed out, the MspA protein demonstrated its striking ability to form a wide range of nanostructures, including a nanochannel containing phase at a carbon surface (HOPG). However, the nanostructured MspA phases redissolved after several days in various aqueous buffers. This effect clearly hampers any electrochemical application using aqueous buffers, for instance, as a nanotechnological building kit for sensing applications. Therefore, we attempted to stabilize formed nanochannels using the hydrophobic homopolymer P(MMA). It could be expected that the phases formed using MspA and P(MMA) differ to various extents from the phases where MspA was used alone. Since very little is currently known about the prospect of self-structuring protein/polymer phases, the results are of great interest with respect to the generation of distinct shapes in the submicro and nanoscale. The experimental approach, as well as the IMAGE analysis procedures were very similar with respect to the studies on MspA on HOPG.

In Figure 16, the effect of the presence of MspA during the buffer deposition from the gas phase onto a carbon surface becomes clear. Without the presence of MspA, only disordered structures of P(MMA) (pre)polymers can be found, whereas distinct and reproducible (nano)structures

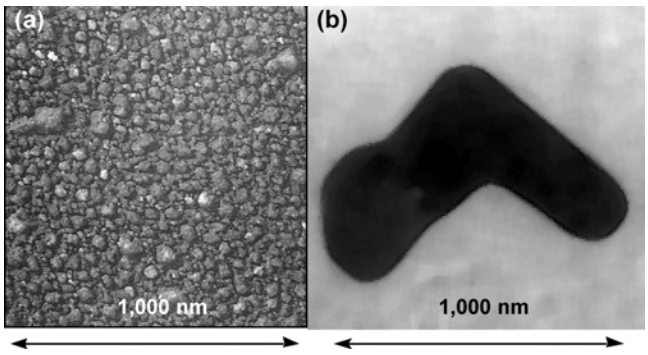

Figure 16. Effect of the deposition of P(MMA)/buffer (c = 2.25 μg/mL) (a) in comparison to MspA/P(MMA)/buffer (c(MspA) = 1.00 μg/mL, (c(PMMA/MMA) = 1.25 μg/mL)); (b) at carbon surfaces (TEM image).

are formed, if MspA is present. This finding provides the first evidence for the importance of MspA for the generation of ordered structures at surfaces.

In order to reach the goal of generating defined (nano)structures at a carbon surface, the general deposition procedure of a MspA/P(MMA) buffer was systematically varied to explore its possibilities [39]. Note that this procedure using buffer sonication and the following deposition of microdroplets at the carbon surface differs from a conventional adsorption procedure, because no equilibrium between MspA/P(MMA) and the surfaces exists. Therefore, the exposition time of the surface toward the MspA/P(MMA) buffer is the decisive factor for the amount of MspA/P(MMA) deposited. Again, the deposition and curing temperature proved to be the most decisive factor. And again, *remarkable and reproducible nanopatterns* at HOPG were discovered.

4.6. Formation of Microletters

When a depositon time of 125 ± 5 s and a deposition temperature of 30 ± 2 °C is chosen, the formation of "microletters" is observed. Typical "letters" are shown in Figure 17. This particular occurrence (thickness > 100 nm) is typical for a deposited pattern that was only investigated by TEM for a short time (less than 60 s).

4.7. Formation of Dendrites and Stars

In Figure 18, dendrites and "stars" generated by deposition of MspA for 175 ± 5 s at 40 ± 5 °C at the chosen carbon surface are shown. The comparison of the occurrence of this micropattern at very low TEM exposition times ($t < 60$ s) and after 300 s of electron beam treatment reveals polymerization of MMA included in the formed micropattern. The average thickness of the formed dendrites and stars was approximately 110 to 120 nm in the beginning of the TEM characterization, whereas the thickness decreased to 25–30 nm after 300 s of continuous electron beam exposure. In addition to the observed polymerization process, evaporation of water and MMA molecules into the high vacuum can be detected. Consequently, the diameter of the TEM beam of approximately 3000 nm can be seen in Figure 18 (300 s). However, this behavior is typical for all micropatterns investigated in this study. In all cases, the geometries initially formed during MspA deposition are retained during the electron beam treatment. This finding makes this simple deposition process of particular interest for the lateral nanostructuring of surfaces.

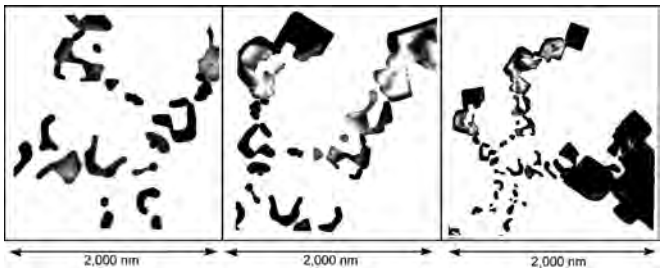

Figure 17. Microletters formed by deposition of MspA/P(MMA)/buffer at the carbon surfaces (TEM image, three different deposition experiments).

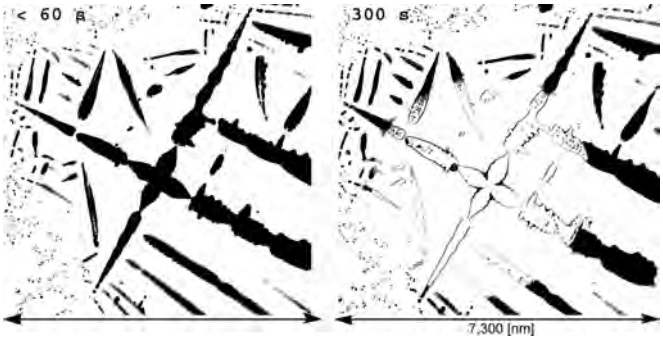

Figure 18. Dendrites and stars formed by deposition of MspA/P(MMA)/buffer at the carbon surface (TEM image) after<60 s and 300 s exposure to the electron beam.

4.8. Electron Beam-Induced Polymerization of MMA in Microletters and Quantitative Analysis of the Micropattern by Using IMAGE

Figure 19 presents a series of images of a microletter, which was continuously treated by the TEM electron beam. Whereas the letter appears to be relatively homogeneous

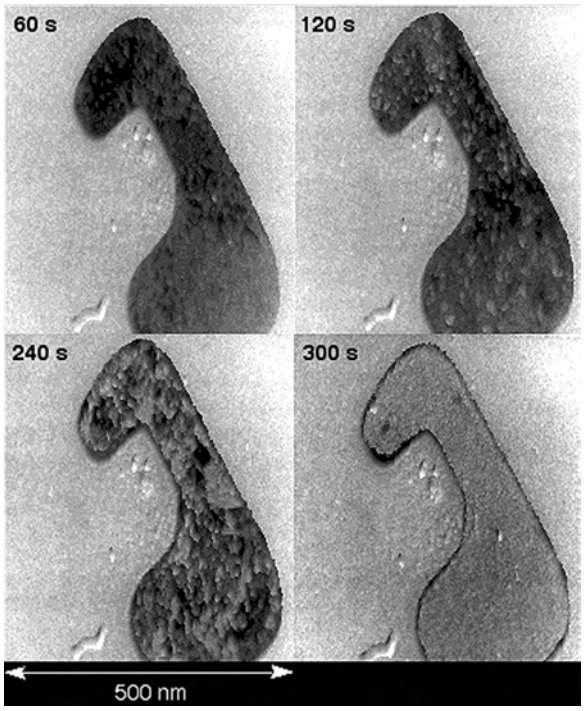

Figure 19. Surface plots of a typical microletter formed by deposition of MspA/P(MMA)/buffer at the carbon surface, calculated by IMAGE using the TEM images as input.

at the beginning of the electron beam fixation process, a patchwork of black and gray spots is present after 120 s and 240 s. However, after 300 s the interior of the microletter becomes homogeneously gray, whereas a sharp edge remains, which represents the exact geometric shape of the letter immediately after its deposition on the carbon surface. The analysis of the TEM images, using the program package IMAGE employing the calibration parameters obtained by the deposition, reveals striking insights into this fixation process. In the beginning of the electron beam exposure, the inner region of the microletter structure is smooth and possesses a thickness of 100–120 nm. In the course of the progressing reaction, holes with a diameter of 2–5 nm appear randomly distributed throughout the whole interior of the microletters. On the bottom of these holes exists an organic layer of a thickness of approximately 25 nm. In conclusion, the depth of the formed holes is approximately 75–95 nm. These hole regions grow consequently until most of the interior consists of an organic layer of 20–25 nm thickness. The surface of this layer structure is obviously rough.

A strong possibility exists that channel-like structures possessing a diameter of approximately 1–2 nm are randomly oriented within this layer. From our IMAGE analysis, it appears that holes, cavities, and/or channels exist at particular locations, where organic material is missing. However, using TEM, we could not elucidate whether channels exist, which are open to the surface of the microstructure. According to the IMAGE calibration procedure, the mass deposited in the interior of the microletters is approximately 2.7×10^{-9} g/cm^2.

In contrast to the interior of the microletters, their border regions form a wall-type structure, which is not affected by the continuous electron beam exposure. The diameter of these walls is approximately 65 nm at the bottom. The deposited mass at the wall regions is considerably higher (2.1×10^{-8} g/cm^2) than in the interior. After 300 s, only minor changes occurred in the fixed microletters at the carbon surface.

The wall regions that form the microstructure's boundaries might be formed from MspA and PMMA, which form hydrophobic aggregates. The chemical composition of these aggregates differs depending on the deposition conditions, such as MspA and PMMA—concentrations and temperature. Neither the deposition of MspA nor PMMA prepolymers alone at the reported experimental conditions resulted in the formation of the microstructures reported here. Since PMMA is highly polydispers ($P_d = 5.2$), it cannot be responsible for the patterning process. Therefore, it is very likely that both MspA and PMMA are the main building components of the wall-type structures: hydrophobic aggregates of MspA and PMMA develop during the deposition of the MspA/P(MMA) buffer microdroplets on the carbon surface. The hydrophobicity of the carbon surface itself may support the formation of these hydrophobic aggregates. Within the formed microstructures, hydrophilic cavities containing mostly MspA in aqueous buffer and a hydrophobic microphase consisting mostly of MMA and polymerization initiator coexist. Perkovic and McConnell succeeded in the mathematical modeling of complex two-dimensional patterns in mixed surfactant bilayers, and also in protein layers, by using a line tension—dipole repulsions model [88]. The observed equilibrium shape of a constant area monolayer was explained from the competition between the line tension of the domain boundary and the dipole-dipole repulsions between the molecular dipoles. Unfortunately, our much more complex and three-dimensional nanostructures cannot be explained as of yet by applying this model. However, we envision the mechanisms that lead to the formation of the distinct pattern during deposition to be very similar to those developed by McConnell in the two-dimensional phase.

Upon electron beam exposure and consequent heating of the microstructures, water as well as some of the MMA monomer evaporates in the high vacuum. The electron beam impact, as well as the increased temperature caused by TEM, leads to either anionic or radical MMA polymerization [89]. The gel effect is well known during MMA polymerization—at enhanced temperature the reaction rate of PMMA formation increases rapidly until a gel is formed from PMMA and the nonreacted MMA. The formation of the gel results in a drastic *decrease* of the polymer volume.

Both the occurrence of the gel effect and the evaporation of H_2O or MMA at the same time may explain the appearance of "holes" during electron beam impact. This process continues until neither H_2O nor MMA remains in the interior of the microstructures. Upon further observation, it was evident that the wall regions do not exhibit the "shrinking effect" during electron beam impact; therefore, we can conclude that only very little "free" H_2O and/or MMA is present in these regions after deposition.

5. CONCLUSION

S-layer proteins and the channel porins from Gram-positive bacteria represent two complementary approaches to new materials, processes, and device architectures for information recording and systems. This approach consists of the formation of protein-based layers (S-layer lattices or hydrophobic (bi)layers, in which MspA reconstitutes) on semiconducting and conducting surfaces. Other surface types, such as liposomes, vesicles, or bacterial membranes will be used in future applications, which can be regarded as spin-offs of the nanotechnology endeavor. Whereas the enormous potential of the S-layer proteins is known to an increasing scientific audience, the channel porin from *Mycobacterium smegmatis* (MspA), which represents a strong challenge to carbon nanotubes as host material for nanodots and nanowires, will be increasingly employed as a nanotechnological building kit.

GLOSSARY

Absorption Movement of ions and water into as organism as a result of metabolic processes, frequently against an electrochemical potential gradient (active) or as a result of diffusion along an activity gradient (passive).

N-acetylglucosamine and N-acetylmuramic acid Sugar derivatives in the peptidoglycan layer of bacterial cell walls.

Adsorption Process by which atoms, molecules, or ions are taken up and retained on the surfaces of solids by chemical or physical binding.

Aliphatic Organic compound in which the main carbon structure is a straight chain.

Amino group An -NH_2 group attached to a carbon skeleton as in the amines and amino acids.

Archaea Evolutionarily distinct group (domain) of prokaryotes consisting of the methanogens, most extreme halophiles and hyperthermophiles, and thermoplasma.

Archaebacteria Older term for the Archaea.

Aromatic Organic compounds which contain a benzene ring, or a ring with similar chemical characteristics.

Bacillus Bacterium with an elongated, rod shape.

Bacteria All prokaryotes that are not members of the domain Archaea.

Biosensor A device designed to detect a specific biological molecule, system of biological molecules, or biologically produced signal.

Biotechnology Use of living organisms to carry out defined physiochemical processes having industrial or other practical application.

Cell Fundamental unit of living matter.

Cell membrane See cytoplasmic membrane.

Cell wall Layer or structure that lies outside the cytoplasmic membrane; it supports and protects the membrane and gives the cell shape.

Covalent Nonionic chemical bond formed by a sharing of electrons between two atoms.

Cyanobacterium Prokaryotic, oxygenic phototrophic bacterium containing chlorophyll a and phycobilins, formerly the "blue-green algae."

Cytoplasm Cellular contents inside the cell membrane, excluding the nucleus.

Cytoplasmic membrane Selectively permeable membrane surrounding the cell's cytoplasm.

Deoxyribonucleic acid (DNA) A naturally occurring polymer composed of deoxyribonucleotides. Although commonly found as a double-stranded, right-handed helix it can adopt one-, three-, and four-stranded forms having a variety.

Electrophoresis Separation of charged molecules, such as nucleic acids, in an electrical field.

Eubacteria Old term for the bacteria.

Eukarya Phylogenetic Domain containing all eukaryotic organisms.

Fluorescent Able to emit light of a certain wavelength when activated by light of a shorter wavelength.

Fluorescent antibody Antiserum conjugated with a fluorescent dye, such as fluorescein or rhodamine.

Gel Inert polymer, usually made of agarose or polyacrylamide, that separates macromolecules such as nucleic acids or proteins during electrophoresis.

Gram stain Differential stain that divides bacteria into two groups, Gram-positive and Gram-negative, based on the ability to retain crystal violet when decolorized with an organic solvent such as ethanol. The cell wall of Gram-positive bacteria consists chiefly of peptidoglycan and lacks the outer membrane of Gram-negative cells.

Hydrogen bond A weak polar bond formed between two electron-rich atoms, one of which is covalently bonded to a hydrogen atom.

Immobilization Conversion of an element from the inorganic to the organic form in microbial or plant biomass.

Immunofluorescence Technique to visualize specific antibodies and any attached homologous antigens by means of conjugating the antibodies to a fluorescent dye.

Ions Atoms, groups of atoms, or compounds, that are electrically charged as a result of the loss of electrons (cations) or the gain of electrons (anions).

Luminescence Generation of light.

Macromolecule Large molecule formed from the connection of a number of small molecules.

Microbiology Study of microorganisms.

Molecule Result of two or more atoms combining by chemical bonding.

Molecular modeling A computer-aided design process in which computational chemistry software programs are used to create models of macromolecules based on electronic structure, and molecular mechanics calculations coupled with 3D experimental data.

Mutant Organism, population, gene, or chromosome that differs from the corresponding wild type by one or more base pairs.

Mutation A change in the information storage mechanism of an evolving system that alters the information it contains but may or not alter the form or function of the system.

Nanopore Pore having dimensions measured in nanometers.

Peptidoglycan Rigid layer of cell walls of bacteria, a thin sheet composed of N-acetylglucosamine, N-acetylmuramic acid, and a few amino acids. Also called murein.

pH Negative logarithm of the hydrogen ion activity. The degree of acidity (or alkalinity) of a soil as determined by means of a glass or other suitable electrode or indicator at a specified moisture content or soil-water ratio, and expressed in terms of the pH scale.

Polar Possessing hydrophilic characteristics and generally water soluble.

Porin A protein which forms at least one channel in a bacterial membrane.

S-layer proteins Proteins at the outside of many bacterial membranes.

Nanotribology

T. Coffey, J. Krim

North Carolina State University, Raleigh, North Carolina, USA

CONTENTS

1. INTRODUCTION

Tribology (from the Greek word "tribos," which means "to rub") is the study of friction, lubrication, and wear, an inherently challenging field requiring much interdisciplinary cooperation. By most recent estimates, improved attention to tribology would save developed countries up to 1.6% of their gross national product, or over $100 billion annually in the United States alone [1]. The magnitude of the financial loss associated with friction and wear arises from the fact that entire mechanical systems, be they coffee makers or automobiles, are frequently scrapped when only a few of their parts are badly worn. In the case of an automobile, the cost of the energy consumed in its manufacture is equivalent to that required to operate it for 100,000 mi [2].

Macroscopic tribological behavior is known to be highly sensitive to the details of interfacial contact at the atomic scale. For example, it is well known that adsorption of molecularly thin coatings on contacting surfaces can reduce their macroscopic friction coefficients by orders of magnitude. Investigations of the origins of such macroscopic tribological behavior should ideally be performed at both atomic length scales (10^{-9} m) and time scales (10^{-12}–10^{-9} s). Such studies, however, have proven to be extremely challenging, as they are performed on buried interfaces that are extremely difficult to experimentally probe.

With the advent of new experimental techniques emerging in the 1980s, a new field involving friction studies at atomistic length and time scales, nanotribology, emerged. The increased interest in nanotribology sparked a variety of discussions and debates concerning the nature of the atomic-scale mechanisms that dominate the dissipative process by which mechanical energy is transformed into heat. Decades-old suggestions that friction could originate in sliding-induced excitation of atomic lattice vibrations (phonons, i.e., sound waves) were reexamined, and suggestions for electronic contributions (associated with electronic motion excited by the sliding process) to friction also emerged. The renewed interest in nanotribology is now beginning to impact mainstream macrotribological considerations [3, 4]. Meanwhile, the results are most relevant to applications such as solid–liquid interfaces, where the complicating factors associated with asperity contacts are less of an issue, and to the MEMS community [5], where machine components with astoundingly small dimensions are rapidly approaching the length scales routinely probed by the nanotribological community. In the wider arena of nanotechnology, energy dissipation and conversion issues are integral to successful device design, construction, and/or operation [6]. This is obviously true when considering device energy efficiency from a profitability point of view, but equally compelling is the fact that any heat released in an inefficient transport process is available to destroy device function: if any portion melts, the device itself is destroyed.

While advances in recent years have been significant, much work lies ahead. This chapter provides an introduction to some of the important topics and concepts in nanotribology, with a focus on friction at the atomic scale. Key experiments and discoveries are detailed, including the experimental techniques employed for studies of nanotribology, the fundamental origins of friction, phononic and electronic contributions to friction, static friction, frictional anisotropy, and the velocity dependence of friction at atomic length and time scales.

2. THE FUNDAMENTAL ORIGINS OF MACROSCOPIC FRICTION

When an object moves along a surface or through a viscous liquid or gas, the forces resisting its motion are referred to as friction. Frictional forces are nonconservative, converting the kinetic energy of materials in sliding contact to internal energy. Thus, if an object is given an initial velocity along a horizontal surface, the temperature of both the object and the surface upon which it slides will increase as the friction resisting its motion brings it to a stop. If an object is initially at rest, a minimum force must be applied to overcome "static friction," giving rise to the familiar phenomenon of an object "jumping ahead" at the instant that sliding is initiated. Static friction, in contrast to kinetic friction, is associated with neither energy "loss" nor sample heating. It is entirely absent for bodies moving through viscous fluids, "viscous friction" being parameterized at low velocities by

$$F \propto v \tag{1}$$

where v is the velocity of the object through the fluid.

For objects sliding along solid surfaces, friction is generally well described on the macroscopic scale by Amontons' law [7]:

$$F = \mu N \tag{2}$$

as reported in most introductory physics textbooks. The "normal load" N in Eq. (2) is the force that presses surfaces in sliding contact together, and μ is the "coefficient of friction." Amontons also reported that the friction force was independent of the apparent area of contact: a small block experiences as much friction as a large block of the same material as long as their weights are equal. A third law, attributed to the French physicist Charles Augustin Coulomb, is frequently included with those of Amontons: the friction force is independent of velocity for ordinary sliding speeds.

One common misconception about how friction originates is that it is always associated with interfacial roughness on some suitably magnified length scale. Surface roughness has, in fact, been ruled out for decades as a viable mechanism for everyday friction. Automobile makers, for example, routinely find that the friction between two surfaces is sometimes less if one of the surfaces is rougher than the other [8]. Furthermore, friction can increase if two surfaces are made smoother. In cold welding, for example, highly polished metals stick together firmly.

Interfacial roughness is, in fact, closely linked to Amontons' law in the sense that atomically flat surfaces in sliding contact are not described by it. The vast majority of surfaces are, of course, not atomically flat. When two such "rough" surfaces touch, contact between them takes place only at their asperities. The actual microscopic area of contact A_c is thus much less than the apparent area of contact A, perhaps by a factor of 10^4. When the surfaces are forced to slide over each other, new contact regions are continuously formed, while others are severed. If the true area of contact is constant on average, and the contacting junctions all have the same shear strength s, then the friction force is

$$F = A_c s \tag{3}$$

Equation (3) has been experimentally verified by a broad range of experimental geometries and a wide range of experimental techniques [9–13]. Enachescu et al. [13], for example, measured the friction force of a tungsten–carbide probe sliding on a boron-doped diamond surface. The friction force for this system was then compared to the local contact conductance, which revealed the true area of contact, and was observed to be linearly proportional to the true area of contact.

The relations $F = A_c s$ and $F = \mu N$ can be linked if one succeeds at establishing the dependence between the true contact area A_c and the normal load N. Many experiments have been performed with this goal in mind, but direct measures of true contact area are extremely difficult to achieve. Theoretical models of contact have therefore been routinely employed to aid in the interpretation of indirect experimental measures. By using contact mechanics models between two spheres, such as those derived by Johnson, Kendall, and Roberts (JKR) [14], Derjaguin, Muller, and Toporov (DMT) [15], and Hertz [16], it has been shown that $A_c \sim N^{2/3}$ for perfect elastic deformation and $A_c \sim N^1$ for plastic deformation. Experimental investigations of contacting spheres have found that, for N^n, n is closer to 2/3 for rubber, wood, plastic, and textiles, and n is closer to 1 for more brittle materials such as glass, diamond, and rock salt. And although only a limited number of materials exhibit $A_c \sim N^1$ for two spheres in contact, a far wider range of materials displays this dependence when multiasperity contact is considered [2]. Note that the true area of contact technically does not drop to zero for zero external load, as molecular adhesive forces are still present.

The dependence of friction on true contact area describes the macroscopic system's response to changes in load, but sheds little light on the physical origins of friction. This information is contained in the shear stress s, the frictional force per unit area of known contact. Bowden and Tabor's group explored this issue extensively, and were able to rule out the possibility that strong bonding at asperity contacts followed by wear was the physical mechanism underlying friction [17]. Indeed, Tabor and Israelachvili, working with an adapted version of the surface forces apparatus (SFA), were the first to provide conclusive experimental evidence that friction could occur in the *total absence* of wear [18, 19].

3. EXPERIMENTAL TECHNIQUES FOR STUDYING NANOTRIBOLOGY

There are three main experimental techniques for studying nanotribology. They are atomic force microscope or lateral force microscope (AFM or LFM), the surface forces apparatus (SFA), and the quartz crystal microbalance (QCM). These three techniques cover a wide range of length scales, time scales, and shear stress (see Fig. 1). LFM is characterized by atomic-scale length measurements, slow sliding speeds (on the order of 1 μm/s), or long time scales, and high shear stress (from 10^4 to 10^{10} N/m^2). SFA has comparatively long length and time scales and medium-range shear stresses (from 10^3 to 10^7 N/m^2). QCM has atomic length scales, short time scales (slip times on the order of nanoseconds), and low shear stress (from 10^{-2} to 10^2 N/m^2).

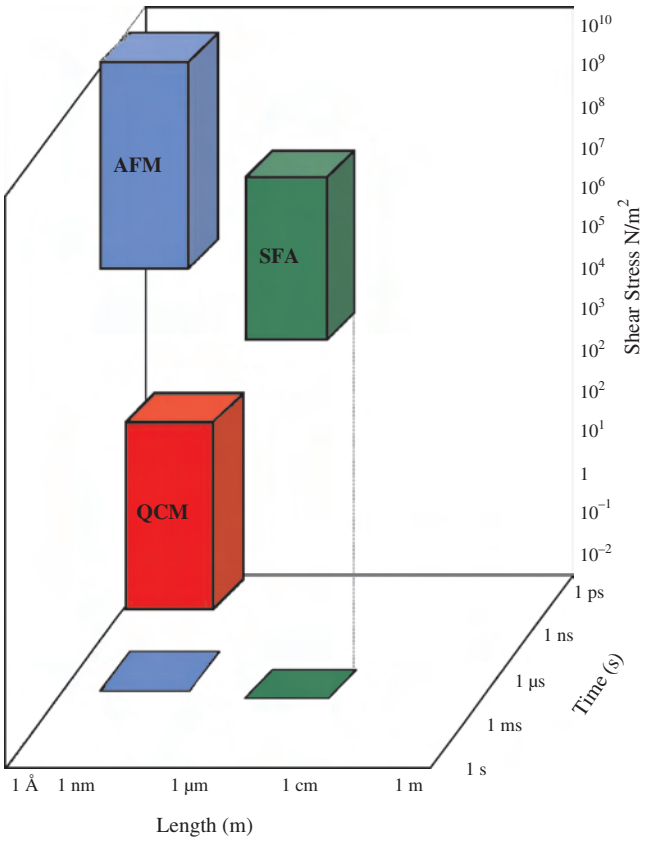

Figure 1. Length scales, time scales, and shear stresses of present-day nanotribological techniques.

The AFM was adapted for atomic-scale friction measurements in 1987 by Mate et al. [20]. An AFM typically consists of a sharp tip (usually several nanometers to hundreds of nanometers in radius at its apex) mounted at the end of a compliant cantilever beam. In LFM, the tip is held in contact with a sample while it is raster scanned across the sample's surface. The forces that act on the tip are determined by measuring the angular deflections of the cantilever. These forces both map out the sample surface and measure lateral forces. Several techniques can be used to detect the motion of the cantilever; however, the most common method is an optical deflection technique. Here, a laser beam is reflected off the back of the cantilever. The laser beam moves in response to the deflection of the cantilever, and the reflected beam's motion is detected by a four-quadrant position-sensitive photodiode. (See Fig. 2.)

The QCM has been used for decades for microweighing purposes, and was adapted for friction measurements in 1986–1988 by Widom and Krim [21–23]. A QCM consists of a single crystal of quartz that oscillates in transverse shear motion (resonance frequencies are typically at 5–10 MHz) with very little internal dissipation (see Fig. 3 [24]). The oscillations are driven by applying an alternating voltage to thin metal electrodes deposited on the surface of the quartz, the electrodes generally prepared so as to present (111) metal orientations at their surfaces. Atomically thin films later adsorbed onto the QCM electrodes produce shifts in both the frequency and the quality factor Q, which are

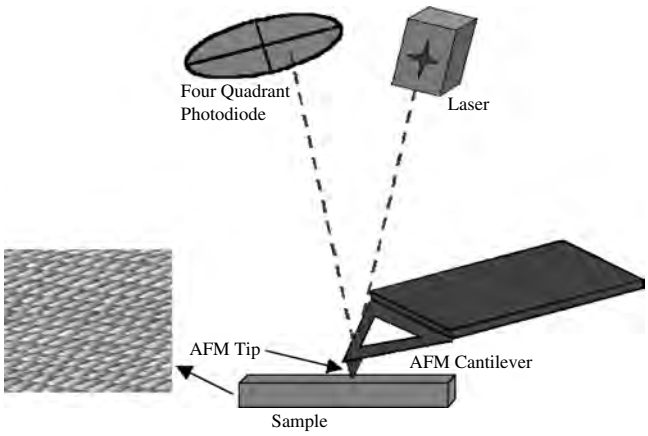

Figure 2. Schematic of the AFM.

indicative of the degree to which the films are able to track the oscillatory motion of the underlying substrate. Friction in this geometry is well characterized by the "viscous friction law" $F/A_c = \eta v$, where v is the average sliding velocity of the adsorbed film constituents. Characteristic slip times τ and friction coefficients (i.e., shear stresses F/A_c per unit velocity) η are determined via the relations [21]

$$\delta(Q^{-1}) = 4\pi\tau(\delta f_o) \quad \eta = \rho_2/\tau \tag{4}$$

where ρ_2 is the mass per unit area of the adsorbate and δf_o is the frequency shift.

Slip times measured by means of QCM are closely linked to the more general topic of energy transfer at an interface, and the vibrational properties of adsorbed molecules [25]. Such vibrations, which underlie heat transfer at an interface, have been studied by means of infrared-reflection-absorption spectroscopy, electron-energy-loss spectroscopy, and inelastic helium scattering. The lifetimes that these techniques determine for the damping of parallel-frustrated translations are of the same order of magnitude, if not identical to, the slip times measured by means of the QCM [26]. The damping rate appears to be little changed in these systems, regardless of the fact that, in the QCM measurements, the vibrational amplitude is larger than several lattice spacings. The fundamental energy dissipative mechanisms involving electronic and phononic effects also appear to be

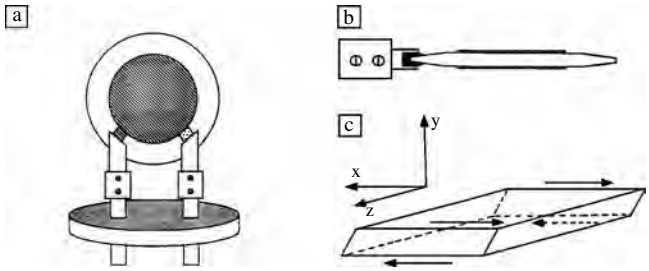

Figure 3. Schematic of the QCM. (a) Front view. The thin quartz disk has metal electrodes deposited onto both faces in a "keyhole" pattern. These electrodes are connected to the leads. (b) Side view. (c) The QCM oscillates in transverse shear mode. Reprinted with permission from [24], M. O. Robbins and J. Krim, *MRS Bull.* 23, 23 (1998). © 1998,

equally viable. Indeed, the QCM slip time is frequently written in terms of separate phonon τ_{ph} and electron–hole τ_{eh} contributions according to $\tau^{-1} = \tau_{ph}^{-1} + \tau_{eh}^{-1}$ [27–32].

The SFA was first developed in the 1950s and 1960s by the Cambridge University group of Bowden and Tabor, and later adapted for friction measurements by Israelachvili in 1973 [18, 19, 33]. The apparatus takes advantage of the fact that the cleavage surface of mica is molecularly smooth, with atomic-step-free areas as great as 1 cm^2. When two mica surfaces are brought into contact, an asperity-free interface is thus formed. The traditional apparatus consists of two cleaved mica surfaces glued to crossed mica cylinders. The contact area and distance between mica surfaces is determined by means of multiple-beam optical interference, with resolution on the order of 0.2 nm or better. The mica surfaces are mounted so that they can be moved vertically and horizontally, and the normal and frictional forces are measured directly from the deflection of a force-mapping spring (see Fig. 4) [34].

4. PHONONIC FRICTION

Tomlinson published an early model, in 1929, of how friction might, in fact, originate at the microscale [35]. In this model, when two surfaces slip across each other, wear-free friction can occur due to the vibration of the atomic lattices. The atoms close to one surface vibrate when the atoms in the opposing surface slip across them. These vibrations are called phonons, or sound waves. The phonons dissipate energy as heat, and this microscopic process is manifested as friction. Motivated by Tomlinson's model, Bowden, Tabor, and colleagues at Cambridge University attempted, in the 1960s, to detect evidence for the phononic contribution to friction, but failed to do so. The idea remained viable, however, as no viable alternate mechanism had presented itself.

Decades later, the concept of phononic friction was independently revisited by Sokoloff et al. in 1978 [36, 37] and McClelland and co-workers in the 1980s, who rederived models similar to the original work of Tomlinson. McClelland, Mate, and colleagues subsequently developed lateral force microscopy (LFM) for studies of atomic-scale friction in an effort to observe phononic mechanisms for friction [20]. To date, the technique has unearthed no direct evidence for phononic mechanisms of friction. It has nonetheless proven to be a revolutionary new probe for studies of atomic-scale friction in particular, and nanoscale science in general.

In 1991, Krim and co-workers reported QCM measurements of the friction of krypton monolayers sliding on Au(111) [38]. They found that solid Kr monolayers sliding on Au(111) had five times longer slip times (lower friction) than liquid monolayers of Kr. In 1994, Cieplak et al. modeled these interesting results [39]. Using standard molecular dynamics algorithms, they reproduced the 1991 experimental results of Krim and colleagues. Their simulations included only one source of friction: phononic friction. Given the close match between their simulations and the QCM experiments, Robbins and colleagues concluded that phononic friction was "the major source of friction" for the krypton on Au(111) system. The combined QCM and numerical results provided the first definitive evidence for the existence of a phononic mechanism for friction.

5. ELECTRONIC FRICTION

In addition to phononic friction, there is another type of dissipation mechanism, electronic, that takes place in electrically conductive materials. In both electronic and phononic friction, kinetic energy associated with the sliding motion at an interface is transformed to heat. The heat is associated with temperature increases in both materials in sliding contact, and is reflected in the phonon populations therein. Phononic dissipative mechanisms involve the direct transfer of energy into the phonon populations. In contrast, electronic mechanisms involve energy transfer into the conduction electrons before transfer to the phonon populations. In one proposed mechanism for electronic friction, the presence of another surface or an adsorbate and the sliding across the metal substrate cause excitations of the conduction electrons near the interface. The excitations generate electron–hole pairs. Electron–hole pairs in metals (in contrast to semiconductors) have very brief lifetimes. When these electron–hole pairs relax, the excess energy is dissipated as heat, and the temperature concomitantly rises. The mechanism is quite distinct from the forces associated with static charge build up on insulating materials.

Persson has suggested that the electronic component of friction μ_{eh} is related to the surface resistivity of an adsorbate–substrate system [26] via

$$\mu_{eh} = n^2 e^2 d \Delta\rho / m n_a \tag{5}$$

Here, n is the number of conduction electrons per unit volume, e is the electron charge, d is the thickness of the metal film, $\Delta\rho$ is the adsorbate-induced increase in film resistivity, m is the adsorbate mass, and n_a is the number of adsorbates per unit area in direct contact with the adsorbate. This is derived for a viscous friction law of the following form:

$$F_{fric} = m \mu_{eh} v \tag{6}$$

where F_{fric} is the force of friction and v is the sliding speed. Definitive proof of electronic contributions to friction is of

great interest since, to date, the vast majority of fundamental theoretical treatments of friction have considered phonon contributions only [40].

Schumacher [41] employed Eq. (5) to infer friction coefficients for a range of adsorbates, and found the slip times to be in the range 10^{-9}–10^{-12} s. The values compared favorably with slip times measured by means of QCM, which probes the total friction $\tau^{-1} = \tau_{ph}^{-1} + \tau_{eh}^{-1}$ [27–32]. In an attempt to quantify the relative contributions of electronic friction to phononic friction, Dayo and Krim compared the electronic friction calculated from electrical resistivity measurements to the total friction taken from QCM measurements for xenon on Ag(111) at 77 K [42]. They observed the resistivity of the Ag(111) film to increase monotonically with the adsorption of the Xe, up to coverages of one monolayer. Above one monolayer, the resistivity increased only very slightly. However, the friction force per unit area required to slide the two-layer thick Xe film was 27% greater than that required to slide the monolayer film [43]. Using Eq. (5), they calculated the electronic contribution to friction, and compared it to the total friction obtained from the QCM, and reported the electronic contribution to be at most 30% of the total for Xe/Ag(111).

There have been several efforts to model the sliding of Xe/Ag(111). In some of these efforts, the models indicate that phononic friction dominates. Tomassone and colleagues [44] reported that the increased number of possible vibrational modes that dissipate energy is greater for a bilayer than a monolayer, and that this is the cause of the increase in friction. In models of the Xe/Ag(111) system by Persson and Nitzan [30], however, the increase in friction from the monolayer to the bilayer was reported to be caused by an increase in the electronic friction. They reported that the second layer pushes the xenon closer to the silver surface, thus increasing the van der Waals contribution to the electronic friction.

Arguably, more direct evidence supporting the importance of the electronic contributions comes from the work published by Dayo et al. [45] in 1998. The group studied the sliding of thin nitrogen films adsorbed on lead surfaces by means of QCM, and observed the friction coefficient to drop by almost half when the substrate became superconducting. The result drew much attention, and sparked criticism as well [46–61]. A somewhat similar experiment found no slippage whatsoever of a nitrogen film at low temperature, and thus no changes in the friction across the superconducting transition [58]. It subsequently became clear, however, that the effect is observable only on substrates of extremely high purity: pinning of the film at low temperature by contamination or defects prevails for all but the cleanest substrates [62, 63]. The experiment remains theoretically puzzling. Indeed, various arguments have been presented that justify, contradict, or partially explain the observation [51–61].

Tribologists are not the only research community to have pondered energy dissipation mechanisms at moving interfaces. An entirely distinct surface science community emerged in the late 1980s, members of which studied both phononic and electronic contributions to energy dissipation within the context of small vibrational motions of atoms on surfaces. Whenever atoms or molecules adsorb on surfaces, new vibrational modes will emerge which are not present in either an isolated surface or the adsorbate alone. The modes which appear include both "internal" (stretching or torsional vibrations within a molecule) and "external" modes, whereby the entire molecule or atom moves as a whole with respect to the surface. These phonon modes for adsorbate–substrate systems can be measured by helium atom scattering (HAS) and related spectroscopies [64, 65]. They can also measure the line width (the lifetime or damping) of adsorbate vibrations, which is indicative of the rate at which the energy of the phonon mode is dissipated into heat. The line width of the adsorbate vibration has been shown to be linearly proportional to the friction coefficient η [66]. Frustrated translational modes, both parallel and perpendicular to the substrate, have been measured. Perpendicular modes (S modes or FT_z modes) mainly probe the energy and damping of the interaction between the adsorbate and substrate. Parallel modes (T modes) probe the curvature of the adsorbate–substrate interaction potential [67–69] and the commensurability between the adsorbate and substrate [69].

From the information given by the phonon dispersion curves and the line width of the adsorbate vibrations gleaned from HAS and related spectroscopies, it should be possible to predict and explain the friction for a given adsorbate–substrate system. For example, since the line width of the adsorbate vibrations is linearly proportional to the friction coefficient, a broader line width should imply a higher friction system. Also, the existence of a Brillouin-zone-center gap for parallel or perpendicular phonon modes indicates commensurability between the adsorbate and substrate [69]. The existence and size of the zone-center gap may therefore predict the degree of lattice match up that causes friction. This understanding, however, is still in its infancy. Although the comparative magnitude of friction between adsorbates and substrates may be predictable, it is still difficult to determine whether the origins of friction for a given system are phononic or electronic. Further well-planned and controlled experiments are necessary to differentiate between phononic and electronic processes. Of particular interest may be the QCM experiments by Mistura and colleagues [62, 70], whereby QCM vibrational amplitudes are sufficiently small so as to be directly comparable to the vibrational sliding distances encountered in the "vibrations at surfaces" community.

6. STATIC FRICTION

One of the most common everyday experiences with friction at the macroscopic scale is the occurrence of static friction: the force to initiate motion (which itself is quite variable, depending, for example, on how long the two surfaces have been in contact) is virtually always larger than that required to keep an object in motion. A closely associated phenomenon is that of stick-slip friction, whereby, for certain sliding speeds, the velocity-weakening dependence of the transition from static to sliding friction leads to repetitive sticking and slipping at the interface, producing the all-too-familiar screeching noises associated with brakes. Although static friction is ubiquitous, it is notoriously difficult to explain at the macroscopic and microscopic length scales.

Static friction and stick-slip motion are also familiar occurrences in nanotribology. Static friction has frequently been measured in the SFA [71, 72]. Atomic-scale stick-slip friction was first measured in the AFM by Mate and colleagues in 1987 [20]. Using an AFM with a tungsten probe on a graphite surface, they found that the frictional force of the probe on the graphite had a periodicity of 2.5 Å, the same periodicity as the graphite surface. Since 1987, atomic-scale stick-slip friction has been observed on many different materials [73–75]. Atomic-scale stick-slip friction can be interpreted as the tip and sample remaining in the minimum potential energy position until a sufficiently strong shear stress is applied to force the tip to move [76]. Interestingly, such stick-slip behavior has always been observed to occur with the periodicity of the substrate lattice—even when the lattice points have multiple atoms (Fig. 5). For example, it is not possible to differentiate between the molybdenum and the sulfur atoms in an MoS_2 surface. The stick-slip periodicity measured by the LFM is 3.16 Å, which corresponds to the distance between MoS_2 molecules in the lattice [77, 78].

Static friction has never been evident in QCM measurements, both solid–solid and liquid–solid interfaces being well described by the viscous friction law in Eq. (1). Given the differences in sliding speeds and geometries among QCM, SFA, and AFM, there was some debate about the underlying reason for the lack of static friction in the QCM. A recent experiment by Mate and Marchon explored this question [79]. In this experiment, they focused on the fact that, while both QCM and SFA measurements of the shearing of liquid films reveal viscous friction, static friction is present only in the SFA geometry. Mate and Marchon, employing a "blow-off experiment," explored whether the open geometry or much greater shear rates of the QCM could account for the difference in the observed behaviors. They blew nitrogen across a liquid film confined in a narrow channel. The laminar flow conditions generated a shear stress on the liquid film at shear rates comparable to those in the SFA. Their results yielded viscous friction, so it was concluded that confined geometries, and not the shear rates, of the SFA and AFM resulted in static friction, while unconfined geometries like the QCM and the "blow-off" experiment are characterized by the viscous friction law.

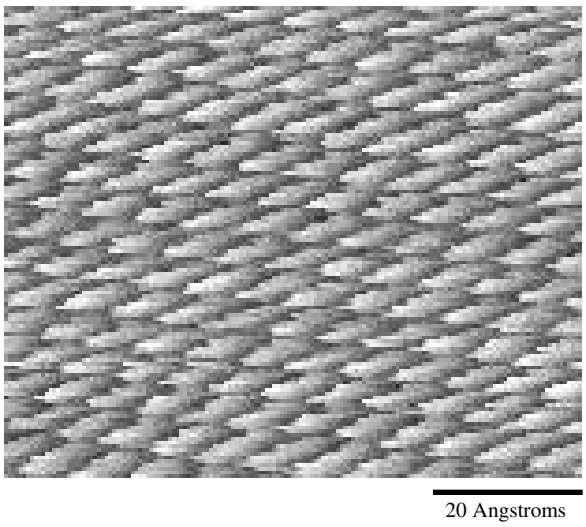

Figure 5. AFM friction force image of atomic stick-slip friction. Acquired in Krim lab with Si_3N_4 tip on muscovite mica. Each sticking point corresponds to one lattice point on the mica surface.

The results are consistent with recent computer simulation experiments [80, 81]. Robbins and colleagues studied the effects that mobile atoms between two contacting crystalline surfaces have on friction. As discussed previously, commensurate crystalline surfaces are expected to have high friction, and they exhibit static friction with or without contaminant atoms between the surfaces. Incommensurate crystalline surfaces, however, have very low friction. In the real world, however, almost all contacting surfaces are expected to be incommensurate, so the existence of static friction is difficult to explain. In their simulations, Robbins and colleagues modeled submonolayer, mobile contaminant films between two incommensurate surfaces. They observed that the mobile molecules found small gaps between the surfaces. Any sliding of the two surfaces will constrict or reduce the gaps in which the mobile molecules settle. The molecules therefore resist sliding motion until the shear stress exceeds some threshold value and they are displaced, resulting in the presence of static friction.

7. VELOCITY DEPENDENCE OF FRICTION

Recent LFM experiments have shown that the velocity independence of friction for multiasperity contacts and macroscale objects does not hold for single-asperity contacts and nanoscale objects [82]. Gnecco and colleagues [83] studied the velocity dependence of friction by means of LFM for a silicon tip sliding on an NaCl(100) surface in ultrahigh vacuum (UHV) for speeds ranging from 5 nm/s to 1 μm/s. They observed the atomic stick-slip friction common to LFM, and also observed that the friction increased logarithmically with the sliding velocity. Employing a modified Tomlinson model, they found that the velocity dependence was attributable to thermal energy that helped to push the AFM tip from one lattice "sticking point" to the next.

In contrast to the logarithmic velocity dependence associated with LFM (a confined geometry), friction data obtained using the open geometry of the QCM are routinely described by the viscous friction law $F = \eta v A_c$. Mak and Krim confirmed the applicability of this law for monolayer coverages of krypton adsorbed on Au(111) at 77 K, for sliding speeds in the range 3–8 cm/s [84]. In contrast to full monolayer coverage, the frictional law appeared to be nonlinear for submonolayer coverages, described by the more general law v^n, with $n < 1$. Numerical simulations have also been performed on the Kr/Au(111) system, indicating a linear friction law for sliding speeds on the order of 10 m/s [39]. The open geometry of Mate and Marchon's "blow-off" experiment, mentioned above [79], also obeyed the viscous friction law, but for shear rates nine orders of magnitude slower.

8. FRICTIONAL ANISOTROPY

There has been much work done on commensurate and incommensurate frictional systems and frictional anisotropy. When two surfaces are commensurate, their lattices match in perfect registry. Theoretically, it has been shown that commensurate systems can have as much as 14 orders of magnitude higher friction than corresponding incommensurate systems. The lower friction levels for incommensurate systems are due to the random positions of atoms with respect to each other on the mismatched lattices. Interfacial forces tend to cancel in this case, resulting in very low friction [85, 86].

There are several experiments that reveal the effect of incommensurability on friction, although none has reported the phenomenal change in friction that is theoretically possible. Most of these studies study the adhesion and friction between like materials or materials with similar lattice spacing, and go from commensurate to incommensurate by rotating the lattices with respect to one another (see Fig. 6). McGuiggan and Israelachvili, for example, employed an SFA to study the adhesion of mica surfaces in distilled water and aqueous KCl [87]. Their results related the adhesion of the mica surfaces to the alignment of the mica surfaces with respect to one another. The adhesion peaked at $\theta =$ 0, 60, 120, and 180° ($\theta = 0$ corresponds to matching lattices), following the sixfold symmetry of the mica lattice. A related study of mica surfaces by Hirano et al. linked the friction of the mica surfaces to their relative orientation [88]. They used a friction tester similar to an SFA, and studied the rubbing of two mica surfaces in both an argon-purged dry atmosphere with the surface temperature of the mica heated above 100 °C to prevent water adsorption. These measurements were then compared to ambient-condition measurements with the mica surface temperatures held at 20 °C. In the argon-purged atmosphere, the friction reached maximum levels when the surfaces were commensurate ($\theta = 0$, 60, 120, and 180°, $\theta = 0$ corresponds to matching lattices) and minimum levels, dropping by a factor of 4 when the surfaces were incommensurate ($\theta = 30$, 90, etc.). In ambient conditions, the frictional anisotropy disappeared, however, owing to the adsorption of water and other contaminants onto the mica surfaces. The result lent support to the idea that frictional anisotropy is purely a surface effect. Hirano and colleagues [89] later employed scanning tunneling microscopy (STM) in UHV to study the sliding of a tungsten wire tip surface on a planar silicon surface. Much like an AFM, they rastered the tungsten tip across the silicon surface, and used a displacement sensor to measure the bending of the tungsten wire caused by the friction between the two surfaces. Employing Hooke's law to extract the frictional force from the displacement of the tungsten tip, they found that the frictional force of the two surfaces in commensurate contact was 8×10^{-8} N. The friction vanished when the surfaces were in incommensurate contact, within their resolution. (The resolution of their instrument was 3×10^{-9} N.)

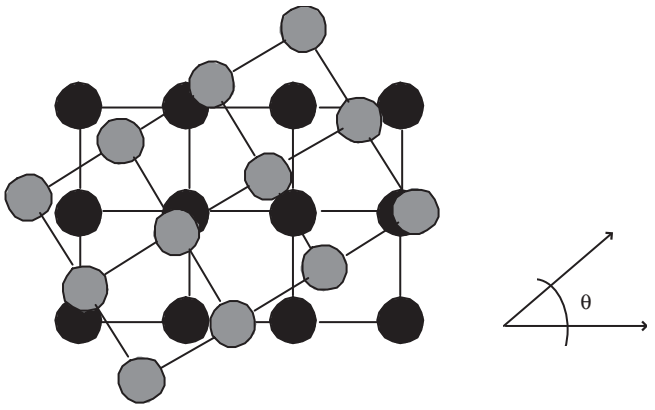

Figure 6. Two identical lattices can be made incommensurate by rotating one lattice by θ and sliding along the new direction.

Not all frictional anisotropy can be related to surface commensurability. In some experiments, frictional anisotropy disappears at low loads when the surfaces are in elastic contact, and is only present at high loads when the surfaces are in plastic contact [90]. Take, for example, an experiment by Ko and Gellman [91] that studied the friction between nickel(100) surfaces in UHV with and without adsorbed surface coatings of sulfur and ethanol. The adsorbed coatings modified the surface lattice from the bare nickel: the sulfur surface is well ordered, with lattice vectors rotated 45° with respect to the bulk nickel, and the adsorbed ethanol is not ordered. The friction in this study was anisotropic, and related to the bulk lattice structure of the nickel. The static friction coefficient was found to be minimized (lower by a factor of 3–4) at a bulk lattice mismatch of $\theta = 45°$, regardless of the modifications to the surface by monolayers of atomic sulfur and up to four monolayers of adsorbed ethanol. Their results suggest that, in some systems in plastic contact, the frictional anisotropy is related to the deformation of the bulk material.

9. CONCLUSIONS

Since the development in the 1970s and 1980s of important new technology that enabled the study of nanotribology, much has been learned. However, nanotribology is a new field with much left to be discovered. There is still much to be learned about the chemical reactions which occur in a sliding contact, the characterization of the microstructural and mechanical properties of the contact regions between sliding materials, bridging the gap between nanotribology and macrotribology, developing realistic computer simulations, explaining the origins of friction, and establishing realistic laboratory test setups which are both well controlled and relevant to operating machinery.

GLOSSARY

Amontons' law At macroscopic length scales, the friction is proportional to the load.

Commensurate When two surface lattices are in perfect registry.

Coulomb's friction law At macroscopic length scales, friction force is independent of sliding velocity.

Electronic friction An energy dissipation mechanism that occurs in electrically conductive materials. During sliding,

energy is transferred to the conduction electrons prior to being transferred to phonons, as in phononic friction.

Frictional anisotropy The fact that frictional forces are dependent on alignment of the surface lattices.

Incommensurate When two surface lattices are not in perfect registry.

Nanotribology The study of friction, lubrication, and wear at atomistic length and time scales.

Phonon The mechanical vibration of an atomic lattice, or sound wave.

Phononic friction The process occurring when the atoms close to one surface vibrate, generating phonons, when the atoms in the opposing surface slip across them. The phonons then dissipate energy as heat, causing friction.

Static friction The force required to initiate motion.

Stick-slip friction The velocity-weakening dependence of the transition from static to sliding friction that leads to repetitive sticking and slipping at the interface.

Tribology The study of friction, lubrication, and wear.

Nanotribology: Friction Force Microscopy

Enrico Gnecco
University of Basel, Basel, Switzerland

CONTENTS

1. INTRODUCTION

The term *tribology* comes from the ancient Greek word *tribos*, which means *to rub*. It was used for the first time in 1966 by Peter Jost, and, in current use, it refers to the study of friction, wear, lubrication, and contact mechanics. *Nanotribology* encompasses the same topics, but it focuses on processes occurring on the nanometer scale. Nanotribology aims to realize two important tasks: (i) to give insight into the microscopic origin of friction and wear and (ii) to exploit the knowledge acquired for the optimization of microdevices. The economic impact of nanotribology is easily imaginable. Significant parts of gross domestic product of industrialized countries are wasted every year due to friction and wear problems which, even if they affect macroscopic machinery, have their origin in complex processes of various natures occurring on the nanometer scale. These processes are even more relevant in data storage and microelectronics industry. The need for high recording densities in magnetic storage devices requires a reduction in the height of the read/write magnetic head with respect to the magnetic medium, which can lead to contact with serious consequences. In microelectromechanical systems, objects a few micrometers in size are repeatedly brought into contact at high speed. In both cases the resistance to rupture of different coatings and components needs to be tested and controlled on the small scale.

The macroscopic results of tribology cannot be directly extrapolated to the micro- and nanoworld. If the linear size of a component is reduced by a factor of 10, the area of its surface is reduced 10 times less than its volume, which implies that the resistive forces, proportional to the area of sliding, are reduced 10 times less than the inertial forces, proportional to the volume of the component. The observation of tribological processes down to the nanometer scale was made possible by the *atomic force microscope* (AFM), introduced by Binnig et al. in 1986 [1]. The AFM reveals the forces acting on a sharp tip sliding on a surface from the deformation of a microcantilever supporting the tip (Fig. 1). The normal force between tip and surface causes the vertical deflection of the cantilever, whereas the friction force causes its torsion. If the vertical deflection is kept constant by a feedback loop, friction can be monitored at a given load while scanning. In such context, the AFM is also referred as the *friction force microscope* (FFM). How to accurately detect friction with AFM is the main subject of Section 2. Other instruments of interest in nanotribology—the surface force apparatus and the quartz crystal microbalance—will be also briefly introduced.

The contact between two macroscopic surfaces involves thousands of microasperities. The apex of the AFM tip sliding on the underlying sample represents a single asperity a few nanometers in size. The mechanics of a single contact differs from that of a multiple contact. If the asperity has a spherical shape the friction or lateral force, F_L, is related to the applied normal force, F_N, by the Hertzian relation $F_L \propto F_N^{2/3}$ [3], which seems to be in contrast with the well-known *Amonton's law*, $F_L \propto F_N$ [4]. However, Amonton's law is recovered when statistical distributions of single asperities are considered [5, 6]. Adhesion plays an important role in the contact region. This effect is considered in extended Hertzian models, which well fit the experiments conducted with the FFM. These models, all based on continuum mechanics, will be discussed in Section 3.

In a well-defined environment, the friction force acting on the probing tip depends on the surface under investigation. Due to the small size of the tip (typical radii of curvature are 10–50 nm) AFMs can map forces on a local scale with extraordinary resolution. An example is given in Figure 2,

which shows a friction map acquired on some hydrocarbon islands surrounded by fluorocarbons. Using a high load it was possible to produce patterns on the hydrocarbon islands, whereas fluorocarbons could not be affected by this treatment. Further examples of friction maps on the nanometer scale are given in Section 4.

Friction maps with atomic features were first detected by Mate et al. on graphite in 1987 [8]. Figure 3a shows a friction map of sodium chloride acquired in ultra-high-vacuum (UHV) conditions, which reproduces the structure of the atomic lattice. A single scan line has a sawtooth shape with the periodicity of the lattice (Fig. 3b). When the scan direction is inverted the lateral force is also inverted. The area of the *friction loop* obtained by scanning backward and forward gives the energy dissipated per scan cycle. The sawtooth shape is due to the *atomic stick-slip* movement of the probing tip, which, driven by the cantilever, jumps periodically from a stable equilibrium position on the lattice to the next one. A simple explanation of the atomic stick-slip is given by the *Tomlinson model* [10], discussed in Section 5. An extension of the Tomlinson model, which includes thermal effects, predicts a logarithmic dependence of friction on the sliding speed, in contrast with the classical *Coulomb's law of friction*,

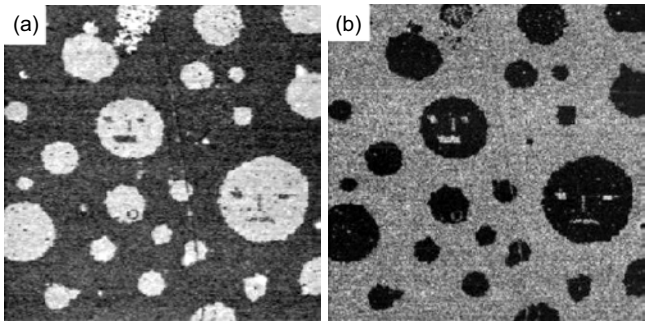

Figure 2. (a) Topography of mixed Langmuir–Blodgett film. Areas of hydrocarbons are surrounded by a "sea" of fluorocarbons. (b) Friction map. which states that friction is speed-independent [4]. Section 6 deals with friction measurements on the atomic scale and related phenomena, as friction anisotropy, dissipative effects "out of contact," and electronic friction.

If the normal load applied on the probing tip exceeds a critical value, the morphology of the surface is permanently modified. *Nanoindentation* can be used to quantify hardness on the nanoscale. In the *nanolithography* technique the AFM is used to produce nanopatterns in a controlled way. In exceptional cases wear processes can be studied down to the atomic scale. For example, Figure 4 shows that the debris extracted from an ionic crystal recrystallized in mounds with the same structure of the undamaged surface. Tip-induced modifications of various surfaces will be presented in Section 7.

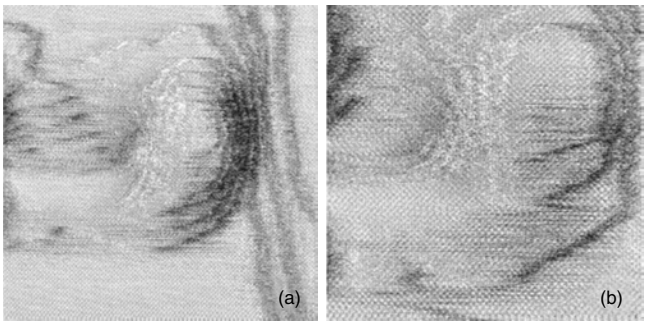

Figure 4. Lateral force images acquired at the end of a groove scratched on potassium bromide. The debris recrystallizes in a mound with ordered structure. Frame sizes: (a) 39 nm, (b) 25 nm. 2. INSTRUMENTS

2.1. Friction Force Microscopy

The atomic force microscope exploits the interaction of a sharp tip sliding on a surface to quantify dissipative processes down to the atomic scale (Fig. 1). The relative motion of tip and surface is realized by a scanner formed by piezoelectric elements, which moves the surface perpendicularly to the tip with a certain periodicity. The scanner can be also extended or retracted in order to vary the normal force, F_N, applied to the surface. This force causes the vertical deflection of the cantilever supporting the tip. If the normal force increases while scanning, due to the local slope of the surface, the scanner is retracted by a feedback loop to keep the force F_N constant. On the other hand, if F_N decreases, the surface is brought closer to the tip by extending the scanner. In such a way, the topography of the surface can be determined line by line. An accurate control of the piezo movement is made possible by a laser beam, which is reflected from the rear of the cantilever into a photodetector. When the bending of the cantilever changes, the laser spot on the detector moves up or down. The difference signal between upper and lower segments $(A - B)$ is proportional to the normal force.

The relative sliding of tip and surface is also accompanied by *friction*. A lateral force, F_L, with the opposite direction of the scan velocity, hinders the motion of the tip. The friction force provokes the torsion of the cantilever and it can be observed with the topography if the photodetector reveals not only the vertical deflection but also the lateral movement of the cantilever while scanning. In practice, this is realized by four-quadrant photodetectors, where the difference signal between left and right segments $(C - D)$ is proportional to the friction force. Incidentally, friction causes also the lateral bending of the cantilever, but this effect is negligible if the thickness of the cantilever is much smaller than its width.

The AFM was first used by Mate et al. to reveal friction with atomic features [8]. In their experiment, Mate et al. used a tungsten wire and a slightly different technique to reveal the forces acting in the contact area. The optical beam deflection was introduced later by Marti et al. [12] and Meyer and Amer [13]. Other methods to measure the forces between tip and surface are based on capacitance detection [14], dual fiber interferometry [15], and piezolevers [16]. In the first method, two plates close to the cantilever reveal capacitance while scanning. The second technique uses two optical fibers to detect the cantilever deflection along two orthogonal directions angled 45° with the respect to the surface normal. In the third method, cantilevers with two Wheatstone bridges at their base are used. Normal and lateral forces are respectively proportional to the sum and the difference of both bridge signals.

2.2. Force Calibration in Friction Force Microscopy

Force calibration is relatively simple for rectangular cantilevers [2]. Due to possible discrepancies with the geometric values provided by manufacturers, it is recommended to use optical and electron microscopes to determine the width w, the thickness t, and the length l of the lever, as well as the tip height, h, and the position of the tip with respect to the cantilever. The cantilever thickness can be also deduced accurately from the resonance frequency, f_0, using the relation [17]

$$t = \frac{2\sqrt{12}\pi}{1.875^2}\sqrt{\frac{\rho}{E}}f_0 l^2 \tag{1}$$

In (1) ρ is the cantilever density, and E is its Young's modulus. The normal spring constant, c_N, and the lateral spring constant, c_L, are given by

$$c_N = \frac{Ewt^3}{4l^3} \qquad c_L = \frac{Gwt^3}{3h^2 l} \tag{2}$$

where G is the shear modulus of the cantilever. The further step consists in measuring the sensitivity of the photodetector, S_z (nm/V). The sensitivity of a beam-deflection AFM is determined by force vs distance curves measured on hard surfaces, where elastic deformations are negligible and the vertical movement of the scanner equals the cantilever deflection. A typical relation between the difference of the vertical signals on the four-quadrant detector, V_N, and the distance from the surface, z, is sketched in Figure 5. When the tip is approached no signal is revealed until the tip jumps into contact at $z = z_1$. Further extension or retraction of the scanner result in an elastic response until the tip jumps again out of contact at a distance $z_2 > z_1$, due to adhesive forces. The slope of the elastic part of the curve gives the required sensitivity, S_z. Assuming that the laser beam is well positioned above the probing tip, the normal and lateral forces are related to the voltage V_N, and the difference between the horizontal signals, V_L, on the photodetector by the following relations:

$$F_N = c_N S_z V_N \qquad F_L = \frac{3}{2}c_L \frac{h}{l} S_z V_L \tag{3}$$

The normal spring constant c_N can be evaluated with alternative methods. Cleveland et al. attached tungsten spheres to the tip, which changes the resonance frequency f_0 according to the formula [18]

$$f_0 = \frac{1}{2\pi}\sqrt{\frac{c_N}{M + m^*}} \tag{4}$$

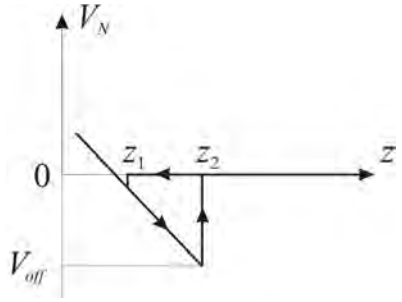

Figure 5. Sketch of a typical force vs distance curve. The tip approaches the sample from right to left. At $z = z_1$ the tip jumps into contact. Further moving results in an elastic bending of the cantilever. Due to adhesive forces, the tip jumps out of contact at $z_2 > z_1$.

In (4) M is the mass of the added object and m^* is a certain effective mass of the cantilever, which depends on its geometry. The spring constant can be deduced from the frequency shifts corresponding to the different masses attached. Hutter and Bechhoefer [19] observed that the constant c_N is related to the area of the power spectrum of the thermal fluctuations of the cantilever, P. The correct relation is $c_N = 4k_BT/3P$, where $k_B = 1.38 \times 10^{-3}$ J/K is the Boltzmann constant and T is the temperature [20]. Cantilevers with different shape require finite element analysis, although in few cases analytical formulas can be derived. Neumeister and Ducker [21] obtained approximate analytical expressions for the normal and the lateral spring constant of V-shaped cantilevers. Surfaces with well-defined profiles are useful *in-situ* tools for calibration [22]. In such a case the the horizontal and vertical components of the total force revealed by the photodetector differ from the normal and lateral components with respect to the surface, F_N and F_L. The geometric relations between these components are used to determine the conversion ratio between volts and nanonewtons as well as the coefficient of friction.

In some cases an adequate estimation of the radius of curvature of the tip, R, is required. This quantity can be evaluated with a scanning electron microscope. Otherwise, well-defined structures such as step sites [23] or whiskers [24] can be imaged. The image of these high-aspect ratio structures is convolved with the tip shape. A deconvolution algorithm that allows extracting the radius of curvature of the probing tip was proposed by Villarrubia [25].

Finally, when calibrating the instrument one must be aware that the accuracy of the piezoelectric scanners is limited by instrumental drifts [26] and typical piezoelectric effects such as nonlinearity, hysteresis, creep, and variation of sensitivity with the applied voltage [27, 28]. An accurate analysis of the errors occurring in the calibration of the lateral forces is given in [29].

2.3. Other Techniques

Beside the atomic force microscope, the *surface force apparatus* (SFA) and the *quartz crystal microbalance* (QCM) are useful instruments in nanotribology.

The surface force apparatus [30, 31] consists of a pair of mica sheets, which are pressed together and reciprocally translated under pressure (Fig. 6). The contact area and distance between mica surfaces can be measured by optical or capacitive techniques with a resolution of 2 Å. The normal and lateral forces are deduced from the deformation of springs. The SFA is commonly used to detect the behavior of lubricant liquids between the two surfaces in contact. As an example, the layering of liquids in discrete strata was observed as a function of the applied load [33]. O'Shea et al. observed a similar effect with an AFM [34, 35]. In such a case, the layering of liquid molecules on graphite and mica surfaces caused stiffness oscillation as the tip–sample distance was varied.

The quartz crystal microbalance, which is commonly used to measure thin film growth, was first applied to nanotribology by Krim and Widom [36]. The QCM consists of a single crystal of quartz, which oscillates in a shear mode with a high quality factor Q. The sliding friction of adsorbed films

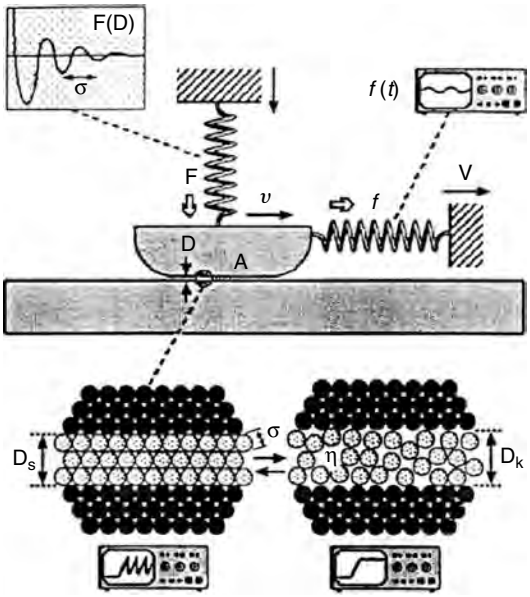

Figure 6. Diagram of a surface force apparatus. Two smooth mica surfaces are separated by a molecularly thin lubricant film. The springs represent any device used to measure the normal and lateral forces between the surfaces. Reprinted with permission from [32], B. Bhushan et al., *Nature* 374, 607 (1995). © 1995, Nature Publishing Group.

is related to the frequency shift and the broadening of the resonance peak of the crystal. Unfortunately, the instrument can reveal only very low friction forces and its application is limited to systems like rare-gas solids on metals [37]. In Section 6.5 we will see how the quartz crystal microbalance was used to detect electronic contributions to friction.

3. MECHANICS OF SLIDING NANOCONTACTS

3.1. Load Dependence of Friction

The lateral force, F_L, between two surfaces in reciprocal motion depends on the size of the *real* area of contact, A, which is usually a few orders of magnitude smaller than the apparent area of contact. From the analysis of several experimental data Bowden and Tabor concluded that friction is proportional to the real area A [38]:

$$F_L = \sigma A \tag{5}$$

The mean lateral force per unit area, σ, is called the *shear strength*. In a first approximation, it does not depend on the normal pressure. Bowden and Tabor assumed that the asperities of the two surfaces in contact are deformed *plastically* while sliding. In such a case the asperities of the two surfaces are compressed until the applied pressure, p, equals a certain yield value, p^*. The resulting area of contact is thus $A = F_N/p^*$, and the well-known Amonton's law is obtained: $F_L = \mu F_N$, where $\mu = \sigma/p^*$ is the *coefficient of friction*. The same idea can be extended to contacts formed by many asperities, and it leads again to Amonton's law. The simplicity of this analysis explains why most of the friction processes

were related to plastic deformation for a long time. However, plastic deformation provokes a quick damage of the surfaces under pressure, which is not so frequently observed while sliding. Thus, the morphology of the surface must be affected by less disruptive mechanisms of deformation.

Elastic deformation can be easily described in the case of a sphere of radius R pressed against a flat surface. In such a case the contact area is [39]

$$A(F_N) = \pi\left(\frac{R}{K}\right)^{2/3} F_N^{2/3} \tag{6}$$

where $K = 3E^*/4$, E^* being an effective Young's modulus, related to the Young's moduli, E_1 and E_2, and the Poisson's numbers, ν_1 and ν_2, of the sphere and plane, by the following relation:

$$\frac{1}{E^*} = \frac{1-\nu_1^2}{E_1} + \frac{1-\nu_2^2}{E_2} \tag{7}$$

The result $A \propto F_N^{2/3}$ does not agree with Amonton's law, $A \propto F_N$. However, a linear relation between F_L and F_N can be derived for contacts formed by several asperities in some important cases. For example, the area of contact between a flat surface and a set of asperities with an exponential height distribution and the same radius of curvature, R, is proportional to the normal force [5]. The same conclusion holds approximately for a Gaussian height distribution. However, the hypothesis that the radii of curvature are the same for all asperities is not realistic. A general model proposed by Persson predicts that the contact area is proportional to the applied load for a large variety of elastoplastic contacts formed by surfaces with arbitrary roughness [6].

Further effects are observed if *adhesion* between the asperities is taken into account. If the range of action of the adhesive forces is smaller than the elastic deformation, Eq. (6) is extended by the *Johnson–Kendall–Roberts* (JKR) *model* [40] to the expression

$$A(F_N) = \pi\left(\frac{R}{K}\right)^{2/3}\left(F_N + 3\pi\gamma R + \sqrt{6\pi\gamma R F_N + (3\pi\gamma R)^2}\right)^{2/3} \tag{8}$$

where γ is the surface tension between sphere and plane. The real area of contact at zero load is finite and the sphere can be detached only by pulling it away with a finite force. This is also true in the opposite case, where the range of action of adhesive forces is larger than the elastic deformation. In such a case the relation between contact area and load has the simple form

$$A(F_N) = \pi\left(\frac{R}{K}\right)^{2/3}\left(F_N - F_{\text{off}}\right)^{2/3} \tag{9}$$

where F_{off} is the negative load that is required to break the contact. The Hertz-plus-offset relation (9) can be derived from the *Derjaguin–Muller–Toporov* (DMT) *model* [41]. To discriminate between the JKR or DMT models Tabor [42] introduced a non-dimensional parameter,

$$\Phi = \left(\frac{9R\gamma^2}{4K^2 z_0^3}\right)^{1/3} \tag{10}$$

where z_0 is the equilibrium distance in contact. The JKR model can be applied if $\Phi > 5$; the DMT model holds when $\Phi < 0.1$. For intermediate values of Φ, the *Maugis–Dugdale model* [43] is consistent with experimental results.

The tip of a friction force microscope is a single asperity sliding on a surface. The previous discussion suggests a nonlinear dependence of friction on the applied load, provided that continuum mechanics can be applied down to nanometer scales. Schwarz et al. [44] observed that the Hertz-plus-offset relation (9) holds on graphite, diamond, amorphous carbon, and C_{60} in argon atmosphere (Fig. 7). Well-defined spherical tips with radii of curvature of tens of nanometers were used. The probing tips were obtained by contaminating standard silicon tips with amorphous carbon in a transmission electron microscope. In order to compare the tribological behavior of different materials, Schwarz et al. introduced an *effective coefficient of friction*, $\widetilde{C}$, which does not depend on the tip curvature. The highest friction coefficient $\widetilde{C}$ was found on C_{60} and the lowest on graphite.

Various groups measured friction vs load curves in UHV in agreement with JKR theory [45–47]. Different materials such as ionic crystals, mica, and metals were considered. Meyer et al. used an original two-dimensional (2D) histogram technique [45]. The normal load is increased or decreased while imaging, which allows one to correlate lateral and normal forces with improved statistics. Carpick et al. extended the JKR relation (8) to include nonspherical tips. For example, in the case of an axisymmetric tip profile $z \propto x^{2n}$, with $n > 1$, the increase of friction becomes less pronounced with increasing n [46].

3.2. Estimation of the Contact Area

In contrast to other tribological instruments, like the surface force apparatus, the area of contact cannot be directly determined with the friction force microscope. An indirect estimation of the contact area is achieved by *contact stiffness* measurements [48]. Figure 8 shows a series of two springs corresponding to the microscope tip apex pressed

against the sample. The effective constant k^z_{eff} of the series is given by

$$\frac{1}{k^z_{\text{eff}}} = \frac{1}{k^z_{\text{contact}}} + \frac{1}{c_N} \tag{11}$$

where c_N is the normal spring constant of the cantilever, and k^z_{contact} is the contact stiffness. This quantity is related to the radius of the contact area, a, by the simple relation

$$k^z_{\text{contact}} = 2aE^* \tag{12}$$

where E^* is the effective Young's modulus introduced in Section 3.1. Unfortunately, typical values of k^z_{contact} are order of magnitudes larger than c_N, and a practical application of Eq. (11) is not possible.

Carpick et al. [49] and Lantz et al. [50, 51] extended this idea to *lateral* deformations. According to several models, the lateral stiffness of the contact between a sphere and a flat surface is [52]

$$k^x_{\text{contact}} = 8aG^* \tag{13}$$

where the effective shear modulus G^* is defined by

$$\frac{1}{G^*} = \frac{2-\nu_1^2}{G_1} + \frac{2-\nu_2^2}{G_2} \tag{14}$$

G_1, G_2 are the shear moduli of sphere and plane. The contact between tip and sample can be modeled again by a series of springs (Fig. 8b). The effective constant k^x_{eff} of the series is now given by

$$\frac{1}{k^x_{\text{eff}}} = \frac{1}{k^x_{\text{contact}}} + \frac{1}{k^x_{\text{tip}}} + \frac{1}{c_L} \tag{15}$$

where c_L is the lateral spring constant of the cantilever, and k^x_{contact} is the lateral stiffness of the contact. As suggested by Lantz et al., Eq. (15) includes the lateral stiffness of the tip, k^x_{tip}, which can be of the same order of the lateral spring constant. The effective spring constant k^x_{eff} is determined by scanning the surface and measuring the slope of the lateral force vs displacement curve (Section 5.1). Once k^x_{contact} is known, the contact radius, a, is easily estimated with Eq. (13).

Carpick et al. applied their method to a silicon nitride tip sliding on muscovite mica in air, whereas Lantz et al. studied the contact between $NbSe_2$ and graphite in UHV. The relations between spring constant and load were fitted by the JKR and the Maugis–Dugdale models respectively. The same models were also consistent with independent measurements of friction vs load. Thus, the hypothesis that friction is proportional to the contact area held in the applied range of loads (up to $F_N = 40$ nN in both experiments).

Another way to estimate the contact area is based on the measurement of the contact conductance, which is proportional to the contact area. Enachescu et al. used silicon cantilevers coated with tungsten carbide to measure both conductance and friction on boron-doped diamond as a function of the applied load [53, 54]. The load dependences of both friction and conductance were fitted independently with the same model (DMT), which was a further confirmation of the hypothesis (5).

4. FRICTION EXPERIMENTS ON THE NANOMETER SCALE

Friction force microscopy is mainly applied to characterize the response of a surface to the localized stress exerted by the probing tip. The large variety of materials investigated by FFM includes solid lubricants, carbon and silicon compounds, ferroelectrics, and even ice. The role of the environment in such a contest is essential. Ambient air, controlled atmosphere or liquids [55], can drastically influence the values of friction forces, as well as their dependence on the scan load and velocity. Only ultra-high-vacuum friction results from the direct interaction of two materials in contact. Atomic-scale experiments in UHV will be discussed later in Section 6. In the same section we will also consider experiments dealing with friction anisotropy and other minor effects.

4.1. Material Contrast Revealed by Friction Force Microscopy

Due to their lubricity properties, *self-assembled monolayers* (SAM) and, in particular, *Langmuir–Blodgett* (LB) *films* are among the most studied materials in nanotribology. LB films can be easily prepared by transferring any desired number of layers on smooth substrates, as silicon wafers or mica, where they form densely packed structures. Figure 9 shows the first FFM measurements on LB films realized by Meyer et al. [56]. Two bilayers of Cd–arachidate were transferred on a silicon wafer. Friction is lower on the areas covered by the lubricant film, and it does not depend on the film thickness. The load dependence of friction is weak, and wear appears when the normal load exceeds 10 nN. Furthermore, small islands of bilayer height could be moved in their entirety, which made possible a direct measurement of the shear strength between the bilayers. The measured value of $\sigma =$ 1 MPa was in agreement with SFA experiments at low loads [57]. Overney et al. [58] studied more complex LB films, formed by mixtures of hydrocarbons and fluorocarbons. Fluorocarbons were observed to be less effective in reducing friction than hydrocarbons, which was again in agreement

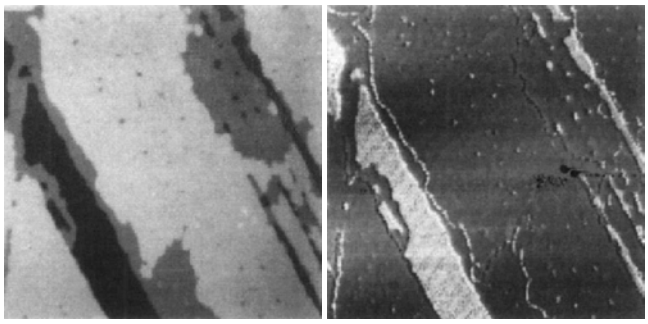

Figure 9. (a) Topography of two bilayers of Cd–arachidate on a silicon wafer. (b) Friction map shows increased friction on the substrate compared to the substrate. Friction is the same on the single and on the couble bilayer. Frame sizes: 2 μm. Reprinted with permission from [56], E. Meyer et al., *Phys. Rev. Lett.* 69, 1777 (1992). © 1992, American Physical Society.

with SFA measurements. Frisbie et al. [59] studied the relation between friction and chemistry on SAMs and found different contrasts when the tip was coated with different functional groups. An extended study with the same purpose was performed by Green et al. [60]. A detailed overview on this topic was given by Carpick and Salmeron [61].

Carbon surfaces were first observed by Mate [62], who studied friction on C_{60}, amorphous carbon, hydrogen terminated diamond, and graphite. The highest friction was found on C_{60}, and the lowest on graphite, which is in agreement with the results by Schwarz et al. (Section 3.1). Buzio et al. [63] applied the idea of the effective friction coefficient introduced by Schwarz et al. to characterize friction on nanostructured carbon films with self-affine morphology. Perry et al. [64] observed that friction on amorphous carbon films increases with increasing hydrogen content. These results are of great interest in the hard disk drive industry, where carbon protective coatings are applied. Lüthi et al. [65] investigated friction on C_{60} islands deposited on NaCl in UHV. Again C_{60} revealed high friction. Furthermore, the islands could be moved over the substrate without breaking and with extraordinary low shear strength $\sigma =$ 0.05–0.1 MPa (Fig. 10). This result suggested to the authors

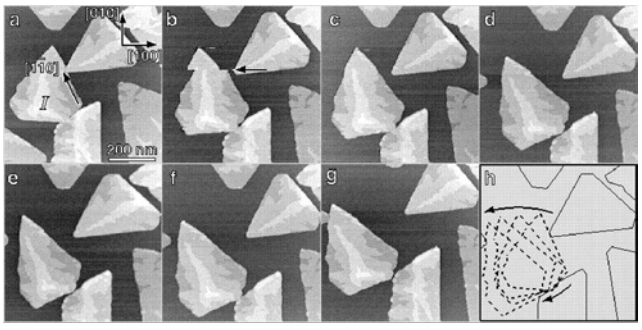

Figure 10. (a)–(g) Sequence of topography images of C_{60} islands on NaCl. An island is rotated and translated from one location to another. Frame sizes: 530 nm. (h) Summary of the movement of the C_{60} island. Reprinted with permission from [65], R. Lüthi et al., *Science* 266, 1979 (1994). © 1994, American Association for the Advancement of Science.

that C_{60} islands might be used as a sled-type transport system on the nanometer scale.

Silicon and silicon oxides have a fundamental role in semiconductor industry. Apart from their electronic properties, mechanical properties are interesting in the development of microdevices, where low friction is required to minimize power consumption. Scandella et al. [66] examined a silicon surface structured by standard photomask lithography and found that friction on hydrogen passivated silicon was larger by a factor 2 than friction on silicon oxide. Teuschler et al. [67] patterned silicon surfaces with a conductive tip, which was subsequently used for characterizing friction. Friction was higher on the modified areas, where the formation of silicon oxide was enhanced. The apparent contrast with the experiment of Scandella et al. is probably due to different crystallinity of the samples. Studies on III–V semiconductors were reported by Garcia and co-workers. Tamayo et al. [68] detected chemical variations of indium alloys with 3 nm resolution. Changes of 10% in indium composition were clearly distinguished in air. Measurements with submonolayer sensitivity were performed on quantum dot structures [69].

Friction force microscopy was also applied to investigate ferroelectric materials. Lüthi et al. [70] and Eng et al. [71] observed significant contrasts between neighboring domains of opposite polarization in friction force maps acquired on GASH (guanidimium aluminum sulphate hexahydrate) and TGS (triglycine sulphate), respectively. On TGS Bluhm et al. measured different friction coefficients, depending on the polarization, the asymmetry of the surface potentials, and also the orientation of the crystallographic lattice with respect to the scan direction [72]. On GASH, the contrast was related only to structural differences, which modify the surface potential experienced by the probing tip. The electrostatic interaction between tip and sample did not affect the friction force significantly.

To conclude this overview, we should also mention the studies of friction on a nanometer thin ice film grown on mica by Bluhm et al. [73]. A friction coefficient $\mu = 0.60$ was measured in a temperature range from -24 to -40 °C, which is comparable to the values obtained in macroscopic experiments [38]. The squeezing of the water layer out of the contact, which was observed in noncontact mode, suggested that dry friction was probably revealed. Other effects like pressure melting and frictional heating were found to be not relevant.

4.2. Role of the Environment

A humidity increase in ambient air leads to the formation of water layers on hydrophilic surfaces and to a consequent capillary interaction between tip and surface [74]. The influence of capillary condensation in FFM measurements was first studied by Binggeli and Mate [75], who found a substantial decrease of friction at 70% humidity on a hydrophilic silicon oxide surface. On less hydrophilic amorphous carbon films and lubricated silicon oxide, the decrease was not observed. Systematic studies of humidity dependence on mica were performed by Schumacher et al. [76]. The formation of an ordered layer of adsorbed water at 40% humidity led to a strong increase in friction. The Hertzian

dependence $F_L \propto F_N^{2/3}$ was also observed. However, friction decreased above 60%, probably because water acted as a boundary lubricant. Putman et al. [77] found out the relation $F_L \propto F_N^{2/3}$ on mica and glass in ambient conditions, whereas friction increased linearly with the normal load in N_2 or Ar atmosphere. This result was explained assuming that the tip roughness was smoothed by a condensed water film, which led to a single asperity contact at high humidity and to a multiasperity contact at low humidity. Capillary condensation leads also to different velocity dependences of friction on the nanometer scale. This effect is discussed in Section 6.3. We should also mention that friction in aqueous solutions depends on the pH [78, 79]. Thus, in principle, it might be possible to differentiate chemical species on a surface simply by changing the pH value of the surrounding medium.

4.3. Topographic Effects

Another factor to take into account when measuring friction with an atomic force microscope is the contribution of the topography to the lateral force signal, which in such a case is not simply proportional to the friction force acting on the probing tip. We have already seen how a surface with well-known local slope the topographic contribution can be used to calibrate the lateral forces (Section 2.2). This is not the case with rough surfaces, where the slope variations, combined with local variations of the contact area, can lead to ambiguous results. These problems have been addressed by Bhushan and co-workers [80, 81].

A particular topography effect is observed at the step edges of crystal surfaces. Meyer et al. [56] found a significant increase of friction at such locations on a NaCl surface in UHV. The same increase was observed when a step was crossed up- or downward (Fig. 11). This result states that the most important role is not taken by simple geometric effects, but by enhanced interaction at the step locations (*Schwöbel barriers*).

Figure 11. Friction image of NaCl. Increased friction is observed on the step sites, both going down and up the steps, which indicates that friction at the step edges is not dominated by geometric effects. 5. FRICTION ON THE ATOMIC SCALE

Friction forces on the atomic scale are characterized by a typical sawtooth behavior, which reflects the structure of the underlying lattice. This phenomenon is due to the stick-slip movement of the probing tip, and it can be well described by a classical model developed by Tomlinson in 1929 [10]. Theoretical studies of stick-slip on the atomic scale were reported by various groups [82–91]. Here, we first derive the main results of the Tomlinson model in one and two dimensions. Thermal effects, which slightly affect these results at room temperature, will be discussed in Section 5.2.

5.1. The Tomlinson Model

The motion of the AFM tip is ultimately related to the atomic structure of the surface and the elastic deformations of the cantilever. The shape of the tip-surface interaction potential, $U(x, y)$, depends on several factors like the chemical composition of the two materials and the atomic arrangement on the tip apex. For sake of simplicity, we will start the analysis in the one-dimensional case and consider a sinusoidal profile with the periodicity of the atomic lattice, a, and a peak-to-peak amplitude E_0. In Section 3.2, we have shown how the elasticity of the cantilever and of the contact area can be described in an unique framework introducing the effective lateral spring constant k_{eff}. If the cantilever moves with a constant velocity V along the x direction, the total energy of the system is then given by

$$E_{\text{tot}}(x, t) = -\frac{E_0}{2}\cos\frac{2\pi x}{a} + \frac{1}{2}k_{\text{eff}}(Vt - x)^2 \qquad (16)$$

Figure 12 shows the energy profile $E_{\text{tot}}(x, t)$ at two different instants. When $t = 0$ the tip is localized in the absolute minimum of E_{tot}. This minimum slightly increases with time due to the cantilever motion, until the tip position becomes unstable at a certain time $t = t^*$. The critical position x^* at $t = t^*$ is determined by equating to zero the second derivative $\partial^2 E_{\text{tot}}(x, t)/\partial x^2$, which gives

$$x^* = \frac{a}{4}\arccos\left(-\frac{1}{\gamma}\right) \qquad \gamma = \frac{2\pi^2 E_0}{k_{\text{eff}} a^2} \qquad (17)$$

The coefficient γ compares the strength of interaction between tip and surface with the stiffness of the system. The

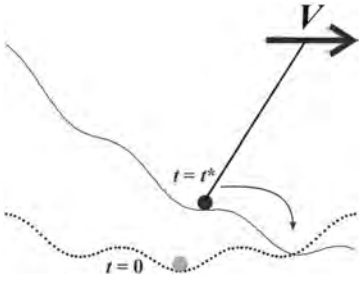

Figure 12. Energy profile experienced by the AFM tip (black circle) at $t = 0$ (dotted line) and $t = t^*$ (continuous line) The tip is dragged by the cantilever, which moves rightward with a constant velocity V. The tip does not move significantly until it suddenly "jumps" at the critical time $t = t^*$.

stick-slip is observed only if $\gamma > 1$ (i.e., if the system is not too stiff or the interaction is strong enough). In what follows, we assume that $\gamma \gg 1$, as usually observed in the experiments. When $t = t^*$ the tip suddenly "jumps" into the next minimum of the potential profile. Just before jumping, the lateral force is [92]

$$F^* = \frac{k_{\text{eff}} a}{2\pi} \tag{18}$$

Figure 13 shows the lateral force F_L as a function of the cantilever position, X. When the cantilever is moved forward, the lower part of the curve in Figure 13 is obtained. If, at a certain point, the direction of motion of the cantilever is suddenly inverted, the force follows the profile in the upper part of the curve. The area of the *friction loop* obtained by scanning back and forth gives the total energy dissipated. The slope of the *sticking* part of the loop is equal to k_{eff} [92].

In two dimensions, the energy of the system is given by

$$E_{\text{tot}}(\mathbf{r}, t) = U(\mathbf{r}) + \frac{k_{\text{eff}}}{2}(\mathbf{V}t - \mathbf{r})^2 \tag{19}$$

where $\mathbf{r} = (x, y)$ and $\mathbf{V}$ is the scan velocity. For example, Figure 14 shows the total energy corresponding to a periodic potential of the form

$$U(x,y) = -\frac{E_0}{2}\left(\cos\frac{2\pi x}{a} + \cos\frac{2\pi y}{a}\right) + E_1 \cos\frac{2\pi x}{a}\cos\frac{2\pi y}{a} \tag{20}$$

The stability of the equilibrium can be discussed introducing the Hessian matrix

$$H = \begin{pmatrix} \dfrac{\partial^2 U}{\partial x^2} + k_{\text{eff}} & \dfrac{\partial^2 U}{\partial x\,\partial y} \\ \dfrac{\partial^2 U}{\partial y \partial x} & \dfrac{\partial^2 U}{\partial y^2} + k_{\text{eff}} \end{pmatrix} \tag{21}$$

When both eigenvalues $\lambda_{1,2}$ of the Hessian are positive the position is stable. Figure 15 shows such regions for a potential of the form (20). The tip follows the cantilever adiabatically as long as it remains in the (++)-region. When the tip is dragged to the border of the region, it suddenly jumps into the next (++)-region.

Thus far we have implicitly assumed that the tip is terminated by only one atom. It is also instructive to consider the

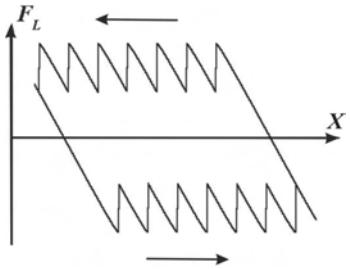

Figure 13. Friction loop obtained by scanning backward and forward. The slope of the sticking part of the loop gives the effective spring constant k_{eff}.

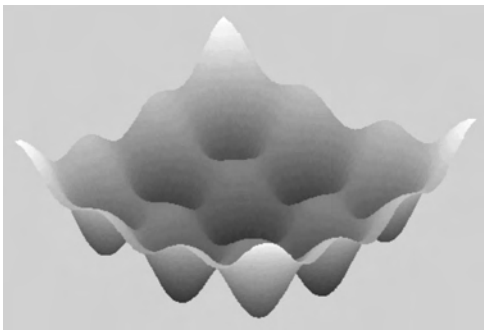

Figure 14. Energy landscape experienced by the AFM tip in 2D.

case of a periodic surface sliding on another periodic surface. In the *Frenkel–Kontorova–Tomlinson* (FKT) *model* the atoms of one surface are harmonically coupled with their nearest neighbors. Let us examine the case of quadratic symmetries, with lattice constants a_1 and a_2 for the upper and lower surface respectively (Fig. 16). In such a context the role of commensurability is essential. In one dimension Weiss and Elmer [94] predicted that friction should decrease with decreasing commensurability, the minimum of friction being reached when a_1/a_2 equals the *golden mean* $\bar{z} = 1 + (1 + (1 + \cdots)^{-1})^{-1} = 0.618$. In two dimensions Gyalog and Thomas [95] studied the case $a_1 = a_2$, with a misalignment between the two lattices given by an angle θ. When the sliding direction changes, friction increases from a minimum value corresponding to the sliding angle $\varphi = \theta/2$ to a maximum value, which is reached when $\varphi = \theta/2 + \pi/4$. The misfit angle θ is related to commensurability. Since the misfit angles giving rise to commensurate structure form a dense subset, the dependence of friction on θ should be discontinuous. The numerical simulations performed by Gyalog agree with these conclusions (Fig. 17).

5.2. Thermal Effects on Atomic Friction

Although the Tomlinson model gives a good interpretation of the basic mechanism of the atomic stick-slip, it cannot explain some minor features observed in the experiments.

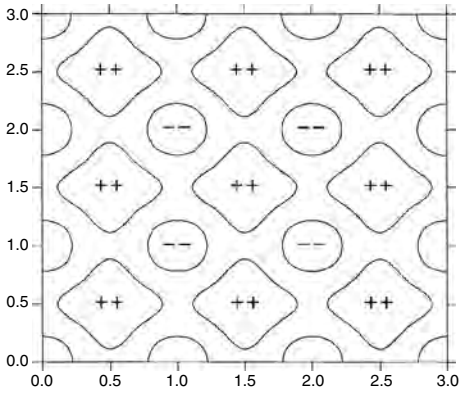

Figure 15. Regions on the (x, y) plane labeled according to the signs of the eigenvalues of the Hessian matrix (21) with the potential (20). Reprinted with permission from [93], T. Gyalog et al., *Europhys. Lett.* 31, 269 (1995). © 1995, EDP Sciences.

For example, the peaks of the friction loop shown in Figure 2a have different heights, which is not the case in Figure 13. Another effect is observed if the scan velocity V is varied. In Section 6.3 we will see that the mean friction force measured in UHV conditions increases with the logarithm of V (Fig. 18). Also this result cannot be interpreted without further assumptions in the model.

Let us focus again on the energy profile in Figure 12. At any time $t < t^*$, the tip jump is prevented by the energy barrier $\Delta E(t) = E(x_{\max}, t) - E(x_{\min}, t)$, where $x_{\max}(t)$ corresponds to the first maximum observed in the energy profile, and $x_{\min}(t)$ is the actual position of the tip (Fig. 19). The quantity ΔE decreases with time, or, equivalently, with the frictional force F_L, until it vanishes when $F_L = F*$. Close to the critical point the energy barrier can be approximated as

$$\Delta E(F_L) = \lambda(\widetilde{F} - F_L) \tag{22}$$

where $\widetilde{F} \approx F^*$. However, at a finite temperature T, the jump can occur *before* the critical value $F_L = F^*$ is reached [9]. The most probable value of F_L, when the jump occurs, is estimated with the *master equation*

$$\frac{dp(t)}{dt} = -f_0 \exp\left(-\frac{\Delta E(t)}{k_B T}\right) p(t) \tag{23}$$

In (23), p is the probability that the tip does *not* jump and f_0 is a characteristic attempt frequency of the system. Using

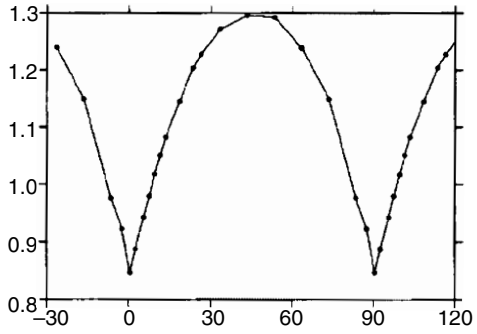

Figure 17. Friction as a function of the sliding angle φ in the 2D FKT model. Reprinted with permission from [95], T. Gyalog and H. Thomas, *Europhys. Lett.* 37, 195 (1997). © 1997, EDP Sciences.

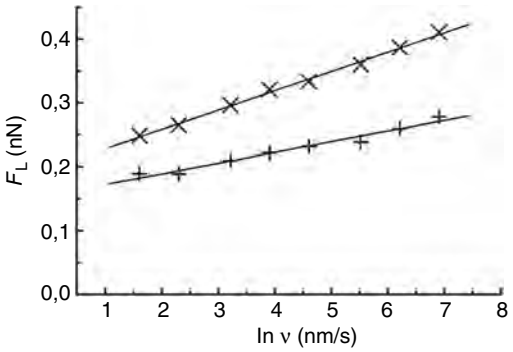

Figure 18. Mean friction force vs scanning velocity on NaCl(100) at $F_N = 0.44$ nN (+) and $F_N = 0.65$ nN (×). Adapted with permission from [9], E. Gnecco et al., *Phys. Rev. Lett.* 84, 1172 (2000). © 2000, American Physical Society.

the approximation (22) the condition of highest probability of jumping, $d^2p(F)/dF_L^2 = 0$, yields [9]

$$F_L(v) = F^* - \frac{k_B T}{\lambda} \ln \frac{V_c}{V} \tag{24}$$

with

$$V_c = \frac{f_0 k_B T}{k_{\text{eff}} \lambda} \tag{25}$$

Thus, the lateral force increases logarithmically with the sliding velocity. However, when the jump occurs very close to the critical point $x = x^*$ the approximation (22) does not hold. This is the case at high velocities, where the probability $p(t)$ does not change significantly, until it suddenly falls down to zero when $t \to t^*$. Thus, friction is expected to be constant at sufficiently high velocities, which agrees with the classical Coulomb's law. This topic is still under investigation.

5.3. Molecular Dynamics Simulations of Friction and Wear

Several authors interpreted sliding friction on the atomic scale with molecular dynamics (MD). Even if huge differences in time-scale make impossible a direct comparison between simulations and real experiments, MD simulations can reveal atomic mechanisms not directly accessible by experiment. Landman et al. [96, 97] predicted atomic-scale

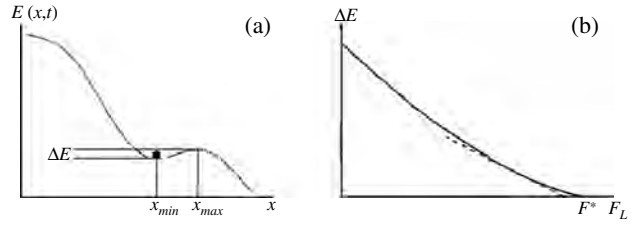

Figure 19. (a) The tip jump in the Tomlinson model at any time $t < t^*$ is prevented by an energy barrier $\Delta E(t)$. (b) Energy barrier ΔE as a function of the lateral force F_L. The dashed line close to the critical value corresponds to the linear approximation (22).

stick-slip for Si and CaF_2 tips sliding on surfaces of the same materials. Harrison et al. [98] observed stick-slip with a weak load dependence for two hydrogen-terminated diamond (111) surfaces, which is in a certain agreement with the experiments by Germann et al. discussed in Section 6.1. Sørensen et al. [99] predicted the occurrence of wear in the case of a copper tip sliding on Cu(100) surfaces (Fig. 20), whereas Cu(111) appeared more resistant. Even this conclusion was somehow confirmed experimentally (Section 6.1). Shluger et al. observed that the scanning process is accompanied by strong displacements of the surface ions inside the lattice and by their transient or permanent adsorption onto the tip at low loads (till 1 nN) [100–102]. Another simulation by Livshitz and Shluger [103] suggested that the adsorbed material adjusts itself leading to an effect of self-lubrication of the tip (Fig. 21). This result may explain why periodic structures can be observed experimentally also at rather high loads. Ohzono and Fujihira [104, 105] considered friction between an ordered organic monolayer of $n-$alkane molecules and a rigid slider with a single protuberance. Incommensurability and tip size comparable to the molecular size were found to be important conditions in imaging the molecular lattice.

A few MD simulations focused on the connection between friction and wear on the nanometer scale. Buldum and Ciraci [106] considered the processes of nanoindentation and sliding of sharp and blunt nickel tips on copper. In the case of the sharp tip quasi-periodic variations of the lateral force were observed, due to stick-slip involving phase transition. One layer of the asperity was deformed to match the substrate during the first slip and then two asperity layers merged into one through structural transition during the second slip. In the case of the blunt tip the stick-slip was less regular. Different mechanisms were observed when the tip is harder than the underlying sample. Komanduri et al. [107] considered an infinitely hard Ni indenter scratching single crystal aluminum at extremely low depths (Fig. 22). In such case a linear relation between friction and load was found, with a high coefficient of friction $\mu = 0.6$, independent of the scratch depth. Nanolithography simulations were performed by Fang et al. [108], who investigated the role of the displacement of the probing tip along the direction of slow

motion between a scan line and the next one. A certain correlation with FFM experiments on silicon films coated with aluminum was found. More complex simulations of nanoindentation are presented in [109–112].

6. FRICTION EXPERIMENTS ON THE ATOMIC SCALE

6.1. Experimental Overview

Figure 23 shows the friction map obtained by Mate et al. on graphite on the atomic scale [8]. The periodicity of the lateral force is the same as of the atomic lattice of the sample. The series of friction loops in Figure 24 reveal the stick-slip effect discussed in Section 5.1 The applied loads are in the range of tens of μN. According to the continuum models introduced in Section 3 these values correspond to contact diameters of 100 nm. A possible explanation for the atomic

features observed at such high loads is that graphite flakes were detached from the surface and adhered to the tip apex [113]. Another possibility is that the contact between tip and surface consisted of few nm-scale asperities and the corrugation was not entirely averaged out while sliding. The load dependence of friction found by Mate et al. was rather linear, with a small friction coefficient $\mu = 0.01$.

The UHV environment reduces the influence of contaminants on the surface and leads to more precise and reproducible measurements. Howald et al. obtained a series of results on ionic crystals with a home-built AFM apparatus in UHV [114]. In Figure 25 a friction map recorded on KBr(100) is compared with a theoretical map deduced from the 2D-Tomlinson model [115]. The periodicity $a = 0.47$ nm corresponds to the spacing between equally charged ions. No

individual defects were observed. This is a common aspect to all friction measurements on the atomic scale. One possible reason is that the contact realized by the probing tip is formed by many atoms, which superimpose and average their effects. Molecular dynamics simulations show that even a single-atom contact may cause rather large stresses in the sample, which lead to the motion of defects far away from the contact area. In a picturesque frame, Meyer et al. said that "defects behave like dolphins that swim away in front of an ocean cruiser" [116]. Howald et al. [117] detected atomic-scale friction on the reconstructed Si(111)7×7 surface. The observation of atomic features was only achieved after coating the tips with polytetrafluoroethylene, which has lubricant properties and does not react with the dangling bonds of Si(111)7×7 (Fig. 26). Bennewitz et al. [118] observed atomic stick-slip on metallic surfaces. Regular features were obtained on the closed-packed Cu(111), whereas sliding on Cu(100) produced irregular and irreproducible patterns (Fig. 27). Molecular dynamics suggested that wear occurs more easily on the Cu(100) [110]. This conclusion was achieved with copper tips in computer simulations. The assumption that copper covered the tip apex used in the experiment was supported by current measurements. Atomic stick-slip on diamond was observed by Germann et al. [120]

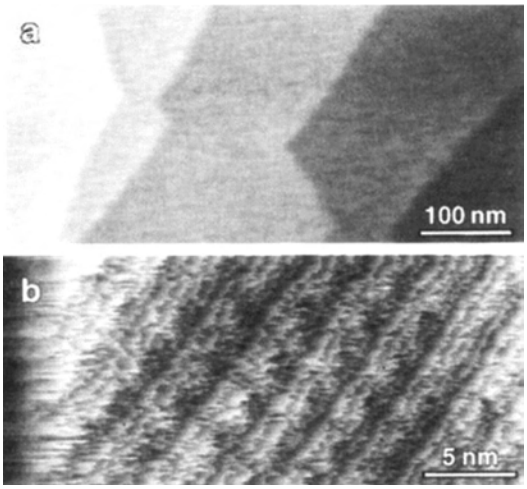

Figure 26. Topography and (b) friction image of Si(111)7 × 7 measured with a PTFE coated Si tip. Reprinted with permission from [117], L. Howald et al., *Phys. Rev. B* 51, 5484 (1995). © 1995, American Physical Society.

with an apposite diamond tip, prepared by chemical vapor deposition, and, a few years later, by van der Oetelaar and Flipse [121] with standard silicon tips. The values of friction had huge discrepancies corresponding to the presence or absence of hydrogen on the surface. Morita et al. [122, 123] measured friction on MoS_2 with a 2D-FFM apparatus, which could reveal forces even perpendicular to the scan direction. The features in Figure 28 correspond to a zigzag walk of the tip, which is consistent with the 2D-Tomlinson model [86, 87]. Analogous studies were conducted on mica and NaF [124]. The 2D stick-slip on NaF was detected with normal forces lower than 14 nN, whereas loads up to 10 μN could be applied on layered materials without damage. The zigzag walk on mica was also observed by Kawakatsu and Saito [125] with an original 2D-FFM with two laser beams and two quadrant photodetectors.

6.2. Friction Anisotropy

The importance of the misfit angle in reciprocal sliding of two flat surfaces discussed in Section 5.1 was first observed by Hirano et al. [126] in the contact between two mica sheets. Friction increased when the two surfaces formed

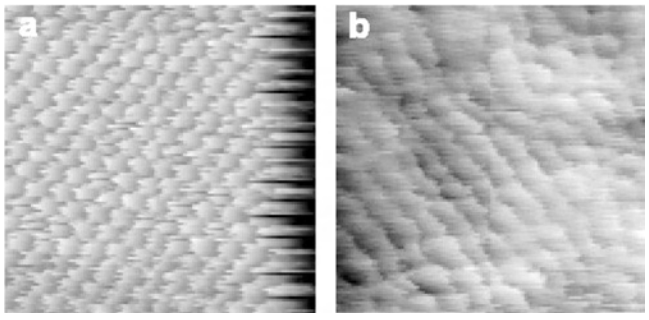

Figure 27. Friction images of (a) Cu(111) and (b) Cu(100). Frame size: 3 nm. Reprinted with permission from [119], R. Bennewitz et al., *Trib. Lett.* 10, 51 (2001). © 2001, Plenum Publishing Corporation.

commensurate structures, in agreement with theoretical results. In more recent measurements with a monocrystalline tungsten tip on silicon, Hirano et al. [127] observed *superlubricity* in case of incommensurability. Overney et al. [128] studied the effects of friction anisotropy on a bilayer lipid film and found that different molecular alignments resulted in significant variation of friction. Liley et al. [129] observed islands of a lipid monolayer on mica, consisting of domains with different molecular orientation (Fig. 29). The angular dependence of friction reflected the tilt direction of the alkyl chains of the monolayer revealed with other techniques. In their experiments on C_{60} islands (Section 4.1) Lüthi et al. found that friction is independent of the sliding direction. This was not the case in other experiments by Sheehan and Lieber [130], who observed that the misfit angle is relevant when MoO_3 islands are dragged on the MoS_2 surface. In such a case, sliding was possible only along low index directions. The weak orientation dependence found by Lüthi et al. was probably due to the large mismatch of C_{60} on NaCl. Another example of friction anisotropy is given by carbon nanotubes. A dramatic increase of friction was observed when a nanotube was moved in the directions corresponding to commensurate contact with a graphite surface [131].

6.3. Velocity and Temperature Dependence of Friction

The velocity dependence of friction was investigated relatively late. Zwörner et al. observed that friction between silicon tips and diamond, graphite, or amorphous carbon is

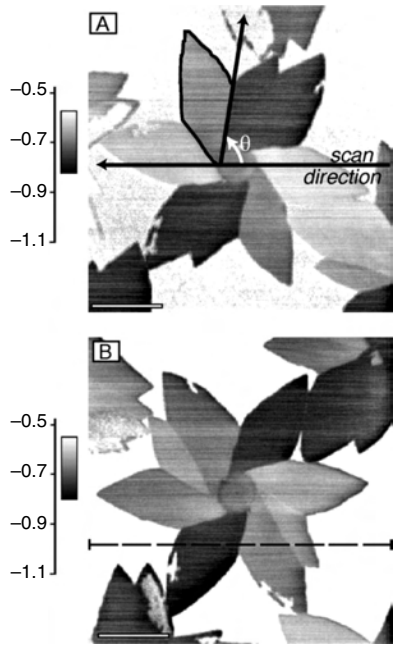

Figure 29. Friction images of a thiolipid monolayer on a mica surface. Reprinted with permission from [129], M. Liley et al., *Science* 280, 273 (1998). © 1998, American Association for the Advancement of Science.

constant with scan velocities, V, of few μm/s [132]. Friction decreased when V was reduced below 1 μm/s. On lipid films on mica, Gourdon et al. [133] found a critical velocity $V_c = 3.5$ μm/s, which discriminated between an increasing friction and a constant friction regime (Fig. 30). Although these results were not explained with thermal activation, we argue that the discussion in Section 5.2 gives the correct interpretative key. A clear observation of a logarithmic dependence of friction on the micrometer scale was reported by Bouhacina et al. [134] on triethoxysilane molecules and polymers grafted on silica with sliding velocity up to $V =$ 300 μm/s The result was explained with a thermally activated

Eyring model, which does not differ significantly from the model discussed in Section 5.2 [135, 136]. The first measurements on the atomic scale were performed by Gnecco et al. [9] and Bennewitz et al. [118] on sodium chloride and copper in UHV. In both cases a logarithmic dependence of friction was observed up to $V = 1$ μm/s, in agreement with Eq. (24). Higher values of velocities were not explored, due to the limited range of the scan frequencies accessible with the FFM on the atomic scale. Riedo et al. [137] realized the importance of the surface wettability in the velocity dependence of friction. A logarithmic increase in controlled atmosphere was only observed on hydrophobic surfaces. Hydrophilic surfaces, on the contrary, revealed a logarithmic *decrease* of friction with velocity, which was related to thermally activated nucleation of water bridges between tip and sample asperities. The rate of such a decrease depends drastically on humidity.

Thus far we have used thermal activation to explain the velocity dependence of friction. The same mechanism predicts also that friction should change with temperature. According to the master equation (23) the probability of a tip jump is reduced at low temperatures T until it vanishes when $T = 0$. In this limit case, thermal activation is excluded and the lateral force F_L is equal to F^*, independently of the scanning velocity V. Stick-slip processes at low temperatures have not been reported at our knowledge. However, a significant increase of the mean friction with decreasing temperature was measured by He et al. [138]. Neglecting the logarithmic contributions, Eq. (24) predicts $(F^* - F_L) \sim T$ for the temperature dependence of friction, which is in agreement with the experimental results.

6.4. Dissipation in Noncontact Atomic Force Microscopy

Energy dissipation is also observed when the AFM is operated in noncontact mode (NC-AFM); that is, the cantilever is excited close to its resonance frequency and the energy required to keep the oscillation amplitude constant is monitored [139]. The origin of this additional dissipation is manifold. Apparent energy dissipation may arise from inharmonic cantilever motion, artifacts from the phase controller, or slow fluctuations round the steady-state solution [140, 141]. Velocity dependent dissipation is observed in case of electric- and magnetic-field mediated Joule dissipation [142, 143]. Hysteretic dissipation due to atomic instabilities [144, 145] and hysteresis due to adhesion [146] can also play a role. Energy dissipation can be also measured by exciting the torsional oscillation of the cantilever [147]; in the future it is not excluded that the energy losses observed with FFM and NC-AFM will be considered in a unified frame. A detailed review of dissipation phenomena in noncontact force microscopy is given by [148].

6.5. Electronic Friction

The role of the electrons in friction processes was first suggested by Persson [149]. If small particles of mass m are adsorbed on a thin conducting film the electronic friction

force $F_{L,\mathrm{el}} = m\eta_{\mathrm{el}}v$ gives rise to an additional resistivity

$$\Delta\rho = \eta_{\mathrm{el}}\frac{mn_a}{(ne)^2 d} \tag{26}$$

where n is the number of conduction electrons per unit volume, n_a is the coverage of the adsorbed particles, and d is the film thickness. Experiments in agreement with this effect were performed by Krim et al. [37], who related the tribological properties of thin adsorbed films to changes of the Q-factor of a quartz crystal microbalance. In such way, it was found that slip times for ethane and ethylene monolayers adsorbed on silver and chemisorbed oxygen/silver surfaces are different, arguing that electronic contributions to friction should be considered whenever conducting surfaces are involved [150]. More recently, Dayo et al. [151] proved that friction of incommensurate N_2 on lead drops abruptly at the superconducting transition temperature $T_c \approx 5$ K, which was related again to an electronic contribution to friction. Further experiments are discussed in the review article by Mason [152].

7. WEAR ON THE NANOMETER SCALE

If the normal force F_N applied with the AFM exceeds a critical value depending on the tip shape and the material under investigation, the surface topography is permanently damaged. Among several examples of tip-induced wear of a surface [11, 65, 115, 153–158], wear of the tip was also reported [159, 160]. In some cases wear can be exploited to create patterns with well-defined shape. This is the subject of nanoindentation and nanolithography.

7.1. Nanoindentation

Nanoindentation is performed by increasing and then decreasing the normal load with a hard tip without scanning. The *Berkovich indenter*, formed by a three-sided diamond pyramid, is the most common tool for such a purpose. The indentation pit can be subsequently characterized with the AFM. *Nanohardness* is calculated by dividing the loading force by the projected residual area of the indentation. The geometry of the tip is the most important source of uncertainty in this kind of measurements [161]. Nanohardness tends to decrease when the normal load increases. However, hard and fragile materials react in a different way. For example, Bhushan et al. found that nanohardness falls when $F_N = 35$ mN for Si(111), but not on Si(100) [162].

Besides hardness, the Young's modulus can be obtained from the slope of the unloading curve [163]. A load-displacement curve obtained on Si(100) is shown in Figure 31. The hysteretic appearance means that deformation is not fully elastic. For compliant materials such as polymer blends, magnetic tapes, etc. both loading and unloading curves do not differ.

7.2. Nanolithography

If the AFM tip is scanned with high load, debris can be removed from the underlying surface. Although this technique does not differ from *ploughing* commonly used in agriculture, the results can be surprising when observed on the atomic scale (Fig. 3). Before discussing the few experimental results reported on such a level, we should mention here the importance of nanoscratching in realizing well-defined patterns thanks to the precise control of the tip movement made possible by the piezoelectric elements of the AFM. In such a way, for example, superconducting nanoconstrictions (*Josephson junctions*) [164], or surface quantum wells [165], were created.

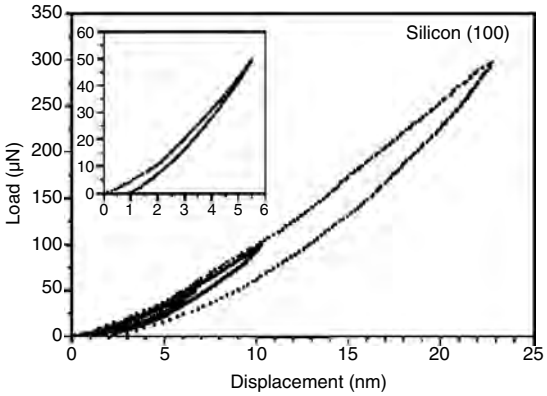

Figure 31. Load-displacement curves at different loads for Si(100). Reprinted with permission from [162], B. Bhushan et al., *Philos. Mag.* 74, 1117 (1996). © 1996, Taylor & Francis, Ltd.

The first atomically resolved images of the damage produced by scratching the AFM tip on an ionic crystal surface were reported by Gnecco et al. [11]. In Figure 3a a small mound grown at the end of a groove on KBr is shown under different magnifications. The groove was created a few minutes before imaging by repeated scanning with the normal force $F_N = 21$ nN. The image shows a lateral force map acquired with a load of about 1 nN; no atomic features were observed in the corresponding topography signal. Figure 3b shows that the debris extracted from the groove recrystallized with the same atomic arrangement of the undamaged surface. Although it is not straightforward to understand how the wear process was initiated and how the tip transported the debris, important indications are provided by the profile of the lateral force F_L recorded while scratching. Figure 32 shows some friction loops acquired when the tip was scanned laterally on 5×5 nm^2 areas. The mean lateral force multiplied by the scanned length gives the total

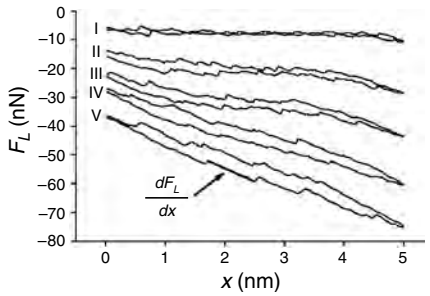

Figure 32. Friction loops acquired while scratching the KBr surface on 5 nm long lines with different loads $F_N = 5.7$ to 22.8 nN. Reprinted with permission from [11], E. Gnecco et al., *Phys. Rev. Lett.* 88, 215501 (2002). © 2002, American Physical Society.

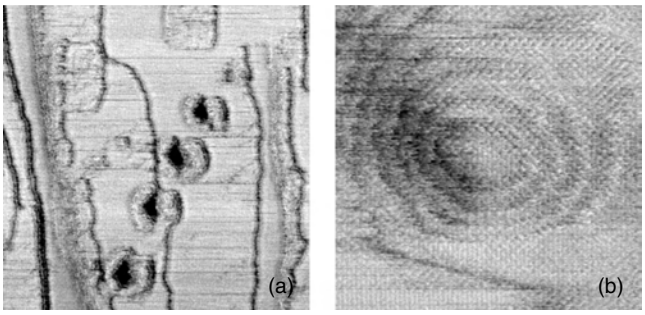

Figure 33. (a) Lateral force images of the pits produced with $F_N = 5.7$ to 22.8 nN. Frame size: 150 nm. (b) Detailed image of one of the pits with pseudo-atomic resolution. Frame size: 20 nm. energy dissipated in the process. The results of the tip movement are the pits in Figure 33a. Thanks to the resolution obtained in the lateral force images (Fig. 33b), the number of removed atoms can be directly estimated from the maps. This allowed us to evaluate that 70% of the dissipated energy went into wear-less friction. Figures 32 and 33 clearly show that the damage increased with increasing load. On the other hand, varying the scan velocity between 25 and 100 nm/s did not produce significant changes.

A different kind of wear was observed on layered materials by Kopta and Salmeron [166], who removed layers from a muscovite mica surface with the normal force $F_N =$ 230 nN (Fig. 34a). Fourier filtered images acquired on very small areas revealed the different periodicities of the underlying layers, which reflect the complex structure of the muscovite mica (Fig. 34b, c). To interpret their results, Kopta and Salmeron assumed that wear of mica initiates from atomic defects. When the defects accumulate beyond a critical concentration, they grow to form the scars shown in Figure 34. Such a process was once again related with

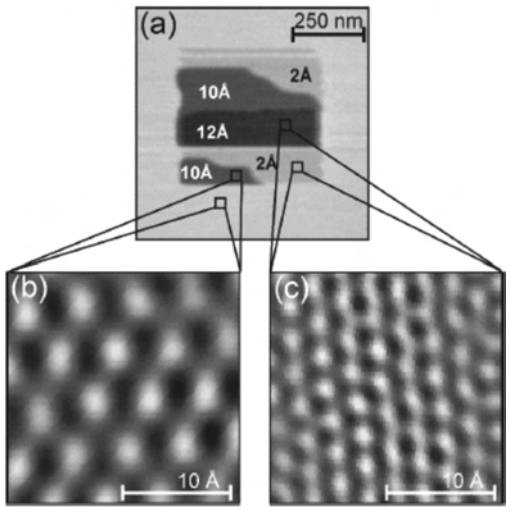

Figure 34. (a) Topography image of an area scratched on muscovite mica with $F_N = 230$ nN. (b,c) Fourier filtered images of different regions. Reprinted with permission from [166], S. Kopta and M. Salmeron, *J. Chem. Phys.* 113, 8249 (2000). © 2000, American Institute of Physics.

thermal activation. The number of defects created in the contact area $A(F_N)$ is [167]

$$N_{\text{def}}(F_N) = t_{\text{res}} n_0 A(F_N) f_0 \exp\left(-\frac{\Delta E}{k_B T}\right) \tag{27}$$

where t_{res} is the residence time of the tip, n_0 is the surface density of atoms, and f_0 is the attempt frequency to overcome the energy barrier ΔE to break a Si–O bond (this quantity depends on the applied load). When the defect density reaches a critical value, a hole is nucleated. The friction force during the creation of a hole was also estimated with thermal activation, which led to the formula [167]

$$F_L = c(F_N - F_{\text{off}})^{2/3} + \gamma F_N^{2/3} \exp(B_0 F_N^{2/3}) \tag{28}$$

The first term on the right gives the wear-less dependence of friction in the Hertz-plus-offset model (Section 3.1); the second term is the contribution of the defect production. The agreement between Eq. (28) and the experiment is clearly visible in Figure 35.

7.3. Tribochemical Wear

Like friction, wear is also influenced by the surrounding environment. Nakahara et al. [168] could induce degradation of the cleavage steps on the hygroscopic crystal $NaNO_3$ at humidity higher than 45%. Diatomic steps splat into monatomic steps and the material was dragged to the terrace above. After repeated scanning, rows of material were piled up. Humidity-dependent layer removal was also observed by Thundat et al. [169] on lead pyrophosphate by scanning at humidity >25%. In such a case the increase of capillary forces at high humidity was proposed as the wear mechanism, instead of the sample dissolution.

7.4. Metallic Nanocontacts

An interesting case of wear processes is provided by nanometer-sized metallic contacts under stress. If the contact is smaller than the mean free path of the electrons, the conductance is given by the Landauer–Buttiker formula [170]

$$G = \frac{2e^2}{h} \sum_k T_k \tag{29}$$

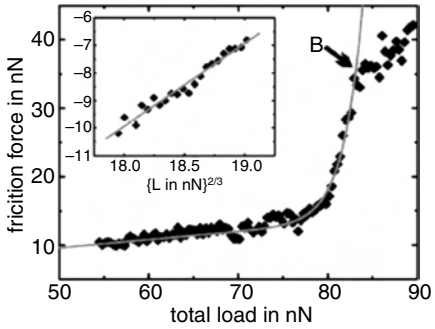

Figure 35. Friction vs load curve during the creation of a hole in the muscovite mica. Reprinted with permission from [166], S. Kopta and M. Salmeron, *J. Chem. Phys.* 113, 8249 (2000). © 2000, American Institute of Physics.

where T_k is the transmission probability for the kth electron conduction channel. The number of channels is proportional to the contact area, and T_k is close to 1, so that the conductance G is proportional to the contact area.

Rubio et al. [171] brought into contact a tip and a sample of gold to form a single asperity contact. A small bias voltage was applied and the current through the contact was measured. Figure 36a shows the conductance of a tip, which was pulled back from the sample after the formation of the contact, and Figure 36b shows the corresponding force. The conductance changes stepwise, and each step is associated with a relaxation in the normal force F_N, which, otherwise, increases elastically. Each jump can be associated with an atomic rearrangement of the contact, which changes the number of conduction channels.

8. CONCLUSIONS

We have emphasized the variety of friction and wear processes occurring in different physical systems, which have been investigated with the atomic force microscope. The unique capability to detect and control forces between a sharp nanometer-sized tip and a surface could reveal processes occurring on surfaces in motion down to the atomic scale, and a lot of information could be extracted also at a fundamental level (load and velocity dependence of friction).

Considering that it is practically impossible to report all the results currently obtained by friction force microscopy around the world, we mainly focused on some original experiments, which, in our opinion, led to a better understanding of friction and wear processes on the nanometer scale. The scenario can be extended by further readings from books and review articles on this subject [61, 116, 172–175].

Even if the experiments discussed constitute a significant breakthrough in our understanding of tribology, much work is still to be done. Subjects like temperature dependence of friction or friction changes in phase transitions require further investigation. The subject of friction and wear on the nanometer scale is extremely wide, and we believe that the observation of nature and the needs of technology will suggest new exciting experiments in this field.

GLOSSARY

Amonton's law The Amonton's law states that friction is proportional to the applied load. It is verified in macroscopic friction experiments.

Atomic stick-slip Mechanism in which the friction force between a sharp tip and a crystal lattice repeatedly builds up and then quickly slips at each atomic site.

Coulomb's law of friction The Coulomb's law of friction states that kinetic friction is independent of the sliding velocity. It is approximately fulfilled in macroscopic friction experiments.

Derjaguin-Muller-Toporov (DMT) model Model for contact and friction which includes the effect of asperity adhesion forces. The range of action of adhesive forces is assumed larger than the elastic deformation.

Frenkel-Kontorova-Tomlinson model Model for friction which considers a layer of atoms connected to a rigid upper plate via springs. The layer feels a spatially periodic potential. The plate is driven by a constant velocity.

Johnson-Kendall-Roberts (JKR) model Model for contact and friction which includes the effect of asperity adhesion forces. The range of action of adhesive forces is assumed smaller than the elastic deformation.

Maugis-Dugdale model Model for contact and friction which includes the effect of asperity adhesion forces. Its range of applicability lies inbetween the JKR and the DMT model.

Quartz crystal microbalance Piezoelectric transducer which allows a mass change to be converted into a resonant frequency change.

Surface force apparatus Device used to measure the interaction force between two macroscopic surfaces as a function of surface separation.

Tomlinson model Model for friction which considers a single atom connected to a rigid upper plate via a spring. The atom feels a spatially periodic potential. The plate is driven by a constant velocity.

Nanotribology of Carbon Films

F. L. Freire Jr., R. Prioli

Pontifícia Universidade Católica do Rio de Janeiro, Rio de Janeiro, Brazil

CONTENTS

1. INTRODUCTION

Amorphous carbon films are made of clusters of sp^2-hybridized carbon atoms, with typical size of 1 nm, connected to each other by sp^3-hydridized carbon atoms. The electronic and optical properties of these materials are mainly controlled by the size of the sp^2 clusters, while the mechanical properties are given by the degree of interconnectivity of the amorphous skeleton, that is, the fraction of sp^3-hybridized carbon atoms present in the matrix [1]. Film properties can be tuned by choosing the deposition technique with the appropriate deposition conditions. Among the different deposition parameters, the energy of the impinging ions plays the most important role and controls the sp^2/sp^3-hybridized carbon atoms fraction. In this way, films with properties typical of polymers, *polymer-like films*, or of graphite or diamond, *graphite-like* and *diamond-like films*, respectively, can be synthesized. On the other hand, the incorporation of elements such as nitrogen, silicon, or fluorine can optimize some of these properties [2] or even induce the formation of new nanostructured materials, such as the *fullerene-like* carbon films, films with strongly interacting curved graphene planes. The fullerene-like structure results from curving of the graphene planes induced by nitrogen incorporation and is similar to that found in carbon nanotubes and fullerenes [3].

The study of the nanometer scale of the physical phenomena related to the interaction of surfaces in contact and in relative motion, nanotribology, was made possible with the invention of the atomic force microscope in 1986 [4]. These phenomena are extremely important in situations like manipulation of atoms and molecules in surfaces, as well as in the operation of electromechanical devices. For example, it was recently demonstrated that the knowledge of the energy dissipation mechanism when an atomic force microscope tip scratches the surface of a hard film might be useful for surface chemical and mechanical modifications with high spatial resolution [5]. For complete understanding of the phenomena involved, basic studies on the friction laws in nanoscale are necessary. In the last decade, with the development of friction force microscopy, the study of wear and friction properties of the materials has received increasing attention [6, 7]. Despite this, the study of the lubricant and tribological properties of carbon-based films and other nanostructured materials is still in the beginning stages and deserves more work for a complete description of the tribological processes on the nanometer scale.

In the next sections, we will briefly review present knowledge on the properties and structure of amorphous carbon films as well as current applications. We will follow with a short discussion of the basic concepts involved in both atomic force microscopy and friction force microscopy. After that, we will discuss recent results on the tribological properties of carbon-based films. We will devote special attention to the effects of the incorporation of hydrogen and nitrogen into amorphous carbon (a-C) films.

2. AMORPHOUS CARBON FILMS

Carbon films are presently being used in a wide variety of applications. In particular, films deposited by magnetron sputtering, plasma-enhanced chemical vapor deposition (PECVD) and filtered cathodic vacuum arc (FCVA) are used as protective overcoats for automotive components, shaving blades, biomedical implants, and computer hard disks [1]. The use of hydrogenated carbon films as the interconnect dielectric in ultra-large scale integrated chips was also proposed [8]. In addition to these many applications, a-C films are materials with considerable interest from an intrinsically basic point of view, and they have been the subject of intensive research in the last three decades.

Since the pioneering work of Aisenberg and Chabot [9], hyperthermal (energies ~1–1000 eV) carbon-containing

Edited by H. S. Nalwa
Volume 7: Pages (899–917)

species have been extensively used for the synthesis of a-C films [10]. The subplantation model suggests that the deposition of hyperthermal species is a shallow implantation process, where the incorporation of carbon species in the subsurface layers followed by large internal stresses is the dominant mechanism, responsible for the formation of a sp^3 carbon rich dense phase, the diamond-like phase [11–13]. The energy of the impinging species plays the main role in the control of the carbon bonding hybridization. In fact, the evolution of the dense phase in a-C films occurs by a preferential displacement mechanism. It occurs when the incident ion energy is sufficient for the displacement of atoms with low displacement energy, E_d, the sp^2-hybridized carbon atoms, but it is insufficient for the displacement of high E_d atoms, the sp^3-hybridized carbon atoms. In subplantation, the increased density stabilizes sp^3 hybridization over sp^2 hybridization. For some experimental conditions, a-C films with up to 80% of carbon atoms with sp^3 hybridization can be obtained. These films are called tetrahedral amorphous carbon (ta-C) films and can be hydrogenated or not. For films deposited by FCVA using C^+ beams, the maximum fraction of sp^3 hybridization occurs at around 100 eV [14], which is in good agreement with subplantation model predictions [11].

Amorphous carbon films present important properties that are closely related to the film microstructure [15]. Following Robertson [1], the sp^3 bonds are responsible for the high hardness, which can reach ~80 GPa (Young's modulus of 700–800 GPa) in ta-C films grown by filtered arc and laser ablation methods, and because sp^2 bonds are weaker than sp^3 bonds, the respective π states of these bonds lie closer to the Fermi level, controlling the gap size and the optical properties of the materials. By choosing the deposition technique and the appropriate deposition parameters, the ratio between carbon atoms in sp^2 and sp^3 hybridization can be tuned and the film properties can be controlled.

The incorporation of hydrogen in the amorphous skeleton also plays an important role, as is illustrated in Figure 1. In this figure, a ternary phase diagram of the amorphous carbon–hydrogen system is presented. Besides the 100% sp^3 (diamond) and 100% sp^2 (graphite) phases, a-C films with the fraction of sp^3 bonding in the range between 5 and 80% can be produced. The hydrogen content of these films can vary from 0 to 50 at.%. The amorphous hydrogenated carbon (a-C:H) films can be deposited by both sputtering and PECVD techniques in a large range of sp^2/sp^3-hybridized carbon atom ratios. Depending on the deposition conditions, substrate-bias voltage, substrate temperature, pressure, and gas precursor atmosphere, they can be either diamond-like (sp^3-rich films) or graphitic-like (sp^2-rich films). However, a-C:H films with high H content (~50 at.%) and a high fraction of carbon atoms with sp^3 hybridization have a polymeric character. The region of larger H content is forbidden, because this corresponds to molecules, not a continuous network solid. Recently, it was shown that the subplantation model could be applied to describe the mechanisms of a-C:H growth by PECVD. In fact, the internal stress and hardness of a-C:H films deposited by radio frequency (rf)-PECVD in pure methane atmosphere show a dependence with the self-bias that is well described by the subplantation model. In this case, hardness and stress presenting

maxima at around −100 V of self-bias voltage, V_b, for films deposited at 1 Pa [16]. At this pressure the energy of the impinging ions is essentially eV_b, where e is the electron charge.

One way of changing a-C:H film properties is through the incorporation of different elements such as N, F, and Si during the film growth. The incorporation of Si, for example, stabilizes sp^3 carbon bonds and improves the thermal stability of a-C:H films [17]. The incorporation of fluorine in a-C:H films has also attracted interest in the last few years. Despite the remarkable lubricant properties of poly(tetrafluoroethylene), recent research on fluorine incorporation into a-C:H films is mainly motivated by its electrical characteristics. In fact, to improve the switching performance of future ultra-large scale integrated circuits, insulator films with dielectric constants lower than that of SiO_2 are needed to reduce the capacitance of interlayer insulators [8]. Fluorinated amorphous carbon (a-C:H:F) films have been proposed as possible candidates due to their low dielectric constant [18–22]. These films can be plasma deposited in a wide compositional range, the film fluorine content being determined primarily by the precursor atmosphere [19]. It has been found that the dielectric constant decreases with an increase in the F/H ratio of the precursor atmosphere for films deposited by PECVD [19]. However, the poor thermal stability of a-C:H:F films inhibits their application as a low K dielectric in semiconductor devices, because important thickness reduction was observed for annealing temperatures higher than 300°C [22]. Notwithstanding the interest in the dielectric properties of fluorinated amorphous carbon films, not much attention has been paid to the effect of fluorine incorporation on the mechanical and tribological properties of a-C:H films [23–26]. Similarly, the effect of ionic bombardment during a-C:H:F film growth has not been investigated in great detail [25, 27]. The incorporation of fluorine increases the film surface energy, and because

one makes the choice of the appropriate set of deposition parameters a hard, anti-adhesive, and low friction coating can be deposited with a high deposition rate [28].

In the last few years, an important portion of the research effort on a-C:H films was dedicated to the study of the nitrogen incorporation [29, 30]. The main purpose of this research effort was the intention to synthesize the β-C_3N_4 solid, proposed by Liu and Cohen [31], structurally analogous to β-silicon nitride (sp^3-carbon atoms bonded to sp^2-nitrogen) and with mechanical properties comparable to those of crystalline diamond. Many attempts to synthesize β-C_3N_4 samples have failed: high pressure–high temperature techniques produced only graphitic materials [32, 33], and the film deposition techniques usually produce amorphous films [34, 35]. In fact, only in a few cases was the presence of some small crystalline grains embedded in an amorphous matrix reported [36, 37]. In these cases, an electron diffraction pattern somehow related to the predicted one was obtained from those grains. The difficulties in synthesizing β-C_3N_4 were tentatively explained by molecular dynamics calculations showing that strong nitrogen incorporation into the amorphous carbon network catalyzes carbon undercoordination, which in turn causes the nitrogen to develop CN double and triple bonds [38]. Electron energy loss spectroscopy measurements support these calculations, because they show that nitrogen incorporation into amorphous carbon films, as also observed in amorphous hydrogenated carbon films [39], induces an increase in the fraction of carbon atoms presenting sp^2-hybridization [40]. Results provided by neutron and X-ray diffraction experiments also revealed that nitrogen incorporation induces a transformation of carbon hybridization from sp^3 to sp^2 states, with the presence of both C═N and C≡N bonds [41, 42].

Nitrogen incorporation into a-C:H films was found to modify the structure and properties of these films. Concerning the mechanical properties, a reduction on the internal compressive stress was observed, with minor changes in the mechanical hardness [43–45]. Concerning the modification of electrical and optical properties, it was found that nitrogen could electronically dope a-C:H films with the simultaneous reduction of the electronic defect density. This makes possible the use of a-C:H:N films as a semiconductor material [46, 47].

In an attempt to avoid the metastability of β-C_3N_4, a new approach was tried: the growth of superlattices involving very thin layers, a few nanometers thick, of carbon nitride and transition metal nitrides, the last one providing a lattice-matched structural template to seed the growth of the β-C_3N_4 phase. The production of a hard (~50 GPa) and fully crystalline carbon nitride composite material was claimed to be achieved [48, 49]. In a recent publication, a detailed structural characterization of this material was performed, but, unfortunately, despite the fact that the presence of sp^3-hybridized carbon was revealed by several analytical techniques, Raman and electron energy loss spectroscopies [50], it was not possible to clearly determine the presence of the β-C_3N_4 phase.

Despite the difficulties in synthesizing crystalline β-C_3N_4 or any other crystalline structure of carbon nitride, amorphous carbon–nitrogen films, a-CN_x, especially those deposited by reactive sputtering, are very interesting because of their application as protective coatings. In fact, a-CN_x films with hardness of ~20 GPa have been obtained by using different configurations of sputtering deposition systems: direct current (dc)- or rf-magnetron, ionized magnetron, and unbalanced dc-magnetron [51–53]. The substrate bias is the relevant parameter to optimize the mechanical and tribological properties of the films: a negative substrate bias is necessary for the production of hard a-CN_x films with improved tribological properties. The results of hard disk durability tests show that carbon–nitrogen coatings have greater wear resistance than pure argon-sputtered carbon films [54, 55]. As a consequence, a-CN_x films are currently being used as the protective coating on many commercial hard magnetic disk systems [56]. The effects of the substrate temperature on the film microstructure were also investigated. As a general rule, films deposited at low temperatures onto a floating substrate are amorphous, and the nitrogen content and the deposition rate decrease with increasing deposition temperature. Cuomo and collaborators [57], based on infrared (IR) absorption spectroscopy results, proposed a structure for a-CN_x films deposited by rf-sputtering onto a floating substrate that they called paracyanogen-like, a solid polymer form of cyanogen, —$(CN)_n$—. This material is formed by aromatic rings with C—N and C═N bonds, connected to hydrogen or CN radicals.

On the other hand, high-resolution transmission electron microscopy experiments performed on a-CN_x films deposited at temperatures higher than 250 °C revealed the presence of distorted graphite-like structures consisting of buckled and curved basal planes, giving rise to a fullerene-like microstructure [58]. Fullerene-like carbon (FLC) films with strongly interacting graphene planes have the unique properties of being hard and extremely elastic [3, 58]. The curving of graphene planes facilitates the formation of sp^3 bonds between intersecting graphene planes, resulting in a predominantly covalent sp^2 network. The highly elastic nature (up to 90% elastic recovery after indentation) of the FLC films makes it difficult to extract hardness values with the nanoindentation technique. However, the Young's modulus of FLC thin films measured using the surface acoustic wave method is approximately 500 GPa [3]. FLC films can be deposited using magnetron sputtering [58], laser arc [59], and localized high-pressure arc discharge (LHPA) [3]. In magnetron sputtering, high growth temperature (for formation of graphene sheets) and approximately 15% nitrogen in an $Ar + N_2$ atmosphere are required for the formation of the fullerene phase [58]. The presence of nitrogen in a hexagonal graphite lattice favors the formation of pentagons, inducing curvature in the graphene planes. In the laser arc and LHPA techniques, the *fullerene-like* structure results from the covalent interlinking of large fullerenes, nanotubes, and nanoparticles emitted from the cathode during the discharge.

Concerning the application of a-C films as tribological coatings, the protection of the hard magnetic disk deserves special attention, because it represents a unique combination of the latest technologies in tribology, thin film deposition, fluid mechanics, magnetism, and materials science. A schematic view of a hard magnetic disk is presented in Figure 2. With the recent development of magnetic

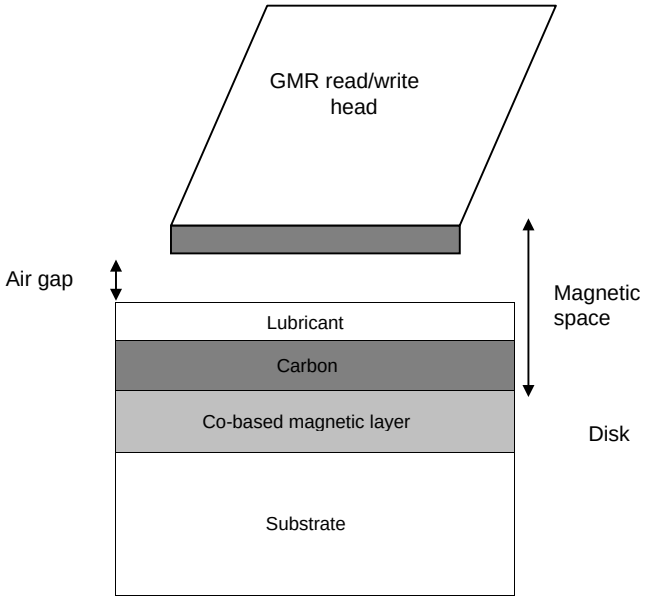

Figure 2. Schematic diagram of a hard magnetic disk and head.

devices, specially after the introduction of the magneto-resistive readers, the areal bit density in hard disks increased more than 60% a year, density that increased even faster in the last few years after the introduction of the giant magneto-resistive read technology. Today, even using a conservative approach, the goal of 100 Gbit/inch^2 could be achieved in less than 4 years from today [60]. As the recording density grows, reader stripe dimensions are vanishing. Head/magnetic media spacing must be reduced to achieve those densities. In fact, coatings that are around 1 nm thick will be needed, as shown in Figure 3, together with very restrictive conditions on surface roughness and lubricant layers. The spacing between the slider and the disk is steadily reduced and the disc revolutions per minute is heading toward 20,000 and beyond [61]. With the current load–unload technology, the overcoat is expected to provide some tribological protection together with protection against corrosion that requires a dense coating with low defect density. Under these conditions, drive performance improvement has to be necessarily combined with mechanical and tribological durability.

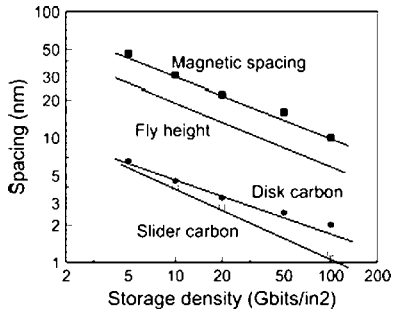

Figure 3. Variation of the carbon coating thickness on disk and sliders, the magnetic space, and the fly height with storage density. Reprinted with permission from [63], J. R. Robertson, *Thin Solid Films* 383, 81 (2001). © 2001, Elsevier Science.

Together with an important effort to extend to lower thickness the current coating technologies, that is, carbon nitride films deposited by pulsed magnetron sputtering [62], a lot of effort has been devoted to preparing a new generation of coatings, the ta-C films, based on mass selected ion deposition techniques [63], which are supposed to be able to fulfill all the requirements to achieve the goal of 100 Gbits/inch^2.

3. FORCE MICROSCOPY

3.1. Atomic Force Microscopy

A variety of instruments can be used to study friction, but it was after the invention of atomic force microscope (AFM)/friction force microscope (FFM) in the late 1980s that the field of tribology has gained new impulse. The force microscope has made possible the study of very low friction forces in a precise way. The instrument working principle of the AFM/FFM is very simple: a small tip is brought into contact with a surface, in a very controlled way, and scanned over the surface. While scanning, the normal and lateral movements of the microscope tip can be acquired. The normal movement of the tip is related by Hook's law to the normal force while its lateral movement, caused by the moment of the friction force acting on the tip–surface interface, is related to the friction forces.

In Figure 4, a typical AFM/lateral force microscope (LFM) scheme is presented. Usually, the samples are placed on the top of a piezoelectric tube ceramics that is going to control the lateral scan and the normal movements of the sample related to the tip. When scanning, the tip movement is measured by a position-sensitive photodetector. Although the top minus bottom (T – B) output from the detector is proportional to the tip normal displacement, the left minus right signal (L – R) is proportional to the torsion of the AFM tip. To keep the normal forces between the AFM tip and the sample constant during the scan, the T – B signal is compared with a reference value. Its difference, called error signal, is then used by the microscope feedback system to

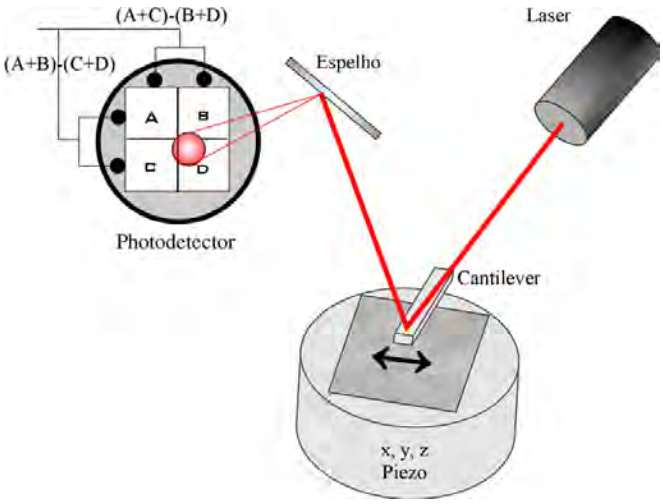

Figure 4. Schematic diagram of an atomic force microscope.

correct the distance between the tip and the sample, keeping the normal force constant during the whole image. If the feedback system is turned off, the piezoelectric ceramics are no longer moved in the normal direction, keeping the sample's height nearly constant. On this operational mode, the cantilever deflections are recorded as a function of the sample position. These two operational modes are then called constant force and constant height modes and have in common the fact that the total normal force, acting between the tip and surface atoms, is repulsive. In general, images with "low" resolution or large scan areas are performed in the force constant mode while high resolution images are acquired in the constant height mode. In Figure 5 we present two examples of these extreme cases and show an image obtained from an a-C film deposited by sputtering and an image obtained from a highly oriented pyrolytic graphite (HOPG) surface.

The AFM also has two additional modes that are called the noncontact and tapping mode. In both cases, instead of acquiring the direct bending of the cantilever tip, the amplitude, phase, or frequency from a mechanically vibrated tip is acquired. This signal is again compared with a reference value and its error is used by the feedback system to correct the sample height. While in the tapping mode the force sensed by the vibrated tip ranges from attractive to repulsive, in the noncontact mode the forces are predominately attractive.

A typical force curve obtained in an AFM is presented in Figure 6. In such an experiment, the sample is moved upward or downward with the use of the piezoelectric ceramics while the cantilever deflection is acquired. In region 1, the tip is far from the sample surface, thus no effective force is sensed by the AFM tip. As the sample is moved upward, that is, the distance between tip and sample decreases, the cantilever tip bends toward the sample (region 2), indicating that the forces between them are attractive. As the sample keeps moving upward, the tip comes close to the surface so that the net interaction force becomes repulsive (region 3). As the sample is moved downward, the tip remains in contact with the sample surface, due to its adhesion to the surface (region 4), until the force at the cantilever overcomes the tip–surface adhesion. The reader has to note that the attractive forces between tip and surface during its approach are caused mainly by Van der Waals forces, the repulsive forces are caused by the repulsion of the tip–surface atom's electronic clouds, and finally, the tip–surface adhesion is caused mainly by the capillary condensation of water between the tip and the surface.

As mentioned above, the tip movement can be translated into forces by Hook's law. Therefore, the calibration of the AFM cantilever and its displacement sensor for friction forces is essential for the successfully measurement of friction forces. First, the elastic normal bending and torsion constants of the cantilever have to be calculated, which is usually done with measurement of the cantilever's

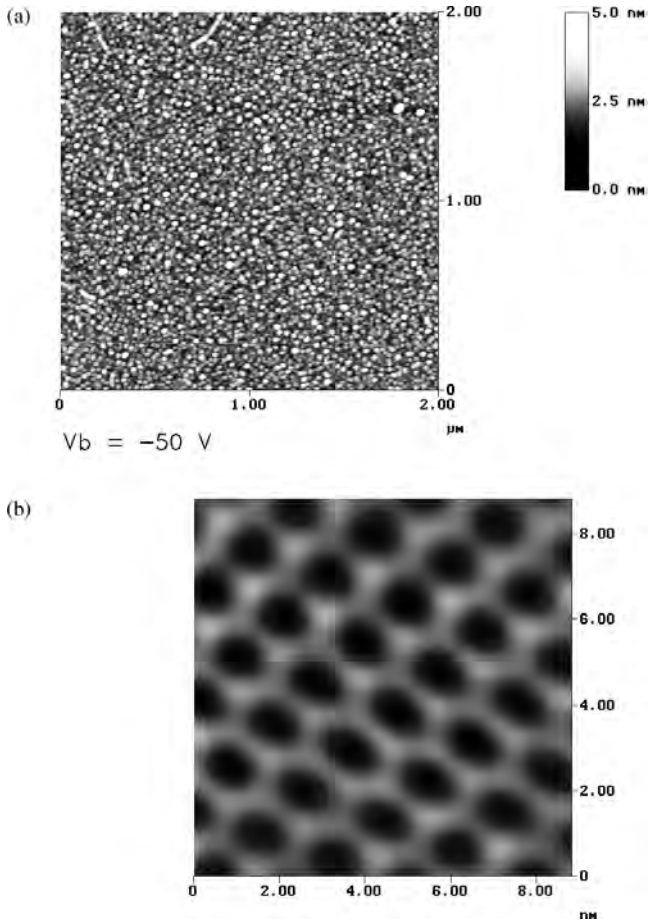

Figure 5. (a) Amorphous carbon film deposited by sputtering using bias voltage of −50 V and (b) boric acid single crystal (H_3BO_3) images obtained by the AFM.

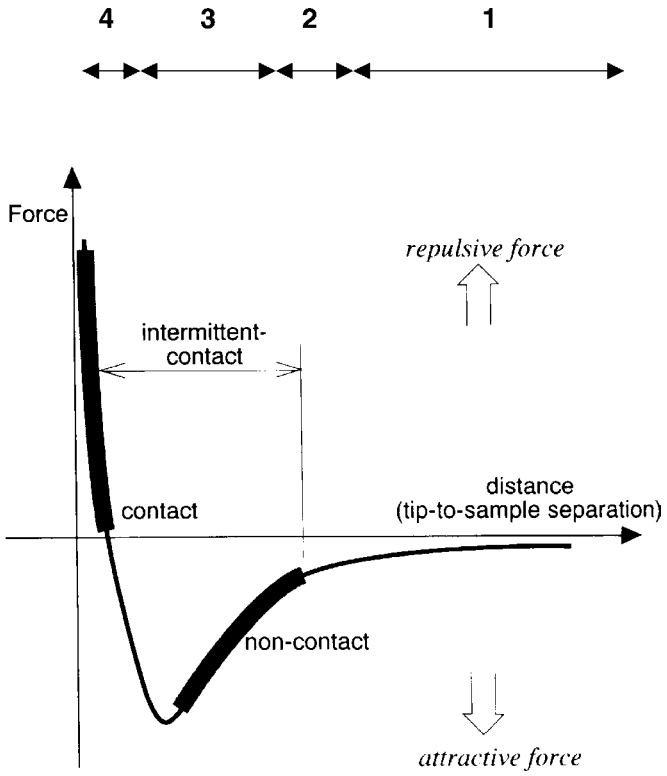

Figure 6. Typical force curve obtained with an AFM.

dimension by electronic microscopy and the use of a well-known static mechanics procedure [64]. Then, the displacement sensor can be calibrated to translate the normal and torsion bending angles in normal and friction forces [65].

3.2. Friction Force Microscopy

The energy that is dissipated at the interface when two materials are brought into contact and move with respect to each other is determined by the friction forces acting at the materials' interface. As defined, friction is always regarded as the force that opposes the movement of the surfaces. It was studied a long time ago by prominent scientists such as Leonardo da Vinci, Guillaume Amonton, and Charles A. Coulomb, among others [66]. They stated that friction is independent of the surface's contact area, that it is proportional to the normal forces acting between the surfaces, and that the kinetic friction is independent of the surface's relative velocity. Unfortunately, these laws seem to be no longer valid.

As observed by Mate et al. [67], the lateral movement of the scanning tip on a surface is shown to follow an atomic scale stick and slip behavior. The result obtained from a HOPG surface is shown in Figure 7. Here it was shown how the frictional force behaves during the stick and slip process as the surface is rastered in the xy plane. In this experience the sample is moved back and forth with the velocity of 40 nm/s in the x direction and 0.2 nm/s in the y direction. The critical friction force before the first slip occurs varies, depending on the position of the tip with respect to the graphite lattice. The slips occur where the image suddenly changes from bright to dark. Figure 7 clearly illustrates how the atomic structure of the surfaces influences the frictional properties of the tip–surface interface. The image shows the periodicity of the HOPG surface potential.

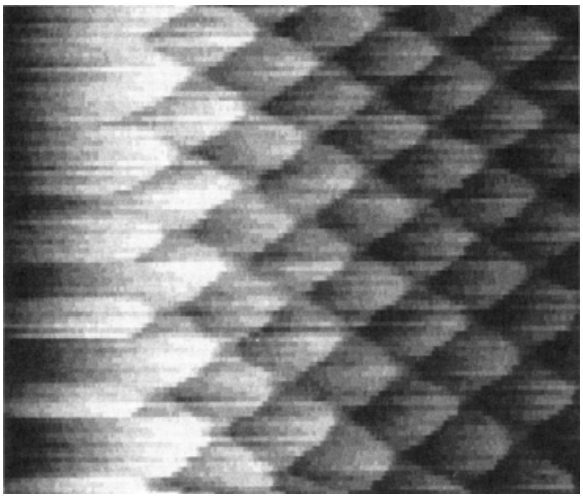

Figure 7. The frictional force in the x direction as a function of x and y. The intensity of the image is scaled to the friction force with the bright areas corresponding to 1.8×10^{-6} N. Only scans in the left-to-right direction are shown. The size of the image is 2 to 2 nm^2, and no correction from piezoelectric scanners was done. The load is 5.6×10^{-6} N, and the wire spring constant is 2.5 kN/m. Reprinted with permission from [67], C. M. Mate et al., *Phys. Rev. Lett.* 59, 1942 (1987). © 1987, American Physical Society.

The atomic scale stick and slip is believed to be responsible for the energy dissipation at the tip–surface interface. In such a case, a mechanism introduced by Tomlinson in 1929 [68] can be used to explain the energy dissipation. He proposed that some irreversible process in the passage of one atom past another must exist to explain the energy dissipation in pure conservative potentials.

The stick–slip movement of the scanning tip can be simulated in either one or two dimensions. Usually, a simple oscillator model as proposed by Tomlinson is used to simulate the FFM images in which the microscope tip slides over the corrugation of an atomically flat surface. This has been mainly performed in periodic potentials, generally described by sinusoidal potentials [69]. The calculations show that the FFM images present the surface potential periodicity instead of atomic resolution [70] and that the cantilever stiffness and scanning direction are important to the friction force images [71, 72]. The movement of the microscope tip can be understood by an analysis of the system's potential energy [6, Chap. 4]. The tip sticks in a surface minimum, until the elastic force in the tip–surface system overcomes friction. Then the tip jumps directly to the next surface minimum, leading to an atomically periodic stick–slip movement, as represented in Figure 8. As a consequence, only part of the surface potential is probed by the microscope tip, leading to images that contain only the periodicity of the analyzed surface. Recently, it has been shown that the FFM resolution is governed by the quotient between the average potential interaction energy and the average elastic energy stored on the tip before the jumps. It was also shown that there is an optimal velocity with which the scanning tip better senses the surface potential [74].

Studies on the influence of the normal force on friction revealed that at low normal forces, in contrary to what is observed in the macroscopic scale, the friction forces strongly depend on the real tip–surface contact area [75]. Friction is observed to be proportional to the contact area,

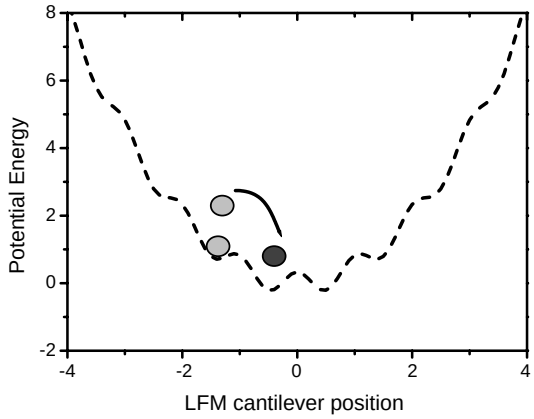

Figure 8. The system's total potential energy as a function of the LFM cantilever position. The dashed and solid lines represent the potential, while the gray and black dots represent the microscope tip position. Note that, as the cantilever is scanned, its tip gets pinned in a local surface minima (dashed line) until the elastic energy is high enough to overcome the friction barrier (solid line). Thus, the tip slides to the next surface minima (gray → black balls).

and the proportionality coefficient is defined as the interface shear strength. It has been shown by Kaneko et al. [76] that, if the microscope tip does a multiasperity contact with a surface, the dependence of friction with the normal force becomes linear because the contact asperities can increase with an increase in the normal force. They have also shown that if the tip does a single asperity contact with the surface, the relations between the friction and the normal forces are no longer linear. A change from multi-asperity to single asperity contact is shown to be caused by the capillary condensation of water on the microscope tip.

The influence of the environmental conditions on the friction experiments is not restricted to changes in the kind of tip sample contact. The role of water condensation was investigated in detail for silicon wafers, and the results for the friction forces revealed the importance of the surface energy in defining the thickness of the water film and its effects on the friction forces [77]. It was shown by Riedo et al. [78] that the capillary condensation of water strongly influences the dependence of friction on the scanning velocity. The formation of a capillary bridge increases the adhesion between the tip and a surface, leading to an increase in the force necessary to move the tip with respect to the surface. As the scanning tip moves faster, the time that the system has to built up the capillary decreases, leading to a decrease in the force necessary to move the tip on the surface.

In fact, the dependence of friction on the scanning velocity may be explained with a combination of three different models. At very low scanning velocity ($v \to 0$), the energy dissipation is shown to be mainly caused by the nonlinear dynamics of the moving parts [79–81]. At higher velocities, friction is shown to present a logarithmic dependence with velocity. This logarithmic dependence is explained by a combination of thermally activated stick–slip behavior [82, 83] and the kinetics of nucleation of water bridges between the moving parts [78]. In force microscopy the main energy dissipation process that is believed to occur when the tip is scanning on a surface is phononic excitation. Whereas at very low scanning velocities, the nonlinearity of the tip motion together with the coupling of its 2 degrees of freedom, is responsible for the energy exchange between its vibration modes [84, Chaps. 1, 6, and 7], at higher velocities, the discontinuous nature of the sliding tip movement is able to excite the normal modes of vibration on the scanned surface, raising its temperature.

4. NANOTRIBOLOGY RESULTS

4.1. Adhesion

When two surfaces in vacuum or in a gaseous environment come close, they usually experience attractive forces, such as Van der Waals forces. Once in contact, they are inevitably deformed because of their finite elasticity. Contact between two solid bodies can be described by the model of Johnson, Kendall, and Roberts (JKR) [85] or by the model of Derjaguin, Muller, and Toporov (DMT) [86]. Both models are based on an earlier analysis by Hertz [87], who considered two elastic bodies in contact under an external load but ignored attractive forces. In the JKR approach, the effective steady-state pressure in the contact area is assumed to be the superposition of the elastic pressure and of the attractive surface forces, which acts only over the contact area. As a result, a tensile force is necessary to separate the adhering surfaces. For two spherical particles this pull-off force is given by

$$F_{\mathrm{JKR}} = 3\pi R\gamma \tag{1}$$

where γ is the effective solid surface energy and R is the reduced radius of curvature of the two surfaces ($R = R_1 + R_2/R_1R_2$).

The DMT model is an alternative model that also accounts for noncontact forces in the vicinity of the contact area. It predicts a slightly higher pull-off force of

$$F_{\mathrm{DMT}} = 4\pi R\gamma \tag{2}$$

Both models are limiting cases of a more general description [88]. The JKR model is appropriate for large, soft bodies with high surface energy, and for hard solid bodies with low surface energy, the DMT model should be applied [89, 90].

For an AFM tip interacting with a carbon film surface, we can model the tip–surface interaction as a sphere contacting a flat surface, the DMT theory describes the adhesion force as

$$F_{\mathrm{ad}} = 2\pi R W_{\mathrm{ad}} \tag{3}$$

where R is the radius of curvature of the sphere and W_{ad} is the work of adhesion defined as

$$W_{\mathrm{ad}} = 2(\gamma_{\mathrm{tip}}\gamma_{\mathrm{surface}})^{1/2} \tag{4}$$

where γ is the surface free energy of the tip and of the surface [91]. From this model it is seen that adhesion forces scale directly with the radius of curvature of the tip. Therefore, to correct for changes in tip geometry and to probe the inherent properties of the carbon film surface, one needs to normalize the adhesion forces by the radius of curvature of the AFM tip [92].

When two surfaces come in contact, contact occurs on a large number of asperities. To develop a fundamental understanding of friction and wear mechanisms in lubricated contacts, experiments in a single asperity contact need to be conducted. The development of the atomic force makes possible the investigation of the adhesion forces and its influence on the tribological performance of coatings in a single asperity contact regime.

One of the first discrepancies between the macroscopic behavior and the friction on the nanometer scale was revealed by studies designed to investigate the dependence of friction forces with the contact area. The fundamental friction law, first proposed by da Vinci and reproposed by Amonton more than three centuries ago, can be written as

$$F_F = \mu F_L \tag{5}$$

where F_F is the friction force, μ is the friction coefficient, and F_L is the normal load force. The friction coefficient is constant for a given pair of materials in a wide range of

loads and independent of the apparent contact area. This condition is fulfilled when the contact area, A, is proportional to the normal load. It was shown that for rough surfaces (multiasperity contact) in an elastic regime, it occurs if the asperities follow a statistical height distribution [93–95]. Moreover, when the normal load increases and plastic deformation occurs, an increase of the contact area is verified so that the relation contact area, $A \sim F_L$, remains valid and so follows Amonton's law.

In a single-contact regime the situation is different. In fact, load-dependent studies of frictional properties of graphite, diamond, amorphous carbon, and fullerene thin films were performed in argon atmospheres and ambient conditions by Wiesendanger and collaborators [96] using specially prepared silicon tips with well-controlled tip point shape and radius. Their results reveal that in the low load regime, that is, in a regime where wear and plastic deformations can be neglected, the friction force did not follow direct dependence with the applied load. The data were explained using a theoretical model based on a Hertzian-type tip–surface contact, which predicts a dependence of the contact area with the normal force of $A \sim F_L^{2/3}$ [87]. With this result, the authors show that friction is proportional to the contact area and that the shear stress was constant within the applied pressure, leading to a $F_F \sim F_L^{2/3}$ dependence of the measured frictional forces. These experiences showed that single asperity contact mechanical models are valid for tip radii down to a few nanometers, at least when the tip has a well-defined tip–surface contact area. In nanoscale the normal force must take into account the attractive adhesion forces

$$F_N = F_L + F_a \tag{6}$$

where F_N is an effective normal force that takes into consideration both the normal load F_L and the adhesion force F_a. The adhesion force is taken as the maximum negative bending force of the cantilever on the tip approach curve.

Many experimental works are devoted to determination of the adhesion forces in carbon film surfaces and many other surfaces [92]. In a pioneer investigation, Binggeli and Mate [97] showed that the adhesion force measured in different ambient, relative humidities ranging from 80 to 98%, can be considered as a constant for a-C films deposited by sputtering.

The effects of hydrogen on adhesion force of a-C:H films were carefully investigated by Perry and collaborators [98]. They showed that the adhesion force increases with the hydrogen content in films deposited by sputtering in Ar–H_2 atmospheres. Because they used a tip with the same chemical composition, oxidized tungsten in this case, they concluded that the observed increase arises from an increase in the surface free energy of carbon films that follows the hydrogen content in the films. The friction coefficient measured in the same samples also increased with the hydrogen content, following the adhesion force behavior.

The effect of nitrogen incorporation was also investigated for films deposited by ion beam sputtering using a second argon beam as an assistance beam [55]. The authors, using an AFM with a Si_3N_4 tip, operating in air, showed an increase from 25 to 32 nN for adhesion forces measured in a-C and a-CN_x films, respectively. Despite higher adhesion at the interface, a-CN_x films showed a smaller friction coefficient than did a-C films—0.14 and 0.28, respectively. The contact radius calculated using the Hertz model was about 0.2 nm and almost equal for both coatings. The authors concluded that the shear strength of CN_x was lower than that of carbon and could partially explain why friction is lower in CN_x than in carbon films.

4.2. Friction

As previously mentioned, the laws that control the friction at the macroscopic scale are well known: the friction force (F_F) increases with the applied normal load (F_L) and it is independent of both the contact area and the velocity [66]. The studies carried out since the invention of the friction force microscope reveals that some of these laws are no longer valid on the nanometer scale. To investigate this new experimental domain, the study of carbon-based materials occupies a special place. A recent review of tribological properties of carbon films shows that, in all environments, the macroscopic tribological behavior of these films was controlled by an interfacial graphitic transfer layer formed during friction [99]. However, in nanoscale, those energy-dissipating mechanisms are far from being well understood. Some authors claimed that the dissipation of friction energy could take place by phonon excitation [100]. A second proposed mechanism takes into consideration the dissipation via electron–hole pair excitation [101]. Amorphous carbon films represent a remarkable opportunity to investigate friction mechanisms because materials with different microstructures, the sp^2/sp^3 ratio, for example, can be easily synthesized.

The FFM experiences showed that single asperity contact mechanical models are valid for tip radii down to a few nanometers, but only when the tip has a well-defined tip–surface contact area. These experimental results also show that, in nanoscale, the normal force must take into account the attractive adhesion forces; that is, $F_N = F_L + F_a$. Wiesendanger and collaborators [96] show that, for measurements performed in argon atmospheres, the friction in C_{60} films is higher than those for a-C films and diamond surfaces. In ambient air, the friction is higher than friction forces measured in a water-free ambient. For atmospheric exposed surfaces, a-C films have friction higher than that for diamond. In both cases, the lowest friction forces were always determined for HOGP samples.

Following this first work, several other groups performed a comparative study of the friction properties of different carbon-based films. Among them we mention the investigation performed by Riedo and collaborators [102]. They studied diamond-like films with different fractions of sp^3-hybridized carbon atoms and CN_x films with different contents of nitrogen ($0.2 < x < 0.3$), both deposited by laser ablation. The Raman results obtained from the samples show that, depending on the laser fluence, the content of sp^3 hybridization can be controlled, and it is higher for films deposited at the higher power laser in a nitrogen-free atmosphere. These films have 53% sp^3-hybridized carbon atoms and are called diamond-like carbon (DLC). The FFM measurements were performed in ambient conditions using a

silicon nitride tip. To avoid plastic deformation, the loads were restricted to 20 nN.

As was observed before by Bushan and Sundarajan [103, 104], the topographical images of CN_x and a-C films obtained simultaneously with the friction force images revealed that the friction forces map essentially follows the surface topography, as can be seen in Figure 9. In this figure the topographical image of a CN_x film was compared with the friction image in the forward and backward scan direction taken simultaneously. In Figure 10, we show the friction forces for HOGP, CN_x, and DLC films for an applied load of 12 nN. The figure shows the forward and backward scans with the friction force being proportional to the difference between the two. It is clear from the figure that the friction force in HOPG is by far the lowest one and that the friction force measured on the CN_x film is of the same order of magnitude as the one obtained from a DLC, but slightly lower. The authors claimed that the friction forces obtained from a-C films with sp^3 fractions in the range of 34–53% are equal within experimental errors. Similar behavior was observed for CN_x films with different nitrogen content; that is, in this case the friction forces are independent of the amount of nitrogen incorporated in the films.

The investigation of the friction force as a function of the normal load reveals that CN_x film results show linear dependence between the friction force and the load force, indicating a multiasperity contact, while the results obtained from a-C films nicely follow a two-thirds power law, $F_F \sim F_N^{2/3}$, as expected from a single asperity contact. Because a similar silicon nitride tip is used in all instances, the differences observed between DLC and a-CN_x films can be attributed to the lower surface roughness of the former. Because on nanoscale the Amonton's law $F_F = \mu F_L$ is no longer valid, the friction coefficient defined in that way is not well suited for comparing tribological behavior of different materials in the case of single asperity contact. The friction coefficient was determined by the linear regression of F_F versus F_N, that is, taking into account the adhesion forces, and the following results were obtained: $\mu = 0.009 \pm 0.003$ for HOPG, $\mu = 0.167 \pm 0.03$ for CN_x films, and $\mu = 0.208 \pm 0.03$ for DLC films. These results seems to support the phonon mechanism as the dominant one for energy dissipation, because the friction coefficient in DLC films is independent of the sp^3 fraction films, and, more important, the DLC films have

a higher friction coefficient compared with HOPG. If an electron–hole excitation mechanism played an important role, the opposite behavior should be expected.

Thin CN_x films, 1–10 nm thick, deposited by ion beam-assisted deposition (IBAD) were investigated by friction force microscopy [105]. Raman spectra from these films are quite similar to those obtained from films deposited by laser ablation and mentioned previously, suggesting the same microstructure [102]. Forward–backward scan cycles were obtained and the friction coefficient determined in the wear-less regime (load of 1 μN) is on the order of 0.12, a value that increases to 0.22–0.24 for higher loads (10 μN). No thickness dependence was observed in the range of 1–10 nm. These values for the friction coefficient were on the same order as the previous ones. Khurshudov et al. [55] using an AFM equipped with a silicon nitride tip (10–20 nm radius) also measured the friction forces for a-CN_x ($x = 10$ at.%) films deposited by IBAD. The measurements were performed at a velocity of 10 μm/s and at ~60% of relative humidity and show that the friction force measured for a-CN_x films was systematically 20% lower when compared with the friction force measured in a-C films deposited by the same technique, confirming the general trend showing that the friction force (or friction coefficient) measured in CN films is slightly smaller compared with the values obtained from a-C films deposited with the same technique using similar deposition conditions.

Films with different contents of nitrogen deposited by PECVD, a-C:H(N) films, were also investigated by friction force microscopy using a silicon nitride tip with measurements performed in air [106]. The results are summarized in Figure 11. It is clear from this figure that, despite a substantial increase of the sp^2 fraction upon nitrogen incorporation (data taken from Ref. 107), the friction coefficient is constant, supporting the idea that phonon excitation is the dominant energy dissipation mechanism. The increase in film surface roughness with the increase of the sp^2 fraction was observed before for a-C films deposited by C^+ beams [108] and seems to play a secondary role in the definition of friction forces in this case.

A comparative FFM study of a-C films deposited by different techniques was carried out by Sandararajan and Bushan [109]. Films deposited by electron cyclotron resistance (ERC)–chemical vapor deposition (CVD) using ethylene as a precursor gas, rf sputtering of a graphite target in argon atmosphere, FCVA, and direct ion beam deposition from methane dissociation were studied. The results for the friction coefficient were obtained with a diamond tip at a 4 μm × 4μm scan size in a load regime where no wear was observed. The results for friction coefficients were determined for films with thickness in the range of 3.5–20 nm. The thinner films have higher friction coefficients independent of those deposited using the same technique. These results contradict the results obtained by Bai et al. [105] for CN_x films mentioned above. The systematic investigation of the coating failure by the AFM topography image reveals the direct correspondence between high friction and coating failure area. This problem is critical in the case of sputtered carbons films, where reliable coatings with thickness below 5 nm could not be obtained.

The fundamental laws of tribology predict that the friction is independent of the velocity. Friction force microscopy measurements on carbon-based compounds have also been performed to investigate this question on the nanometer scale. In a first report, Zwörner et al. [110] determined that the friction forces are constant over a wide range of velocities. Metal-containing carbon films, Me–C:H, with Me = Au and W were also investigated, and the results show that in the range of 0.1–10 μm/s, the friction force measured by the FFM is constant [111]. In another investigation, constant friction coefficients were reported for ta-C and FLC films in the velocity range of 0.1–40 μm/s [112]. The results are shown in Figure 12. In this case, the ta-C films were deposited by FCVA while the fullerene-like carbon films were deposited using an unfiltered LHPA discharge,

introducing the carrier gas (nitrogen) via a 1 mm hole in the graphite (99.99% purity) target. The friction force measurements were carried out using an AFM operated in the friction force regime. The friction force (forward and reverse cycles) images were acquired at constant normal load, and the total normal force is composed of the adhesion force between tip and sample surface and the applied load. The cantilever-bending constant and the calibration method proposed by Liu et al. [66, 113] were used to obtain the absolute values of the friction coefficients. Nanostructured carbon films deposited by supersonic cluster beam were also studied by friction force microscopy [114]. These clusters have a fullerene structure and linear and planar structures [115]. The friction coefficients reported are in excellent agreement with the values obtained for FLC films [112]—$\mu = 0.12 \pm 0.2$—considering that the values reported for the nanostructured films depend on the region of the sample and the size of the clusters and varies from 0.10 to 0.14, the higher value being obtained from films deposited with the larger clusters.

Gnecco et al. [83] determined a logarithmic increase of the friction force with the velocity for ultrahigh vacuum friction force microscopy measurements performed on NaCl (100) single crystals. These results were interpreted in terms of a thermally activated stick and slip behavior and the friction being due to the cohesive forces between the two surfaces in contact. It was shown that these forces increase with the scanning velocity and this logarithmic dependence was explained by a modified one-dimensional Tomlinson model [68]. Similar velocity dependence, that is, a logarithmic increase of the friction forces within the velocity was observed for DLC coated silicon substrates for friction force microscopy measurements performed on air [116].

A recent investigation carried out by Riedo et al. [78] showed that the presence of water in the ambient air changes this situation. In fact, they investigated the friction dependence of amorphous carbon films with different surface energy and showed that the friction forces were velocity dependent, confirming the logarithmic character of this dependence. However, not only increasing behavior was observed. For other materials, such as CrN films, a decrease in the friction forces with velocity was verified. This fact occurs when the measurement is performed in air and the dependence with the velocity becomes stronger for atmospheres with higher humidity. In this situation, capillary effects due to water vapor condensation must be taken into consideration. In a humid environment, the force resulting from the condensation capillary liquid bridges at many different points along the tip–sample contact area is responsible for a velocity dependence force. When the tip is at a fixed position, this capillary force increases as a function of time, because of the continuous formation of liquid bridges at the tip–sample interface. When the tip is scanning the sample surface, the time available for liquid bridges decreases as a function of the velocity, and so, the capillary forces. Hence the capillary forces acts in opposition to atomic stick and slip, causing a decrease of friction with increasing velocity. This effect obviously depends on the hydrophobicity of the sample surface. For hydrophilic surfaces, this mechanism can be predominant and friction decreases with velocity. The velocity dependence behavior observed experimentally can be understood as a competition between two mechanisms, the cohesive forces responsible for the stick and slip movement and the kinetics nucleation of water meniscus between the moving parts.

Experimental data obtained in air from a-C:H and a-C:H:F films deposited by PECVD are shown in Figure 13 [117]. The results clearly show the existence of the logarithmic velocity dependence. It is observed that the increase of the hydrophobicity of the carbon–fluorine films, represented in this case by the contact angle, is responsible for the progressive increase of the slope of the friction forces dependence with velocity, in agreement with the model proposed by Reido et al. [78].

The dependence of the friction coefficient with the surface energy is illustrated in Figure 14, where the friction coefficient obtained from hydrogenated carbon films deposited by sputtering [98] and a-C:H and a-C:H:F films deposited by PECVD are plotted as a function of the contact angle [97]. The friction coefficients were determined by the linear regression of F_F versus F_N, that is, taking into account the adhesion forces, and show a clear correlation with the surface energy: the higher the contact angle, the lower the friction.

These results for the friction coefficient show the importance of the study of the adhesion forces and capillary condensation for the complete description of the friction behavior. The first systematic investigation of this problem was carried out by Binggeli and Mate [97, 118]. In Figure 15 their results for both the friction coefficient and adhesion force as functions of the relative humidity are presented for a-C films and silicon dioxide. The sliding speeds were on the order of micrometers per second. The slope of the friction versus load curve provided the friction coefficient and the extrapolation to zero loads, the adhesion force. In this experiment, the linear dependence between friction and applied load was an indication of the multiasperity contact among the AFM tip and sample surface. The results show that the friction coefficient decreases for silicon oxide surface but not for carbon films upon the increase of the relative humidity. The same behavior was observed for the adhesion force. The difference between the two samples was explained in

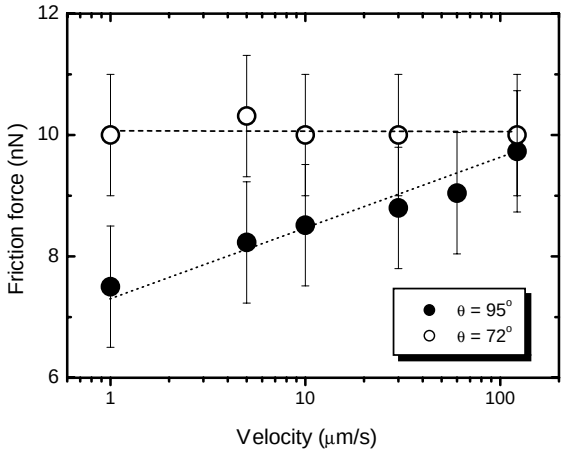

Figure 13. Friction coefficient as a function of the scanning velocity for films with different contact angle: $\theta = 95°$ for a-C:H film and $\theta = 72°$ for a-C:H:F film [106]. The lines are only to guide the eyes.

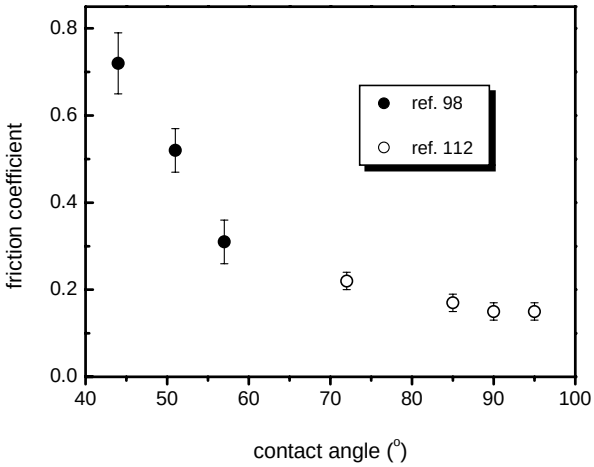

Figure 14. Friction coefficient as function of the contact angle for a-C:H films deposited by sputtering [108] and a-C:H and a-C:H:F films deposited by PECVD [106].

terms of the hydrophilic nature of the oxide, where water molecules are strongly bounded to hydroxyl groups. The friction coefficient for a-C films is nearly constant and equal to 0.3. A similar experiment was performed for a lower relative humidity regime (0–60%) and showed a slight increase of the adhesion force upon a humidity increase [92]. This apparent contradictory behavior can be explained as follows. For very low relative humidity, there is an increase in the number of the meniscus bridges, which results in a progressive increase of the friction. It occurs more or less independently on the surface energy of the samples. When the relative humidity is higher, the hydrophobicity of the film surface plays the decisive role.

The influence of hydrogen content in a-C:H films tribology is important in either the macroscopic or nanoscopic scale. In fact, in a review article by Erdemir [119] the role of hydrogen in the tribological behavior of diamond and diamond-like films was extensively discussed. This article showed that, for films deposited by PECVD in CH_4–H_2 atmospheres, the friction coefficient measured by conventional techniques in dry nitrogen (humidity = 0%) can be extremely low ($\mu = 0.003$) when the samples were grown in a very high H/C ratio in the precursor atmosphere (H/C = 10). On the other hand, it can be very high ($\mu = 0.65$) when measured in a hydrogen-free film. With an increasing the humidity, the friction coefficient of the hydrogen-free film dropped to 0.25 and for the film deposited in a hydrogen-rich atmosphere the friction coefficient increased to 0.06. The superlubricity of the a-C:H films was explained in terms of the almost complete elimination of covalent bonds at the carbon film surface by hydrogen passivation of carbon dangling bonds [119, 120]. The C—H bonds (stronger than C—C bonds) inhibit the covalent interaction with the atoms of the counterface materials and, thus, cause low adhesion and friction.

These arguments must be valid on the nanometer scale. In Figure 16 the results obtained by friction force microscopy from a-C:H films deposited in $CH_4 + H_2$ atmospheres by ECR–CVD [121] are shown. The friction coefficients obtained by Erdemir and collaborators [122] are also presented. The trend observed for both sets of data are the same: a decrease in the friction coefficient for films deposited in a hydrogen-rich atmosphere. It is interesting to note that films with high hydrogen content (up to 40 at.%) deposited by sputtering in Ar–H_2 atmospheres [98, 123] show exactly the opposite behavior; that is, the friction coefficient increases with the hydrogen content of the films. The different effects of the plasma film surface interaction in the case of $Ar + H_2$ mixtures in a sputtering chamber and in the case of hydrocarbon–H_2 mixtures in PECVD deposition are still not well understood. Probably they are responsible for the behavior observed for the a-C:H films, because the dangling bond density in the uppermost surface layer of a-C:H films certainly depends on the deposition technique used.

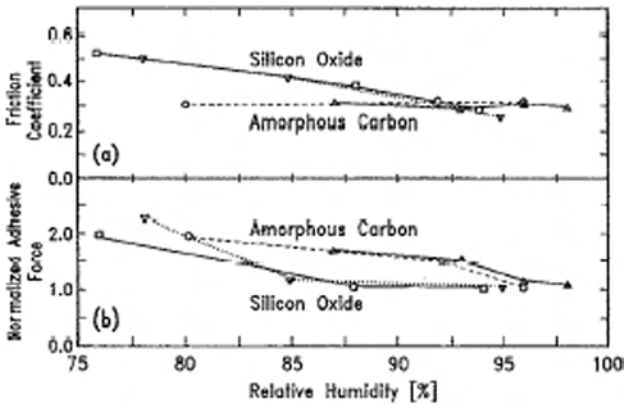

Figure 15. Friction coefficient and normalized adhesive forces during sliding as a function of relative humidity. Two typical measurement series for clean silicon wafers with silicon oxide and amorphous carbon are shown. Adhesive forces have been normalized by setting the lowest value to 1 to account for different tip radii in the separate experiments. Reprinted with permission from [97], M. Bingelli and C. M. 4.3. Wear

The demands resulting from the continuous increase of the storage density of computer hard disks and from the reduction of the loads and dimensions used in microelectromechanical systems; that is, thinner protective and anticorrosive coatings with lower surface roughness, together with the spreading of the use of the AFM motivate a large experimental effort to understand the wear behavior, in nanoscale, of carbon-based films deposited by different techniques [124]. In fact, it was demonstrated that it is possible to enter in a subnanometer scratching resistance testing regime using a standard AFM with diamond-tipped cantilevers [103]. As was also discussed before for the friction studies, a comparison of results obtained by different groups is not straightforward because the authors frequently did not report a complete structural characterization of the films under investigation. The comparison of the absolute values of wear data, the scratch depth, for example, is nontrivial, because sometimes not taken into account is the fact that the constant applied force on the cantilever cannot overcome the extra resistance force arising from the larger tip–surface contact area at deeper groove depths. On the other hand, some authors explicitly take into consideration the blunting of the tip when presenting their data [109].

Hydrogenated carbon films are a good example of this situation. These films can be deposited by sputtering with different hydrogen content by changing the ratio between Ar and H_2 gases in the camera. The control of the hydrogen content can also be achieved in a-C:H films deposited by PECVD techniques by changing the hydrocarbon–hydrogen precursor gas mixtures. Hydrogenated films deposited by sputtering were investigated by Jiang et al. [123]. The 25 nm thick sputtered films were scratched with an AFM diamond tip with a loading force of 28 μN and were imaged by the same tip after 16 wear cycles. The results show that the scratch depth increases from 4 to 30 nm with the increase of hydrogen content in the films, which varies from 2 to 40 at.%. The scratch depth of 30 nm measured for the hydrogen richest film means that the film is completely removed by the AFM tip. Nanoindentation measurements show that the hardness decreases with the increase in the hydrogen content from 9 to 6 GPa. A similar investigation was carried out by Wiens et al. [125]. From similar tests, they show that the scratching resistance decreases with the amount of hydrogen incorporated in the film for loads of 17 and 23 μN.

Sputtered hydrogenated carbon films were also studied by Anoikin et al. [126]. They deposited 10 nm thick a-C:H films onto AlMg/NiP/Cr/Co-based magnetic layer smooth disks (average surface roughness of 0.5 nm). The tip velocity was 1 μm/s and the load force was in the range of 10–15 μN. The films were deposited in Ar (a-C films), $Ar + H_2$ (a-C:H films), and $Ar + N_2$ (a-C:N films), and the amount of hydrogen and nitrogen was measured and Raman analysis was performed on each sample. Despite the fact that it is not possible to obtain the sp^2/sp^3 ratio directly from the Raman results, the position of the G-band can be used, in a qualitative way, to infer an increase (shift to higher wavenumbers) of the amount of sp^2-hybridized carbon atoms in the film or of the size of the graphitic domains [127]. The results are resumed in Table 1. They show that for films with nearly the same amount of hydrogen, the scratch depth decreases when the sp^2 fraction increases. When we compare the results for scratch depth obtained for films deposited by sputtering with those obtained by ion beam deposition of hydrocarbon species, in the same experimental conditions, this correlation is even clearer. The results obtained from sputtered films and presented in Table 1 show a direct correlation between hardness and the scratch depth, considering that films with higher sp^3 fractions usually have higher hardness [15, 63].

Table 1. Hydrogen content, G-band position, and scratch depth for several a-C films [123].

Materials	H content (at.%)	G-band position (cm^{-1})	Scratch depth (nm)
a-C	13.5	1582	14
a-C:H	25.4	1575	7
a-C:N	9.1	1569	4
a-C (IBAD)	18.9	1535	0.5
Graphite [127]	—	1584	—

Hydrogenated carbon films deposited by ECR–microwave plasma CVD were also studied for different chemical composition [121]. In this case the precursor atmosphere was a mixture of H_2 and methane, and the authors varied the amount of hydrogen in the mixture from 0 to 71%. The wear depth as a function of the number of wear cycles is presented in Figure 17. A load of 100 μN was applied, and each sample was submitted to 20 wear cycles. The wear rate decreases with the hydrogen content of the films. In this work, Raman results were presented and clearly show that a-C:H films have an increasingly graphitic character when the gas precursor mixture became richer in hydrogen: the G-band shits to higher wavenumber and its width reduces upon the increase of the amount of H_2 in the plasma atmosphere. The Raman results suggest a hardness reduction upon the hydrogen incorporation. The same group investigates the effect of the self-bias voltage in films deposited by ECR–microwave plasma CVD using a CH_4 (50%)–H_2 (50%) mixture [128]. Again the Raman result revealed an

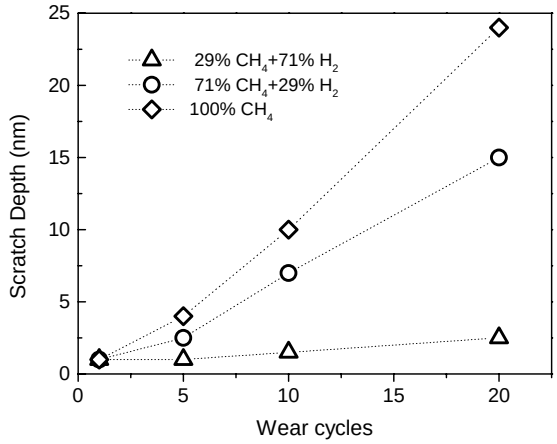

Figure 17. Wear depth as a function of the number of cycles for different hydrogen content in CH_4-H_2 atmospheres. Reprinted with permission from [121], T.-H. Fang et al., *Thin Solid Films* 396, 166 (2001). © 2001, Elsevier Science.

increase in the graphitic character of the films upon the self-bias increase. The wear test performed under a load of 200 μN, revealed the better wear resistance performance for the a-C:H film deposited at the higher bias voltage. Because the amount of hydrogen effectively incorporated in the films is not reported in this article, as well as the film hardness, it is difficult to compare these results with other data reported in the literature that shows an opposite behavior, especially in the case of the hydrogen content of the films.

A systematic investigation of the wear resistance for a-C films deposited by different techniques was carried out by Sundararajan and Bhushan [109]. Films deposited by ECR-CVD, sputtering, FCVA, and direct ion beam deposition were studied. They performed the scratch test using a pyramidal diamond tip mounted onto a platinum-coated stainless steel of stiffness of 40 N/m. The test consisted of 10 cycles over a scan length of 5 μm with a velocity of 10 μm/s and at a given load. In Table 2 we compare the data obtained at a load of 60 μN for films with the same thickness, 20 nm. Despite the lack of structural characterization of the tested samples, we can expect, as also claimed by the authors, that the film hardness closely follows the sp^3-hybridized carbon atom fraction. As previously discussed the results listed in Table 2 revealed that the scratch depth increases when the film hardness decreases.

Sundararajan and Bhushan [109] also performed wear tests. In this experiment, the tip scans a 2 μm $\times$ 2 μm area at a required load at 4 μm/s for a certain number of cycles. Then, the normal load was lowered to 1 μN, and the scan size was set to 4 μm $\times$ 4 μm to image the wear region. A detailed description of this procedure can be found in Ref. 129. Wear is not uniform, but it is initiated at the nanoscratches, indicating that surface defects (with high surface energy) act as initiation sites [103]. The wear test results showed that films 20 nm thick deposited by FCVA and ECR–CVD have excellent wear resistance for loads up to 80 μN. These deposition techniques provide films with similar performance even for thickness as low as 5 nm, but in this case for a maximum load of 20 μN. For very thin films, 3.5 nm thick, ECR–CVD deposited films have better performance. In fact, a-C films 3.5 nm thick deposited by FCVA are easily delaminated. On the other hand, 20 nm thick films deposited by ion beam deposition show a negligible wear depth for tests at 60 μN. For higher loads, the film is completely removed by the AFM tip. However, thinner ion beam deposited films have better wear behavior than the films deposited by a filtered cathodic arc and a performance quite similar to the one obtained by films deposited by ECR–CVD. In fact, for films 5 nm thick, the better performance was obtained for ion beam deposited films that show wear depths of around 2 nm for loads of 25 μN. At this load the AFM tip completely removed the films deposited by the other techniques. For thickness of 3.5 nm, both ECR–CVD and ion beam deposited films have the same performance under loads of 20 μN. On the other side, sputtered carbon films have the worst wear resistance, independent of the thickness. The results obtained for thicker films show that at least for a-C thick films the wear depth, as well as the scratch depth, closely follows the film hardness. However, for thinner films different behavior was observed. The better wear performance was obtained for ion beam and ECR–CVD deposited films that have an elastic modulus similar to that of the silicon substrates, whereas films deposited by a cathodic arc have the higher elastic modulus. This fact suggests that thinner coatings share load with the substrate, causing its deformation. Then, cracks can be created and propagate, resulting in the film delamination. The high internal stress of the cathodic arc deposited coatings aids propagation of cracks and facilitates spreading of the failed region compared with other coatings [130]. In this way, an analysis of the wear depth for very thin films must take into account the critical load required to fail the coating during the test.

Table 2. Hardness, elastic modulus, and scratch depth for carbon films prepared by different deposition techniques [1090000].

Material	Deposition technique	Hardness (GPa)	Elastic modulus (GPa)	Scratch depth (nm)
Diamond	—	100	1000	—
a-C	FCVA	24	240	$\sim$0

a-C:H	Ion beam	19	140	8
a-C:H	Sputtering	15	140	20

ta-C films were studied by Martínez et al. [131]. The films were deposited by filtered cathodic vacuum arc. The wear test was performed with an AFM equipped with a diamond tip that scans an area of 3 μm $\times$ 3 μm with a scanning frequency of 1 Hz. To obtain films with different hardness the substrate voltage was varied from -20 to -350 V. Films with thickness of around 100 nm were scratched with loads of 10 and 40 μN and the scratch depth can hardly be measured with the diamond tip and was estimated to be of the order of 1 nm, similar to those reported in Table 2 for films deposited by FCVA with 20 nm, and much lower than the 27 nm for bare silicon previously reported by Bushan and Koinkar [132]. These results confirm the high wear resistance of thick ta-C films and show a direct correlation between film hardness and wear resistance.

A scratch test can also be performed with very low loads and soft tips such as the silicon nitride tip to obtain information about the wear mechanism in hard carbon films. An AFM 3D image of a scratch profile on a ta-C film is shown in Figure 18 [112]. In this case 30 nm thick films were deposited by FCVA with a bias of -80 V applied to the substrate to produce films with an sp^3/sp^2 ratio of about 80%. The scratch test was performed using a Si_3N_4 tip of $k = 0.77$ N/m, scanning velocity of 2 μm/s, 1024 cycles, and a total normal force of 470 nN. The image was obtained with the same tip used to scratch the surface.

The scratch depth as a function of the normal load was plotted in Figure 19 for ta-C films. In the macroscopic scale, wear of ta-C films is strongly influenced by a shear layer of graphite that is built up at the interface of the slider tip and the ta-C surface during sliding. Although this graphitic layer may reduce the dissipated energy at the interface, it may also increase the surface wear. As the normal force is increased, the friction force also increases, leading to larger energy dissipation at the tip–surface interface [133]. However, on a nanometer scale, the presence of a low-density layer sp^2 surface layer, approximately 1 nm thick for ta-C

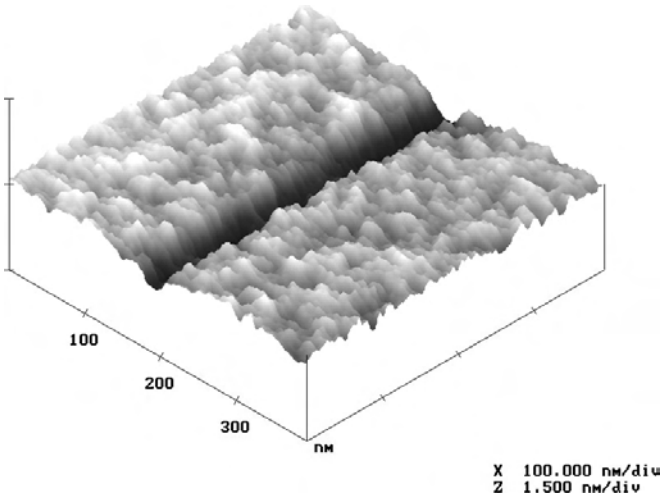

Figure 18. The result (topography image) of a scanning scratch test on a ta-C film performed with a Si_3N_4 atomic force microscope tip of $k = 0.77$ N/m, scanning velocity of 2 μm/s, 1024 cycles, and a total normal force of 470 nN [102].

films deposited with ion energy of ~100 eV, at the surface of the film due to the subplantation mechanism during film growth probably plays an important role [134]. This layer may be easily worn during the scanning process leading to the wear observed at the film surface. It is proposed that most of the wear observed at the ta-C films surface is caused by the removal of this low-density layer already present at the film surface. In fact, the measurement shows that after the complete removal of this layer the wear process stops and the wear depth remains constant, despite the increase of the normal force.

The influence of the number of scanning cycles on the ta-C wear can be seen in Figure 20. The normal force applied by the tip on the surface was kept constant at 470 nN and the humidity was 43%. The wear depth increases for scanning cycles up to 512 (forward + backward scans), above which it remains constant. This fact is in agreement with the hypothesis mentioned above that the microscope

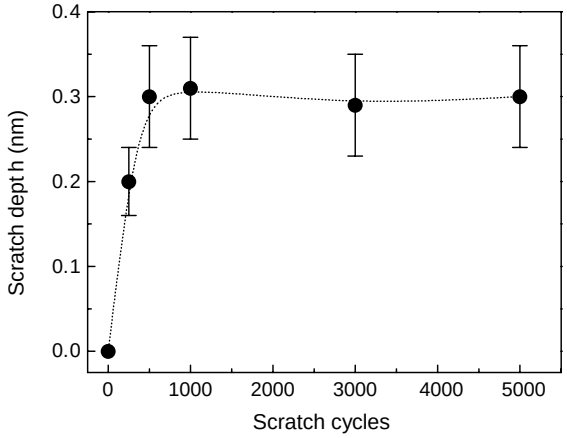

Figure 20. The influence of the number of scanning scratch cycles on the wear of ta-C films [102]. The line is only to guide the eyes.

tip only removes the low-density graphitic layer present at the ta-C film surface.

The effect of the film composition on the wear resistance has received increasing attention with the introduction of carbon–nitrogen films as protective coatings. One of the first efforts to establish a comparison between the scratch resistance, in nanoscale, of amorphous carbon films and carbon–nitrogen films was that of Miyake and collaborators [135]. They measured the wear depth as function of the load of films deposited by reactive ion-plating. In the range of loads from 50 to 100 μN, they show that for nitrogen-containing carbon films the wear depth was on the order of one tenth of the depth measured in carbon films deposited using the same technique.

More recently, a study of sputtered carbon–nitrogen films was performed by Wiens and collaborators [136]. Argon–nitrogen atmospheres were used to sputter a graphite target and the substrate was not biased. For films with nitrogen content between 6 and 18 at.%, the scratch depth under loads of 5 μN decreases from 1 to 0.7 nm. The same test performed with loads of 3 μN shows a decrease of the scratch depth from 0.5 to 0.3 nm. The scratch test was done using a diamond tip and scanning velocity of 0.2 μm/s. Raman analysis carried out in these samples suggested that the films with higher scratch resistance have lower sp^2 content. The same group [137] performed a more detailed investigation and the wear behavior of a-CN films deposited by FCVA was studied. They found an opposite behavior for the scratch depth upon nitrogen incorporation into sputtered films and FCVA-deposited films. For sputtered films, nitrogen incorporation reduces the scratch depth and for FCVA-deposited films it results in an increase of the depth. Unfortunately the authors did not report the values either for elastic modulus of sputtered films or for the position of the G-band for nitrogen-incorporated FCVA-deposited films. The results are presented in Table 3.

Carbon–nitrogen films deposited by ion beam-assisted deposition were also studied [105]. The films have a nitrogen content of 11 at.% and the hardness is 22 GPa. The wear depth for 10 nm thick films submitted to a load of 10 μN is on the order of 1 nm. These values are higher than those obtained by Wiens et al. [125] for sputtered films with

Table 3. Nitrogen content, elastic modulus, Raman G-band position, and scratch depth for a-CN films deposited by sputtering and filtered cathodic vacuum arc techniques.

Deposition technique	Nitrogen content (at.%)	Elastic modulus (GPa)	G-band position (cm^{-1})	Scratch depth (Å)
FCVA	0	480	1558	0.7
FCVA	6	400	—	0.8
FCVA	12.5	150	—	1.5
FCVA	14.5	120	—	1.5
Sputtering	0	—	1584	4
Sputtering	6	—	1580	3.5
Sputtering	8.5	—	1579	3.7
Sputtering	14	—	1578	3.2
Sputtering	18	—	1575	3

Note: The wear test was performed using a diamond tip at a normal load of 2.8 μN [136, 137].

Table 4. Friction coefficient for several carbon based materials measured by FFM in air.

Materials	Friction coefficient
a-C films deposited by resistive evaporation [96]	0.45 ± 0.04
a-C films deposited by ion assisted sputtering [55][a]	0.28
a-C films deposited by ion assisted sputtering [114]	0.22 ± 0.02
a-C films deposited by laser ablation [102]	0.21 ± 0.03
Diamond [96]	0.25 ± 0.06
ta-C deposited by FCVA [112]	0.15 ± 0.03
ns-C (small clusters material) [114]	0.10 ± 0.04
ns-C (large clusters material) [114]	0.14 ± 0.05
FLC films [112]	0.12 ± 0.03
HOPG [102]	0.009 ± 0.003
HOPG [114]	0.004 ± 0.001
HOPG [96]	0.0012 ± 0.0009

[a] Experimental errors are not quoted by the authors.

Table 5. Friction coefficient for CN_x films (N content of the order of 10 at.%) measured by FFM in air.

Materials	Friction coefficient	
	a-C	a-CN
a-C:H films deposited by PECVD [106]	0.22 ± 0.05	0.25 ± 0.06
a-C films deposited by ion-assisted sputtering [55][a]	0.28	0.14
a-C films deposited by laser ablation [102]	0.21 ± 0.03	0.17 ± 0.03

[a] Experimental errors are not quoted by the authors.

similar nitrogen content. The possible explanation for this large dispersion of data can be found in the formation of the fullerene-like structure in nitrogen–carbon films deposited by sputtering and many other techniques [58]. In this case the high elasticity of the materials certainly influences the wear resistance of the films. It is possibly more important when low loads were applied.

We investigated the case of FLC films deposited using an unfiltered localized high-pressure arc discharge [112]. The scratch test was performed using a Si_3N_4 tip of $k = 0.77$ N/m and scanning velocity of 2 μm/s. The scratch depth as a function of the normal load is shown in Figure 21. The wear of the surface was verified only when we scratched the surface with normal forces of at least 200 nN. Increasing the normal force beyond this point leads to an increase of the wear depth. The resistance to scratching of FLC films may be attributed to the high elasticity nature of the films [3]. The tip may deform the surface while scanning, but this mechanical change is promptly restored due to the high film elasticity. Once a permanent surface modification is achieved the film wear is influenced by the energy dissipated at the tip–surface interface and increases with the applied normal load.

5. CONCLUSIONS

The development of friction force microscopy in the last years resulted in significant progress in the understanding of either the basic friction laws and in the tribological performance of several coatings. Among those coatings, hard carbon films occupy a special place.

Concerning the basic friction law, it was clear that in nanoscale the friction forces depended on the contact area and that the relation between friction and load forces was no longer linear. In addition, it was shown that the velocity dependence behavior of the friction forces could be understood as a competition between two mechanisms—the cohesive forces responsible for the stick and slip movement and the kinetics nucleation of water meniscus between the moving parts—resulting in a logarithmic dependence of friction with the scanning velocity.

The friction coefficients measured in air by friction force microscopy for several carbon-based materials are listed in Table 4. It was clear that, despite the large discrepancies among the different experimental reports, the friction coefficient for HOPG is at least 1 order of magnitude lower compared with the friction coefficient obtained from a-C films. Among those different films, the nanostructured carbon films and the fullerene-like carbon films have lower friction coefficients while diamond-like carbon films show

friction coefficients similar to the one measured in diamond surfaces.

The incorporation of hydrogen was also investigated, but it is very difficult to determine its role precisely. In fact, if on one side, the deposition of a-C:H films by PECVD in highly hydrogen diluted atmospheres resulted in a decrease of the friction coefficient due to the complete saturation of surface dangling bonds, the opposite effect was observed for a-C:H films deposited by sputtering, where the increase of the hydrogen content in the films resulted in higher friction coefficient. On the other side, the incorporation of nitrogen, as a general rule, induced a slight reduction in the friction coefficient as one can see in Table 5.

Concerning wear behavior, scratch tests performed on carbon films thicker than 10 nm revealed that the wear resistance of these materials increased with the film hardness. For carbon–nitrogen films, the situation is more complex and the dispersion of the experimental data can be attributed to high elastic recovery of the films. It is due to the presence of nitrogen in a hexagonal graphite lattice that favors the formation of pentagons, inducing curvature in the graphene planes, responsible for the elastic behavior of the films. It is of importance also for fullerene-like films. For these materials, when low loads are applied the elastic deformation of the films can drastically reduce the wear when the sample surface is scanned with an AFM tip.

GLOSSARY

Adhesion A consequence of the forces that act at the materials' contact area to causes their sticking.

Atomic force microscopy/microscope (AFM) A microscope able to observe surfaces at atomic and molecular scale by measuring the interaction forces between a sharp tip and a surface.

Friction Force opposing relative motion of two objects that are in contact.

Friction force microscopy/microscope (FFM) A microscope able to measure the friction forces between a sharp tip and a sample surface at atomic and molecular scale.

Fullerenes Molecular forms of pure carbon, with a cage-like structure of carbon atoms. The number of atoms ranges from 60 up to a few hundred carbon atoms.

Nanotribology The science and technology of interacting surfaces in relative motion at atomic and molecular scales. This includes friction, wear, adhesion, and lubrication.

Sputtering Method used to deposit thin films in which a plasma is used. The plasma ions are used to bombard the target atoms that will condense out on a substrate, placed inside the deposition chamber, depositing a film.

Thin films Films with thickness less than 100 μ.

Wear The removal of material from surfaces in relative motion as a result of surface contact or abrasive or chemical action.

Nanotubes for Nanoelectronics

Zhi Chen

University of Kentucky, Lexington, Kentucky, USA

CONTENTS

1. INTRODUCTION

Carbon nanotubes (CNTs) have emerged as a viable electronic material for molecular electronic devices because of their unique physical and electrical properties [1–7]. For example, nanotubes have a lightweight and record-high elastic modulus, and they are predicted to be by far the strongest fibers that can be made. Their high strength and high flexibility are unique mechanical properties. They also have amazing electrical properties. The electronic properties depend drastically on both the diameter and the chirality of the hexagonal carbon lattice along the tube [8–10].

Carbon nanotubes were discovered by Iijima in 1991 at the NEC Fundamental Research Laboratory in Tsukuba, Japan [1]. Using a transmission electron microscope (TEM), he found carbon tubes consisting of multiple shells (see Fig. 1). These early carbon tubes are called multiwall nanotubes (MWNTs). Since then, extensive research has been focused on synthesis and characterization of carbon nanotubes. In 1993, Ijima's group [11] and Bethune et al. [12] at IBM Almaden Research Center at San Jose, California, synthesized carbon nanotubes with a single shell, called single-wall nanotubes (SWNTs). Because of their simple and well-defined structure [13], the single-wall nanotubes serve as model systems for theoretical calculations and for critical experimental studies. Since then, the physical and electrical properties of carbon nanotubes have been studied extensively. Only a few years ago, people began to utilize carbon nanotubes' unique electrical properties for electron device applications. Up to now, there has been no extensive review to cover the progress in nanoelectronic devices using carbon nanotubesy.

In this chapter, I aim to present extensive review on progress in electronic structure and transport properties of carbon nanotubes and nanoelectronic devices based on carbon nanotubes ranging from quantum transport to field-effect transistors. This chapter is organized as follows. It begins with brief review of the progress in micro- and nanoelectronic devices prior to carbon nanotubes (Section 2). Then the synthesis and physical properties of carbon nanotubes will be discussed in Section 3. Nanoelectronic devices based on carbon nanotubes including single-electron transistors (SETs), field-effect transistors, logic gates, and memory devices will be reviewed in Sections 4 and 5. The chemical doping, junctions, and metal–nanotube contacts will be described in Section 6. Finally, nanofabrication based on carbon nanotubes including controlled growth and selective placement of nanotubes on patterned Si substrates will be reviewed in Section 7. Since the discovery of carbon nanotubes, over 1000 papers on carbon nanotubes have been published. It is unlikely that every paper will be included in this chapter, because most papers dealt with synthesis, physical, and chemical properties of nanotubes. In this chapter, I will focus on electrical properties of nanotubes, nanoelectronic devices constructed with nanotubes, and nanotube-based nanofabrication.

2. PROGRESS IN NANOELECTRONICS PRIOR TO NANOTUBES

In 1959 Richard Feynman delivered his famous lecture, "There is Plenty of Room at the Bottom." He presented a vision of exciting new discoveries if one could fabricate materials and devices at the atomic and molecular scale. It was not until 1980s that instruments such as scanning tunneling microscopes (STM), atomic force microscopes (AFM), and near-field microscopes were invented. These instruments

provide "eyes" and "fingers" required for nanostructure measurement and manipulation [14]. The driving force for nanoelectronics is the scaling of microelectronic devices to nanoscale, which is the engine for modern information revolution. The microelectronics revolution began in 1947 when John Bardeen, Walter H. Brattain, and William Shockley of Bell Telephone Laboratories invented the first solid state transistor, the Ge point-contact transistor [15]. Solid state transistors had far superior performance, much lower power consumption, and much smaller size than vacuum triodes. People began to produce individual solid state components to replace the vacuum tubes in circuits in a few years after the invention. In 1958, Jack Kilby of Texas Instruments conceived a concept for fabrication of the entire circuit including components and interconnect wires on a single silicon substrate [16]. In 1959, Robert Noyce of Fairchild Semiconductor individually conceived a similar idea [15]. This concept has evolved into today's very-large-scale integrated circuits or "microchips," which consist of millions of transistors and interconnect wires on a single silicon substrate. The major driving force for this revolutionary progress is miniaturization of transistors and wires from tens of micrometers in the 1960s to today's tens of nanometers. The scaling down of transistor and interconnect wires led to more and more transistors being incorporated into a single silicon chip, resulting in faster and more powerful computer chips. With the success in microelctronics and of the semiconductor industry, it is natural to consider extending the micrometer size devices to nanometer size devices.

2.1. STM/AFM-Based Nanofabrication

There was not much progress in nanoelectronics until the 1980s. In 1981, the scanning tunneling microscope, invented by G. K. Binnig and H. Rohrer of IBM Zurich Research Laboratory, produced the first images of individual atoms on the surfaces of materials [17]. Later the STM was used to modify surfaces at the nanometer scale and the manipulation and positioning of single atoms on surface was achieved [18]. In 1993, Crommie et al. [19] eloquently demonstrated with a "quantum corral" where the STM can be used not only to characterize the electronic structure of materials on a truly quantum scale, but also to modify this quantum structure. This suggested that the STM and AFM might be used for atom-by-atom control of materials modification, leading to atomic resolution. This potential motivated researchers to attempt to use STM and AFM for nanolithography [20–25]. This task has not been easy due to the irreproducibility of the modifications, the slow "write" speed, and the difficulty of transferring such fine manipulations into functioning semiconductor devices [21]. Until now, reliable fabrication and robust pattern transfer for linewidths below 10 nm has not been achieved yet.

2.2. Metal-Oxide-Semiconductor Field-Effect Transistors

As early as the 1920s and 1930s, a concept for amplifying devices based on the so-called *field effect* was proposed with little understanding of the physical phenomena [26, 27]. After 30 years, the field-effect transistor based on the SiO_2/Si structure finally became practical [28]. Since that time, the metal-oxide-semiconductor field-effect transistor (MOSFET) has been incorporated into integrated circuits and has grown to be the most important device in the semiconductor industry ranging from memory chips, microprocessors, and many other communication chips. Figure 2a shows the structure of an *n*-channel MOSFET. It consists of *p*-type Si, heavily doped n^+ source and drain, and an insulated gate. When the gate voltage is zero, the region underneath the gate oxide is *p*-type. There are two pn^+ junctions near the source and the drain. When applying a voltage across the source and the drain, either of the two pn^+ junctions is reverse biased. Thus the transistor conducts no current. When the gate voltage is larger than zero but less than its threshold voltage, depletion happens underneath the gate oxide, which is still not conductive. When the gate voltage is larger than its threshold voltage, an inversion layer (*n*-type) is induced underneath the gate oxide, which forms a conduction channel connecting both source and drain. Thus the transistor conducts current. The typical *I–V* curves for an *n*-MOSFET with a gate length of 0.25 μm and a width of 15 μm are shown in Figure 2b. The driving force behind this

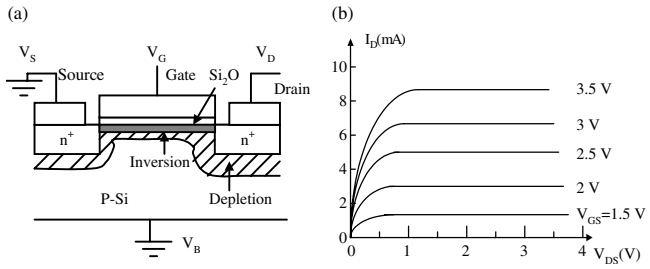

Figure 2. (a) Schematic structure of a Si MOSFET used in various microchips for digital signal processing and (b) its current–voltage characteristics.

remarkable development is the cost reduction and performance enhancement of integrated circuits (ICs) due to the continuous miniaturization of transistors and interconnect wires. The continuous scaling of transistors and the increase in wafer size has been and will continue to be the trend for the semiconductor industry. The transistor gate length (feature size) has been dramatically reduced for the past three decades [29, 30]. The lateral feature size or linewidth of a transistor has been shrunk by almost 50 times from about 10 μm to the 100 nm range, allowing over 10,000 times more transistors to be integrated on a single chip. Microprocessors have evolved from their 0.1 MHz ancestors used for watches and calculators in the early 1970s to the current 2 GHz engines for personal computers. Memories have grown from 1-Kb pioneers used almost exclusively for mass storage in central computers to the 128/256-Mb dynamic random access memory commonly used in personal computers today. Most advanced chips on the market now have feature sizes of 100 nm. According to the Semiconductor Industry Association's *International Technology Roadmap for Semiconductors* [31], the feature sizes for lithography were projected as follows: *130 nm in 2001, 100 nm in 2003, 80 nm in 2005, 35 nm in 2007, 45 nm in 2010, 32 nm in 2013, and 22 nm in 2016*. The wafer size has increased from 2 inches in the early 1970s to the current 12 inches. Therefore, the performance of ICs has been dramatically improved, and the cost for manufacturing has been dramatically reduced. However, the device scaling is approaching its limit. It was suggested that MOS device scaling might not be extended to below 10 nm because of physical limits such as power dissipation caused by leakage current through tunneling [32–34]. In addition, once electronic devices approach the nano- and molecular scale, the bulk properties of solids are replaced by the quantum-mechanic properties of a relatively few atoms such as energy quantization and tunneling. It is therefore important to search for alternative devices for Si MOS devices.

2.3. Quantum-Effect Devices

In order for a transistor-like device to operate on the nano- and molecular scale, it would be advantageous if it operated based on quantum mechanical effects. Even though the study of single-electron charging effects with granular metallic systems dates back to the 1950s [35, 36], it was the research of Likharev in 1988 that laid much of the groundwork for understanding single-charge transport in nanoscale tunnel junctions [37, 38]. When a small conductor (island) is initially neutral, it does not generate any appreciable electric field beyond its border. In this state, a weak external force (due to electric field) may bring in an additional electron from outside. The net charge in the island is $(-e)$ and the resulting electric field repulses the following electrons which might be added. In order to have an electron to be added it needs to overcome the charging energy and its kinetic energy. Thus, the electron additional energy E_a is given by

$$E_a = E_c + E_k$$

Here E_c is the charging energy that is given by

$$E_c = \frac{e^2}{C}$$

where e is the charge of electron and C is the capacitance of the conductive island. The kinetic energy is expressed as

$$E_k = \frac{1}{g(\varepsilon_F)V}$$

where $g(\varepsilon_F)$ is the density of states on the Fermi surface and V is the volume of the island.

For the island diameter > 2 nm, $E_c \gg E_k$. Thus

$$E_a \approx E_c = \frac{e^2}{2C}$$

For the 100 nm-scale island, E_a is of the order of 1 meV, corresponding to $\sim$10 K in temperature. If the island size is reduced to below 10 nm, E_a approaches 100 meV, and some single-electron effects become visible at room temperature.

Among quantum-effect devices, single-electron transistors have been most extensively studied [38–40]. The basic structure of a SET is shown in Figure 3a. An island or quantum dot is placed between two electrodes (source and drain) with the third electrode (gate) is placed by its side. When a voltage is applied, an electron tunnels onto the island and the charging energy is increased by $E_a \approx e^2/2C$ and this increase acts as a barrier to the transfer of any further electrons. At small source–drain voltage, there is no current. The I–V characteristic is shown in Figure 3b. The current is blocked from $-V_c$ to V_c, called *Coulomb blockade*. When the source–drain voltage is increased and reaches a level greater than V_c, where the energy barrier is eliminated, electrons can cross the island and the current increases with the applied voltage. The threshold voltage V_c is a periodical function of gate voltage.

Coulomb charging effects were originally observed in metallic film by Gorter in 1951 [35]. The first successful metallic single-electron transistor was made by Fulton and Dolan in 1987 [36]. They used a relatively simple technique in which two layers of aluminum were evaporated *in-situ* from two angles through the same suspended mask formed by direct e-beam writing. Since then, single-electron transistors have been demonstrated in numerous experiments using a wide variety of device geometry, materials, and techniques. SETs based on metallic nanodots were fabricated. Chen et al. [41] reported that SETs with metal dots of 20–30 nm and gaps of 20–30 nm were fabricated by ionized beam evaporation. The electrical results showed clear Coulomb blockade at temperature as high as 77 K. Novel lateral metallic SETs can be based on gold colloidal particles. These particles are very uniform in size and can be obtained in a range

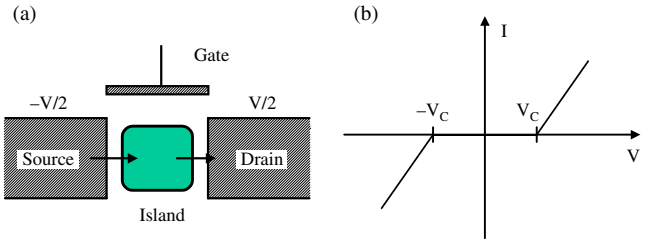

Figure 3. (a) Schematic structure of a capacitively coupled single-electron transistors and (b) its source–drain dc I–V curves.

of sizes. The devices can be fabricated by placing the particles in the gap between the source and drain. Klein et al. [42] obtained the Coulomb blockade characteristics based on gold colloidal particles at 77 K. Nakamura et al. [43] fabricated Al-based SETs, which operated at 100 K. Shirakashi et al. [44] fabricated Nb/Nb oxide-based SETs at room temperature ($T = 298$ K). The further reduction of the tunnel junction is performed by scanning probe microscope (SPM)-based anodic oxidation. The Coulomb blockade characteristics were clearly shown at room temperature.

Single-electron effects have also been observed in a number of semiconductor based structures. The first device was realized by squeezing the two-dimensional electron gas (2DEG) formed at the AlGaAs/GaAs heterostructure [45]. It consists of a pattern of metal gates evaporated onto the semiconductor surface. The voltages were applied to the gates to squeeze the 2DEG so that islands and tunnel barriers were formed. Coulomb blockade can be observed if the regions are sufficiently squeezed. Coulomb blockade effects have also been demonstrated on silicon based devices. A number of experiments have been reported on structures based on silicon-on-insulator (SOI). This is particularly important because silicon processing technology is the mainstream technology in the semiconductor industry. The silicon based SET technology can be easily integrated into the mainstream technology once it is successful. Ali and Ahmed [46] showed the first SOI-based SETs with clear Coulomb blockade. Leobandung et al. [47] also demonstrated silicon quantum-dot transistors with a 40-nm dot. The Coulomb blockade was clearly seen at temperature of 100 K. Takahashi et al. [48] and Kurihara et al. [49] scaled the silicon-based SETs to make significantly smaller islands and obtained Coulomb oscillation at temperatures approaching room temperature. Zhuang et al. [50] reported fabrication of silicon quantum-dot transistors with a dot of $\sim$12 nm with a clear Coulomb blockade at 300 K. Guo et al. [51] successfully fabricated a silicon single-electron transistor memory, which operated at room temperature. The memory is a floating gate MOS transistor in silicon with a channel width ($\sim$10 nm) smaller than the Debye screening length of a single electron and a nanoscale polysilicon dot (7 nm $\times$ 7 nm) as the floating gate embedded between the channel and the control gate. Storing one electron on the floating gate screens the entire channel from the potential on the control gate and leads to a discrete shift in the threshold voltage, a staircase relation between the charging voltage and the shift. SETs based on Si nanowires have also been demonstrated [52]. It was shown that quantum wires with a large length to width ratio show clear Coulomb oscillations at temperatures up to 77 K.

3. SYNTHESIS AND ELECTRICAL PROPERTIES OF CARBON NANOTUBES

3.1. Synthesis of Carbon Nanotubes

Although this chapter focuses on nanoelectronic devices, I still cover some of synthesis methods and approaches which may be helpful for interested readers. It should be pointed out that I am unable to include all the papers in synthesis because extensive research has been conducted for growth of carbon nanotubes.

Although multiwall carbon nanotubes were discovered in 1991 by Iijima, it is quite likely that such MWNTs were produced as early as the 1970s during research on carbon fibers [2]. The multiwall carbon nanotubes discovered in 1991 were obtained from the fullerene soot produced in an arc discharge [1]. As early as in 1986, Saito of the University of Kentucky studied the soot produced by a candle-like methane flame. A quartz fiber was inserted into the flame from the side and left there for a certain period of time [53]. When the fiber was raised to a certain height, a smooth film was coated on the fiber surface, which appeared to be brown in color. With increase of the sampling height beyond the critical height, the color of the deposited material changed from brown to black, and its surface appearance also changed from smooth to a rough and bumpy structure. The SEM analysis identified the rough surface material to be soot and the initial light brown material from the methane flame to be polyhedral-shaped crystal-like particles [54]. The deposit from the acetylene flame had a spider-web shape of entangled, long, narrow diameter strings, of which the detailed structure remained unknown until recent TEM study [55]. It was a surprise that the recent TEM study showed that the entangled long strings synthesized in 1986 are *carbon nanotubes*, which were discovered later by Iijima in 1991. Recently Saito's group repeated his 1986 experiments and synthesized CNTs using methane flames [56] and ethylene flames [57]. In 1993, Iijima and Ichihashi [11] synthesized single-wall carbon nanotubes of 1-nm diameter. Bethune and co-workers [12] also, at the same time, synthesized single-wall carbon nanotubes using cobalt catalyst. The research on carbon nanotubes really took off when Smalley and co-workers at Rice University found a laser ablation technique that could produce single-wall carbon nanotubes at yields up to 80% instead of the few percent yields of early experiments [58–60]. Kong and co-workers [61] at Stanford University used a chemical vapor deposition (CVD) technique to grow carbon nanotubes by decomposing an organic gas over a substrate covered with metal catalyst particles. The CVD approach has the potential for making possible large-scale production of nanotubes and growth of nanotubes at specific sites on patterned Si substrates [62, 63].

3.2. Electronic Structures of Carbon Nanotubes

Just in one year after the discovery of carbon nanotubes, their electronic structures were theoretically studied based on local-density-functional calculation [8], tight-binding band-structure calculation [9, 10, 64]. Figure 4a shows how to construct a carbon nanotube by wrapping up a single sheet of graphite such that two equivalent sites of the hexagonal lattice coincide; that is, point C coincides with the origin (0, 0) [65]. The wrapping vector $\mathbf{C}$, which defines the relative location of the two sites, is specified by a pair of integers (n, m) that relate $\mathbf{C}$ to the two unit vectors $\mathbf{a}_1$ and $\mathbf{a}_2$ ($\mathbf{C} = n\mathbf{a}_1 + m\mathbf{a}_2$). A tube is called "armchair" if n equals m, and "zigzag" in the case $m = 0$. All other tubes are of the "chiral" type with a finite wrapping angle

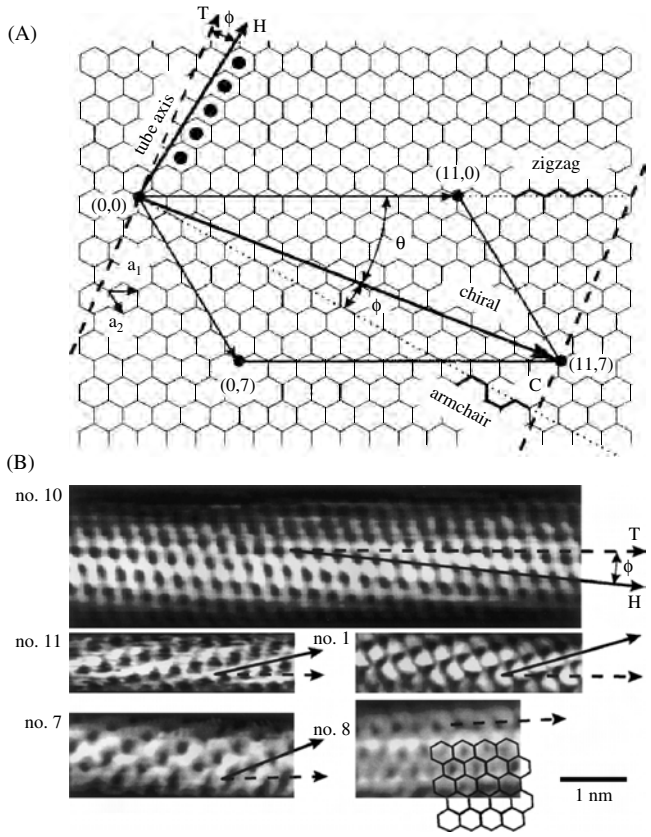

Figure 4. Relation between the hexagonal carbon lattice and the chirality of carbon nanotubes. (A) Construction of a carbon nanotube from a single graphene sheet by rolling up the sheet along the wrapping vector C. (B) Atomically resolved STM images of individually single-wall carbon nanotubes showing chirality. Reprinted with permission from [65], J. W. G. Wildoer et al., *Nature* 391, 59 (1998). © 1998, Macmillan Magazines Ltd.

ϕ ($0° < \phi < 30°$). Figure 4b shows the STM images of single-wall carbon nanotubes [65]. Tube 10 has a chiral angle $\phi = 7°$ and a diameter $d = 1.3$ nm, which corresponds to the (11, 7) type of panel A. The dependence of the electronic structure of nanotubes on the tube indices (n, m) can be understood by taking the two-dimensional graphene sheet as a starting point. In the circumferential direction (along **C**), the periodic boundary conditions $\mathbf{C} \cdot \mathbf{k} = 2\pi q$ can be applied, where **k** is the wave vector and q is an integer. This leads to a set of allowed values for k, which can be substituted into the dispersion relations for the tube, with q representing the various modes. Electronic energy band structure calculations [3, 8–10, 64] predicted that armchair ($n = m$) tubes behave like metallic. For all other tubes (chiral and zigzag) there exist two possibilities. If $(n - m)/3$ is an integer, tubes are expected to be metallic, and if $(n - m)/3$ is not an integer, tubes are predicted to be semiconducting with an energy gap depending on the diameter. The energy gap can be expressed as $E_{\text{gap}} = 2\gamma_0 a_{\text{C–C}}/d$, where γ_0 is the C–C tight-binding overlap energy, $a_{\text{C–C}}$ is the nearest neighbor C–C distance (0.142 nm), and d is the diameter. Figure 5 shows the calculated energy band structure of zigzag nanotubes (12, 0) in (c) and (13, 0) in (d). [The geometric structure of the tubes and the first Brillouin zone of a graphene sheet are

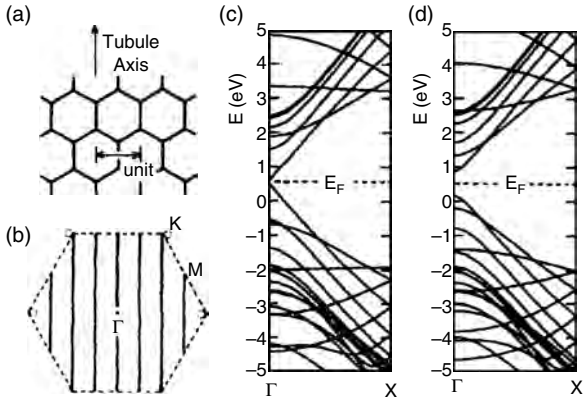

Figure 5. (a) The geometric configuration for a single-wall carbon nanotube $(n, 0)$. (b) The first Brilluoin zone of a graphite sheet and the wave vector allowed by the periodic boundary condition along the circumference for $n = 6$ (solid lines). Band structures of (c) (12,0) and (d) (13,0) single-wall nanotubes. Reprinted with permission from [9], N. Hamada et al., *Phys. Rev. Lett.* 68, 1579 (1992). © 1992, American Physical Society.

shown in (a) and (b).] The tube (12,0) is metallic, satisfying the condition of $(n - m)/3$ being integer; and the tube (13,0) is semiconducting with an energy gap of 0.697 eV, which falls into the category of $(n - m)/3$ being noninteger. Figure 6 shows the calculated energy band gaps of tubes $(n, 0)$ with $n = 6$–15. For $n = 6$, 9, 12, 15 [i.e., $(n - m)/3$ is integer], energy gaps are almost zero, and for $n = 7, 8, 10, 11, 13, 14$, [i.e. $(n - m)/3$ is noninteger], the energy gaps are ranging from 0.6 to 1.2 eV. Figure 7 shows the calculated one-dimensional (1D) electronic density of states for (a) a (9,0) nanotube and (b) a (10,0) nanotube [66]. The 1D density of state (DOS) of both nanotubes shows a series of spikes. Each spike corresponds to the energy threshold for an electronic subband caused by the quantum confinement of electrons in the radial and circumferential directions of nanotubes. The (9,0) nanotube is metallic and the (10,0) tube is semiconducting.

Experimental measurements [65, 67] of the energy bands of nanotubes confirmed these theoretical calculations. Figure 8a shows a selection of I–V curves obtained by scanning tunneling spectroscopy (STS) on different tubes [65]. Most curves show a low conductance at low bias, followed by several kinks at larger bias voltages. Figure 8b shows

the dI/dV curves. There are two categories: the one has a well-defined gap values around 0.5–0.6 eV and the other has significantly larger gap values of ∼1.7–2.0 eV [65]. The gap value of the first category agrees very well with the predicted gap values for semiconducting tubes. As shown in Figure 9c, the energy gap decreases as the tube diameter d increases. This also agrees well with theoretical gap values obtained for an overlap energy $\gamma_0 = 2.7 \pm 0.1$ eV, which is close to the value $\gamma_0 = 2.5$ eV suggested for a single graphene sheet [3]. The very large bandgaps observed for the second category of tubes, 1.7–2.0 eV, are in good agreement with the values of 1.6–1.9 eV obtained from one-dimensional dispersion relations for a number of metallic tubes with $(n - m)/3$ being integer [65]. These metallic nanotubes are expected to have a small but finite DOS near the Fermi energy (E_F) and the apparent "gap" is associated with DOS peaks at the band edges of the next one-dimensional modes. Sharp van Hove singularities in the DOS are predicted at the onsets of the subsequent energy bands, reflecting the one-dimensional character of carbon nanotubes (see Fig. 7). The derivative spectra indeed show a number of peak structures (Fig. 8b). For semiconductors, it has been argued that $(dI/dV)/(I/V)$ represents the DOS better than the direct derivative *dI/dV*, partly because the normalization accounts for the voltage dependence of the tunnel barrier at high bias [68, 69]. In Figure 9, $(dI/dV)/(I/V)$ is shown, where sharp peaks are observed, resembling that predicted for van Hove singularities. The experimental peaks have a finite height and are broadened because of hybridization of wave functions. Raman scattering experiments also support the one-dimensional subband of nanotubes [70, 71]. Resistivity measurements of armchair SWNTs also suggested their metallic behavior, consistent with the theoretical calculation [72, 73]. In addition, momentum-dependent high-resolution electron energy-loss spectroscopy was performed on purified SWNTs [74]. Two groups of excitations have been found.

One group is nondispersive and the energy position is characteristic of the separation of the van Hove singularities in the electronic DOS of the different types of nanotubes. The other one shows considerable dispersion and is related to a collective excitation of the π-electron system [74].

As pointed out by Dresselhaus [66], these results [66, 67] showed a wide range of helicities for SWNTs which contradict the narrow distribution of chiral angles determined by Raman scattering experiments [71] carried out on SWNT ropes synthesized by the same technique. In addition, van Hove singularities (energy threshold for an electronic subband) were also clearly resolved [65] in the experimental DOS of both chiral and achiral nanotubes. The observation of these well-separated and clearly resolved sharp spikes in the DOS of SWNTs with chiral symmetry was not expected [66]. Further calculation of the $\sigma + \pi$ electron densities of states of chiral carbon nanotubes using a tight-binding Hamiltonian showed that the electronic structures of SWNTs with chiral symmetry are similar to the zigzag and armchair ones [73, 74]. Fluorescence has also been observed directly across the bandgap of semiconducting carbon nanotubes, supporting the theoretical calculation of energy band structure of carbon nanotubes [77]. Most SWNTs synthesized using the current technologies are ropes consisting of many individual SWNTs. The first-principle calculation of electronic band structure of close-packing of individual nanotubes (10,10) into a rope showed that a broken symmetry of the (10,10) tube caused by interactions between tubes in a rope induces a pseudogap of about 0.1 eV at the Fermi level [78]. This pseudogap strongly modifies many of the fundamental electronic properties of carbon nanotube ropes. Structures of molecular electronic devices ultimately depend on tuning the interactions between individual electronic states and controlling the detailed spatial structure of the electronic wave functions in the constituent molecules. It is amazing that the two-dimensional images of electronic wave functions in metallic SWNTs have been obtained using STS [79]. These measurements reveal spatial patterns that can be directly understood from the electronic structure of a single graphite sheet. This represents an elegant illustration of Bloch's theorem at the level of individual wave functions.

3.3. Quantum Transport of Carbon Nanotubes

The electrical transport experiments on individual tubes are highly preferred. The first measurements on individual nanotubes were carried out on MWNTs [80–84]. Langer et al. [82] reported on electrical resistance measurements of an individual MWNT down to a temperature of $T =$ 20 mK. The conductance exhibited a $\ln T$ dependence and saturated at low temperature. A magnetic field applied perpendicular to the tube axis increased the conductance and produced aperiodic fluctuations. Their data also support two-dimensional weak localization and universal conductance fluctuations in mesoscopic conductors. These early studies on MWNTs suggested defect scattering, diffusive electron motion, and localization with a characteristic length scale of only a few nanometers. In addition, the electrical properties of individual MWNTs have been shown to vary strongly from tube to tube.

3.3.1. Ballistic Transport

It came as a surprise when the first experiments on individual SWNTs showed that nanotubes could have delocalized wave functions and behave as true *quantum wires* [85, 86]. Electrical measurement indicates that conduction occurs through well separated, discrete electronic states that are quantum-mechanically coherent over long distance, at least >140 nm [86]. Theory predicts that the electrons flow ballistically through carbon nanotubes and that the conductance is quantized [87–90]. Quantized conductance results from the electronic waveguide properties of extremely fine wires and constrictions. When the length of the nanotube is less than the mean-free path of electrons, the electronic transport is ballistic (i.e., each transverse waveguide mode or conduction channel contributes $G_0 = 2e^2/h$ to the total conductance). Theoretical calculation indicates that conducting single shell nanotubes have two modes or two conduction channels [87–90]; this predicts that the conductance of a single-walled nanotube is $2G_0$ independent of diameter and length. Another important aspect of ballistic transport is that no energy is dissipated in the conductor and the Joule heat is dissipated at the contacts of metal and nanotubes. Conductance measurements on MWNTs revealed that only one conduction channel G_0 exists in MWNTs, which conduct current ballistically over a length of 4 micrometers [91]. Recently, quantized conductance has been observed in SWNTs [92], which has two conduction channels $2G_0$, in agreement with the theoretical calculation. Theoretical studies also suggests that conduction electrons in armchair nanotubes experience an effective disorder averaged over the tube's circumference, leading to electron-mean-free paths that increase with nanotube diameter [93]. This increase should result in exceptional ballistic transport properties and localization lengths of 10 μm. For (10,10) armchair nanotubes, the mean-free path of 7.5 μm is obtained [93].

The fundamental reason for ballistic transport of carbon nanotubes is their *perfect* symmetric and periodic structure. It was shown that defects introduced into the nanotubes serve as scattering centers [94], which destroys the perfect structure. Theoretical calculation also showed that the absence of backscattering was demonstrated for single impurity with long range potential in metallic tubes [95–97] and a stepwise reduction of the conductance was inferred from multiple scattering on a few lattice impurities [98, 99]. Therefore, chemically doped semiconducting SWNTs may behave as diffusive conductors with shorter mean-free paths. It has been reported experimentally that mean-free paths of SWNTs are lower than the ones of reported structurally equivalent metallic SWNTs [100]. The backscattering contribution to the conductivity has been demonstrated to be more significant for doped semiconducting systems [101].

3.3.2. Other Transport Properties

Zeeman Effect Tans et al. [86, 102] observed an excited state by applying a magnetic field perpendicular to the tube axis, which moved relative to the ground state at a rate corresponding to a g-factor of 2.0 ± 0.5, consistent with the expected free-electron Zeeman shift. Cobden et al. [103] later studied the spin state by applying a magnetic field along the tube axis of the nanotube rope. It is concluded that as

successive electrons are added, the ground state spin oscillates between S_0 and $S_0 + \frac{1}{2}$, where S_0 is most likely zero. This results in the even/odd nature of the Coulomb peaks, which is also manifested in the asymmetry of the current–voltage characteristics and the peak height [106]. It is suggested that the g-factor of the Zeeman split is 2.04 ± 0.05 [104].

Aharonov–Bohm Effect When electrons pass through a cylindrical electrical conductor aligned in the magnetic field, their wavelike nature manifests itself as a periodic oscillation in the electrical resistance as a function of the enclosed magnetic flux. This phenomenon reflects the dependence of the phase of the electron wave on the magnetic field known as the Aharonov–Bohm effect [105], which causes a phase difference, and hence interference, between partial waves encircling the conductor in opposite directions. Theoretical studies showed [86, 106] that upon applying a magnetic field along the tube axis, the electronic structure of a carbon nanotube drastically changes from a metal to a semiconductor or from a semiconductor to a metal during variation of magnetic flux ϕ. The energy dispersion without the spin-$\boldsymbol{B}$ interaction is periodic in ϕ, with a period ϕ_0, as a result of the Aharonov–Bohm effect. Magnetoresistance measurements were carried out on individual MWNTs, which exhibit pronounced resistance oscillations as a function of magnetic flux [107]. The oscillations are in good agreement with theoretical predications for the Aharonov–Bohm effect in a hollow conductor with a diameter equal to that of the outermost shell of the nanotubes. Significant electron–electron correlation has been observed in experiments [108]. Electrons entering the nanotube in a low magnetic field are observed to have all the same spin direction, indicating spin polarization of the nanotube. When the number of electrons is fixed, variation of an applied gate voltage can significantly change the electronic spectrum of the nanotube and can induce spin-flips [108].

Luttinger Liquid Electron transport in conductors is usually well described by Fermi-liquid theory, which assumes that energy states of electrons near the Fermi level E_F are not qualitatively altered by Coulomb interactions. In one-dimensional systems, however, even weak Coulomb interactions cause strong perturbations. The resulting system, known as Luttinger liquid, is predicted to be distinctly different from its two- or three-dimensional counterpart [109]. Coulomb interactions have been studied theoretically for SWNTs [110, 111] and MWNTs [112]. Long-range Coulomb forces convert an isolated (N,N) armchair carbon nanotube into a strong renormalized Luttinger liquid [110]. At high temperatures, anomalous temperature dependence for the interaction, resistivity due to impurities, and power-law dependence for the local tunneling density of states were found. At low temperatures, the nanotube exhibits spin-charge separation, signaling a departure from orthodox theory of Coulomb blockade. Experimental measurements of the conductance of bundles ("ropes") of SWNTs as a function of temperature and voltage confirmed these theoretical studies [113].

4. SINGLE-ELECTRON TRANSISTORS

4.1. Single-Wall Carbon Nanotubes

In 1997, Bockrath et al. [85] reported the first single-electron transport of a single bundle containing 60 single-wall carbon nanotubes (10,10) with a diameter of 1.4 nm at a temperature of 1.4 K. The device structure (Fig. 10, left inset) consists of a single nanotube rope and lithographically defined Au electrodes. The device has four contacts and allows different segments of the nanotube to be measured. The device was mounted on a standard chip carrier and contacts were wire bonded. A dc bias (V_g) was applied to the chip carrier base to which the sample was attached. This dc bias can be used as gate voltage V_g to modify the charge density along the tube. Figure 10 shows the I–V characteristics of the nanotube section between contacts 2 and 3 as a function of temperature T. The conductance is strongly suppressed near $V = 0$ for $T < 10$ K. Figure 11A shows conductance G versus gate voltage V_g at $T = 1.3$ K. The conductance curve consists of a series of sharp peaks separated by regions of very low conductance. The peak spacing varies significantly. The height of peaks also varies widely with the maximum peak reaching e^2/h, where h is the Planck constant. The peak amplitude decreases with T (Fig. 11B) while the peak width increases with T (Fig. 11C). These phenomena can be understood based on Coulomb blockade effect described in Section 2.3. In this device, transport occurs by tunneling through the isolated segment of the rope. Tunneling on or off this segment is governed by the single-electron addition. The period of the peaks in gate voltage, ΔV_g, is determined by the energy for adding an additional electron to the rope segment.

In the same year (1997), Tans and co-workers [86] at Delft University of Technology built molecular devices using a metallic (armchair) SWNT as a quantum wire. Figure 12 shows the structure of the device. An individual SWNT with a diameter of ~1 nm is lying across two Pt electrodes with a separation of 140 nm. The third electrode located ~450 nm

away from the nanotube functions as a gate. Their original idea is to build a single-electron transistor using a SWNT as a quantum wire. The electrical measurement was carried out at a low temperature of 5 mK. The typical current–voltage characteristics at various gate voltages are shown in Figure 13a. The coulomb charging effect is clearly observed. Coulomb charging occurs when the charging energy $E_c = (e^2/2C) \gg kT$. At low temperature, the Coulomb blockade effect can be observed. The two traces in Figure 13b were taken under identical conditions and show an occasional doubling of certain peaks. This bistability was regarded as the result of switching offset charges that shift the potential of the tube [86].

Chemical doping was used to achieve quantum dots and junctions for single-electron transistors [114]. Electrical measurements of the potassium (K) doped nanotube reveal single-electron charging at temperature up to 160 K [114]. The quantum dot is formed by inhomogeneous doping along the nanotube length [115–119]. The p–n–p junction

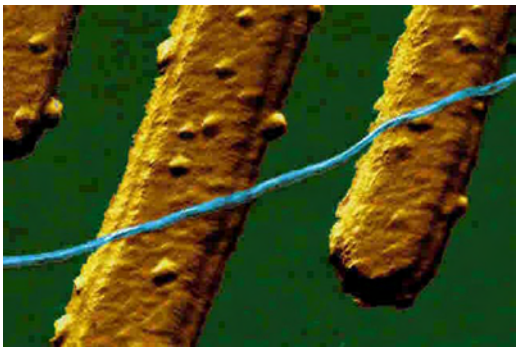

Figure 12. AFM tapping-mode image of a single-wall carbon nanotube on top of a Si/SiO_2 substrate with two 15-nm-thick Pt electrodes. Reprinted with permission from [86], S. J. Tans et al., *Nature* 386, 474 (1997). © 1997, Macmillan Magazines Ltd.

was obtained by chemical doping. The transport measurements of the junction showed that a well defined and highly reproducible on-tube single-electron transistor has been achieved [115]. It has been found that strong bends ("buckles") within metallic carbon nanotubes [2] act as nanometer-sized tunnel barriers for electron transport [116]. Single-electron transistors operating at room temperature have been fabricated by inducing two buckles in series within an individual metallic SWNT by manipulation with an AFM [117, 118]. The island with a length of 25 nm has been achieved and the resulting SET clearly showed the Coulomb blockade effect at room temperature [118]. Room temperature SETs have also been fabricated from SWNTs using V_2O_5 nanowires as masks for selective chemical doping [118]. Single-electron devices based on SWNTs with the line-shaped top gates [120], triple-barrier quantum dots [121], suspended quantum dots [122], field-induced p-type quantum dots [123], and kink-induced quantum dots [124] were fabricated. The microwave response of coupled quantum dots in SWNTs has also been measured [125]. The Coulomb oscillations for different microwave power were similar to those for different bias voltages without microwave.

Collins and co-workers [126] investigated electrical transport by sliding the STM tip along a nanotube. Figure 14 shows the schematic procedure for measuring nanotube characteristics using a single STM tip. From a position of stable tunneling (Fig. 14A), the STM tip was initially driven forward ~100 nm into the nanotube film (Fig. 14B). After retraction of the tip well beyond the normal tunneling range, nanotube material remained in electrical contact with the tip (Fig. 14C). Conductivity measurements were carried out by sliding the STM tip down along the nanotube while the tip remained electrically connected with the nanotube (Fig. 14D). The continuous motion of the tip allowed electrical characterization of different lengths of the nanotube. This technique results in a position-dependent electrical transport measurement along the extended lengths of selected nanotubes. A series of I–V curves were recorded

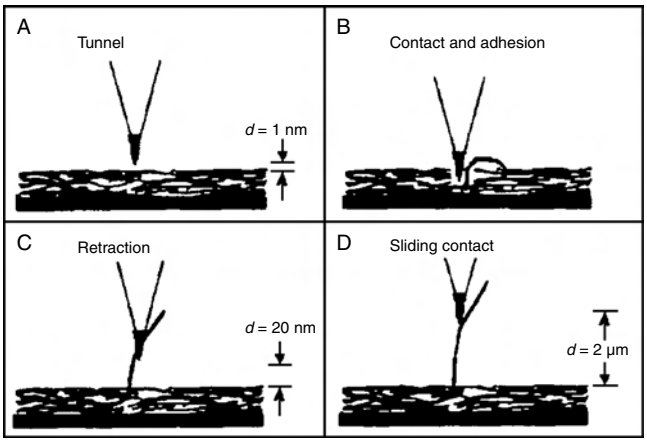

Figure 14. Schematic of the procedure for measuring nanotube characteristics with a single STM tip. Reprinted with permission from [126], P. G. Collins et al., *Science* 278, 100 (1997). © 1997, American Association for the Advancement of Science.

at positions 1600, 1850, 1950, and 2000 nm as shown in Figure 15. The first three curves are nonlinear but nearly symmetric. At a position of 2000 nm the I–V characteristics abruptly changed to a marked rectifying behavior (Fig. 15D). This response (Fig. 15D) was reproducible and persistent for positions up to 2300 nm before the nanotube was broken. It was suggested by Collins et al. [126] that the position-dependent behavior gives strong evidence for the existence of localized, well-defined, on-tube "nanodevices" with response characteristics consistent with the theoretical predictions. The extreme changes in conductivity were caused by contact with the localized nanotube defects that greatly altered the local $N(E)$. Although the injected current predominantly indicates a graphitic behavior for the nanotube rope, a nanotube defect at the contact point would obscure and dominate the transport characteristics. For example, the existence of a pentagon–heptagon defect in the otherwise perfectly hexagonal nanotube wall fabric can lead to sharp discontinuities in the electronic density state along the tube axis. It is possible to have one portion of the nanotube with metallic characteristics almost seamlessly joined to another portion that is semiconducting. This "junction" constitutes a pure-carbon Schottky barrier. The sliding STM probe indicates exactly this type of behavior as its position moves along the length of a nanotube by only a few nanometers, indicating the existence of a localized nanotube nanodevice.

4.2. Multiwall Carbon Nanotubes

Although single-electron transistors were made first from SWNTs [85, 86], a few reports [127–132] can be found for fabrication of SETs using MWNTs. Roschier et al. [127] of Helsinki University fabricated single-electron transistors using MWNTs through manipulation by a SPM. Figure 16 shows the experimental procedure for rotating and moving a nanotube, and eventually the tube was set across the electrodes with a gap of ~300 nm. The electrical measurements of the device were done at low temperatures

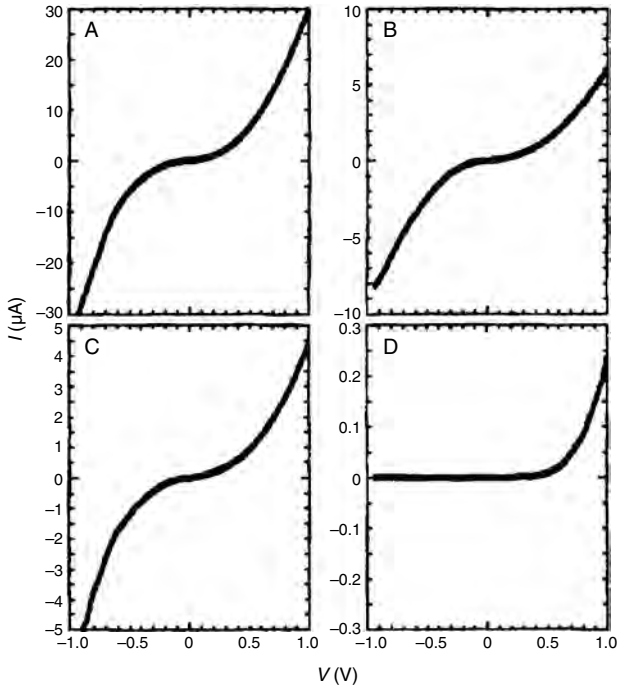

Figure 15. Different types of current–voltage characteristics, obtained for contact points at different heights of (A) 1600, (B) 1850, (C) 1950, and (D) 2000 nm along the carbon nanotube. down to 4 K. The measured I–V curves display a 15 mV wide zero current plateau across zero-voltage bias as shown in Figure 17. The Coulomb blockade effect is clearly observed below a few Kelvin and the nanotube behaves as a SET. The asymmetry of the gate modulation, illustrated in the inset for $V_{\text{bias}} = 10$ mV, indicates a substantial difference in the resistance of the tunnel junctions. There is a clear hysteresis in the I–V_{bias} curve at $T = 120$ mK. It is suggested that this phenomenon can be attributed to charge trapping, in which single electrons tunnel hysteretically across the concentric tubes. Roshier et al. [128] later constructed low-noise radio-frequency (rf) single-electron transistors using MWNTs. Contact resistance between a metal and a nanotube is commonly on the order of quantum resistance $R_Q = h/e^2 = 26.6$ kΩ. Hence, quantum fluctuations do not destroy charge quantization and thus it is possible to construct sensitive electrometers based on electrostatically controlled single-electron tunneling. The rf-SETs are the best electrometers at present [133]. As reported by Schoelkopf et al. [133] of Yale University, the sensitivity of rf-SETs based on Al islands approaches $1.2 \times 10^{-5} e/\sqrt{\text{Hz}}$, near the quantum limit at high frequencies. However, at frequencies below 1 kHz, these devices are plagued by the presence of $1/f^{\alpha}$ noise ($\alpha \sim$1–2). The origin of $1/f^{\alpha}$ noise is the trapping and detrapping of charges either in the vicinity of the island or on the surface of the nanotube or in the tunnel barrier [134, 135]. One way to reduce the $1/f^{\alpha}$ noise in SETs is to avoid contact of the central island with any dielectric material. In research by Roshier and co-workers [128], a freestanding MWNT across two electrodes was used as the island. The MWNT was moved onto the top of the electrodes by an AFM tip. The $1/f^{\alpha}$ noise of the SET is $6 \times 10^{-6} e/\sqrt{\text{Hz}}$ at 45 Hz, close to the performance in the best metallic SETs.

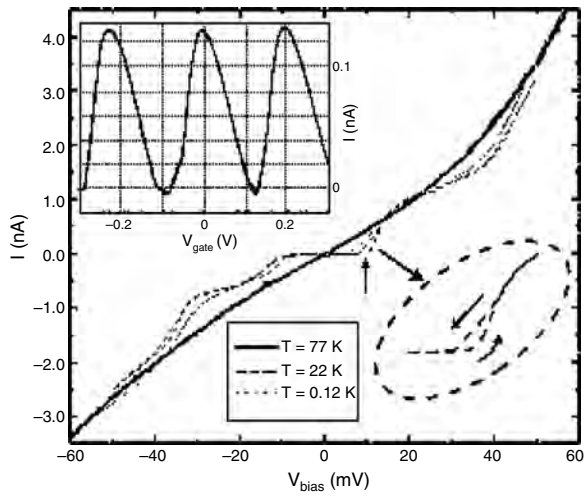

Figure 17. Measured I–V_{bias} curves at different temperatures when the gate is at zero bias. The inset shows the gate modulation at $V_{\text{bias}} = 10$ mV (indicated by the arrow) at $T = 120$ mK. The enlargement in the lower right corner shows the hysteretic behavior of the current. 5. FIELD-EFFECT TRANSISTORS, LOGIC GATES, AND MEMORY DEVICES

5.1. Field-Effect Transistors

The significance of the paper by Tans et al. [86] is not in the quantum effect, but in the gate-induced modulation of conductance of the metallic nanotube. Field-effect transistors were first demonstrated using a single semiconducting SWNT by Tans et al. [136], and using both a SWNT and a MWNT by Avouris et al. [137–140]. Figure 18 shows the structure of the carbon nanotube field-effect transistor (CNTFET) [137]. The two electrodes are separated by 300 nm and gate oxide (SiO_2) is 140 nm. Figure 19 shows output characteristics of a SWNT-FET consisting of a single SWNT with a diameter of 1.6 nm for several values of the gate voltage. It is clearly seen that the source–drain current is modulated by electric field. The field effect of the MWNT-FET device was not observed [137]. The hole mobility is estimated to be 20 $\text{cm}^2/\text{V s}$. In 1999, Dai and co-workers [141] reported fabrication of FET using SWNTs controllably grown on substrates. Figure 20 shows the I–V curves at various gate voltages [141]. The asymmetry of the I–V curves was regarded as being inherent to the metal–tube–metal system. I–V curves after exchanging the source and drain show nearly unchanged asymmetry. These results suggest that the observed asymmetry is not caused by asymmetrical parameters such as different contact resistance at the two metal–tube contacts [141]. It was suggested that the asymmetry of I–V curves is due to high source–drain bias [141]. The transconductance was estimated to be 0.1 mS/μm.

5.1.1. Scaling of CNTFET

Theoretical studies [142] showed that the performance can be significantly improved if the channel length and gate oxide can be further scaled down. The I–V characteristics are similar to the ballistic Si MOSFETs except for the occurrence of quantized channel conductance. Because of ballistic transport, the average carrier velocity reaches 2.7×10^7 cm/s [145]. Theoretical studies [143] also show that the CNTFET can be scaled down to at least 5 nm. Because of the ballistic transport, there is no energy dissipation except at contacts, and terahertz operation may be possible. Recently Wind and co-workers at IBM [144] improved their CNTFET

structure with top gate and very thin gate oxide (15 nm). Figure 21 shows the device structure and its output characteristics. A single-wall carbon nanotube with a diameter of 1.4 nm was used as a semiconductor nanowire. The source and drain were defined by e-beam lithography with a gate length of 260 nm. I–V curves show excellent saturation and on–off ratio of 10^5. Table 1 shows a comparison of key device performance parameters for a 260 nm gate length p-type CNTFET with those of state-of-the-art Si MOS transistors, a 15 nm gate Si p-type MOSFET [145] and a 50 nm gate SOI p-type MOSFET [146]. It can be found that a CNTFET has superior performance over Si MOSFETs. A CNTFET exhibits a much higher ON current ($I_{on} = 2100\ \mu A/\mu m$), reasonable OFF current ($I_{off} = 150$ nA/μm), and very high transconductance (2321 μS/μm). It should be noted that the transconductance of the 15 nm gate Si p-MOSFET is only 975 μS/μm [145].

5.1.2. High Mobility

In [144], Wind et al. did not characterize the hole mobility during transport. I will analyze the hole mobility as follows. Because the I–V curves follow the classical transport model, the transconductance in saturation is expressed as [147]

$$G_{msat} = \frac{\mu_p C_{ox} W}{2L} |V_G - V_T|$$

where μ_p is the hole mobility. L and W are the gate length and gate width separately. C_{ox} is the gate oxide capacitance. V_G is the gate voltage and V_T is threshold voltage (−0.5 V). The gate width is considered to be half of the perimeter of the CNT (diameter = 1.4 nm). Thus the mobility can be calculated using

$$\mu_p = \frac{G_{msat} 2L}{C_{ox} W |V_G - V_T|}$$

Based on the given data of the transistor structure, the hole mobility is 2018 $cm^2\,V^{-1}\,s^{-1}$. This is much larger than the ideal hole mobility in bulk Si (~400 $cm^2\,V^{-1}\,s^{-1}$) and 200 × higher than the hole mobility (12 $cm^2\,V^{-1}\,s^{-1}$) derived from the 15 nm gate p-Si MOSFET [145]. *These surprising data indicate the potential of carbon nanotubes for high-speed device application similar to III–V compound semiconductors such as GaAs.* It was reported that SWNTs are extremely pure systems with large Fermi velocities of $v_F = 10^6$ m/s and ballistic transport over long distance [65, 91, 148]. Considering its unique 1D quantum wire electronic band structure and ballistic transport over long distance, it is highly possible for SWNTs to have extremely high mobility.

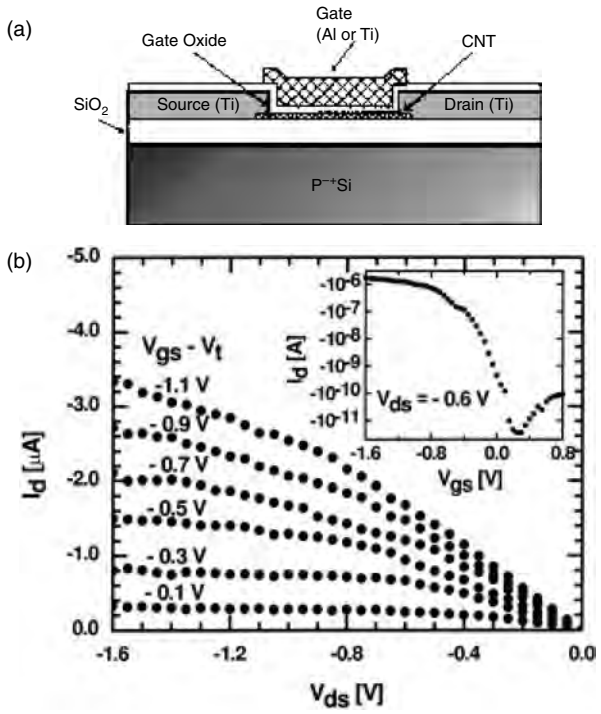

Figure 21. Schematic cross-section of top gate CNFET showing the gate and source and drain electrodes. (b) Output characteristic of a top gate *p*-type CNFET with a Ti gate and a gate oxide thickness of 15 nm. The gate voltage values range from −0.1 to −1.1 V above the threshold voltage, which is –0.5 V. Inset: Transfer characteristic of the CNFET for $V_{ds} = -0.6$ V. The high mobility of nanotube transistors estimated by the present author has been confirmed by Rosenblat et al. [149] and Kruger et al. [150]. Rosenblat et al. [149] constructed a carbon nanotube transistor using an electrolyte as gate, which was inspired by the study of doping effects using electrochemical gating [150, 151]. Figure 22 shows the device structure [149]. Catalyst islands containing $Fe(NO_3)_3 \cdot 9H_2O$, $MoO_2(acac)_2$, and alumina nanoparticles were defined on SiO_2. Carbon nanotubes were then grown by chemical vapor deposition. The source and drain with a separation of 1–3 μm (channel length) were defined using

Table 1. Comparison of key device performance parameters for a 260 nm gate length *p*-type CNTFET with those of state-of-the-art Si MOS transistors: a 15 nm-gate *p*-type Si MOSFET and a 50 nm gate *p*-type SOI MOSFET.

Types of transistors	CNTFET [144]	Si MOSFET [145]	SOI MOSFET [146]
Gate length (nm)	260	15	50
Gate oxide thickness (nm)	15	1.4	1.5
Threshold voltage (V)	−0.5	−0.1	−0.2
I_{ON} (μA/μm) @ $V_{DS} = V_{GS} - V_T = 1$ V	2100	265	650
I_{OFF} (nA/μm)	150	~500	9
Subthreshold slope (mV/dec)	130	~100	70
Transconductance (μS/μm)	2321	975	650

photolithography and a lift-off process. A micropipet is used to place a small (~10–20 μm) saltwater droplet (NaCl solution) over the nanotube device. A voltage V_{wg} applied to a silver wire in the pipet is used to establish the electrochemical potential in the electrolyte relative to the device. Then the electrolyte functions as a liquid gate. The output characteristics of the electrolyte carbon nanotube FET are similar to those in Figure 21. The transconductance of the transistor reaches its maximum ~20 μS at a gate voltage of −0.8 V. The mobility inferred from the conductance measurement is in the range of 1000 to 4000 $cm^2\,V^{-1}\,s^{-1}$. The maximum on-state conductance is also shown for the same samples. Values on the order of e^2/h are routinely obtained, within a factor of 4 of the theoretical limit of $4e^2/h$. Fuhrer et al. [152] reported the hole mobility in a SWNT of 9000 $cm^2\,V^{-1}\,s^{-1}$, which is the highest value ever reported.

In addition, the field effect is clearly shown even at a temperature of 5 K with a spikelike conductance, which is attributed to the van Hove singularities [153]. AFM tips were used to apply pointlike local gates to manipulate the electrical properties of an individual SWNT contacted by Ti electrodes [154]. The AFM tip contacting on a semiconducting SWNT causes depletion at a local point, leading to orders of magnitude decrease of the nanotube conductance, while local gating to a metallic SWNT leads to no change in conductance [154]. Theoretical study also suggests that a quantum dot is formed because of the induced *n*-type together with the *p*-type near the metal contacts when a positive gate voltage is applied on the *p*-type SWNT [155]. The induced quantum dot enhances the conductance.

Because the energy bandgaps of semiconducting SWNTs are inversely proportional to their diameter, large-diameter SWNTs have smaller energy bandgaps. Transistors made of large-diameter SWNTs exhibit ambipolar field-effect transistor behavior [156, 157]. Theoretical study showed that the energy gap of a semiconducting nanotube can be narrowed, when the tube is placed in an electric field perpendicular to the tube axis (e.g., in the FET case) [158]. This band-structure modulation may affect the electrical properties of CNTFETs. No experimental research has been reported regarding this phenomenon. For characterization of the semiconductor/oxide interface, capacitance–voltage measurement is usually carried out on MOS capacitors. Theoretical study showed that the calculated C–V curves reflect the local peaks of the 1D DOS in the nanotube [159]. This might be used for diagnose the electronic structure of nanotubes, providing a more convenient approach than STM. However, experimental measurement of the capacitance in nanoscale is not easy because the accumulation capacitance of a 1-μm long nanotube MOS capacitor is only 1.5×10^{-4} pf or 1.5 pf/cm [159].

5.2. Logic Gates

In 2001, several groups [160–162] demonstrated logic circuits using carbon nanotube transistors. Bachtold et al. [160] showed inverter, NOR gate, static random access memory (SRAM), and ring oscillator. Derycke et al. [161] and Liu et al. [162] showed the CMOS inverter using both n- and p-channel CNTFETs. Figure 23 shows individual device structure and layout [160]. Unlike the previous nanotube transistor structure using back gate, which applies the same gate voltage to all transistors, the transistor structure consists of a microfabricated Al wire with native Al_2O_3 as gate insulator, which lies beneath a semiconducting nanotube that is electrically contacted to two Au electrodes. The channel length is about 100 nm and gate oxide thickness is about a few nanometers. This layout allows the integration of multiple nanotube FETs. The transistor is a p-type enhancement mode FET with transconductance of 0.3 μS and on–off ratio of at least 10^5. The transistor can operate at an ON current of 100 nA and an OFF current of 1 pA. The basic logic elements such as inverter, NOR gate, SRAM, and ring oscillator were constructed as shown in Figure 24. The inverter exhibits very good transfer characteristics. When input voltage is -1.5 V (logic 1), the output voltage is 0 V (logic 0). When the input voltage is switched to 0 (logic 0), the output becomes -1.5 (logic 1). Although the transition is not as sharp as a Si MOSFET, it is still competitive. Because this inverter is constructed using a single transistor, the standby current is still high. The ring oscillator shows good oscillation waveforms although the oscillation frequency is low in this pioneer stage. The inverters have been constructed using complementary nanotube FETs similar to Si CMOS structure (complementary MOS), leading to minimum standby power consumption [161, 162]. Figure 25 shows the CMOS inverter based on both n- and p-CNTFETs and its transfer characteristic [161]. A single nanotube bundle is positioned over the gold electrodes to produce two p-type CNTFETs in series. The device is covered by PMMA and a window is opened by e-beam lithography to expose part of the nanotube. Potassium is then evaporated through this window to produce an n-CNTFET, while the other CNTFET remains p-type. The transfer characteristics show much better transition region (more steep slope).

5.3. Memory Devices

A concept for molecular electronics exploiting carbon nanotubes as both molecular device elements and molecular wires for reading and writing information has been proposed [163]. Each device is based on suspended, crossed nanotube geometry that leads to bistable, electrostatically switchable ON/OFF states. The device elements are naturally addressable in large arrays by the carbon nanotube molecular wires making up the devices. These reversible, bistable device elements could be used to construct nonvolatile random access memory and logic function tables at an integration level approaching 10^{12} elements per cm^2, and an element operation frequency in excess of 100 GHz [163]. However, strictly speaking, these memory devices or logic gates are not made of CNTFETs. Several groups [152, 164–166] reported fabrication of memory devices using nanotube field-effect transistors. Air-stable n-type, ambipolar CNTFETs were fabricated and used in nanoscale memory cells [164]. The n-type transistors are achieved by annealing nanotubes in hydrogen gas and contacting them by cobalt electrodes. Due to their nanoscale capacitance, CNTFETs

are extremely sensitive to the presence of individual charges around the channel, which can be used for data storage that operate at the few-electron level [165]. Figure 26 shows the threshold voltage shift due to storage of charges (a,b,c), device structure (d), and the voltage signal (V_{out}) due to charge storage [164]. In addition, the data-storage stability of over 12 days has been achieved [165].

6. DOPING, JUNCTIONS, AND METAL–NANOTUBE CONTACTS

A key technology advancement for the success of semiconductor industry is achievement of *n*- and *p*-type doping, junctions, and Ohmic contacts between metal and

semiconductor. It is critical to achieve doping, *pn* junctions, and Ohmic contacts for carbon nanotubes so that nanotube electronics may evolve into a large industry.

6.1. Chemical Doping

Antonov and Johnson [167] observed current rectification in a molecular diode consisting of a semiconducting SWNT and an impurity. It was suggested that rectification resulted from the local effect of the impurity on the tube's band structure. It is not clear what type of impurity it was. Lee et al. [168] reported doping of SWNTs by vapor-phase reactions with bromine and potassium. Doping decreases the resistivity of SWNTs at 300 K by up to a factor of 30 and enlarges the region where the temperature coefficient of resistance is positive, which is the signature of metallic behavior. It was reported [169, 170] that potassium (K) doping of SWNTs creates *n*-type carrier (electrons). The doping effects were studied using the transistor structure. The SWNT ropes were placed on top of Au electrodes that have 500 nm separation. The electrodes were fabricated on the oxidized n^+-Si substrate which serves as gate. The Au electrodes serve as source and drain. Figure 27 shows conductance vs gate voltage for an undoped nanotube rope (open circles) and an nanotube doped with potassium (solid circle) [169]. For the undoped nanotube, the conductance increases with decreasing gate voltage, indicating *p*-type behavior. For the K-doped nanotube, the conductance increases with increasing gate voltage, indicating *n*-type behavior. The typical values for the carrier density are found to be ∼100–1000 electrons/μm and the effective mobility of electrons is $\mu_{eff} \sim$ 20–60 in early time [169]. Derycke et al. [171] reported two methods for conversion of SWNTs from *p*-type to *n*-type. The first method involves conventional doping with an electron donor and the second

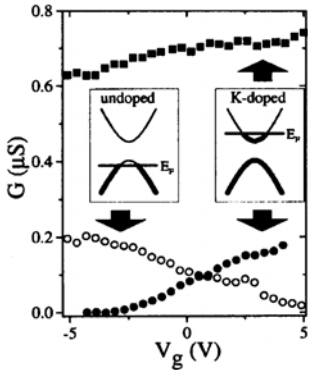

Figure 27. The conductance decreases with increasing gate voltage for an undoped sample (open circles), indicating *p*-type behavior. Left inset shows the energy band corresponding to this case. The conductance increases with increasing gate voltage after potassium doping at a high doping level (solid squares) and at a low doping level (solid circles). Right inset shows the energy band corresponding to this situation. Reprinted with permission from [169], M. Bockrath et al., *Phys. Rev. B* 61, R10606 (2000). © 2000, American Physical Society.

consists of annealing the metal nanotube contacts in vacuum to remove adsorbed oxygen. It has been found that the main effect of oxygen adsorption is not to dope the bulk of the nanotube, but to modify the Schottky barriers at the metal–semiconductor contacts [172, 173]. It also found that boron-doped MWNTs showed an enhanced room temperature conductivity [174]. However, theoretical calculation showed that H_2O adsorption on a SWNT reduces conductance [175].

6.2. Junctions and Metal–Nanotube Contacts

Zhou et al. [176] published the first attempt for controllable chemical doping of individual carbon nanotubes to achieve *pn* junctions. Figure 28 shows the device structure for potassium doping and the resulting energy band structure [176]. The SWNT used in the doping experiments has a diameter of ~2 nm and a length of 3.5 μm and is placed across two metal electrodes. A back gate is used to modulate the carrier concentration by applying voltage on the gate. A polymethylmethacrylate (PMMA) layer of 340 nm thickness covers the left half of the nanotube, leaving the right half exposed. Prior to doping, SWNT is a *p*-type semiconductor. Potassium doping of the SWNT is carried out in vacuum by electrical heating of a potassium source. Figure 29A shows the I–V_g curves [176]. When $V_g < -1$ V (Regime I), hole accumulation is achieved in the SWNT, leading to p^+ in the PMMA protected area due to increase in hole concentration and n in the exposed region due to compensation of electrons. In Regime II, electron concentration begins to increase, resulting in p^+n^+ junction. I–V curves of p^+n and p^+n^+ junctions are shown in Figure 29B and C. In the forward bias regime, a nice *pn* junction diode is demonstrated. However, the reverse bias breakdown voltage is too small to be qualified as a diode [176]. Anyway, this is the first result showing some possibility for fabrication of nanotube-based *pn* junction diodes.

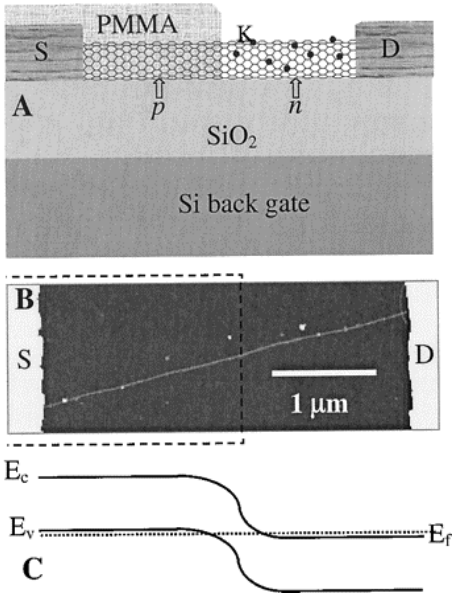

Figure 28. An SWNT with modulated chemical doping. (A) Device scheme with the SWNT contacted by two Ni/Au electrodes. The right half of the SWNT is doped by evaporating K atoms (black dots) from an alkaline metal at 10^{-6} Torr. Based on theoretical calculation, Chico et al. [177] proposed metal/semiconductor or semiconductor/semiconductor junctions, made of SWNTs, and based on the introduction of topological defects in nanotubes. By introducing a pentagon and a heptagon into the hexagonal carbon lattice, two tube segments with different electronic structures can be seamlessly fused together to create semiconductor–semiconductor or metal–semiconductor junctions [172, 178, 179]. Two carbon nanotubes have also been fused together by high electric field [180]. The CN_x/nanotube junctions have been synthesized by a microwave plasma assisted CVD method [181]. It is of particular interest that two SWNTs were crossed over each other to form junctions [182]. Theoretical study also suggests that negative differential resistance may be observed in metal–nanotube–metal structures [183]. Figure 30 shows the AFM image of a nanotube junction with a sharp kink of about 40° [172]. The kink consists of five to seven defects. Figure 31 shows the I–V characteristics of the kink metal–semiconductor junction [172]. The rectification effect is clearly seen in the figure. A model has been proposed for the kink-shaped carbon nanotube Schottky diode, where the gate voltage modulation is included [184, 185]. It has been observed that the nanotube Schottky diodes [172, 179] and the nanotube *pn* junctions [176] exhibit much lower reverse-bias breakdown voltage than conventional, micrometer-size Schottky diodes and *pn* junctions. A theoretical model has been proposed to describe the potential barrier shape in ultrasmall Schottky diodes [186]. It is suggested that for diodes smaller than a characteristic length l_c (e.g., 80 nm for $N_d = 10^{17}$ cm^{-3}), Schottky barrier thickness becomes a function of the diode size. Consequently, the contribution of tunneling to the total conductance is dramatically enhanced, resulting in lower reverse breakdown voltage in nanoscale diodes [186]. The carbon nanotube "T" junction with heptagons or pentagons for joints has been proposed theoretically [187]. However, experimentally no "T" junction has been observed. Instead, "Y" junctions have been produced through an anodic aluminum oxide (AAO) template [188, 189] and directly on substrates [190–196]. Theoretical calculation confirms the rectification

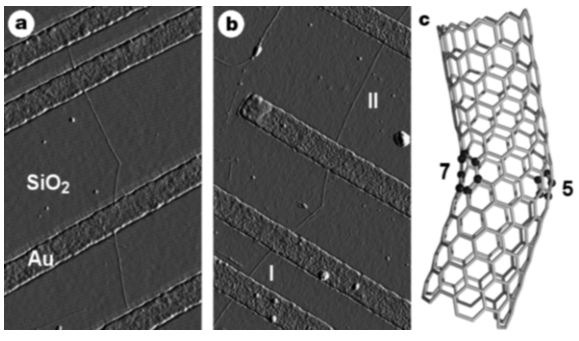

Figure 30. Tapping-mode atomic force microscope amplitude images of examples of nanotube junction devices. (a) and (b) Nanotubes that contain a single kink of 36° and 41° respectively. (c) Illustration of the carbon-bond network of a kink junction constructed between an "armchair" tube and a "zigzag" tube, where 5 denotes a pentagon, 7 denotes a heptagon, and the atoms in the pentagon and heptagon are highlighted by dark balls. Figure 31. Current–voltage characteristics across the metal–semiconductor junction of (a), showing rectifying behavior. The data are taken at 100 K. The results at room temperature are similar, but the data are noisier. Inset in (a): the I–V curve for the upper straight segment measured at room temperature. In (a), the gate is grounded. In (b): the gate voltages from right to left are 2, 1, 0, −1, −2, and −4 V respectively. Inset in (b): expanded view of the small-current region which shows more clearly the onset of conduction for both bias polarities. Reprinted with permission from [172], Z. Yao et al., *Nature* 402, 273 (1999). © 1999, Macmillan Magazines Ltd.

effect of "Y" junctions [197–199]. When the positively biased metal–nanotube contact (source electrode) is locally gated with a negative gate voltage, a dramatic increase in transport current occurs because the Schottky barrier thickness is reduced due to accumulation of holes near the contact [200]. For the negatively biased metal–nanotube contacts, the gate voltage has no effect on transport because no Schottky barrier exists there [200]. Therefore, by positioning the gate locally near one of the contacts, the nanotube FET is converted into a rectifying diode [200].

Zhang et al. [201] fabricated the first real Ohmic contacts between SWNTs and Ti by solid solid reaction: C (nanotubes) + M (solid) → MC (solid), where M is metal. The reaction was performed at a temperature ranging from 800 to 1000 °C in ultrahigh vacuum or an inert atmosphere to avoid volatile reactant [201]. The continuous transformation of the SWNT to carbide is controlled by the diffusion of

M to the C/M interface. The I–V curves showed a straight line when the bias voltage is swept from −1 to 1 V, indicating a true *Ohmic contact* [201]. The resistance at the contact is ∼0.3 kΩ [201], much better than the contact resistance (∼20 kΩ) for the direct metal/nanotube contacts [202, 203].

7. NANOTUBE-BASED NANOFABRICATION

Carbon nanotubes exhibit Coulomb-blockade effects, ballistic transport, and field effects. Of particular importance is the field effect that may lead to the carbon nanotube electronics era. However, a critical issue for successful realization of carbon nanotube electronics is how to manipulate the nanotubes so that large-scale manufacturing is possible.

7.1. Manipulation of Nanotubes Using AFM and STM

Since discovery of carbon nanotubes [1], for electronic device research, the majority of research has been focused on manipulation of carbon nanotubes using the STM or AFM [86, 118, 127, 163, 203–223]. Tans et al. [86] deposited SWNTs on the SiO_2/Si substrate which had patterned metal electrodes. An individual nanotube wire was put across the Pt electrodes, which was imaged by an AFM. Physical manipulation of nanotubes with the AFM tip, like rolling, sliding, bending, and buckling, has been used to investigate mechanical properties of nanotubes [211, 212]. Roschier et al. [127] positioned a semiconducting multiwalled nanotube between two gold electrodes at the SiO_2 surface. The 410 nm long MWNT was manipulated and positioned on the gold electrodes by the AFM tip. Soh et al. [203] synthesized SWNTs on the patterned catalytic islands, which are contacted with metal pads. Lefebvre et al. [204] developed a method to assemble SWNT circuits using a tapping mode AFM. Nanotubes can be controllably translated, rotated, cut, and placed on top of one another by varying the tip–sample force and the tip speed. These operations can construct complex nanotube circuits. Of particular interest is that the suspended SWNT can be deformed locally by the AFM tip, leading to a decrease in conductance of the nanotube by two orders of magnitude [217–219]. This effect can be used to construct nanoelectromechanical devices. Tight-binding simulation showed that this effect is caused by the formation sp^3 bonds because of the mechanical pushing action of the tip [217, 218]. Collins et al. at IBM [205] demonstrated a simple method for permanently modifying MWNTs by using current-induced breakdown to eliminate individual shells one at a time. Carbon nanotubes can withstand remarkable current densities, exceeding 10^9 A/cm^2, because of their strong carbon–carbon bonding. However, at high enough current nanotubes ultimately fail. In MWNTs, this failure occurs in air at a certain threshold power through the rapid oxidation of the outermost carbon shell. The mechanism for the breakdown initiation is the current-induced defect formation. By using the electrical breakdown technique, they can remove the MWNT shells one by one. This controlled breakdown technique is also performed with the help of STM or AFM. Study of the reliability and current carrying capacity showed that under high current density ($>10^9$ A/cm^2) no observable failure in the nanotube structure and no measureable change in the resistance are detected at temperatures up to 250 °C and for time scales up to 2 weeks [224]. *Although these processes and techniques are especially useful for study of nanotubes' physical properties, they may not be appropriate for large-scale fabrication of nanotube-based devices and circuits with high yield.*

7.2. Controllable Growth and Placement of Nanotubes

Before we can think about building sophisticated nanotube-based circuitry, we must find how to grow the nanotubes in specific locations, orientations, shapes, and sizes, as well as how to construct nanotube devices at specific locations and how to connect nanotube devices with each other.

7.2.1. Vertically Aligned Carbon Nanotubes

Li et al. [225, 226] reported the first large-scale synthesis of vertically aligned carbon nanotubes by using CVD catalyzed by iron nanoparticles embedded in mesoporous silca. Vertically aligned arrays of isolated tubes with spacing between the tubes of about 100 nm were controllable through the pores. This method has been extended to grow freestanding carbon nanotubes on glass substrates at lower temperature (<700 °C) using nickel film as catalysts by CVD [227–229] and also on Si substrates [231]. Because the mesoporous structure of silica was not uniform, the controllability of tubes was not very good. It is well known that the porous structure of AAO film exhibits hexagonal close-packed nanopores with large-scale periodicity and high densities [232–234]. Highly ordered and vertically aligned carbon nanotube arrays was obtained when growth of nanotubes was carried out on AAO porous structure with cobalt particles deposited into the bottom of the pores [235–241]. Figure 32 shows the procedure for fabrication and growth and the scanning electron microscope (SEM) image of arrays of nanotubes [236]. It should be noted that these highly ordered CNT arrays were successfully fabricated on aluminum substrates. In order to incorporate the carbon nanotubes into the Si electronics, growth of aligned nanotubes on Si substrates is imperative. AAO films were cracked at about 300–400 °C, whereas AAO on N_b was not damaged at 1100 °C in He gas because the thermal expansion coefficient of N_b is close to that of AAO. It is suggested that the N_b layer under AAO may afford the durability for the high temperature process [242]. CNTs were grown on the AAO film based on 100-nm N_b film [242]. Unfortunately, the as-grown nanotubes were not uniformly controllable and sparse nanotubes were grown [242]. Hu et al. at the University of Kentucky [243, 244] successfully fabricated highly ordered CNT arrays on *silicon substrate* using AAO template by the flame synthesis technique (see Fig. 33). In the process, the Al film was not completely consumed during anodization and the Al film that remained between the AAO and Si substrate served as a buffer layer, resulting in smooth surface without cracks after the high temperature process. This demonstrated the feasibility for integration of carbon nanotube devices with Si integrated circuits.

7.2.2. Horizontally Aligned Carbon Nanotubes

The first horizontally aligned growth of carbon nanotubes was successfully carried out by Kroto's group at the University of Sussex, UK, and Cheetham' group at the University of California at Santa Barbara, USA [245]. The cobalt film deposited on a silica substrate was etched into tracks 1–20 μm wide using a laser beam. Laser beam generates tracks free of cobalt, leaving cobalt particles evenly positioned along the edges of the tracks. Carbon nanotube growth was carried out using pyrolysis of 2-amino-4,6-dichloro-*s*-triazine. After growth, dense nanotubes were found lying inside tracks and aligned from one edge to the other edge of a track [245]. This is the first synthesis of horizontally aligned nanotubes. Dai et al. [63, 141, 203, 246–253] continued extensive research on controllable growth of horizontally aligned carbon nanotubes on patterned Si substrates. A network of suspended SWNTs was grown from Si towers [249]. These suspended SWNTs might be used for interconnect of nanodevices. In order to enhance the directionality of growth, the electric field is introduced horizontally, resulting in better aligned growth of SWNTs as shown in Figure 34 [252]. This was also inspired by the field-assisted growth of vertically aligned CNTs [254]. It was suggested that the self-directed growth between the neighboring pillars is due to the swing of the nanotube cantilever which contacts a catalyst particle in liquid phase as the nanotube grows [255]. These results confirm the possibility of self-assembled wiring of nanostructures. MWNTs were grown from the cleaved side of a $Si/SiO_2/Si$ mulitlayer structure to control the diameter of nanotubes [256]. In order for large-scale fabrication of nanodevices using CNTs, alternative selective placement of CNTs other than an AFM or STM is desirable. Controlled placement of SWNTs on prepatterned Si substrates has been achieved by a combination of the highly selective adsorption of SWNTs onto open regions of amino-functionalized SiO_2 in a polymer resist, followed by lift-off [257]. Controlled placement has also been achieved by electrical field-assisted alignment of CNTs under ac electric field [258]. Of particular interest is the utilization of nanotubes for nanolithography. One example is to use nanotubes as AFM tips to write nanopatterns [259]. Figure 35 shows the AFM image of a 10 nm wide line (SiO_2) fabricated by a nanotube tip [259]. Nanoelectrodes with a spacing of

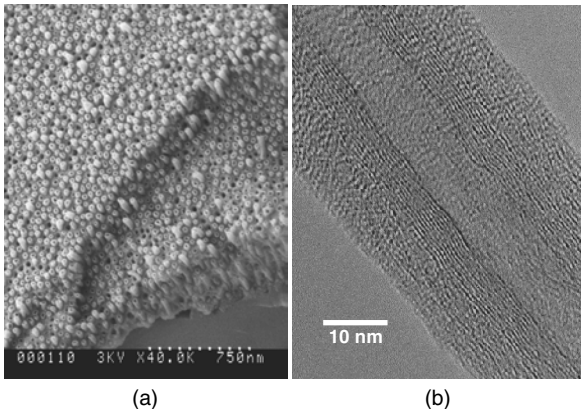

Figure 33. (a) Cross-sectional SEM images of CNT arrays (about 500 nm long) on Si substrate fabricated in our laboratories. (b) TEM image of a CNT grown from the Al_2O_3 template showing multiwalls. Figure 34. SEM images of suspended SWNTs grown in various electric fields. The spacing between the outer poly-Si electrodes is 40 μm in (a) and (b), and 100 μm in (c). Reprinted with permission from [252], Y. Zhang et al., *Appl. Phys. Lett.* 79, 3155 (2001). © 2001, American Institute of Physics.

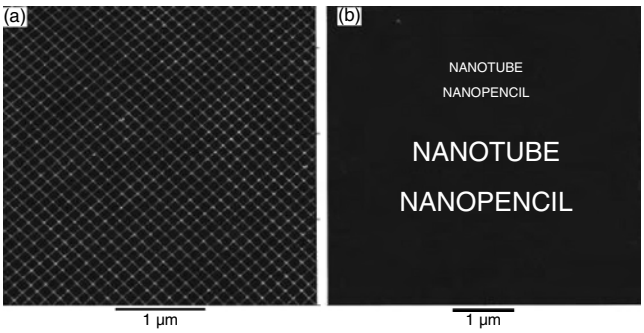

Figure 35. (a) AFM image of 2 nm tall, 10 mm wide, and 100 nm spaced silicon-oxide (light) lines fabricated by a nanotube tip. Bias voltage = −9 V; speed = 10 m/s; cantilever amplitude during lithography = 0.55 nm; cantilever amplitude = 9.6 nm. (b) Silicon oxide "words" written by the nanotube tip. Reprinted with permission from [259], H. Dai et al., *Appl. Phys. Lett.* 73, 1508 (1998). © 1998, American Institute of Physics.

~30 nm have been demonstrated using a carbon nanotube as a shadow mask, where a nanotube was suspended on PR supporters [260]. Figure 36 shows the schematic of the approach and Figure 37 shows the AFM image of the gold electrodes with a gap of ~30 nm [260]. Carbon nanotubes have also been used as masks for plasma etching where a ~20 nm nanowire beneath the nanotube was formed after etching [261].

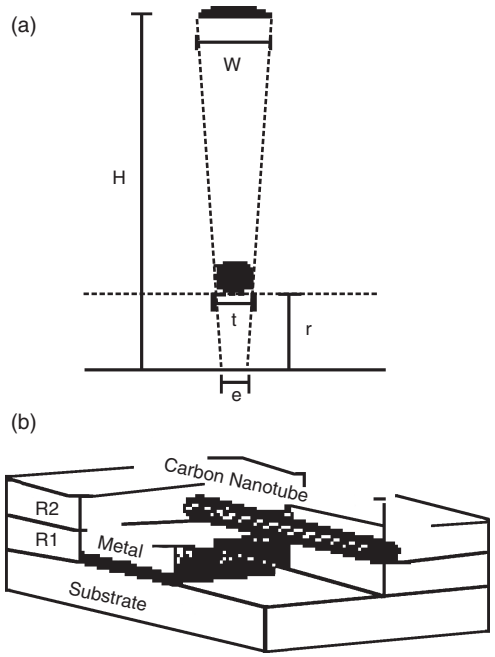

Figure 36. (a) In a shadow mask method, the shadow or gap size (ε) depends only on geometrical factors: the mask width or tube diameter (t), the tube–substrate distance (r), the evaporation source distance (H), and width (W). (b) Carbon nanotubes are incorporated between two layers of e-beam resist (R1 and R2) to act as a shadow mask preventing metal deposition at one point along a thin wire. The figure illustrates the process after metal deposition. Reprinted with permission from [260], J. Lefebvre et al., *Appl. Phys. Lett.* 76, 3828 (2000). © 2000, American Institute of Physics.

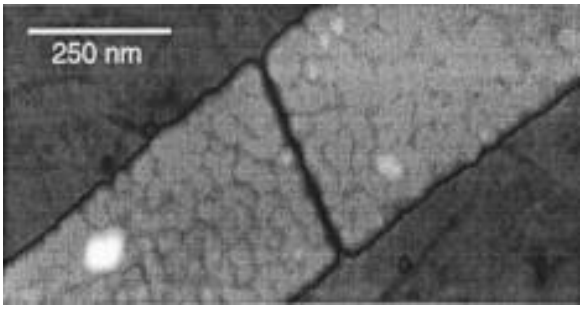

Figure 37. AFM image of a sub-30 nm gap in a 350 nm wide gold wire fabricated using a SWNT bundle. Individual SWNTs or small SWNT bundles (dark gray lines in the image) have been contacted using this method. Reprinted with permission from [260], J. Lefebvre et al., *Appl. Phys. Lett.* 76, 3828 (2000). © 2000, American Institute of Physics.

8. SUMMARY

Carbon nanotube-based nanoelectronics have been reviewed extensively, including electronic structure and transport properties of carbon nanotubes, various electronic devices, and nanotube-based nanofabrication. Since the discovery of CNTs for more than 10 years, great progress has been made in this field. Theoretical calculation predicted the one-dimensional energy band structure of single-wall carbon nanotubes with ballistic transport up to a few micrometers. Experiments successfully confirmed the theoretical predication. There have been demonstrations of the basic functions of carbon nanotube-based nanoelectronic devices such as single-electron transistors, field-effect transistors, logic gates, and memory devices. There is an almost limitless number of new geometries and topics waiting to be explored and all kinds of new structures to be created [262]. Upon comparison of their performance, carbon nanotube field-effect transistors are superior over Si MOS transistors. It is very promising to use carbon nanotube field-effect transistors as building blocks for large-scale integrated circuits when the current silicon technology reaches the end of its roadmap.

However, incorporation of the CNT devices to the existing Si manufacturing process is still far away. The current practice of fabrication of CNT transistors relies on arduous contacting of randomly distributed CNTs from suspension or time-consuming manipulation by AFM. Although great progress has been made in controllable growth and placement of carbon nanotubes, a planar process with high yield, which is the cornerstone of silicon technology, has not yet been achieved in the carbon nanotube process [263]. It is believed that in the next 10 to 20 years progress in process technologies for fabrication of carbon nanotube-based devices and circuits will eventually pave the way for electronics revolution in the molecular or nanoscale.

GLOSSARY

Atomic force microscope (AFM) A system with a mechanical tip scanning over a substrate to sense the atomic forces. The signal from the atomic forces can be synthesized into an image, which is capable to exhibit images of atoms of the substrate. It can also be used to manipulate atoms.

Carbon nanotube One or several graphite sheets that is wrapping together co-axially to form a tube-like material. If it has only on sheet, it is called single-wall carbon nanotube. If it has several sheets, it is called multi-wall carbon nanotube.

Field-effect transistor A three-terminal device with its two-terminal conductivity being totally controlled by the third terminal. In digital electronics, it usually functions as a switch.

Logic gate A device consisting field-effect transistors functions as a switch with "1" representing conduction and "0" representing non-conduction.

Memory devices A device that can store information in the form of "1" and "0."

Nanoelectronics Electronics built from nanoscale components.

Scanning tunneling microscope (STM) A vacuum system with an electrical tip scanning over a substrate to induce electrons tunneling into the substrate. The signal from the tunneling electrons can be synthesized into an image, which is capable to exhibit images of atoms of the substrate. It can also be used to manipulate atoms.

Single-electron transistors A device that exhibits staircase conductivity due to single-electron charging effect usually at low temperature.
