CONTENTS

1. INTRODUCTION

Load and depth-sensing indentation, also known as the nanoindentation technique, started to be developed in the 1980s, and nowadays is being continuously improved. The experimental device is based on recording load, depth, and time during the indentation process. The physical models and experimental systems are based on contact mechanics adapted to conditions of very low applied loads and indenter displacements. This means sensitivity of the applied load and tip penetration on the order of micronewtons and nanometers, respectively.

The determination of the mechanical properties of nanostructured materials is a new and very interesting area. Nanostructured materials are characterized by nanoscale structures with a significant volume comprised of surfaces, interfaces, and grain boundaries, giving properties vastly different and often greatly superior to their bulk-metallic, ceramic, and polymeric counterparts. They can be produced by different techniques to form a myriad of engineered structures. These advances will provide better sensors, medical diagnostics, displays, data storage technologies, and surface protection coverings. However, the determination of their mechanical properties and how these properties are measured in nanostructured materials are in constant revision. As a result, an intense effort has been made in recent years to adapt and develop methods in order to measure deformation and fracture properties at the nanoscale. At the same time, experimental and theoretical work is being done to determine and understand the properties and processes influencing the mechanical behavior and fracture in small volumes. Advanced and novel characterization and testing methods, as well as analytical, continuum, and atomistic simulations, are being continuously developed. Of particular interest are those studies that extend over length scales from atomistic to nanometer or from nanometer to submicron, and thus provide insight regarding length-scale effects.

The characterization of mechanical properties at nanoscale includes: structure–property relationships at the nanoscale in nanostructured materials, composites, films, multilayers, and functionally graded materials; mechanical properties of bulk materials at the nanoscale; deformation and fracture processes at the submicron scale; dislocation emission at probes and crack tips at the nanoscale; effects of intrinsic stresses on properties and fracture; creep measurement and mechanism determination; tribological properties of nanostructured material; comparative results for the modeling of submicron-scale indentation, scratch, and wear response; and development of standards tests to measure mechanical properties at the submicron scale.

The purpose of this review is to show the reader the basic concepts of nanoindentation, and how it can be used to determine mechanical surface properties in the nanoscale regime. These concepts include the basic equations, a brief discussion about theoretical models, the equipment calibrations, and the correct choice of an appropriate indenter. In the following, focus will be given to a series of application results for modified surfaces and thin films (coatings),

tailoring the use of this technique. The further tendencies about using load and depth-sensing indentation are also shown.

This chapter consists of four parts. First, a definition of nanoindentation and some comments with respect to how this technique can be useful for nanoscience and nanotechnology are given. Historical aspects, fundamental equations, and experimental methodology follow. A third part concerns the most important applications and principal results that can be found in the literature. Finally, some discussions about new applications, recent developments in the technique and in the theoretical approach, as well as future perspectives are also taken into consideration.

Nanoindentation is a term used to designate indentation experiments where very low loads are used to press a hard indenter into a surface in a controlled way at submicronmeter penetration depths. As an important feature of the process, the applied load, the indenter displacement, and the time are continuously recorded during the experiment. Due to its versatility, nanoindentation is one of the most important methods to obtain the mechanical properties in the near-surface regions, and it can be applied to practically all types of solid materials.

The Vickers and Brinnel conventional tests use the indentation image to measure the contact area which is necessary to calculate hardness. Unlike this, in nanoindentation, the contact area is obtained from the load and displacement data recorded in a complete load–unload cycle, without the necessity of imaging methods. If more elaborate analyses are performed, other mechanical properties, such as elastic modulus, residual stresses at the surface, strain rate sensitivity, toughness of brittle materials, and adhesion quality of thin films, can be determined by applying the nanoindentation technique.

The determination of nanomechanical properties is a new field, as well as practically all areas in nanoscience and nanotechnology. For this reason, there is a considerable gap to link the mechanical properties from a continuum mechanics approach to an atomistic point of view. This atomistic approach takes into account the forces and movements of individual atoms or groups of atoms that are not considered in continuous mechanics. Atomic force microscopy (AFM) gives us a better understanding of the weak mechanical forces that govern the behavior of atoms in the surface of the materials. However, AFM is not well suited to determine the behavior of the material in a region deeper than a few atomic layers under the surface. Nanoindentation that presents high depth and load resolution is very useful to correlate the nanoscale mechanical behavior with the material structure. In the near future, an improved modeling and interpretation of load versus displacement data is expected since a considerable effort is being developed in the nanoindentation area. The new incoming equipment will probably become better. For these reasons, nanoindentation will continue to play an important role in nanotechnology development.

Surface mechanical properties of several different materials, like metal nanocomposites, polymer films, metal surfaces, coatings, and microelectromechanical systems (MEMS), are being determined by applying the nanoindentation technique. Tailoring modified surfaces to improve mechanical and tribological applications requires a good knowledge of the mechanical properties at the material surface. Knowledge of the hardness, elastic modulus, and wear resistance is very important to specify the correct application for newly developed materials used in the electronic, automotive, or aerospace industry. Then, nanoindentation has an important role in the analysis of nanoscale mechanical properties of materials, and its application is continuously increasing. Finally, despite the fact that results will be more consistent, a great effort must yet be made to adequately interpret the depth and load-sensing indentation data because the deformation process under the indenter is very complex.

2. FUNDAMENTALS OF NANOINDENTATION

In this section, the basic principles of nanoindentation are presented. Historical aspects are described, and it is shown how this technique is used to obtain the surface mechanical properties of materials. Far from being a complete treatise about the theme, the present section can be considered more like a straight guide to understand how nanoindentation can be applied to the study of nanoscale mechanical properties of surfaces and thin films. More advanced works and extended reviews about this theme are indicated in the text.

2.1. Historical

Indentation experiments have been extensively used since the middle of the last century to measure the hardness of materials [1]. However, techniques for probing the mechanical properties of materials at nanoscale were developed only in the early 1980s. This mechanical probing consists of a load and depth-sensing indentation, which gives information about the surface mechanical properties of materials at depths lower than 1 μm. Pioneer works of Pethica et al. [2, 3] showed the first results of indentation at nanoscale that were obtained with an instrumental device that is known now as nanoindentation equipment. They developed an electromechanical apparatus that was used to obtain the hardness at nanoscale. A few years after that, a sequence of other articles were published, showing a great instrumental development, and a new research area on mechanical surface properties was established. The original equipment's purpose was to measure hardness at nanoscale. However, nanoindentation is now used in a wide spectrum, and the recorded data obtained from the indentation are applied to determine different mechanical properties. Other independent works were done in the same period [4, 5], and equipment of different designs, but for the same purpose, were constructed. All of these works were important for developing this new research area.

In conventional indentation methods such as Vickers and Brinnel tests, the hardness is obtained from the ratio of the applied load to the area of the residual impression, which is determined by image methods. However, for indentation at

nanoscale, imaging methods demand a long time, and very special techniques are necessary to obtain the actual area. Sometimes it is very difficult, if not impossible, to make good images from indentations when very low loads are used. Now, with the depth-sensing indentation, it is possible to measure the hardness without imaging the indentation impression.

Pethica et al. [2, 3] reported the use of an area function to calculate the indentation area for a determined indenter penetration depth. The method is based on the knowledge of the shape of the indenter, and on the fact that the material normally conforms to the shape of the hard indenter. The contact area was obtained from final depth after the unloading. However, this first method was not correct as it did not consider the elastic recovery of the sample.

Doerner and Nix [6] later elaborated a method to determine the hardness, and additionally the elastic modulus, from load versus displacement data. In their method, the unloading curve is considered to be governed by the elastic properties only. In addition, the elastic recovery is considered similar to that obtained from a flat cylindrical punch, where the contact area remains constant during the unloading process. Since the elastic recovery from unloading a flat punch is linear [7], they extrapolated the initial part of the unloading curve by a linear fit to obtain the contact depth, which gives better results than at maximum depth or at the residual depth that was previously used in the area function. As an improvement, with this new method, the elastic modulus of materials surface could then be obtained from the loading and unloading data. However, this approach does not give accurate results since the areas measured by imaging methods give different values when compared to the ones obtained by the Doerner and Nix [6] method.

Oliver and Pharr [8], in 1992, described the necessary approach to make nanoindentation a widely acceptable probing method to obtain hardness and the elastic modulus in practically every kind of surface. Their article is the most cited in the nanoindentation area at the present moment. The principle, called the Oliver and Pharr method, is practically a standard when it is necessary to obtain hardness and the elastic modulus from load–unloading curves using load and depth-sensing indentation. After that, a great number of papers were presented showing new improvements on how to obtain new properties of materials from nanoindentation data, and they are described in the following as each aspect is being discussed. In what follows, the basic principles are presented, and some recent improvements in analysis and data interpretation are discussed.

2.2. Basic Principles

2.2.1. Depth and Load-Sensing Equipment

A schematic diagram of equipment that is often used in depth-sensing indentation is shown in Figure 1. It consists of a system of a vertical axis supported by springs to a cell. The indenter is at the end of the axis, as shown in Figure 1. The system is composed of a force actuator, normally an electromagnetic shaker actuator, and a sensor of depth that is generally a capacitance displacement gauge. Other systems that use electrical force applied by capacitance plates

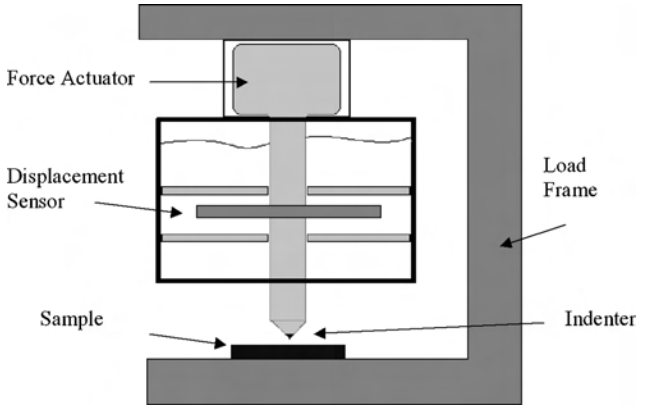

Figure 1. Schematic of a nanoindenter showing the various equipment parts.

or piezoelectric actuators are also used in different equipment designs.

The force actuator normally is capable of applying forces as lower as 1 μN, and the displacement gauge sensor can give a depth resolution better then 0.1 nm. However, for measurements at depths lower than 20 nm, additional rigor and care are needed to obtain useful results. The maximum load used in this kind of equipment is normally about 500 mN. On the other hand, if better displacement and load resolutions are necessary, the maximum load is normally lower, and the depth resolution is increased for shallow penetration. An extensive description with details of different equipments used in nanoindentation, as well as their calibration processes, is presented by Bhushan [9].

Some nanoindentation machines allow the user to build an indentation pattern in a two-dimensional array by using a previous programming. These arrays can consist of a combination of a linear x and y pattern in order to form different two-dimensional geometrical figures like a square, a rectangular, or also triangular shapes. A typical example of an indentation shape produced by a Nanoindenter XP™ is shown in Figure 2. The distance between each indentation can also be programmed, and in the most general case, it is about 50 μm in order to avoid residual deformation

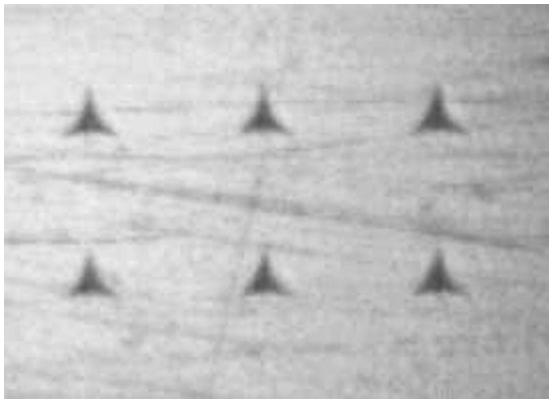

Figure 2. Typical two-dimensional indentation pattern obtained by a Nanoindenter XP™ machine. The distance between the indents is 50 μm.

generated by indentations. This resource permits an easy method to map the mechanical properties in a composite surface, for example. At low loads, the nanoindentation area is small. Then one indentation can be made inside a single grain. In this case, it is also possible to make several indentations, and after that, to make some chemical attack to reveal the grain boundaries. Finally, the indentation position inside or at the grain boundary of grain may be verified, and the different behavior analyzed.

2.2.2. Load x Displacement curve

A typical load versus displacement curve, obtained from the recorded data, is shown in Figure 3. The loading curve presents a typical parabolic behavior which is associated with elastic–plastic deformations during the loading. The maximum tip penetration $h_{\max}$, the contact depth h_c, the residual penetration after unloading h_f, and the measured stiffness S are indicated in Figure 3. The elastic recovery after the unloading corresponds to the difference $h_{\max} - h_f$. The form of these curves, including small changes in the increasing depth rate or in the elastic recovery under unloading, can give information about the surface response to the applied load, and consequently about the mechanical properties at the surface.

2.2.3. Basic Equations

During the indentation process, indenter–sample contact presents elastic and plastic components. Figure 4 shows a schematic view of the indentation contact during loading and after unloading. It was verified by Oliver and Pharr [8] that the unload curve behaves as a power law function

$$P = \alpha(h - h_f)^m \tag{1}$$

where h_f is the final depth after complete unload and P is the load.

Oliver and Pharr [8] showed that the tip contact depth into the sample material h_c at maximum load $P_{\max}$ can be obtained by analyzing the unload curve. Based on the work

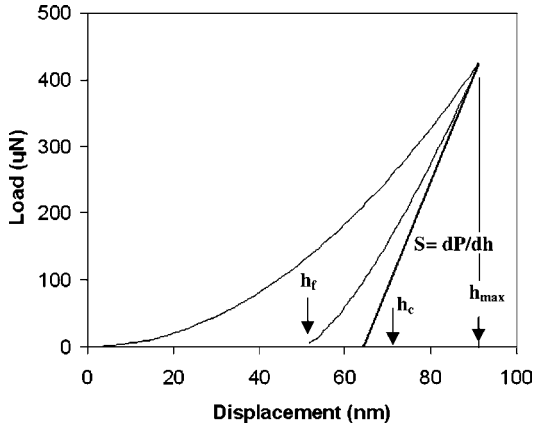

Figure 3. Typical load versus displacement curve showing the loading and unloading parts, the maximum tip penetration ($h_{\max}$), the contact depth (h_c), the final depth h_f, the system stiffness (S), and the elastic recovery.

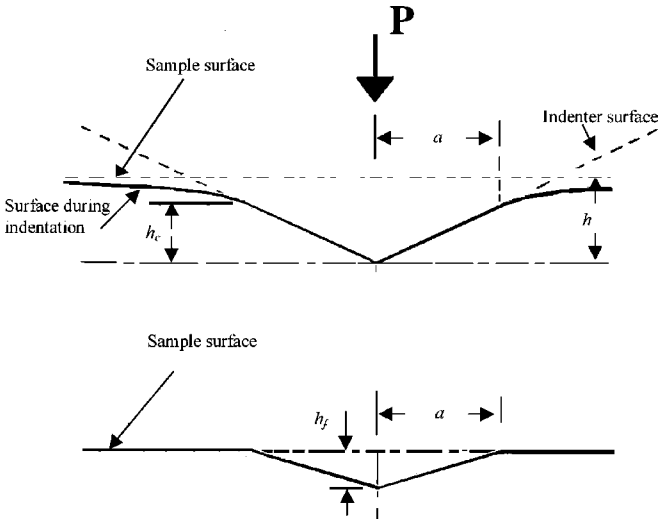

Figure 4. Schematic view of sample surface during and after the indentation, showing the parameters definition used in the equations.

of Sneddon [7] and Doerner and Nix [6], they proposed a method that considers the unload curve as being due only to elastic recovering. The proposed equation, which is the basis for hardness and elastic modulus measurements, is

$$h_c = h_{\max} - \varepsilon \frac{P_{\max}}{S} \tag{2}$$

with S being the unload stiffness,

$$S = \frac{dP}{dh} \tag{3}$$

determined in the initial part of unloading curve. In Eq. (2), ε is a parameter that depends on the tip shape, and is equal to 0.75 for a triangular-based pyramidal Berkovich tip normally used in nanoindentation.

According to the method, the reduced elastic modulus is related to the measured values by the relation

$$E_r = \frac{\sqrt{\pi}}{2} \frac{S}{\sqrt{A}} \tag{4}$$

and

$$\frac{1}{E_r} = \frac{(1 - \nu^2)}{E} + \frac{(1 - \nu_i^2)}{E_i} \tag{5}$$

where the i index indicates the values for the indenter material, and values not indexed correspond to the indented sample material.

The projected contact area is calculated from the contact depth. For a perfect Berkovich indenter, the expression is $A = 24.5h_c^2$ where h_c is the contact depth from Eq. (1). The hardness is then obtained from the usual expression:

$$H = \frac{P}{A} \tag{6}$$

2.2.4. Calibration, Errors, and Limitations

The correct evaluation of mechanical properties from load and depth-sensing indentation depends on the minimization of errors [10] and the comprehension of the method's limitation. However, even in the case of a well-calibrated machine, good results are not obtained if the sample presents a high surface roughness. Another problem appears when the material presents pile up at indentation. Pile up increases the contact area that is not correctly determined when the Oliver and Pharr method is used. Then the calculated values of hardness and elastic modulus are lower than the actual values [11].

The errors and limitations in load and depth-sensing indentation can be separated into three major different groups: calibration of the equipment and determination of contact surface, calibration of the area function for the indenter, and sample effects, such as roughness and pile up. In the following, the calibration processes and how these errors affect the results are detailed.

A correct calibration of the indentation system is very important. Force and displacement calibrations are performed only at installation, and when the system is modified. The following calibration step is to obtain the compliance of the machine. The compliance of an ideal machine for a nanoindentation test must be very low. In this case, the frame machine presents only a small deformation when the load is applied to the sample. However, every machine suffers some deformation during the test. Then, the machine compliance must be deducted from the total compliance obtained from load versus displacement in order to calculate the elastic behavior of the sample. This is done by indenting a sample with high loads, as proposed by Oliver and Pharr [8]. Samples of well-known mechanical properties (like Al and fused silica) are indented at high loads, and the stiffness from the unload is obtained accurately. Considering that the machine is not perfectly rigid, the unload stiffness (dP/dh) has contributions from the elastic responses of both the sample under test and the instrument. The compliance of the instrument $C_f = 1/S_f$ is then incorporated as

$$\frac{1}{S} = \frac{1}{S_s} + \frac{1}{S_f} \tag{7}$$

with S_s being the sample contribution and S_f the machine frame stiffness.

$$\frac{dh}{dP} = \frac{1}{S} = \frac{1}{2E^*}\sqrt{\frac{\pi}{A}} + \frac{1}{S_f} \tag{8}$$

Then, for a Berkovich indenter where $A = 24.5h_c^2$, we have

$$\frac{dh}{dP} = \frac{1}{S} = \sqrt{\frac{\pi}{24.5}}\frac{1}{2E^*}\frac{1}{h_c} + \frac{1}{S_f} \tag{9}$$

Frame compliance is obtained from the data of indentations made at high loads. Values of $1/S$ are plotted versus $1/A^{1/2}$ or $1/h_c$. The data are then extrapolated to an infinite depth or $h_c^{-1} = 0$, and then S_f is calculated. The obtained value is known as the frame compliance of the machine. A common value for load and depth-sensing indentation machine compliance is about 0.1 nm/mN, which corresponds to a frame stiffness of 10^7 N/m.

Environmental effects such as thermal variations and vibrations are another source of errors. Nanoindentation tests have a high sensitivity to temperature changes due to the different values for the thermal expansion coefficients of different materials in the structure frame. Consequently, it is necessary to minimize the thermal fluctuations in the room where the machine is installed. The effect of mechanical vibrations is normally avoided by using a nonvibrating table, and enclosing the machine in an acoustic-damped cabinet.

Thermal drift rates lower than 0.1 nm/s are necessary when small-scale indentations are being performed. Nanoindentation is normally performed at room temperature since the effect of thermal drift is higher when it is necessary to maintain a constant high temperature. However, there are machines suited to operate at temperatures of about 100 °C. In this case, the entire structure composed of the frame, motors, and measurement head are maintained at the same high temperature inside an oven at a constant temperature. This maximum temperature operation is limited by the electrical and electronic components that are inside the oven. Some other high-temperature systems perform nanoindentation at high temperatures, but nanoindentation at high temperatures is still a very complex process.

Another routine calibration is to determine the tip's area as a function of indentation depth. In practical situations, the indenter is not completely sharp, but it shows some roundness at the end, and some errors can be observed because of this fact. Mencik and Swain [10] described a series of errors that are present in the nanoindentation data, which can be due to several factors like tip blunt effects and surface roughness.

The correct determination of the projected contact area as a function of the contact depth is very important to obtain the values for hardness and elastic modulus. Pyramidal indenters present a round end, while spherical indenters are never perfectly spherical. Then, it is necessary to compensate these effects. Scanning electron microscopy and atomic force microscopy performed in real Berkovich indenters showed that indenters with a radius of about 20 nm can be considered relatively good, "sharp" indenters. Berkovich tips extensively utilized have an indenter radius larger than 20 nm. To take into account the blunting of the tip, Oliver and Pharr [8] proposed a relation of the projected contact area to the contact depth that can be described by the equation

$$A(h_c) = 24.5h_c^2 + C_1h_c + C_2h_c^{1/2} + C_3h_c^{1/4} + \cdots + C_8h_c^{1/128} \tag{10}$$

where C_1–C_8 are constant, and determined by fitting the hardness versus penetration data of materials supposed to have a constant hardness at different depths, such as fused silica. Indentations at different loads are performed, and then the area function coefficients are fitted to obtain a constant hardness versus depth profile. This procedure is the most used method to correct the Berkovich rounding tip.

In a recent work, Thurn and Cook [12] presented an analysis of the area function for nanoindentation. A two-parameter area function, obtained from the harmonic average of a spherical tip profile and a perfect conical profile,

was proposed. According to the authors, the two-parameter area function adequately describes the Berkovich indenter tip contact area over the entire load range used in the indentation tests. The calculated projected contact areas for indentations were compared with values obtained from scanning electron microscopy (SEM) observation. Values of the modulus and hardness determined using the two-parameter area function are very similar to the ones obtained using the eight-parameter area function of Oliver and Pharr [8].

The calibrations of spherical indenters are normally made by performing indentations in fused silica in the elastic limit. Then the Hertz elastic model

$$P = \frac{4}{3} E_r R^{1/2} h_e^{3/2} \tag{11}$$

is used to obtain the actual radius of the indenter. However, normally, the radius is not constant, and then some area function is needed to correct the hardness and elastic modulus obtained. A good review of these corrections was presented by Fischer-Cripps [13]. Another calibration process was suggested by Swadener and Pharr [14].

An important factor that limits the determination of the actual surface mechanical properties by nanoindentation is related to the sample surface finishing quality [15–16]. The samples should be flat to have good results under nanoindentation tests. A perfect orthogonal approximation of the tip relative to the surface is more difficult in rough surfaces. In almost all cases of a present roughness, the measured mechanical properties change from point to point in the sample surface, making it difficult to obtain a correct interpretation of the results.

Bobji and Biswas [15–16] analyzed the effect of roughness on hardness values measured by nanoindentation. They established a relation between the penetration depth normalized with respect to a roughness scale parameter. The practical usefulness of their model was verified by the numerical simulation of nanoindentation on a fractal surface. They found that an increase in surface roughness also causes an increased deviation in hardness measured values. They presented a method to deconvolute the effect of roughness in arriving at real hardness characteristics of the near-surface region of a material. The major conclusion they obtained is that, knowing the indenter geometry and given the roughness and penetration depth, it is possible to deconvolute the effect of roughness on measured hardness using a simple algebraic equation, to determine the actual mechanical property profile of the surface region. However, a problem emerges, which is the lack of good knowledge of the indenter geometry.

Other methods to overcome the surface roughness can also be used in order to minimize its influence on the hardness and elastic modulus values: (1) to estimate a correct zero depth surface contact point by analyzing the stiffness of the sample at the contact, and comparing it with similar results in a flat surface [17]; or (2) to determine the hardness based on the stiffness at maximum loading [18], where the contact area is calculated from the loading stiffness at the loading and unloading curves. Using this method and an analysis of the extrapolated contact depth from the loading curve, it is possible to obtain the hardness [19]. In this case, the hardness calculation does not depend on the knowledge of surface contact, and consequently, it may be independent of the knowledge of surface roughness. The usefulness of these two methods, with respect to the direct Oliver and Pharr method, can be observed by comparing the data in Figure 5. The hardness profiles correspond to a Ti nitride surface created by glow discharge at high temperature. A high surface roughness is present. Drastic differences in hardness profiles are observed when the results from the two methods are compared to the one obtained by the Oliver and Pharr method. Both correcting methods agree very well, and the reported values are according to the literature data on titanium nitride hardness.

In a purely elastic contact regime, all materials always sink in during indentation, while for elastic–plastic contact, the material may either sink in or pile up. In some cases, material flowing up from the indentation cavity may occur, as shown in Figure 6. The indenter still maintains contact with the surface, but in this case, the real contact depth becomes larger than the penetration depth obtained from the Oliver and Pharr method. In materials that show pile up, the actual hardness is lower than measured by the Oliver and Pharr method. Bolshakov and Pharr [20] performed a finite-element analysis of the pile-up effect on the measurement of the contact area, hardness, and elastic modulus by load and depth-sensing indentation methods. They found that the parameter $h_f/h_{\max}$, which can be measured experimentally, can be used as an indication of when the pile-up effect is an important factor. According to the authors, pile up is significant only when $h_f/h_{\max} > 0.7$ for materials that do not appreciably work harden. For these materials, if pile up is not considered, the contact area may be underestimated by as much as 60%, and as a consequence, an overestimation of the hardness and elastic modulus occurs. For materials that moderately work harden or in the case of $h_f/h_{\max} < 0.7$, pile up is not a significant factor, and the Oliver and Pharr data analysis procedure can be expected to give reasonable results. The same metal may present different behavior with respect to pile up, depending on the presence of an annealed or cold-worked state. Well-annealed samples present much less pile up than cold-worked samples of the same metal.

Measurements of pile up and sink in of material around Vickers and spherical indentations in metals and ceramics

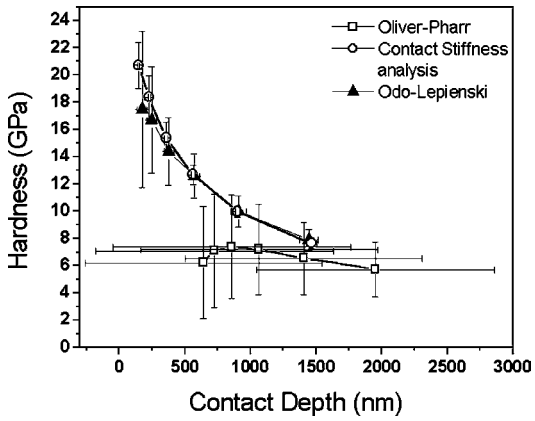

Figure 5. Hardness profile for a high rough Ti-modified surface obtained by using the Oliver and Pharr method [8], contact stiffness analysis [17], and Odo–Lepienski method [19].

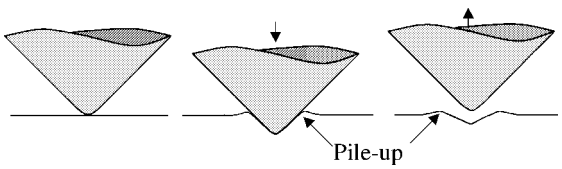

Figure 6. Pile-up phenomena during indentation.

were made by Alcalá and coworkers [21]. They found that surface displacement at the contact boundary under applied load and in the unloaded state is correlated with the uniaxial strain hardening exponent n. Sinking in predominates in materials where $n > 0.2$. A state of nonuniform deformation is detected around Vickers indents, in contrast to the case of spherical indentation, where the deformation state is more uniform as a result of the axisymmetry of the contact conditions. The average (mean) surface deformation state around the contact perimeter in Vickers indents follows a similar correlation with n as that found for spherical indentation. The study of pile up and sink in is very important to the analysis of instrumented indentation experiments.

3. APPLICATIONS

Load and depth-sensing indentation are applied to practically every kind of solid material. This wide field of applications can be attributed to the facility of use since it does not require more than a relatively flat and not rough surface. Comparative results are straight forwardly obtained, being very useful to determine the effect of some parameter variation in the production or treatment of a specimen. In this section, the application and some results of load and depth-sensing indentation in different kinds of materials are presented. The objective is to show the major applications and to discuss the principal results in order to give the reader a direct way to analyze some of the most important fields of nanoindentation application. In addition, some nonconventional and very specific applications are described to show the technique capabilities and new ways to determine the mechanical properties of materials.

Some of the major applications of the nanoindentation technique, as indicated by the number of published articles in the last ten years, are listed: (1) determination of the hardness and elastic modulus of deposited thin films and coatings, principally metallic thin films and diamond-like carbon films; (2) determination of mechanical properties of irradiated materials including ionic irradiated surfaces and plasma-based ion implantation; and (3) study of mechanical properties of brittle materials, such as hardness, elastic modulus, toughness, and adhesion properties.

Some new and not totally well-developed areas where the depth and load-sensing indentation is being applied are: plasticity at low dimensions, mechanical properties of nanostructured materials, stress–strain simulation and residual stress determination, viscoelastic properties of polymers, and the creep and strain rate effect on the deformation of materials at low temperature. In these cases, non-Berkovich indenters may also be used to access mechanical properties other than hardness and elastic modulus.

3.1. Determination of Mechanical Properties of Coatings

In one of the first attempts to obtain the hardness of modified surfaces and coatings using depth and load-sensing indentation, Jonsson and Hogmark [22] developed a useful method for high applied loads based on the tip area function. Some progresses were described by Burnett and Rickerby [23] and Burnett and Page [24]. But independent of all efforts, hardness measurements based on these models are only completely successful for thick layers (on the order of several micrometers) because substrate effects are present, and it is not so clear yet how they can be excluded from the hardness profiles [25–28].

Nowadays, technological advances to produce surface coatings (thin films) and new materials at nanometer scale play an important role in technological applications. The thickness in these situations is reduced to the order of a tenth of a micrometer or less, and consequently, nanoindentation practically is the unique technique indicated to obtain mechanical properties in these regions.

In the following, the principal results of the mechanical characterization of deposited coatings by nanoindentation methods are pointed out.

3.1.1. Variation of Mechanical Properties According to Deposition Process

Coatings are predominantly produced by physical vapor deposition (PVD) and chemical vapor deposition (CVD) processes, which are being continuously developed and improved, with their indication depending on the end product [29–31]. The surface properties are strongly dependent on the bonding nature of the film structure and the substrate [32]. Coatings with an intense covalent bond nature have a tendency to present the highest hardness values, while metals are the lowest, and ionic coatings have intermediate values. Typical applications of coatings are scheduled below simultaneously with their basic composition [33–34]:

- magnetic and electronic films (Nd–Fe–B; Sm–Fe–N; Al–Co; Fe–Co; Cu; Au)
- optical films (SiO_2; TiO_2; Al_2O_3; Ta_2O_5; ITO)
- decorative, hard, and wear-resistant films (Ti–Al–N; Ti–O–N; B–Ti–Nb–N; DLC; Ti–Al–O–N; h–BN; c–BN; Zr–Cu–N; SiC; VC; VN; TiC; WC; AlN; CrAlY)
- corrosion barriers (Nb–Cr; Fe–Cr alloys; Ti–Al–Cr–N–C)
- solid lubricants (MoS_2; C60, V_2O_5, W_3O)

Figure 7 shows the range of hardness and elastic modulus values that can be obtained by using the nanoindentation technique for different material compositions and at different deposition processes as found in the literature. The values present a great dispersion associated not only with the different tailoring processes, but also with different methodologies to obtain the mechanical properties.

Despite the substrate influence on the hardness or film modulus values, typical load/unloading curves can be used to obtain global information about the film-tailoring process. In a comparative study of different coatings, it was recommended to extract these values at a depth on the order of 10% of the coating thickness or, as in some situations, obtain

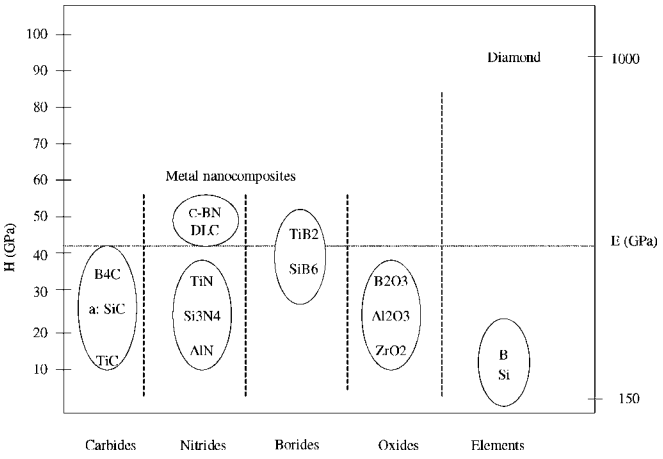

Figure 7. Hardness and elastic modulus of coatings for different deposition processes.

the ones at depths that were reached at the same applied load [25, 28, 36].

Detailed studies of hardness, elastic modulus, and elastic recovery for metal nanocomposite coatings were performed by Musil et al. [36] and Kourtoukova et al. [37]. They showed the relation between hardness to elastic modulus (E/H), hardness to elastic recovery (E^2/H^3), and elastic modulus to elastic recovery (E/W_e and H/W_e) that can be used to tailor the best ensemble of mechanical properties, depending on the end application of the coating.

Literature data are very extensive on the subject of mechanical and tribological properties of coatings using the nanoindentation technique. These properties, referred to before, are strongly dependent on the deposition process used, and the following references are indicated to the reader to be consulted:

- carbides and nitride-based coatings [38–53]
- DLC coatings [54–86]
- metal and oxide coatings [87–92]
- polymeric coatings [93–95]

3.1.2. Effect of Substrate on Coating Characterization

A very large number of articles were written to describe the effect of the substrate in the determination of mechanical properties of thin films [22, 25, 96–105]. Several models were developed to describe the nanoindentation hardness and elastic modulus variation as a function of penetration to film thickness ratio [20, 23, 27, 106–109]. However, this problem continues without a satisfactory solution, and new models are expected to appear in the future. The major difficult factor for modeling the film–substrate behavior under indentation is the complex triaxial stress state in the region constituted by the film, the indenter, and the substrate.

The effect of the substrate in the determination of the hardness of thin films is schematically shown in Figure 8. The elastic zone during indentation is not restricted to the film, but also reaches the substrate. Substrate plastic deformation also occurs for deeper penetrations.

Tsui and Pharr [11] analyzed the effect of hard substrates on the nanoindentation mechanical property measurement

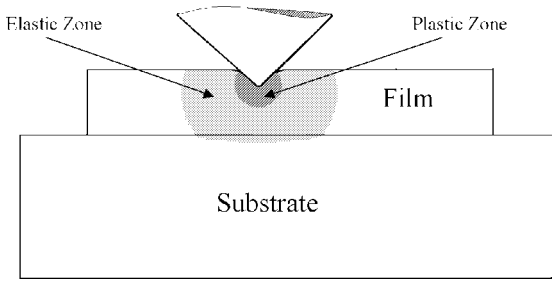

Figure 8. Schematic drawing of the elastic and plastic zone in film substrate.

of soft films. In their work, substrate effects on the measurement of mechanical properties of thin film of aluminum on glass have been studied experimentally by nanoindentation methods. The hardness and elastic modulus of aluminum films with thicknesses of 240, 650, and 1700 nm sputter deposited on glass were systematically characterized as a function of indenter penetration depth using standard nanoindentation methods. They performed scanning electron microscopy and atomic force microscopy of the hardness impressions that revealed that indentation pile up in the aluminum is significantly enhanced by the substrate. It was found the substrate also affects the form of the unloading curve in a manner that has important implications for nanoindentation data analysis procedures. According to the referred article, nanoindentation measurement techniques can overestimate the film hardness and elastic modulus by as much as 100%, depending on the indentation depth, with the largest errors occurring at depths approximately equal to the film thickness. They also verified that indentation pile up in soft aluminum films is significantly enhanced when the films are deposited on hard substrates. In the case where the indentation depth is be about one tenth of the film thickness, the substrate-induced enhancement of pile up is negligible.

Saha and Nix [26] recently performed a study on the effects of the substrate on the hardness and film modulus using the nanoindentation technique. Different films of Al and W were deposited over substrates like Al, Si, glass, and sapphire. The intrinsic hardness and elastic modulus of the films were analyzed using the relation

$$\frac{P}{S^2} = \frac{\pi H}{4\beta^2 E^{*2}} \tag{12}$$

where P is the applied load, S is the contact stiffness, H is the hardness, E^* is the reduced modulus, and β is a tip geometrical constant. According to referred authors, for homogeneous materials, P/S^2 is constant with depth. Then, plotting P/S^2 versus depth may provide useful information about the substrate effect for different combinations of hard film/soft substrate and soft film/hard substrate. The substrate influence is small for soft film over hard substrate. On the other hand, for hard film over soft substrate, the film hardness can be obtained only for total indenter penetrations lower than 10% of the film thickness. Of course, correction of the contact area is needed because pile up will be necessary if the traditional Oliver and Pharr method is used. Considering elastic modulus measurements, the strong effect of

the substrate exists because the elastic field presents a long-range character, and special care must be taken in order to extract the actual elastic modulus value for the film material. For a large mismatch between the film and substrate modulus, King's analysis to estimate the film modulus is indicated [27].

3.2. Surface Modification by Ion Irradiation

Ion implantation (II) and plasma-based ion implantation (PBII) processes are also well established to offer wide possibilities for the surface modification of materials. The application potential of these modified surfaces is very high in the different fields of the modern technology, like the microelectronic, metallurgical, and biological industries. However, these processes are different with respect to coating deposition processes. Atomic species are introduced in the near-surface region by a nonequilibrium process which depends on the parameters used, like ion energy, ion current, chamber vacuum, and temperature conditions. The modified surface region can then be constituted of embedded phases, buried layers, and also, under some conditions, to form a coating layer. In the general case, a graded region is produced from the near-surface to deeper regions. The modified region is, in almost all cases, localized at depths on the order of ten nanometers to thousands of nanometers. Because of this, the nanoindentation technique is the most indicated to obtain mechanical properties such as hardness, elastic modulus, as well as elastic recovery and surface toughness.

Nitrogen is the most used atomic species that has been irradiated to improve surface hardness in metals by II or PBII processes because of its ability to form nitride compounds. However, other atomic species like C, B, Cr, Ti, and O can also be used to prevent wear and corrosion [110]. Notwithstanding, there exist a great number of commercially available metal alloys; the number of reported works in the literature about mechanical properties obtained by the nanoindentation technique for metal surfaces modified by II or PBII is small. Equally as performed for coatings, the influences of the substrate (matrix) and very near-surface region need to be excluded, or at least minimized, in order to obtain the actual hardness and elastic modulus values for the ionic modified surfaces. Surface modifier processes typically produce graded regions. These regions may be formed by a natural oxide layer, the presence of a solid solution of implanted ions, and some stoichiometric phases. The description of a unique hardness value for the material surface is then almost impossible. Consequently, it is recommended to analyze the ionic effect on surface hardening by using the hardness-to-depth profile to compare the different physical parameters of the irradiation process used to modify the surface.

A typical hardness profile for the pure iron surface submitted to N ion implantation is shown in Figure 9. The N peak position is around 70 nm in depth for both substrates. High hardness occurs in the near-surface region, and slowly decreases until it reaches the substrate value. The high surface hardness is attributed to the formation of iron nitrides. The distribution range of the N ions is not sharply defined (it is a Gaussian-like distribution). Then N atoms in solid solution are also present before and after the ion peak

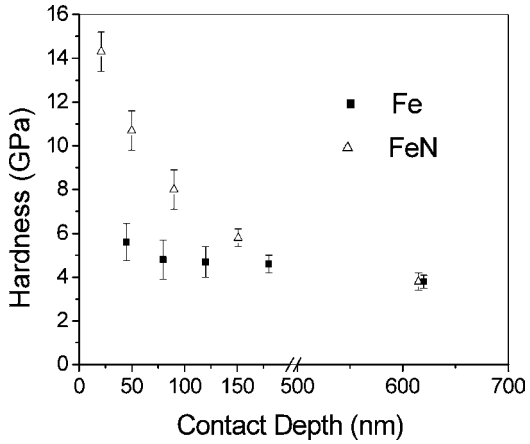

Figure 9. Hardness values as a function of depth for N irradiated iron.

position. Because of the influence of high hardness in this graded region, substrate hardness values are only reached at very deep depths.

Table 1 summarizes the hardness values obtained using the nanoindentation technique (low applied loads $\leq$100 mN), in different commercial metals and metals alloys submitted to different ion irradiation processes (II and PBII).

Additional mechanical property information can also be extracted from the load/unloading curves in the surfaces modified by II or PBII processes. It is well known that II or PBII processes introduce surface damage. The damage profile is basically a function of the ion species and its energy. In this region, atomic displacements, vacancies, Frankel pairs, and extended defects are observed. These defects may alter the elastic field in the region around the tip contact, delaying the plastic deformation by increasing the tip ending pressure, and finally reaching the necessary energy to emit dislocations and form microcracks. This specific phenomenon can be observed in a load/unloading cycle, and it is characterized by a typical tip incursion (pop in) [111]. The extension of the tip incursion at an applied load and time can be then used to estimate the energy to create dislocations. The pattern of the tip incursion allied to electronic microscopy was then used to confirm these hypotheses. At this point, it is important to distinguish this phenomenon from pop in that occurs in dislocation-free materials.

Polymers are also widely used in most industrial applications due to their excellent chemical and physical properties, easy working processes, and low operational costs. On the other hand, when polymers are submitted to load-bearing and abrasive conditions, the mechanical and tribological properties need to be enhanced. The use of II and PBII processes has shown to be a very efficient technique to modify polymer surfaces because there is a large energy transference in II and PBII processes when compared to other more traditional processes like X-ray, γ-ray, ultraviolet rays (UV light), and electron beams. The polymers present a lower bond strength compared to metals, ceramics, or semiconductors; then the transferred energy to the electrons and atoms by the incoming ions stimulates chemical reactions and chain scissions that, at the final stage of the process, produce hardening and stiffening of the polymer surface by a cross-linking mechanism of the chains or

Literature data about mechanical and tribological properties, using the nanoindentation technique, of polymers, like polyisoquinoline (PIQ), poly-2-vinylpiridine (PVP), polyacrylonitrile (PAN), polyethylene (PE), polycarbonate (PC), polyetherimide (PEI), polystyrene (PS), Kapton polypropylene (PP), polypropylene (PP), polystyrene (PS), polyethersulfone (PES), polyethylene terephthalate (PET), polyhedral oligomeric silsesquioxane (POSS), poly(ether ether ketone) (PEEK), polystyrene (PS), fotoresist AZ 1350, C_{60} films, and plasma-formed polymers, in a bulk or coating form, submitted or not to surface-modifying processes, can be obtained by consulting the references [68, 127–141].

3.3. Hardness at Nanoscale: Anisotropy, Grain Size Effect, and Indentation Size Effect

The study of very small-scale indentation has increased in the last few years. A considerable effort has been made in theoretical and practical aspects of this problem. At very low loads, nanoindentation is being used to understand the strain gradient plasticity and dislocation emission from the plastic region under the indenter.

At larger scales of indentation, a number of models exist for plastic flow, but as experimental scales shrink, properties change; then these models may not be applicable. A detailed understanding of the atomic-level processes that contribute to the initial nucleation of dislocations, their motion, and multiplication will greatly facilitate the design of tailored materials with specific mechanical properties.

Nanoindentation tests performed at very small penetrations increase the probability that some indentations occur only inside one grain in the material, and then anisotropy effects are very important. At high loads, hardness is obtained from a mean value from several grains. At low loads in nanoindentation tests, the hardness value may correspond to one grain only. For polycrystalline materials, the crystalline orientation of the indented grain relative to the tip geometry is not well known. In addition, for well-annealed metals, the typical dislocation separation is about 1 μm, and the region under the tip should behave close to that of a perfect single crystal, that is, a dislocation-free specimen. Consequently, the understanding of the contact mechanics of small volumes becomes increasingly important.

Corcoran et al. [142] developed a study of the anomalous plastic deformation of single-crystal Au(111), Au(110), and Au(100) surfaces under nanoindentation, and observed a yield behavior composed of a series of discrete yielding events separated by elastic deformation. The onset of this behavior is in agreement with calculations for the theoretical shear strength of gold. Good quantitative agreement is found between the experimental results and a model developed for the nucleation and multiplication of dislocations by a simple Frank–Read source under the indenter tip.

In another paper, Fougere et al. [143] used nanoindentation to measure the Young's modulus for nanocrystalline Fe samples produced by inert-gas condensation and warm consolidation. The samples had grain sizes of 4–20 nm and a residual porosity of 2–30% calculated relative to conventional Fe. Values of the Young's modulus for the nanocrystalline Fe are reduced relative to values for conventional, fully dense Fe. According to the above authors, the observed reductions in the Young's modulus for both the nanocrystalline and the conventional porous Fe can be described adequately by several theories utilizing spheroidal porosity.

It is well known that hardness is observed to increase in metals with decreasing indentation size, especially in the submicrometer depth regime [144, 145]. Conventional theories of plasticity do not include material length scales. In these theories, the flow stress at any particular point in a solid is only related to the strain at that point. Some new theories have appeared where the deformation is influenced by the strain gradient present at that point, and related to the concept of geometrically necessary dislocations [146].

In their article, Nix and Gao [146] proposed that the indentation size effect for crystalline materials can be modeled using the concept of geometrically necessary dislocations. Their model describes the variation of hardness with penetration depth as given by

$$\frac{H}{H_0} = \sqrt{1 + \frac{h^*}{h}} \tag{13}$$

where H is the hardness for a given depth of indentation h, H_0 is the hardness in the limit of infinite depth, and h^* is a characteristic length that depends on the shape of the indenter, the shear modulus, and H_0. They observed, from indentation experiments on annealed (111) copper single crystals, cold-worked polycrystalline copper, and single crystals of silver, that this relation is well obeyed. One interesting scale aspect is that indentation hardness can drop by more than a factor of 2 with increasing depth, and this depth dependence appears to be more accentuated in single crystals than polycrystals. Whether this is strictly due to the difference in the initial dislocation density and/or number of sources is still under investigation.

Tymiak et al. [147] studied the plastic strain and strain gradient with nanoindentation at very low penetration depths. Plastic strains and their respective strain gradients produced by nanoindentation have been theoretically interpreted and experimentally measured at shallow indentation depths for spherical and wedge indenters. For a sharp wedge, both experimental continuum-based and theoretical geometrical approaches suggest the strain gradient decreasing with increasing indentation depth. For spherical indentation, theoretical geometrical analysis yields a depth-independent strain gradient proportional to $1/R$. Tungsten and aluminum single crystals exhibit about a factor of 2 decrease in hardness with increasing depth, irrespective of either increasing or decreasing average strain gradients.

Kiely and collaborators [148] performed nanoindentations on Au single-crystal surfaces. They observed two distinct regimes of plastic deformation, which are distinguished by the magnitude of discontinuities in load relaxation. At lower stresses, relaxation occurs in small deviations from elastic behavior, while at the higher stresses, they take the form of large load drops, often resulting in complete relaxation of the applied load. These major events create a relatively wide plastic zone that subsequently deepens more rapidly than it widens. They proposed two regions of plastic relaxation result from two distinctly different processes. In the first region, deformation likely occurs through the nucleation, glide, and locking of several dislocations, resulting in deformation several atomic layers deep. At higher stress levels, dislocation multiplication occurs, and produces mobile dislocations.

3.4. Applications Using Different Indenter Geometries

Several indenter geometries are used in nanoindentation tests. The most common is the Berkovich indenter, which is a three-sided pyramid, with the face angle to normal equal to 65.3°. This indenter has the advantage of being well suited to obtain mechanical properties at a small depth since it is possible to obtain indenters with a relatively sharp end, and at the same time, a good relation contact area to depth. Other indenters commonly used are Vickers, conical, spherical, cube-corner, and the flat-end shape. Each one of these indenters has some advantages and disadvantages. Indenters with different shapes are normally used to obtain mechanical properties diverse from hardness and elastic modulus, although these properties can also be obtained using indenters with a geometry other than Berkovich.

3.4.1. Berkovich

The great majority of results obtained by nanoindentation tests are performed by using Berkovich indenters. A Berkovich indenter has a three-sided pyramidal shape, with angles of 65.3° between the normal and the median of each face, and 76.9° between the normal and each corner line. For a perfectly sharp indenter, the projected contact area is $A = 24.5h^2$, where h is the contact penetration depth. A Vickers four-sided pyramidal indenter has the same area function with respect to the depth penetration relation as a Berkovich indenter. Berkovich indenters are the most used in nanoindentation tests. Although real indenters are never perfectly sharp, three-sided pyramidal indenters such as Berkovich are normally less blunt than four-sided indenters like Vickers.

3.4.2. Vickers

Vickers indenters are also used in load and depth-sensing indentation machines. However, since it is more difficult to obtain sharp Vickers indenters at small depths, its use is more common for some hard materials and higher loads [149]. Some theoretical work also has been performed, comparing Vickers and conical indenters [150, 151].

3.4.3. Spherical Indenters

Spherical indentation was one of the first tests to determine the hardness of material. The Brinnel test is one of the most used to determine the hardness in a macroscale [1]. Francis [152] describes the deformation mechanisms of plastic spherical indentation, in an attempt to correlate the deformation mechanism to the pressure distribution under the indenter as a function of depth penetration.

Spherical indentation has an interesting, and at the same time challenging, aspect: the contact between the indenter and surface is not self-similar, that is, the contact angle increases continuously with penetration. This characteristic permits us to determine properties such as the elastic-to-plastic transition. However, analysis of loading–unloading curves is more complex because the contact angle is varying continuously.

Spherical indenters are widely used, not only to obtain the hardness of the material. A number of papers were published about the application of spherical indentation to determine the hardness and other mechanical properties of materials [153–156].

Depth and load-sensing indentation with spherical indenters is also used to simulate a relationship between the stress and strain, in a similar way as in an uniaxial applied stress, and then to try to obtain the yield strength from appropriate models and nanoindentation load–unload tests. Herbert

and coworkers [157] performed uniaxial tests and nanoindentation tests with spherical indentation in order to explore the accuracy to predict the uniaxial stress–strain behavior of aluminum alloys from nanoindentation tests. They related that spherical indentation can be successfully used to establish an engineering estimate of the elastic modulus and yield strength of Al alloys. However, nanoindentation tests could not reproduce the physical shape of the uniaxial stress–strain curve.

The use of spherical indentations to obtain good results is a more challenging matter. Since spherical indenters are not perfect in the majority of cases, presenting a profile that is not a perfect spherical surface, they are very sensitive to calibration. In most cases, the area and the frame compliance calibrations cannot be obtained from indentations in a unique sample as proposed by Oliver and Pharr for pyramidal indenters. Spherical indenters sometimes show a more acute surface, in others a more blunt surface, and also irregular, not spherical shapes. These effects are not easily incorporated to the area calculus as in the case of the blunt effect of pyramidal indenters. Then each case must be analyzed very carefully. Swadener and Pharr [158] presented a calibration method for nanoindentation with spherical indentation. They proposed to perform indentation on two ceramic materials to the same contact depth. The results are then used to determine the radius of the spherical indenter and the machine compliance. Another analysis of the basic equations and methods to use spherical indenters with load and depth-sensing indentation machines was presented by Fischer-Cripps [13].

Residual stress determination is another application of spherical indentation. Several studies have been performed to determine the residual stress at the surface from indentation techniques. Carlsson and Larsson [159] performed pyramidal indentation in materials with residual stress using pyramidal indenters, and they found that the effect of residual stress on load–unload curves with pyramidal indenters and on measured hardness is small. However, as the contact angle in spherical indentation increases with penetration, the sensitivity to residual stress is higher for spherical indentation than for pyramidal indentation. For these reasons, spherical indentation may be useful to obtain the residual stress at surfaces of metallic materials. A new experimental technique for making measurements of biaxial stress using load and depth-sensing indentation using spherical indenters was presented by Swadener et al. [160]. The residual stress at the surface is obtained from analysis of the mean pressure p_m as a function of the ratio a/R, a being the contact radius and R the indenter radius. The presence of residual stress causes an increases in the values of mean pressure during indentation for the same contact area.

3.4.4. Cube-Corner and Other Sharper Indenters

The indentation of ceramic and other fragile materials can generate cracks, such as radial cracks at the indentation corners and conical cracks. The presence of cracks can be useful to determine the toughness of fragile materials [161, 162]. Then, by measuring the extension of a radial crack at indenter corners, it is possible to determine the toughness of the fragile material. However, radial cracks are not normally observed in indentations with a Berkovich indenter if the applied loads are in the range commonly used in nanoindentation because fragile materials have a critical load for crack initiation. Consequently, cracks are not formed for loads lower than the critical load. It was observed that this critical load is a function of the contact angle between the indenter face with respect to the sample's surface [161]. Increasing the contact angle, the critical load decreases. Loads of about 400 mN are necessary to generate radial cracks at the indentation's corner for Berkovich or Vickers indentation in soda lime glass. On the other hand, a load as low as 20 mN can cause radial cracks when cube-corner indentation is performed in the same material [163, 164]. Because of their low critical load, cube-corner indenters are used in toughness measurements with load and depth-sensing indentation.

Indentation fractures at low loads with a cube-corner indenter are used to study the toughness and adhesion characteristics of thin films [28, 165, 167]. The maximum loads that can be applied by nanoindenters are normally not high enough to induce surface cracks if Berkovich pyramidal indenters are used. However, with sharp indenters, the toughness can be obtained from determination of the radial crack length with different loads and a model proposed by Anstis and Lawn [161, 162]. Some additional difficulties appear when it is necessary to determine the length of cracks because, as loads, the lengths are also very small. The validation of toughness values for thin films cannot be completely established since it can be verified by other methods in the same way as in the case of a bulk material. In thin films, there are also the effects due to the presence of the substrate and the interface region. The characterization of thin-film fragile behavior is a challenging matter since, in nanoindentation tests, it is very difficult to eliminate the effect of the substrate. In addition, it is possible to perform analysis of the adhesion, by qualitatively determining the delamination and interfacial behaviors, with cube-corner indentation. However, the models used to obtain adhesion energy and toughness values need further development.

The use of indenters sharper than the Berkovich indenter has become more frequent recently. The most used of this sharper indenter is the cube-corner geometry, where the angles of the corners are 90°. Cube-corner indenters are normally used in order to evaluate the material's resistance to microcrack initiation and propagation [168] and residual stresses in ceramic materials [169]. In addition, analyses comparing the unload curves obtained with cube-corner, Berkovich, and spherical indentation are also being performed [170]. Nanoindentation results made using indenters with different triangular pyramidal geometries are described by Ikezawa and Maruyama [171].

Malzbender et al. [28], in a review article, described the practical use of nanoindentation and scratch tests in determining the mechanical properties of thin coatings. They presented the major methods to determine the mechanical properties of coatings, with emphasis on brittle coatings.

3.4.5. Flat-End Indenters and Viscoelastic Behavior

The determination of mechanical properties of polymers from nanoindentation tests needs special care due to their viscoelastic behavior. The penetration and load are now

dependent on the strain rate. The indenter penetration depends on the loading time being higher if the test is performed at lower rates. Even at constant load, the penetration depth continues to grow. The values of the hardness and elastic modulus measured by nanoindentation are then dependent on the time and strain rates used in the experiment. For this reason, it does not make sense to define a unique value hardness for a polymer since it depends on the strain rates and interval times used in the experimental procedure. The elastic modulus is also not well defined, the values being obtained from nanoindentation tests higher than those measured from uniaxial tension tests in bulk materials. Much work, however, has been done to determine the mechanical properties in polymers despite this additional difficulty caused by their viscoelastic behavior [172–174].

An additional capability of nanoindentation is to measure the viscoelastic properties of polymers. In order to do so, flat-end cylindrical indenters are normally used. The contact area being constant during penetration, the pressure distribution for a determined depth under the indenter can be considered almost constant if low loads are used. Basic equations of flat punch nanoindentation on polymers are presented by Cheng et al. [175]. The standard three-element viscoelastic material indented by an axisymmetric flat-ended indenter was investigated theoretically. The solutions of the equations of viscoelastic deformation were derived for the standard viscoelastic material for compressible as well as incompressible solids. They analyzed both the flat-punch creep test and the load-relaxation test, providing a fundamental basis for probing the elastic and viscous properties of coatings with nanoindentation tests.

3.5. Scratch Test

A scratch test consists of drawing a surface with a tip applying a normal load (P). Since the nanoindentation system permits very good control in the applied force and penetration depth, it is only necessary to add a tangential movement actuator to obtain a very well-controlled scratch test at nanoscale. The used tip can be conical, spherical, or pyramidal. Theoretical studies have been developed in order to understanding the contact mechanical at nanoscale. Buldan and coworkers [176] presented a very interesting study on the contact at atomic scale of an indenter, and subsequent pulling and dry sliding of a sharp and blunt metal tip on a metal surface. They used molecular dynamics methods and empirical potential on an embedded-atom model to determine the atomic structure evolution and the variation of the normal and lateral forces. The results are very different for each of the diverse tips used in the study. Finite-element analysis of the deformation during indentation and scratch tests on elastic–perfectly plastic materials was performed by Bucaille and Felder [177]. The understanding and quantification of elastic and plastic deformation during a scratch test was presented by Jardret and coworkers [178].

Basically, in a scratch test, the load can be applied in two different ways: (1) a constant load during the entire scratch, or (2) an increasing load (ramp loading) from an initial to a maximum value at the end of the scratch. Lateral force transducers, adapted to a DSI device, are used to measure the lateral force (F) that acts on the scratch tip. If the applied load P tends to zero, and if ploughing is absent, it is possible to estimate the friction coefficient by using

$$\frac{F}{P} = \mu_a + \mu_p \tag{14}$$

where μ_a is the adhesion friction coefficient and μ_p is the ploughing friction [179, 180].

Additional mechanical properties, like elastic modulus, hardness, and fracture toughness, may also be obtained qualitatively by using a scratching test [180–186]. To calculate the hardness, it is necessary to include two components: the scratch hardness H_s and the ploughing hardness H_p [179–185]. For a perfect plastic surface, H_s is obtained by using

$$H_s = \frac{P}{A^*} \tag{15}$$

where

$$A^* = \frac{\pi w^2}{8} \tag{16}$$

is the load-bearing area and w is the local width of the scratch. On the other hand, H_p is defined by

$$H_p = \mu_p \frac{P}{A_p} \tag{17}$$

where A_p is the projected contact area in the normal direction to the tip movement, and is obtained by

$$A_p = R^2 \sin^{-1}\left(\frac{w}{2R}\right) - \frac{w}{2}\left(R^2 - \frac{w^2}{4}\right)^{1/2} \tag{18}$$

with R the tip radius and

$$w = 2\left(2Rh - h^2\right)^{1/2} \tag{19}$$

where h is the tip penetration depth.

Particularly for coatings, the load/displacement curve and its characteristics provide a simple method to obtain the critical load that produces a coating detachment if the scratch device is used in the linear ramp loading mode. The load-displacement curve can show an abrupt discontinuity. Using additional imaging analysis, it is observed that this region corresponds to the onset of the detachment. The critical load to produce cracks is defined by these observations. This process permits us to obtain a measure of the coating/substrate adhesion quality. Of course, the failure modes (cohesive and interfacial) and the load that produces the detachment will depend on the substrate properties, the coating thickness, the tip shape, the loading rate, the friction coefficient, and the surface quality [187–192].

The models to describe the adhesion quality by using the scratch test basically employ the fact that the detachment occurs due to a chipping process on the front side of the tip, with the elastic strain energy realized by an interfacial fracture at the critical load. According to Bull and coworkers [192], detachment occurs when the in-plane compressive

stresses in front of the tip create conditions to induce a critical stress normal to the interface by a Poisson effect. The interfacial fracture energy Γ_i is then obtained by

$$\Gamma_i = \frac{1}{2}\frac{t}{E_c}\left(\frac{\nu_f \mu_c P_c}{A_c}\right)^2 \tag{20}$$

where A_c is the cross-section area at critical load P_c, E_c is the coating elastic modulus, t is the coating thickness, ν_f is the Poisson ratio, and μ_c is the friction coefficient. A modified model of Attar and Johannesson [190] shows that a tangential force is required to remove the coat; on the other hand, Burnett and Rickerby [193] concluded that the elastic–plastic indentation stress is dominant for low friction and thick coats.

Some recent literature reporting scratch tests on the surfaces of different materials, including coatings and bulk, are: for PET films by using a spherical tip at constant load, Beake and Leggett [194]; for fullerene films at constant and ramped load, Lopes [195]; for Cr and CrN films, Hones and coworkers also use constant and ramped loads [196]; a discussion about DLC interface tribology by Menon [197]; Li et al. for metal-particle magnetic tapes [198]; Qi and coworkers for nitrogenated diamond-libe carbon films (CN_x) [199]; Hones and coworkers on hard chromium tungsten nitride coatings [200]; for TiN/SiN_x multilayer coatings, Chen and coworkers [201]; Nelea and coworkers on hydroxyapatite thin films [202]; Charitidis and coworkers, a comparative study of the nanoscratching behavior of amorphous carbon films [203]; investigations of nano- and macrowear of magnetic tape head materials by Tan et al. [204]; in Shen and coworkers, a study of tribological properties of coating/substrate systems in micrometer and nanometer scales [205]; nanotribology studies by Wei and coworkers of Cr, Cr_2N, and CrN thin films using constant and ramped load nanoscratch techniques [206]; evaluation of the adhesion of TiN films using nanoindentation and scratch testing by Toparli and Sasaki [207]; a review of the mechanical properties and tribology of thin sol–gel MTMS coatings by Malzbender and coworkers [28]; indentation depth recovery in a poly(methyl methacrylate) sheet on the microlength scale by Adams and coworkers [208]; nanotribology and surface chemistry of reactively Ti–B–N hard coatings by Ott and coworkers [209]; and hard coating adhesion on ion-implanted polymer using nanoscratch tests by Guzman and coworkers [210].

3.6. Pop-In in Loading Curves

Load-displacement indentation curves in some materials show sudden discontinuities on depth penetration. These discontinuities are called pop ins. A pop-in event may be associated with different aspects, depending on the kind of tested material and its mechanical properties.

A series of articles reporting the applications of nanoindentation to measure the mechanical properties of materials was published, showing the sudden penetration of the indenter, which is followed by elastic or elastic–plastic deformation. Pop ins may occur in very small load indentations made in well-annealed single-crystal materials [211–219]. Other types of pop ins occur during the indentation of hard films deposited over very soft materials [220], and in the case of surface cracking in brittle materials during loading [139].

Pop in also occurs during the indentation of lamellar materials like graphite and mica. Figure 10 shows load versus displacement curves for four different lamellar materials: graphite, mica, GaSe, and NbS_2. Lamellar materials are characterized by highly perfect cleavage, so they readily may be separated into very thin leaves. Indentation tests in these materials present, as a special feature, a deformation process that is practically elastic for pyramidal indenters, even at high loads [221–224]. If the elastic energy is high enough, a sudden plastic deformation occurs and, in most cases, the subsequent deformation may also continue to be elastic.

The mechanical properties of lamellar InSe and GaSe single crystals have been studied by means of nanoindentation tests by Mosca and collaborators [222]. The course of plastic deformation induced in the crystals by application of a definite shear stress through the penetration of a Berkovich tip indicates that the deformation occurs predominantly by pop-in events along easy slip directions, having a fairly elastic character between displacements. Hardness anisotropy along the crystal axes is clearly seen, and the measured elastic modulus presents a discrepancy smaller than 5% in comparison with theoretical calculations performed using previous experimental values of the elastic constants.

Some authors [142] attribute the pop-in excursion to dislocation creation and multiplication by Frank–Read sources. However, in lamellar crystals, which present very different bonding energies at perpendicular directions, the dislocation multiplication by this kind of source does not appear to be the major mechanism to accommodate the plastic deformation during pop-in events. Alternatively, another mechanism that considers the disruption (breaking) of crystal layers and their slip into the existing ones in a layer intercalation process is proposed by Veiga and Lepienski [221].

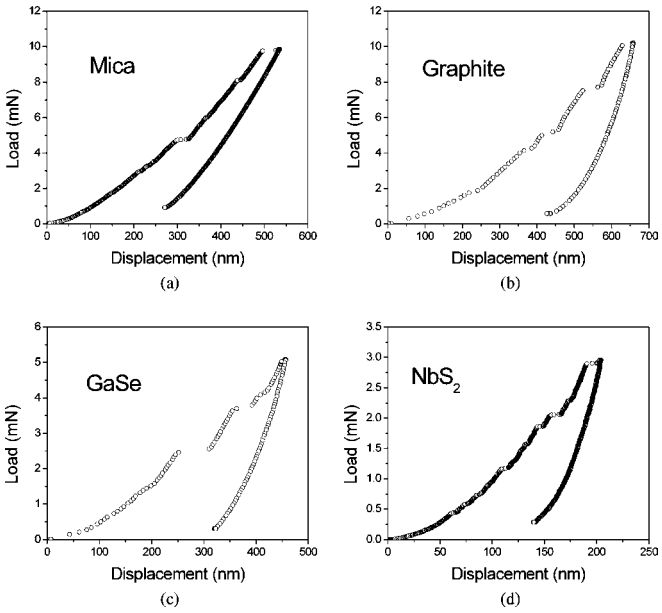

Figure 10. Pop-in events in load versus displacement curves for four different lamellar materials. (a) Mica. (b) Graphite. (c) NbS_2. (d) GaSe.

Gouldstone et al. [211–212] reported nanoindentation experiments followed by TEM and AFM observations on single-crystal and polycrystal Al thin films and polycrystal Cu thin films on Si substrates. They concluded that both single-crystal and polycrystal thin films exhibit periodic displacement pop ins at essentially constant loads during load-controlled nanoindentation. The first displacement pop in appears to occur when the maximum shear stress at the indenter tip is on the order of the theoretical shear strength of the material. The nanoindentation response of the film in between the displacement bursts was found to be purely elastic, and representative of the behavior under a "sharp" Berkovich indenter.

The study of pop-in events can be very helpful to understand the deformation mechanisms that occur under the indenter as the load is applied.

4. THEORETICAL ANALYSIS OF DEPTH-SENSING INDENTATION

Considerable efforts have been undertaken to develop comprehensive theoretical and computational models, in an attempt to elucidate the mechanics and mechanisms of indentation, and to characterize the mechanical properties [225–229]. These models normally are developed based on elastic–plastic models.

Advances in modeling are being obtained by interactive studies, where simulations are verified by experiments and vice versa. The computational simulation of indentation by finite-element methods has been extensively used since the 1970s [230–236].

The first theoretical analysis of indentation was made by Hertz, who examined the elastic contact between two spherical solids [237]. In the context of P–h measurements, for the case of a flat surface (with infinite radius of curvature) which is indented by an elastic sphere of radius R, Hertz showed that

$$P = \frac{4}{3} E_r R^{1/2} h^{3/2} \tag{21}$$

where P is the load, h is the displacement, E_r is the reduced elastic modulus, and R is the indenter radius.

Analyzing the plastic deformation of a spherical indentation, Meyer [1] proposed an empirical relation

$$P = \frac{Ka^m}{(2R)^{m-2}} \tag{22}$$

where m is the hardening factor, a is the contact radius, R is the indenter radius, and K is a material constant. Considering a stress–strain relationship given by

$$\sigma = \sigma_0 \varepsilon^n \tag{23}$$

where σ is the stress, ε is the strain, and n is the strain hardening, Tabor [1] correlated the strain hardening n to the m hardening factor of Meyer by

$$m = n + 2 \tag{24}$$

Johnson [238] suggested that the outcome of a sharp indentation test on elastic–plastic materials will fall into one of three levels, depending on the parameter Γ

$$\Gamma = \frac{E \tan \beta}{(1 - \nu^2)\sigma_y} \tag{25}$$

where E is the elastic modulus, ν is the Poisson coefficient, σ_y is the flow stress at first yield, and β is the angle between the sharp indenter and the nondeformed surface of the material.

According to Johnson, for $\Gamma < 3$, considered level I, very little plastic deformation occurs during the indentation, and the properties can be derived from an elastic analysis. In level II, for $3 < \Gamma < 40$, an increasing effect of plasticity is observed. In this region, both the plastic and elastic properties of the material must be taken into account. Based on the solution of the expansion of a spherical cavity from Hill, and considering the fact that the pressure in the region beneath the indenter is mostly hydrostatic, Johnson suggested that the mean pressure, and consequently the hardness, could be expressed by

$$H = \frac{2}{3}\sigma_y \left(1 + \ln \frac{E \tan \beta}{3(1 - \nu^2)\sigma_y}\right) \tag{26}$$

For $\Gamma > 40$, the plastic deformation is present all over the contact area, and the elasticity no longer influences the hardness value of the material. In this region, the hardness can be given by relation

$$H = C\sigma_y \tag{27}$$

where C is a constant that only depends on the geometry of the sharp indenter. Sometimes σ_y is substituted by σ_r, which corresponds to the flow stress at a plastic strain ε_r. The observed value of C varies from 2.5 to 3 for metals.

Hainsworth et al. [239] observed that the loading curve obtained by depth-sensing indentation experiments can be described by

$$P = Kh^2 \tag{28}$$

where K is a constant. This relationship was tested by finite-element calculation by Zeng and Rowcliffe [240]. The dimensional analysis of Cheng and Cheng [241] supports this assumption. According to Hainsworth et al. [239]

$$K = E\left(\phi\sqrt{\frac{E}{H}} + \psi\sqrt{\frac{H}{E}}\right)^{-2} \tag{29}$$

where E is the elastic modulus, H is the hardness, and ϕ and ψ are empirical constants. The values obtained from Hainsworth were $\phi = 0.194$ and $\psi = 0.903$.

Malzbender et al. [242] derived an analytical expression for the indentation load–depth relation during loading, given by

$$P = E_r\left(\frac{1}{\sqrt{24.5}}\sqrt{\frac{E_r}{H}} + \varepsilon\sqrt{\frac{\pi}{4}}\sqrt{\frac{H}{E_r}}\right)^{-2}(h + \xi)^2 \tag{30}$$

where E_r is the reduced modulus, ε is the geometrical constant which take a value of 0.72 for a conical indenter and 0.75 for a paraboloid, and ξ is a correction for blunt tips.

Larsson [243] developed an investigation of the contact of a sharp indenter under rigid-plastic conditions using theoretical and numerical approaches. He found that, in a general situation, where stress–strain relations are not idealized, there is no single representative value of the uniaxial stress–strain curve that can be used in order to evaluate the global parameters at contact.

There is an important effort underway in the theoretical analysis of nanoindentation. However, analytical models are not available due to the complexity of the problem. Then, finite-element methods are the most promising ways to analyze the contact of a hard indenter with a solid material.

5. CONCLUSION

Nanoindentation is a powerful technique to determine the surface mechanical properties in the nanoscale regime in practically all kinds of solid materials. This technique is especially important for new materials developed by nanoscience and nanotechnology applications. The method is based on the analysis of the load–unload curve, which allows us to obtain information about the elastic–plastic surface behavior in a well-controlled way.

Hardness and elastic modulus values are measured using known analysis methods which are widely accepted nowadays. However, certain additional care is necessary in measurements performed under extreme conditions, such as when the elastic–plastic behavior is strongly dependent on the ratio H/E, or when soft surfaces show pile up around the indenter and very hard surfaces present a sink-in effect. In these situations, the measured values of the hardness and elastic modulus may show deviations from the actual values. Additional care is also recommended for measurements on thin films where the substrate influence is an important factor.

The more common indenters used in nanoindentation are the Berkovich and Vickers tips, but additional information about the mechanical surface properties may be accessed by other kinds of indenters:

- Surface fracture toughness for brittle materials can be studied by using a cube-corner indenter.
- Viscoelastic properties, typical for polymer materials, can be obtained by using cylindrical or flat punch indenters.
- Surface adhesion quality between the coating substrate and residual stress at the surface can be studied by using spherical indenters.

A scratch test performed by using a modified nanoindentation machine can also give extra information about the mechanical surface properties, especially for coatings. However, it is not very clear because of their complexity, and mainly due to the frictional force. The obtained results are qualitatively correct, but more theoretical work is needed in order to compare the different results.

Despite the great number of published papers relating mechanical surface properties acquired by using nanoindentation, supplementary efforts still need to be performed on the theoretical approach in order to quantify and better understand the results in the nanoscale regime.

As a future challenge, it is necessary to develop nanoindentation devices that permit us to perform indentations at higher temperatures. In some materials, temperature dependence on their ductile-brittle behavior occurs, and it may be better investigated if high-temperature nanoindentation is available in the future.

GLOSSARY

Chemical vapor deposition (CVD) process used to product coatings or thin films by using chemical route.

Diamond-like carbon (DLC) a hard noncrystalline carbon film grown by CVD or related techniques, and that contains predominantly sp^2 carbon–carbon bonds.

Friction coefficient In tribology, denotes the dimensionless ratio between the tangential friction force and the normal applied force in a two-body interaction.

Hardness Relative resistance of a metal or other material to denting, scratching, or bending. Denotes, for a solid material, the resistance to penetration by other bodies. The equation used to calculate the hardness is the ratio between the applied load and the residual area produced by the penetration ($H = F/A$). Value depends on the method used for measurement.

Ion implantation Process where atomic species are introduced in the near-surface region by a nonequilibrium process which depends on the parameters used, like ion energy, ion current, chamber vacuum, and temperature conditions. The modified surface region can then be constituted of embedded phases, burried layers, and also, under some conditions, to form a coating layer. In the general case, a graded region is produced from the near-surface to deeper regions.

Nanohardness Denotes, for a solid material, the resistance to penetration by other bodies for depths at nanometerscale.

Nanohardness test Hardness measurement based on analysis of loading–unloading load versus depth curve in nanoscale regime. The indenter used can be Berkovich, Vickers, cube corner, flat end, and cylindrical.

Nanoindentation Process of indenting a solid surface by a pointed hard material at very low load using a load and depth-sensing device to obtain the surface hardness.

Nanoindenter Device constructed to perform nanoindentation and capable of measuring hardness and elastic modulus of material surfaces in the nanoscale regime.

Physical vapor deposition (PVD) process used to produce coatings or thin films by using a physical route.

Plasma-based ion implantation Surface modifier process based on two approaches one for conventional ion implantation, and the other to give thermally enhanced diffusion. The plasma sheath around the target expands dynamically, and permits the target surface to be uniformly treated, forming a modified layer.

Nanomechanics of Nanoscale Materials

Robert Geer

University at Albany, State University of New York, Albany, New York, USA

CONTENTS

1. INTRODUCTION

1.1. Nanotechnology

The fields of nanotechnology and nanoscience represent an intersection of multiple, sometimes diverse, fields of science with a single commonality: manipulation and functionalization of matter at the nanometer-length scale. As defined by the National Nanotechnology Initiative (NNI), a document crafted by the Interagency Working Group on Nanoscience, Engineering and Technology, nanotechnology "... is concerned with materials and systems whose structures and components exhibit novel and significantly improved physical, chemical, and biological properties, phenomena, and processes due to their nanoscale size" [1]. The essence of this statement revolves around so-called emergent properties or processes that are a sole result of the nanoscale engineering of matter. The NNI goes on to state, "Reducing the dimensions of structures leads to entities, such as carbon nanotubes, quantum wires and dots, thin films, DNA-based structures, and laser emitters, which have unique properties. Such new forms of materials and devices herald a revolutionary age for science and technology, provided we can discover and fully utilize the underlying principles."

The fundamental capability to manipulate the nanoscale organization of matter and control its mechanical, electrical, optical, chemical, and/or biological functionality is not a completely novel idea. For example, R. P. Feynman predated the realization of a nanotechnology solution to integrated circuit fabrication by more than four decades. In the late 1950s, Feynman gave his now famous "Plenty of Room at the Bottom" talk, where he presented the idea of a nanometer scale or molecular scale logic device [2]. Such devices are attractive for a variety of reasons. Molecules comprise structures with characteristic length from subnanometer to hundreds of nanometers. Hence, they bridge the dimensional regime between current lithographic structures and atomic sizes. Moreover, the tremendous flexibility in the design and chemical synthesis of molecular structures provides a broad adaptability with respect to potential device functionality, device implementation, and device operation. Virtually every other field of technology development possesses parallel potential with respect to the device miniaturization and integration conceivable via nanotechnology.

The emergent functionality of nanoscale structures and devices has its origins in the unique aspects of quantum mechanics and molecular self-assembly. The quantum-mechanical or wave nature of matter can be exploited to tailor electronic, optical, and chemical properties of a given material system, while the penchant for matter to spontaneously organize at the molecular-length scale provides novel structural templates with which to manipulate the quantum-mechanical boundary conditions that are so critical to controlling quantum phenomena. This is not to say that quantum-mechanical effects are not present in macroscale systems, or that molecular-level self-assembly guarantees new material functionality. Rather, it is the exploitation of the two in concert that opens vast new areas of technological promise.

Current examples of nanotechnological breakthroughs are continuously emerging. The discovery of molecular-scale graphene tubes, dubbed carbon nanotubes, typifies the potential impacts of nanotechnology [3]. By virtue of the propensity of carbon atoms to form threefold coordinated 2-D atomic sheets and the structural perfection of such sheets when rolled into a tubular geometry, entirely new mechanical, chemical, and electrical functionalities have been demonstrated. Such sheets exhibit mechanical properties superior to virtually all macroscopic materials with respect to the combination of strength, flexibility, and light

Edited by H. S. Nalwa
Volume 7: Pages (21–46)

weight. Likewise, the perfection of the carbon atomic configuration in such nanotubes has led to the confirmation of the ballistic transport of electrons along the direction of the tube axis. Interestingly enough, the structural details of the "rolling" of the graphene sheet can be exploited to program metallic or semiconducting electronic properties of the nanotube. There is certainly no analogous macroscopic system which possesses such a rich variety of functionality. Hence, this electrical programmability certainly qualifies as an emergent property. Other examples of emergent functionality associated with the nanoscale control of materials include quantum well and quantum dot phenomena exploited for optoelectronic applications of semiconductors, and the rich fields of macromolecular self-assembly that have led to entirely new paradigms for chemical and biological sensor development.

1.2. Mechanics Versus Nanomechanics

As noted previously, the advances promised by the nanoscale material manipulation of matter "... herald a revolutionary age for science and technology, provided we can discover and fully utilize the underlying principles." The "underlying principles" referred to in this statement are those that govern the modification of the conventional understanding of a system as nanoscale effects or phenomena emerge. Consider the case for nanomechanics. The conventional theories for mechanics and the mechanical properties of materials are perhaps the oldest and best studied of all the classical physical sciences. Although it was recognized early on that the microscopic aspects of materials governed their mechanical properties (e.g., the nature of chemical bonding and the microscopic aspects of surface and interface morphology), the validity of so-called continuum elastic mechanics to correctly describe the mechanical properties of materials (even down to micrometer-length scales) has been self-evident for small deformations. However, as the relevant length scale for mechanical deformation of a material system decreases to that of the interatomic or intermolecular spacing, the theories of continuum mechanics are expected to break down. At such length scales, realistic modeling of the mechanical response of a material or structure must take into account the quantum nature of the material. For example, in crystalline materials, the presence of lattice defects, impurities, and grain boundaries must be included to correctly describe the evolution of internal strains resulting from internal and externally applied stresses. This constitutes classical dislocation theory [4]. (The term "classical" is applied to this theory since it treats the crystal imperfection itself as a mathematical singularity, while assuming that the atomic or molecular displacements in the near vicinity of the imperfection are small and sufficiently well described by continuum elastic mechanics.) Of course, there exist entire classes of inelastic mechanical phenomena that are successfully described by empirical or semiempirical classical continuum theories. Simply enumerating them is beyond the scope of this chapter.

In light of the success of such classical continuum theories, it is natural for one unfamiliar with the field to ask whether or not emergent mechanical phenomena at the nanometer-length scale are to be expected at all. Yes and no are both correct answers to this question. The equations of classical elasticity are based on linear response theory; a stress applied to a solid will produce a deformation (strain) linearly proportional to that stress. This linear relationship is a direct result of the electrostatic potential energy of an atom, ion, or molecule as a function of its relative displacement in virtually all bulk materials. For small atomic displacements from an equilibrium position, this potential energy varies quadratically, leading to a linear restoring force (similar to a spring force). As long as this constraint is satisfied, elastic response may be expected, even if the spatial extent of the object is only a few nanometers [5]. However, by tailoring the atomic or molecular interaction forces within a material, as well as its physical-length scale, dramatic departures from elastic behavior may be observed and exploited. In contrast, it has also been shown that certain nanoscale systems can possess linear response behavior at strains well beyond the limits of conventional elastic materials [6].

Thus, there is no question that nanoscale-manipulated materials may "... exhibit novel and significantly improved ..." mechanical properties or phenomena. The challenges in this field of "nanomechanics" encompass the discovery process by which the underlying principles behind such manipulation are investigated and understood.

1.3. Overview of Present Work

The goal of this work is to review critical areas of research in the fields of nanomechanics of nanoscale materials and structures that represent vital efforts in the development of nanotechnology. This document is not a monograph on the theory of mechanics nor is it a compendium of experimental approaches in the study of mechanics. Rather, it focuses on recent experimental and theoretical investigations of emergent mechanical behavior at the nanoscale. Detailed overviews are presented regarding nanomechanical material systems, as well as the development of new instrumentation that will enable the underlying principles of nanomechanics to be more fully elucidated. To optimize the accessibility of this work to the widest possible audience, broader narrative descriptions of the phenomena under consideration are combined with more formal theoretical and experimental summaries. The necessary mathematical definitions of material mechanical properties or summaries of relevant experimental or computational methodologies will be introduced as required. A background in theoretical or experimental materials science or engineering is not required, although a familiarity with the physical principles of mechanics and elasticity will be helpful.

The work is separated into four major sections. The first section comprises a review of newly developed characterization and metrology instrumentation that is enabling the direct measurement of material mechanical properties on the nanometer-length scale. The successful introduction of direct "nanomechanical imaging" is absolutely essential for the degree of fundamental understanding of the mechanics of nanoscale materials necessary for technological exploitation. The second section reviews perhaps the most important nanoscale system with respect to emergent nanomechanical functionality, nanotubes. The third section

reviews the most recent work regarding nanotube composites, and the fourth section details extremely recent work regarding the mechanics of nanoporous materials for applications in nanoelectronics.

To this point, no significant mention is made considering the field of microelectrical mechanical systems (MEMS) or its more recent incarnation, nanoelectrical mechanical systems (NEMS). Traditionally, MEMS has focused on micromachining 3-D structures utilizing the materials of the integrated-circuit (IC) industry. As MEMS has matured, it has provided entirely new experimental platforms from which to test and evaluate the dependence of material and structural mechanical properties as a function of reduced length scale. However, the vast majority of MEMS experimental and theoretical work will not be discussed as conventional elastic continuum models provide an excellent framework for characterizing relevant mechanical properties of MEMS structures.

2. NANOMECHANICAL IMAGING

Macromechanical characterization is an extremely mature field. The basic theory of mechanics was founded on empirical observations that solid bodies exhibit a deformation of some sort (i.e., shape or volume) under the action of applied forces [4]. Standard continuum mechanical theory describes the change in distance between any two points in a solid under the application of an external stress. Assuming linear response, this treatment results in the conventional definitions of elastic constants (bulk modulus, shear modulus, Poisson's ratio, etc.) and the generalized form of Hooke's law. Mechanical characterization beyond elastic behavior is primarily concerned with the onset of inelastic (plastic) deformations and the investigation of material hardness, fracture toughness, and yield (tensile/compressive) strength. Consequently, the study of mechanics is, in large part, the study of deformation. The study of nanomechanics is no different from the previous discussion of nanomaterials illustrated. Recall that the elastic response of an ideal ordered material is directly determined by the local electrostatic atomic, ionic, or molecular potential energy well, the minimum of which is approximately parabolic. If the local atomic, ionic, or molecular mechanical response is preserved in nanoscale structures, it is reasonable to assume that some analogy to "classical" mechanics will exist, and that analogs to classical mechanical measurements will exist. This assumption is the foundation for the fields of nanoindentation, nanotribology, and nanomechanical imaging. These techniques, generally, utilize some type of point contact probe with a nanometer characteristic length scale. Classical mechanics has, for the most part, been used to interpret the results of such experiments, providing empirical confirmation of the propriety of such models. Acoustic, optical, and ultrasonic microscopy techniques have long been the choice for the micrometer-scale characterization of certain surface and subsurface mechanical properties of solids; however, the inherent resolution limitations in far-field lenses and/or coupling media have limited their application at the nanoscale [7]. Nanotribology is an exciting vibrant field and, although intimately related to nanomechanics, is beyond the scope of this review [8]. Nanoindentation is the culmination of decades of empirical research, and is now on the verge of a truly nanoscale characterization technique, although it is typically implemented as a destructive methodology better suited to planar surfaces than nanoscale structures [9]. Since the rising fields of nanoscience and nanotechnology focus on emergent functionality, it is appropriate to restrict detailed discussions to those methodologies that provide not only nanoscale resolution, but that are appropriate for the characterization of nanoscale structures and devices. Consequently, this section will focus on nanomechanical imaging, defined as the cadre of techniques capable of spatially resolving the variation of mechanical properties of nanomaterials, structures, and devices on the nanometer-length scale. Since the mechanics of these techniques use models developed, in part, for nanoindentation, it will be referenced throughout this discussion. The remainder of this section is organized as follows. First, a brief overview is presented of the simple mechanics of a point-probe contact with a surface. This is followed by a brief description of the experimental apparatus used to control such contacts with nanoscale precision, and to exploit them for the extraction of nanomechanical image data. Third, the development and application of a variety of these techniques will be reviewed with respect to the current literature. Lastly, a review of recent results will be presented to demonstrate the potential of nanomechanical imaging and its coming role in the development of nanotechnology.

If an object is of insufficient size or disposition to measure its deformation upon application of an external stress to determine elastic moduli, it is often necessary to apply a point probe to characterize mechanical properties. Hertz was the first to treat such a situation to determine the deformation of two objects in direct contact under an external load [10–11]. (The original problem treated two hemispherical surfaces. A sphere/plane system was recovered by letting one radius diverge to infinity.) The situation and the necessary parameters are outlined in Figure 1. Assuming only elastic deformation (short-range forces) and no interfacial adhesion between the tip probe and sample surfaces, the relation between the contact radius a of the tip/sample contact and the load F is

$$a^3 = \frac{3FR}{4E_r}, \qquad E_r \equiv \left[E_T^{-1}\left(1-\nu_T^2\right) + E_S^{-1}\left(1-\nu_S^2\right)\right]^{-1} \quad (1)$$

where the S and T subscripts denote the sample and tip, respectively. E_r is defined as the reduced Young's modulus.

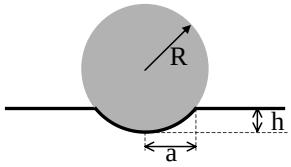

Figure 1. Idealized representation of the elastic deformation of a sphere/plane contact. Note that the radius R of the sphere is defined predeformation.

Taking the origin at the center of the contact area and defining r as the radial distance in the plane of the sample, the elastic indentation h as a function of r is given by

$$h = \frac{3P}{8aE_r}\left(2 - \frac{r^2}{a^2}\right), \qquad r \le a \tag{2}$$

At the apex of the tip, this relation can be rephrased:

$$F = \sqrt{E_r^2 R h^3} \tag{3}$$

The classical derivation of this indentation raises questions regarding its applicability in realistic situations due to the presence of long-range attractive forces (van der Waals), electrostatic forces (surface charging), capillary forces, or general adhesive forces, and not least of all, the quantum-mechanical limit if the mechanical contact is reduced to the atomic-length scale. Several models discussed below include the former effects. And although a number of authors have considered atomic-scale models for tip interaction with respect to the relatively small forces used in topographical imaging, no solely quantum models have addressed mechanical response [12–16]. Although no formal criterion has been universally adopted, it is assumed here (and consistently shown in the vast majority of the experimental literature) that the mechanical response for a surface with a contact radius on the order of 5 nm or larger can be described by elastic mechanics.

If an adhesion energy is associated with the contact area, the local profile of the tip/sample deformation is changed. Johnson, Kendall, Roberts, and Sperling (JKRS) included an adhesion energy w in the Hertzian problem [17–18]. The solid–solid contact deformed locally into a connective neck due to adhesion, resulting in a modified contact area radius:

$$\begin{aligned} \frac{F}{\pi R w} &= a^3 \frac{E_r}{\pi R^2 w} - a^{3/2}\sqrt{\frac{6E_r}{\pi R^2 w}} \\ \frac{hE_r^{2/3}}{(\pi^2 w^2 R)^{1/3}} &= \frac{a^2 E_r^{2/3}}{(\pi w R^2)^{2/3}} - \frac{2}{3}\sqrt{\frac{6aE_r^{1/3}}{(\pi w R^2)^{1/3}}} \\ w &\equiv \gamma_T + \gamma_S - \gamma_{TS} \end{aligned} \tag{4}$$

Here, $\gamma_{T(S)}$ refers to the tip (sample) surface energy, and γ_{TS} is the interfacial energy. Although typically applied to soft materials with large radii, this model has been shown to be applicable over a wide range of materials and nanoprobe tips [19]. An alternate model which reduces artifacts in JKRS theory related to stress variation at the edge of the connective neck was developed by Derjaguin, Muller, and Toporov (DMT), wherein the surface forces are assumed to act only in an annular region just outside the contact radius [20].

$$\begin{aligned} \frac{F}{\pi R w} &= a^3 \frac{E_r}{\pi R^2 w} - 2 \\ \frac{hE_r^{2/3}}{(\pi^2 w^2 R)^{1/3}} &= \frac{a^2 E_r^{2/3}}{(\pi w R^2)^{1/3}} \end{aligned} \tag{5}$$

In all cases, the force–displacement relation depends upon the elastic (or elastic/adhesive) property of the solid. These relationships have been applied to describe the interactions of scanning probe microscope tips and sample surfaces to relate contrast in the scanned image to sample mechanical properties. However, to understand their application, it is necessary to first review the operation of scanning probe microscopes.

The scanning probe microscopy (SPM) platform consists of a nanoscale probe tip placed on or near (∼nm) a surface, and scanned across that surface using a high-resolution piezoceramic crystal scanner (Fig. 2). The probe tip interacts with the surface, and transduces some type of surface-related signal into a digital intensity which is collected into a spatially resolved image with an appropriate raster. The positional control of the piezoscanner is subangstrom, and enables tremendous spatial resolution of the signal transduced by the probe tip. In most cases, the scans are carried out in a feedback mode, where the tip signal is kept constant as the tip is scanned across the sample surface. An early example of such an approach was the so-called scanning tunneling microscope (STM) [21–23]. In an STM, the tip consists of an ultrasharp metal probe which is kept at a reference voltage with respect to a conductive surface. When the tip is brought sufficiently close to the conducting surface (by a piezoscanner), it is possible to measure a current associated with electrons tunneling from the tip to the sample (for separations less than a few nanometers). In this manner, scanning the tip at a constant height permits the measurement of the local density of electronic states (LDOS) at the surface. If the LDOS is constant, the tunneling current between the tip and sample primarily depends on the tip–sample separation, and a feedback circuit can be applied during the scan to keep this current constant by adjusting the tip height during the scan using a vertical piezoceramic scanner. This results in a nanometer-scale image of the surface topography. A separate SPM implementation is the so-called atomic force microscope (AFM) [24] or scanning force microscope (SFM). In the SFM, the nanoprobe typically consists of a pyramidal tip on the end of a micromachined Si cantilever (Fig. 3) [25]. The tip is brought close to the sample. As the tip–sample separation decreases, a long-range attractive van der Waals force deflects the cantilever toward the sample. This is measured via a laser reflected from the backside of the cantilever into a differential photodiode where the deflection of the laser

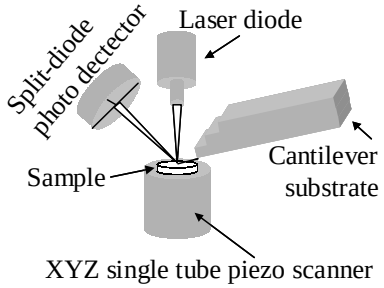

Figure 2. Schematic of conventional SPM configuration. The laser diode beam is focused onto the back of the cantilever at the sample. Deflection of the laser beam due to tip motion is recorded by the split photodetector. This intensity variation is incorporated into a feedback loop incorporating the z axis of the piezoscanner. The x–y axes of the scanner are used to raster the tip across the sample surface.

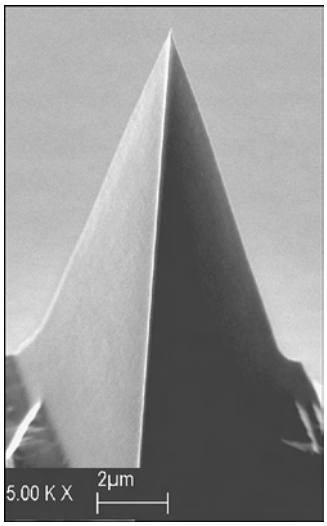

Figure 3. Electron micrograph of pyramidal tip of an Si cantilever.

is calibrated to the change in tip height. If the tip is brought into contact with the sample and scanned across the sample surface, the deflection of the tip can be used to determine the sample topography. Usually, a feedback mode is established wherein the deflection of the cantilever is kept constant by adjusting the relative z position of the tip or sample using a vertical piezoceramic scanner. From this point of view, the end of the pyramidal tip is a nanomechanical probe when a load is placed on the tip in contact with a surface. Although the AFM has been used in a wide range of configurations, we will only focus on those relevant to nanomechanical characterization. An SFM can be used as a nondestructive nanoindentor. However, due to the low spring constant required to provide a high surface topography sensitivity, the tip can only "indent" relatively soft materials. Still, by oscillating the tip below the fundamental resonance of the cantilever against a surface, and measuring the resultant oscillation amplitude as the tip is scanned across that surface, it is possible to record an image for which the intensity is proportional to the mechanical response. This mode is conventionally referred to as force-modulation microscopy (FMM) since the tip–sample force is modulated as the sample is scanned [26–30]. A simple theoretical treatment of this mode was treated by Burnham and co-workers to investigate not only the low-frequency (FMM) mechanical response, but also the high (superresonant) frequency response supplied to the sample by a piezooscillator fixed to the sample [31].

That model is detailed in Figure 4. The sample elastic properties are modeled as a simple spring of spring constant k_i with damping β_i. Assuming that $E_T \gg E_S$, the quantity k_i is linearly related to the sample Young's modulus, and is referred to as the contact stiffness. The details of this relationship are dependent upon the choice of model used. The time dependences of the tip and sample along with the equation of motion are [31–32]

$$\begin{aligned} z &= z_o + z_1\cos(\omega t); \quad d = d_o + d_1\cos(\omega t - \delta) \\ m^*\ddot{d} + 2m^*\beta_c\dot{d} + k_c d &= 2m^*\beta_c(\dot{z} - \dot{d}) + k_c(z - d) \end{aligned} \tag{6}$$

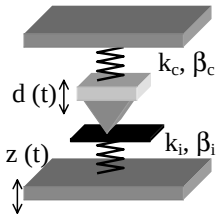

Figure 4. Schematic of tip–sample model used by Burnham et al. The time-dependent vertical position of the sample is denoted by $z(t)$. The resulting deflection of the tip is denoted by $d(t)$. $k_{c,i}$ and $\beta_{c,i}$ denote the spring stiffness and damping constants of the tip and sample, respectively.

The effective mass of the oscillator is defined in terms of the resonant frequency of the cantilever: $\omega_o = (k_c/m^*)^{1/2}$. This is the classic damped-coupled oscillator problem. Solving the equation of motion yields the frequency dependence of the relative displacement ratio d_1/z_1 and the phase δ:

$$\begin{aligned} \frac{d_1}{z_1} &= \frac{k_i\sqrt{1 + (2m^*\omega\beta_i/k_i)^2}}{\sqrt{(k_i + k_c - m^*\omega^2)^2 + 4m^{*2}\omega^2(\beta_i + \beta_c)^2}} \\ \tan\delta &= \frac{2m^*\omega[\beta_i(m^*\omega^2 - k_c) + \beta_c k_i]}{k_i(k_i + k_c - m^*\omega^2) + 4m^{*2}\omega^2\beta_i(\beta_i + \beta_c)} \end{aligned} \tag{7}$$

These results yield two important limiting cases with respect to SFM mechanical imaging modes. Consider the low-frequency ($\omega \ll \omega_o$) and high-frequency ($\omega \gg \omega_o$) limits of this motion:

$$\begin{aligned} \frac{d_1}{z_1} &\approx \frac{k_i}{k_i + k_c}, \qquad \text{for } \omega \gg \omega_o \\ \frac{d_1}{z_1} &\approx \frac{k_i\omega_o^2}{k_c\omega^2}, \qquad \text{for } \omega \gg \omega_o \end{aligned} \tag{8}$$

The low-frequency limit is indicative of the conventional FMM mode. Here, the ratio of the tip deflection (experimentally measured quantity) to the sample oscillation amplitude is only sensitive to the surface mechanical properties if the contact stiffness is on the order of the cantilever spring constant. Hence, if the cantilever is "soft" enough to measure nanoscale topography, it will only be capable of qualifying the spatial dependence of the surface modulus for soft materials. Consequently, FMM is primarily a tool used for polymeric or soft materials. The high-frequency limit is more intriguing from the viewpoint of nanomechanics. At high frequencies, the cantilever cannot follow the driving frequency (superresonant motion), and the driven tip oscillation amplitude decreases as a square of the driving frequency. However, the prefactor of this amplitude depends linearly on the ratio of the surface contact stiffness to the cantilever spring constant. In other words, large deflection implies large, local contact stiffness. Imaging in this mode can provide a signal directly proportional to the surface Young's modulus. Since the contact area of the tip is still on the order of the radius of curvature of the pyramidal tip (~5–20 nm), this mode (christened SLAM by Burnham for scanning local acceleration microscopy) is truly capable of imaging the mechanical properties of a wide range of

materials. Care is required in this technique as the superresonant frequency must fall within the bandwidth of the photodiode detector of the SFM. Also, the expression [Eq. (7)] is valid only in the limit of amplitude-independent contact stiffness, that is, a linear force–displacement response. This is not strictly true in the case of the aforementioned JKRS or DMT models due to the force-dependent area of the contact (even in the case of a flat-end punch) [17, 18, 20]. Consequently, the calibration of SLAM images requires detailed knowledge of the true contact stiffness so that a region of model validity can be determined. However, the simplicity of the model is a major advantage in data interpretation and image artifact identification.

A variation of this approach was investigated several years earlier by Yamanaka et al. [33–34]. Similar to SLAM, an out-of-plane surface vibration was applied to the sample. This approach considered ultrasonic frequencies beyond the response of the photodiode, so the direct oscillation of the cantilever was not observed. However, at high oscillation amplitudes (typically >0.4 nm), a nonzero dc tip deflection was observed. This observation implied that the nonlinear force–displacement curve was being probed, as expected from the models presented above. Moreover, the use of such frequencies reduced the tip oscillation amplitude dramatically, rendering it effectively immobile. As such, the tip constituted (on the high-frequency time scale) an infinitely stiff surface against which the sample periodically is indented [34]. Ideally, then, the force–displacement curve for the tip–sample indentation should precisely correspond to the models presented above. The appearance of a nonzero dc displacement of the tip implies that a nonlinear region of the force–displacement curve is being probed. The oscillation amplitude at which this nonlinearity appears is then related to the slope of the linear portion of the F versus h curve, that is, the contact stiffness. This imaging mode has been referred to as ultrasonic force microscopy or UFM.

The critical concept for mechanical imaging via UFM is the inherently nonlinear interaction of a scanning-probe cantilevered tip in contact with a surface that is undergoing out-of-plane ultrasonic vibrations at a frequency far exceeding the resonant frequency of the cantilever [33]. In such a case, the cantilever is inertially damped and, on the ultrasonic time scale, effectively rigid [34]. Hence, the surface rigidity of materials with contact stiffness orders of magnitude higher than the cantilever spring constant can be quantitatively measured. To illustrate how surface nanomechanical rigidity can be extracted via UFM, Figure 5 shows a schematic of a prototypical force–displacement curve for a rigid nanoprobe tip in contact with a surface. Negative displacement (indentation) of the sample by the tip results in a strong repulsive force. For positive displacement, an attractive force exists between the tip and sample until the sample is pulled away from the tip. This attractive force may result from van der Waals forces, adsorbed fluid layers, or other types of adhesive interactions.

For a scanning probe tip in static contact with a surface, the relative tip–sample distance is h_o and the tip–sample contact force is F_o. Apply an ultrasonic out-of-plane oscillation $\Delta h(t) = h_o + A\cos(\omega t)$. If A is small, the average of the force excursion ΔF is approximately equal to F_o, that is,

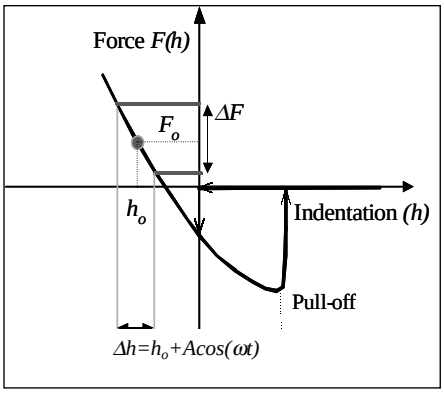

Figure 5. Schematic force–displacement curve for nanoprobe tip and a sample surface. $F(h)$ is the applied force. h is the relative displacement between the tip and the undeflected sample surface.

the tip undergoes no average displacement. If the oscillation amplitude is increased, the nonlinear region of the curve must be included to correctly calculate the average force on the cantilever tip [35]:

$$\langle F(h_o, A)\rangle = \frac{\omega}{2\pi}\int_0^{2\pi/\omega} F(h_o - A\cos(\omega t))\,dt \qquad (9)$$

$$k_c z_c = \langle F(h_o, A)\rangle \qquad (10)$$

where k_c and z_c are the cantilever spring constant and tip deflection, respectively. A simulation of this ΔF as a function of oscillation amplitude A is shown in Figure 6 using the JKRS model [17–18]. The inset in Figure 6 highlights a critical feature of this average force. There is a "kink" or slope discontinuity in the averaged force, which appears for oscillation amplitudes exceeding a certain threshold value A_{th}, for which the tip approaches pull off. This slope discontinuity in $\langle F(h_o, A)\rangle$ translates into a sudden increase in steady-state tip deflection [19]. The threshold amplitude is directly related to the slope of the force–response curve, defined as the contact stiffness between the sample surface and tip

$$S(h) \equiv \frac{\partial F}{\partial h} \qquad (11)$$

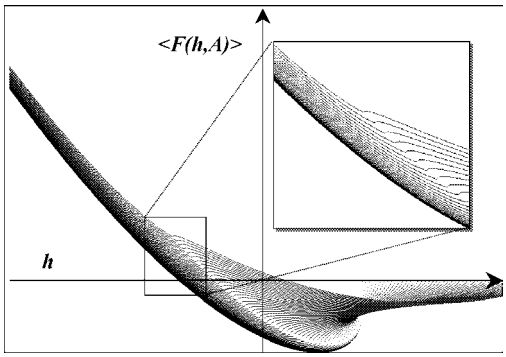

Figure 6. Simulated average tip–sample force–displacement curves for increasing values of A using Eq. (9) and the JKRS model (normalized units). Inset details the discontinuous slope resulting from oscillation amplitudes approaching or exceeding tip pull off.

In the repulsive regime of the force–displacement curve, S is related to the reduced Young's modulus of the tip and the sample. The details of this relationship depend on the complexity of the model used to describe the tip–surface interaction. For a simple Hertzian contact [10–11]

$$S_{\text{Hertz}} = \sqrt[3]{6\overline{F}RE_r^2} \tag{12}$$

$\overline{F}$ is the average force, and R is the scanning probe tip radius. For a more realistic approach, such as the JKRS model, the relationship is more complex, and can be extracted using a forward modeling approach based on curves similar to those in Figure 6.

As noted above, it is critical for the oscillation frequency to *significantly exceed* the fundamental cantilever resonance frequency (typically hundreds of kilohertz). In this frequency domain, the cantilever is inertially damped, not responding quickly enough to the oscillation to be deflected. For cantilever probes designed for use with conventional SPMs, this superresonant frequency typically exceeds 1 MHz [33]. The indentation of such tips at the forces of interest are totally elastic, and do not damage the sample. Frequencies as high as 80 MHz have been used, although higher order cantilever flexural resonance effects must be considered or instabilities may arise [36–37].

Since A_{th} depends monotonically upon the sample contact stiffness, its spatial variation will provide a map of the surface elastic response. Periodic ramping of the vibration amplitude beyond A_{th} as the tip is scanned across the sample provides elastic maps in the same fashion as topographic images. Figure 7 shows a simulated average tip deflection resulting from the application of a triangular-modulated vibration amplitude to the tip–sample displacement [36]. In the half cycle containing the ramp, note the discontinuity at A_{th}. Experimentally, this periodic tip deflection is extracted for modulation frequencies that are large compared to the tip–displacement feedback frequency in a normal topography mode, but small compared to the response frequency of the SPM photodiode detector used to measure tip deflection (typically, a few kilohertz). Experimental results are shown in Figure 8 for UFM tip deflection responses from aluminum and polymer substrates [38]. The differentiation of threshold voltages between the two materials is clearly

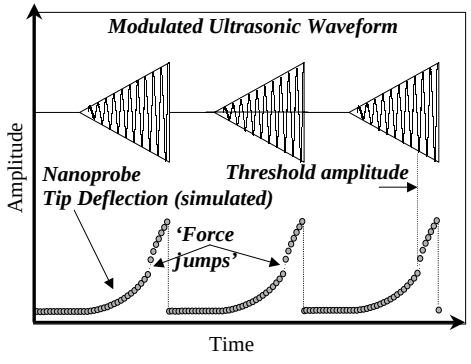

Figure 7. Simulated deflection response of a cantilevered tip (bottom) to a modulated ultrasonic vibration (top). Note that the onset of tip deflection requires a threshold amplitude.

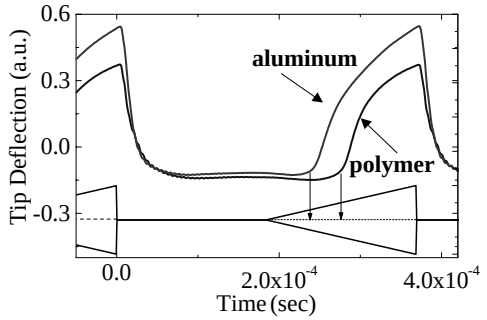

Figure 8. Experimental ultrasonic tip-deflection curves obtained from aluminum (upper curve) and polymer (lower curve) surfaces. Arrows denote the onset of tip deflection, estimating threshold amplitudes. The ramped modulation envelope for the ultrasonic sample vibration is shown at the bottom of the figure.

resolved. To translate these tip-deflection curves into pixilated mechanical image maps, lock-in amplification is used to translate the area under each curve into a raster-scan pixel intensity.

Determination of the sample modulus from these data can be carried out by mapping the amplitude response of the tip deflection to extract the functional dependence of the threshold amplitude versus F_o [33, 35, 39]. Extracting the amplitude variation of the "kink" (Fig. 7) provides the necessary information to determine the static or zero-amplitude contact stiffness from which the Young's modulus can be calculated. Figure 9 displays the ultrasonic tip-deflection response as a function of applied tip force F_o for a spin-on polymer film. The inset in Figure 9 plots the variation of threshold amplitude against increasing force. Assuming a Hertzian response for the contact stiffness, the reduced Young's modulus was directly calculated to be 4.8 GPa using a known tip radius and the absolute vibration amplitude (determined from an optical vibrometer). Using this methodology, Young's modulus measurements have been undertaken for materials ranging from nanoporous silicates ($E_r \sim 2$ GPa) to Si_3N_4 ($E_r \sim 300$ GPa). Application of this technique by Dinelli et al. reported relatively large sample-to-sample variations of modulus measured using this method [35]. This variation is significantly reduced for measurements carried out in vacuum following a low-temperature bake to remove surface-adsorbed water

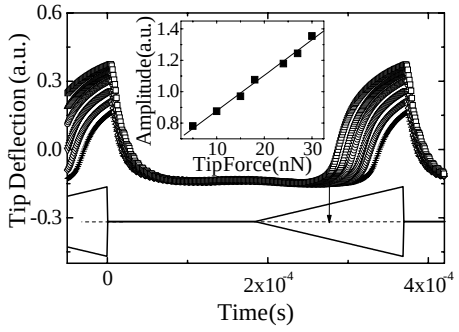

Figure 9. Variation of ultrasonic tip deflection as a function of applied tip force F_o for a polymeric film. The variation of threshold amplitude is apparent. Inset plots this variation as a function of applied force.

films. For silicon oxide films, recent work has demonstrated an absolute error for modulus determination of <25%. Relative local variations on a single sample (point to point) are less than 1% [40].

Burnham et al. described this mode as the "mechanical diode" mode in that the deflection response to an imposed vibration was not symmetric [31]. UFM has been used by that group and a host of others to characterize multiple nanoscale systems to investigate the nanomechanical variations of materials. One of the earliest applications of UFM was by Yamanaka et al. to image subsurface edge dislocation lines in highly oriented pyrolytic graphite [34, 41]. Their work revealed near-surface edge dislocations in the UFM scan as low-contrast lines against a bright field. No associated features were evident in the topography. The subsurface sensitivity of UFM (as for FMM) is attributed to the elastic deformation region in the vicinity of the tip/sample contact. Using a simple static picture, it is reasonable to assume that defects in the near-surface region would alter the local effective modulus. This is the picture commonly used for nanoindentation (usually for a much larger tip/surface contact area). A more accurate picture for the UFM case is one of wave propagation. In the reference frame of the sample, the tip impinges with ultrasonic frequency, and the average displacement of the tip depends upon the surface boundary conditions and the transfer of acoustic energy [42]. A localized defect below a solid surface will affect the average tip displacement if it is within the volume probed by the evanescent acoustic wave excited in the sample. Initial estimates placed these defects within approximately 10 nm of the surface. More recent work by the same authors have not only used UFM as a probe for such subsurface edge dislocation lines, but have also used the pressure field below the tip to induce dislocation motion. By observing the dislocation as a function of load, they were able to displace a single dislocation by 20 nm for a load increase of 80 nN. Reduction of this load permitted the defect to move to its original location. The observation of such dislocation motion is a truly remarkable achievement in nanomechanics. Burnham et al. also used UFM to image subsurface mechanical variations. In that case, a thin polyamide film was applied over a GaAs grating (250 nm period). The polyamide thickness was not revealed in [31] so the depth sensitivity could not be inferred.

Geisler et al. specifically considered sensitivity of UFM to large subsurface voids in Si [43]. The experiment consisted of ion milling angled voids in the cross section of a single-crystal Si wafer. A void ceiling height varied linearly, providing a controlled void depth. From the point of view of mechanics, the deflection of the Si as the tip was scanned across the region resulted from deflection rather than deformation (compression). The contact stiffness of the surface was modeled using finite-element analysis (FEA) to obtain an effective deflection map. Initial investigations assigned a maximum detectable microvoid depth of ~200 nm. However, the large contact forces required in this method often resulted in significant wear of the tip [43].

Altemus and co-workers similarly utilized the UFM to map the deflections of suspended microstructures (cantilevered mirrors) to investigate oscillation-induced hardening of the Au–Cr–Si trilayer beam [44]. After prolonged oscillation ($\sim 10^9$ cycles), slight gradations in the UFM intensity were observed that presumably resulted from high-amplitude induced wear. The gradations most likely reflect variations in the effective high-frequency contact stiffness as subresonant effects would most likely not be observable via UFM.

The capability of UFM to investigate variations of the surface elasticity of higher modulus materials was demonstrated for Ge quantum dots grown (QDs) grown on a silicon surface. Kolosov and co-workers carried out a UFM investigation of such a system [45]. QDs were deposited following Kaimins [46]. Their data showed a clear UFM contrast difference between the Si ($E_{\text{bulk}} = 164$ GPa) and Ge ($E_{\text{bulk}} = 121$ GPa). More recently acquired data on the same structures are shown in Figure 10 [47]. As in [45], the quantum dots possess a relatively unimodal diameter distribution peaked near 100 nm. The QD height was typically 15 nm (~50 Ge monolayers). Closer inspection of the UFM image in the region between the large Ge QDs reveals lower gradations of elastic contrast. When compared to the topographic image, these areas represent plateaus approximately 0.4 nm in height. We associate these regions with a single or double Ge monolayer [48–49]. The ability of UFM to apparently distinguish the mechanical response of only a few monolayers of Ge is impressive, and an important demonstration of its utility for nanomechanical imaging. Since no comparable studies have been published regarding SLAM on similar structures, it is difficult to gauge the comparative sensitivity of the two.

The application of UFM for other nanoparticle films has recently been examined. An investigation of the nucleation of thin Cu films was carried out to investigate the ability of UFM to distinguish between nanoscale Cu clusters and an underlying TaN film. The Young's modulus for Cu varies between 110 and 120 GPa, depending upon processing [50–51]. E for crystalline Ta is approximately 189 GPa, while for TaN, E can exceed 300 GPa, although typical vapor-phase processed TaN can exhibit mechanical moduli variations of 40% below that maximum [52]. Consequently, it would be expected that UFM imaging of Cu nanoparticles on a TaN substrate would appear as low-contrast islands on a bright background. Figure 11 shows a series of images for

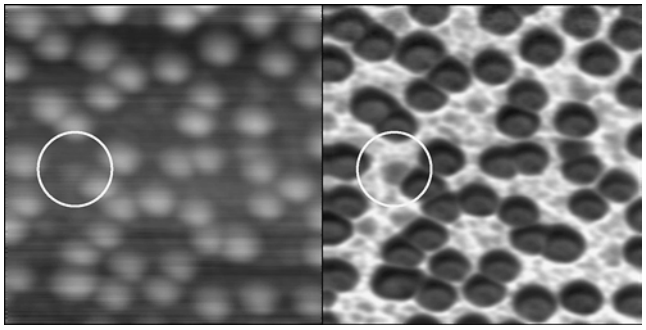

Figure 10. 1 μm × 1 μm AFM scans (left) and UFM scans (right) of Ge QDs on Si. The bright background of the UFM scan corresponds to the higher modulus Si substrate. The gray contrast gradations between the dark 100 nm diameter Ge QDs are tentatively identified as monolayer islands of Ge. One such area is highlighted in both scans by the white circle.

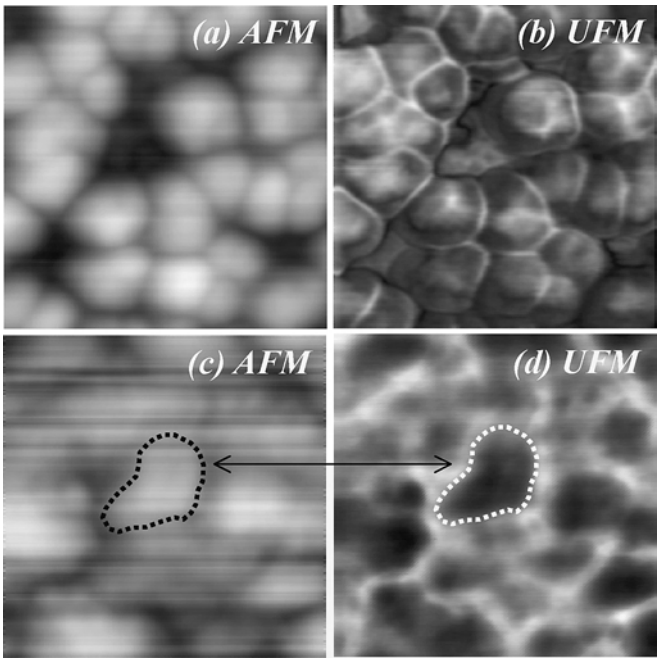

Figure 11. 0.4 μm $\times$ 0.4 μm AFM and UFM scans of Cu grains nucleated on a TaN substrate. (a) AFM and (b) UFM of a 25 nm thick (nominal) Cu film. The UFM contrast is dominated by variations within grains. The bright regions at grain boundaries result from an increased tip/sample contact area. (c) AFM and (d) UFM scans of a 5 nm thick (nominal) Cu film. In the UFM image, the Cu grain appears as a dark area on a bright substrate. The thickness of the outlined grain in (c) and (d) is approximately 5 nm. The medium contrast regions above this grain correspond to Cu regions ~1.5 nm in thickness.

Cu nanograins on a TaN substrate (images have undergone no postimage processing, including flattening). The UFM image clearly separates Cu nanograins from the substrate. A 5 nm thick grain highlighted in Figure 11 has a clear contrast differential from the TaN substrate [53]. From topographic analysis, the medium-contrast areas correspond to Cu as thin as 1.5 nm (~five monolayers). Larger Cu grains from thicker (~25 nm films) are also shown in Figure 11. Here, the entire surface has been covered by Cu, and the UFM contrast largely results from variation of tip/surface contact area at grain boundaries or slight variations of contact stiffness within individual grains.

Although Cu can be considered soft compared to the Si_3N_4 tips typically used for UFM, such may not be the case for materials like TaN, as described above. The limits of applicability for UFM have been examined in detail for such high-stiffness materials. Dinelli et al. considered modulus extraction from UFM analysis of polished silicon and sapphire surfaces [35]. Using the JKRS model to carry out simulations of the tip–sample force–displacement response curves acquired from UFM scans, extracted moduli were in good agreement with expectations if the tip–surface contact area remained relatively constant. This work specifically notes complexities introduced into the UFM force–displacement response curve analysis of the tip radius of curvature variation as a function of applied force. This variation is above and beyond the simple elastic deformation predicted by a simple Hertzian model. For example, Dinelli et al. note that, for investigations of the contact stiffness of silicon, the effective tip radius of curvature may increase from an effective value of 6 nm for a low-load-force (~70 nN) to an effective value of 25 nm for a load force of 280 nN. Such challenges are not unexpected for tip and sample moduli of the same order.

However, despite system-dependent complexities in quantitative modulus extraction, the relative modulus sensitivity of UFM is well established. Kolosov and co-workers examined an impressively wide range of material systems via UFM to explore the capabilities of the technique [39]. In addition to the Ge QD work referenced above, UFM investigations of carbon fiber composites, polymer–polymer composites, two-phase Langmuir–Blodgett films, polymer–glass laminates, and immobilized proteins have been undertaken. In each case, UFM imaging revealed nanoscale mechanical variations associated with nanoscale composition. In the case of thin-film laminates, UFM revealed areas of delamination between the thin film and the substrate. This was demonstrated for thin silicon oxide films deposited on PET (polyethylene terephthalate) polymer substrates [54]. Similar phenomena have been observed very recently for the delamination of metal films on polymers. Figure 12 shows the stress-induced delamination of a 50 nm thick Ta film on a polyaromatic polymer substrate (SiLK® polymer, Dow Chemical Corporation). The topography scan clearly reveals a large hillock feature associated with buckling of the Ta film. Corresponding UFM measurements reveal a clear drop in contrast at the edge of the raised region, denoting a dramatic increase in mechanical compliance of the Ta film. Since no compositional variation of the Ta film was evident via spectroscopic analysis, the compliance loss was assumed to result from delamination. An interesting feature of this UFM scan is the high-contrast region at the crest of the raised Ta buckle. It is possible that the UFM tip is sampling a local increase in contact stiffness due to a micromechanical

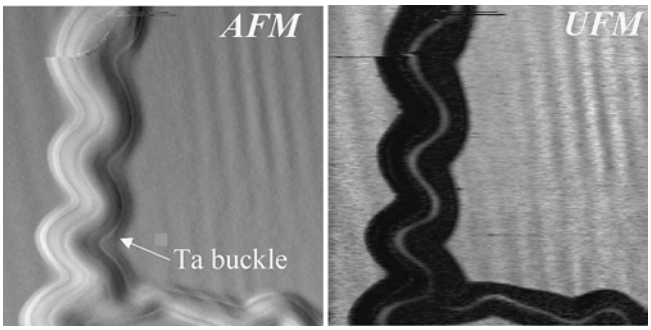

Figure 12. 20 μm $\times$ 20 μm AFM (left) and UFM (right) scans of a 50 nm Ta film deposited on Dow Chemical's SiLK polymer. The AFM scan highlights a buckled section of the Ta film. The corresponding UFM scan reveals the dramatically increased compliance of this region. The high-contrast line running along the center of the delaminated region may result from a micromechanical "arch" effect. The striations at the upper right quadrant of both images correspond to topographic and mechanical compliance corrugations, respectively, presaging the onset of delamination.

arch effect of the Ta film. Investigations into this phenomena are continuing.

As the above discussion notes, surface contact stiffness is affected by a wide array of phenomena related to both the material under investigation as well as the particulars of the nanoprobe used. Consequently, a lower estimate of the sensitivity of UFM to pure modulus variation is of significant interest. Dinelli and co-workers carried out such an investigation using cross-sectional UFM imaging of a GaAs–$Al_xGa_{1-x}As$ supper lattice (lattice constant ~200 nm) [35]. Their work showed that relative changes in the elastic modulus as low as 0.08% (corresponding to a Δx of Al as low as 0.1) were observable in UFM. This is a truly remarkable sensitivity.

Geer and co-workers have recently investigated the use of UFM for integrated-circuit (IC) and nanomaterial characterization [54–57]. The surface mechanical variation of IC interconnect test structures consisting of inlaid (damascene) Al lines in a low-dielectric-constant polymer (benzocyclobutene) was investigated with respect to variations in the polymer modulus resulting from IC processing. The damascene technique used in IC processing consists of the formation of recessed trenches and vias in a dielectric layer via reactive plasma processing (so-called reactive ion etching) [58]. In this manner, an IC interconnect pattern can be "transferred" into a dielectric layer. The recessed features are coated with a TiN barrier layer (to inhibit Al diffusion in the polymer), and subsequently filled with Al metal through vapor deposition [59]. The excess Al is removed via a chemical mechanical planarization (CMP) process resulting in an extremely flat inlaid pattern of transistor interconnect wires [60]. This process is repeated until a multilevel metal interconnect circuit is fabricated that completes the functioning IC circuit. Polymeric dielectrics have been under intense investigation in IC fabrication recently, owing to their low dielectric constant and associated reduction in *RC* losses during chip operation. However, the dramatic mismatch of mechanical properties between metal lines (in some cases <100 nm wide) and polymer dielectrics places limitations on the internal stresses that can be tolerated during the thermal excursions of chip operation. Consequently, to accurately model chip stability, it is important to know the variation in mechanical properties of such dielectrics during their deposition. The reactive ion etch process that is used to "dig" the trenches in the dielectric can also result in changing local polymeric reaction properties [61]. UFM analysis of these structures (Fig. 13) revealed that the reactive ion etch effectively "hardened" the polymer near the exposed surface [54]. This hardening resulted from selective removal by the ion etch of carbon, leaving an SiO_2-rich polymer at the surface of the recessed feature [62]. No such characterization currently used in IC processing has been able to provide such direct evidence of process-induced mechanical variation of materials.

Moreover, UFM has also shown the potential for imaging the surface damage of polymeric materials. Figure 14 shows UFM and topography scans for a region of an Al/polymer IC test structure after CMP [63]. In the UFM image, the lateral lines are Al-filled trenches in the polymer matrix. There is an associated topography (Al lines are slightly depressed relative to the polymer). The UFM also reveals striations

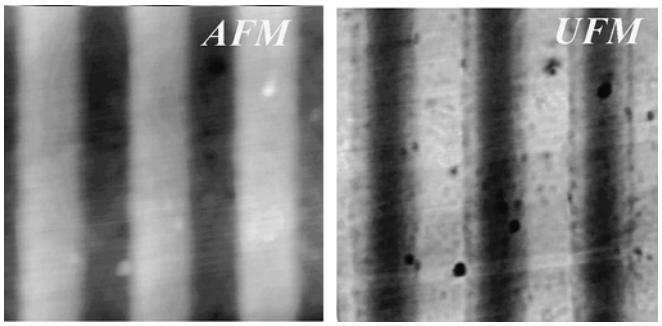

Figure 13. 2.0 μm × 2.0 μm AFM (left) and UFM (right) plan-view scans Al lines (dark regions in topography) in a polymer matrix (bright regions in topography). In the UFM scan, the contrast is reversed, as expected for an elastic image map. Note the local variation of the contrast within the polymer at the edges of the trench walls. This increase in elastic modulus result from silicon–oxide polymer formation in the polymer after exposure to a reactive-ion etch plasma.

crisscrossing the trench field. These striations look similar to scratches, not unexpected after CMP processing. However, the "scratches" have no corresponding feature in the topography image, and only occur in the polymer region. Preliminary investigations associate these features in the UFM image with mechanical stressing in the polymer that results in cross-link bond breakage in the polymer, resulting in a lower local Young's modulus [64]. The reduction of cross linking in these areas also reduces the local shear modulus, and permits relaxation of topographical variations, leading to the featureless topography scan.

Similar behavior relating to the nanomechanical imaging of surface-deformed polymers was carried out by Iwata and co-workers [65]. An AFM tip was used to locally deform or scratch the surface of a polycarbonate film. The local stresses induced the organization of the local carbon nanobundles [66]. In this work, UFM demonstrated

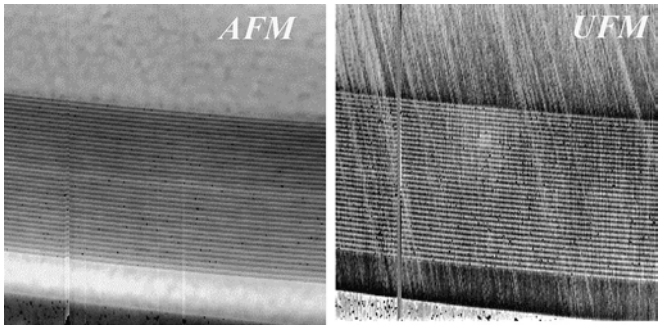

Figure 14. 40 μm × 40 μm AFM (left) and UFM (right) plan-view scans of an Al trench field (horizontal lines) in a polymer matrix. The sample was planarized via chemical mechanical planarization. In the UFM, vertically oriented striations are evident. These striations are not evident in the AFM image, and are believed to result from local bond breaking in the polymer due to the action of the CMP abrasive. Although not visible at this magnification, the striations are not continuous across the Al regions.

sufficient sensitivity for the observation of slight elastic variations of the modified PC surface. The bundles grew in vertical extent with repeated scan scratching, yet the associated bundle mechanical response decreased. The associated contrast of the UFM images of individual bundles decreased, consistent with the threshold behavior of the cantilever response. It was suggested by the authors that the increase of the mechanical bundle compliance is indicative of the microcracks or voids due to the local tip-induced stresses associated with repeated scratching.

Recently, Kolosov has expanded the applicability of UFM by demonstrating so-called waveguide UFM or W-UFM. In such a mode, the ultrasonic vibration is introduced to the cantilever, and not the sample. If a higher order flexural vibration is excited, the tip of the sample will oscillate as an antinode for the standard vibrating beam problem. However, the suppression of the fundamental resonance mode will still restrict the overall cantilever rigidity, resulting in the indentation of the sample against the tip, similar to conventional UFM. In fact, the tip–sample force–displacement response curves for the two techniques are quite similar [67].

Ultrasonic force microscopy offers exceptional sensitivity to surface contact stiffness. Although no quantitative comparison has been carried out, preliminary work by Shekhawat et al. implies that it may be superior to SLAM from the perspective of overall sensitivity. However, the difficulty of quantitative analysis for high-stiffness materials via UFM resulting from contact area variations demands further technique development. A parallel technique developed for nanomechanical imaging offers a different route for the qualitative and quantitative analysis of surface contact stiffness and modulus, so-called acoustic atomic force microscopy (AAFM). Early use of AAFM was reported by Arnold and co-workers [68–70]. It used a slightly different experimental apparatus for mapping the surface elastic response. However, for all intents and purposes, it is essentially the same as UFM when the sample oscillation amplitude is large enough to probe the nonlinear region of the tip–sample force–displacement response curve. The notable difference is the utilization of AAFM in the *linear regime* for extraction of the contact stiffness. Linear regime AAFM (also referred to as ultrasonic AFM by Quate and co-workers [71]; the tendency of each group to define a unique acronym for their particular experimental configuration is confusing for newcomers to the field) is similar to Burnham's SLAM. However, Burnham modeled the AFM cantilever tip as a simple spring, and hence one resonance. The groups of both Arnold and Quate took a more involved approach, and solved the full dynamical equation of a cantilevered tip in contact with the surface. As the surface load of the tip is varied, the resonant frequency spectrum of the cantilever is modified. Hence, the varying surface contact stiffness probed by a cantilevered tip as it is scanned across a sample surface will result in a modified resonance spectra for the cantilever. At a given point on the sample surface, determination of the shift in the cantilever resonance is used to extract the contact stiffness and determine, if desired, the Young's modulus of the surface.

Assuming a linear response, the relation between the surface contact stiffness k_i and a resonant frequency spectra $k_n^2 = f_n\sqrt{4\pi^2 12\rho/(b^2E)}$ [72], the surface-modified cantilever frequency spectrum is given by [69]

$$\frac{k_i}{k_c}\begin{bmatrix} -(\cosh k_nL_1 \sin k_nL_1 - \sinh k_nL_1 \cos k_nL_1) \\ \quad \times (1 + \cos k_nL' \cosh k_nL') \\ +(\cosh k_nL' \sin k_nL' - \sinh k_nL' \cos k_nL') \\ \quad \times (1 - \cos k_nL_1 \cosh k_nL_1) \end{bmatrix} = 2\frac{(k_nL_1)^3}{3}(1 + \cos k_nL \cosh k_nL) \tag{13}$$

Here, L is the total cantilever length, b is the cantilever thickness, L_1 is the base-to-tip length of the cantilever, L' is the tip-to-end length of the cantilever, and E is the Young's modulus of the cantilever material. For cantilever width a, the cantilever spring constant k_c is given by

$$k_c = \frac{Eb^3a}{4L_1^3} \tag{14}$$

Rabe and co-workers used the shift in resonance to qualitatively map the elastic response of a surface [69]. For a given point on a sample, the contact stiffness was approximated. Crozier et al. [71] and Yaralioglu et al. [73] extended this analysis with the development of an iterative algorithm to fit the shifts of multiple resonant peaks of the cantilever spectrum at points on the sample to determine, with high precision, the calibrated contact stiffness. Application of this technique to the film thickness measurement represented an impressive achievement for nanomechanical characterization.

The culmination of this approach for ultrasonic-based scanning probe microscopy has recently been reported by Yamanaka's group [74]. They have modified the conventional AAFM configuration to include a feedback circuit to maintain cantilever resonance as the tip is scanned across the sample with a minimal increase in image acquisition time. Hence, a true nanoscale "map" of the cantilever resonance frequency can be obtained and used for conversion to contact stiffness data (although quantitative conversion has yet to be done). That technique demonstrated some of the highest resolution images to date regarding subsurface dislocations in graphite, and promises a bright future for the direct nanoelastic imaging of materials.

A variety of other related techniques for nanomechanical imaging have been reported; however, the majority represent variations of those discussed with respect to the introduction of lateral oscillation or combinations of high and low frequencies to the tips and samples [75–79]. A unique, and possibly powerful, technique for probing the elastic AND viscoelastic properties of materials at the ultrasonic time scale was recently put forth by Kolosov and Briggs [80–81]. This technique combines W-UFM and UFM. The heterodyne interference of the two vibrations produces a low-frequency amplitude modulation that traverses the nonlinear portion of the force response curve in much the same fashion as the externally modulated ultrasonic vibration in conventional UFM. However, the phase coherence of the two vibrations yields a temporally calibrated phase image that can resolve time shifts on the nanosecond time scale.

Hence, viscoelastic (dynamic) nanomechanical imaging is possible through so-called heterodyne UFM (HFM). In this

mode, two ultrasonic vibrations are applied to the measuring system. One ultrasonic vibration is applied to the tip, which acts as a mechanical waveguide, while a second ultrasonic vibration is applied to the sample (as in conventional UFM). This results in coherent oscillations of the tip and sample surfaces at the local point of contact [80]

$$\begin{aligned} z_S &= A_S \cos(\omega_S t + \phi_S) \\ z_{\text{tip}} &= A_{\text{tip}} \cos(\omega_{\text{tip}} t) \end{aligned} \tag{15}$$

Here, the tip vibration waveform acts as a temporal reference. The temporal phase delay associated with the surface vibration waveform is designated by ϕ_S. A linear force–displacement relationship between the tip and sample would result in no average cantilever deflection. However, a nonlinear force–displacement curve yields a heterodyne coupling between the two oscillations. This is seen by expanding the tip–sample force in a Taylor's series to second order in the tip–sample separation, and calculating the average force responsible for cantilever deflection

$$\begin{aligned} &k_c \langle z_{\text{tip}}(\omega_{\text{tip}}, \omega_S, A_{\text{tip}} A_S) \rangle \\ &\quad = \frac{1}{\tau} \int_0^\tau F(z_{\text{tip}} - z_S)\, dt \\ &\quad = \frac{1}{\tau} \int_0^\tau \left(\chi_1 (z_{\text{tip}} - z_S) + \chi_2 (z_{\text{tip}} - z_S)^2 + \cdots \right) dt \end{aligned} \tag{16}$$

χ_1 and χ_2 denote first- and second-order "spring constants," respectively, associated with the force–displacement curve. The cantilever deflections resulting from both oscillations [Eq. (15)] are substituted into Eq. (16) and time averaged over the response time τ of the SPM photodiode detector (hundreds of kilohertz). Only the nonlinear term is nonvanishing. Likewise, the high-frequency terms are replaced by their rms values, and the remaining time dependence corresponds to the heterodyne or difference frequency term

$$\begin{aligned} &\langle z_{\text{tip}}(\omega_{\text{tip}}, \omega_S, A_{\text{tip}P} A_S) \rangle \\ &\quad = \frac{\chi_2}{k_c} \left\{ \frac{A_{\text{tip}}^2}{2} - A_{\text{tip}} A_S \cos[(\omega_{\text{tip}P} - \omega_S)t - \phi_S] + \frac{A_S^2}{2} \right\} \end{aligned} \tag{17}$$

The deflection of the tip is now dynamically linked to the viscoelastic response of the sample to the ultrasonic vibration. The phase term ϕ_S represents the dissipative lag/lead in the surface response with respect to the tip reference frequency. In the vicinity of an interface, this dissipation is directly linked to a local loss tangent, indicative of the adhesive or interfacial bonding strength. For continuous materials, the dissipation is due to a classical viscosity. Extracting the spatial dependence of this phase term provides image contrast indicative of the dynamics of materials, material interfaces, and defect structures with the same nanometer spatial resolution as UFM.

Experimentally, the two oscillations are applied to the tip and sample by two matched piezocrystals attached to the tip substrate and the base of the sample, respectively, and driven by a separate waveform with a mixer/filter circuit providing the heterodyne frequency to an RF lock-in amplifier for amplitude (χ_2) and phase (ϕ_S) extraction. Although the amplitude calibration is more complex than that for UFM, the phase can be imaged directly, as displayed in Figure 15 for an integrated-circuit test structure consisting of square 5 μm polymer pads inlaid within an Al layer [60, 82]. The right panel data of Figure 15 were acquired with both ultrasonic vibration amplitudes above threshold for Al and the polymer. The left panel data of Figure 15 were acquired with both amplitudes below threshold. No phase variation is seen in the latter since the response is linear, validating the simple model presented above. The phase difference between the Al and polymer regions ~10 ns. Data were taken at a carrier frequency of 3 MHz. Recent efforts in our laboratory have demonstrated HFM operation up to 80 MHz. The 1° relative phase resolution of our HFM system provides a temporal (phase lag) resolution less than 40 ps.

3. NANOTUBE MATERIALS

3.1. Introduction: Description of Molecular Nanotubes

In 1991, nanotubes of carbon were discovered by Sumio Iijima in carbon deposits on an arc-deposition system similar to that used for the production of C_{60} (termed Buckminsterfullerene) [3]. From a structural perspective, a single-walled carbon nanotube (SWNT) can be visualized as consisting of a single (graphene) sheet rolled into a tube. To maintain the periodic structure of the 2-D honeycomb lattice formed by the carbon atoms within the sheet, there is a discrete relationship between the tube diameter and the chirality of the tube [83, 84]. This relationship is summarized in Figure 16, and utilizes a simple 2-D lattice notation. The diameter and chirality of a given SWNT are defined by an integer pair (n, m) which denotes a point on the edge of a graphene sheet that is mapped onto the origin (0, 0) as the sheet is rolled. Rolled (n, 0) graphene sheets are referred to as zigzag tubes as C atoms on an open end form such a pattern. Rolled (n, n) graphene sheets are referred to as armchair tubes as the C atoms on an open end form undulating hexagonal tiles (see Fig. 16). Rolled (n, m) sheets, where $n \neq m$, are typically referred to as chiral, although the use of this taxonomy varies throughout the literature.

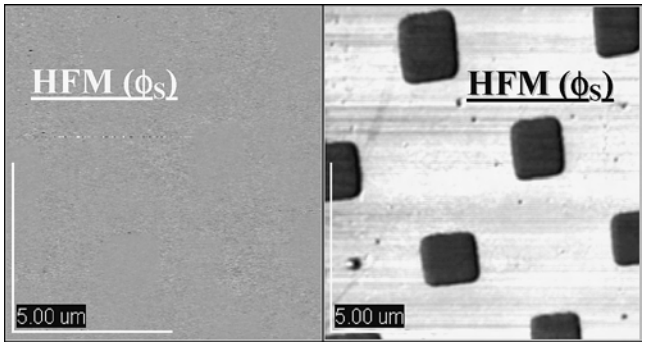

Figure 15. HFM phase maps (10 μm × 10 μm scans) for tip and sample vibrations below (left) and above (right) threshold amplitude, respectively, for polymer/Al test structure. The dark regions are polymeric plugs in an Al field. The structure was fabricated using IC processing. The reduced contrast for the polymeric regions correspond to an increase in the viscoelasticity compared to the Al.

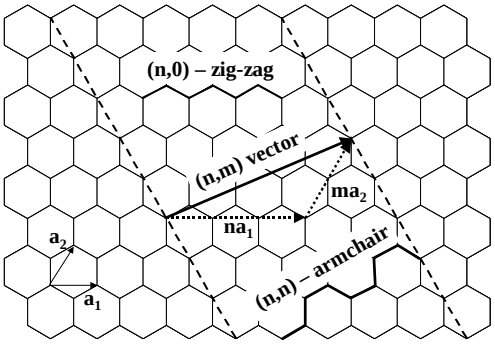

Figure 16. Schematic diagram outlining how a 2-D graphite sheet is "rolled" to form a nanotube. The diagonal dotted lines denote graphene sheet edges that, if joined, would form a (3, 2) nanotube.

Multiwall carbon nanotubes (MWNTs) consist of multiple nested (graphitic) sheets rolled into a tube. The spacing of these sheets has been experimentally measured at 0.34 nm, only slightly larger (3–5%) than the c spacing of conventional graphite [84]. SWNTs typically possess diameters in the 1–5 nm range, and lengths ranging to many microns. Depending upon the method of synthesis and purification, SWNTs entangle to form nanoropes [85–86]. The cross section of these ropes consists of individual SWNTs on a triangular lattice. For example, the SWNT ropes investigated by Yu et al. consisted of 1.35 diameter SWNTs on a triangular lattice with a center-to-center distance of 1.7 nm [87]. As expected, MWNT diameters are significantly larger, ranging from 7 to over 200 nm. Multiwall NTs also form fibrous ropes, the mechanical properties of which will be discussed next.

From a mechanics perspective, two fundamental properties of NTs are of interest. First, the planar sp^2 bonding of the carbon atoms in the graphene sheets provides for an enormous mechanical modulus, that is, a very low strain is seen for a given in-plane applied stress [88]. And, in stark contrast to fourfold coordinated sp^3 bonding of carbon in diamond or diamond-like materials, the quantum-mechanical electron energy levels of an sp^2-bonded graphene sheet may permit electron conduction [89–90]. Second, the energetics of NT growth are often suitable for the production of crystal defect-free SWNTs or MWNTs [91]. This is a truly remarkable mechanical feature in that the presence of crystalline defects dramatically impacts mechanical properties.

3.2. Mechanical Definitions, Theoretical Predictions for NT Mechanical Properties, and Experimental Studies

As noted by Salvetat et al., [92], knowledge of the Young's modulus of a material is the first step toward its use in practical structural applications. For a long, thin rod of arbitrary cross-sectional area A_o, the Young's modulus is defined as the ratio of the axially applied stress (F/A_o) to the fractional axial deformation $(\delta l/l_o)$: $E = (Fl_o)/(\delta l/A_o)$. The Young's modulus can also be defined in terms of the bulk modulus K and the shear modulus μ of a material: $E = 9K\mu/(3K + \mu)$. In the simplest terms, the shear modulus is the ratio of the applied stress to the strain of a material in the case where a deformation changes the shape of a body, but not its volume. The opposite case is true for the bulk modulus. It represents the stress/strain ratio for a deformation changing the volume of a body, but not its shape (hydrostatic). Both K and μ are defined assuming a linear relationship between the applied stress and strain. The Young's modulus for both SWNTs and MWNTs has been calculated, simulated, and measured in a variety of methods which are described in more detail below. Some groups model nanotubes as deformed sheets wherein the strain energy due to bending is linearly proportional to a bending modulus κ, defined as the second derivative of the surface energy density with respect to curvature. For a tube, $\kappa = Ea/(1 - \nu^2)$, where ν is Poisson's ratio and a is the tube wall thickness. Also of interest for the nanomechanics of NTs is the tensile or yield strength (defined as the stress beyond which the strain varies nonlinearly or, alternately, as the maximum stress which may be applied to the material without perturbing its stability [93]).

One of the earliest theoretical studies of the mechanical properties of SWNTs was carried out by Robertson et al. [83]. They investigated the lattice energetic of carbon NTs for all (n, m) nanotubes with radii less than 0.9 nm using two related many-body empirical potentials and local density functional (LDF) theory [94]. The many-body potentials included atomic core–core repulsive terms and attractive terms related to the C valence electrons. It was found that the tensile or compressive strain energy per carbon atom of an SWNT relative to an unstrained tube varied as $1/R^2$, where R is the tube radius. In addition, it was found that the Young's modulus associated with tube elongation decreased with decreasing radius, that is, smaller nanotubes became softer, depending on the helical (n, m) structure of the nanotube. The former observation agrees well with the expectation of continuum elastic models for the strain energy density of a uniform tube [83, 95]

$$\frac{\sigma}{A} = \frac{Ea^3}{24R^2} \tag{18}$$

where A is the area of the NT, a is the representative thickness of the NT wall (~0.34 nm), and E is the Young's modulus. Robertson noted that agreement between simulation and continuum elastic theory persisted to radii as low as 0.2 nm. This result was not completely surprising. A tube consisting of a graphene sheet would be expected to maintain a Young's modulus near that of the C_{11} elastic constant in graphite (corresponding to the elastic modulus parallel to the basal plane), as long as the atomic level deformation induced by the wrapping was low. This is obviously the case for large radii.

In studying the deformation properties of carbon SWNTs, Bernholc and co-workers calculated the Young's modulus and Poisson's ratio via a molecular dynamics framework based on many-body interatomic potentials [96–98]. As with the earlier work of Robertson et al. [83], a high degree of correspondence between the modeled mechanical response and results of classical mechanical theory was found. Their MD simulations predicted a modulus of 5.5 TPa and a Poisson's ratio of 0.19 [96]. The latter is fully 550% larger

than the C_{11} elastic constant (basal plane modulus) of graphite, while the Poisson's ratio is significantly lower than the value of 0.33–0.34 of graphite [50]. At this point, a comment is required regarding the calculation of E for atomically thin tubular shells. From the perspective of continuum elastic energetics, the Young's modulus is also defined as the second derivative of the system energy with respect to strain at equilibrium normalized to system volume. This is the practical definition used for virtually all simulations or analytical models as the energy functional is directly accessible. However, it opens the question of the actual wall thickness of an SWNT. At molecular-length scales, it may not be reasonable to characterize the thickness of an SWNT with the lattice spacing of MWNTs or the c-axis spacing of graphite. Consequently, the use of an elastic modulus such as E, which is, by definition, normalized to a classically defined cross-sectional area, may have little meaning in that a well-defined value for the NT cross-sectional area does not exist. More recently, several groups working on this problem from a simulation or theoretical perspective have stated results only in terms of the product aE to avoid the ambiguity inherent in applying a classical "wall thickness" to a structure of single-atom thickness [99–100]. For the MD simulations previously described, a wall thickness of 0.066 nm was used. When replaced with the value of 0.34 nm (an upper estimate for the wall thickness in MWNTs) and akin to the c-axis spacing in graphite, a value for E of 1.07 TPa is obtained. Suffice it to say that, when compared in terms of aE, the MD work presented here continues to agree with more recent theoretical (and, as will be shown, experimental) results.

An empirical force-constant model, wherein the atomic interactions near an SWNT equilibrium structure are approximated by the sum of pairwise harmonic potentials, was used by Lu to calculate elastic properties of SWNTs and nanoropes [101]. Values of $E = 0.97$ TPa were obtained using an SWNT wall thickness of 0.34 nm, and were virtually constant as a function of SWNT helicity and radius. A value for Poisson's ratio of 0.28 was determined that possessed the same insensitivity to (n, m). The Young's moduli of crystalline nanoropes of SWNTs were calculated, and ranged from 0.80 to 0.43 TPa as the number tubes per rope varied from 5 to 15, respectively.

More recently, a broad range of computational and analytical approaches has been applied to the accurate calculation of Young's modulus in CNTs. Yao and Lordi took a finite temperature, molecular dynamics (MD) simulation approach for the calculation of E for SWNTs [102]. Using the universal force field of Rappé and co-workers [17], simulations were carried out on SWNTs 10 nm in length, ranging in diameter from approximately 0.2 nm for a (5, 5) tube to 1.4 nm for a (20, 20) tube. For relatively large (20, 20) tubes, the Young's modulus determined from the simulations was approximately 0.97 TPa. This is quite close to the value of C_{11} measured in graphite ($\sim$1 TPa [104]). However, as the SWNT radius was decreased, the MD simulations predicted a 15% increase in E to 1.12 TPa for the (5, 5) SWNT. The increase was attributed in large part to corresponding increases in torsional strain that develop as the C sp^2 bonds are deformed at a smaller tube radius. The variation of strain energy with NT size had been previously studied [105–106], but the ability for the MD simulation to potentially predict this behavior more accurately was attributed directly to the inclusion of a torsional term in the bond energy calculation, which turns out to be most sensitive to the variation of E with decreasing radius. Yao and Lordi also simulated thermal vibrations of SWNTs clamped at one end, similar to TEM-based techniques, to experimentally measure E (see below). Their simulations, ranging from temperatures of 300 to 2000 K, yielded temperature-independent vibrational mode frequencies that matched well with continuum elastic model predictions.

Similar studies were carried out by Goddard and co-workers using molecular dynamics and molecular mechanics techniques, but for (n, n), $(n, 0)$, and $(2n, n)$ SWNTs [107]. They obtained values for the bending modulus κ of 0.96 TPa for (n, n) tubes, 0.91 TPa for $(n, 0)$ tubes, and 0.94 TPa for $(2n, n)$ tubes. They also calculated Young's moduli for SWNT bundles or ropes. Within the bundle, the SWNT axes define a triangular lattice. The lattice spacing varied from 1.68 nm for (n, n) tube bundles to 1.65 nm for $(n, 0)$ and $(2n, n)$ tube bundles. Strain energies for these ropes were calculated, and Young's moduli of 640, 648, and 673 GPa for the (n, n), $(n, 0)$, and $(2n, n)$ ropes, respectively, were obtained. The comparison between the bending moduli calculated in this work and Young's moduli of other techniques is complicated by a dimensional inconsistency. Although the strain energies are defined conventionally, Goddard and co-workers report the bending moduli in units of gigapascals, and do not define the normalization of the wall thickness required for conventional definitions of κ [107].

Rubio and co-workers have carried out predictive calculations for E of SWNTs using tight-binding (TB) and pseudopotential-based density function theory methodologies [99]. To avoid the wall thickness problem, the Young's modulus, alternately defined in elastic systems as the volume-normalized second derivative of the system energy with respect to strain (at equilibrium), is instead normalized to the SWNT surface area. Their TB model followed that of Porezag et al. [108], containing band-energy terms and a repulsive pair potential. As with similar techniques used for band calculations of conventional materials [109], the successful application of this technique depends upon a generalized eigenvalue equation for a nonorthogonal basis set. As with previous continuum elastic and calculational approaches, an inverse quadratic dependence of strain energy on tube diameter was found [83]. Assuming a carbon SWNT wall thickness of 0.34 nm, their corresponding results for E ranged from 1.26 TPa for a (20, 0) carbon SWNT to 1.22 TPa for a (6, 6) SWNT. In addition, the authors calculated the Poisson's ratio, defined here as

$$\nu \cdot \varepsilon = -\frac{R - R_{\text{eq}}}{R_{\text{eq}}} \tag{19}$$

The Poisson's ratio varied from 0.27 for a (20, 0) tube to 0.25 for a (6, 6) tube. Considering the sidewall thickness used for the determination of E, these results agreed reasonably well with other approaches, and confirmed that, in certain respects, the elastic behavior of carbon SWNTs should mirror that of in-plane graphite. An important aspect of this

work is the prediction that E will decrease rapidly as the tube radius decreases. This tends to agree with earlier comments made by Robertson et al. [83], but contradicts the intuitively appealing result of other groups that E should increase with smaller radius tubes due to the increased energy associated with the rolling strain [102]. Despite the significant theoretical and modeling efforts ongoing for nanotube structures, this issue seems not to be resolved.

Mechanical strain energies and Young's modulus for straight and bent SWNTs were also calculated by Xin et al. [110]. In contrast to prior investigations that used continuum elastic theory, molecular dynamics simulations, or empirical many-body potentials, a band-theory approach was taken here [111–112]. It was noted from a straightforward calculation that the strain energy of straight SWNTs originates from the curvature-induced electronic energy change. Consequently, determination of the electronic energy of all of the occupied bands was carried out to provide predictions for SWNT mechanical properties. The band-structure calculation utilized a nearest neighbor tight-binding approach [111]. Such approaches have been widely used to calculate graphene and SWNT electrical properties. Strain energies were calculated for a tube of cross-sectional radius R subjected to a bending deformation (bending radius $= \rho$). The R dependence of the bending energy E_b related to the strain energy E_s of a straight tube determined from the tight-binding model agreed well with continuum elastic theory predictions [113]

$$E_b = E_s + \frac{\lambda}{R^2} \tag{20}$$

From the tight-binding calculation carried out by Xin and co-workers, $\lambda = 0.7$ eV/atom. This is a further confirmation that continuum elastic theory provides a valid framework within which to predict nanotube mechanical behavior.

In this same work, however, a Young's modulus of approximately 5 TPa is predicted. This magnitude exceeds other estimates by a factor of 5. However, it should be noted that the SWNT wall thickness calculated by Xin et al. is approximately 0.07 nm, and differs significantly from the conventional value of $a = 0.34$ nm used for the calculation of E by most other authors (noted previously). In terms of the product aE, the results from this tight-binding model match well with other simulations.

Theoretical calculations of SWNT mechanical properties have also been carried out using local density approximation cluster models. As applied by Zhou et al., a linear combination of atomic orbitals is used to solve the Schroedinger equation directly, applying appropriate boundary conditions to remedy the problem of dangling bonds present at the edges of the cluster [93]. Such an approach makes fewer initial restrictions on the form of the electron wave function as do tight-binding approaches. A 156 atom NT was used for purposes of calculation [114–115]. A value of Young's modulus of 0.76 TPa was calculated, somewhat lower than previously discussed values (assuming a wall thickness of 0.34 nm). A value of Poisson's ratio of 0.32 (slightly lower than that of graphite, ~0.33–0.34) was also determined from these calculations. It should be noted that, unlike molecular dynamics approaches, the density-of-states methodology used here also provides specific information regarding carbon–carbon bonding states. It was found that, upon rolling the graphene sheet into an (n, n) conformation, the overlap integral of σ bonds in the graphene plane decreased by approximately 7%. In contrast, the overlap integral of π bonds increased by about 2.4%, and the total overlap integral decreased by approximately 4%. The decrease of the overall overlap integral leads to a lower net bonding energy compared to graphite. In addition, the reduced bond overlap will broaden the effective interatomic electrostatic potential well, and reduce the Young's modulus compared with that of basal plane graphite (~1 TPa). It is interesting to note that, in this work, the curvature effect tends to weaken the σ bonding, but strengthens the π bonding, which may have implications with respect to the electronic functionality of NTs.

Fewer theoretical and simulation efforts have been carried out with respect to the elastic moduli of MWNTs. Using the empirical force constant model referenced earlier, Lu predicted an increase of E with the number of walls from a value of 0.97 TPa for a single (5, 5) SWNT to a value of 1.11 TPa for an MWNT with seven nested tubes about a (5, 5) core [101]. A Poisson's ratio value of 0.27 was insensitive to the number of MWNT walls. For these studies, as most others, a 0.34 nm spacing is assumed. The critical aspect of MWNT modeling is proper inclusion of the electrostatic energies associated with the adjacent graphitic walls. No dramatic effects have been predicted with respect to linear response to elastic strain. However, several groups point to significant effects of wall–wall coupling in nonlinear (inelastic) deformation, and they will be discussed next.

Experimental determination of the Young's modulus for SWNTs and MWNTs has utilized a wide array of approaches. The groundbreaking work was carried out on MWNTs by Treacy et al., resulting from an observation that the free ends of cantilevered SWNTs appeared fuzzy in a TEM [116]. Subsequent thermal studies revealed that poor TEM focus resulted from thermal vibrations. Using classical mechanical beam theory, the vibration frequency spectrum ω_n of a uniform clamped tube [116, 95]

$$\omega_n = \frac{\beta_n^2}{2L^2}\sqrt{\frac{E\left(R_i^2 + R_o^2\right)}{\rho}} \tag{21}$$

was used to estimate the E experimentally, assuming a thermodynamic equipartition concerning the SWNT vibrational mode energies. Above, R_i and R_o represent the inner and outer SWNT tube radii, respectively, ρ is the in-plane mass density, L is the tube length, and β_n is a set of numerical coefficients. Fitting the observed thermal dependence of the vibration amplitude to the above expression, E_{measured} varied from 0.4 to 3.7 TPa for wall numbers ranging from approximately 5 to >25. Although the uncertainties in the data were quite large and dominated by experimental errors, there was an increase in E attributed to thinner tubes. These studies were extended and refined by Krishnan et al. with respect to SWNTs [117]. Using the same basic experimental techniques and stochastically driven oscillator theory for the SWNTs, a refined error analysis was presented, and an

average Young's modulus of 1.3–0.4/+0.6 TPa was determined. Similar to the work on MWNTs, measured values of E for SWNTs ranged from ~0.3 to 2.7 TPa. The origin of experimental errors stems from the accurate determination of the thermal vibration amplitude to the accurate calculation of the free length of individual NTs. Regardless, these studies represent a breakthrough for nanomechanical measurement. Note that the clamped beam models used to calculate E from experimental data require similar assumptions regarding the NT wall thickness as did the theoretical efforts [95]. All experimental work summarized here typically used a value of 0.34 nm SWNT wall thickness (or MWNT wall spacing). Hence, their elasticity data should be compared with correspondingly normalized values of E from theoretical calculations.

More direct measurements of SWNT mechanical response were undertaken by Salvetat et al. that exploited the surface adsorption of SWNT ropes to nanoporous templates to form suspended SWNT rope "beams" clamped at both ends by surface van der Waal forces [118]. The ropes were modeled as a continuous cylindrical object characterized by an elastic modulus E_r (Young's modulus renormalized by bending) and a shear modulus μ. The elastic modulus decreased from a maximum of 1.2 TPa (for a 3 nm diameter rope) to values as low as 0.07 TPa for a 20 nm diameter SWNT rope. The measured shear modulus acted in many respects similarly, ranging from 6.5 to 0.7 GPa for ropes of diameter 4.5 and 20 nm, respectively. Although the error values for these elastic constant measurements are reported at $\pm 50\%$, the estimation of E_r for the thinnest ropes is consistent with that of individual NTs. In this work, the shearing was assumed to occur between SWNTs only, that is, shearing of individual SWNTs was ignored. An inherent difficulty in work of this sort is the possibility of defects or breaks of single SWNTs in the ropes. Such effects are cited as a possible source for error, and are primarily responsible for the low value of μ.

In contrast to the beam-bending approach utilized above, Ruoff and co-workers conducted a series of impressive experiments wherein SWNT ropes were literally welded to a cantilevered probe tip inside an SEM, and carried out direct tensile testing driven by a piezoelectric deflector [119]. In these experiments, the base of the nanorope undergoing testing was entangled within a nanorope mat produced via the standard arc-discharge method. By knowledge of the force constant of the cantilevered probe tip, the Young's modulus of multiple nanoropes (assumed to be comprised of (10, 10) SWNTs) was directly measured, and varied from 0.32 to 1.47 TPa, with a mean of 1.0 TPa. These data are in excellent agreement with other experimental measurements and a larger body of theoretical work.

Since the increased size of multiwalled carbon nanotubes and corresponding MWNT ropes increases experimental accessibility, a wide range of mechanical measurements have been performed on these systems. Pan et al. pulled individual MWNT ropes as long as 2 mm to carry out direct tensile strength measurements using conventional test kits [120]. The linear portion of the stress–strain curve thus generated was used to directly measure E. The average value thus determined was 0.45 ± 0.23 TPa. Akita and co-workers used a slightly more elegant approach by attaching an MWNT segment directly to a micromachined cantilever while using a second cantilever applied to the tube to carry out compressive strain testing. The MWNT was considered as a classic beam, and the measured buckling force was assumed described by Euler beam theory ($F_{\text{buckling}} \sim \pi^2 EI/2L^2$; L = length, I = MWNT inertial moment) to extract a Young's modulus of 0.46 TPa (no errors were quoted). Using an experimental approach similar to Treacy and co-workers to extract elastic moduli from nanotubes, Gao considered MWNTs grown pyrolytically [121]. Similar thermal vibrations were observed via TEM from individual MWNTs, and the conventional analogy between the MWNT and a vibrating uniform beam clamped at one end was used to infer the modulus from the thermally stimulated vibration amplitudes [95]. In this work, the authors erroneously label the modulus used in such a model as a bending modulus. For the classical clamped beam problem, the modulus is defined as Young's modulus [4, 95]. Their results suggest an average value of E for their tubes of 0.03 TPa. This value is dramatically lower than prior experiments. The authors note that the expected high density of structural defects in pyrolytically grown MWNTs is the most likely cause. For MWNTs possessing so-called volume defects (areas of the tube with reduced radii), the effective value of E was as low as 0.002 TPa. It is clear that structural defects in NT structures can have dramatic effects on the mechanical properties.

The previous discussions have centered on nanotubes made from carbon. However, there is no physical principle limiting the composition of such structures to carbon. Vaccarini et al. have nicely summarized theoretical and some experimental results for nanotube compositions ranging from the standard carbon to BN, BN_3, BCN_2, GaSe, WS_2, and MoSe. Hernandez and co-workers carried out theoretical investigations of BN, BC_3, BCN_2, and C_3N_4 SWNTs as well [88]. From a physical point of view, all compounds exhibiting layered structures in the bulk phase are likely to form nanotubes, with the caveat that the "layered" structure possesses dramatically anisotropic bonding as is found in graphite. For example, BN carbon nanotubes possess the same honeycomb sheet structure of carbon NTs; however, B and N atoms populate alternating sites. The same (n, n) notation can be used to describe the tube structure, although the "unit hexagon" is composed of equal B and N atoms. Utilizing TB models (see above), the BN SWNT Young's modulus varied from 0.75 to 0.92 TPa for tube radii varying from 0.5 to 2.5 nm, respectively. The increase of modulus with increasing tube radius mirrored theoretical results for corresponding carbon SWNTs using the same computational approach. The same authors note that the Poisson's ratio was similar for all NT compositions studied [88]. And once again, the results for BN nanotubes compared well with simple continuum elastic approaches.

Molecular dynamics and ab initio total energy methods were applied to BN nanotube modeling by Srivastava et al. [122]. A value $E = 1.2$ TPa was determined. Contrary to carbon nanotubes, however, the bond strain inherent in confinement of B–N sheets in tube form tends to expel the N atoms and subduct B atoms, providing an atomic-scale corrugation at the tube surface. Hernandez and co-workers

obtained lower values for BN SWNT Young's moduli generated from TB models [99]. 0.84 TPa $< E <$ 0.91 TPa were determined for tube geometries ranging from (6, 6) to (20, 0). No significant dependence on size or chirality was found. Typically, other composition SWNTs displayed Young's moduli in similar ranges, with the exception of C_3N_4 tubes where E dropped to ~0.6 TPa. In all cases, the highest values of E from simulations corresponded to carbon tubes. From an experimental point of view, measurements of BN nanotube elastic moduli were carried out in precise analogy to those for carbon tubes. Using the thermal vibration amplitude methodology, Chopra and Zettl measured the BN MWNT Young's modulus to be 1.22 ± 0.24 TPa [123]. This compares well with the theoretical result of Srivastava et al. [122]; however, it exceeds estimates from other simulations [93]. Still, the body of experimental and theoretical work on noncarbon nanotubes makes clear the ubiquity of extremely high-modulus nanotube structures provided a high degree of structural perfection exists.

From the viewpoint of elastic properties, an impressive degree of agreement between experimental and theoretical studies of carbon (and other) SWNTs and MWNTs is evident. The question arises as to the promise of nanotechnology. Do the high values of E constitute an emergent nanomechanical property? Although the point may be argued, it is clear that easily synthesized arrays of these nanostructures with near-perfect elastic properties can be produced. The fact that the measurements confirm that these materials possess superior properties compared to larger (microscale) carbon fibers justifies the classification of NTs as nanostructured materials with emergent properties.

The remainder of this section will provide a brief overview of investigations of inelastic properties of nanotubes, namely, tensile strength (defined experimentally as the maximum force sustainable during a stress–strain test) and strain-induced defect generation. Utilizing the tensile strain test kit described earlier, Pan et al. measured the tensile strength of MWNT ropes to be 1.33 GPa [120]. Early theoretical studies [124] suggested that the tensile strength of carbon NTs should be similar to carbon whiskers (~20 GPa). Further refinement of the experimental studies by the same group, including a Weibull analysis of a collection of MWNT ropes, yielded an average tensile strength value of 3.6 GPa [125]. More recently, Yu and co-workers undertook high-resolution tensile strength studies of carbon SWNT ropes, and measured breaking strengths that ranged from 13 to 52 GPa [126]. The experimental mean value was ~30 GPa. The wide variance of the breaking strength values are attributed to various experimental and SWNT rope geometric factors and, most importantly, the lack of information regarding the continuity of individual SWNTs within the rope. However, their results clearly establish that a 5% strain is reproducibly achievable in carbon NT systems.

This value of this so-called breaking strain has been verified by a number of experimental studies as representative of a strain necessary for crystalline defect generation in the graphene or graphitic sheets of SWNTs or MWNTs, respectively. Before reviewing these results, it is important to appreciate the C–C bond orientation as a function of NT helicity. For the so-called armchair (n, n) NT geometry, C–C bonds are either normal to the axis of the tube or rotated by angles of $\pm 30°$ to that axis. Zigzag $(n, 0)$ tubes possess C–C bonds either parallel to the tube axis or rotated by angle of $\pm 60°$ to that axis. The normally oriented bonds of the (n, n) tubes present the greatest moment to axial strain, compressive or tensile. Consequently, inelastic deformation would be expected to vary significantly on the tube helicity. Although the currently available experimental data present only anecdotal corroboration of this observation, theoretical and simulation-based studies confirm, in detail, this effect.

Experimental studies have also demonstrated the incredible flexibility of NTs against nonrecoverable deformation. Falvo et al. reported AFM studies of MWNTs wherein tubes were subjected to large buckling strains by the AFM tip. Kink angles varied from 90 to ~180° [127]. Of particular interest were two phenomena. First, topographic rippling was observed along the tube axis, as is expected from continuum shell theory [128, 129]. Away from the kinks, the rippling was somewhat recoverable; however, topographic variations at the kink positions appeared permanent. In no case was tube breaking observed, a testament to the flexibility and strength of NTs, even in a highly deformed state. In fact, topographical imaging studies have been carried out on completely collapsed MWNTs [126] or nanotube ribbons that possessed remarkable flexibility. It should be noted that an isolated ribbon or collapsed NT is energetically less stable than its tubular analog [107]. The aforementioned experimental analysis explicitly calculated the stabilizing effect of the attractive NT/substrate interaction to demonstrate its crucial role in observing such deformed NT structures.

Nanotube kinking was observed via TEM studies soon after their discovery [84, 130]. Continuum shell analysis was typically invoked to describe these deformations, although no formal justification for the applicability of those theories was provided, with the exception of the $1/R^2$ dependence of the "elastic" nanotube strain energy compared to that of a single graphene sheet. Groundbreaking work regarding a theoretical basis for nanotube deformation was carried out by Bernolc and co-workers through MD simulations and a continuum shell model [96, 130]. The authors considered inelastic deformation formation in carbon SWNTs under compression, bending, and torsion. With respect to bending strain, simulations for a 1.2 nm diameter tube predicted kink formation at a bend angle of ~30°. The critical curvature C_c associated with tube kinking is described by an empirical relation fit to the simulation results

$$C_c = \frac{1.49}{d^2}\left[1 + \frac{9.89}{d^5}\cos(6h)\right] \tag{22}$$

where d is the tube diameter and h characterizes the helicity ranging from 0 [zigzag or $(n, 0)$] to $\pi/6$ [armchair or (n, n)]. The formation of double kinks was observed and, interestingly, simulations implied that the bending deformations were completely recoverable up to bending angles of 110°. Deformation of SWNTs under compressive strain was also predicted by their simulations. For strain $\varepsilon > 5\%$, a characteristic double-fin flattening occurred. At higher strains, a three-fin flattening occurred before broad buckling deformations set in. MD simulations of excessive torsional stress resulted in the flattening and twisting of the nanotube into a ribbon-like structure [91]. Utilizing a continuum shell model,

the authors considered inelastic deformation perturbations in terms of the stability of axial and azimuthal ripples. A stability analysis against such rippling yielded critical strains $\varepsilon_c = (0.077\ \text{nm})d^{-1}$, which agree well with the MD results noted previously.

MD simulations were further used to investigate strain release in SWNTs through defect generation. Bernholc and co-workers [131] investigated the static and dynamical properties of such tubes under uniaxial tension. At high temperatures (~1800 K), (5, 5) tubes under a 10% axial strain spontaneously generated crystal defects via C–C bond rotation. This defect, referred to as a Stone–Wales transformation, rotates the C–C bond normal to the tube axis, generating a double pentagon–heptagon defect (so-called 5–7–7–5 defect). This is pictured in Figure 17. Using classical potential calculations, the formation energy of 5–7–7–5 defect formation was calculated, and shown to be stable for various (n, n) SWNTs at strains between 5 and 6%. If it is assumed that such defect generation is a precursor to mechanical yield, these calculations support the aforementioned experimental studies. From the onset of the 5–7–7–5 defects, simulations predict unbinding of the defect pairs, and subsequent strain-induced motion along appropriate armchair glide planes. Higher order defect generation (e.g., 5–7–5–8–5) were also predicted prior to tube "breaking" which, in simulations, proceeded by unraveling of carbon strips from the edge of the tube until final separation occurred. The motion of defects thus implies a certain degree of ductility for SWNTs.

The propensity of (n, n) SWNTs to generate C–C bond rotation defects has important implications regarding the relative ductile behavior of nanotubes as a function of helicity [132]. In an extension of the aforementioned simulation work, Nardelli examined defect generation in $(n, 0)$ and (n, m) tubes. As expected, the orientation of C–C bonds in $(n, 0)$ tubes dramatically altered the stability of C–C bond rotation defects under applied strains [132]. In fact, the lack of defect generation and subsequent defect motion in these NTs dramatically reduced their ductile properties. Consequently, a theoretical "ductility phase diagram" was developed, and is adapted in Figure 18 to describe the (n, m) domains where brittle versus ductile behavior is expected. Experimentally, confirmation of this phase diagram is challenging due to the uncertainty of temperature effects and

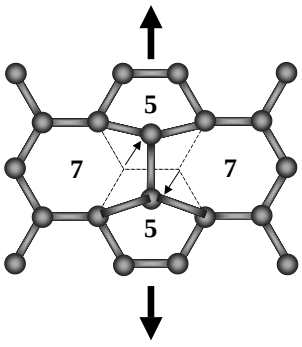

Figure 17. Schematic of a Stone–Wales transformation occuring in an (n, n) nanotube under axial tensile stress. For sufficient stress, the defects can separate and alter the local chirality of the tube.

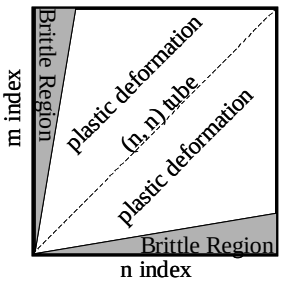

Figure 18. Ductility phase diagram for carbon nanotubes adapted from [132]. Brittle behavior is expected as zigzag geometries are approached due to the unfavorable energetics of defect generation through C–C bond rotation.

activation energies for the bond defects. However, it provides an important roadmap for investigation.

In an attempt to quantify the appearance of such defects in SWNTs under applied strain, Zhao et al. investigated the relevant activation energies using large-scale quantum calculations [133]. The generation of 5–7–7–5 defects at large applied strains was investigated for both (n, n) and $(n, 0)$ tubes—specifically, the activation barriers for defect generation computed by constrained relaxation along the simplest kinetic pathway leading to defect formation. The resulting activation energies were prohibitively large, and ranged from 8.6 eV for a (5, 5) SWNT to 9.9 eV for a (9, 0) SWNT at zero strain. Even at strains as large as 10% (far beyond the breaking strain observed in laboratory experiments), the 5–7–7–5 activation energies exceeded 4 eV, implying a vanishingly small defect generation density at or near room temperature. Consequently, it was concluded that such bond rotation in strained NTs (near room temperature) is unlikely due to the energetics of the problem. The authors note that prior agreement between estimates of the 5% strain required for 5–7–7–5 defect stability and the experimentally observed breaking strain is most likely fortuitous, and note that, for some tubes, the breaking strain exceeds 5%. A more likely scenario describing the mechanical failure of actual SWNTs and MWNTs is the nucleation of yield or failure at frozen-in defects resulting from the growth process. As the field of nanomechanics of nanotubes progresses, it will be critical to further address the roles of defects and defect generation with respect to the inelastic processes.

The validity of continuum elastic theory to treat NTs was specifically considered by Govindjee and Sackman [100]. Their primary result rested on conventional assumptions made by a number of experimental and theoretical works concerning the calculation of the moment of inertia for a tube. Through a rigorous analysis of the error associated with incorrect geometrical assumptions regarding INT, it was shown that errors in E exceeding 200% were possible. The authors suggested a geometrical correction to avoid such errors. With the exception of the geometrical subtleties in correctly calculating inertial moments, the physical validity of linear (elastic) response to describe small deformations in NTs was not challenged. Harik also investigated the applicability of classical "bending beam mechanics" to NTs based on a length scale analysis [134]. Basically, NTs were separated into two classes. For small diameter/length ratios and

for NT radii large compared to the hexagonal atomic lattice spacing, it was appropriate to apply beam-like shell theory. For long NTs with radii on the order of the atomic lattice spacing, a solid beam approach was warranted. A scaling analysis of buckling was presented to determine the dependence of critical buckling strain with the NT aspect ratio as a function of the NT diameter.

Due to the challenges in the scanning force microscopy of high aspect-ratio structures, very little direct nanomomechanical mechanical imaging has been carried out on nanotubes. Very recently, Ajayan and Geer have undertaken UFM imaging of chemical-vapor-deposited MWNTs [84] to investigate the axial variation of MWNT rigidity associated with volume defects (axial variation of tube radius). Initial results of this work are shown in Figure 19. The MWNT has a nominal diameter of 63 nm, determined by AFM height measurements. The apparent 200 nm width results from tip convolution. The axial variation of the UFM response is axially symmetric over the central uniform region of the tube. The UFM contrast lines parallel to the tube axis are due to variations in the tip–tube contact area during the scan. Near the edges of the scan, however, there are significant variations of the UFM response associated with the radius variations of the volume defects. These variations, in contrast, are associated with modulation of the mechanical response due to the variations in tube radius. It is clear, as noted by Gao et al. [121], that such volume defects could significantly alter the mechanical response (effective Young's modulus) of the tube. Investigations into quantitative modulus extraction from such measurements are continuing.

4. NANOTUBE COMPOSITES

Clearly, nanotubes (carbon or otherwise) present a class of materials of extremely high modulus and, in some cases, extremely high yield strengths. Exploitation of these nanomechanical properties has been most aggressively sought in the field of nanocomposites to extend the performance of conventional carbon fiber composites. In addition, the unique electrical and thermal conduction properties of NTs provide other avenues for nanocomposite material design. From a purely mechanics point of view, the critical parameter for composite performance is the interfacial stress transfer ability (sustainable load transfer) between the matrix and the reinforcing component (typically fibrous) [135]. This elevates materials processing issues, including NT alignment, NT dispersion, and NT/matrix interfacial adhesion to a level equal to that of NT materials properties. Early studies noted poor adhesion between NTs and an epoxy matrix [84, 136] following cutting of a crude composite with a microtome. The NTs were essentially pulled from the composite during the process, and effectively aligned. While highlighting the strength of carbon NTs, this early observation underscored material challenges in NT-based nanocomposite engineering.

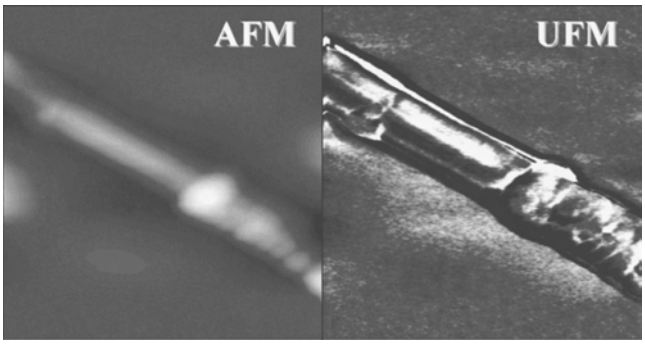

Figure 19. AFM (left) and UFM (right) image data of a carbon MWNT deposited via chemical vapor deposition (1 μm $\times$ 1 μm scan). The nominal diameter of the uniform section is 63 nm (image not corrected for tip convolution). The tube consists of a central uniform region and two defected regions near the edges of the scan. The defected regions are characterized by axial variations of the tube radius (so-called volume defects [121]). Significant modulus variations (apparent in the UFM scan) accompany these defects.

Wagner et al. investigated the nanotube–matrix stress transfer efficiency of composites consisting of arc-deposited MWNTs dispersed in a urethane/diacrylate oligomer prior to curing [137]. Their results indicated an increase in this stress transfer efficiency by over an order of magnitude compared to conventional carbon fiber-based composites. This increase is attributed to a possible "2 + 2" cycloaddition reaction occurring at the polymer/NT interface. Fragmentation of nanotubes within the composite during stress testing lends credence to the high interfacial adhesion in this system. Characterization of the load-transfer ability of carbon nanotubes was also investigated by Schadler and coworkers [138]. The optimization of load transfer requires a high interfacial shear modulus to effectively transfer the applied load to the fiber. Important factors in optimizing this modulus are micromechanical interlocking between fiber and matrix, and bonding (either covalent or van der Waals) between the two. For NTs (5% by weight) dispersed in a Shell Epon 828 epoxy resin, Schadler noted an increase in the tensile modulus E_T from 3.1 GPa for the epoxy alone to 3.78 GPa for the composite. The compression modulus exhibited a larger increase from $EC = 3.63$ to 4.5 GPa. The hysteretic nature of the stress–strain curves in the composite is attributed to either poor bonding between the matrix and the outer surface of the nanotube, or slipping within individual MWNTs, resulting in load transfer to only the outermost layer. Compared to the earlier work of Wagner et al. [137], the latter was presumed responsible.

For composites requiring high uniaxial strength, NT alignment and dispersion are critical parameters. Anisotropic mechanical stress was shown to align NTs in a thermoplastic polymer. Zhou and co-workers dispersed MWNTs produced via the arc-discharge method into a chloroform/polyhydroxyaminoether (PHAE) mixture [139]. Anisotropic stress was applied to the postdried composite mixture (50% NT by weight) at 373 K. After cooling and release, the NT orientation distribution was characterized via X-ray diffraction and transmission electron microscopy. The former revealed an NT mosaic of approximately $\pm 23^\circ$ roughly parallel to the composite stretching direction. Internal fractures in the composite displayed NT pull out similar to previous work, highlighting the need for optimization of NT/composite adhesion in the PHAE/NT system.

Composite films consisting of polyvinyl–alchohol (PVA) and MWNTs were studied by Shaffer and Windler [140].

Using short-fiber composite theory, they inferred an elastic modulus of the MWNTs of 150 MPa, approximately three orders of magnitude lower than direct measurements. This implies poor stress transfer properties of the matrix/NT interface, most likely driven by the polymer system considered. In contrast, Qian et al. [141] examined a polystyrene composite containing 1% by weight carbon MWNTs. The elastic stiffness and tensile strength of the NT composite increased 39 and 25%, respectively. Similar to other studies of NT composites, fracture in the NT/polystyrene system revealed NT pull out from the matrix. Increases in composite performance were also observed by Andrews et al. for 5% (by weight) SWNTs dispersed in pitch precursors (Ashland A500 petroleum pitch) [142]. Increases in the tensile strength from 500 MPa (pure pitch) to 850 MPa (pitch + SWNTs) were observed. The measured modulus values were 35 and 80 GPa without and with SWNTs, respectively.

As noted, stress transfer is the key figure of merit for the exploitation of nanotube mechanical properties in composites. Hence, the optimization of matrix/nanotube adhesion is critical. Liao and Li carried out theoretical investigations of a double-wall nanotube/polystyrene system using classical elasticity theory and molecular mechanics simulations to investigate this [135]. In their study, no covalent bonding was specifically considered. Rather, the simulations implied that electrostatic and van der Waals interactions between the polystyrene molecules and the nanotube surface dominated the adhesion energy. These authors also noted that mechanical deformation of the nanotube in the matrix will contribute to the adhesion. Their work pointed to mismatches in the coefficient of thermal expansion (CTE) as an important source of such deformation. Simulations of composite "cooling" from the melt implied that CTE mismatches were the primary cause for stress-induced nanotube deformations that resulted in corresponding adhesion improvements. A possible experimental route to optimize electrostatic pathways to increase NT/matrix adhesion was taken by Gong et al. [143]. That group utilized nonionic surfactants to improve the processing of NTs in an epoxy matrix with respect to dispersion and interfacial adhesion. An increase in the elastic modulus of 30% was seen; however, no comparative conclusions could be drawn regarding the modification of interfacial adhesion.

One aspect not already discussed is the effect of the multiwall nature of the tube during deformation in a nanocomposite matrix. Simplistic models assume a uniform "nonslip" bending of MWNTs in elastic composites. However, intershell slipping may significantly alter the mechanical response of the composite. This issue was considered in detail by Ru [144]. Using a multiple-shell model to study the compressed buckling of MWNTs, Ru incorporated a direct van der Waals coupling between the interior NT walls. Compared to an equivalent "single-wall" shell, the axial buckling strain for the multiple-shell model exhibited significant degradation (proportional to $1/N$, where N is the wall number). This degradation was attributed to interwall slips during bending. Although such an effect has not been demonstrated experimentally, it is an extremely important result in mapping the potential performance of MWNTs in composite applications.

Nanocomposites have also been exploited for other aspects of nanomechanical research. Li et al. used a nanocomposite to infer the elastic modulus of SWNT ropes [145]. Such ropes were dispersed in a polyvinyl chloride resin, and subjected to standard mechanical testing. Similar to other studies, nanotube pull out was a common feature of the fracture surface, and it was noted that the stress transfer from the SWNT bundles to the matrix resin was poor. From these experiments, average tensile strengths of the composites, the SWNT ropes, and the individual SWNTs were measured at 3.6, 7.5, and 11.5 GPa, respectively, on the basis of the rule of mixtures. The anomalously low value of the latter quantity is more indicative of the poor adhesion at the resin/NT interface rather than the true mechanical property of the SWNT itself.

5. NANOMECHANICS OF NANOPOROUS MATERIALS FOR DIELECTRIC APPLICATIONS

Some of the most interesting materials under investigation for nanotechnology applications are nanoporous materials. The field of nanoporous silicates is well established and far ranging. Leading applications for such materials have included nanotemplating and catalysis development. The latter has generated massive research efforts because of the exceptionally high surface-to-volume ratio of these materials due to the high pore densities achievable. For such applications, the mechanical response of these materials has been of secondary importance compared to chemical reactivity and pore morphology. Recent research in the integrated-circuit community has modified this priority. Nanoporous materials composed of silicate or polymeric materials have been engineered to possess extremely low dielectric constants [146]. For vapor-deposited silicon oxide ($\varepsilon \sim 4$), dielectric constants less than 1.8 can be achieved. This represents an incredible improvement with respect to RC dissipation in an IC interconnect line, especially for IC chips in which the interconnect line width is <130 nm. In that case, the time that it takes to establish a high-voltage pulse on a 'word" or "bit" line often exceeds the turn-on time for the associated transistor. Consequently, the capacitance of the interconnect can be the performance limiter of the entire chip [147].

Although the dielectric properties of nanoporous materials are attractive for such applications, the mechanical properties are inadequate, and represent an obstacle for integration into an IC chip. This has driven the need for nanoscale mechanical characterization to document the elastic modulus of these materials, not only for bulk values of E or E_r, but also for process-induced variations in mechanical properties. Early in the development of nanoporous silica for IC applications, Smith et al. reported moduli, as determined by isostatic compression, as low as 1 MPa for high pore density and low silicate density [148]. Compared to the 110 GPa modulus of the Cu lines to be embedded in such a dielectric matrix, the mechanical weakness of such nanomaterials presented a significant challenge. Such materials were clearly not suitable for the rigors of IC processing. As the development of nanoporous materials for this

application has matured, more typical values for porous silicate bulk Young's moduli are closer to 2 GPa, measured by nanoindentation [149–151]. From a measurement technique point of view, however, the use of nanoindentation must be considered carefully. The dramatic indentation deformation of nanoindentation for such soft materials limits the accuracy of the technique, especially for such thin films. It has been pointed out by Baklanov and co-workers that such errors may be as large as 500%, depending on the material studied [150, 152]. They reported Brilliouin light scattering and surface acoustic wave measurements of the mechanical properties of nanoporous organosilicate films as a function of porosity. The films were produced by spin coating and curing methylsilsesquioxane (MSSQ) polymers using a processing protocol designed to vary porosity from 10 to nearly 40%. The composition of the cured nanoporous films is dominated by the silicon oxide polymeric matrix, although organic moieties are still incorporated, depending on the length of cure and the connectivity of the pores. The Young's modulus measured from both Brillouin scattering and a surface acoustic wave technique were in reasonable agreement, and varied from approximately 1.8 GPa at 16% porosity to 0.8 GPa at 38% porosity. However, corresponding Young's modulus measurements carried out on the same materials using nanoindentaiton yield values that range from 3.5 to 2 GPa over the same porosity range. The dramatic error was attributed to incorrect analysis of the nanoindentation data when applied to such thin films ($\sim$0.6 μm). Specifically, these authors cite the inadequacy of current modulus extraction algorithms that were developed for stiff films on stiff substrates or stiff films on soft substrates to accurately extract moduli for thin, soft films on stiff substrates [150, 152].

More conventional mechanical measurements of porous dielectrics have also been carried out. Kloster et al. investigated the modulus, hardness, and interfacial adhesion of porous organosilicate glass thin films for potential use as low-k dielectric films for integration in IC chips as an insulator for metal interconnect lines [153]. Nanoindentation was used to acquire modulus and hardness data, and a conventional four-point bend configuration [154] was used to extract interfacial adhesion energy. The nanoindentation sampling depth was kept below 150 nm to try to avoid substrate stiffening, as noted by Baklonov. Nanoporosity of the films varied from 0 to 60%. Pore size was not reported, although it was expected to be less than 4 nm. The Young's modulus varied from 8.7 GPa for a nonporous organosilicate film (0.6 μm in thickness) to less than 0.5 GPa for a 60% porous film. Hardness values exhibited a far more precipitous decrease from 1.59 to 0.07 GPa over the same porosity range. Recall that nanoindentation hardness is characterized by the load at which the subsurface pressure at the plastic deformation below the indentor tip ceases to increase. At this point, indentation proceeds via plastic deformation over the entire deformation field [9]. Hardness values are extremely sensitive to the model used, but usually are assumed proportional to yield strength, and are measured accordingly. Consequently, for such thin soft films as those reported in [153], large uncertainties should be assumed.

Experimentally, porosity must be distinguished from pore distribution to accurately characterize the mechanical properties of nanoporous materials [155]. Recently, Aoi et al. have carried out a finite-element analysis of the mechanical properties of nanoporous materials, with emphasis on the prediction of nanomechanical properties, taking into account pore distribution [156]. For inorganic nanoporous materials (silicate based), their analysis predicted two specific regimes of linear decrease of modulus with increasing porosity (i.e., decreasing density) for random pore orientation. Specifically, for silicon oxide, a modulus of 70 GPa is expected for a maximum density of 2.5 g/cm^3 (0% porosity). For a pore size on the order of 2–4 nm, the modulus will decrease to less than 1 GPa for 50% porosity. In this regime, it is expected that little or no pore aggregation is occurring. Beyond 50% porosity, however, the decrease in slope virtually disappears as additional pore aggregates form. Hence, a significant change in the relation between porosity and modulus occur when pore distribution (i.e., aggregation) occurs. When viewed on a semi log–log plot of relative modulus as a function of relative density, their data were approximately linear, implying a power-law behavior. This behavior was summarized via the following law [156]:

$$E_{\text{por}} = E_{\text{solid}} \left\{ \frac{\rho_{\text{por}}}{\rho_{\text{solid}}} \right\}^{(3+(2\alpha/3))} \tag{23}$$

where E is the conventionally defined Young's modulus, ρ represents the density of the respective materials, and α is a pore aggregation factor. The qualitative interpretation of this law is straightforward. If nanopores are disordered, α characterizes how quickly pore aggregation will affect the modulus for a specific value of density. If pore aggregation occurs at a relatively high density, the effective modulus will be normalized downward very quickly. If, however, the nanopores are ordered such that pore aggregation is suppressed, then α vanishes, and the scaling of the modulus with density will be maintained for all film densities. This relationship between pore aggregation and density has been verified experimentally, yielding values for α around 3.

Preliminary surface nanomechanical imaging studies of porous dielectric films have been undertaken by Shekhawat

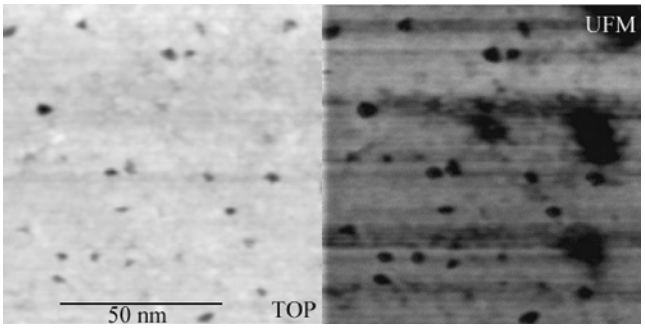

Figure 20. AFM (left) and UFM (right) image data from a nanoporous silicate film (100 nm $\times$ 100 nm scan area). Nanodepressions are evident in the AFM scan. Taking into account tip convolution effects, some of these nanodepressions are less than 2 nm in diameter. The extent of the nanodepressions is slightly increased in the UFM scan. Note the larger regions of depressed stiffness (low-contrast areas) evident in the UFM image. These features are totally absent in the AFM images, and are identified with reduced stiffness due to compositional nonuniformity or subsurface defect aggregation.

and co-workers [157]. Representative data are shown in Figure 20. The surface topographical features correspond to nanometer-sized depressions. Such features have not been previously reported, although variations in the processing of individual films with respect to cure and organic volatilization may be responsible. The UFM image corresponding to this topography is intriguing. The nanodepressions possess a reduced elastic response in the immediate vicinity. Also, a large area of reduced mechanical compliance is observed. There is no corresponding feature in the topography. This "soft area" has been tentatively identified as a region of high subsurface defect density. In an attempt to use ion bombardment to "harden" nanoporous silica films, Bakhru and co-workers investigated the effects of a 50 keV Ar ion flux on the mechanical properties of 1.0 μm thick Xerogel® films [158]. An ion dose of 10^{16} Ar ions/cm^2 was delivered to the film. Preliminary nanoindentation data suggest a hardening of the films by 30%. However, significant sample-to-sample variability was noted. To clarify the potential effects of the film nanostructure on the modification of the Xerogel nanomechanical properties, AFM and UFM imaging were undertaken. These data are shown in Figure 21. Topography measurements reveal a significant increase in surface roughness following Ar ion exposure from 0.3 nm (rms) to 3.4 nm (rms). More interestingly, however, is the effect of Ar ion bombardment on individual Xerogel grains. Comparison of the UFM images before and after ion implantation shows a dramatic increase in local compliance within certain domains and slight decreases in others. The localized modification of the Xerogel domain mechanical response may result from ion-induced bond breaking of the silicate polymer matrix, but at this time, there is no clear explanation why such effects would modify the mechanics of the local domain structure, as shown in the figure. Clearly, the quantitative application of nanomechanical imaging in materials such as these will provide a greater insight into their nanoscale properties.

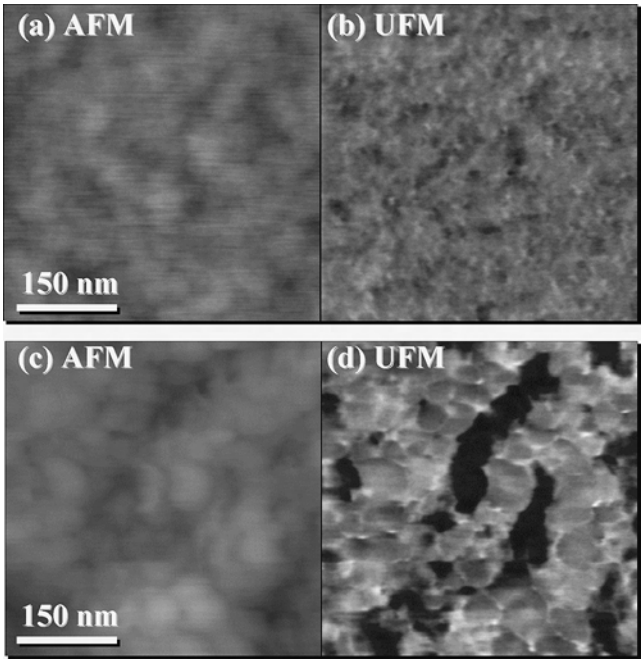

Figure 21. (a) AFM image of unimplanted Xerogel film (1 μm thickness, 0.3 nm rms roughness). (b) UFM image corresponding to the topography in (a). (c) AFM image of Xerogel film following implantation of 50 keV Ar ions (10^{16}/cm^2). The rms roughness has increased to 3.4 nm, and the domain structure has coarsened considerably. (d) UFM image of the same area reveals a significant modification of the mechanical compliance of the Xerogel domains. Note the dramatic softening of certain domains (low contrast) and stiffening of others (higher contrast).

6. CONCLUDING REMARKS

The ability to synthesize and characterize nanoscale materials and devices has opened broad avenues for nanoscience endeavor and nanotechnology development. As with the vast majority of research fields, more questions remain than have been answered concerning the fundamental degree of control of nanoscale properties and the extent to which this control can be exploited technologically. The field of nanomechanics of nanomaterials is no different. Classical approaches for describing nanomechanics have remained remarkably robust, but the limitations have already become apparent with respect to defining classical dimensions to quantum-mechanically defined objects, that is, the wall thickness of a nanotube or the true contact area of a nanotip interacting with a surface. As the scale of nanomechanical devices and imaging techniques approaches 1 nm and beyond, it might well be expected that entirely new formulations will be required.

GLOSSARY

Acoustic atomic force microscopy (AAFM) An implementation of SPM where the variation of the flexural resonance spectrum of an SPM cantilever as it is scanned over a sample surface is used to extract local mechanical properties from that surface.

Acoustic microscopy A nondestructive analytical technique whereby acoustic waves are transmitted or reflected from a material using acoustic lenses to elucidate mechanical properties, mass density, or acoustic properties of materials.

Atomic force microscopy (AFM) An implementation of SPM wherein the deflection of a cantilevered tip scanned over a sample surface is converted to a surface topography map, typically, with subnanometer out-of-plane resolution.

Bending modulus (κ) The second derivative of surface energy density with respect to curvature. For a tube, $\kappa = Ea/(1-\sigma^2)$, where σ is Poisson's ratio and a is the tube wall thickness.

Bulk modulus (B) Typically defined as the ratio of a hydrostatically applied pressure to the resulting fractional change in volume.

Cantilevered tip A pyramidal tip placed at the end of a triangular or rectangular (diving board) micromachined silicon cantilever. Used as surface probes in SPM. Typically, the radius of the tip is on the order of 10 nm. Spring constants of cantilevered tips range from 0.01 to 10 N/m.

Contact stiffness (S) The first derivative of a surface-restoring force with respect to out-of-plane surface displacement.

Continuum elastic theory Fundamental theory of the deformation of solids. Assumes that a system can be approximated as a completely continuous body, and that deformations due to external stresses are elastic (completely reversible).

Crystal defects Departures from a perfect, periodic structure in a crystal lattice. Typical defects include dislocations (extra or missing rows or planes of atoms), vacancies (missing atoms), interstitials (additional atoms between lattice sites), or disclinations (coordination number defects).

Density functional theory (DFT) An analytic or numerical modeling technique (often for an electronic structure) wherein a local electronic or probability function is variationally optimized to calculate the ground or excited states of a system.

Derjaguin, Muller, and Toporov theory (DMT theory) Theory of nanoscale deformation of a tip at an adhesive surface wherein surface adhesive forces are restricted to a fraction of the contact area.

Elasticity The quality of elastic response: linear dependence of restoring force on displacement.

Finite-element analysis (FEA) A numerical modeling technique for which a continuous system (solid or fluid) is represented by a 3-D mesh or matrix of finite-sized elements. The response of the entire system to external stresses, temperature changes, applied fields, and so on is determined by solving classical equations of motion (Newton's equation, Maxwell's equations, Navier–Stokes equation, etc.) at the interfaces of each element.

Force modulation microscopy (FMM) An implementation of SPM wherein the oscillation amplitude of a cantilevered tip in contact with a substrate is measured as the tip is scanned over a surface. For surfaces exhibiting a contact stiffness below the cantilever spring constant, such scans can reveal the spatial variation of surface mechanical properties.

Graphene Referring to a hexagonal atomic structure of carbon as in a single a–b plane of graphite.

Hertzian contact Model of a surface–surface contact for which only contact forces (short-range electrostatic forces) are considered. Long-range and adhesive forces are ignored.

Heterodyne force microscopy (HFM) An implementation of SPM wherein heterodyne coupling of sample and cantilever ultrasonic vibrations (via the nonlinear-force displacement relationship of a scanning probe tip at a surface) is used to probe the nanometer spatial variations of surface visoelastic properties.

Integrated circuits (ICs) Semiconducting devices and associated electrical interconnects integrated on a single substrate via multilayer, photolithography-based processing.

Johnson–Kendall–Roberts–Sperling theory (JKRS theory) Theory of nanoscale deformation of a tip at an adhesive surface assuming the validity of classical elastic theory.

Local density of states (LODS) In the context of the electronic properties of a material, the LDOS is the number of quantum mechanical states per unit volume that can be occupied by an electron.

Molecular dynamics (MD) Numerical modeling paradigm wherein an empirical or analytically derived potential is used to calculate atomic or molecular configurations based on the numerical solutions to the Newtonian or quantum mechanical equations of motion.

Mechanical resonance Dynamic condition wherein a mechanical system is driven at a natural vibration frequency.

Microelectrical mechanical systems (MEMS) Term typically applied to 2-D or 3-D microstructures fabricated using the techniques of integrated-circuit fabrication.

Nanocomposite A multicomponent composite material where the spatial size or modulation of at least one of the components is characterized by a nanometer-length scale.

Nanoindentation Mechanical characterization technique wherein material modulus, hardness, and fracture strength are measured by indentation with a pyramidal or tetrahedral tip. The indentation is typically on the order of microns.

Nanomaterials Engineered materials exhibiting unique properties resulting from the manipulation of the material structure or composition at the nanometer-length scale.

Nanomechanical imaging Direct imaging of mechanical properties (modulus, visoelasticity, etc.) with nanometer-scale resolution via near-field microscopy.

Nanomechanics The mechanics of nanometer-scale contacts and the deformation of nanoscale structures.

Nanorope Term typically applied to bundles of nanotubes in a hexagonal arrangement forming a rope-like braid.

Nanotribology The study of tribology (frictional interactions of surfaces) at the nanometer-length scale.

Nanotube A nanometer-scale tube formed by wrapping single or multiple atomic layers in a cylindrical geometry. The former is referred to as a single-wall nanotube (SWNT). The latter is referred to as a multiwall nanotube (MWNT). Diameters range typically from 2 to >100 nm. Typically formed by graphene sheets of carbon nanotubes. Can also be formed by a number of other inorganic compounds.

Organosilicates A term typically applied to solids or chemical compounds involving siloxane groups with organic ligands.

Piezoelectric The property of a material lacking inversion symmetry whereby application of physical stress results in a change in the polarization of the material. Conversely, application of an external voltage to a piezoelectric material will induce a spatial deformation.

Plasticity Nonelastic response of a material to an applied stress wherein a nonrecoverable (plastic) deformation is induced.

Poisson's ratio (σ) Ratio of the transverse compression to the longitudinal extension of an object subjected to a tensile stress.

Quantum dot (QD) Term typically referring to nanometer-scale semiconductor particle (synthesized chemically in nanopowder form or grown on an appropriate substrate) exploited for unique electrical or optoelectronic properties due to quantum-mechanical localization phenomena.

Reduced Young's modulus ($E_r \equiv E/(1-\sigma^2)$) Conventional Young's modulus normalized by Poisson's ratio.

Shear modulus (μ) Typically defined as the ratio of the applied shear stress to the fractional transverse displacement of an object.

Scanning local acceleration microscopy (SLAM) An implementation of SPM whereby the deflection of the cantilevered tip is proportional to the tip acceleration, and can be related to the mechanical properties of the substrate.

Scanning probe microscopy (SPM) Any number of techniques in which a local probe is rastered across a surface with subnanometer precision to characterize topographic or material properties. Examples include scanning tunneling microscopy (STM), in which local tunneling currents between a scanning tip and a substrate are used to map the local density of electronic states, or atomic force microscopy (AFM), where the local deflection of a cantilevered tip by contact or van der Waals forces is recorded as the tip is scanned over a surface to measure surface topography.

Tensile strength Typically defined as the longitudinal force or stress applied to a material for which nonreversible deformation results.

Tight-binding approximation (TB) An approximation for solving quantum-mechanical equations of motion for a material in which it is assumed that electrons are localized near the parent ion.

Ultrasonic force microscopy (UFM) An implementation of SPM wherein an out-of-plane ultrasonic vibration is applied to a sample on which a cantilevered tip (in contact) is scanned. For sufficient vibration amplitude, a tip-deflection signal proportional to the local sample modulus is obtained.

van der Waals forces Weak, long-range forces resulting from induced electric dipole fields. Typically varies inversely as the separation to the sixth power.

Viscoelasticity Dynamics of elastic deformation, including the temporal response of materials to an elastic deformation.

Xerogel Trade name referring to a nanoporous silicate material.

Young's modulus (E) Typically defined as the ratio of the applied longitudinal stress to the fractional I longitudinal deformation of an object.

Nanomembranes

Cees J. M. van Rijn, Wietze Nijdam

University of Twente, Enschede, The Netherlands

CONTENTS

1. MEMBRANE TECHNOLOGY

1.1. Introduction

Membranes play an essential role in nature as well as in our industrial society today. Biological membranes have an essential exchange function in the metabolism of all living species. By these exchange processes a single cell can be supplied with nutrients and the cell can excrete waste products through its outer cell membrane. Moreover, these exchange processes enable communications between different cells, by exchange of, for example, hormones, which made the development of complex life forms possible.

Considering that the first membrane experiments have already been carried out in the 18th century, using membranes (from Latin *membrana*, a thin sheet) of biological origin [1], industrial membrane separation with synthetic membranes has been strongly developed since the introduction of the asymmetric polymeric membrane [2] in the early 1960s. See Figure 1.

Most of the synthetic membranes today obtained with a phase inversion process have an inner spongelike structure which contributes to an additional fluid resistance and *a fortiori* a diminished operational product flux at a given transmembrane pressure. Also the retention of particles, proteins, and other coagulates is not only determined by the pores present in the skin layer but also by the sponge support structure itself. Moreover, in certain cases, like clarification of beverages, cleaning agents must be removed completely after cleaning to prevent contamination of the beverage. Various attempts have been made to downscale sieve-shaped filters that do not exhibit these problems, like track-etched membranes and anopore membranes (see Figs. 14 and 15 in Section 1.3). However, both membrane types lack the possibility of adjusting the pore size freely in conjunction with highest achievable porosity.

Using nano- and microtechniques originating from semiconductor technology it is possible to fabricate thin membranes with perfectly uniform pores [3]. The membrane, the microsieve, was made using flat substrates, thin-layer deposition techniques, photolithography, and high-resolution etching methods. Microsieves and nanosieves (with pore size <100 nm) may be used for many filtration applications, but they can also be used as a scaffold to study particles, microorganisms, and lipid bilayer that are retained or adhere to the surface of the micro/nanosieve. See Figure 2.

The screening of facilitated transport of a wide variety of molecules through natural and artificially constructed porins (e.g., ionchannels) in lipid cell membrane layers is an increasing object of interest. A prerequisite therefore is the construction of adequate micro- and nanobiotools obtained with novel nano- and microengineering techniques.

Current biotechnological separations (e.g., food, beverage, and pharmaceutical industry) and also membrane bioreactors are fast developing applications of artificial membranes. Also there are emerging applications, such as affinity membranes (e.g., protein purification), biosensors (e.g., glucose sensors), biohybrid organs (e.g., artificial livers), and artificial tissue structures.

Application of novel membrane structures also requires development of appropriate models for properties and processes applying nanotechnology. Properties related to design and analysis of separation processes in particular, such as adsorption, diffusion in external force fields, and other fluid parameters, play an important role here. For a good understanding of nanomembrane technology, good models for all underlying phenomena must be present.

1.2. Membrane Processes

In the chemical process industry one often encounters the problem of separating a mixture in its components. Using membranes one can in principle carry out the majority of these separation processes and may complement or form

Volume 7: Pages (47–82)

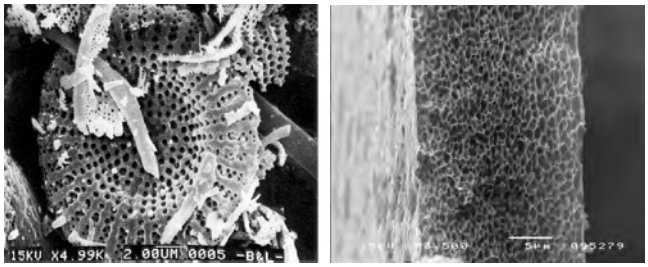

Figure 1. Scanning electron microscope (SEM) photographs. Left: a microporous skeleton of a diatomaceous earth fossil. Diatom cells are enclosed by cell walls made largely of silica (SiO_2). This glassy shell, or frustule, consists of two tightly fitting halves often resembling a flat, round, or elongated box. The minute perforations allow dissolved gases and nutrients to enter and exit. Right: cross-section of a microporous synthetic polyethersulfon membrane obtained with a phase inversion process. The membrane may have at least one outer skin layer with a mean pore size smaller than that of the inner part. Courtesy of Aquamarijn Research/Membrane Technology Group, University of Twente.

an alternative for chemical processes like distillation, extraction, fractionation, adsorption, etc. Advantages of membrane filtration are, among others, that there is a low energy consumption, the separation can be carried out continuously, up-scaling is relatively simple, and membrane technology can be used for almost any kind of separation.

The success of a membrane application or process is closely related to the intrinsic properties of the membrane. Interfacial interactions between membrane surface, surrounding environment, and solutes govern membrane performance to a great extent. These interactions have considerable impact on transport characteristics, selectivity, fouling propensity, and bio- and hemocompatibility of the membrane, especially in biotechnological and medical applications, where highly adsorptive solutes such as proteins are present and the adsorption and consecutive fouling of the membrane lead to considerable losses in flux, selectivity, and performance [5]. See Tables 1 and 2.

Right: Drawing of the lipid bilayer (cell membrane) of a human red blood cell, showing the single-pass transmembrane protein glycophorin. Reprinted with permission from [4], S. Chien, *Microvascular Res.* 44, 243 (1993). © 1993, Academic Press.

1.2.1. Filtration through Size Exclusion

Molecular Sieves In 1756 Cronstedt discovered a selection of natural porous minerals which, when heated, produced steam. Due to this phenomenon he called them zeolites from the Greek for boiling stone (zeo from zein—to boil; lithos—stone). In 1949, Milton working at Union Carbide produced the world's first manmade zeolites, the most important being Linde A and X. Linde A has gone on to become one the most widely used zeolites. Zeolites are highly crystalline alumino-silicate frameworks comprising $[SiO_4]^{4-}$ and $[AlO_4]^{5-}$ tetrahedral units. T atoms (Si,Al) are joined by oxygen bridges. Introduction of an overall negative surface charge requires counterions (e.g., Na^+, K^+ and Ca^{2+}).

Synthetically they are made by a crystallization process with use of a template (e.g., tetrapropyl ammonium) that builds a self-assembling skeleton together with the silicon, aluminum, and oxygen atoms. Afterward the template is removed (e.g., by heating, the calcination process) leaving small nanosized holes and tubes along the crystal planes of the zeolite structure. The framework structure may contain linked cages, cavities, or channels, which are of the right size to allow small molecules to enter (i.e., the limiting pore sizes are roughly between 3 and 10 Å in diameter). In all, over 130 different framework structures are now known.

Zeolites have the ability to act as catalysts for chemical reactions which take place within the internal cavities. An important class of reactions is that the class is catalyzed by hydrogen-exchanged zeolites, whose framework-bound protons give rise to very high acidity. This is exploited in many organic reactions, including crude oil cracking, isomerization, and fuel synthesis. Zeolites can also serve as oxidation or reduction catalysts, often after metals have been introduced into the framework. Examples are the use of titanium ZSM-5 in the production of caprolactam, and copper zeolites in NO_x decomposition. See Figure 3.

Top layers of zeolites have also been deposited on many microporous support materials (e.g., alumina) to study their gas selective properties or to separate branched monomers (e.g., alkenes) from unbranched ones.

Table 1. Some membrane separation processes arranged according to the mechanism of separation.

Separation mechanism	Membrane separation process
Size exclusion (filtration)	nanofiltration, ultrafiltration, microfiltration
Solubility/diffusivity	reverse osmosis, gas separation, pervaporation, liquid membranes
Charge	electrodialysis

Table 2. Filtration processes with their properties and application.

Filtration process	Pore size	Separation capability	Pressure (bar)	Application
Molecular sieving	0.3–1 nm	branched molecules versus unbranched molecules	0–3	gas separation with zeolite molecular sieves
Nanofiltration	1–10 nm	permeation of low molecular (200–20,000 daltons) substances	5–25	purification of sugar from acids and salts weight from dyes, water treatment
Ultrafiltration	5–100 nm	retention of viruses, bacteria, dissolved substances with molecular weight between 10,000 and 500,000 daltons	0.5–5	dairy industry, beverage industry, pharmaceutical industry, separation of water from crude oil, separation of fruit and vegetable extracts, waste water treatment
Microfiltration	50 nm–5 μm	retention of bacteria, Colloids, protozoa (*Cryptosporidium Legnonella*)	0.5–3 0.5–3	prefiltration in water treatment, dye industry, beverage clarification, removal of bacteria, etc.

Nanofiltration Nanofiltration is a relatively young description for filtration processes using membranes with a pore size ranging from 1 to 10 nm. This term has been introduced to indicate a specific domain of membrane technology in between ultrafiltration and reverse osmosis. One of the first researchers using the term "nanofiltration" was Eriksson in 1988 [6]. But already some years earlier a company called FilmTec started to use this term for their NF50 membrane which was supposed to be a very loose reverse osmosis membrane or a very tight ultrafiltration membrane [7]. See Figure 4.

But the history of nanofiltration dates back further in time. In 1970 Cadotte et al. already showed that reverse osmosis membranes, a nanofiltration membrane with slightly smaller pore size, could be made out of polyethyleneimine and toluenediisocyanate, forming a polyurea [8]. This membrane, the NS l00, was different in several aspects from the then-existing reverse osmosis membranes. It was the first reverse osmosis membrane not made by a phase inversion process using cellulose acetate or polyamide plus it showed a high salt retention.

All ceramic and some polymeric nanofiltration membrane are considered to be nanoporous, and most of the polymeric nanofiltration membranes are regarded as "dense," which means that no fixed pores are present in the membrane, but they contain a network structure that can be charged or uncharged.

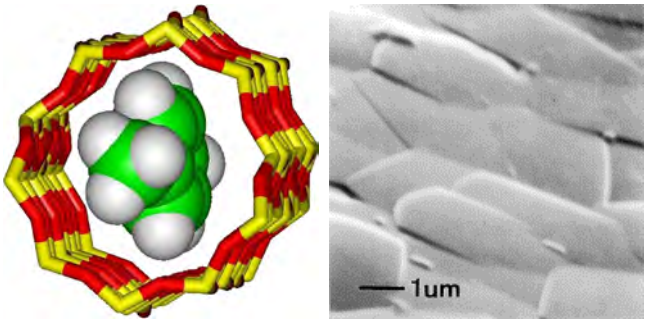

Figure 3. Left: Paraxylene molecule can diffuse freely in the open channels of silicalite. Right: top view of MFI-type ordered zeolite (molecular sieve) crystals having orthogonal nanopores of 0.55 nm on a silicon substrate. Courtesy of TOCK, TU Delft.

In several transport models for nanofiltration the pore size is used as a parameter to describe the morphology of the membrane [9, 10]. However, this concept of pores may be considered as hypothetical for several polymeric nanofiltration membranes. Bowen and Mukthar [11] mentioned that the determination of an effective pore size by transport models should not mean that those pores really exist in nanofiltration membranes. The hindrance to transport is the same for ions passing through the polymer network of a specific membrane as for ions passing through pores having these effective sizes.

In general nanofiltration membranes are used to separate relatively small organic compounds and (multivalent) ions from a solvent. However, in most of the applications with aqueous solutions, such as waste water, drinking water, and process water, the transport mechanisms are not yet fully understood. In the case of separation of organic solvents new developments of polymeric membranes are continuously showing up, where the solvent stability of these polymeric membranes is frequently studied and improved. These polymeric membranes may suffer from swelling when wrongly chosen.

Typical applications of these membranes are the separation of salts from dye solutions or the separation of acids from sugar solutions for the extraction of the purest products in highly concentrated form.

Ultrafiltration and Microfiltration Ultrafiltration membranes are porous membranes (in the range of 5 to 50 nm) that have a distinct, permanent porous network through

Figure 4. Schematic drawing of separation processes that occur in nanofiltration membranes.

which transport occurs [12, 13]. The separation of micro-organisms, bacteria, and solids from the liquid is mainly based on size and is pressure driven. The term ultrafiltration has been introduced to discriminate the process from microfiltration with a more narrow retention behavior. The membranes, in most cases polymeric, are either used in dead-end mode or in cross-flow mode. In dead-end mode all liquid is forced to pass the membrane, where in cross-flow mode, a tangential flow across the membrane is used to minimize a fouling layer, thereby keeping the filtration process ongoing [14]. See Figures 5 and 6.

For the retention of larger particles microporous membranes (with pore size from 50 nm to 5 μm) can be used. As an example, a feed containing macromolecules (e.g., proteins) is contacted with a membrane that contains small pores. The particles to be separated (the macromolecules) are withheld from flowing through the pores; the solution itself can flow through the pores. The reason that the particles cannot freely enter the pores is their geometric size, although interaction with the pore may also be of importance. In this case the properties of the membrane are also dependent on the structure of the membrane, together with the intrinsic properties of the membrane material. Separation of larger particles (e.g., micro-organisms) usually proceeds according to the same mechanism.

1.2.2. Separation by Solution–Diffusion Process

To achieve separation on a molecular scale a relatively dense membrane is required. In this membrane the separation of components takes place based on differences in diffusivity and differences in solubility. At the feed side, the components are being dissolved in the membrane and transported by diffusion through the membrane with a driving force acting inside the membrane. At the permeate side, the components leave the membrane. Separation results from differences in the solubility of the components into the membrane material and differences in velocities of diffusion through the membrane. The driving force is solely caused by properties of the membrane material, like affinity, and not of porosity (the geometry) of the membrane. Because the transport is a result of the solubility and the diffusivity, the separation is being called the "solution–diffusion" mechanism.

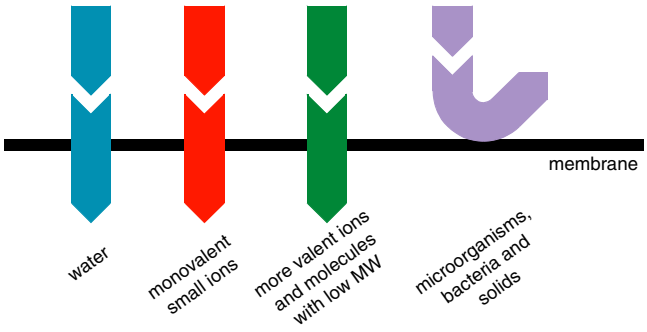

Figure 5. Schematic drawing of separation processes that occur in ultra- and microfiltration membranes.

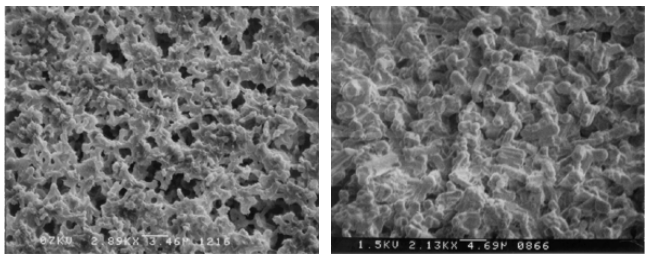

Figure 6. SEM micrographs of synthetic membrane filters. Left: Organic phase separated membrane filter. Right: Ceramic sintered filter. Courtesy of Aquamarijn Research.

Three main separation processes will be considered, reverse osmosis, gas separation, and pervaporation.

Reverse Osmosis In the reverse osmosis process, the processing liquid is being transported through the membrane under high pressure [15]. The membrane retains most of the ions in the liquid and larger solids and the process is often used to produce high quality water. Polymeric reverse osmosis membranes have no macroscopic pore structure but consist of a polymer network in which solutes can be dissolved. Like the membranes used for dialysis purposes, the membrane for reverse osmosis usually consists of a material that swells due to the processing liquid (e.g., water). This solvent-swollen network may be considered as a porous system comparable to dialysis membranes, although the structure of the latter is more loose than that of reverse osmosis membranes. It is difficult to distinguish single pores, as these are not fixed in place or in time due to the flexibility of the polymer chains

The distinction between dense and porous membranes is not very discrete. The membrane structure during the separation process then consists for a considerable part of volume that is filled with the feed. Membranes for dialysis purposes can easily consist for 50% of its volume of water. This volume may be called the pore volume, although the membrane matrix does not contain any distinct pores.

Gas Separation Gas separation (for example, separation of acid gases from natural gas or hydrogen in production processes) with polymeric membranes has become a widely known process for the last three decades. However, already over more than 150 years ago it was known that rubber balloons filled with gas lost their gas due to diffusion through the balloon wall [16, 17]. The real novel concept for gas separation using membranes was introduced by Monsanto [18]. Their membranes were able to recover hydrogen gas from the ammonia production.

For gas separation membranes it is difficult to achieve a good selectivity. The separation is being performed under harsh conditions and the membrane stability suffers under the presence of the process gas [19, 20]. For instance, CO_2 is a plasticizer (softener) for the polymer material, thereby weakening the membrane structure and thus decreasing the selectivity [21].

The preferred membrane for gas separation consists of a thin (<1 μm) top layer, supported by a rigid support with negligible transport resistance [22]. The thin top layer, the permselective layer, determines the overall gas flux. See Figure 7.

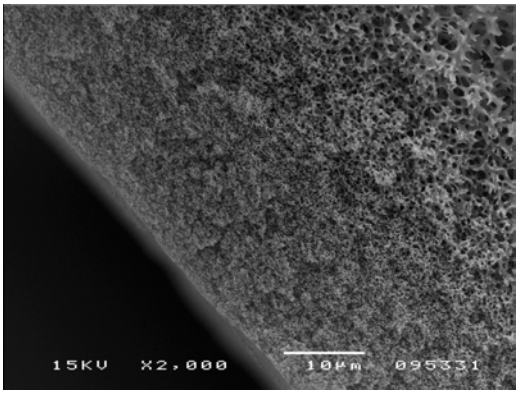

Figure 7. SEM cross-section of an asymmetric polymeric gas separation membrane with a gas selective dense skinlayer. Courtesy of Aquamarijn Research/Membrane Technology Group, University of Twente.

Membranes can be classified on the basis of their morphology or the separation process [18]. Current gas separation membranes are thin dense films, integrally skinned asymmetric membranes, or composites mainly prepared from glassy polymers [7]. Asymmetric membranes have a dense top layer and a porous substructure and are formed by a phase inversion process [19]. Composites have a dense top layer and a porous substructure. The top layer is created in a separate step for example by coating. In both cases, the permselective top layer should be as thin as possible to achieve a high flux. The substructure should have good mechanical strength with negligible gas transport resistance. Thin polymeric films by themselves are too weak to withstand the high differential gas pressures required in gas separation operations. Membranes with a support layer are therefore the most applied ones. The advantage of a composite membrane is that the top layer and the support can be optimized separately.

Pervaporation Pervaporation is a membrane separation process that can be used for the separation of liquid–liquid mixtures with an azeotropic composition or mixtures of components with a relatively small difference in volatility (dehydration of ethanol, acetic acid; removal of ethanol from a fermentation product). The transport occurs according to the solution–diffusion model through the nonporous membrane [23]. The diffusion through the membrane is in general enhanced by a lower partial pressure on the permeate side of the membrane (vacuum or a pure inert gas). Because the process uses low energy it is an advantageous alternative for conventional techniques like distillation.

The mixture flows through modules, where it passes along the membranes. The component to be removed is vaporized through the membranes and collected at very low pressure in a vacuum vessel. It is then condensed and purged out. A vacuum pump extracts the noncondensables and maintains the required vacuum. This vaporization cools down the processed mixture, which must be reheated to maintain the highest flux through membranes. Main applications are wine and beer dealcoholization, removal of organic solvents from aqueous streams, aroma recovery and concentration, and waste water purification.

1.2.3. Separation by Charge

In charge separation processes (membrane electrodialysis4), molecules in a liquid stream are being split in a positively charged and in a negatively charged ion. Using a combination of an anionic and a cationic membrane, water can be split in H^+ ions and OH^- ions. Combining this with liquids containing salts, direct acids and alkaline solutions can be made. In industrial applications this gives the opportunity for direct control of the pH of a process stream (juice industry and fermentation reactors) [24–26].

The anion exchange membranes carry fixed positive charges; the cation exchange membranes carry fixed negative charges. The presence of mobile counterions compensates these electrical charges: they carry a charge opposite that of the fixed charge, whereas the counterions are transported in the applied electric field.

A special type of ion exchange membrane is the bipolar membrane. It contains both the anionic membrane and the cationic membrane, but one of the membranes is permeable only for anions and the other only for cations. So there is no transport through the membrane possible. At the surface where the two types of membranes meet, water is split into OH^- and H^+ and these ions are transported out of the membrane. By this process no gases are being formed. Electrodialysis with bipolar membranes can be used to replace electrolysis of water, but with a wider variety of applications. Of course care should be taken that the two streams are separated from each other to prevent recombination into water [5, 27, 28]. See Figure 8.

The replacement of electrolysis by membrane electrodialysis seemed to be very promising two decades ago, but it was found that it is difficult to meet the specifications on a large scale. The available membranes did not have the ideal membrane requirements like a very high selectivity (the bipolar membrane layers are also permeable to salt co-ions), very high membrane permeability (yet the membrane layers add extra membrane resistance), and good long term stability

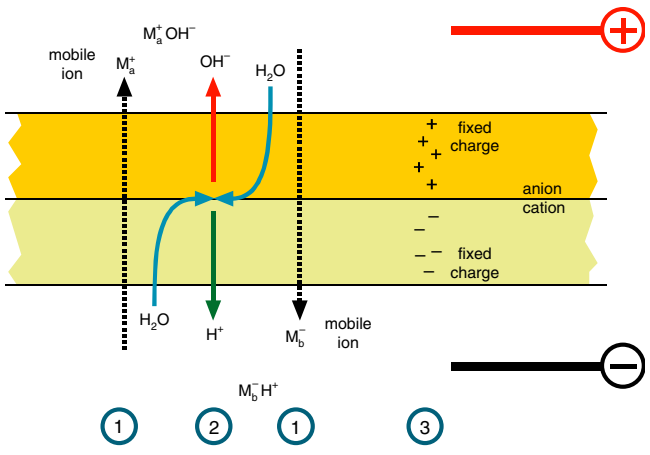

Figure 8. Processes that occur in and around an ion exchange membrane. In an externally applied electrical field (3) water is split in the membrane and the water ions are being transported (2) out of the membrane. If the membrane is permeable for ions (1), positively charged ions will move through the membrane toward the OH^- ions. Negatively charged ions will move toward the H^+ ions.

(the membranes are being attacked by a high concentration of alkaline, being produced in electrodialysis).

1.3. Membrane Structures

The structure of a membrane is vital for the performance of the membrane. The membranes are either symmetrical, where the properties of the membrane do not change through the cross-section of the membrane or they are asymmetrical (also known as composite). In the latter case the membrane is composed of a thin selective layer and a strong support layer. With some techniques it is possible to create both membrane and support layers in one single preparation step.

Asymmetric membranes are advantageous here compared to symmetric membranes because the flux determining top layer is thin, while the sublayer is responsible for the mechanical strength. A schematic representation of symmetric and asymmetric membranes is given in Figure 9.

Asymmetric membranes offer great possibilities in optimizing the membrane separation properties by varying the preparation parameters of especially the thin top layer. Also the ongoing development of polymers throughout the decades, like polysulfone (1965), polyether-ether-ketone (1980), and polyetherimide (1982), offers product engineers more and more possibilities for new membrane types.

1.3.1. Ceramic Membranes

Most ceramic membranes have an asymmetrical membrane structure with either a dense or a porous skin layer. The rough porous support is made of sintered ceramic particles [alumina (Al_2O_3), titania (TiO_2), and zirconia (ZrO_2)] that are gradually (in three to five steps) decreased in size before the top layer is applied. Typically the final layer of the support has a pore size between 1 and 5 μm. The preferred shape of ceramic membranes is a rod, because flat discs have shown to be too brittle.

Building the ceramic rod starts with making the support by injection molding the inner core with largest particle size. As long as the rod is not yet sintered (i.e., green phase), the paste of ceramic materials can be shaped freely. The rod is prebaked (fired) and subsequently a finer particle coating is applied by dip coating. This process of dip coating and firing is repeated several times until the final support coating is applied.

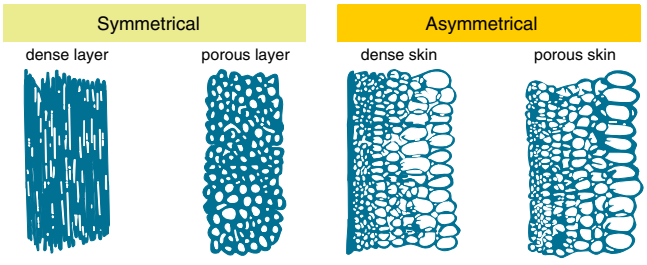

Figure 9. Schematic drawing of different membrane types. The membranes can be made as a fiber (circular) or as a flat sheet.

In the last step the skin layer is being applied, often again by several steps of dip coating, giving the membrane its separation properties. The whole stack is sintered for final fixation of all particles and ceramic substances. See Figure 10.

A typical α-alumina tube has a pore size of to 110–180 nm and is good for use as a microfiltration or an ultrafiltration membrane. For a finer membrane a γ-alumina layer can be applied on top of the α-alumina layer. By means of dip coating of a sol–gel, for example, from a Boehmite sol (γ-AlOOH) [29], a thin layer can be formed on top of the α-alumina. This layer is subsequently dried and heated up to 700 °C. By adding aluminum isopropoxide [Al(iso-$OHC_3H_7)_3$] in distilled water, a Boehmite sol can already be formed at 80 °C. Every dip coating and subsequent controlled drying step forms a layer with a thickness of around 0.5 μm [30]. During the drying the alumina solidifies, yielding a porous shell of alumina. The shell is then being hardened (calcined) by heating for several hours at high temperatures. The duration and temperature determine the final pore size, which for a γ-alumina layer is between 3 and 7 nm.

The grain size has also influence on the mechanical and physical properties of the ceramics: with decreased grain size, the membranes sized grains are stronger, are less brittle, and have higher temperature resistance [31, 32].

For certain applications an even finer pore size is wanted, for instance in a molecular sieve (separating gases, e.g., H_2/CH_4, H_2O/CH_4). In a chemical vapor deposition process [tetraethoxysilane and methyltriethoxysilane] an ultrathin silica can be applied that decreases the pore size even more. By carefully adjusting the gas flows through the rod and process temperatures, voids in the γ-alumina layer can be blocked, as the silica layer prefers to grow inside the voids. This is beneficial for the separation behavior of the silica layer, as the selectivity of the membrane increases [30]. The silica layer can also be applied in a multilayer sol–gel deposition [33, 34] instead of having an intermediate γ-alumina layer.

The process of sintering of particles can be applied to ceramics and polymers. Sintered polymeric membranes usually are macroporous membranes (pore size > 50 nm) but have after sintering the advantageous properties of ceramic membranes. See Figure 11.

Advantageous Properties of Ceramic Membranes

- Ceramics do not absorb water and do not swell. Swelling is a common problem with many materials, because when the membrane material absorbs water, the pore size increases, resulting in less retention.

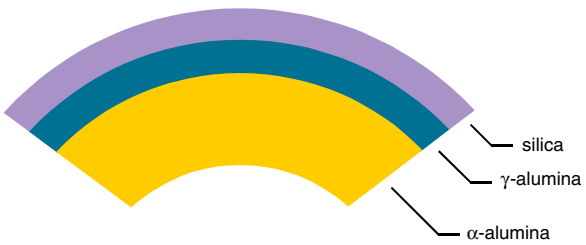

Figure 10. Schematic view of the different layers in a ceramic rod.

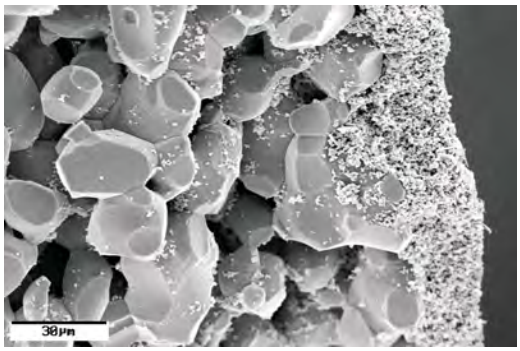

Figure 11. SEM photograph of a sintered ceramic membrane with a pore size of 800 nm. Courtesy of University of Karlsruhe.

- Ceramics are thermally stable. The membranes allow processes to be run at high temperatures. This makes the filtration for viscous fluids like oils easier, because their viscosity decreases.
- Ceramics are wear resistant (physically hard). This allows harsh cross-flow conditions beneficial for the removal of particles or cake layer, without damaging the membrane.
- Ceramics are chemically resistant. Most chemicals can be filtered or used during cleaning without attacking the membrane.

1.3.2. Polymeric Membranes

Due to the variety in properties of polymers and the processes to obtain these polymers, over the years many processes have been developed to obtain porous membranes.

Template Leaching Mixing two different components and molding this mixture into a certain heterogeneous structure, after which one of the components is removed by selective leaching, is a process used in the preparation of porous glass membranes.

Stretching of a Polymeric Film Dense polymeric films or foils can be stretched thereby generating voids in the film. By this method microfiltration membranes are formed. It is a technique that is commonly used for, for example, semipermeable membranes (for outdoor breathable clothing) with stretching a hydrophobic foil (for example PTFE). Best results are obtained with crystallizable polymers.

Phase Inversion A common technique to prepare the asymmetric membranes is phase inversion. While the process yields membranes in the whole spectrum from microfiltration to gas filtration, the membranes can be coated afterward to obtain other separation characteristics (by coating or interfacial polymerization).

Phase inversion (introduced by Cestings) is a very versatile technique. In one single process step various types of membranes can be made that have a porous support with or without a skin layer, where the skin layer can be dense or porous with a well defined pore size.

Phase separation is the process of changing a one-phase casting solution into at least two separate phases. The casting solution is uniform in chemical composition and in physical structure throughout the material. In all phase separation processes for membrane manufacturing, this casting solution is split into at least two phases: a solid material-rich phase that forms the porous/nonporous structure of the membrane and a material-poor phase that will be removed from the membrane. See Figure 12.

The phase separation is generally a thermodynamically driven process. After casting the solution onto a flat glass plate (or rotating cylinder in a continuous process) the formation of the pores starts by changing the composition of the solution, the temperature, or the pressure. The composition of the casting solution may be changed by bringing the casting solution in contact with a liquid not well miscible with the material. By changing the solution, the polymer solidifies and the pores are created.

Not only by immersion of the casting fluid in a nonsolvent can the solidification be started. It can also occur by evaporating a solvent from the casting solution or by reaction of components in the casting solution resulting in a nonsolvent agent.

Because for every polymeric material there is a combination of solvents/nonsolvents possible, the process can be used to produce a wide variety of membrane materials.

After solidification the polymers may be cross-linked or cured to improve functional properties (like strength and chemical resistance).

The types of phase separation processes are classified into six categories:

- Vapor-induced phase separation (VIPS), which is also known as “dry casting” or “air casting.” The evaporation of the solvent in the casting solution will result in a dense or porous product depending on the material and the used solvent/solute mixtures. The vapor may contain water or organic solvent molecules that may be absorbed by the casted film and will influence the porosity of the product.
- Liquid-induced phase separation, mostly known as “immersion casting” or “wet casting”: This process normally yields dense or porous products depending on the material and the solvent and nonsolvent mixtures used. This technique may be combined with VIPS for polymer solutions with, for example, two solvents with different boiling points [35, 36].
- Thermally-induced phase separation, frequently called “melt casting”: The material may solidify to a dense or porous product of a material-solvent-additive mixture

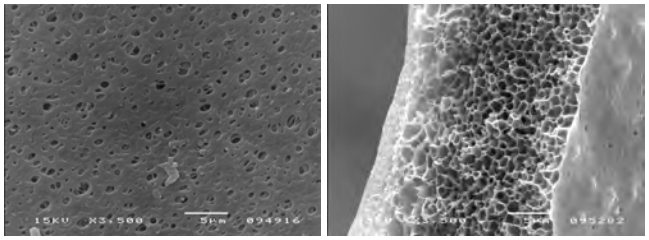

Figure 12. SEM photographs of liquid induced phase separated polymeric membranes. Left: top view skin layer. Right: cross-section showing a relatively dense skin layer on the retentate side and an open skin layer at the permeate side. Courtesy of Aquamarijn Research/Membrane Technology Group, University of Twente.

by varying the temperature of the material-solvent during the casting process.
- Colloidal-induced phase separation: A phase separated colloidal solution is used to perform structure arrestment on the microfabricated mold. For example, a polymerizable bicontinuous microemulsion can be applied onto the mold or a sol/gel mixture of a ceramic material. The pore morphology can be tuned by the addition of a co-solvent resulting generally into smaller pores.
- Pressure-induced phase separation, "pressure casting": The casting solution may contain for example a saturated dissolved gas. Reduction of the pressure (or increase of temperature) will induce growth of gas cells in the casting solution with a closed cell or open cell morphologies and a typical size of 0.01–1000 micrometers.
- Reaction-induced phase separation: A casting solution containing monomers starts to react and initiate phase separation due to for instance increase in molecular weight or production of a nonsolvent.

Coating of Membranes Existing (porous, polymeric) membranes are often coated to prepare composite membranes. On top of an asymmetric, porous membrane a thin layer of a polymeric solution is deposited resulting in a membrane with separation properties determined by the thin layer.

A second possibility is coating the complete membrane by a polymer that is not influencing the separation characteristics of the skin layer of the asymmetric membrane (a nonselective polymer). By this the voids in the asymmetric membrane can be plugged and the selectivity of the original membrane is increased.

Interfacial Polymerization A coating can also be applied by interfacial polymerization. In this technique the pores in the membrane are first filled with a liquid A. After immersing the membrane in a bath containing a reactant for liquid A, a polymer is being formed at the interface between liquid A and the bath. By this a new selective layer is being formed in the pores of the membrane.

1.3.3. Nanocomposite Membranes

There are a large number of nanofiltration and gas separation applications with membranes made from a polymeric or an inorganic material. The application of, for example, a polymeric material for a separation membrane depends of course upon both the throughput and the purity of the product transported through the membrane. This means that the permeability coefficient and the selectivity should be as large as possible. However, it has been found that simple structural modifications, which lead to an increase in product flux, usually cause a loss in permselectivity and vice versa [37–41]. This so-called "trade-off" relationship is well described in the literature [42, 43]. In recent years, the efforts and successes in synthesizing a variety of nanostructured hybrid materials have provided a new degree of freedom for the development of advanced materials with enhanced separation properties [44]. See Figure 13.

Nanocomposites represent a current trend in developing novel nanostructured materials. They can be defined as a combination of two or more phases containing different compositions or structures, where at least one of the phases is in the nanoscale regime. Kusakabe and his co-workers [45] already reported in 1996 that the permeability of CO_2 in a polyimide/SiO_2 hybrid nanocomposite membrane is 10 times larger than in the corresponding polyimide.

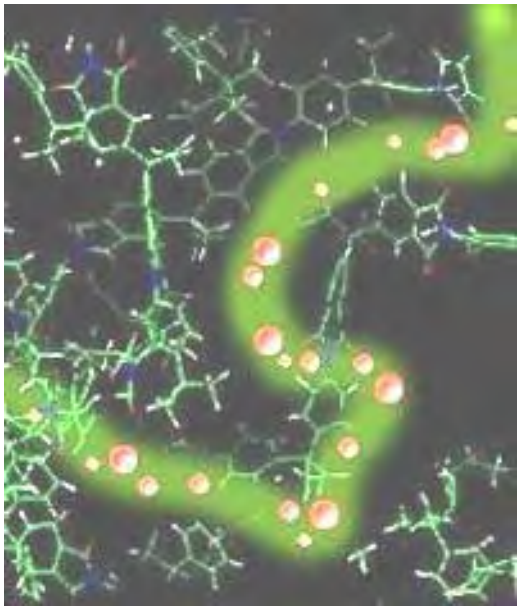

Figure 13. Gas molecules (red) move through the spaces between the polymer chains (in green). The larger the spaces, the faster and more selective the movement. The finding, which appeared in *Science*, describes a new type of nanoparticle-enhanced filter for separating compounds at the molecular level. Reprinted with permission from [46], A. Hill et al., *Science* 296, 519 (2002). © 2002, American Association for the Advancement of Science.

Another application is the use of zeolite nanocrystals (10–100 nm) to combine the advantages of polymers and zeolites while overcoming the shortcomings of both. Polymer–zeolite nanocomposite membranes can be developed for air separation as a promising alternative to the conventional energy-intensive cryogenic distillation. Utilization of polymer–zeolite nanocomposite membranes shows a route to achieve a modified polymer matrix offering high molecular sieving selectivities ($O_2/N_2 > 20$) while maintaining polymer processing conditions.

For any molecule to move across a membrane, it must go through a solution–diffusion process. The molecule first has to get into the membrane—the solution part of the process—then diffuse through it. Recently novel gas separation nanomembranes have been obtained with inorganic silica nanoparticles, with contradictory, but very useful, properties. It was shown that larger molecules dissolved much faster into the membrane, and once in, moved right through to the other side before the smaller molecules had completed the first step.

Silica nanoparticles embedded in a carbon base may help in the future to produce gases free of impurities. Because of the nanocomposite's ability to trap molecular-sized impurities it could be further used in processes such as biomolecule

purification, environmental remediation, sea water desalination, and petroleum chemicals and fuel production [46].

1.3.4. Other Membrane Structures

Track Etched One of the most successful attempts to manufacture the best membrane (a sieve) is the track-etched membraney. For the production of track-etched membranes, dense polymeric films (polycarbonate or polyester) are randomly exposed to a high-energy ion bombardment or particle radiation. This bombardment damages the polymeric chain in the dense film, leaving small "tracks." Subsequently the polymer can be etched specifically (in an acid or alkaline solution) at the ends of the damaged track. The pores that are being formed are cylindrical channels and very uniform in size. However, the membrane has a low porosity, due to the fact that the chance for an overlap between two pores increases with the porosity (the density of the radiation). The membranes are often used in laboratories for analysis. See Figure 14.

Anodized Alumina Membranes The formation of the pores of an anodized alumina membrane is a self-assembling process. By anodization of aluminum in an acidic solution, a highly ordered structure of pores in the Al_2O_3 matrix can be obtained. Due to lattice expansion by the oxidation of the aluminum, an anisotropic potential distribution, and heat development during anodization, the self-organization process forms the pores. The membranes are relatively thick, resulting in long pores with a pore size ranging from 20 to 200 nm. The pore size is very uniform (see also Fig. 15). However, the membranes are unsupported and need, depending on the application, a second support.

Microsieve Most of the previously described porous membranes have a spongelike structure, which makes it difficult to clean the inside of the membranes. Also the retention of particles, proteins, and other coagulates is not only determined by the porous top layer, but also by the sponge support structure. Moreover, in certain applications, like clarification of beverages, the cleaning agents must be removed completely after cleaning to prevent contamination of the beverage. However, it is nearly impossible to remove cleaning agents that are left behind in dead-end pores. Until recently the best sieve structures were the track-etched and

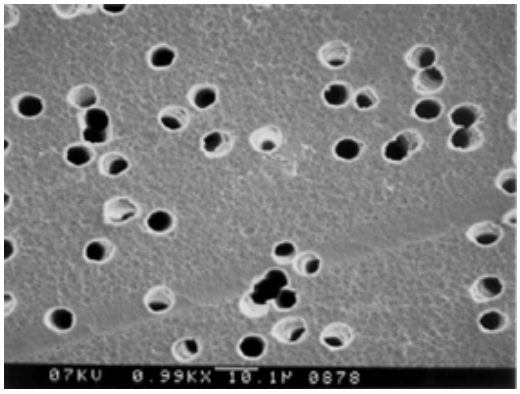

Figure 14. SEM micrograph of polymeric track etched membrane filter. Courtesy of Aquamarijn Research.

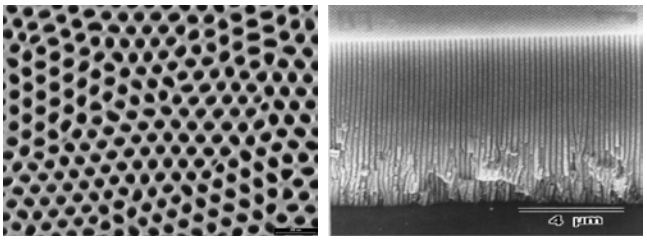

Figure 15. SEM photograph of an anopore membrane with a pore size of 50 nm. Left: top view. Right: side view. Note the vertical pore/channel structure. Reprinted with permission from [201], H. Asoh et al., *J. Electrochem. Soc.* 148, 152 (2001). © 2001, The Electrochemical Society.

the anopore membrane. However, both membrane types lack the possibility of adjusting the pore size freely in conjunction with the highest achievable porosity.

Using techniques used in semiconductor technology it is possible to fabricate thin membranes with perfectly uniform pores [3]. The membrane, the microsieve, was made using flat substrates, thin-layer deposition techniques, photolithography, and high-resolution etching methods.

2. NANO- AND MICROENGINEERED MEMBRANE TECHNOLOGY

Micro- and nanoengineering refers to the technology and practice of making three-dimensional structures and devices with dimensions on the order of micrometers, respectively nanometers. When looking at such small devices, a number of physical effects have different significance on the micrometer scale compared to macroscopic scales. This includes such topics as micromechanics, which deals with the moving parts of micro/nanoengineered devices, and micro/nanofluidics, which deals with the fluidic properties of such small devices.

The two constructional technologies of microengineering are microelectronics and micromachining. Microelectronics, producing electronic circuitry on silicon chips, is a very well developed technology. Micromachining is the name for the techniques used to shape the structures and moving parts of microengineered devices. In recent years micromachining and microengineering have become synonyms, also because of the advent of nanoengineering techniques (i.e., techniques capable of shaping structures below the 100 nm scale). See Figure 16.

The formation of micro- and nanopores in a thin but strong membrane structure and its potential applications is the key element in engineered membrane technology. Up to now relatively large pores ($\gg$1 micrometer) were made in thin foils or membranes with conventional microperforation methods (e.g., laser drilling, electroforming). With microengineering techniques originating from the semiconductor industry, it is relatively easy to downscale and form submicrometer pores (down to 500 nm) using conventional photolithographic methods, with, for example, contact masks and wafer steppers.

Many applications, especially filtration applications, prefer pores in a membrane with a low flow resistance (i.e., the length of the pore should be as small as possible). Therefore

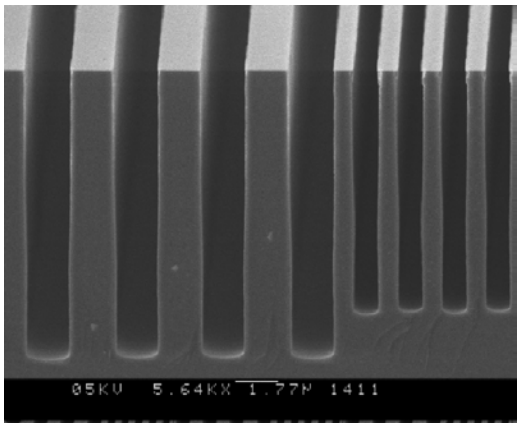

Figure 16. Micromachining: Deep trench etching in silicon. Reprinted with permission from [47], H. V. Jansen, Plasma Etching in Microtechnology, Thesis, 1996.

van Rijn and Elwenspoek [48] introduced the microsieve, a very thin membrane with a specially designed macroperforated support structure to strengthen the thin membrane. See Figures 17 and 18.

Using supported microsieve structures and submicrometer lithography techniques from the semiconductor industry it is relatively straightforward to produce microsieves with submicrometer features. The microengineered pores, which are well defined by photolithographic methods and anisotropic etching, allow, for example, accurate separation of particles by size. The membrane thickness is usually smaller than the pore size in order to keep the flow resistance small (one to three orders of magnitude smaller than other types of filtration membranes). See Figure 19.

Various lithographic process flows will now be discussed for economical production of microsieves with a high effective use of the membrane area. Also new nanopatterning techniques like laser interference lithography, shadow mask techniques (nanostencilling), and micro/nanocontact printing will be presented.

2.1. Micro- and Nanolithographic Patterning

2.1.1. Contact Mask Lithography

The contact mask technique makes use of a mask that is in direct contact with the photolacquer layer during illumination with a suitable UV light source. The sizes of the patterns in the mask are copied 1 to 1 to the size of the obtained patterns in the photolacquer layer. Practically contact masks can be used if the smallest feature sizes are larger than 0.5 micrometer, dependent on the wavelength of the used UV source.

Figure 20 shows how the contact mask technique is used to produce a microsieve with a specially designed support structure in a silicon ⟨100⟩ wafer. During the KOH etching process silicon is etched from the back side as well as from the front side through the pores of the silicon nitride membrane. See Figure 21.

A big disadvantage of using direct contact between the mask and the photolacquer layer is that the presence of small particles or contaminants (>1 micrometer!) between

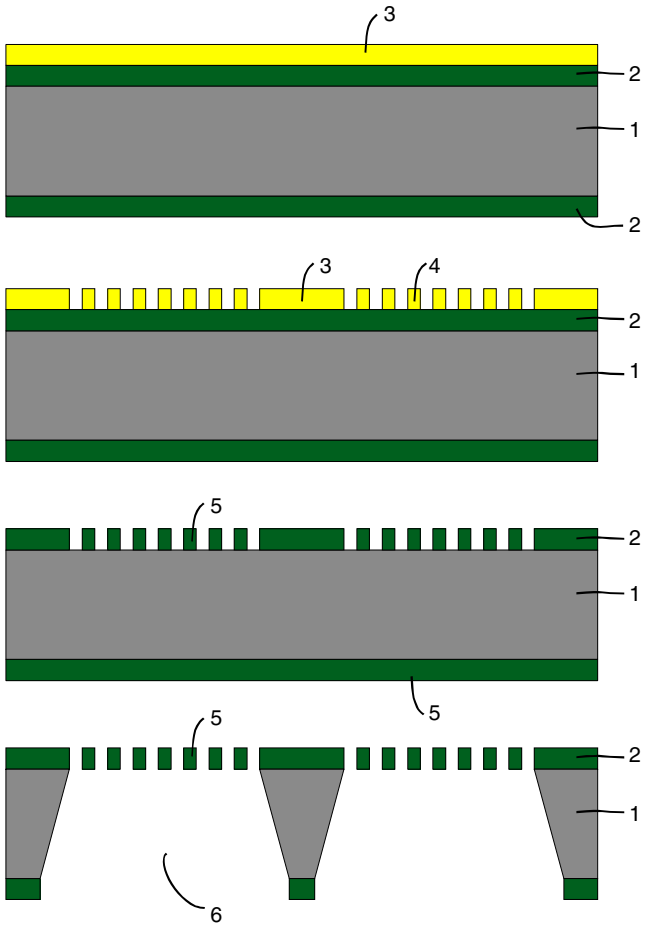

Figure 17. Basic process steps to produce a microsieve. Layer 2 is, for example, a low stress silicon nitride that is deposited on a 380 μm thick polished silicon wafer 1 by means of LPCVD (low-pressure chemical vapor deposition). On this 1 μm thick silicon nitride layer 2 a photosensitive lacquer layer 3 is formed by spin-coating. This layer is patterned with small pores 4 by exposing it to ultraviolet (UV) light through a photomask and subsequently developing it. The pattern in the photosensitive layers 3, 4 is transferred into the silicon nitride membrane 5 by means of RIE (reactive ion etching) with a CHF_3/O_2 plasma.

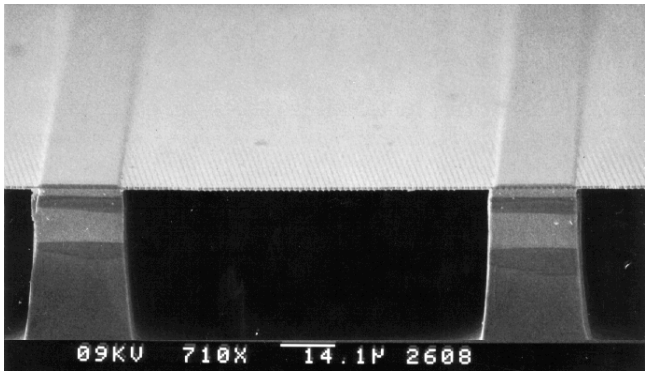

Figure 18. SEM micrograph of a microsieve with a membrane and a support structure. Courtesy of Aquamarijn Research.

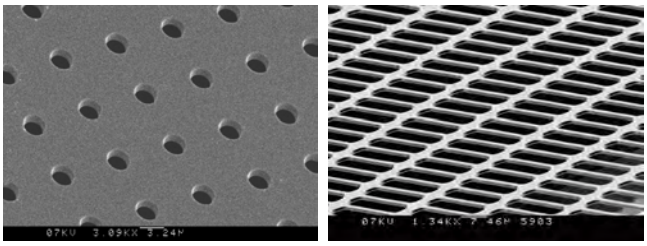

Figure 19. SEM micrograph of a microsieve with circular and slit-shaped pores. Courtesy of Aquamarijn Research.

the mask and the photolacquer layer may blur the pattern transfer. The amount of blurring is of course directly related to the ratio of the wavelength of the used light and the smallest feature size. Defect-free processing of wafer sized microsieves with small perforations is therefore virtually impossible even in high class clean room environments. A particle with a size of 10–20 micrometer between the

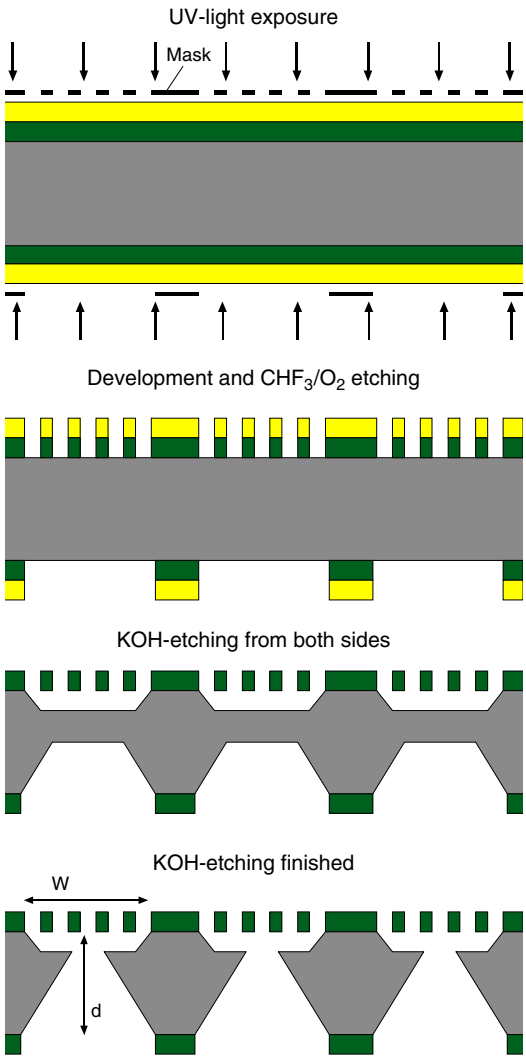

Figure 20. Fabrication process of a microsieve with contact mask lithography.

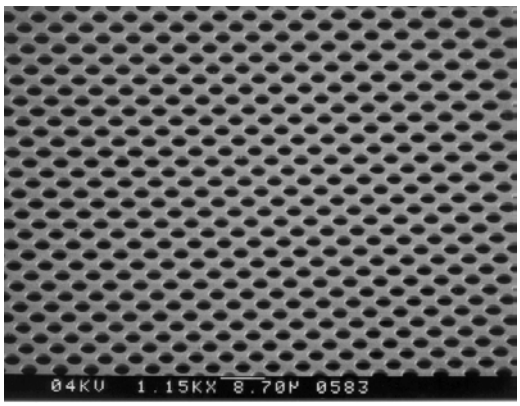

Figure 21. SEM micrograph of the surface of a microsieve where the silicon is etched and removed via the perforations in the membrane. Courtesy of Aquamarijn Research.

contact mask (e.g., patterned chromium layer on a glass plate with thickness 2 mm) and the lacquer layer is able to blur or destroy the pattern transfer over an wafer area larger than 1–100 mm^2. For wafer sized microsieves or for microsieves with a pore size smaller than 1 micrometer one often makes use of other more modern lithographic techniques, such as wafer steppers, to produce microsieves.

2.1.2. Wafer Stepper Lithography

In light projection lithography [49–51] an optical lens system is used to project the pattern of the mask onto the photolacquer layer (contact-free technique). The blurring of the pattern is now only restricted to the size of the particles present on the photolacquer layer. The projection system often reduces the pattern of the mask between 1 and 10 times with respect to the projected pattern in the lacquer layer. The typical lacquer area that can be projected in one step is about 1–2 cm^2. More steps (of the wafer stepper) are therefore needed to project the full wafer (3–12 inch diameter). A typical single step time is 1–2 seconds. This time cannot easily be reduced because of the mechanical repetition step time and the minimum exposure time per light shot. Although wafer steppers are very expensive (new generation >5 M euro) they are very economical in mass production applications. Also it is relatively more easy to get smaller pattern dimension (e.g., 0.12 micrometer linewidths) than contact mask applications due to the use of high resolution lenses with a large numerical aperture. See Figure 22.

Additional advantages are that the mask pattern is relatively large and can be made with relatively cheap laser writers.

Lithographic reduction has historically been accomplished by optimizing the parameters in the Rayleigh model for image resolution: In this model [53, 54], image resolution = k_1/NA, and depth of focus = $k_2\lambda/\mathrm{NA}^2$, where λ = exposure wavelength and NA = numerical aperture (k_1, k_2 are constants for a specific lithographic process). To pattern devices with decreasing feature sizes, photolacquer exposure wavelengths were reduced and numerical apertures were increased [55, 56]. See Table 3.

2.1.3. E-beam and Future Semiconductor Lithography

Electron beam lithography (EBL) is a specialized technique [57, 58] for creating the extremely fine patterns required by the modern electronics industry for integrated circuits. Derived from the early scanning electron microscopes, the technique in brief consists of scanning a beam of electrons across a surface covered with a resist film sensitive to those electrons, thus depositing energy in the desired pattern in the resist film. The process of forming the beam of electrons and scanning it across a surface is very similar to what happens inside the everyday television or cathode ray tube display, but EBL typically has three orders of magnitude better resolution (typical spot size for EBL is 18 nm). The main attributes of the technology are (1) it is capable of very high resolution, almost reaching the atomic level; (2) it is a flexible technique that can work with a variety of materials and an almost infinite number of patterns; (3) it is slow, being one or more orders of magnitude slower than optical lithography; and (4) it is expensive and complicated—electron beam lithography tools can cost many millions of dollars and require frequent service to stay properly maintained.

The first electron beam lithography machines, based on the SEM, were developed in the late 1960s. Shortly thereafter came the discovery [59] that the common polymer PMMA (polymethyl methacrylate) made an excellent electron beam resist. It is remarkable that even today, despite sweeping technological advances, extensive development of commercial EBL, and a myriad of positive and negative tone resists, much work continues to be done with PMMA resist on converted SEMs.

Currently, electron beam lithography is used principally in support of the integrated circuit industry, where it has two niche markets. The first is in mask making, typically the chrome-on-glass masks used by optical lithography tools. It is the preferred technique for masks because of its flexibility in providing rapid turnaround of a finished part described only by a computer-aided design file. The ability to meet stringent linewidth control and pattern placement specifications, on the order of 20 nm each, is a remarkable achievement. See Table 4.

Second, EBL is used for research into the scaling limits of integrated circuits and studies of quantum effects and other novel physics phenomena at very small dimensions. Here the resolution of EBL makes it the tool of choice. A typical application is the study of the Aharanov–Bohm effect [60, 61], where electrons travelling along two different paths about a micrometer in length can interfere constructively or destructively, depending on the strength of an applied magnetic field. Other applications include devices to study ballistic electron effects, quantization of electron energy levels in very small structures, and single electron transistors [62, 63].

To see these effects typically requires minimum feature sizes of 100 nm or less as well as operation at cryogenic temperatures.

Alternative Techniques It is prudent to consider possible alternatives before committing to EBL technology. For chrome-on-glass optical mask fabrication, there are optical mask writers available that are based either on optical reduction of rectangular shapes formed by framing blades

Table 3. Deep UV and extreme UV monochromatic laser light sources.

Wavelength (nm)	Laser type
248	KrF
193	ArF
157	F_2

Table 4. New predictions (year node potential solutions) for the ever decreasing linewidths from the 1999 ITRS Lithography Roadmap.

Year	Linewidth	Lithographic tool
1999	180 nm	KrF
2002	130 nm	KrF + RET, ArF
2005	100 nm	ArF + RET, F2, EPL, PXL, IPL
2008	70 nm	F2 + RET, EPL, EUV, IPL, CBDW
2011	50 nm	EUV, EPL, IPL, EBDW
2014	35 nm	EUV, IPL, EPL, EBDW
>2014		innovative technology

Note: KrF, ArF, and F2 are laser types. RET is resolution enhancement technology, including phase-shift-mask technology for enhanced resolution. EPL is electron projection lithography. EUV is extreme ultraviolet. IPL is ion projection lithography. PXL is proximity X-ray lithography. EBDW stands for electron-beam direct-write techniques.

or by multiple individually controlled round laser beams. Although at present EBL is technologically ahead of optical mask writers, this may not continue in the future. However, EBL will continue to provide a resolution advantage over the optical mask writers which may be important for advanced masks using phase shift or optical proximity correction. For 1:1 mask fabrication (i.e., X-ray), EBL will continue to be the most attractive option.

Optical lithography using lenses that reduce a mask image onto a target (much like an enlarger in photography) is the technique used almost exclusively for all semiconductor integrated circuit manufacturing. Currently, the minimum feature sizes that are printed in production are a few tenths of a micrometer. For volume production, optical lithography is much cheaper than EBL, primarily because of the high throughput of the optical tools. However, if just a few samples are being made, the mask cost (a few thousand dollars) becomes excessive, and the use of EBL is justified. Today optical tools can print 0.12 μm features in development laboratories, and 0.08 μm should be possible within a few years.

By using tricks, optical lithography can be extended to 0.1 μm or even smaller. Some possible tricks include overexposing/overdeveloping, phase shift and phase edge masks, and edge shadowing [64]. The problem with these tricks is that they may not be capable of exposing arbitrary patterns, although they may be useful for making isolated transistor gates or other simple sparse patterns. Another specialized optical technique can be used to fabricate gratings with periods as small as 0.2 μm by interfering two laser beams at the surface of the sample. Again, the pattern choice is very restricted, although imaginative use of blockout and trim masks may allow for the fabrication of simple devices [65].

X-ray proximity printing may be a useful lithographic technique for sub-0.25 μm features [66]. Again, it requires a mask made by EBL, and since the mask is 1:1 this can be a formidable challenge. Especially if the throughput required exceeds the limited capabilities of EBL, this may be an attractive option. The disadvantage is that X-ray lithography is currently an extremely expensive proposition and the availability of good masks is limited. It also requires either a custom built X-ray source and stepper or access to a synchrotron storage ring to do the exposures. With care, X-ray lithography can also be extended to the sub-0.1 μm regime [67].

Another technique to be discussed is ion beam lithography. The resolution, throughput, cost, and complexity of ion beam systems is on par with EBL. There are a couple of disadvantages, namely, limits on the thickness of resist that can be exposed and possible damage to the sample from ion bombardment. One advantage of ion beam lithography is the lack of a proximity effect, which causes problems with linewidth control in EBL. Another advantage is the possibility of *in-situ* doping if the proper ion species are available and *in-situ* material removal by ion beam assisted etching. The main reason that ion beam lithography is not currently widely practiced is simply that the tools have not reached the same advanced stage of development as those of EBL.

2.1.4. Laser Interference Lithography

In 1995 van Rijn [3] proposed for the first time the use of laser interference lithography for the production of micro- and nanoengineered membranes (micro- and nanosieves). Because of the relatively simple periodic structures (orifices and slits) that are needed for the production of nanosieves and the fact that laser interference is potentially a very nonexpensive patterning technique [68–72] that is also applicable on nonplanar surfaces (very large focus depth) this method will be discussed more in detail, also because there is little published material on this subject so far [73]. In 1996 in a collaboration of van Rijn [74] with G. J. Veldhuis [127], A. Driessen, P. Lambeck, and Professor C. Lodder of the University of Twente an existing laser apparatus was modified to obtain photolithographic patterns for the development of nanosieves and isolated magnetic domains [76].

Double Laser Interference Exposure Technique When two planar waves of coherent light interfere, a pattern of parallel fringes will appear. These fringes can be used for the exposure of a photosensitive layer. See Figure 23.

The depth of focus of this method is dependent on the coherence length of the light and can be on the order of meters or more, compared to (sub)micrometers for conventional optical lithography systems. As a result the demands on substrate flatness and wafer positioning are less critical.

After the first exposure the substrate is rotated over 90° and exposed to laser interference lines again. Now the gratings cross each other and after development a square array of lacquer pores (Fig. 24, left) remains. The exposure time of the photolacquer layer is a critical factor. In case the exposure time is chosen larger the middle pattern of Figure 24 will be obtained. Upon further increasing this time isolated photolacquer dots (right) remain.

Device Fabrication with Relatively Short Exposure Time Part of an incoming plane wave is reflected by the mirror and interferes with the undisturbed part of the wave to form an interference pattern (grating) on the substrate surface. To produce the plane wave, TE polarized light of an argon laser with a wavelength $\lambda_{uv} = 351.1$ nm is spatially filtered and expanded by focusing it onto a pinhole. See Figure 25.

If the light intensity of each beam is I_0, the radiance on the surface is given by

$$I = 4I_0 \sin^2\left(\frac{\pi x}{\Lambda_x}\right)$$

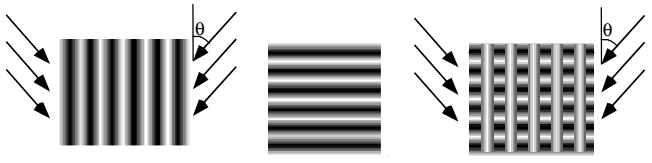

Figure 23. Left: first exposure of the substrate with the photolacquer layer. Middle: rotation of the substrate 90°. Right: second exposure of the substrate.

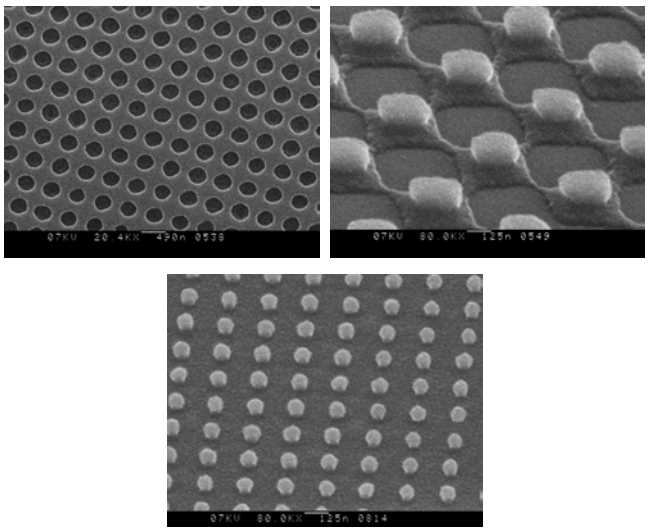

Figure 24. SEM micrograph of photolacquer layer that remains after a double exposure in the laser interference setup. Left: short exposure time, middle: intermediate exposure time. Left and middle: Courtesy of J. Micromech. Microeng. Right: long exposure time. Courtesy of Aquamarijn Research.

with Λ_x the fringe period in the x-direction planar to the photolacquer layer:

$$\Lambda_x = \frac{\lambda_{\mathrm{UV}}}{2 \sin \theta}$$

Here λ_{uv} is the wavelength of the laser light in the medium that surrounds the substrate (usually air) and θ is the half-angle between the two beams. The smallest period that can theoretically be obtained occurs for $\theta = 90°$ and is equal to $\lambda_{\mathrm{uv}}/2$.

The smallest period that can theoretically be obtained with our configuration is $\Lambda = \lambda_{\mathrm{uv}}/2 = 175$ nm. The corresponding minimum pore size (with a porosity >30%) will be approximately $175/2 = 88$ nm. At low porosity of course smaller pore sizesa can be made.

Since the beam is only split for a short path length near the substrate, this setup is very insensitive to mechanical instabilities and no feedback loop [77] is required to stabilize the interference pattern.

The thickness of the photosensitive layer needs to be chosen with care to avoid problems with the periodic pattern normal to the substrate surface due to interference between the incoming beam and the one reflected on the substrate surface. Its period is given by $\Lambda_\perp = \lambda_{v\varpi}/2n \cos\theta_n$ where n is the refractive index of the photoresist and $2\theta_n$ is the angle between the beams inside the resist. We used $\theta = 20°$ and with $n = 1.7$ at $\lambda_{v\varpi} = 351.1$ nm we find $\Lambda = 510$ nm and $\Lambda_\perp = 105$ nm. Therefore the thickness of the photoresist layer is chosen smaller than 105 nm.

The area that can be patterned using our mirror of 2.5×2.5 cm^2 equals approximately 9×9 mm^2 for $\Lambda = 510$ nm.

In Figure 26, the backside of a support (1), a single crystalline 3″ ⟨100⟩-silicon wafer with a thickness of 380 μm, is pre-etched to a thickness of 15 μm using optical lithography and conventional KOH etching (25%, 70 °C). On the front side of the pre-etched support (1) a layer (2) of amorphous low stress [78] silicon rich silicon nitride with thickness 0.1 μm is deposited by means of LPCVD by reaction of dichloresilane (SiH_2Cl_2) and ammonia (NH_3) at a temperature of 850 °C. Except at the area where the microsieve pattern will be formed an etch mask layer (3) of sputtered chromium with a thickness of 30 nm is deposited.

On top of this chromium layer (3) a layer (4) of positive resist was spun and patterned using interference lithography. A 100 nm thick layer (4) of positive photoresist (Shipley S1800 series) was spun, followed by a 5 min prebake at 90 °C to evaporate the solvent. The resist was exposed to the

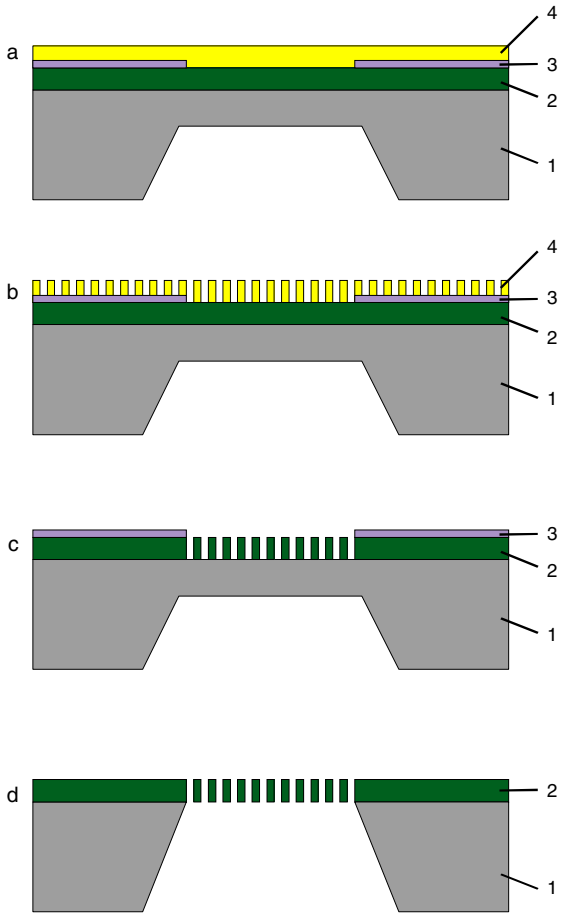

Figure 26. Schematic representation of the fabrication process of a microsieve. The numbers indicate the silicon support (1), the silicon nitride membrane (2), the chromium etch mask (3), and the photoresist layer (4).

interference line pattern for 45 s. The intensity of the incoming light in the exposed area was measured to be 2 mW/cm^2 for normal incidence ($\theta = 0°$). After rotating the substrate over 90° the exposure was repeated. The resist was developed for 15 s in a 1:7 mixture of Shipley–Microposit 351 developer and deionized water and dried by spinning. The exposure time was chosen such that only at the crossings of the grid lines (after first and second exposure) does the resist receive enough energy to be removed completely after development. Therefore a two-dimensional pattern of pores is created in the resist. A SEM picture of the exposed (2×45 s) and developed resist is given at the left in Figure 26. The diameter of the pores in the photoresist depends on the duration of exposure, herewith giving a possible tool to vary the pore size at a constant pore to pore distance. However, when the exposure time is chosen too long (2×75 s) the pores in the resist pattern may become too large and will overlap (Fig. 26, middle).

Next the interference pattern is transferred into the silicon nitride membrane layer (2) by means of CHF_3/O_2 reactive ion etching at 10 mTorr and 75 W for 2 minutes forming the required perforations. Subsequently the silicon underneath the membrane layer (2) is anisotropically etched with an SF_6O_2 plasma at 100 mTorr and 100 W for 10 minutes with an etch rate of 2 μm/min in order to form the macroscopic openings in the support (1). Figure 27 shows a SEM photograph of the resulting perforated membrane layer (2) showing a very regular pore pattern, the pore size being 260 nm with a pore to pore spacing of 510 nm. The pore size was very uniform over the whole 9×9 mm^2 area.

Microsieves with pore sizesa down to 65 nm have been fabricated using double-exposure laser interference lithography. The pores are obtained with an inverse process, as the direct process of pore formation in photolacquer has a narrow process latitude. An array of posts is transferred into an array of pores by evaporating chromium onto the posts, followed by a lift-off in acetone. The resulting patterned chromium layer is used as an etch mask for plasma etching of the silicon nitride membrane. See Figures 28 and 29.

2.1.5. Nanocontact Printing and Etching with Phase Separated Membranes

Aloys Senefelder used in 1796 a porous stone (in Greek, *lithos*) as a tool for printing by patterning the stone with ink attracting (hydrophobic) and ink repelling (hydrophilic) regions. Lithography for semiconductor mass fabrication and other microsystem and nanotechnology applications has nowadays regained interest in inexpensive microprinting methods as an alternative or complement on current high tech optical wafer stepper technology. A need exists therefore in the art for a convenient, inexpensive, and reproducible method of plating or etching a surface according to a predetermined pattern. The method would ideally find use on planar or nonplanar surfaces and would result in patterns having features in the micrometer and submicrometer domain. Additionally, the method would ideally provide for convenient reproduction of existing patterns. Additionally, the need exists for the fabrication of surfaces that can pattern portions (e.g., SAMs) amenable to attachment of biological species, such as antibodies, antigens, proteins, cells, etc., on the (sub)micrometer scale.

The study of self-assembled monolayers (SAMs) is an area of significant scientific research. Such monolayers are typically formed of molecules each having a functional group that selectively attaches to a particular surface, the remainder of each molecule interacting with neighboring molecules in the monolayer to form a relatively ordered array. Such SAMs have been formed on a variety of products including metals, silicon dioxide, and gallium arsenide using relief printing with a molded stamp made from polydimethylsiloxane (PDMS) [79]. The upper relief part of the stamp provided with a suitable SAM coating is then being contacted

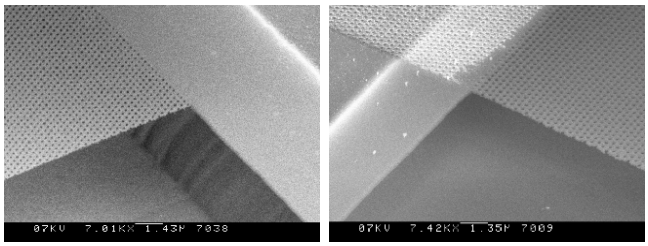

Figure 29. SEM micrograph of a high-porosity microsieve made with the lift-off method. Courtesy of Applied Optics Group, University of Twente.

with a product with a high affinity for the SAM species and a conformal SAM pattern is formed on the product (e.g., alkanethiol pattern on a gold coated product).PDMS is a rather elastic and relatively strong material very well suited for reproducible contacting purposes on nonplanar surfaces; however, it lacks a microporous microstructure for enabling functional fluid (ink) transport to the product domains or to enable other functional properties as will be described.

In Figure 30 three basically different printing techniques are represented.

Microporous stamps 21 (Fig. 30) with (alternating) regions with a dense skin layer and adjacent regions with a (porous) layer without the skin layer have easily been made with a phase separation process by locally removing the skin layer by, for example, oxygen plasma etching with the aid of a perforated mask shielding the remaining dense skin layer regions. The stamps are made with a phase separation process with the aid of a mold having patterned regions with sharp protrusions penetrating the microporous layers and patterned regions without such sharp protrusions where a dense skin layer is formed. In case the skin layer is not dense but nanoporous the skin layer can of course first be hermetically sealed without sealing the microporous part of the stamp with, for example, a hydrophilic coating (e.g., aliphatic and cyclic olefin-based polymers, or fluoropolymers or silicon based polymers). The stamps may also be subpatterned through use of photosensitive precursors in the casting solution of the product.

In one embodiment a (coplanar) stamp 11 with alternating nanoporous hydrophilic and dense hydrophilic surface regions is locally filled with an aqueous chromium etch solvent and brought into contact with a substrate having a chromium layer with a thickness of 20 nm. Whereas the dense regions 13 locally protect the chromium layer, in the nanoporous regions 12 an exchange between the chromium layer and the etch solvent may result in a locally dissolved and patterned chromium layer. Instead of chromium, many other materials or combinations of materials are applicable (e.g., aluminum, metal oxides and nitrides, metals, semiconductors, polymeric lacquer layers, etc.). The chromium layer may be replaced by a one phase lacquer layer and the solvent may be replaced by a second phase vulcanizing agent for the one phase lacquer layer. Instead of solvents also reactive gases can be used to etch patterns (e.g., SF_6 to etch and pattern silicon products). The microporous stamp can also be used to dab or adsorb locally a liquid or viscous layer that has been casted on a product. Dabbing may be improved by locally compressing the microporous regions during the contact of the stamp with the product. See Figure 31.

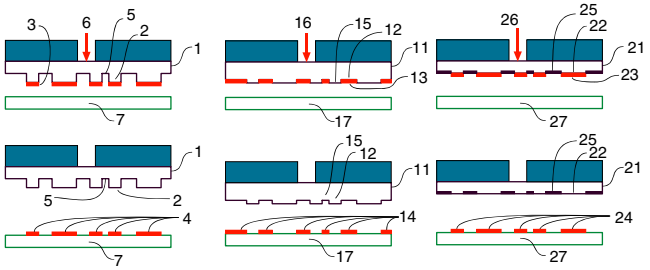

Figure 30. Left: the art of relief printing. The upper relief part 2 of the stamp 1 provided with a suitable ink coating 3 is contacted with a substrate 7 with a high affinity for the ink species and a conformal pattern 4 is formed on the substrate 7. The lower relief part 5 may be made ink repelling with a suitable coating (e.g., PVA, PVP) in order to avoid smearing of the pattern 4 of ink originating from sections 5. The upper relief part of the stamp 1 is provided with a macro- or nanoporous structure to contain ink or to transport ink from an injection point 6 for reproduction or continuous printing of the pattern 4 on the substrate 7. Middle: the art of gravure printing. The engraved part 12 of the stamp 11 provided with a suitable ink coating 13 is then contacted with a substrate 17 with a high affinity for the ink species and a conformal pattern 14 is formed on the substrate 17. The nonengraved part 15 may be made ink repelling with a suitable coating (e.g., PVA, PVP) in order to avoid smearing of the pattern 14 of ink from sections 15. The engraved part of the stamp 11 is provided with a macro- or nanoporous structure (cf. SEM picture below: engraved part is microporous, nonengraved part has a dense skin layer) to contain ink or to transport ink from an injection point 16 for reproduction or continous printing of the pattern 14 on the substrate 17. Right: the art of planographic printing (i.e., art lithography). The ink delivering part 22 and the nonink delivering part 25 of the stamp 21 are not determined by a difference in height but are made by the provision of suitable ink repelling and ink attracting coating s. The stamp 22 with a suitable ink coating 23 on part 22 is then contacted with a substrate 27 with a high affinity for the ink species and a conformal pattern 24 is formed on the substrate 27. Part 25 may be made ink repelling with a suitable coating (e.g., PVA, PVP) in order to avoid smearing of the pattern 24 of ink to sections 25. Part 22 is provided with a macro- or nanoporous structure to contain ink or to transport ink from an injection point 26 for reproduction or continuous printing of the pattern 24 on the substrate 27. Also in another embodiment part 25 may be microporous and filled with an ink repelling medium (e.g., water; Senefelder 1796).

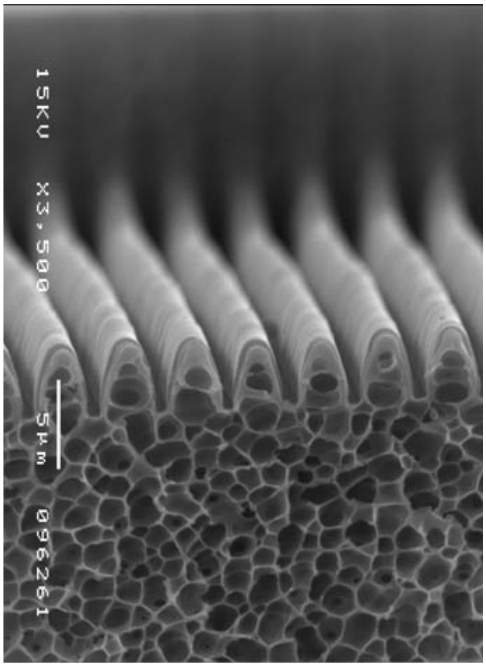

Figure 31. Left: Microporous stamp 1 produced with a phase separation process on a suitable mold. At left is a cross-section of a polyimide microporous microprinting tool with a smooth skin layer as obtained with a phase separation process. Courtesy of Aquamarijn Research/Membrane Technology Group, University of Twente.

In order to facilitate mask alignment of different mask stamping steps and to reduce thermal expansion differences between the stamps and the product, stamp regions parts are provided on a transparent (e.g., Pyrex, borosilicate glass) support material with the same thermal expansion coefficient as the substrate. Preferentially the microporous parts leading to the injection point have a high inner porosity to reduce flow resistance and a relatively small total dead volume in order to reduce the amount of adsorbed species.

In some cases it has proven to be useful to first print an ink pattern with the stamp on an intermediate dense or microporous transfer foil that transfers the ink pattern subsequently to the substrate, especially foils which have a well defined wetting contact angle with the selected ink medium.

The substrate may also first be provided with a suitable adsorbive nonsplattering or nanoporous (sacrificial) coating for more adsorption of the ink (e.g., obtained with a phase separation method). In another embodiment this nanoporous coating is made by deposition of an aluminum layer with a thickness of 200 nm on a silicon wafer and transforming this aluminum layer to a nanoporous (porosity 60–90%) honeycomb structure with thin vertical walls (pore spacings 10–50 nm) by anodic oxidation techniques well known in the art. Silicon and many other materials with different layer thicknesses can be transformed as well with anisotropic etching techniques for similar purpose. After the local deposition of the ink or an etch resistant lacquer in and/or on this layer, and preferentially dissolving the remaining uncovered layer, the substrate is ready for further processing steps.

Of course stamps may also be used for the formation of microstructures or microtransfer molding on planar and nonplanar surfaces of polymeric, ceramic, or metallic articles.

2.2. Fabrication of Micro/nanosieves with Silicon Wafers

Most of the processed silicon wafers today have a ⟨100⟩ orientation. The ⟨111⟩ planes etch approximately 200–1000 times slower than other oriented planes. This means that the ⟨111⟩ planes practically function as an etch stop. In order to obtain a silicon microsieve with a high degree of perforation, KOH etching must be carried out from the back side as well as through the pores on the front side. The etch rate on the front side decreases for smaller pores. For 1 μm pores it is roughly one order of magnitude smaller than the etch rate on the back side. If the wafer thickness is d, the width w of the openings on the back side must be approximately $d\sqrt{2}$ (depending on the etch rate underneath the membrane) to etch through the wafer, due to the 54.74° angle between the ⟨111⟩ planes and the wafer surface. For a 3-inch wafer with a 375 μm thickness this would result in membrane fields of approximately 530 μm width. Scaling up to 4-inch or 6-inch wafers with a thickness of 525 and 675 μm would give fields of 740 respectively 950 μm. As large fields are weaker than smaller fields, usually small additional support bars are etched underneath the membrane to reduce l (cf. Fig. 32).

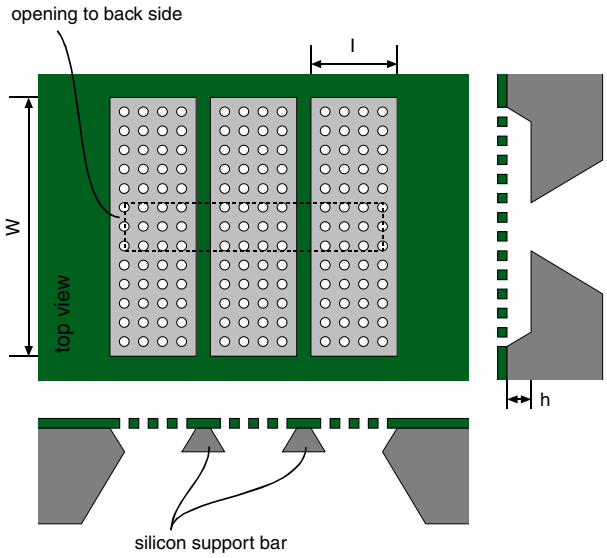

Figure 32. Top view of a membrane field that has been split up by small silicon support bars. The dashed line indicates the channel to the back side of the wafer.

2.2.1. Wet Etching through the Pores

However, for pore diameters below about 1 μm problems occur due to pressure buildup of the hydrogen gas that is created during KOH etching. Figure 32 shows that the silicon is etched through the pores. The gas can only escape through the pores in the hydrophilic membrane if its pressure exceeds the bubble-point pressure P_b, given by [80],

$$p_b = \frac{4\gamma \cos\theta}{d}$$

where γ is the surface tension of the KOH solution, θ is the liquid–solid contact angle, and d is the diameter of the pores. After the hydrogen gas has pushed the liquid out of a pore it will form a bubble on top of this pore. When the contact angle of the bubble with the pore wall becomes 0°, the gas pressure reaches a maximum value. For our KOH solution with an estimated value [81] for γ of 0.075 N/m, this reduces to

$$p_b = \frac{0.30}{d}$$

The bubble-point pressure increases for smaller pores. If the pore size is below a certain value, the gas can break the membrane. The maximum pressure $p_{\max}$ that an unperforated rectangular membrane can stand has been calculated by van Rijn et al. [115]:

$$p_{\max} = 0.69\frac{h\sigma_{\text{yield}}^{3/2}}{lE^{1/2}}$$

This equation shows that a decrease in size of the membrane field leads to a stronger membrane. A critical step in microsieve manufacturing is the release of the perforated membrane from the silicon support. Hydrogen gas that is created during KOH etching of the silicon builds up a pressure that might damage the membrane. Especially for submicrometer perforated membranes rupture is

likely to occur. Two different approaches were investigated to avoid the pressure problem. The first approach is based on plasma etching instead of KOH etching. Since no liquids are involved, the gaseous reaction products do not have to exceed a bubble-point pressure to escape through the pores. Using an SF_6/O_2 plasma and cryogenic substrate cooling, submicrometer perforated membranes were successfully released. A second approach is the formation of gas-escape channels to the back side of the wafer. This was achieved by using wafers with a ⟨110⟩ orientation, which allows for the possibility to etch channels with vertical sidewalls. With this second method also membranes with submicrometer pores were successfully released. The advantage over plasma etching is the possibility to process large batches. Furthermore, thanks to the vertical sidewalls thick (and thus strong) wafers can be used, while small (and thus strong) membrane fields are obtained. See Figure 33.

2.2.2. ⟨100⟩ Silicon Wafers

The base material of a microsieve is a ⟨100⟩ oriented silicon wafer. The wafer is coated with a silicon-rich nitride layer (intrinsic stress 10^8 Pa) by means of LPCVD. This layer is perforated using photolithography and reactive-ion etching with a CHF_3/O_2 plasma. Finally the silicon underneath the perforated layer is partially removed by anisotropic KOH etching to form a support.

This last step is crucial for the production of microsieves. If the silicon is etched from the back side with a KOH solution, a substantial part of the membrane will not be released due to the oblique ⟨111⟩ crystal planes in the ⟨100⟩ wafer. A much better result is obtained when etching takes place from the back side as well as through the pores on the front side. An additional advantage of this method is the possibility to etch extra support bars underneath the membrane (see Fig. 34).

The hydrogen bubbles that arise from KOH etching (25%, 70 °C) cause a pressure buildup underneath the membrane. This pressure may cause rupture of the membrane. An investigation was made of under what conditions KOH etching through the pores is still applicable and of the possibilities of dry etching to release the membrane.

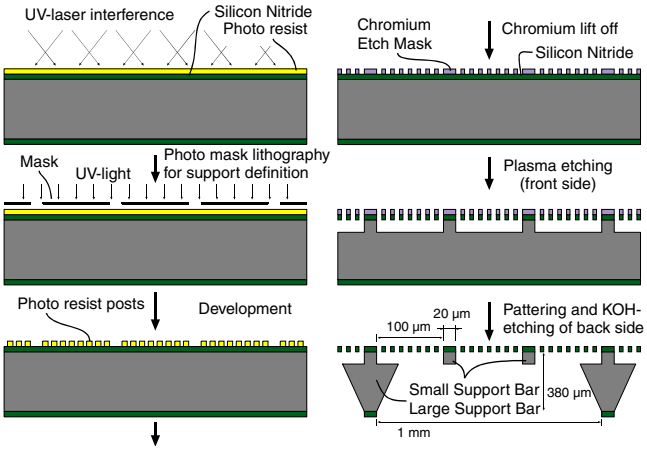

Figure 33. Fabrication process of a microsieve using laser interference lithography.

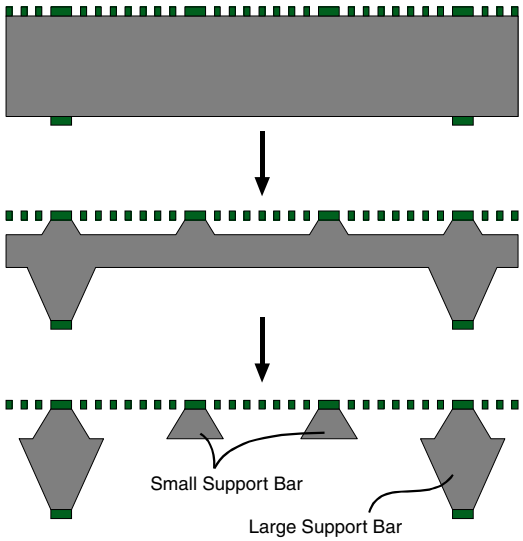

Figure 34. Releaseof the perforated membrane by anisotropic KOH etching from both sides of the wafer.

Dry Etching through the Pores In order to overcome the problems of wet etching, another possibility is releasing the membrane with the use of dry etching through the pores. The basic idea is given in Figure 35.

A patterned etch mask (photolacquer or chromium) is used to perforate the silicon nitride layer by CHF_3/O_2 etching. The mask is not removed from the nitride layer, as it will serve again as a mask for the silicon dry etching. The use of an isotropic etch gas is not satisfactory, because the small support bars would be etched away. Therefore an anisotropic-etch recipe is required, with just enough undercut to remove all the silicon between the pores. Plasma etching gives such an anisotropy that the ions can be accelerated

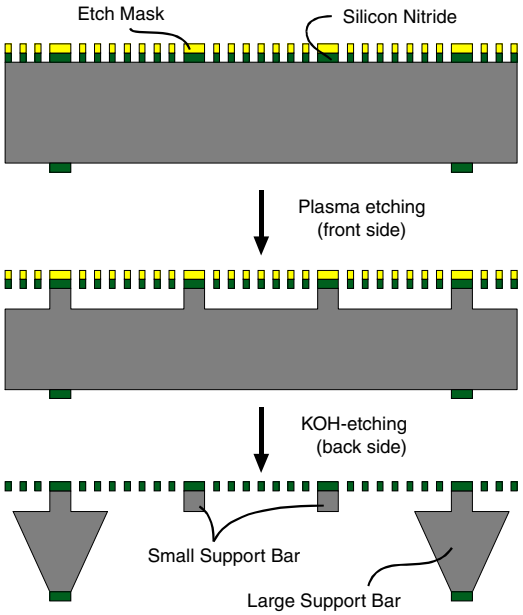

Figure 35. Process scheme for the release of perforated membranes by plasma etching.

into a vertical direction by an electric field. SF_6/O_2 mixtures are normally used, as SF_6 etches silicon isotropically while O_2 gives an anisotropic profile by passivating the silicon sidewalls of the trenches via LPCVD [83]. In order to obtain a higher etch selectivity between the silicon support and the silicon nitride membrane, the etch step was performed in an apparatus with cryogenic substrate cooling (Plasmalab 100, Oxford Plasma Technology [84–86]).

In contrast to KOH etching the depth of the channel underneath the membrane does not seem to be influenced by the pore size. The porosity will play a much more important role in the silicon etch rate, as it determines the amount of plasma that can enter the channel. See Figure 36.

2.2.3. ⟨110⟩ Silicon Wafers

The possibility of creating vertical channels in ⟨110⟩ silicon by KOH etching allows for the formation of small and therefore strong membrane fields. Buildup of a hydrogen pressure no longer occurs, as the gas can escape through the channels (see also Fig. 39). Furthermore the vertical anisotropy makes it possible to construct very thick and thus strong microsieves. For the new fabrication process a chromium etch mask is used instead of photolacquer. This chromium mask has an additional advantage of giving better defined pores, herewith improving the filter performance.

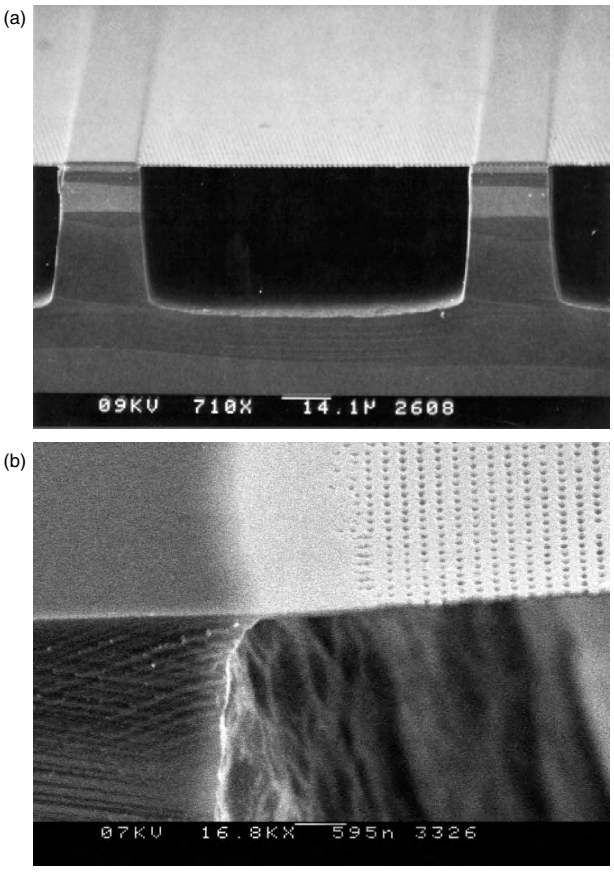

Figure 36. Shown are (a) 45 min, −130 °C, 400 nm pores and (b) 45 min, −130 °C, 70 nm pores, SF_6/O_2 etching through very small pores. Courtesy of Aquamarijn Research.

KOH etching on ⟨110⟩ wafers gives vertical walls but unfortunately two oblique ⟨111⟩ planes disturb the possibility to make small channels. However, as the shortest width of the fields determines the membrane strength, long but thin slit-shaped channels would still give strong membranes (see Fig. 37). For ⟨110⟩ wafers the walls of such channels have mutual angles of 70.53° and 109.47°. The walls are vertical, but in the sharpest corners (70.53°) the oblique planes arise with an angle of 35.26° relative to the horizontal ⟨110⟩ plane. A schematic view of such a channel is given in Figure 38. In this figure the silicon nitride on the front side has not been patterned yet, in order to etch the silicon only from the back side.

The channel length l has been chosen such that the two oblique planes intercept at the membrane layer on the top of the wafer before crossing each other. The front view in Figure 38 shows that the angle between the oblique planes and the wafer surface is 30° in the direction parallel to the long vertical walls. This means that in order to etch through the entire wafer the length of the channel has to be larger than $2d\sqrt{3}$. For the channel width w the only restriction that applies is given by flow-resistance requirements. The width should be chosen such that the channel resistance becomes much smaller than the resistance of the attached membrane field. It can be calculated that—even for extremely porous membranes—a width of 100 μm is sufficiently large.

Using the new ⟨110⟩ method the microsieves can be made much thicker—and thus stronger—than with the conventional ⟨100⟩ method, as the vertical anisotropy makes the membrane width independent of wafer thickness. Since the aspect ratio of the trenches can be as much as 600 it can be expected that etching of deeper grooves will not cause any problems for the KOH solution (25%, 70 °C) we used [87]. For concentrations above 30% the formation of ⟨311⟩ planes has been reported, which disturbs the possibility to etch deep trenches [88]. The maximum etch rate of the ⟨110⟩ planes occurs for a KOH concentration of 25% and is nearly twice the etch rate of the ⟨100⟩ planes [89].

As the slit-shaped channels can be made very small, they can be placed close together, thus creating membrane fields with small widths. Figure 39 gives a schematic illustration of the fabrication process of a microsieve on ⟨110⟩ silicon.

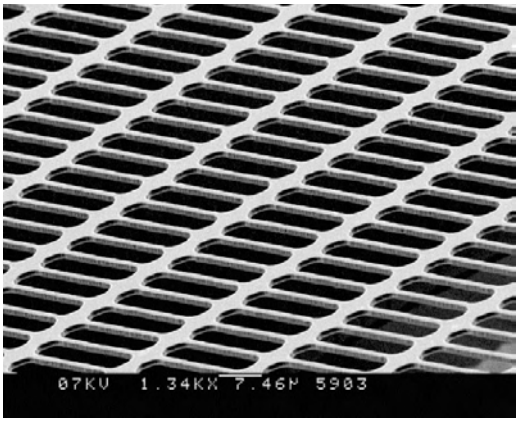

Figure 37. SEM micrograph of a microsieve with slit-shaped pores. Courtesy of Aquamarijn Research.

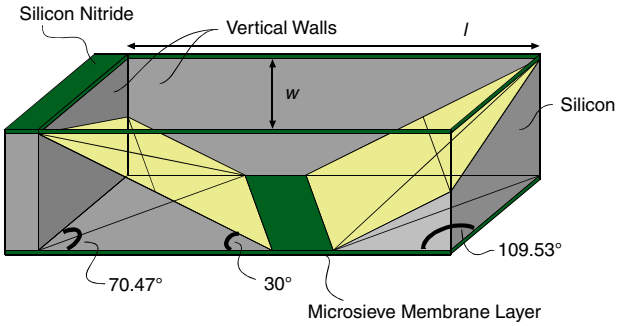

Figure 38. Schematic view of a slit-shaped pore after KOH etching of a ⟨110⟩ wafer. The shaded walls inside the channel on the right are ⟨111⟩ planes. Two planes are oblique and four planes are partly vertical.

Instead of a photolacquer mask a patterned chromium layer was used as a mask for plasma etching. This layer is obtained either by a lift-off process on photolacquer dots or by wet etching of the chromium through pores in a photolacquer layer. Before plasma etching of the membrane, vertical escape channels are etched in a KOH solution. Subsequently the membrane is patterned by plasma etching, using the chromium as the etch mask. Expected differences in etch rate due to variation in heat conduction between the released and unreleased parts of the membrane were not observed: the pores are uniform over the entire surface. For very small pores or very thin membranes it may be necessary to do an isotropic HF/HNO_3 etch to release the membrane and make a small space underneath it (third step in Fig. 39).

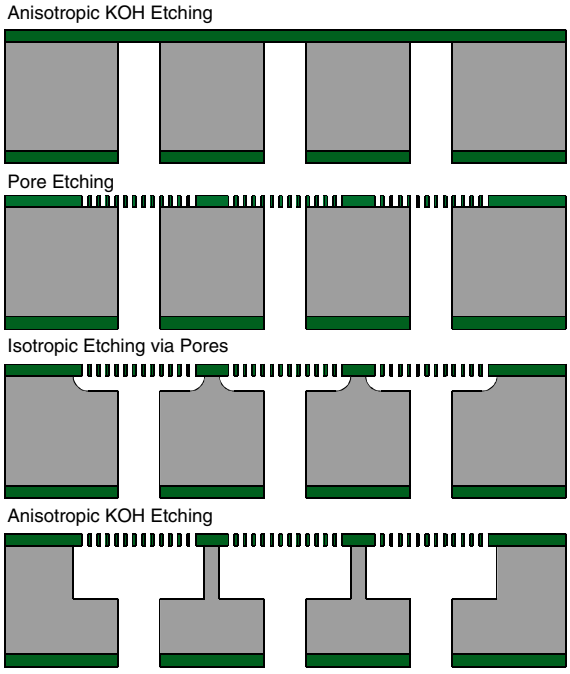

Figure 39. Schematic view of the microsieve fabrication on a ⟨110⟩ wafer. First vertical wall KOH etching in ⟨110⟩ silicon, then silicon nitride etching of the pores followed by release of the membrane with isotropic etching of silicon, and finally KOH etching to make the distance between the perforated membrane and the wafer larger.

If the HF/HNO_3 solution is chosen in the right composition (less then 1 part 50% HF on 100 parts 69% HNO_3), no hydrogen gas will be formed during this release process. The function of the small space underneath the membrane is to give the gas an escape route to the vertical channels. In the discussion we will calculate the required depth for this space.

Using the new method a microsieve was fabricated with slit-shaped perforations and a porosity of 75%. SEM micrographs of this sieve are shown in Figure 40. The shortest walls underneath the membrane should be partly vertical, but instead they are somewhat oblique with a rough surface. This is probably caused by the presence of the perforated membrane, as the back side of the wafer does show the vertical walls.

2.3. Research and Applications with Nanosieves

2.3.1. Patterning of Nanostructures

With laser interference lithography it is easily possible to reduce pore sizesa in microsieves to the nanometer regime, herewith giving birth to "nanosieves" [74]. A known technique to pattern surfaces on a substrate is to evaporate a material through a thin membrane (shadow mask) with well-defined openings [90] (see Figs. 42 and 43). It is also well known to use such shadow masks as a poor man's technique to make patterns on a substrate if photolacquer patterned layers are too elaborate or not wanted. Shadow masks with nanosized perforations may therefore be used in applications such as ion beam etching [91], electron beam patterning, near field optics, etc. Reactive ion etching through a shadow mask can be used for direct etching [3] of a (nano)pattern in a substrate (for example metal or polymeric foils).

Self-assembly (Nano)mask Preparation The micro/nanopattern may for instance be formed by using particles with a uniform size, for example a silica dispersion or a latex suspension, with particle sizes ranging from 5 nm to 5 μm.

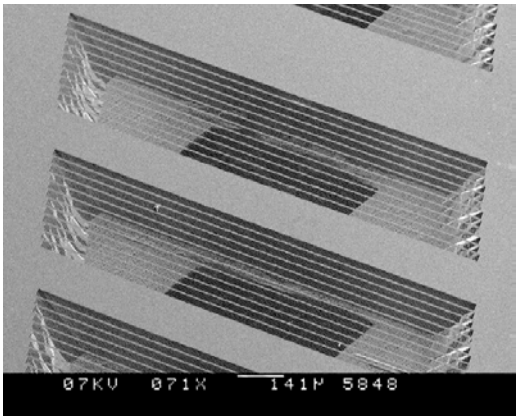

Figure 40. High-porosity microsieve fabricated on a ⟨110⟩ silicon wafer. Through the slit-shaped pores some typical etch angles can be recognized. Courtesy of Aquamarijn Research.

This suspensions may directly be formed on a substrate with use of a spin coating or evaporation technique. A more or less ordered distribution of particles will then be found in the pattern forming layer on the support. After the evaporation of the solvent of the suspension a very thin metal layer (e.g., a 10 nm chromium layer) may be deposited (e.g., by means of vapor deposition, i.e., sputtering or evaporation) on the substrate and on top of the particles, for example silica particles with a diameter of 30 nm. The silica particles are then solved in a buffered HF solution and a perforated chromium layer remains with perforations of approximately 20–30 nm in diameter depending on the chromium deposition conditions (correction for shadow effect of deposition). The chromium layer may be used as a membrane layer or alternatively as a mask layer for the (dry) etching of a membrane layer underneath the chromium layer (see Fig. 41).

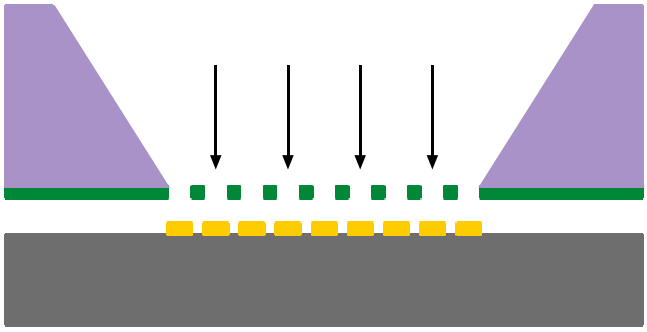

Figure 42. A nanosieve may be used as a shadow mask (nanostencil) for evaporation of material (e.g. gold) through the pores of the nanosieve. Reprinted with permission from [92], J. Brugger et al., *Microelectron. Eng.* 53, 403 (2000). © 2000, Elsevier Science.

2.3.2. Nanosieves for Photonic Structures

Recently, there has been growing interest in photonic bandgap materials, which have a spatially periodic refractive index with a lattice constant on the order of the wavelength of light, because of potential scientific and technological applications based on their unique light propagation properties [94]. However, experimental surveys of the optical properties of photonic bandgap materials have been limited due to the difficulty in preparing well-constructed samples except in the long wavelength region [95, 96].

Photonic crystals are novel materials with unique optical properties [97]. The crystals have a periodic modulation of the refractive index. As a result, the dispersion of light will be described by a band structure analogous to those of electron wave atomic crystals. Under the right conditions a photonic crystal can exhibit a photonic bandgap: light in a certain range of optical frequencies is forbidden in the crystal [98]. The existence of a photonic bandgap enables an unprecedented control of spontaneous emission and propagation. By locally disturbing the periodicity, a defect-associated photon state is created which can be used to guide light.

A photonic crystal slab is a thin film with a two-dimensionally periodic refractive index modulation in the plane [100, 101]. In a photonic crystal slab the light is confined to the crystal plane by a classical slab waveguide construction. For in-plane wave vectors a bandgap can be created. Thus, the slab has applications in light guiding without the need for a full bandgap in all three dimensions. Optimal performance of the photonic crystal slab is expected when the slab is mirror symmetric in the vertical direction (i.e., when the material on both sides of the slab has equal refractive index at least in the region of the near-field tail of the in-plane propagating light) [102].

Photonic crystals are fabricated by periodically arranging materials with highly dissimilar refractive index. To obtain a bandgap in the visible the periodicity of the index modulation has to be in the submicrometer range, <350 nm. For the fabrication of photonic crystal slabs electron beam lithography has been by far the most frequently used technique, since it is one of the few techniques that fulfills the accuracy requirements on these length scales [103]. However, due to its "direct sequential write" character e-beam lithography is time consuming for large area structures, plus uniformity errors in periodicity can occur due to errors (or quantization roundings) in the beam alignment. It would be highly advantageous to define the entire periodic pattern at once. Laser interference lithography (LIL) has proven its ability to generate uniform periodic submicrometer patterns over very large areas (on the order of square centimeters) [74, 104]. A combination of large area patterning with LIL and local patterning with a direct writing method (e.g., a focused ion beam [105]) is ideal for future fabrication of photonic crystal slabs with arbitrarily shaped light-guiding defects.

In Figure 44 a combination of LIL with focused ion beam (FIB)-assisted deposition is presented. Highly uniform freestanding photonic crystal slabs have been fabricated, extending over areas as large as a few hundred micrometers squared, with the possibility to introduce any kind of defect structure. In this way is realized, to our knowledge, the largest photonic crystal slab (100 μm $\times$ 4 mm) for visible radiation. Long line defects, extending over more than 1 mm, were also introduced.

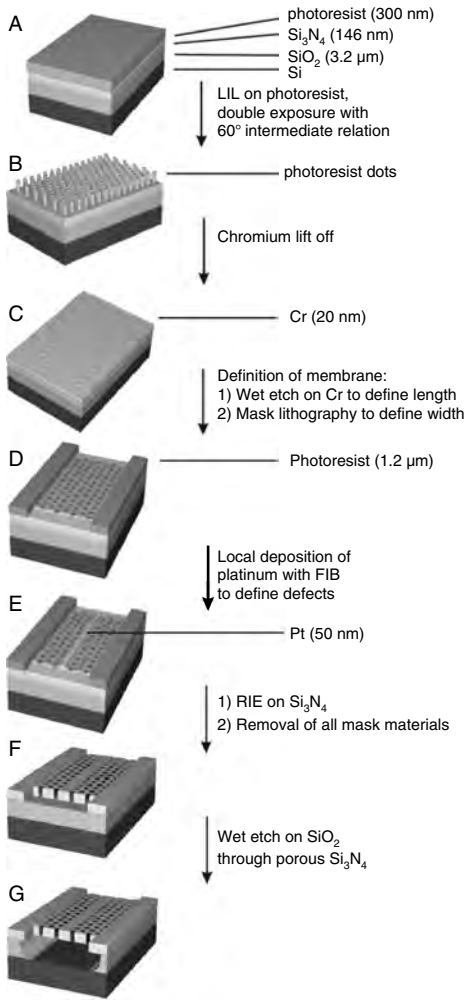

Figure 44. Schematic representation of the procedure which combines large area patterning through laser interference lithography and local introduction of defect structures through FIB-assisted deposition. The dimensions in these pictures are chosen for illustrative clarity and are not to scale. Note that a slab of 100 μm $\times$ 4 mm contains over 4.5 million holes. A photoresist layer on top of a Si_3N_4 (146 nm), SiO_2 (3.2 μm), and Si layer stack (A) is converted into a large area triangular dot pattern with LIL (B). By chromium lift-off a thin, highly selective etch mask containing holes is formed (C). Next, the etch mask is divided into smaller sections by mask lithography (D). Local deposition of platinum is used to define defect structures of any shape in the photonic crystal slabs. Here, we demonstrate the introduction of a line defect (E). By RIE the structure is etched into the Si_3N_4 layer, after which Pt, Cr, and photoresist are removed (F). By a wet etch through the holes the underlying SiO_2 layer is removed and the freestanding Si_3N_4 photonic crystal slabs are formed (G). Reprinted with permission from [99], L. Vogelaar et al., *Adv. Mater.* 13, 1551 (2001). © 2001, Wiley-VCH.

In the photonic crystal slabs Si_3N_4 ($n = 2.16$ at $\lambda =$ 670 nm) and air acted as high and low index material, respectively. A triangular lattice of air holes in the Si_3N_4 layer was fabricated in order to obtain a bandgap for TE modes (polarization in the plane of the crystal). By making the slab freestanding (i.e., embedded in air on both sides), we obtain the desired vertical mirror symmetry of the crystal slab. See Figures 45 and 46.

The advantage of LIL is that the entire periodic pattern is created at once. A high accuracy and flexibility of FIB deposition to introduce line defects in the extended crystals has been used. In principle, any defect is possible. The combination of LIL with FIB deposition opens avenues for more optical applications of photonic crystals. Due to its simplicity and scope, FIB-assisted LIL is a promising alternative for e-beam lithography in the fabrication of photonic materials. See Figure 47.

***Alumina Photonic Crystals* [*106*]** Anodic porous alumina with an ideally ordered air-hole array with a 200 to 250 nm lattice constant exhibits a two-dimensional (2D) photonic bandgap in the visible wavelength region. The air-hole preparation process was based on Al pretexturing by imprinting with a mold (cf. Fig. 66 in Section 4.3), followed by the anodization of Al in acid solution.

The depth limit of the ordered air holes is due to the disturbance of the arrangement of the air holes along with the growth of the oxide layer during anodization. For the application of 2D photonic crystals to a wide range of scientific and technological fields, an air-hole array with a higher aspect ratio is required. Anodization in a phosphoric acid solution under a constant voltage condition of 195 V yielded an air-hole configuration with a lattice constant of 500 nm. See Figures 48 and 49.

Figure 50 shows the typical transmission spectra of the anodic porous alumina with a 500 nm lattice constant. The filling factor of the air holes was 0.1. In Figure 50a, which presents the transmission spectra for H polarization light, distinct dips in the transmission were observed for both the J and X directions. The observed position and width were in good agreement with the theoretical prediction based on the plane-wave method for the triangular lattice of air holes in the alumina matrix [107].

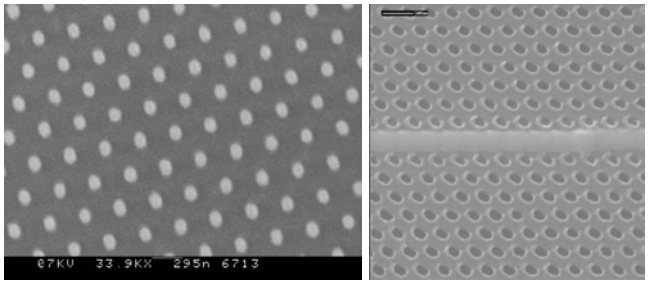

Figure 45. Left: SEM image of triangular photoresist dot pattern with a period of 300 nm after laser interference lithography. The uniform pattern extends over an area of the order of a centimeter squared. Right: FIB image of an approximately 50 nm thick platinum line covering holes in a 20 nm thin chromium mask. The platinum line defines a defect structure in the photonic crystal slab and is deposited locally with a focused ion beam. Courtesy of Adv. Materials.

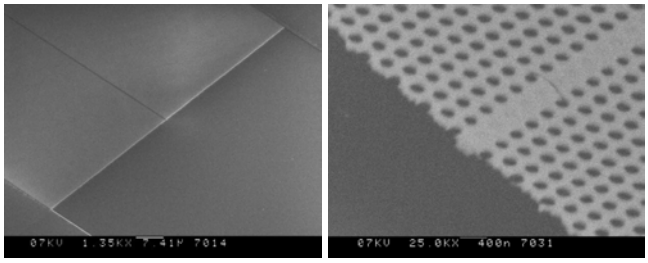

Figure 46. Left: SEM micrograph of the end face of a photonic crystal slab between the support bars. This 146 nm thin slab is freestanding across 100 μm and has a length of 4 mm. Right: SEM micrograph, close-up of the defect line in the photonic crystal slab. The highly uniform triangular hole pattern has a period of 297 nm. The axial widths of the elliptical holes are 212 and 164 nm. The shape of the holes appears unharmed by the presence of the defect line. The defect is expected to form a multimode waveguide for visible light (estimated central wavelength 670 nm). Right: Courtesy of Adv. Materials. Left: Reprinted with permission from [99], L. Vogelaar et al., *Adv. Mater.* 13, 1551 (2001). © 2001, Wiley-VCH.

2.3.3. Nanoengineered Membrane Separation Technology

Introduction Nanosieves may be used as a stencil for patterning or as a photonic crystal, but they may also be used as a proper solid support for much thinner membrane layers, or to put it simply: as a thin functional membrane in the pores of another supporting membrane structure.

The advantage of this nanoarchitecture is that a decoupling is made between the thickness of the functional membrane layer and the strength of the support membrane layer. This nanoarchitecture will be of use in processes (e.g., gas separation, ultrafiltration, etc.) in which the flux through the functional membrane layer is diffusion limited. It even would be possible to obtain gas separation/molecular sieve membrane layers (e.g., silicon oxide, silicalite) with a thickness of a few nanometers that would enable gas molecules

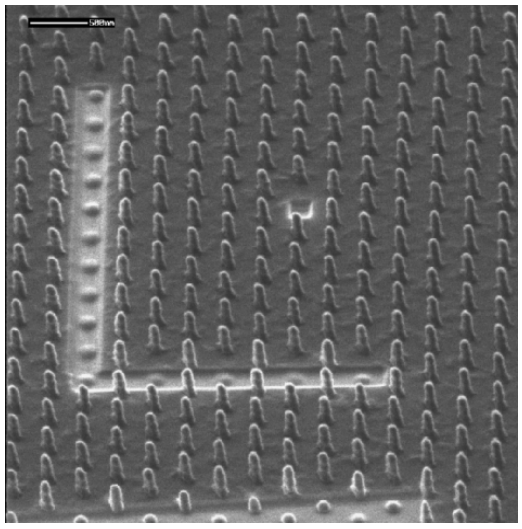

Figure 47. SEM micrograph of a FIB-assisted removal of a number of pillar structures obtained with laser interference lithography. Courtesy of Applied Optics Group, University of Twente.

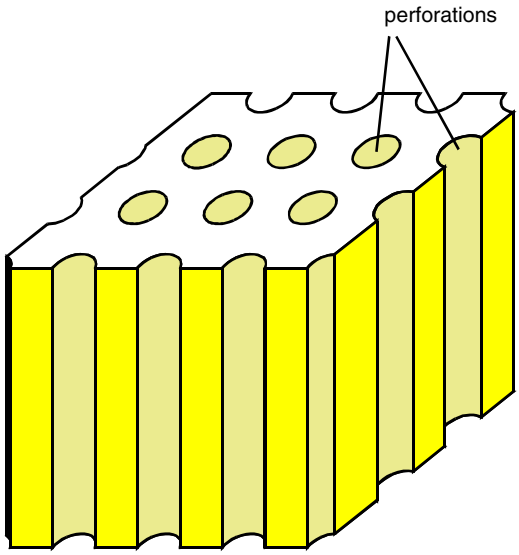

Figure 48. Schematic diagram of a 2D photonic crystal using anodic porous alumina.

to pass the membrane ballistically [108] without colliding with the walls inside the membrane. Very high fluxes may be expected in this case.

An estimate of the maximum pressure load q of such a thin functional membrane with thickness h, width l, Youngs modulus E and yield stress σ may be obtained with an

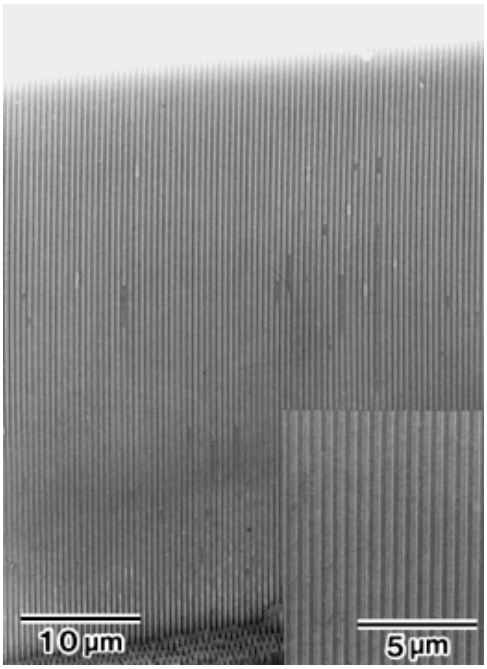

Figure 49. SEM micrograph of the highly ordered anodic porous alumina. Anodization was conducted in 0.1 M phosphoric acid solution at 0 °C at 200 V for 360 min. The lattice constant and filling factor were 500 nm and 0.3 μm respectively. The inset shows an enlarged view of the air-hole array at the bottom region of the anodic porous alumina. Figure 50. Transmission spectra of anodic porous alumina for (a) H and (b) E polarization light for the Γ–J (- - -) and Γ—X (—) directions. The lattice constant and filling factor were 500 nm and 0.1 respectively. Reprinted with permission from [106], H. Masuda et al., *Jpn. J. Appl. Phys.* 39, 1039 (2000). © 2000,

earlier expression:

$$\sigma_{\text{total}} = \sigma_{\text{tensile}} + \sigma_{\text{bend}} \underset{x=0}{\overset{u \gg 1}{=}} 0.29(1 + 1.47/0.37)\sqrt[3]{\frac{q^2 l^2 E}{h^2}}$$

Using current values for a silicon oxide membrane layer with a thickness of only 1 nm and width of 1000 nm, a maximum pressure load is obtained of 16 bar, a value comparable with (e.g., a silicon nitride layer with a thickness of 1 μm and width of 200 μm) the maximum pressure load of the membrane support layer itself. See Figure 51.

Microengineered membranes have also been the subject of study at other institutes for example, for air filtration and particle counting applications [109]. Following earlier work of van Rijn [3] palladium membranes for hydrogen separation have also been recently made using a microsieve structure as a support for a very thin palladium membrane (<200 nm) for, for example, small scale fuell cell applications [110]. Also membranes with straight nanometer sized pores (20 nm) have recently been made for cell immunoisolation and biomolecular separation applications [111–113] following formerly presented nanopore construction technologies [3] with use of conventional lithographic techniques (see Fig. 52).

In a membrane layer 2 of silicon nitride with thickness 1 μm parallel grooves with a depth of 1 μm and a length of

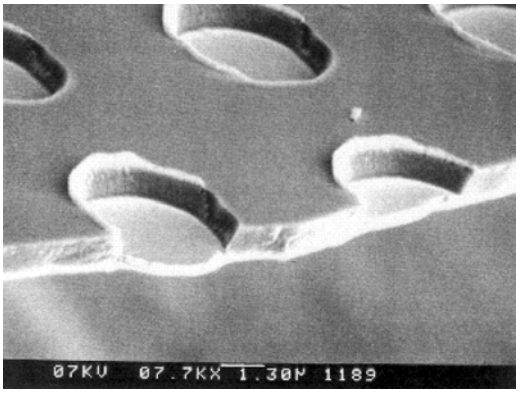

Figure 51. Pd membranes with a thickness of 200 nm and diameter 4 μm hanging in the pores of a silicon nitride membrane with a thickness of 1 μm. Reprinted with permission from [3], C. J. M. van Rijn, Membrane Filter as well as a Method of Manufacturing the Same, PCT Application 95/1386206.

10 μm are being etched with reactive ion etching techniques. A sacrificial layer 3 of silicon dioxide is grown uniformly with a uniform thickness of 20 nm by means of chemical vapor deposition of tetraethoxysilane at elevated temperature. Square to the grooves a line pattern (not shown in the figures) is etched in the sacrificial layer 3 with a depth of 20 nm, a width of 1 μm, a length of 1000 μm, and a spacing of 10 μm with standard lithographic techniques using a buffered HF solution as a selective etchant. Over the sacrificial layer 3 and in the grooves a groove filling layer 4 with a thickness of 2 μm is deposited (e.g., a polysilicon layer). The groove filling layer 4 is then planarized by polishing or etching such that the grooves remain at least partially filled with groove filling material 4. The groove filling material 4 is then at least partially directly connected to the membrane layer 2 near the line pattern. Subsequently, the sacrificial layer 3 is removed from using the buffered HF solution such that channel-like pores 5 with a width of 20 nm, a depth of 1 mm, and a lateral length of 10 μm are realized. Openings are etched in the support 6 using KOH as an etchant and the patterned silicon nitride layer 1 as an etch mask. With the process it is possible to make very small pores without alignment of the mask for the parallel grooves and the mask for the line pattern.

An intermediate layer between the membrane layer 2 and the support 6 may be applied as a selective etch stop, for example silicon nitride or alumina.

The membrane may also be used as a separation filter (potential low diffusion times), for instance for *in vivo* screening of blood cells, or in a sensor [3, 114] or actuator system. This will give a clear advantage for microsensors and actuators that are processed with use of thin film technology.

Desai et al. [113] have studied the use of nanoporous membrane filters with pore sizesa of 25 and 50 nm for biosensor applications according to the manufacturing scheme of Table 5. Some typical diffusivity parameters found with their membranes in comparison with conventional membranes are listed in Table 6.

2.3.4. Microfiltration of Lager Beer

The Grolsche Bierbrouwerij Nederland and Aquamarijn Micro Filtration started a collaboration in 1995 with the purpose of investigating the possibilities of replacing diatomaceous earth (kieselguhr) filtration of lager beer with microsieve filtration [115].

Nowadays tubular ceramic or polymeric membrane systems are being developed as an alternative for classical packed bed diatomaceous earth (see Fig. 1) dead-end filtration. Complications in using these type of filtration membranes are yeast cell clogging and protein adsorption leading to a fast flux decline and subsequent elaborate in-line cleaning procedures. A pilot plant was built in which the performance of the microsieves was tested. Clarification of lager beer is an important operation during the brewing process. Rough beer is filtered in order to eliminate yeast cells and colloidal particles responsible for haze. Common beer-filtration systems are based on kieselguhr. However, the exploitation costs of these systems are rather high. See Figure 53.

Cross-flow microfiltration with polymeric or ceramic membranes may be an alternative. Several studies have been carried out, but often problems like poor permeate quality (i.e., high turbidities or protein and aroma retention) or insufficient fluxes are encountered [116, 117]. Experiments at the Grolsch breweries in which a microsieve was used for the filtration of beer [118] showed a permeate flux of 4×10^3 l/m^2/hr during a period of at least 5 hours without any increase in transmembrane pressure (see Fig. 54).

This flux is one to two orders of magnitude higher than typical fluxes obtained with diatomaceous earth or other membranes. In the experiments the formation of a cake layer was diminished by using a cross-flow configuration in combination with backpulse techniques and a transmembrane pressure of only 20 cm H_2O (0.02 bar). As the microsieve is made of an inert material it may be cleaned with aggressive chemicals or by steam sterilization. After cleaning the new permeate still has the tendency to foam. Many other membranes may give problems on this point, as it is difficult to remove cleaning agents from the large inner surface and from dead-end pores. An additional advantage is the absoluteness of the filtration: the uniform pores do not permit a single yeast cell to pass through the sieve. See Figure 55.

Moreover, extensive cleaning procedures are required, as beer turns out to cause severe fouling [117, 119, 120]. Ceramic membranes have an advantage over polymeric membranes regarding fouling, as they can withstand harsh cleaning methods. However, the obtained fluxes are usually significantly lower. Ceramic membranes with a small flow resistance would therefore be highly desirable for beer filtration. Microsieves made with silicon micromachining consist of a thin microperforated silicon nitride membrane attached to a macroperforated silicon support. The membrane thickness is of the order of the pore size, thus allowing high fluxes and relatively simple cleaning procedures. Moreover, the membrane is optically flat and smooth (surface roughness typically below 10 nm), which hampers adsorption of foulants. Furthermore, the pores are uniform in size and distribution, which may be important for quality control.

Table 5. Interaction of albumin with membranes is also measured by looking at the difference between the initial albumin concentration and the final concentration; the differences can be attributed to both protein diffusion and adsorption [113].

	Whatman (albumin concentration)		Millipore (albumin concentration)		Micromachined (albumin concentration)	
Time (min)	Absolute	(g/dl)	Absolute	(g/dl)	Absolute	(g/dl)
0	0.381 ± 0.004	3.88 ± 0.02	0.423 ± 0.003	4.31 ± 0.03	0.395	3.980 ± 0.003
420	0.002	3.58 ± 0.02	0.398 ± 0.003	4.05 ± 0.03	0.394	3.970 ± 0.002
Change in albumin concentration	0.352 ± 0.004	0.30		0.26		0.01

Table 6. Membrane parameters and calculated diffusivities [113].

	Whatman	Millipore	Micromachined
membrane thickness (μm)	1 (asymmetric pores)	105	5
Porosity (%)	50	70	0.86
Effective area (mm^2)	4	5.6	0.041
Effective diffusivity	4.00E−07	5.292E−05	1.025E−08
Absolute diffusivity ($D_{\text{eff}}/A_{\text{eff}}$)	1.00E−07	9.45E−06	2.50E−07

Membrane fouling during filtration of lager beer with microsieves can well be studied through in-line microscopic observations. Ph.D. student S. Kuiper [121] was willingly asked in 2000 by Aquamarijn to perform a number of experiments with lager beer from The Grolsche Bierbrouwerij at Enschede. All microsieves with a pore size less than 1.2 μm for this study were manufactured by Aquamarijn (with thanks to Dimes at Delft for the photolithography).

It was observed that the main fouling was caused by micrometer-sized particles, presumably aggregated proteins and/or polysaccharide/cellulose residues. These particles formed flocks covering parts of the membrane surface. Most of the flocks could be removed by a strong temporary increase in cross-flow. Underneath the flocks a permanent fouling layer was formed inside the pores. This made frequent removal of the flocks crucial in delaying the process of permanent in-pore fouling.

Besides the fouling process the influence of pore size on permeate flux and turbidity was investigated. Centrifuged beer appeared to give a significantly clearer permeate than rough beer. For centrifuged beer and a microsieve with a pore diameter of 0.55 μm a haze of 0.23 European brewery convention (EBC) was obtained during 10.5 hours of filtration at an average flux of 2.21×10^3 l/m^2 hr. For a sieve with slit-shaped perforations of 0.70×3.0 μm^2 a haze of 0.46 EBC was obtained during 9 hours of filtration at an average flux of 1.43×10^4 l/m^2 hr. This flux is about two orders of magnitude higher than is commonly obtained with membrane filtration of lager beer. Concentration of the beer by a factor of 12 in a 3 hour run hardly influenced the magnitude of the flux. See Table 7.

3. NANOENGINEERED BIOMEMBRANES

3.1. Introduction

The research goal in biomembrane science is to study the function of natural biomembranes and to engineer new types of biomembrane materials on the nanometer scale [122–124]. Natural biomembranes, in particular lipid bilayer cell membranes, have an important function in biological molecular exchange (metabolism) and signal transduction processes (e.g., immune reactions, hormone detection) of the living cell. Generally, these processes are mediated across the cellular membrane wall by a transmembrane channel and pores for molecular exchange [125–127] and for signal transduction [128, 129].

Most gram-negative bacteria possess an inner and an outer cellular membrane wall. The inner one contains a

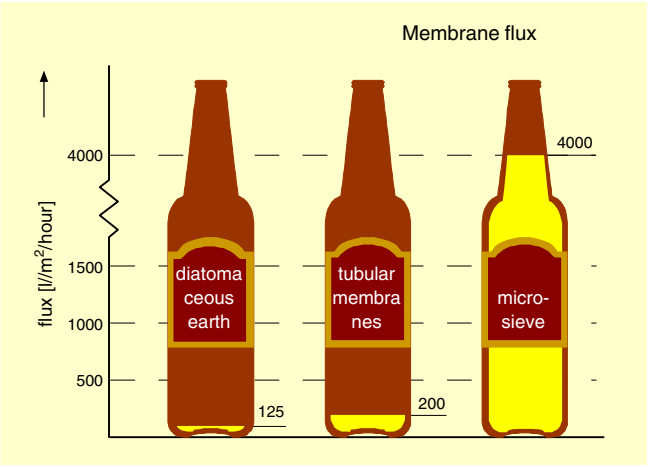

Figure 55. Flux comparison of yeast cell filtration methods. Reprinted with permission from [115], C. J. M. van Rijn et al., *Proc. EBC Congress* 501 (1997). © 1997,

Table 7. Results of three long-run experiments.

	Porosity (%)	Average beer flux (l/m^2 hr)	Initial beer flux (l/m^2 bar hr)	Water flux at 20 °C (l/m^2 bar hr)	Permeate haze (EBC)
0.70 μm slits	31	$14.3 \cdot 10^3$	$18 \cdot 10^4$	$18 \cdot 10^5$	0.46
0.80 μm circles	22	$7.24 \cdot 10^3$	$5.6 \cdot 10^4$	$5.8 \cdot 10^5$	0.58
0.55μm circles	24	$2.21 \cdot 10^3$	$1.8 \cdot 10^4$	$4.7 \cdot 10^5$	0.23

"dense" lipid bilayer, which is electrically closed, so that no ions or other hydrophilic substrates can cross the barrier without the help of highly specific membrane proteins. This inner cell wall is separated from the outer one by an aqueous phase filled with water-soluble polymers, the peptidoglycan. In contrast, the outer cell wall is fairly permeable to smaller solutes below a molecular weight of about 400 Da. Such substances can freely permeate under a concentration gradient through general diffusion porins in the outer cell wall. The most prominent of the general diffusion porins is OmpF (outer membrane protein F) [130, 131] which is very stable and does not denaturate, for example, in 4 M GuaHCL, 70 °C or in 2% SDS. In case of lack of nutrition, the pure diffusion process is too slow and the bacteria need to enhance the efficiency of the translocation functions. For those cases, nature has created a series of rather specific and highly sophisticated membrane channels. An extensively studied example is the malto-oligosaccharide specific channel LamB, or maltoporin [132] of *Escherichia coli*. Nanoengineered porins in artificial lipid or also block copolymer biomembranes may allow observation of the crossing of a single substrate molecule through the porin channel. A well studied example [133] is the α-hemolysin porin in a diphytanoylphosphatidylcholine (lipid) bilayer. See Figure 56.

High-resolution measurements of ion currents through single porin channels to probe, for example, neutral solute transport [134] have already been shown. Also the screening of facilitated transport of a wide variety of molecules [135], for example, to study antibiotic uptake through porins, to test for toxins, etc., is an object of ongoing interest.

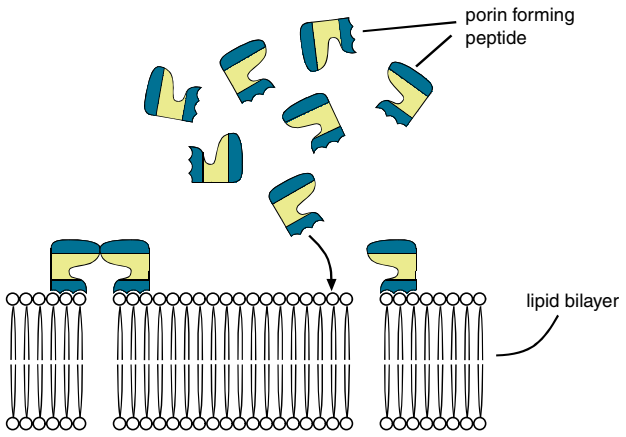

Figure 56. Schematic illustration of the assembly of a pore channel with (α-hemolysin) peptide oligomers in a (diphy-tanoylphosphatidylcholine) lipid bilayer. Intermediate structures of the assembly process are not considered.

3.1.1. Surface Layers

In microorganisms of almost every taxonomic group of walled eubacteria and archaeobacteria [136, 137] the outer cell wall has a nanoporous crystalline surface layer (S-layer). This surface layer is composed of a single protein or glycoprotein species with molecular weights ranging from 40,000 to 200,000 and can exhibit either oblique, square, or hexagonal lattice symmetry [138–140]. See Figure 57.

An important feature of these nanoporous structures is their repetitive physicochemical properties. Pores passing through S-layers show identical size and morphology and are in the range of ultrafiltration membranes. Functional groups on the surface and attached in the pores may be well aligned and are accessible for specific molecules in a very precise fashion. S-layer proteins also reveal the ability to self-assemble into two-dimensional crystalline arrays in suspension, on solid supports, at the air/water interface, and on lipid films [141].

Modification of S-layers [145] would allow several possibilities including the manipulation of pore permeation properties, the introduction of switches to open and close the pores, and the covalent attachment to surfaces or other macromolecules through defined sites on the S-layer protein. S-layer proteins can also be produced in large amounts by continuous cultivation of S-layer-carrying organisms. S-layer proteins can be considered biopolymeric membranes with properties ideally tailored by nature for many biotechnological applications [146], as matrices for the immobilization of a variety of materials including biologically active macromolecules [147, 148] and for functionalization of synthetic materials. The regular pore properties of S-layers are in contrast with the amorphous pore structure of phase inversion membranes and may therefore be used to produce artificial biomembranes showing excellent molecular mass cutoff separation capabilities [149]. See Figure 58.

One of the most common organisms used for producing S-layer-carrying cell wall fragments and S-layer protein for biotechnological applications is *Bacillus stearothermophilus*

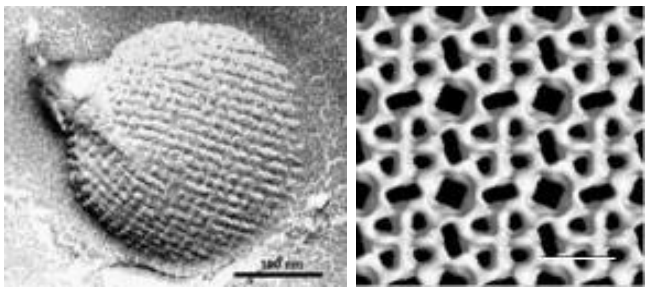

Figure 57. SEM photograph of a liposome with a nanoporous cell envelope (surface layer). Right: a reconstruction of an S-layer structure (bar = 10 nm). S-layers are formed by self-assembly and are made of protein and glycoproteins (MW 40,000–200,000) with an oblique, square, or hexagonal 2D crystal structure with typical lattice constants between 5 and 30 nm and a thickness of 5–10 nm. Courtesy of Nanosearch membrane GmbH.

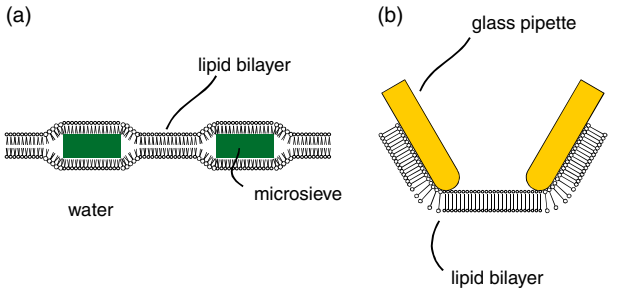

Figure 58. (a) Schematic illustration of a "black" lipid membrane generated by the method of Montal and Muëller on a micro/nanosieve. Originally this method involved the generation of a lipid bilayer over a septum with an orifice of 40–800 micrometers [142, 143]. For this purpose either a small drop of lipid dissolve in alkane is placed on the opening of the septum [144] or the membrane is formed from two lipid monolayers at an air/water interface by the position of the hydrocarbon chains through an aperture made in a hydrophilic partition which separates the two monolayers. (b) Schematic illustration of a lipid bilayer, generated on the tip of a patch clamp pipette.

PV72, for which a synthetic growth medium has been developed [150, 151]. S-layers have also been used for the production of S-layer based ultrafiltration membranes (SUMs) [152]. SUMs are produced by S-layer self-assembly or by depositing S-layer-carrying cell wall fragments on normal microfiltration membranes. Adsorption studies and contact angle measurements have confirmed that these SUMs are net negatively charged and basically hydrophilic [153].

S-layers may also be used as matrices for covalent binding of biologically active macromolecules, such as enzymes (invertase, glucose oxidase, glucuronidase, L-glucosidase, naringinase, peroxidase), ligands (protein A, streptavidin), or mono- and polyclonal antibodies. S-layer-carrying cell wall fragments with immobilized protein A could be applied as escort particles in affinity cross-flow filtration for isolation and purification of human IgG from serum or of monoclonal antibodies from hybridoma cell culture supernatants [154, 155]. SUMs with immobilized monoclonal antibodies were also used as reaction zones for dipstick-style immunoassays [156]. For this purpose, human IgG was either directly coupled to the carbodiimide-activated carboxyl groups of the S-layer protein, or it was adsorbed onto a SUM with covalently bound protein A. Alternatively, human IgG was biotinylated and bound to a SUM onto which streptavidin was immobilized in a monomolecular layer [157]. See Figure 59.

The experimental use of crystalline bacterial surface layer proteins (S-layers) as combined carrier/adjuvants for vaccination and immunotherapy has since 1987 progressed in three areas of application: immunotherapy of cancers, antibacterial vaccines, and antiallergic immunotherapy. See Figure 60.

3.1.2. Block Copolymer Membranes

Self-assembly of reactive amphiphilic block copolymers may also be used to prepare nanostructured hydrogel membranes with exceptional permeability properties [158]. Although the block copolymer membranes (PMOXA–PDMS–PMOXA triblock) are two- to threefold thicker than conventional

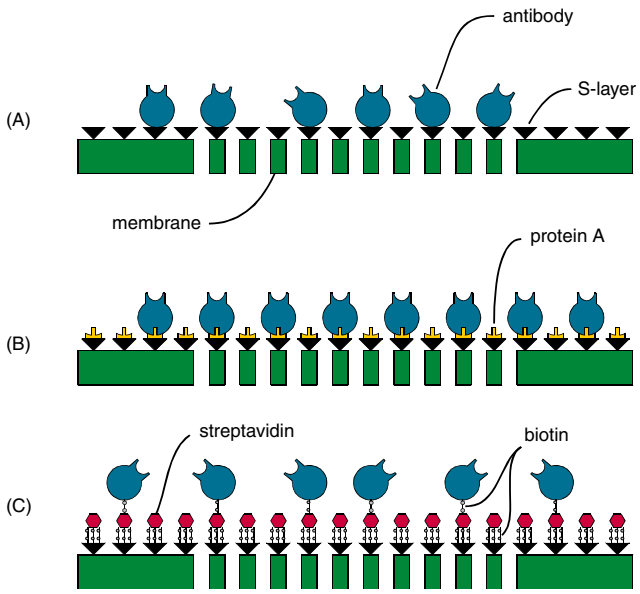

Figure 59. Schematic drawing illustrating the immobilization of IgG to carbodiimide-activated carboxyl groups of the S-layer protein of SUMs (A), to protein A covalently bound to the S-layer lattice (B), and after biotinylation to a streptavidin-modified SUM (C).

lipid bilayers, they can be regarded as mimetic of biological membranes and can further be used as a matrix or scaffold for membrane-spanning proteins [159]. Surprisingly it has been found that the proteins remain functional, despite the thickness of the membranes and even after polymerization of the reactive block copolymers [160]. The unique combination of block copolymers with membrane protein based channels allows the preparation of mechanically stable, defect-free membranes and nanovesicles [161] that have highly selective permeability and/or specific recognition sites. See Figure 61.

The block copolymer/protein hybrid shells of the nanovesicles can be regarded as a semipermeable membranes separating their internal volume from the external solution. This property opens a convenient approach to trigger the gating transition of OmpF. Large polyelectrolyte ions, such as polystyrene sulfonate, will not permeate, and

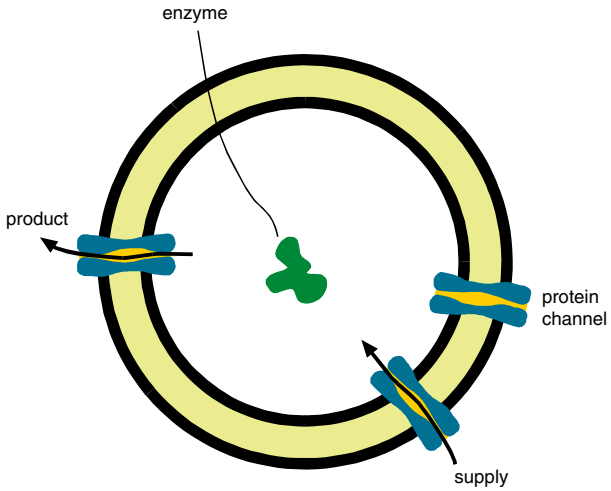

Figure 61. Schematic view of a bioreactor/nanovescicle formed by a poly-2-methyloxazoline–polydimethylsiloxane–poly-2-methyloxazoline (PMOXA-PDMS-PMOXA) triblock copolymer with encapsulated enzyme. Channel proteins in the shells of the bioreactors control the exchange of substrates and products. Reprinted with permission from [158], C. Nardin and W. Meyer, *Rev. Mol. Biotechn.* 90, 17 (2002). © 2002, Elsevier Science.

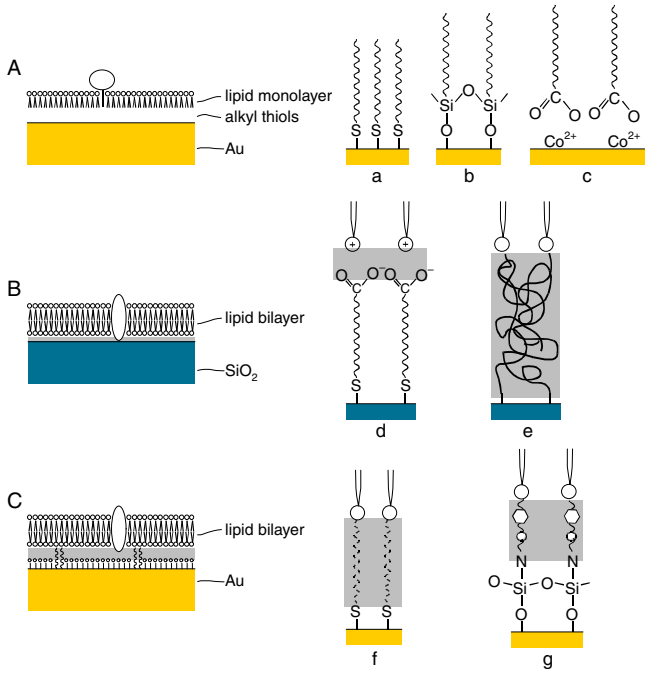

Figure 62. Architectures of supported membranes [126]. Three basic strategies are sketched here, together with some possibilities for their realization. (A) A phospholipid monolayer on a hydrophilic base layer, which in most cases consists of rigidly packed alkyl chains. This base layer may be produced by the self-assembly of alkylthiols on gold (a), of alkylsilanes on oxide surfaces (b), by the Langmuir–Blodgett (LB) transfer of a monolayer of fatty acid salts to a hydrophilic surface (c), or by the coupling of a rigid hydrophilic polymer to the surface (not shown). The phospholipid monolayer on top is either formed by entropy-driven self-assembly in solution or transferred horizontally from the air–water interface. This monolayer configuration is suited for the observation of processes on the membrane surface or for anchoring peripheral membrane proteins. (B) A phospholipid bilayer on a hydrophilic surface. This surface may be a clean glass, quartz, or silicon oxide surface on which bilayers may be formed by vesicle spreading or by two-step LB transfer. Gold surfaces must be functionalized with hydroxy-, carboxy-, or amino-terminated thiols to confer hydrophilicity; for bilayer spreading, surface charge can be exploited by using charged lipids (d). The formation of bilayers supported on a hydrophilic polymer is also possible (e). The incorporation of transmembrane proteins in such a "coating" bilayer has been demonstrated. (C) An anchored phospholipid bilayer on a hydrophilic surface. To mimic the natural situation more closely, phospholipid derivatives must be used as hydrophilic anchors for the membrane, and the interstices on the surface must either expose a hydrophilic material or be correspondingly functionalized. Anchor lipids may be thiolipids on gold (f), lipids coupled by a cross-linker to oxide surfaces (g), His-lipids, succinimidyl-lipids, etc. In this configuration, the membrane must be formed by self-assembly from vesicle suspensions or detergent solutions; it is well suited for the accommodation of transmembrane proteins. Courtesy of S. Heyse, *Biochimica et Biophysica Acta*.

therefore the sodium counterions will be distributed inside and outside the nanovesicles according to Donnan equilibrium conditions, giving rise to a Donnan potential. If this potential exceeds the critical value necessary for closure of OmpF, the substrates can no longer enter the interior of the nanoreactor vesicle (i.e., the reactors are then deactivated). The closure is a reversible process, and decreasing the potential below 100 mV may reactivate the nanoreactor vesicles. This could be carried out by diluting the system with buffer or by increasing the Na^+ concentration in the system.

Peptide nanochannels or nanotubes have also been formed by cyclo([L-Trp-D-Leu]$_3$-L-Gln-D-Leu) in phospholipid multilayers obtained by air drying on a substrate [162]. Nanotubes formed from cyclo([L-Trp-D-Leu]$_4$) have also been allowed to assemble into preformed monolayers of dodecanethiol or octadecyl sulfide deposited on gold films [163].

Bonding of the bilayer can be adjusted by coating of the membrane using a matching precoat, for instance high-quality alkyl monolayers. The stability of the precoat is of very high importance for the final stability of the total stack [164, 165]. See Figure 62.

3.2. Biosensors

Micro- and nanoengineering technologies offer revolutionary possibilities for biosensors and sensor arrays for drug and chemical screening and environmental monitoring. When a cell membrane detects (senses) a target molecule, it can turn electrical currents on or off by opening or closing molecular channels. When the channels are open, charged ions can pass in or out of the cell. These ions would not pass through the otherwise insulating membrane. When these channels open, the ion flow creates a potential difference across the membrane, which in turn creates a current. Such biosensors have a huge range of potential uses, especially in medicine, for detecting drugs, hormones, viruses, and pesticides and to identify gene sequences for diagnosing genetic disorders. The ability to detect the modulation of cell membrane channel activity by the binding of therapeutic agents is considered crucial for rational and efficient drug discovery and design. Since combinatorial libraries of potential therapeutic compounds are rapidly growing, fast and highly

sensitive methods for functional drug screening are required. An attractive possibility is the use of self-assembled tethered membranes containing specific channel receptors as the sensing element in an otherwise solid-state biosensing device. Massive arrays of individually addressable microsensors with integrated fluid handling are conceivable. Even very simple sensor designs offer valuable advances in low-cost sensing for clinical medicine and the food and hygiene sectors. The much-discussed "artificial nose" containing a dense array of receptor sites affording unambiguous identification of molecular species could analyze the breath of patients for known chemical signatures of diseases such as liver cirrhosis and lung cancer.

3.2.1. Scaffolds

Microengineered membranes coated with titanium with a pore size of 500 nm have also been used [166] as a scaffold for a functional monolipid layer obtained by the coalescence and spreading of corresponding lipid vesicles on the membrane surface.

Micro- and nanoengineered membranes can further be used as a scaffold for the construction of functional 2D nanoarchitectures to probe, for example, selective molecular transport and controlled release properties of biomedical molecules. See Figure 63.

Cornell et al. [167] have elaborated tethered supported lipid bilayers into devices that will sense both large and small analytes. The impedance of the bilayers depends upon the density of open gramicidin channels. In one manifestation, an analyte (such as a protein) with two antigenic sites binds to antibodies at the membrane surface disrupting a preexisting channel with the disadvantage that the response is a diminution of a large preexisting signal. In a second manifestation, channels are opened when an analyte, which can in this case be a small molecule, releases half channels from an immune complex in the upper leaflet of the bilayer so that they can find half channels in the lower leaflet. Another promising approach is stochastic sensing with engineered pores [168]. Stochastic sensing is based on the detection of individual binding events between analyte molecules and a single pore. The read-out is the single-channel electrical current. The frequency of the binding events is determined by the concentration of the analyte. The nature of the binding events (e.g., the magnitude and duration of the associated signal) is determined by the properties of the analyte. The ability to identify an analyte by its characteristic signature is a distinctive feature of stochastic sensing. Engineered versions of α-hemolysin were first used to detect and quantify divalent metal ions.

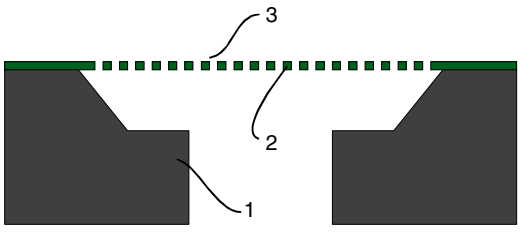

Figure 63. Support structure 1 with a nanoengineered scaffold 2 for a functional membrane layer 3.

4. NANOTUBES

4.1. Introduction

Nanotubes can be defined as hollow cylindrical structures and constructs with an inner diameter smaller than 100 nm. The current worldwide research is mainly focused on:

- *Peptide nanochannels and tubes* that can be found in cell membranes acting as size or charge selective barriers between the inner an outer lipid bilayer cell membrane and can also be artificially constructed and be used as molecule specific biosensors (see the section? on nanoengineered biomembranes).
- *Carbon and carbonlike dense and open nanotubes* that can be grown selectively on appropriate prepared substrates and can be used for molecule specific adsorption/separation processes or for electrical nanowiring applications.
- *Templated nanotubes or tubules* in which, for example, an anodized alumina membrane is used as a template for the deposition of appropriate materials (carbon, gold, etc.) inside the long cylindrical pores (diameter 50–200 nm) of the alumina membrane. Procedure: immerse an alumina membrane in a solution of organometallic nickel, evaporate solvent, leaving Ni film in pores, form nanotubes in membrane pores via CVD of carbon from ethylene decomposition [169]. Increasing deposition time yields solid carbon nanofibersa rather than hollow tubes. Recently silica nanotubes [170, 171] have also been obtained. Other tubular structures formed by heavier element compounds have been predicted, such as GaSe [172], and synthesized, such as WS_2 and MoS_2 [173].

4.2. Carbon Nanotubes

Two types of carbon nanotubes exist: those originally observed by Iijima [174, 175] were multiwall nanotubes, formed by concentric shells of apparently seamless cylinders of graphene, having a separation between them similar to that in graphite. More recently, single-wall nanotubes (SWNTs) have also been synthesized. As their name indicates, these consist of a single seamless cylinder of graphene [176]. Soon after the discovery of carbon nanotubes it was proposed that other compounds forming graphite-like structures, such as BN [177], BC_3 [178], BC_2N, and CN [179], could also form nanotubular structures and indeed BN, BC_3, and BC_2N have already been synthesized [180]. SWNTs were first synthesized in an arc discharge in the presence of a transition metal catalyst [181, 182]. Since then significant efforts have been directed at optimizing conditions for the arc production of SWNTs [183, 184]. For example, a modification of the arc discharge process allowing production of high-quality nanotube material within a restricted region of the apparatus has been reported [185]. However, the overall nanotube yield for this process remains relatively low. Other methods for SWNT synthesis have also been developed. An efficient SWNT production method is the laser vaporization of graphite/transition metal catalyst targets in a heated oven, which can produce nanotube yields of $>70\%$. SWNT syntheses by metal-catalyzed disproportionation of carbon monoxide and catalytic decomposition of acetylene have also been reported [186].

Ren et al. [187] discovered that vertically aligned multiwall carbon nanotubes could also be grown using plasma enhanced chemical vapor deposition (PECVD). Other plasma techniques nowadays are hot filament PECVD [187], dc (glow discharge) PECVD [188], microwave PECVD [189], and inductively coupled plasma PECVD [190]. See Figure 64.

Structural studies with transmission electron/scanning electron microscopes revealed that these nanofibersa contained the catalyst at their tips which suggests a tip-growth mechanism. Over a large range of diameters (30–400 nm), the structures were hollow (i.e., large inner diameters, hence "tube"like) with graphene planes running parallel to the length axis, and bamboo-type defects along its length.

The field of prospective applications of carbon nanotubes continues to expand in nanofluidics and nanofiltration applications. Carbon nanotubes might be used as a nanopipets [192], as sieves for DNA sequencing applications, for enantiomer separation, etc. A fundamental issue is the ability of a fluid to wet the interior of a CNT as this would facilitate solution chemistry inside CNTs [193]. The surface of pure graphite is hydrophilic; the contact angle of water on graphite is 80–90° [194]. Different studies reveal different results [195–197] on the wettability of pure carbon nanotubes. The addition of impurities during the manufacturing of the nanotubes or surface modification steps afterward might be a solution to overcome serious wetting problems. See Figure 65.

4.3. Templated Nanotubes and Nanofiltration

Classical filtration membranes and in particular anodized alumina membranes [199] and nanosieves [200] may also be transformed to nanotubular structures by deposition of appropriate materials in the filtration pores or channels. They will enable new ways of separating and detecting analytes for applications in chiral separations and single-molecule sensing. See Figure 66.

Nanotubule membranes are easy to make and each pore in the membrane essentially is a nanobeaker in which chemistry can occur. Metals can be deposited inside the pores, either electrochemically or through so-called electroless plating by using a reducing agent to plate the metal from the solution. Nanotubules of inorganic materials such as silica or titania can be prepared through sol–gel chemistry, and carbon nanotubules can be made through chemical vapor deposition of ethylene inside the pores. See Figure 67.

The nanotubules come out embedded in a membrane, aligned, and monodisperse—that is, of uniform diameter and of a uniform length equal to the thickness of the membrane. Depending on deposition reaction times, thin- or thick-wall tubules are formed. The tubules can be capped on both ends to create a cluster of individual confined

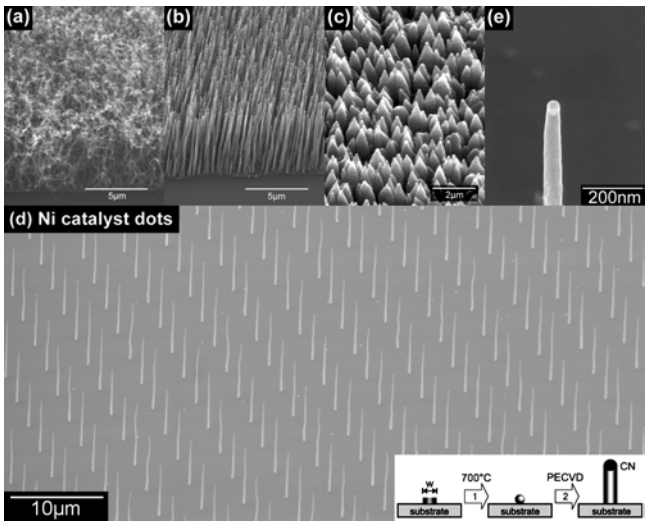

Figure 64. The possibilities of the dc PECVD process. A substrate containing thin film Ni catalyst is exposed to C_2H_2 and NH_3 gases at 700 °C [i.e., standard thermal CVD, (a)] with the exception that the substrate is biased at −600 V (i.e., to initate dc glow discharge). The degree of nanotube/nanofiber vertical alignment depends on the magnitude of the voltage applied to the substrate during growth and −600 V produced the straight structures of (b). The thickness of the thin film Ni catalyst was found to determine the average diameter and inversely the length of the nanofibersa. The yield and density of the nanofibersa were controlled by the use of different diffusion barrier materials under the Ni catalyst. The shape of the structures could be varied from very straight nanotubelike to conical tiplike nanofibersa by increasing the ratio of C_2H_2 in the gas flow (c). Example of patterned growth of CN (d). Close-up of vertically grown nanotube (e). Reprinted with permission from [191], K. B. K. Teo et al., University of Cambridge, UK.

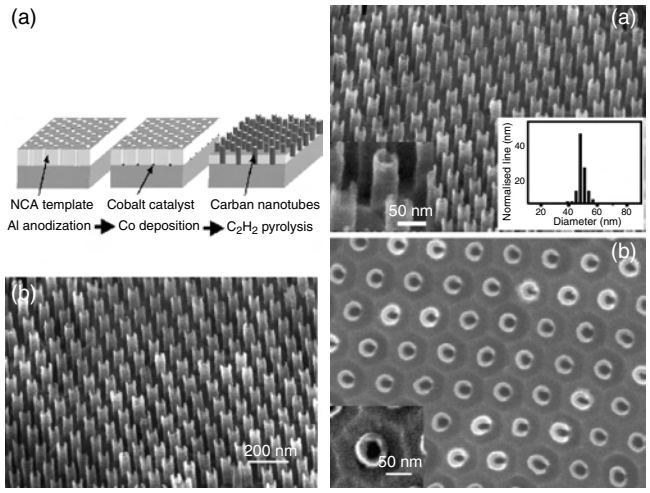

Figure 65. Highly ordered carbon nanotube arrays. Top left: Process scheme of fabrication. Bottom left: SEM image of the resulting hexagonally ordered array of carbon nanotubes fabricated using the method in (a). Top right: SEM image showing oblique view of periodic carbon nanotube array. The inset at the lower left is an enlarged view of the tubes. The inset at the lower right is a histogram of the nanotube diameter showing a narrow size distribution around 47 nm. Top view SEM image, bottom right: carbon nanotubes showing hexagonal close-packed geometry. The hexagonal cells have sides approximately 57 nm long and the intercell spacing is 98 nm. The slight splitting of the tube ends and the apparent increase in tube wall thickness is an artifact of the nonspecialized ion-milling apparatus that was used in the experiments. The inset shows a close-up view of a typical open-ended carbon nanotube in its hexagonal cell. Reprinted with permission from [198], J. Li et al., *Appl. Phys. Lett.* 75, 367 (1999). © 1999, American Institute of Physics.

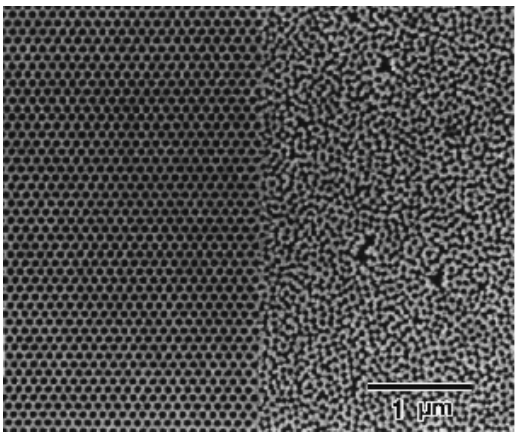

Figure 66. SEM micrograph of ordered nanochannels in anodic porous alumina. The anodizing of Al was conducted under a constant voltage condition in an oxalic acid solution. The hole interval of anodic porous alumina, in other words, the cell size, was determined by the applied voltage used for anodization. It was reported that the cell size has a good linear relationship with the applied voltage, where the proportionality constant of cell size for a specific applied voltage is approximately 2.5 nm/V. In the case of the sample shown, anodizing was conducted under a constant voltage of 40 V after pretexturing of a 100 nm period. Ideally ordered hole development was observed only in a pretextured area (left), while random development of holes took place in the untreated area (right). The hole interval corresponded to that of the pretextured concaves of Al. From this result, it was concluded that concave features formed by indentation could act as an initiation point and guide the growth of channels. Reprinted with permission form [201], H. Asoh et al., *J. Electrochem. Soc.* 148, 152 (2001). © 2001, The Electrochemical Society.

spaces, or the membrane can be removed to release individual nanotubules. The generality of this template-based synthetic methodology broadens the scope of nanomaterials that can be prepared. One of the ealiest separation applications to be explored was selective-ion transport. A simple experiment with a gold nanotubule membrane in a U-tube cell demonstrates this phenomenon [202]. On one side of the membrane is a feed solution containing KCl, which is colorless, and the cationic dye methylene blue. On the other side is a receiver solution of KCl. After a while, the colorless receiver solution turns blue, indicating transport of the cationic dye across the membrane. But when the feed contains permanganate anion, which is red, the receiver

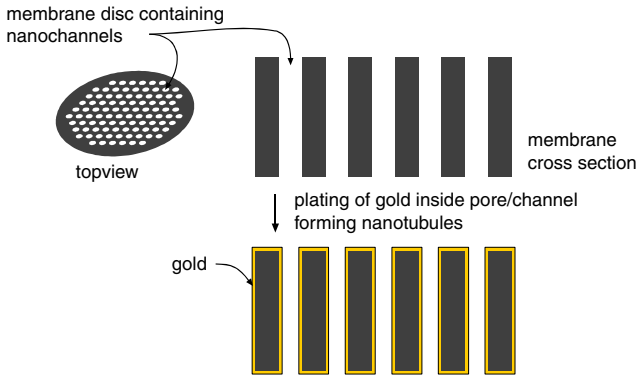

Figure 67. Schematic overview of the formation of nanotubules.

remains colorless. The anion, although smaller than the cationic dye, cannot cross the membrane. Only cations pass because the nanotubule walls have excess negative charge due to adsorbed chloride ions. The excess charge can also be controlled by applying a potential to the membrane provided that the membrane material is electrically conductive. If a positive potential is applied, the nanotubule wall will have excess positive charge and the nanotubule membrane will reject cations and transport only anions. At negative applied potentials, the membrane will transport cations and reject anions. At the specific potential where the wall is electrically neutral, the membrane will be nonselective. Thus, the nanotubules make up a switchable ion-exchange membrane [203]. Having shown these membranes to have charge- and size-based selectivities, attempts were made to engender chemical selectivity by modifying the chemistry of the nanotubule walls in which alkyl and other groups are attached to the nanotubule walls through gold–sulfur bonds [204, 205]. Cysteine is a thiol as well as an amino acid. So it has both amino and carboxyl groups. At low pH, it will be positively charged; at high pH, it will be negatively charged. Lee and Martin have shown [206] that the cysteine-decorated membrane rejects cations at low pH and anions at high pH.

Chiral separation is important in the pharmaceutical industry, as it has become clear that the enantiomers of drugs produced as racemic mixtures could have very different properties. Lakshmi et al. [207] used a "sandwich" assembly to separate D-phenylalanine from L-phenylalanine. Kobayashi et al. [208] achieved the highly sensitive detection at 10^{-11} M with unadorned gold nanotubule membranes through which an ionic current passes.

GLOSSARY

Biomembrane Natural membrane consisting of a lipid bilayer and certain protein channels for specific ion exchange.

Biosensor Device to measure chemical composition of liquid or gas using a cell membrane. Especially for use in drug screening and health and environmental monitoring.

Chemical vapor deposition (CVD) Chemical vapor deposition, a process to form thin layers of specific solid material from a gas phase.

Filtration (ultra, nano, micro) Selective permeation of any kind of molecule, bacteria, micro-organism or particle through a device, usually a thin membrane using the properties of the membrane (most basic on size selection, but more specific by difference in affinity with different molecules).

Laser interference lithography (LIL) Light exposure method using two coherent laser beams, thereby obtaining a regular line pattern. With LIL line patterns with a typical width down to 100 nm can easily be achieved. With multiple exposures, dot or hole patterns can be formed.

Lipid bilayer Natural dense membrane made from two long molecules, each with a polar head and a nonpolar tail. The molecules are arranged such that the nonpolar tails are in line with each other. By this the membrane has a hydrophilic inside and thus acts as a barrier for ions and hydrophilic liquids.

Membrane Boundary used to separate two phases. Depending on the properties of the membrane, selective transport can take place between the two phases through the membrane.

Micromachining Technique originating from the semiconductor technology used to fabricate mechanical structures and devices with typical sizes between 0.1 and 100 micrometers. The technique started with silicon material, but nowadays also polymers are being used.

Microsieve Thin, flat membrane made of silicon nitride with silicon support, having pores in a regular pattern with a very uniform pore size. Using micromachining, the pore size can be adjusted according to the application. Due to the thin membrane layer and high porosity, the flow resistance is very small.

Nanocontact printing Patterning method used to print inks, proteins, or any kind of liquid with the use of (porous) stamps containing a pattern with nanodimensions.

Nanolithography Exposure method to form patterns in light sensitive lacquers having a resolution well below 500 nm. Techniques that can be used are e-beam, ion beam, X-ray (synchrotron), or laser interference lithography.

Nanotubes Fiber structures with a diameter less than 200 nm. Due to the construction of the tube (a highly ordered molecular structure), the tubes are used for research toward new materials (strong fibers, highly conductive materials).

Phase inversion Process to form a solid material out of a liquid mixture of a polymer and a solvent/nonsolvent.

Photonic crystal Ordered regular structure with a lattice dimension in the range of the wavelength of light. By locally altering the lattice, light can be propagated or blocked.

Self-assembled monolayer (SAM) A single molecule thick layer that is arranged highly ordered without using special patterning techniques. The structure of the molecule itself organizes the position of the molecule. Used for thin layers with a special affinity to certain materials.

Nanomotor F_1-ATPase

Pia D. Vogel

Southern Methodist University, Dallas, Texas, USA

CONTENTS

1. INTRODUCTION

It has been known for a long time that enzymes and proteins undergo large conformational changes while they perform their biological tasks. The catalytically active regions of enzymes need to sequentially open to bind their specific substrates; they then close to allow the specific chemical reaction to occur in a defined chemical environment and finally open up again up to allow the product to be released.

Other proteins have evolved to perform physical work by actively transporting or moving other molecules or proteins within cellular systems. Examples of these type of proteins are the following: (a) The kinesin motor proteins "walk" along "tubulin-rails" transporting vesicles along given pathways in the cell. (b) The sliding of actin protein filaments on myosin motor filaments cause the contraction of whole subcellular organizations in muscle cells during muscle contraction or allow migration of eukaryotic cells. (c) Other proteins such as dynein together with tubulin permit movement of whole, free cells like sperm cells and protozoa. Many of these systems require energy in the form of adenosine-5′-triphosphate (ATP) to power the respective conformational transitions. (d) Bacteria use the energy stored in proton gradients that are generated across a phospholipid membrane to drive the rotary movement of flagella. These are elongated structures that enable bacteria to swim to their source of nutrition.

All in all, coordinated movement is a concept that nature has used and perfected for billions of years. Only within the past few years, when humans have started to design smaller and smaller artificial devices, reaching into the nanometer scale, have these cellular and subcellular natural organizations been termed with names such as "nanomotors." However, the design of these motor proteins is intriguing, and it is fascinating to envision the potential use of biological devices within nanomechanical arrangements.

In this chapter I will focus on an enzyme whose physiological function is not that of a physical motor. The enzyme was designed to synthesize ATP, Nature's universal energy currency, by using the energy inherent in food sources or in the sunlight (depending on the origin of the enzyme). The enzyme is called the F_0F_1-ATP synthase, and it is, like ATP itself, ubiquitous in all organisms. The ATP synthase has intrigued researchers for more than four decades for a variety of different reasons. In an article entitled "The ATP Synthase—A Splendid Molecular Machine," published in 1997 [1], Paul D. Boyer from the Molecular Biology Institute at UCLA stated that "All enzymes are beautiful, but the ATP synthase is one of the most beautiful as well as the most unusual and important." Boyer shared the 1997 Nobel Prize for Chemistry with John E. Walker and Jens Skou. Both Boyer and Walker received the prize for their accomplishments in elucidating the structure and mechanism of the ATP synthase. In this chapter I will discuss how the ATP synthase accomplishes its natural goal, the synthesis of ATP, while also being Nature's smallest and so far most efficient molecular motor.

2. ATP SYNTHASE, STRUCTURE, AND MECHANISM

The F_0F_1-ATP synthase, an enzyme found in all organisms, has intrigued scientists for almost 40 years. This highly asymmetric protein assembly drives one of Nature's most challenging and probably the most important chemical reaction, namely the synthesis of ATP. The challenge of this reaction is the formation of an anhydride bond between adenosine-5′-diphosphate (ADP) and inorganic phosphate (P_i) in an aqueous environment that would usually favor ATP hydrolysis and not the synthesis reaction. The energy

Volume 7: Pages (83–89)

for the synthesis reaction is provided by the flow of protons down an electrochemical gradient and across the corresponding energy coupling membrane. In bacteria this membrane is the plasma membrane, in eukaryotes it is the mitochondrial membrane, and in photosynthetic organisms this process mostly takes place in the thylakoid membrane of chloroplasts. In mitochondria and bacteria, the synthase efficiently couples the oxidation of NADH to the formation of ATP. Nicotinamide adenine dinucleotide in the reduced form (NADH) is a redox equivalent that is generated when an organisms digests nutritious compounds like sugars, fats, or proteins. The reducing energy (in the form of two electrons) that is stored in NADH is utilized in the respiratory chain (Fig. 1), where the electrons are transferred in stepwise redox processes to oxygen. This process leads to the reduction of oxygen to form water while NADH is oxidized to NAD^+ (Fig. 1). During these redox processes protons (H^+) are pumped across the energy-coupling membranes by the membrane enzymes involved. The energy stored in the generated proton gradient drives the ATP synthesis as we will see next.

In photosynthetically active organisms, a light-driven proton translocation is coupled to the endergonic formation of the terminal phosphoryl anhydride bond of ATP ($ADP + P_i \rightarrow ATP$).

Under certain *in vivo* conditions, for example, in some bacteria when they live in an anaerobic environment, the reaction of the synthase can be reversed so that an ATP hydrolysis-driven proton pumping occurs.

Under physiological conditions, the free energy that is stored in the terminal (β–γ)-anhydride bond of an ATP molecule is about -9×10^{-20} J, equaling about -50 kJ/mol of ATP, depending on the cellular conditions.

The ATP synthases from different organisms are highly conserved. Much of the research on F_0F_1-ATP synthases has focused on the bacterial enzyme from *Escherichia coli*, mainly because molecular biological tools are easily available, but also because the *E. coli* enzyme is simpler in subunit composition and can be readily purified in rather large quantities. A second favored source for purifying the ATP synthase or substructures thereof is the thermophilic bacterium PS3. In addition to easy availability, the PS3 enzyme is also very stable at ambient and even elevated temperatures.

In all organisms the synthase consists of two components: the membrane embedded F_0 sector that is responsible for the translocation of protons and the membrane associated F_1 part that contains the sites for nucleoside triphosphate synthesis (Fig. 2). Both parts of the enzyme are highly asymmetric. The F_0 part of the *E. coli* enzyme consists of three different polypeptides a, b, and c with a stoichiometry of 1a, 2b, and 9–12 copies of the c subunit per functional unit [2]. Subunits a, b, and c are membrane integral and a and c are directly involved in proton movement through the membrane (for review, see [3]). Subunit b has an N-terminal membrane anchor. The residual amino acids of the protein protrude into the cytoplasm and interact, at least partially, with the F_1 part of the synthase, linking it to the membrane.

F_1 is the catalytic part of the synthase and consists of the five different subunits α through ε with three copies each of the major subunits α and β and one copy each of the minor subunits, γ, δ, and ε [4]. If this F_1 part is removed from the membrane and uncoupled from the proton gradient, it is only capable of net ATP hydrolysis, owing to the lack of driving force provided by the proton gradient. This part of the enzyme is therefore also named the F_1-ATPase.

It has been known since the 1980s that six nucleotide binding sites are located on the α and β subunits. The three binding sites that are located on the β subunits are

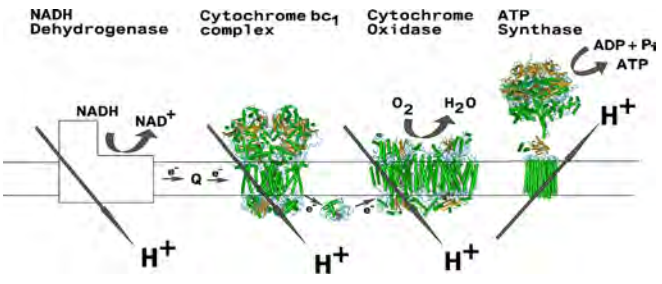

Figure 1. The respiratory chain. Electrons are transferred from NADH and H^+ to an enzyme called NADH dehydrogenase. From there the electrons are further transported along the membrane systems using the mobile carriers, coenzyme Q and cytochrome *c*. At the respective enzymes, NADH dehydrogenase, cytochrome bc_1 complex, and cytochrome *c* oxidase, the energy from the electron transfer is transduced into pumping of protons across the membrane. The resulting proton gradient drives the synthesis of ATP by the F_0F_1-ATP synthase. Where possible, the X-ray structural models of the corresponding proteins were created using Cn3D version 4.0 from the NCBI. The molecular coordinates of the protein structures can be found in the Protein Data Bank (cytochrome bc_1 complex, PDB-file: 1BGY; cytochrome *c*, PDB-file: 1GIW; cytochrome *c* oxidase, PDB-file: 1OCZ; and F_0F_1-ATP synthase, PDB: 1QO1).

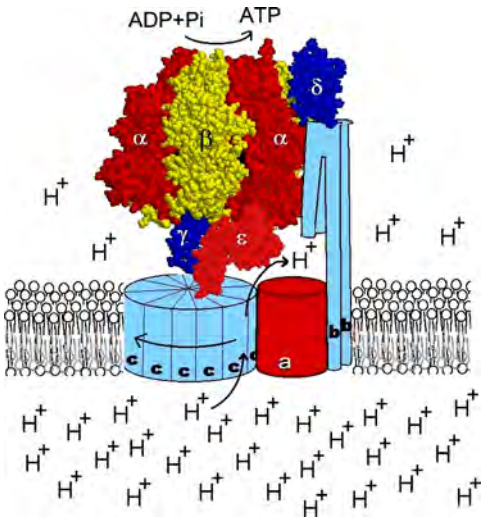

Figure 2. Model of the F_0F_1-ATP synthase. The diagram shows the two portions of the ATP synthase. The polypeptides a, b, and c are at least partially embedded in the membrane and are constituents of the F_0 portion of the membrane. Subunit a and the ring of c subunits are involved in the translocation of protons across the membrane. The membrane-associated F_1 part consists of subunits α, β, γ, δ, and ε and is responsible for the synthesis of ATP. The subunits $ab_2\alpha_3\beta_3\delta$ are considered to be the stator to the rotary motor. Subunits $c_{9-14}\gamma\varepsilon$ were shown in different experiments to rotate during catalysis (for more information see text).

catalytically active (catalytic sites) and show strong positive catalytic cooperativity. When all three sites are filled with substrate, the rate of catalysis is at least 10^5 times faster than if only one substrate is bound to the catalytic sites; for more details see [5–7]. The function of the three sites located on the α subunits remains unclear, and they are usually referred to as noncatalytic sites.

In the late 1970s, Boyer presented a model for the reaction mechanism of the ATPase that was termed the "binding change mechanism." One of the tenets of the theory stated that every one of the catalytically active nucleotide binding sites of the ATPase is in a different structural and functional state at any given time during catalysis and during sequential catalytic cycles; all of the sites go through the same states. While one of the sites is ready to bind the substrates, ADP and P_i, a second site has both these substrates bound, and a third site is in a conformation that allows the actual bond formation between ADP and P_i, resulting in elimination of water and the synthesis of ATP. The binding change mechanism model further states that the energy for the synthesis of ATP is solely required to release the product from the active site and not for the actual formation of the (β–γ)-anhydride bond. Experiments indicated that the equilibrium between ADP + P_i and ATP in the catalytic site is close to unity. The idea that these sites sequentially participate in this mechanism suggested that binding of substrate at one site promotes the release of product at a second site. This proposed mechanism beautifully accommodated the data that had been gathered about structure, subunit composition, and catalysis of the enzyme. One important question that remained at this point was what type of conformational transition enables the catalytic sites to sequentially change their conformation and function. The first suggestion that a rotation of internal subunits was part of the catalytic mechanism was published in the early 1980s, also by Boyer [8, 9] (for review see [10]).

Tremendous progress in our knowledge about the mechanism of ATP hydrolysis and synthesis was made in the past decade, gaining even more momentum when a high resolution structural model of the beef heart mitochondrial F_1-ATPase was presented in 1994 by Walker's group [11]. An X-ray crystallographic model of the beef heart mitochondrial ATPase is shown in Figure 3. The model gives detailed information about the structure of the nucleotide binding sites. In the model two of the catalytic sites are rather similar in conformation, whereas the third catalytic site differs significantly from the others in structure. This third side does not have a nucleotide bound (at least in the crystal structure), and a whole section of the binding site is rotated to form a very open conformation (able to release product). The model shows all the noncatalytic sites to be very similar in structure.

Several other structural models of various subassemblies of F_1 or F_0F_1 from a variety of different sources have become available over the last few years [12–16], increasing our knowledge about the structural basis of the ATPase and ATP synthase.

The structural models made rational mutagenesis of key residues within the nucleotide binding sites possible and allowed researchers to monitor the occupancy of the nucleotide sites during turnover using biophysical techniques

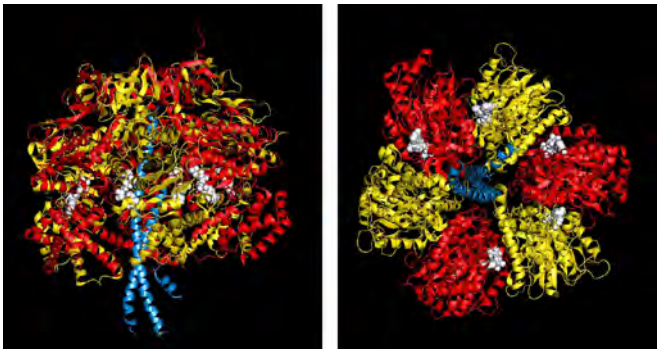

Figure 3. X-ray structural model of the mitochondrial F_1-ATPase [10] Left: side view, right: view from the membrane surface. The molecular coordinates of a variety of different F_1-ATPases from different sources are available in the Protein Data Bank. Here the model is based on the coordinates of the beef heart mitochondrial enzyme as described in [10]. The model was created using the program Rasmol and the molecular coordinates from the Protein Data Bank.

[17]. These biophysical data suggested that at maximal turnover conditions and saturating ATP, all three catalytic sites are occupied in F_1 as well as in solubilized F_0F_1 [17–20]. Experiments from our group using electron spin resonance spectroscopy and spin-labeled nucleotides suggested that under equilibrium conditions almost all nucleotide binding sites are filled [21–23].

3. ROTATIONAL MECHANISM OF THE F_1-ATPase

For about 15 years researchers tried to provide evidence that rotation of some of the subunits in F_1 was indeed a part of the mechanism of the ATPase. Especially after the X-ray structural models of the F_1 clearly placed the γ-subunit into the central cavity inside the ring of three α and three β subunits and showed its asymmetric interactions with the $\alpha_3\beta_3$ ring, it became likely that γ may be the subunit rotating relative to $\alpha_3\beta_3$. In different chemical and biophysical approaches, Cross's [24, 25] and Junge's [26] groups presented strong evidence that indeed such rotation was taking place. However it took until 1997 for Yoshida's group to unequivocally show in real time that F_1-ATPase is indeed a molecular motor [27]. In Figure 4 we present a diagram of the experimental set-up that Noji et al. [27] used to show that rotation occurs. A substructure of the F_1-ATP synthase from the thermophilic bacterium PS3 was used. This substructure only contains the subunits α and β as well as the γ subunit that resides in the middle of the $\alpha_3\beta_3$ ring. This assembly is very stable and hydrolyzes ATP efficiently. The β subunits of the construct were genetically modified to carry a series of histidine amino acid residues, each at one end of the polypeptide. These polyhistidines or "His-tags," as they are called, bind tightly to nitrilo triacetic acid that has a Ni^{2+} ion chelated to the carboxylic acid moieties. This compound is commonly abbreviated as Ni-NTA. In the "rotation" experiment, glass coverslips were covered with Ni-NTA. In a second step, the His-tagged F_1 was added to the top of the coverslips which resulted in F_1 that was immobilized "head down" onto the plates through

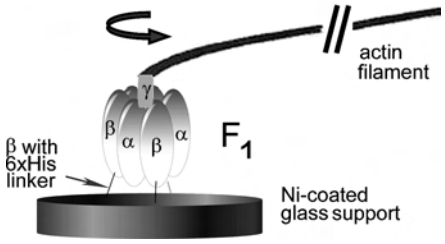

Figure 4. Diagram of a F_1-ATPase–actin construct as it was used to show rotation of the γ-subunit relative to $\alpha_3\beta_3$ (for details of the experiment see [27]). A substructure of the F_1-ATPase that consists only of $\alpha_3\beta_3\gamma$ from the thermophilic bacterium PS3 was used and genetically engineered to contain polyhistidine residues (His-tags) at the β subunits. The His-tags were tightly bound to glass coverslips that are covered with a Ni–NTA substrate (see text). The γ subunit was further genetically and chemically modified to carry biotin that again bound tightly to streptavidin, a protein with strong affinity to 4 molecules of biotin. Actin monomers were also chemically modified with biotin, polymerized under appropriate conditions, and finally decorated with actin-specific fluorescent dyes. The preformed actin filaments were attached to the F_1 motor via the streptavidin protein. Rotation of the actin filament was observed in a fluorescence microscope.

its His-tags. The γ subunit that protrudes from the other end of the $\alpha_3\beta_3\gamma$ substructure was also genetically modified to contain cysteine residues that can be reacted with sulfhydryl-specific reagents. Here the cysteines were modified with a bifunctional reagent that introduced a biotin molecule to the γ subunit of F_1. Biotin is a small organic molecule that very tightly and specifically binds to a protein called strepavidin. Streptavidin contains four binding sites for biotin, so after binding of streptavidin to the biotin molecule that was attached to the γ subunit, biotinylated actin filaments were added to the construct. We mentioned actin before as another example of a part of a molecular motor. Actin, as part of the contractile apparatus of the muscle and part of the cytoskeleton of individual cells, is a globular, monomeric protein that spontaneously polymerizes to form stable filaments under appropriate conditions. In the experiment described by Noji et al. actin monomers were biotinylated and subsequently allowed to polymerize. In addition, a fluorescent dye was introduced into the experiment, which made the formation of the filaments visible under appropriate excitation for fluorescence to occur. Addition of such modified actin filaments was the final step in the visualization of a very impressive molecular motor. With a fluorescence microscope, Noji and colleagues were able to observe the rotation of the γ subunit in real time.

In the initial experiments, they observed rotation of actin filaments of up to 4 μm in length in the presence of ATP for several minutes and hundreds of revolutions. The rotation always occurred counterclockwise when viewed from the direction of the membrane (or here from the top). Between 0.2 and 10 revolutions/s were observed, depending on the length of the filaments attached (1–4 μm). To put this into a "macroscopic" perspective, the "height" of the F_1-construct from the glass plate to the end of subunit γ is about 15 nm, and the length of the actin filament that can be rotated by this motor is up to 4 μm, or 4000 nm, which makes it about 260 times the size of the F_1 molecular motor. If one imagines F_1 to be the size of a human being, about 1.50 m tall, that motor would be able to rotate a construct that is 400 m long and roughly 1 m in diameter in an aqueous environment.

It was, however, not a trivial undertaking to observe the rotation. Thousands of assembled F_1-actin filament constructs had to be monitored and stringent controls were necessary to show without a doubt that ATP hydrolysis-dependent rotation of the γ subunit really took place. Considering the complicated setup of the experiment and the dimensions of the reaction partners, this is perhaps not so surprising indeed. In the meantime, a number of research groups have repeated the experiments using F_1-ATPases from different sources and of different substructure composition.

More recently, various research groups were able to show that the ring of c subunits of F_0 within the membrane rotates. When the driving force of the proton gradient across a membrane is strong enough, the downhill flow of the protons drives the rotation of the ring of c subunits within the membrane, resulting in the rotation of the γ subunit. It appears that the rotation of the γ subunit in itself causes the necessary conformational change to allow ATP to be released from the ATP synthase. In the opposite direction, hydrolysis of ATP resulted in the rotation of subunit γ as was shown in the soluble, nonmembrane-associated system. This subunit γ rotation then caused the rotation of the ring of subunits c, resulting in the pumping of protons across the membrane in an ATP-driven fashion [28–31] (for reviews, see [32 and 33]).

A diagram of the construct used to explore the rotation of the ring of c subunits is shown in Figure 5. In a recent paper [34] it was shown, using chemical cross-linking of various subunits of the F_0F_1 synthase, that when the rotor subunits c are immobilized onto Ni–NTA-coated glass plates using histidine tags and a Ni–NTA surface, the subunits of the synthase that usually do not participate in rotation (a, b_2, and the $\alpha_3\beta_3$ ring, also called the stator subunits) rotated when ATP was added as a fuel to the artificially prepared membrane systems. The results strongly indicated that the

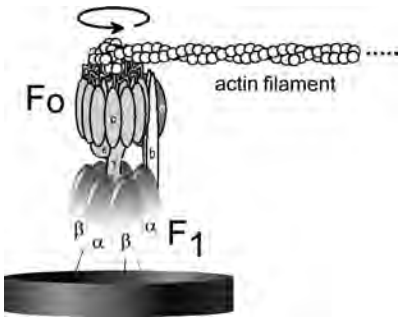

Figure 5. Diagram of a construct to show the rotation of the ring of subunits c (for more details see [30]). In addition to the histidine tag that allows the F_1 portion of the enzyme to be immobilized on glass slides, a second affinity tag (here a so-called Strep-tag) was introduced to the ring of subunits c. Strep-tags efficiently bind to streptavidin or related proteins and also bind to biotin molecules that were attached chemically to a fluorescently labeled actin filament. The rotation of the actin filament again can be observed in a fluorescence microscope.

membrane-embedded F_0F_1-ATP synthase could be divided into mechanical units that rotate relative to each other upon powering the system with fuel, ATP, or a H^+ gradient.

4. ENERGY AND TORQUE OF ROTATION

Isolated F_1-ATPase hydrolyzes ATP at a rate of about 300 molecules/s. For the load-free motor this would correspond to 100 revolutions/s because 3 ATP molecules are hydrolyzed per full rotation. The rotation of subunit γ was shown to be a three-step process [35–39], with each step corresponding to the hydrolysis of 1 ATP molecule. At low ATP concentrations (1 μM) even smaller rotational substeps of 90° and 30° were resolved [39] that were attributed to the binding of ATP and the release of ADP. Using the F_1-actin filament construct with 1 μm filament length and low ATP concentrations that only allow slow rotation, Yasuda et al. [40] observed distinct steps where the actin filament rested in 120° intervals.

Calculated from the rotational velocity, the torque reached during rotation is >40 pN·nm. By comparison, the sliding force that linear motors like myosin and kinesin (that were mentioned in the Introduction) generate is much smaller. Myosin produces a sliding force of 3–6 pN [41, 42] and kinesin a force of 5 pN [43]. The energy required to generate the torque in F_1 is about 8×10^{-20} J for a 120° rotation step. The free energy that is provided by the hydrolysis of one ATP (one ATP is hydrolyzed for a 120° rotation) is about 9×10^{-20} J. In other words, Nature has designed here a nanomotor, the ATP synthase, which runs at more than 90% efficiency. The efficiency may even be higher if the viscoelastic mechanics of the ATPase–actin construct are considered.

In two "head-to-head" papers [44, 45], Junge and coworkers studied the effects of slow viscoelastic relaxation of the actin filament on the torque generated by the F_0F_1 holoenzyme. The construct they used is depicted in Figure 6.

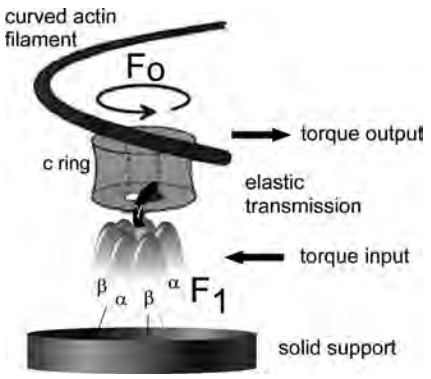

Figure 6. Diagram of an experiment to determine the torque generated by the ATPase (for more details see [44]). The basis of the experiments to determine the torque generated by the F_0F_1-ATP synthase is as described in the legend to Figure 3. The F_1 part is fixed to glass slides using oligo-histidine tags and a Ni–NTA-coated surface. The ring of c subunits carries Strep-tags that allow the actin filament to bind. The analysis of the viscoelasticity of the actin filament was performed using video microscopy in an inverted fluorescence microscope.

The results of these experiments and theoretical analysis suggest that indeed the torque that is generated by the synthase (here being powered by the electrochemical proton gradient) exceeds 40 pN · nm and was estimated to be more in the range of 50 ± 6 pN · nm. There were only very small variations in the torque output of the motor, implying a soft, elastic power transmission between the two parts of the motor, F_0 and F_1. This elastic transmission seems to be an essential feature to allow this biomotor to perform under such high turnover rates. The higher torque value that was calculated also shows that indeed this nanomotor works with almost perfect energy efficiency.

5. POWERING NANOELECTROMECHANICAL SYSTEMS

Very soon after details of the rotary mechanism became known, researchers started to investigate the nanomechanical world. Montemagno and his co-workers pioneered in this work and reported the "powering [of] an inorganic nanodevice with a biomolecular motor" in *Science* in 2000 [46, 47]. It is interesting to note that at the time this research was performed, Montemagno and his group were located at the Cornell University in Ithaca, NY. From this same university some 40 years before, Racker, Penefsky, and co-workers reported that they had isolated a soluble "factor" from beef heart mitochondria that hydrolyzed ATP [48]. They reported that this factor could restore ATP synthesis in mitochondrial membranes that had lost this ability during isolation. They called this interesting protein the "factor 1" or F_1 for ATP synthesis.

The Montemagno group used a substructure of the F_1-ATPase from the thermophilic bacterium PS3 that contains only the basic rotor assembly consisting of the subunits α, β, and γ, similar to the experiments described by the Yoshida group [27]. In initial experiments, procedures for the specific attachment and positioning of the nanoelectromechanical systems (NEMS) were tested [47]. Using electron beam lithography, an array pattern was etched on a 25 mm coverslip. The coverslips were then patterned with metal substrates such as gold, copper, or nickel. A synthetic peptide containing a polyhistidine tag as described above was allowed to attach to the metal-coated coverslips. The peptide had a microsphere covalently attached to the opposite side, and laser tweezers were used to test the strength of the attachment to the metal surface. Nickel was found to be the most promising candidate, and, therefore, in their following paper [46], the group presented a method to generate nanofabricated Ni posts of a diameter of 50–120 nm and a height of 200 nm. Ni posts were chosen as a "stand" for binding the ATPase motor to prevent problems that are associated with "dragging" the "propeller" unit in close proximity to the base of the motor. Nickel propeller rods were generated and their dimensions were optimized for optical detection and minimal friction during the rotation process. The propellers were then coated with biotinylated peptides that also carried histidine tags. The polyhistidines allowed binding of the peptides to the Ni rods, while the biotinylation allowed

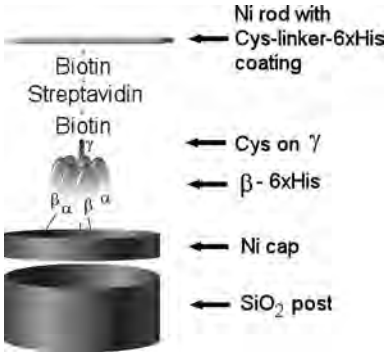

Figure 7. Diagram of a nanoelectromechanical system as developed by the Montemagno group, (for more details see [46]). An F_1 substructure containing $\alpha_3\beta_3\gamma$ is immobilized via His-tags onto Ni post structures with a diameter of 50–120 nm and a height of 200 nm. Subunit γ was biotinylated and using the biotin–streptavidin–biotin construct, a spacer is formed that binds to prefabricated Ni rods that have been covered with His-tagged oligopeptides. Upon addition of ATP, the ATP-driven rotation of the γ subunit can be visualize as a rotation of the Ni rod.

the interaction of the propellers with F_1 that carried a streptavidin protein at the γ subunit. Functional NEMS were constructed by sequential addition of the individual components: F_1-ATPase was biotinylated at its γ subunit through specific modification of engineered cysteine residues in the appropriate position. The biotinylated F_1 was placed onto the Ni posts by virtue of the histidine tags that were located at the β subunits of the constructs. Next, streptavidin was bound to the biotin molecules attached to the γ subunit and finally the Ni propellers decorated with biotinylated peptides were added and assembled onto the motor. One model for an appropriate design is shown in Figure 7.

Finally, and most ingeniously, the F_1 part of the NEMS was further modified to contain a chemical switch that allowed the system to be turned on or off, without having to run the motor out of its power source, ATP [49]. Using computational design methods [50–53] and molecular biological methods Hellinga and co-workers constructed a binding site for Zn^{2+} ions. Using the original construct of the motor with an actin filament attached to the γ subunit, they showed that rotation occurred in the absence of Zn^{2+} ions, was inhibited in the presence of Zn^{2+}, and could be reestablished when Zn^{2+} was removed from the mixture. A very similar approach was used by Hisabori and co-workers [54] who introduced a chemical switch into the γ subunit that could be turned off in the presence of oxidants such as $CuCl_2$ and switched back on upon reduction with dithiothreitol, a reducing agent, and thioredoxin, which is found to be a natural regulator of the ATPase that is found in chloroplasts.

6. OUTLOOK

The first steps for the ATP synthase into the "nano-world" have already been successfully performed. Whether it will be used as a pump in nanoscale chemical reaction chambers, a three-step switch to modulate flow of fluids or electricity, or even a motor to drive nanosubmarine structures, it will be solely up to the imagination of researchers, both in engineering and in natural sciences, to see the future and limitations of use for such highly intriguing devices.

GLOSSARY

Adenosine-5′-diphosphate (ADP) Corresponds to ATP with one less phosphoryl group.

Adenosine-5′-triphosphate (ATP) A biological molecule that is used in all organisms for short-term energy storage.

Biotinylation Chemical linking of biotin to another biomolecule.

His-Tag A series of (usually) six histidine residues that are genetically attached to recombinantly produced proteins. The histidine residues form complexes with Ni^{2+} ions and allow affinity purification of the corresponding proteins.

Inorganic phosphate (P_i) Salt of phosphoric acid.

Micromolar (μm) One micromole of a compound dissolved in 1 liter of a solvent. One micromole equals 10^{-6} mole.

Nanoelectromechanical system (NEMS) An inorganic particle (here a Ni rod) that is linked to a biological system (here the F_1-ATPase).

Ni-Nitrilo triacetic acid (NTA) Nitrilo triacetic acid that has Ni^{2+} ions chelated to the carboxylic acid moieties. The reagent is commonly used for affinity chromatography to specifically bind proteins that have oligo histidine tags attached.

Nanoparticle Drug Delivery to the Brain

K. Ringe, C. M. Walz, B. A. Sabel

Otto-von-Guericke Universität Magdeburg, Magdeburg, Germany and Nanopharm AG, Center for Neuroscience Innovation and Technology, Magdeburg, Germany

CONTENTS

1. INTRODUCTION

The blood–brain barrier (BBB) protects the brain against toxic substances that circulate in the bloodstream. Although this is life-supporting protection for the brain, the existence of the BBB is a severe limitation for the delivery of most drugs to the brain because they do not cross the BBB in sufficient amounts. A large number of potentially useful drugs, such as cytostatics and central nervous system (CNS)-active agents, do not cross the BBB at all or in insufficient quantities. However, for therapeutic reasons methods to increase the bioavailability of drugs in the brain are needed to deliver drugs to the brain which are usually blocked from entering the brain by the BBB.

One possible way to achieve this goal is to attach drugs to nanoparticles and thus transport them across the BBB. Nanoparticles are solid colloidal particles, ranging in size from 1 to 1000 nm (usually 200–300 nm), and they are a rather useful "drug delivery system" to target drugs to the brain. Here, we review the structure and the role of the BBB and describe the manner whereby molecules normally pass through the BBB. Furthermore, we will discuss how nanoparticles can be prepared and purified and review their physicochemical properties and drug release mechanisms. We then discuss the evidence that nanoparticles can be used to deliver drugs to the brain in the living animal and document their usefulness in some animal models.

2. TRANSPORT OF MOLECULES ACROSS THE BLOOD–BRAIN BARRIER

In some cases potentially useful compounds to treat brain disorders are injected into the bloodstream or given orally, but they do not reach the brain at all or not in sufficient amounts (insufficient bioavailability). Therefore, therapeutic efficiency to treat brain diseases is diminished or prevented because systemic administration of the drug does not lead to an effective brain concentration [1–4]. There are many reasons why this may be the case: the molecules may be too large, they have unfavorable physiochemical properties (such as polar functional groups), they may be metabolized by enzymes before reaching their target (the brain), or they may be extruded at the cerebrovascular endothelium well before reaching the brain cells (neurons) upon which they should act. The major reason why drugs do not reach the brain is the existence of the BBB [5–7]. To develop methods to overcome this barrier, a good understanding of its nature is required.

2.1. The Physiology of the Blood–Brain Barrier

The BBB is not one single structure or membrane in the brain, but it is created by the way the blood vessels in the brain are organized. Thus, understanding the BBB requires an understanding of the anatomy and physiology of the blood vessels in the brain. Both large and small capillaries form a richly branched and complex network throughout the entire brain tissue. Like a chimney made of individual bricks, the brain blood vessels consist of a monolayer of endothelial cells that are connected with each other by tight junctions (zonulae occludentes) [8]. The part of the cell's membrane facing the bloodstream is called the "luminal" membrane [9–11], and the side which is exposed to the actual brain tissue is called the "abluminal" membrane. This part faces the extracellular liquid of the brain parenchyma where pericytes and endfeet of astrocytes surround the blood vessels.

The most important site of the BBB lies at the cerebral microvessels, that is, the very fine vessels that have extremely small diameters. Because endothelial cells are very polarized, that is, essentially similar to the epithelium, they exhibit very low pinocytic activity and possess a high number of mitochondria that are needed for the multiple energy-dependent active transport mechanisms found in endothelial cells [12].

Peripheral vessels in the rest of the body can much more easily transport molecules across their membrane because they are fenestrated and have many active transcellular transport mechanisms. In contrast, in central blood vessels of the brain, even small molecules like antibiotics have great difficulty crossing the barrier and only a limited number of molecules can actively cross the endothelial cells. Here, the endothelial cells use specific transport systems to allow the influx of glucose, iron, amino acids, peptides, small organic acids, and others. This is necessary so that substances which are critical for brain metabolism and function can gain fast and efficient access to the brain via specific energy-dependent carrier mechanisms at the endothelium [13].

2.2. The Role of Pericytes

Pericytes, which are located on the abluminal side of the endothelial cells, are also part of the BBB. Pericytes are a physiological heterogeneous cell population and are found on all microvessels in nearly every organ [13], but they never cover the entire blood vessel. The pericytes, which are located on the "brain side," are encapsulated by the basal membrane of the endothelial cells, and they are responsible for the synthesis and release of different components of the basal membrane and the extracellular matrix such as collagen and glycosaminoglycocan [14]. The basal membrane of the endothelial cells and that of the pericytes are closely attached to each other so that both cells have a common basal membrane [15]. Electron microscopy studies have revealed fenestrations between pericytes and endothelial cells [16], and pericytes have contractile properties that may play a role in the regulation of the blood flow. Several molecules are involved in these contractile functions such as actin, myosin, tropomyosin, vimentin, and desmin [17–19]. Pericytes have an important role in the function of the BBB. They are responsible for the maintenance of the barrier function and the stability of the vessel [20].

2.3. The Role of Astrocytes

Astrocytes (which are brain glia cells) also contribute to the BBB, and they are attached with their endfeet to the pericytes and the endothelial cells. Astrocytes are glial cells responsible for the homeostasis and the ion regulation in the brain [20], but their endfeet cover the blood vessels only partially. In contrast to endothelial cells and pericytes, astrocytes are not connected to other cells by tight junctions, and they do not have a common basal membrane. Therefore, polar molecules (such as proteins) can enter the interstitial liquid and be directly transported to the pericytes and the endothelial cells [21].

That astrocytes are important for the induction and maintenance of the BBB properties can be deduced from the following observations in cell cultures: in the presence of astrocytes or medium conditioned by astrocytes, endothelial cells express markers important for BBB characteristics and develop tight junctions [9–11]. On the other hand, endothelial cells promote the development and differentiation of astrocytes. This interaction between both cell types actually occurs even when there is no contact between the two cell types, indicating that some soluble, extracellular factors are mediators of BBB development.

3. TRANSPORT MECHANISMS OF THE BLOOD–BRAIN BARRIER

Although the BBB is a fairly "tight" structure when "unfriendly" molecules try to enter the brain, it does have several mechanisms to allow "friendly" molecules to get in. Among them are active, carrier-mediated transport mechanisms for relatively small molecules, an absorptive-mediated endocytosis mechanism for positively charged peptides, and receptor-mediated endocytosis mechanisms specific to certain peptides. For the structure of the BBB see Figure 1.

3.1. Transport of Anionic Compounds

Various anionic compounds are transported across the BBB by the monocarboxylic acid transporter (MCT) [22, 23]. Lactic acid, for example, is transported by a specialized mechanism and not by nonionic passive diffusion [24, 25].

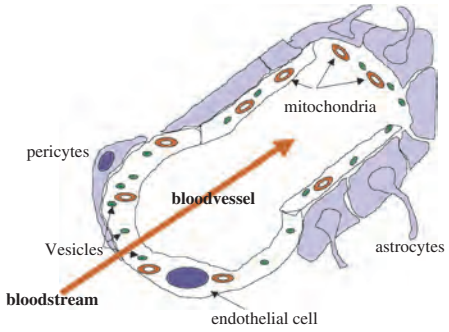

Figure 1. The blood brain barrier (BBB).

MCT1 is present in the BBB and acts as a transport mechanism for lactic acid and other monocarboxylic compounds [26].

3.2. Transport of Cationic Compounds

Cationic compounds enter the brain by passive diffusion and also by carrier-mediated transport, which is believed to be the mechanism of action whereby several drugs cross the BBB [27–32]. An endogenous hydrophilic amine, choline, has been demonstrated to be taken up by a carrier-mediated transport mechanism [29–31], and a carrier-mediated amine transport system is likely to be responsible for transport of cationic compounds across the BBB.

3.3. Transport of Peptides

Because peptides are usually relatively large, hydrophilic, and unstable, efficient permeation into the brain generally does not occur [33]. However, certain relatively small peptides are transported by carrier-mediated transport mechanisms, and others cross the BBB by transcytosis including receptor-mediated transcytosis and absorptive-mediated transcytosis.

3.4. Carrier-Mediated Transport of Peptides

Because the transport of glutathione across the BBB is saturable [34, 35], carrier-mediated transport that has a high efficiency comparable to the brain uptake of single amino acids such as phenylalanine and cysteine is probably involved.

3.5. Absorptive-Mediated Endocytosis

Absorptive-mediated transcytosis is triggered by electrostatic interactions between the positively charged moiety of the peptide and the negatively charged plasma membrane surface region [36–39]. If one attempts specific targeting to the CNS, absorptive-mediated transcytosis is not expected to be useful, because absorptive-mediated transcytosis or endocytosis also functions in other tissues such as kidney and liver [38].

3.6. Receptor-Mediated Endocytosis

To get peptides to cross the BBB they need to be manipulated in a manner such that penetration into the brain is achieved. Sometimes this is achieved by synthesis of chimeric peptides. They are formed by covalent binding of the nonpermeable but pharmacologically effective portion of the peptide to an appropriate vector that can be transported across the BBB [38]. In this case, the chimeric peptide is first transported into the brain endothelial cytoplasm by receptor-mediated or absorptive-mediated endocytosis. The intact chimeric peptide is then transferred into the brain's interstitial space by receptor-mediated exocytosis. Subsequently, the binding between the vector and the pharmacologically active peptide is cleaved and, finally, the released peptide exerts its pharmacological effect in the brain [36, 38, 40, 41].

3.7. Efflux by P-Glycoprotein

Several anticancer drugs such as vinca alkaloids and anthracyclines exhibit lower accumulation in the brain than would be expected from their lipophilic properties [42, 43]. Furthermore, tumor cells show a resistance to anticancer drugs such as anthracyclines and other nonrelated compounds [44]. This multidrug resistance is accompanied by overexpression of the transmembrane P-glycoprotein and a decrease of drug concentration in the resistant cells compared with that in drug-sensitive cell lines [45, 46]. P-glycoprotein molecules are located at the luminal side of the endothelial cells and their function is to serve as an energy-dependent efflux pump and transport various drugs out of cells, thus decreasing their accumulation in the cytoplasm, and, as a consequence, reducing their efficiency [46–48]. P-glycoprotein has a very broad substrate specificity [49–51].

3.8. Transport of Drugs across the BBB

Given the highly selective nature of the BBB, the question arises as to how drugs that usually do not cross the BBB can still be delivered to the brain. An estimated 99% of all potential drugs are clinically useless because the BBB prevents them from getting into the brain. Thus, finding ways to overcome the BBB are of great clinical significance.

There are two fundamental ways to get drugs into the brain. The first and most invasive method is application of the drug directly into the brain. This can be done by intracerebral injection or infusion or by artificial drug delivery systems such as polymer implants that release drugs in a sustained manner [52]. For example, anticancer drugs are often applied by intraventricular infusion, but this is a rather invasive technique with high risks. In view of the rapid turnover of the cerebrospinal fluid, however, the pharmacological compound is rapidly removed from the brain into peripheral blood vessels and the diffusion-dependent concentration in the parenchyma is far below desirable levels.

The second and most favorable method is to manipulate or "trick" the BBB, so that neurologically active compounds can be given systemically by oral, intramuscular, or intravenous application.

Here, several different approaches are possible: osmotic opening of the BBB or pharmacologically by raising the lipophilicity of the drug using chimeric molecules or by attaching drugs to nanoparticles [53].

3.9. Osmotic Opening of the BBB

The BBB can be opened by osmosis or by biochemical and pharmacological means [54–56]. Application of hyperosmotic mannitol and arabinose solutions results in the local reversible destruction of tight junctions, thus increasing the permeability of the endothelial cells. For example, hyperosmolar urea solution withdraws water from the endothelial cells and leads to shrinkage of the cells and consequently to an opening of the tight junctions. As one can easily imagine, the major disadvantage of this method is that the brain loses its protection from neurotoxic substances for a certain period of time, which results in significant unwanted side effects such as brain edema [54–56].

A similar approach is the infusion of a vasoactive substance such as bradykinin or leukotriene, which increases vesicular transportation activity of the endothelial cells.

3.10. Pharmacological Approaches

Among the pharmacological approaches the most common one is increasing the lipophilicity of the drug and using chimeric proteins as well as cationized antibodies. Chimeric proteins can be transported via receptor-mediated or adsorptive-mediated transcytosis [57, 58]. Prodrugs are an excellent example of such drug manipulations. With this method, the original compound is manipulated to make it more lipid-soluble, providing greater brain penetration. However, increased lipid solubility may significantly alter pharmacokinetic parameters such as clearance and half-life, which, for chlorambucil derivatives, is undesirable [58].

The third and in our mind the most desirable method to get a drug across the BBB is the novel technique of nanoparticle drug delivery. Compounds can be attached to or incorporated into nanoparticles, which serve as a universal "drug delivery system," allowing many pharmacological agents to cross biological barriers.

4. NANOPARTICLES AS A DRUG DELIVERY TOOL FOR BRAIN TARGETING

Over the last few years work in the laboratories of Kreuter [59, 60] and Sabel [61–64] has demonstrated the usefulness of nanoparticles as a universal tool to deliver drugs to the brain. The evidence is consistently mounting that important diseases of the brain can be treated by a combined nanoparticle/drug approach, and brain tumor treatment, in particular, has been accomplished in animal models. A variety of experiments have been carried out to date using various animal species and different behavioral paradigms and disease models, all of which substantiate the value of nanoparticles as a novel drug delivery method.

To understand the usefulness and potential of nanoparticle technology for drug delivery to the brain, we shall first describe methods of preparation, the mechanism of drug binding and release, and evidence of toxicity and efficacy. We will also briefly discuss practical matters that are important for clinical use of nanoparticles such as sterilization procedures, stability, and purification issues and then discuss the evidence indicating their usefulness as a tool for delivery of drugs to the brain.

5. PREPARATION OF NANOPARTICLES

There are different methods to manufacture nanoparticles: (1) emulsion polymerization, (2) interfacial polymerization, (3) solvent evaporation, (4) solvent deposition, and (5) denaturation. The properties of nanoparticles vary with different polymers, stabilizers, and surfactants used during the manufacturing process. Each excipient added may have an influence on the bioavailability of the drug carried, the brain drug uptake, and the stability of the drug in the plasma [65].

5.1. Emulsion Polymerization

Emulsion polymerization is one of the most rapid and most frequently used methods for nanoparticle preparation. Here, the monomer is added to a continuous phase, usually an aqueous phase at room temperature under constant stirring conditions. It is also possible to use an organic phase as the continuous phase. The polymerization can be initiated either by free radicals or by ion formation. The polymerization is initiated by the reaction of a monomer molecule with an initiator molecule. Triggers for the initiation of the reaction can be ultraviolet (UV) light, hydroxyl ions, or high-energy radiation. The polymer chain starts to grow when these initiated monomer ions or monomer radicals react with other monomer molecules. Additional monomer is solubilized in surfactant micelles or emulsified in larger droplets. After completion of polymerization, the reaction mixture is filtered, neutralized, and purified by centrifugation to remove any residual monomer. An example for an anionic process is the preparation of "poly(alkylcyanoacrylate) nanoparticles" and an example for a free radical-initiated emulsion polymerization is the manufacturing of polymethyl methacrylate nanoparticles [66]. The process of emulsion polymerization has numerous advantages. Compared with other methods, it is rapid and in general there is no need to use stabilizers and surfactants. In addition, for industrial requirements it is easily scaled up [67]. In contrast, with the requirement of UV light, radiation, or free radicals to initiate the polymerization process, the incorporation of proteins and peptides during the polymerization is not possible. Furthermore, if one wishes to scale up this procedure, the need for purification of the nanoparticles via dialysis and centrifugation represents a problem [68]. The mechanism of an anionic polymerization is shown in Figure 2.

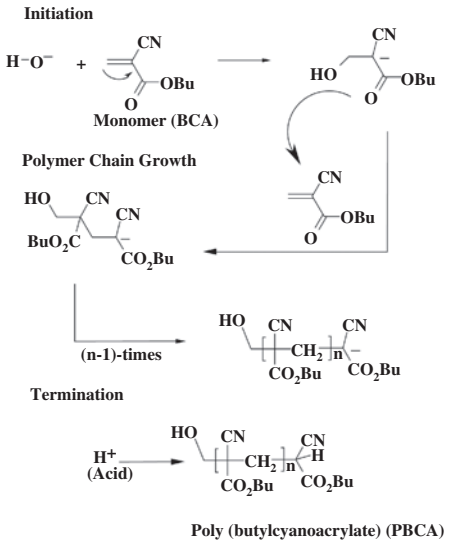

Figure 2. Mechanism of polymerization.

5.2. Interfacial Polymerization

To achieve interfacial polymerization, monomers are polymerized at the interface between two immiscible phases. Interfacial polymerization takes place in a medium consisting of an aqueous and an organic phase, which are homogenized, emulsified, or micro-fluidized by vigorously mechanical stirring. Al Kouhri Fallouh et al. [69] introduced the formation of polyalkylcyanoacrylate nanocapsules. In this process the monomer and the drug are dissolved in a mixture of oil and ethanol (oil/ethanol: $\frac{1}{10}$ to $\frac{1}{200}$) and then slowly added through a small tube or needle to an aqueous phase containing surfactants (poloxamer 188 or 407 or phospholipids). The oil used can be Miglyol or benzylic acid. The primary disadvantage of this method is the occurrence of strong shear forces. This excludes the possibility of adding proteins and peptides during the polymerization process for incorporation purposes. The monomer spontaneously polymerizes and forms nanocapsules that consist of an oil droplet and a polymeric shell [69]. An advantage of this process is that the drug is encapsulated into the nanocapsule and not just adsorbed onto the surface. This would protect it from enzymes, thus preventing premature biodegradation before it reaches the blood brain barrier.

5.3. Solvent Evaporation

The solvent evaporation method is a well-established and frequently used method for the manufacturing of particles with sizes above 1 μm and also sizes of less than 1000 nm. In this process the preformed polymer and the drug are dissolved in a volatile, water-immiscible organic solvent. This organic phase is then added to the aqueous phase under stirring, and the organic solvent is removed by heating and/or under reduced pressure. The polymer precipitates and forms micro- or nanospheres instantaneously, containing the drug dispersed in the polymer matrix network. The particles are then purified by filtration and centrifugation [70]. Examples of this process are the manufacturing of poly(lactic acid) nanoparticles and poly(lactic-coglycolic acid) nanoparticles [71, 72].

5.4. Solvent Deposition

In this process the polymer, e.g., poly(DL-lactide), and phospholipids are dissolved in a volatile organic solvent such as acetone. Then a solution of the drug in benzyl benzoate is added to the organic phase and the reaction mixture is poured into the water phase, which contains poloxamer 188 under moderate stirring conditions. Nanocapsules consisting of an oily core and a poly(lactic acid) shell are formed instantaneously. The organic solvent is then removed under reduced pressure. Partial removal of water also occurs [73, 74].

5.5. Denaturation

Nanoparticles can also be produced by denaturation of natural macromolecules such as albumin and gelatin in an oil emulsion. For this procedure the macromolecule is dissolved in an aqueous solution and the drug is entrapped in an oil emulsion. Then both phases are emulsified using a homogenizer. The size of the forming particles depends on the stirring velocity, slit width, and power of the homogenizer. Then the particles are hardened by cross-linking with an aldehyde, by heat denaturation, or by cooling below the gelation point [75–77].

6. PURIFICATION

All processes mentioned above require purification except for the emulsion polymerization process in some cases, when no surfactant and no organic solvents are used to produce nanoparticles. In general, the organic solvent is removed under reduced pressure and the resulting particles are purified by ultracentrifugation, ultrafiltration, gel chromatography, dialysis, or a combination of these methods. The choice of the appropriate purification method depends on the release properties of the nanoparticles. Inappropriate purification methods can lead to the loss of biologically active agent. Stabilization of the nanoparticles is usually achieved by lyophilization using a cryoprotector (such as mannitol) to prevent agglomerations [66].

7. STABILITY

The stability of poly(butylcyanoacrylate) nanoparticles was examined in water, in phosphate-buffered saline, in acidic medium (0.01 or 0.1 N HCl), and in human blood serum [78, 79]. The authors found that in acidic medium no formation of agglomerates occurred and no degradation took place. The nanoparticles could therefore be stored in acidic medium for several months. In contrast, when suspended in water or phosphate-buffered saline, the nanoparticles agglomerate. Nanoparticle polymers did not degrade in solution as indicated by the fact that they kept their size constant. In human blood serum no formation of agglomerates was observed, and nanoparticles were stable for 8 days. This result supports the possibilty of the use of nanoparticles for intraveneous administration, because microembolisms due to agglomeration are not expected.

8. STERILIZATION

An important prerequisite for the use of nanoparticles clinically is sterilization of the nanoparticle/drug complex. The possibility of sterilizing poly(butylcyanoacrylate) nanoparticles was studied by Sabel et al. [80]. Nanoparticle suspensions and nanoparticle powders were submitted to autoclaving (121° C for 20 min with or without cooling to 70° C afterward) or treated with formaldehyde (60° C). The nanoparticles were prepared using different stabilizers, such as dextran 70,000, poloxamer 188, and polysorbate 85. In most cases the authors detected a significant increase in particle size. For lyophilized nanoparticles no powder was suitable for preparing injectable suspensions. In particular, the resuspension of nanoparticle powders caused problems, which could not be overcome by intensified sonication. Under certain conditions poloxamer 188 suspensions and polysorbate 80 suspensions led to injectable nanoparticle

suspensions. In summary, sterilization of nanoparticles after fabrication is possible under certain conditions, but the favored way to obtain aseptic material seems to be the production of nanoparticles under aseptic conditions.

9. CHARACTERIZATION

The most important feature of nanoparticles is their small size. Therefore, some understanding is needed of how to manipulate and measure the size of nanoparticles. There are many different parameters that influence the size of particles during the manufacturing procedure. These are the pH of the reaction medium, the stirring velocity, the slitwidth, and the duration of ultrasonification. Besides size, there are also other physical parameters important for nanoparticles such as density, molecular weight, crystallinity, release, and degradation properties. The surface charge, hydrophilicity, and hydrophobicity significantly influence the body distribution of nanoparticles and, respectively, the bioavailability of the bound drug. Kreuter [66] reviewed the most common physicochemical methods for the characterization of nanoparticles. The size of nanoparticles is determined using photon-correlation spectrometry. This method, which quantifies light scattering, determines the hydrodynamic diameter of the nanoparticles via Brownian motion. It is important to verify the results obtained by this method using electron microscopy, because larger particles, such as dust or accidential microbial contamination, could lead to incorrect results [81, 82].

10. DRUG LOADING

Drugs can be loaded onto nanoparticles by adding them to a solution that contains previously prepared nanoparticles or by adding them to the reaction mixture during the polymerization process. Both methods can supply (1) a solid solution of the drug in the polymer [83, 84], (2) solid colloidal nanoparticles with dispersion of the drug in the polymer [85], (3) adsorption of the drug onto the surface of the nanoparticle [86], (4) chemical binding of the drug to the polymer [87], or (5) no binding or incorporation at all. Figures 3 and 4 show the two possible ways of drug loading.

The amount of bound drug and the type of interaction of drug and nanoparticles depend on the chemical structure of the drug and the polymer and the conditions of drug loading. The determination of the adsorption isotherm is one

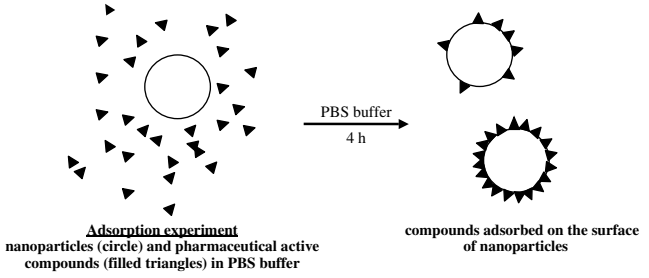

Figure 3. Drug loading of nanoparticles by adsorbtion.

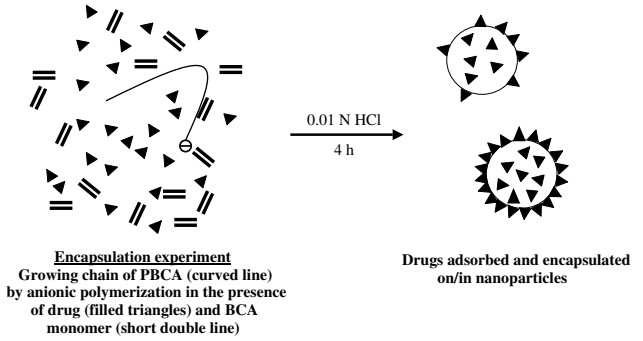

Figure 4. Drug loading of nanoparticles by encapsulation.

possible way to detect the type of binding and the binding rate (mg drug/mg nanoparticle) [88]. Linear sorption isotherms characterize solid solutions [84] and Langmuir- or S-type isotherms characterize surface adsorption [89]. Because nanoparticles are colloidal systems, precise determination of the drug content can be a problem. Therefore, the most reliable way is to separate the nanoparticles from the solution containing unbound drug by ultracentrifugation or gel filtration [90]. The amount of bound drug can be determined by subtracting the drug content in the supernatant from the primary amount of drug present in the suspension [66].

11. DRUG RELEASE

For manipulation of the rate and the timing of the drug release from nanoparticles, a good understanding of the mechanisms of drug release is needed.

There are five possible methods for drug release: (a) desorption of drug bound to the surface, (b) diffusion through the nanoparticle matrix, (c) diffusion through the polymer wall of nanocapsules, (d) nanoparticle matrix erosion, or (e) a combined erosion–diffusion process [66]. The pharmacokinetic analysis of drug release from nanoparticles can be described by a biexponential function

$$C_t = Ae^{-\alpha t} + Be^{-\beta t}$$

where C is the concentration of drug remaining in the nanoparticles at time t, A and B are system characteristic constants, and α and β are rate constants that can be obtained from semilogarithmic plots.

Gupta et al. [91] analyzed the mathematical problems of drug release using doxorubicin as the model drug. They proposed two main pathways of drug release. First, there is a rapid release of drug from the nanoparticles, which could stem from drug adsorbed on the nanoparticle surface. Then a slower, more controlled release takes place, which is possibly related to nanoparticle degradation or diffusion of the drug through the nanoparticle shell. Not only are the diffusion coefficient and the biodegradation rate main factors in drug release, but the biological environment also is important. Plasma proteins could be adsorbed onto the surface of the nanoparticles, so that an additional diffusion barrier is formed. On the other hand, nanoparticles could bind to

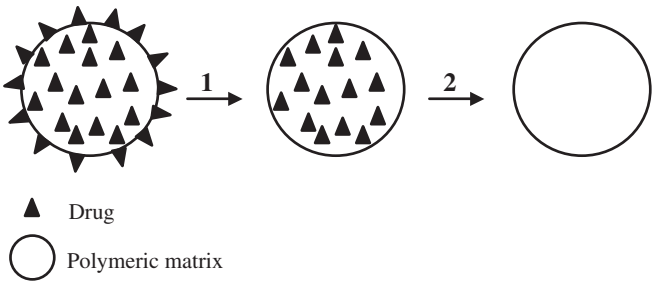

Figure 5. (1) Initial rapid desoption of drug from the nanoparticle surface; (2) Controlled release of drug by diffusion through the nanoparticle matrix and polymer wall. The release is dependent on the nanoparticle biodegradation of the polymer shell.

biological membranes, so that the transport of drugs through these membranes is facilitated. Hence, the results obtained by *in vivo* and *in vitro* drug release experiments are very different. Nevertheless, *in vitro* drug release experiments are very important for quality control reasons; see Figures 5 and 6 [66, 92, 93].

11.1. Ideal Properties of Polymeric-Based Nanoparticles

Before nanoparticles can be considered as a realistic drug delivery method, there are several properties the system needs to fulfill [94]. These are the following:

- stable in blood
- nontoxic
- nonthrombogenic
- nonimmunogenic
- noninflammatory
- no activation of neutrophils
- biodegradable
- avoidance of the reticuloendothelial system
- applicable to various molecules, such as small molecules, proteins, peptides, or nucleic acids (platform technology)
- scalable and inexpensive manufacturing process.

Because poly(butylcyanoacrylate) nanoparticles possess these properties they were reported to be useful tools for drug delivery to the brain in the several *in vivo* experiments. In addition, they exhibit very low (if any) toxicity and are considered to be relatively nontoxic. Their toxicity toward hepatocytes is rather low with an LD50 at about 0.4 mg/2 $\times$ 10^6 cells [95]. The LD50 in mice is 230 mg/kg after intraveneous application [96].

12. BODY DISTRIBUTION OF NANOPARTICLES—BRAIN TARGETING

Before discussing the evidence that nanoparticles are indeed useful to deliver drugs to the brain, we need to consider their fate after being injected into the body.

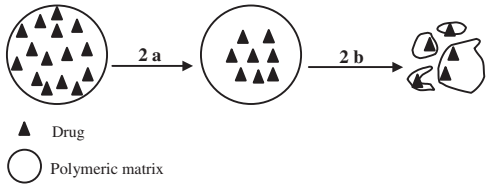

Figure 6. Combined nanoparticle erosion diffusion process. 2a: Diffusion of drug through the polymeric matrix and shell; 2b: Drug release through the biodegradation of the nanoparticle.

12.1. Fate of Nanoparticles in the Body

After intraveneous injection, nanoparticles are taken up very rapidly by the reticuloendothelial system (RES) and distribute especially into the liver (60–90%) and spleen (2–10%) and, to a minor degree, into the bone marrow. The RES consists of phagocytic cells originating from the bone marrow. The cells exist in the whole body, but their highest concentration is found in the liver (Kupffer cells), spleen, and bone marrow. Despite their great usefulness to target the brain, because of their high uptake by the RES after intraveneous injection, only a limited proportion of the nanoparticles actually reach the brain [97, 98]. Unless their surface is modified by special coatings (described below), nanoparticles themselves are of little value for delivery of drugs to the brain.

12.2. Poly(butylcyanoacrylate) Nanoparticles to Permit Transfer across the BBB

In recent years Kreuter et al. [59, 60] and Schroeder et al. [61–64] applied a special procedure to permit brain targeting of nanoparticles. This was accomplished by altering their surface with surfactants. Specifically, polymeric nanoparticles are coated with different hydrophilic surfactants. So far only poly(butylcyanoacrylate) nanoparticles possess the potential to transport drugs across the blood–brain barrier *in vivo* [99].

The most common method is to first fabricate the nanoparticles; then the drug is bound by adsorption on the surface of the nanoparticles or by forming a solid solution or dispersion. Thereafter, a surfactant is added to the nanoparticle/drug complex.

Poly(butylcyanoacrylate) nanoparticles have an average diameter size of about 200–300 nm and are very rapidly biodegraded [97, 100]. Figure 7 shows the two pathways of biodegradation of these nanoparticles. The main pathway consists of enzymatic cleavage of the butylester group of the polymer. The polymeric acid is then formed, and butanol is formed as well. Both metabolites are water soluble and will be excreted by the kidneys. During the other minor pathway, the polymer chain is degraded and formaldehyde is formed in traces, too low to be of physiological concern [101].

The first drug that was successfully delivered to the brain with this approach was the hexapeptide enkephalin, dalargin (Tyr-D-Ala-Gly-Phe-Leu-Arg). These studies were carried out first in the laboratory of Kreuter and subsequently and independently in the laboratory of Sabel.

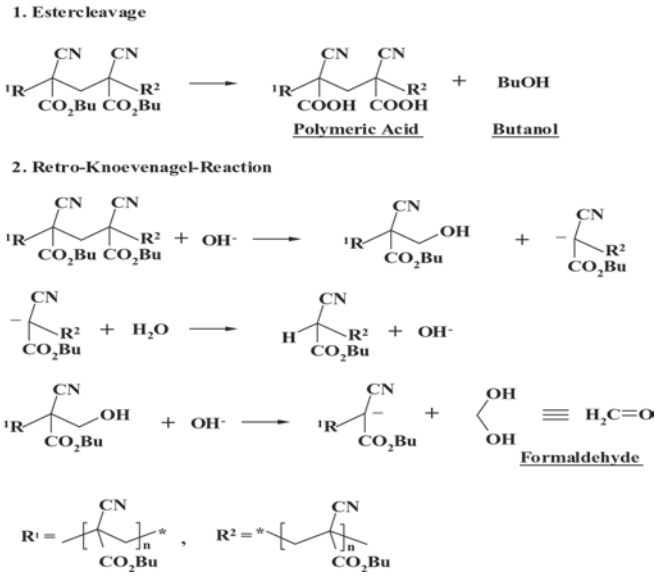

Figure 7. Biodegradation of PBCA-nanoparticles.

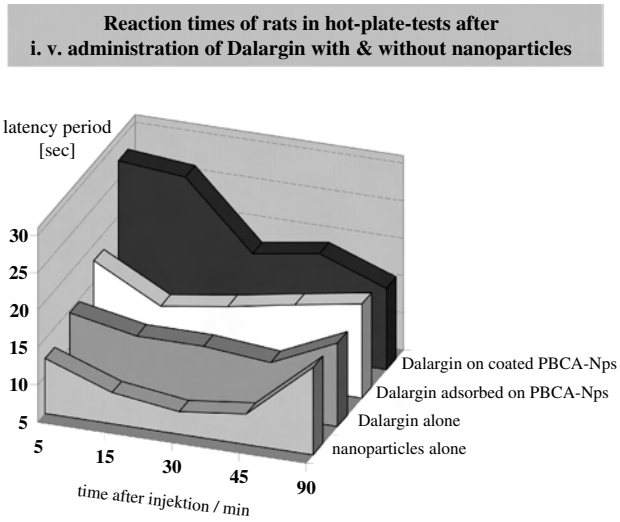

Figure 8. Central analgesic effect of dalargin-loaded nanoparticles coated with polysorbate 80 after i.v. injection.

12.3. Behavioral Evidence That Nanoparticles Can Deliver Drugs across the BBB Using Dalargin

Dalargin is an enkephalin-type peptide that has analgesic (pain-reducing) effects when injected directly into the brain. However, when given intravenously, it does not cross the BBB and no analgesia occurs [59, 102]. Studies to investigate the targeting of dalargin to the brain were carried out using the tail-flick test [59, 102] as well as the hot-plate test [61, 103]. Both tests are useful to quantify pain perception as a behavioral model of drug activity in the brain. When the rat tail is lightly pinched, the rat withdraws the tail by flicking it to the side. If an effective analgesic is given, the flicking does not occur because the rat feels no pain. Thus, one can quantify experimentally analgesic effects of a drug. In the hot-plate test the situation is similar: when placed on a hot plate, the animals will lick their paws. Time to tail flicking and time to paw withdrawal are very sensitive and reliable measures of pain perception and can thus be used to quantify analgesia.

To evaluate the usefulness of nanoparticles crossing the BBB, dalargin was bound to nanoparticles and injected into animals, which were then tested for analgesia. To be sure that drug alone or nanoparticles alone had no analgesic effect, groups of animals that received different treatments were compared: (1) dalargin alone; (2) polysorbate 80 alone; (3) poly(butylcyanoacrylate) nanoparticles alone; (4) a mixture of dalargin and polysorbate 80; (5) a mixture of dalargin and poly(butylcyanoacrylate); (6) a mixture of all three components, dalargin, polysorbate 80, and nanoparticles, mixed immediately before injection; and (7) a suspension of dalargin bound to nanoparticles without coating. After intravenous (i.v.) injection into mice, none of the groups showed an analgesic effect. Only dalargin bound to poly(butylcyanoacrylate) nanoparticles coated with polysorbate 80 produced a significant antinociceptive effect [59, 61, 102, 103]. This clearly showed that dalargin had crossed the BBB. Figure 8 shows the antinociceptive effect after i.v. administration of polysorbate 80-coated nanoparticles loaded with dalargin using the hot-plate test [61]. Apparently the coating with polysorbate 80 was the critical step in achieving the effect. This finding raised the question whether any other coating material may be useful as well.

Therefore, different coating materials in combination with the nanoparticles were used to study the specificity of the coating effect to deliver dalargin to the brain. It was found that polysorbate 20, 40, and 60 coatings have similar, but weaker, analgesic effects compared with polysorbate 80 coating. Poloxamers and poloxamines as well as surfactants of the Cremophor and Brij series [polyoxyethylene-(23)-laurylether] had no effect [60]. Thus, with a particular set of coating materials nanoparticles effectively delivered drugs to the brain after i.v. injection.

12.4. Oral Application of Peptides using Nanoparticle Technology

In the clinical setting it would clearly be desirable to avoid having to inject nanoparticles but rather to make them available also as an oral method for drug delivery. The efficacy of drug delivery to the brain using dalargin-loaded poly(butylcyanoacrylate) nanoparticles after oral application was studied by Schroeder et al. [62]. Different nanoparticle formulations containing dextran 12,000, poloxamer 188, or polysorbate 85 as stabilizer loaded with dalargin were used. No additional coating was used. The formulations were given intraveneously and orally. When polysorbate 85 was used as a stabilizer without coating, a significant analgesic effect occurred after i.v. injection as well as after oral application. Figure 9 shows the analgesic effect after oral application of polysorbate 85-stabilized nanoparticles loaded with dalargin. These results suggest that nanoparticles can also be used as a new tool for oral drug delivery of peptides [62].

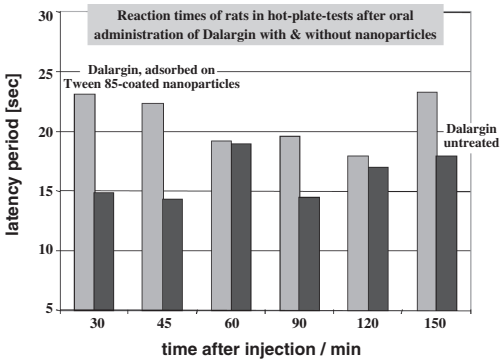

Figure 9. Central analgesic effect of polysorbate 85-stabilized nanoparticles loaded with dalargin after oral administration.

12.5. Nanoparticles as a Universal Method for Drug Delivery Across the BBB

Next the question arose whether such effects can only be achieved with the test drug dalargin or whether nanoparticles are a universal tool for delivery of drugs to the brain. Therefore, different antinociceptive agents, such as kytorphin [63] and loperamide [104] that normally cannot penetrate the BBB, were also tested using nanoparticles. Similarly to the dalargin experiments, analgesic effects of these drugs were observed. Drug solutions and uncoated nanoparticles, which served as controls, had no significant effect on analgesia, but a significant analgesic effect was obtained when nanoparticles coated with polysorbate 80 and polysorbate 85-stabilized nanoparticles without coating were used [63]. Pharmacokinetic studies of amitriptyline, a tricyclic antidepressant, bound to polysorbate 80-coated poly(cyanoacrylate) nanoparticles showed an enhancement in brain area under the curve (AUC) and a reduced serum AUC after i.v. injection. Similar results were also obtained with polysorbate 85-stabilized nanoparticles without coating [63]. AUC is the area under the curve of concentration versus time after adsorption of 20.0 mg/kg amitriptyline onto the surface of the nanoparticles after i.v. injection of amitriptyline-loaded nanoparticles in mice. The amitriptyline concentrations in serum and brain were determined after 5, 20, and 60 min after i.v. injection.

To better understand the mechanisms of action of the injected nanoparticle/drug complex, it is necessary to know its fate after injection. To this end the bioavailability and body distribution of radioactively labeled [^{3}H]-dalargin bound to poly(butylcyanoacrylate) nanoparticles coated with polysorbate 80 were studied by Schroeder et al. [64]. The studies were performed by comparing unbound ^{3}H-labeled dalargin with bound dalargin after i.v. injection into mice. The level of radioactivity in brain preparations was three times higher after i.v. injections of ^{3}H-labeled dalargin bound to poly(butylcyanoacrylate) nanoparticles and coated with polysorbate 80 after 5 and 20 min. In addition, radioactivity levels in the liver were decreased [64]. These results are compatible with the known time course of the analgesic effect found in behavioral studies 5 and 15 min after oral versus i.v. application [61, 62]. The increased dalargin level in the brain and the enhanced serum levels led to the conclusion that the drug is stabilized by the nanoparticles. This finding is also supported by the decreased liver levels. The nanoparticle formulation thus protects the labeled peptide from rapid degradation and uptake by the RES [64], thus permitting higher brain concentrations.

The question also arises whether these findings hold true only for analgesia studies or whether they generalize to other disease models as well. Here, a study by Alyautdin et al. [105] is of interest. They provoked the development of epileptiform seizures using tubocurarine bound to polysorbate 80-coated poly(butylcyanoacrylate) nanoparticles. Tubocurarine, a quaternary ammonium salt that is unable to penetrate the BBB, provokes epileptiform seizures upon direct injection into the brain. An *in-situ* rat brain perfusion technique was used and the electroencephalogram (EEG) was recorded. Tubocurarine-loaded polysorbate 80-coated nanoparticles caused the appearance of EEG seizures after 15 min. None of the controls, such as a tubocurarine solution, tubocurarine-loaded nanoparticles without polysorbate 80 coating, or a mixture of polysorbate and tubocuraine, affected on the EEG. In conclusion, only polysorbate 80-coated nanoparticles were able to transport tubocurarine across the BBB.

12.6. Influence of Nanoparticles on the Metabolism of Drugs

The use of poly(butylcyanoacrylate) nanoparticles as a transport system of antiepileptic drugs, such as valproic acid, was investigated by Schroeder et al. [106]. The authors evaluated the increase in the brain-to-serum ratio of the drug to reduce dose-related side effects in the periphery by using nanoparticles. Changes in the metabolism of valproic acid were also investigated. Mice were given four different i.v. injections: (1) valproic acid alone, (2) valproic acid + nanoparticles (dextran-stabilized), (3) valproic acid + nanoparticles (dextran-stabilized) + Tween 80, and (4) valproic acid + nanoparticles (polysorbate 85-stabilized). Twelve mice were decapitated 5, 20, and 60 min after i.v. injection. The blood was allowed to clot, and serum was taken after centrifugation. The brains were removed, cleaned, and frozen until analysis. The brain and serum levels of valproic acid and its metabolites were determined using a modified gas chromatography–mass spectroscopy assay [107]. It was found that the serum kinetics and the brain tissue levels of valproic acid did not change by administration of valproic acid/nanoparticle formulations compared with the drug alone. However, nanoparticles did influence the metabolism of valproic acid. They inhibited the metabolic degradation of the drug by mitochondrial β-oxidation but did not influence any other metabolic pathway. It was concluded that nanoparticles reduce the toxic side effects of valproic acid therapy by selectively blocking a metabolic pathway. Thus, nanoparticles may serve as a tool to change drug metabolism, probably through a sustained-release mechanism, in a desirable manner.

12.7. Nanoparticles as a Method to Delivery Cytostatic Agents to Treat Brain Tumors

In another line of research, drugs to treat brain tumors were investigated. Gulyaev et al. [108] bound doxorubicin to nanoparticles and then examined their body distribution after i.v. injection to rats. Rats were given four different formulations of doxorubicin (DOX): (1) DOX in saline, (2) DOX in polysorbate 80 in saline, (3) DOX bound to poly(butylcyanoacrylate) nanoparticles, and (4) DOX bound to poly(butylcyanoacrylate) nanoparticles overcoated with polysorbate 80. The two doxorubicin solutions showed a similar body distribution and no significant difference between plasma and organ (brain, liver, spleen, heart, or kidney) concentration. For both nanoparticle preparations a significant decrease in the heart concentration was observed. This is a very important finding, because the use of doxorubicin in the treatment of cancer is limited by its heart toxicity, which had also been noted by Couvreur et al. [109]. Only with the polysorbate 80-coated nanoparticle formulation was a high concentration of doxorubicin (>6 μg/g) achieved in brain and plasma. The low plasma level and brain concentrations (0.1 μg/g, below the detection limit) of the free drug without nanoparticles are caused by their rapid uptake by the RES [110–112]. In addition, polysorbate coating reduced the concentration of doxorubicin in the liver, spleen, and lung [108]. When taken together, these results suggest again that polysorbate 80-coated nanoparticles are a useful drug delivery vehicle for brain targeting. This and other studies by Gelperina et al. [113] described below open new possibilities for the treatment of brain cancer.

To evaluate the efficacy of a DOX–nanoparticle formulation, Gelperina et al. [113] investigated the treatment of rat brain tumors using doxorubicin-loaded, polysorbate 80-coated poly(butylcyanoacrylate) nanoparticles. To test efficacy, rats with intracranially transplanted glioblastoma 101/8 cells were treated with a DOX–nanoparticles formulation in the dose of 3×1.5 mg/kg. After 6 months these animals were killed and a beneficial effect was documented by histological examination of the brain. In the untreated control group all animals died within 17 days after implantation of cancer cells into the brain. In the remaining four groups [(1) nanoparticles + polysorbate (Ps), (2) DOX in saline, (3) DOX + Ps, and (4) DOX + nanoparticles] only one group (DOX + Ps) showed a long-surviving animal. This could have been due to the fact that the BBB might have been partially disrupted as a result of tumor growth. In conclusion, this study provides another indication that polysorbate 80-coated nanoparticles are a useful tool for drug delivery to the brain.

12.8. Other Approaches with Particles for Drug Delivery to the Brain

Nanoparticles are not the only method to increase drug bioavailability. Another approach to reduce RES uptake and to overcome the BBB is the preparation of magnetic microspheres combined with the application of a magnetic field to the brain of rats after intracarotid injection [114]. Two different types of microspheres of 1–2 μm diameter size were prepared: magnetic neutral dextran and cationic aminodextran microspheres. Both kinds of microspheres are prepared by an emulsification process using polysorbate 80 as the emulsifier. The magnetic particles were then injected into the carotid arteries of healthy rats and rats with implanted brain tumor (gliom-2/RG-2). A magnetic field was then applied to the brain. The rats were killed after 30 min and 6 h, and the magnetic particle concentration in the tissues was determined by atomic absorption spectroscopy. In healthy rats only low brain concentrations but high lung and spleen concentrations were found for both microspheres. In tumor-bearing rats, the brain concentration of magnetic cationic particles was increased compared with that of neutral particles. In general, these experiments with magnetic microspheres resulted in increased brain concentrations and decreased concentrations in peripheral organs, but did not show any significance because of the high variability among the groups.

13. MECHANISM OF NANOPARTICLE TRANSPORT ACROSS THE BLOOD–BRAIN BARRIER

Different mechanisms are described to explain the nanoparticle-mediated drug transport to the brain, including creation of a concentration gradient, a general surfactant effect, opening of the tight junctions, endocytosis, and inhibition of the efflux system [99]. Among them the most likely mechanism is the receptor-mediated endocytosis of nanoparticles. Lück et al. [115] found that apolipoprotein E (apo E) adsorbs on the surface of polysorbate 20-, 40-, 60-, or 80-coated nanoparticles after 5 min in human plasma at 37 °C. After separation of the particles from the serum by centrifugation, the adsorbed plasma proteins were desorbed and analyzed by two-dimensional gel electrophoresis. For polysorbate 20-, 40-, 60-, or 80-coated nanoparticles, apo E was found in the serum. In contrast, without coating or with overcoating of nanoparticles using poloxamers 338 and 407, Cremophor EL, or Cremophor RH40, no adsorption of apo E was observed. These results correspond to the findings that only polysorbate 20-, 40-, 60-, or 80-coated nanoparticles induced an antinociceptive effect using dalargin [60]. Kreuter et al. [116] studied the involvement of apo B and E in the mechanism of nanoparticle transport across the BBB. For i.v. injection into mice, poly(butylcyanoacrylate) nanoparticles loaded with dalargin were coated with apolipoproteins AII, B, CII, E, or J without or after precoating with polysorbate 80. In addition, nanoparticles loaded with loperamide were coated with apo E alone or after precoating with polysorbate 80. Furthermore, the antinociceptive effect of polysorbate-coated dalargin-loaded nanoparticles was measured in ApoEtm1Unc and C57BL/6J mice. The authors used the tail-flick test to determine the antinociceptive threshold. It was found that dalargin and loperamide-loaded nanoparticles coated with polysorbate 80 and/or with apo B or E induced the analgesic effect. Nanoparticles with polysorbate-precoating and apo B or E overcoating achieved a significantly higher analgesic effect. In addition, with the apo E-deficient ApoEtm1Unc mice, the effect was notably reduced compared with that in

C57BL/6J mice, from which the ApoEtm1Unc mice were derived. The results led to the conclusion that apo B and E are involved in the mediation of the transport of drugs bound to poly(butylcyanoacrylate) nanoparticles across the BBB. These results and also the studies of Lück et. al. [115] indicate that after i.v. injection apo E and/or B is anchored by the polysorbate on the surface of the nanoparticles [116]. Apo B and E are known to bind to lipoprotein receptors on the surface of cells [117, 118]. Low-density lipoprotein receptors have been identified in rat and monkey brains [119]. They also exist in the brain capillary endothelial cells [119, 120]. Polysorbate 80-coated nanoparticles adsorb the apolipoproteins after i.v. injection and thus seem to mimic lipoprotein particles that are able to interact with members of the low-density lipoprotein receptor family and are taken up via receptor-mediated endocytosis. Bound drugs may be further transported into the brain by diffusion [116].

14. CONCLUSION

Many drugs affecting the brain or spinal cord either do not cross the BBB at all or do not cross it in pharmacologically effective amounts. As a consequence, some drugs affecting the brain have undesirable peripheral side effects that pose a clinical problem. The severe disturbance caused by cytostatic agents used for the treatment of brain tumors are a dramatic example of this point. It is therefore desirable to have a method available whereby drugs can be delivered to the brain and spinal cord more effectively.

Nanoparticle technology is a very valuable method to deliver drugs across the BBB: nanoparticles have a diameter of about 200 nm and they are suspended in an aqueous solution. Depending on the method of the polymerization, drugs are either attached to the surface and/or are incorporated into poly(butylcyanoacrylate) particles. Subsequently, this drug–particle complex is covered by a suitable surfactant (such as polysorbate 80). This complex is then injected intravenously or given orally.

Nanoparticles can be stored either in lyophilized form or in solution. In lyophilized form they are stable for at least 2 years; in neutral solution they are just stable for several days. In acidic solution nanoparticles are stable for at least several months.

The primary advantage of nanoparticles is their ability to adsorb different drugs because a large variety of compounds can be delivered to the brain. Advantages over other methods of delivering drugs to the brain are that (1) they do not open the BBB, (2) potentially any drug can be delivered (hydrophilic or hydrophobic), and (3) the drug does not need to be altered. Furthermore, nanoparticles are known to be nontoxic. Neither the polymer nor the surfactants have any known toxic effect.

Efficacy of the nanoparticle approach has been demonstrated by tests with an analgesic peptide, dalargin, as well as with several other drugs, including cytostatic agents (e.g., doxorubicin). Dalargin normally does not cross the BBB because it only has an analgesic effect when injected directly into the brain. However, when bound to nanoparticles, a marked analgesia is seen when it is given peripherally.

In summary, nanoparticles are a very useful and universal method to deliver drugs to the brain. Industrial applications of the nanosphere technology would have several benefits:

- Nanoparticles deliver drugs to the brain that normally do not cross the blood–brain barrier.
- They reduce peripheral side effects of (approved) drugs that cross the BBB by increasing the relative dose of drugs reaching the brain;
- Nanoparticles can also be used as a screening tool. Delivering drug candidates to the brain by nanosphere technology for initial screening of CNS activity obviates direct CNS injections. It also reduces the need for altering drugs to allow their passage through the BBB, which decreases drug development costs significantly. Furthermore, drugs that come off patent protection can be protected again when used in combination with new drug delivery tools such as nanoparticles.

Nanoparticles thus open new possibilities for the treatment of disorders of the brain that were previously inconceivable. The value of nanotechnology for medicine is therefore obvious. We are confident that nanotechnology will make a major contribution to the advancement of drug treatment by helping drugs to be targeted more efficiently to specific organs, such as the brain. This may also be a means to attack previously untreatable disorders such as brain tumors and other neurodegenerative diseases.

GLOSSARY

Adsorption Binding of substances to a solid surface.

Aldehyde [alcohol + New Lat. *dehydrogenatum*, dehydrogenated], any of a class of organic compounds that contain the carbonyl group, and in which the carbonyl group is bonded to at least one hydrogen; the general formula for an aldehyde is RCHO, where R is hydrogen or an alkyl or aryl group.

Bioavailability After intraveneous or oral administration a drug is distributed throughout the body in different concentrations in several organs.

Chromatography Resolution of a chemical mixture into its component compounds by passing it through a system that retards each compound to a varying degree; a system capable of accomplishing this is called a chromatograph.

Colloid A mixture in which one substance is divided into minute particles (called colloidal particles) and dispersed throughout a second substance. The mixture is also called a colloidal system, colloidal solution, or colloidal dispersion. Familiar colloids include fog, smoke, homogenized milk, and ruby-colored glass.

Cryoprotector Compound such as a sugar that prevents the nanoparticles from the formation of agglomerates.

Denaturation Term used to describe the loss of native, higher-order structure of protein molecules in solution. Most globular proteins exhibit complicated three-dimensional folding described as secondary, tertiary, and quarternary structures.

Dialysis Transfer of solute (dissolved solids) across a semipermeable membrane. Strictly speaking, dialysis refers

only to the transfer of the solute; transfer of the solvent is called osmosis. Dialysis is frequently used to separate different components of a solution.

Dispersion Mixture in which fine particles of one substance are scattered throughout another substance. A dispersion is classified as a suspension, colloid, or solution. Generally, the particles in a solution are of molecular or ionic size.

Enzyme Biological catalyst; enzymes are proteins that accelerate the rates of reactions while experiencing no permanent chemical modification as a result of their participation.

Evaporation Change of a liquid into vapor at any temperature below its boiling point. For example, water, when placed in a shallow open container exposed to air, gradually disappears, evaporating at a rate that depends on the amount of surface exposed, the humidity of the air, and the temperature.

Free radical A molecule or atom that contains an unpaired electron but is neither positively nor negatively charged. Free radicals are usually highly reactive and unstable. They are produced by homolytic cleavage of a covalent bond.

Ion A neutral atom or group of atoms becomes an ion by gaining or losing one or more electrons or protons. Because the electron and proton have equal but opposite unit charges; the charge of an ion is always expressed as a whole number of unit charges and is either positive or negative.

Isotherm Line drawn on a map connecting points of equal temperature. Each point reflects one temperature reading or an average of several readings over a period of time.

Lipid A broad class of organic products found in living systems. Most are insoluble in water but soluble in nonpolar solvents. The definition excludes the mineral oils and other petroleum products obtained from fossil material. Major classes of lipids include the fatty acids, the glycerol-derived lipids, the sphingosine-derived lipids, the steroids and their derivatives, the terpenes and their derivatives, certain aromatic compounds, and long-chain alcohols and waxes.

Phospholipid Lipid that in its simplest form is composed of glycerol bonded to two fatty acids and a phosphate group. The resulting compound called phosphatidic acid contains a region (the fatty acid component) that is fat-soluble along with a region (the charged phosphate group) that is water-soluble.

Polymerization Reaction to create a chemical compound with high molecular weight consisting of a number of structural units linked together by covalent bonds.

Precipitation A process in which a solid is separated from a suspension, sol, or solution. In a suspension such as sand in water the solid spontaneously precipitates (settles out) on standing. In a sol the particles are precipitated by coagulation.

Surfactant A surface-active compound with a hydrophilic and a lipophilic moiety.

Suspension Mixture of two substances, one of which is finely divided and dispersed in the other. Common suspensions include sand in water, fine soot or dust in air, and droplets of oil in air.

Nanoparticle Layers in Multilayers

Diana Nesheva

Bulgarian Academy of Sciences, Sofia, Bulgaria

CONTENTS

1. INTRODUCTION

Over the past several decades, there has been rapidly increasing interest in the preparation of nanometer-sized materials such as superlattices, quantum wires, and quantum dots. This enhanced interest is justified because these materials show a great variety of new properties with respect to three-dimensional ones. Nanostructured or nanophase materials can be classified into four categories according to the shape of their structural constituents: nanophase powders, nanostructured films (including single-layer, multilayer, composite film, compositionally graded film, etc.), monolitic nanostructured materials, and nanostructured composite. The nanostructured materials can contain crystalline, quasicrystalline, and/or amorphous phases.

The search for ultra-thin materials (nanostructured films), in particular, semiconductors, can be traced quite far back (for a review of early work up to 1975, see [1–3]). However, the motivation for their production went up sharply when new types of devices were predicted [4, 5]. Studies of ultra-thin semiconductor layers and multilayer structures containing ultra-thin films have since then increased progressively. Single and multiple quantum wells, single- and double-barrier tunneling structures, incoherent multilayer tunneling structures, etc. have been prepared [6–10] as some of them have been used in production of various devices such as mobile phones, semiconductor photomultipliers, and lasers, etc. [11, 12]. It is important to notice that in crystalline superlattices (periodic multilayer structures built of two consecutively deposited materials) disorder and scattering must be low enough to allow building up of coherent superlattice bandstates and, thus, to prevent destruction of the phase coherence by interface fluctuations. This requirement means that for building up crystalline superlattices, pairs of materials have to be used with a difference in the lattice constants smaller that 1%. Thus, only a limited number of pairs can be applied in the superlattice preparation.

In the beginning of the 1980's, it was shown [13] that superlattices could also be fabricated from amorphous semiconductors (a-Si:H, a-Ge:H, SiO_x, SiN_x, etc.). The lack of long-range order in the structure of amorphous materials induces a great number of defects such as bond-length and bond-angle fluctuations, dangling and floating bonds, etc. This fact, along with the flexibility of amorphous materials, strongly reduces the requirements for matching lattice constants of the constituent materials and makes possible application of a great variety of materials in the fabrication of amorphous multilayers (a-MLs). Regular a-MLs, based on a-Si:H and a-Ge:H, have been prepared by a variety of rather simple and cheaper set-ups (glow-discharge [13], magnetron sputtering [14], plasma- and photochemically enhanced chemical vapor deposition [15–17] techniques), as compared to molecular beam epitaxy [18, 19] applied for crystalline MLs. It has been shown that applying bandgap engineering, new properties can be achieved, based both on classical effects, connected mainly with the influence of the interlayer barriers [20–25], and quantum-size effect (QSE) when the layers are sufficiently thin and the period (or the well layer width) is comparable with the de Broglie wavelengths of the charge carriers (electrons and holes) [20, 26–30]. Four-fold coordinated a-Si:H, a-Ge:H, and similar materials keep the rigid tetrahedrally bonded structure of the respective elemental crystalline semiconductors. In chalcogenide materials coordination number (that is, the number of the nearest neighbors) varies between 2 (for a-S, a-Se, a-Te, and their alloys) and <3 for $Ge_xS(Se)_{100-x}$ compounds. This low-coordination number makes amorphous chalcogenides more flexible than a-Si:H, a-Ge:H, and similar four-fold coordinated materials. Thus, in chalcogenide a-MLs, the level of interface-induced network distortion (and, hence, the concentration of interface defects) is lower than in a-Si, a-Ge-based MLs [23].

The main peculiarity of nanoparticles in nanocomposite films and bulk nanostructured materials is the presence of a large fraction of atoms located at the surface of nanoparticles embedded in a matrix. The large fraction of

Volume 7: Pages (105–123)

low-coordinated atoms at the surfaces of semi-isolated nanocrystals or within the grain boundaries of nanometer-sized composite or polycrystalline materials determines many of their physical, chemical, and mechanical properties [32–35]. The electronic eigenstates and phonons are described by periodic wave functions localized within the nanocrystal. The quantum confinement results in an increase of the bandgap and formation of discrete states at the band edges of semiconductor nanocrystals. The selection rules for optical transitions are relaxed owing to the scattering of the electronic eigenstates and phonons at the grain boundaries, which leads to their mixing and increase of transition probabilities for light absorption and emission. The localization of phonons in the nanocrystals is seen as a shift of the bands in their Raman scattering spectra.

In this chapter, the focus is on fabrication of nanocrystalline materials by nonepitaxial vapor deposition techniques and post-treatment of regular (amorphous or nanocrystalline/amorphous) multilayer structures. Using this approach one can produce either continuous or discontinuous nanocrystalline layers from a great variety of materials. The main advantage of this approach is the possibility for a precise control of the layer thickness during the ML deposition procedure. This makes it possible for the fabrication of nanocrystals (NCs) with desired sizes. In Section 2, a brief description of vapor deposition techniques applied for fabrication of amorphous and crystalline MLs is given. The modes of film growth are also considered. In Section 3, attention is paid to preparation of high-quality periodic amorphous multilayer, thermally and laser-beam induced crystallization of their constituent layers. Special emphasis is put on changes in the crystallization temperature of two-dimensional amorphous materials. Crystallization-induced changes in MLs and material intermixing upon annealing is also considered in this section. In Section 4, preparation of discontinuous metal and semiconductor nanoparticle films is described by means of the multilayer approach and possible mechanisms of nanoparticle formation are discussed.

2. VAPOR DEPOSITION OF THIN FILMS

Vapor processing methods seem to be the only ones that can provide highly pure materials with structural control at the atomic level or nanometer scale [36]. Moreover, vapor processing routs can produce ultra-fine powders, multilayers, and functionally graded materials, as well as composite materials with well-controlled dimensions and unique structures at a lower processing temperature. Vapor processing techniques used for fabrication of nanophase materials can be classified into physical vapor deposition (PVD), chemical vapor deposition (CVD), and aerosol-based processes and flame-assisted deposition methods [36, 37]. The first two have been widely applied for preparation of nanostructured films. PVD can be subdivided into evaporation, sputtering, and ion-plating processes based on the different ways of generating the gaseous species (Fig. 1). The classification of CVD processes based on the different heating methods can be as follows: (1) thermally activated, (2) photo-assisted, (3) plasma-assisted, (4) metalorganic, and (5) atomic layer epitaxy (Fig. 1).

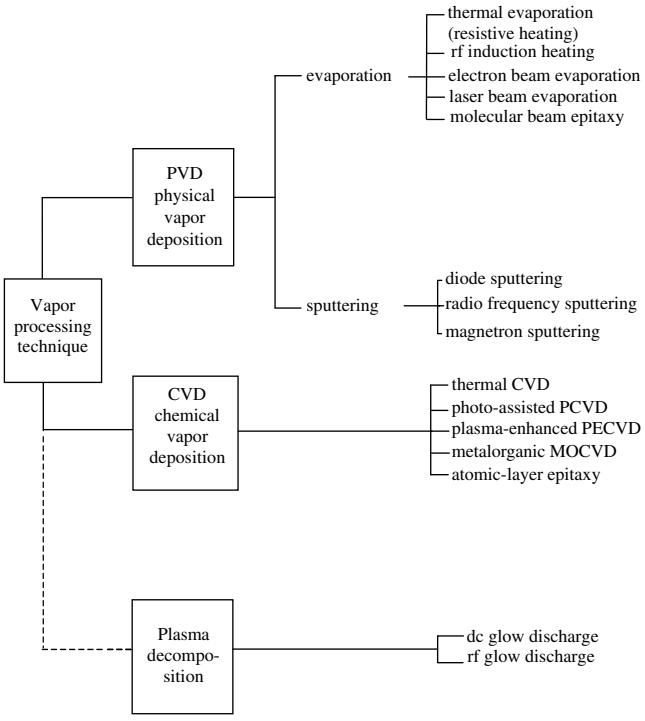

Figure 1. Variants of vapor deposition techniques for the fabrication of nanostructured films.

2.1. PVD Processes

In PVD processes, the particles to be deposited are transformed into the gaseous state by a physical process, either thermal evaporation or an impact process. By heating the kinetic energy of atoms or molecules of a solid or liquid, increases and at high enough temperatures, a significant number of atoms or molecules overcomes the separation energy and evaporate. There are various possibilities for evaporating the material to be deposited. The heat for evaporation can be delivered by resistive heating of a refractory metal, as well as by a laser or electron beam, high-frequency induction, or arc-evaporation. Generally, PVD methods can be mainly distinguished by the size of the ejected particles, by the degree of ionization, and by energy distribution. Moreover, the properties of growing films can also be influenced by the substrate temperature, the gas pressure, and an extra bombardment with high-energy neutral atoms or ions of an inert gas.

2.1.1. Evaporation

The most convenient thermal evaporation method uses resistive heating of a crucible. It works well if no chemical reaction or substantial alloying of the crucible with the evaporant takes place, and the evaporating material has a significantly lower melting point than the crucible. The heating of the evaporant by high-frequency induction is also applicable but only for materials with certain electrical conductivity. In this technique, the evaporating material levitates above the crucible and no pollution from crucible is introduced.

On application of an electron beam gun, the electrons emitted from a tungsten cathode are accelerated by a high

voltage (5–10 kV) and are focused on the substance to be evaporated. The kinetic energy of the electrons is transformed into thermal energy so that the material in the target melts and evaporates in vacuum. There are two advantages in using an electron gun compared with the resistive heating of a crucible: the evaporation rate is significantly higher and there is no alloying of the evaporant with the cold crucible.

The laser ablation technique uses a pulse laser beam of high power for ejecting particles into vacuum. The ejection process is very complicated: a large portion of the ejected particles are ionized and the evaporating beam consists of components of different velocities. Various ejection processes of the target material have been discussed [37]:

1. striking out of flocks by thermal stress (exfoliational sputtering);
2. ejection of fine droplets by a volume change that arises from thermal expansion of the liquid with melting (hydrodynamic sputtering);
3. production of an electronic avalanche similar to that in electric breakthrough and ionizing collisions of electrons (in this case, a highly excited dense plasma in front of the target surface exists);
4. transmission of momentum from the beam on the target surface (collisional sputtering);
5. normal thermal evaporation.

An advantage of laser evaporation is that because of its high energy, alloys can be deposited without significant change of composition as in flash evaporation technique. This process can also be applied reactively.

2.1.2. Sputtering

If ions or atoms with energy several kiloelectronvolts bombard a solid surface, single atoms, molecules, or clusters are produced which are deposited on the surrounding wall of the vacuum chamber [36, 37]. The ions of a noble gas are mostly applied to bombard the solid surface. In standard sputtering equipment, the well-known glow discharge is used as the ion source. It forms if one puts an electric field of several hundreds or a thousand volts between two electrodes which stand separately in a vessel evacuated to about 10^{-1} mbar. In the glow discharge, not only neutral atoms but also ions and electron exist. The electrons are accelerated against the anode by the applied electric field and produce additional ions on the way of impact ionization. The ions are accelerated against the cathode and produce these secondary electrons which produce again so many new ions in the gas by collisional ionization that the ion loss on the cathode is compensated. This means that the discharge is self-sustaining. By the impact of positive gas ions on the cathode, the atoms of the cathode material are ejected and condense on the substrates forming the film. The particles sputtered from the cathode are more than 95% neutral and their average energy is considerably higher (5–20 eV) than that of thermally evaporated atoms (<1 eV). When applying the sputtering technique, one should bear in mind that some further processes take place:

1. the growing film is bombarded by neutral atoms of the inert gas;
2. if the substrate is not properly grounded, it will be bombarded either by ions of the inert gas or secondary electrons that yields heating of the substrate;
3. in case of reactive sputtering, in addition to the mentioned two processes, the reaction rate between the depositing atom and reactive gas on the substrate will be further increased.

Sputtering techniques include diode sputtering, radio frequency (rf) sputtering, and magnetron sputtering. Direct-current (dc) glow discharge sputtering can only be used for conductive targets, while any target regardless of its conductivity can be sputtered using rf sputtering. Magnetron or triode sputtering is used to provide a higher current in the relatively inefficient ion source than that provided by glow discharge. In this case, a higher ionization of the plasma is obtained by introducing electrons into the plasma from a thermionic emitter [38].

Another method for the deposition of films, which is on the border between reactive sputtering and CVD methods, is the decomposition of gases in plasma. With this method, no evaporation source and target are used. The material to be decomposed is admitted as a component of a gaseous compound to the reaction chamber. In the plasma, the molecules of the compound decompose and the desired component is deposited on the substrate. Frequently, a negative bias voltage is put on the substrate so that the growing film is bombarded with ions. An rf or dc voltage may be applied for sustaining the glow discharge. This technique is widely used for deposition of amorphous silicon (a-Si:H) by plasma decomposition of SiH_4.

2.2. Chemical Vapor Deposition

CVD involves thermal dissociation and/or chemical reaction (thermal decomposition (pyrolysis) oxidation, reduction, hydrolysis, nitridation, etc.) of the gaseous reactants on or near the vicinity of a heated surface to form stable solid products [37]. The deposition involves homogeneous and/or heterogeneous chemical reactions leading to the formation of films or powders. During the CVD film deposition, the active gaseous species is generated and transported into the reactor chamber where the gaseous precursor undergoes gas phase reactions forming an intermediate phase. The species of this phase are then absorbed onto the heated substrate, where heterogeneous reactions take place producing the deposit and byproducts. The latter are diffused away from the substrates and transported out from the deposition chamber. The deposit is diffused along the heated substrate surface forming embryos for subsequent growth of the film.

Photo-assisted chemical vapor deposition (PCVD) is a variant of the CVD process that relies on absorption of laser radiation in the substrate to raise its temperature and cause thermal decomposition/chemical reaction of the gaseous precursor to form the required products. Plasma-enhanced CVD (PECVD) uses electron energy (plasma) as the activation method. By supplying electrical power at sufficiently high voltage to a gas at reduced pressure (<10 mbar), breakdown of the gas occurs and generates a glow discharge plasma consisting of electrons, ions, and electronically excited species. The plasma ionizes and decomposes

the reactant gases at a low temperature. Chemical vapor deposition can also be classified according to the type of precursor used. The use of a metalorganic precursor, for example, has led to the development of metalorganic chemical vapor deposition (MOCVD). Atomic layer epitaxy (ALE) is a variant of the CVD process that involves surface deposition for the controlled growth of epitaxial films and fabrication of tailored molecular structures on solid surfaces [39]. "Monoatomic" layers can be grown in sequence by sequentially saturating surface reactions.

2.3. Modes of Film Growth

To understand the deposition of a film on a substrate, it is necessary to consider the nucleation and the later growth separately. Depending principally on the material parameters of the substrate and the deposited material, as well as the supersaturation of the vapor, three different modes of film growth have been observed:

1. If the interaction energy W_{SD} (adhesion) between atoms of the substrate and deposit is much larger than the interaction energy W_{DD} (cohesion) between atoms of the deposit ($W_{SD} \gg W_{DD}$), a subsequent layer will grow after the previous one is completed (layer growth (LG)).
2. If the cohesion energy is larger than the adhesion ($W_{DD} > W_{SD}$), island growth (IG) takes place.
3. The Stranski-Krastanow (SK) growth is a mixture of LG and IG [40].

Stranski-Krastanow growth occurs if the interaction energies have very different dependencies on the distance between the atoms. The increase in the supersaturation leads to a more two-dimensional growth. A drastically increased supersaturation can change the growth mode from IG to LG.

The following processes take place on the substrate surface during the initial IG of films:

(a) the formation of adatoms on the substrate surface by the arrival of the vapor particles;
(b) the diffusion of adatoms on the substrate surface;
(c) the partial desorption of adatoms from the surface into the vacuum;
(d) the statistical nucleation on a substrate surface which is free of defects;
(e) the nucleation on defects;
(f) the growth of nuclei by the capture of adatoms.

For evaporation on an undisturbed surface, the island density increases first by nucleation, goes through a maximum at t_{max}, and then decreases monotonically up to 100% coverage of the substrate surface because of the coalescence of islands. With rising substrate temperature, the nucleation rate and island density decreases and t_{max} increases. A reduction in the arrival rate yields qualitatively a similar result. If the kinetic energy of the vapor atoms that arrive is increased, the nucleation rate and island density increase while t_{max} decreases. With increasing substrate temperatures the mobility of adatoms and clusters increases which favors grain growth, recrystallization, and an increasing order of the microstructure.

Epitaxy means that the growing layer derives its crystalline orientation from the underlying substrate [41]. Generally, the deposition of epitaxial films on single-crystal substrates with evaporation is possible only with a high substrate temperature T_{epi}. It has been observed that for films prepared by sputtering, T_{epi} is less than for films prepared with evaporation of materials. This is due to the higher energy of the particles in sputtering.

Molecular beam epitaxy (MBE) is a refined form of vacuum evaporation. This method involves [18, 42–44] neutral thermal energy molecular or atomic beams impinging on a hot crystalline substrate maintained in an ultra-high vacuum that provides the required source of growth. In the MBE, the substrate temperature and beam intensities of each source are controlled separately as the growth temperature should provide sufficient surface diffusion to allow layer-by-layer growth and well interfaces between layers with minimal bulk interdiffusion. The major drawback of MBE is that it involves the use of expensive and sophisticated equipment with a high running cost. Moreover, production time could be lost because of the long period of time required for the system to be pumped down to the required ultra-high vacuum.

3. CONTINUOUS NANOPARTICLE LAYERS

For device application, precise engineering of nanoparticle size with focus on control in grain boundary and defect density is essential. Fabrication of periodic nanocrystalline/amorphous multilayers is a promising way for production of nanoparticles with desired well-defined sizes. Nanocrystalline/amorphous multilayers have been produced using two main approaches: post-treatment (furnace or rapid thermal annealing, laser beam crystallization) of regular amorphous multilayers or layer-by-layer deposition of nanocrystalline/amorphous layers of similar thickness.

3.1. Preparation of Regular Amorphous Multilayers

Molecular beam epitaxy, as a mature technology, was employed for engineering amorphous/amorphous MLs to atomic precision at the thickness required. Si/SiO_2 periodic MLs were grown [45–47] using the following deposition procedure. A thin Si layer is deposited on substrate and then it is taken out of the vacuum chamber and submitted to 600 s exposure to ultraviolet ozone. This procedure is repeated to create the necessary number of periods. Later, a-Si/SiO_2 periodic MLs have been prepared with electron beam evaporation [48–53] or rf sputtering [54, 55] and *in-situ* plasma oxidation. Plasma-activated gas cell has been used as the oxygen source [48–50]. Plasma-enhanced chemical vapor deposition of a-Si and layer-by-layer plasma oxidation have been used to fabricate a-Si:H/SiO_2 MLs [56]. The thickness of a-Si:H layers has been controlled by the duration time of plasma oxidation of the silicon layers initially deposited. Nanocrystalline Si layers have been grown on SiO_2 by rapid thermal chemical vapor deposition [57].

Regular a-MLs have also been prepared by a consecutive deposition of two materials applying a variety of rather simple and cheaper set-ups, as compared to the MBE normally used for crystalline MLs. Glow-discharge [13, 58, 59], electron beam evaporation [60], plasma- and photochemically enhanced chemical vapor deposition [15–17, 61–65] techniques, and reactive and magnetron sputtering [66–71] have been applied for preparation of a-Si:H- and a-Ge:H-based a-MLs. Physical vapor deposition [23, 26–28, 30, 72–81], laser ablation [20, 82–85], and electron beam evaporation [86] techniques have been used for fabrication of chalcogenide a-MLs. When one applies a nonepitaxial technique for the preparation of a multilayer structure, each layer of this structure (having a thickness between 2 and 20 nm) can be prepared either by one-step (continuous) material deposition or applying a step-by-step approach. Experiments on preparation of a-MLs based on a-Si:H have shown [87] that multilayers prepared by applying the step-by-step deposition of each layer resulted in smoother interfaces and a better periodicity than in the case of continuous deposition of the layers. This approach has also been applied for preparation of selenium-based a-MLs and, thus, high-quality chalcogenide MLs have been produced with smooth and parallel layers [77, 78, 88].

There are few works on layer-by-layer production of nanocrystalline/amorphous MLs. Low-pressure chemical vapor deposition has been used [89–91] to deposit a nanocrystalline nc-Si layer. By controlled, high-temperature thermal oxidation, part of this layer was oxidized to form SiO_2, thus forming a Si/SiO_2 bilayer. This procedure was repeated to build a multilayer structure. Regular multilayer structures of nc-CdSe/SiO_x (Fig. 2), nc-CdSe/GeS_2, nc-Se/SiO_x, and nc-CdSe/ZnSe have also been produced by consecutive thermal evaporation of each material of the respective pair [92–98].

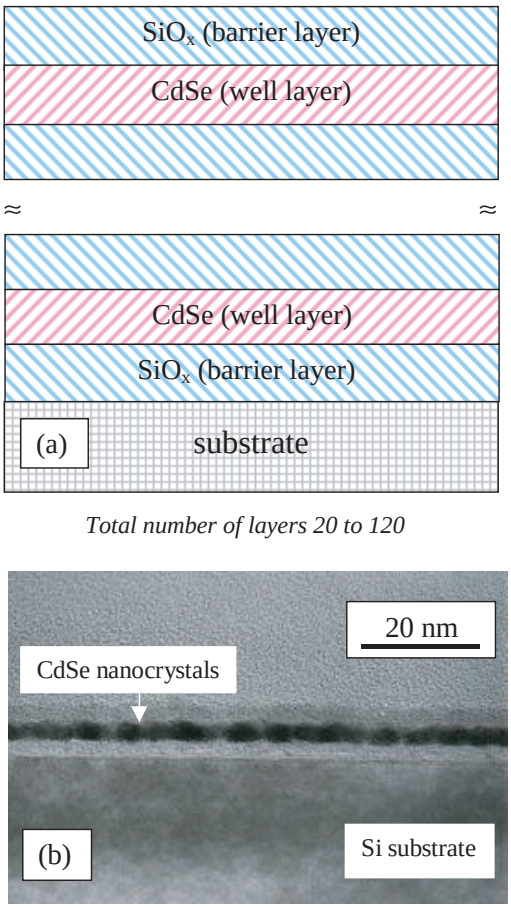

Figure 2. (a) Schematic presentation of a regular multilayer structure: carrier and phonon confinement takes place in the well layers which are made of the material with the narrower optical bandgap. (b) Cross-section view of a SiO_x(5 nm)/CdSe(5 nm)/SiO_x(5 nm) three-layer structure.

3.2. Post-Treatment of Amorphous Multilayers

3.2.1. Thermal Crystallization

Main Features The most convenient way for production of nanocrystalline layers in amorphous MLs is annealing for various times at temperatures around and above the crystallization temperature of the constituent material with a lower crystallization temperature. A standard long-time (>30 min) furnace annealing or rapid thermal annealing (30–60 sec) in an inert atmosphere (Ar, N_2) have been applied to crystallize the layers in a-ML having lower crystallization temperature. Before discussing crystallization, it is interesting to note that the annealing at temperatures close to but below the crystallization temperature (e.g., ~60 min at 350 K for a-Se in a-Se/a-CdSe MLs [88, 99, 100], 20 min at 720 K for a-Ge in a-Ge:H/a-GeN_x MLs [101], etc.) causes a disorder reduction in a-MLs. Besides, upon annealing at temperatures below the crystallization temperature, some authors have observed a thermally induced reduction in the effective interface width, which has been related to negative sublayer interdiffusion [88, 102]. At temperatures higher than the crystallization temperature of the "low-temperature" layers of a-MLs, microcrystal formation takes place (e.g., in a-Ge sublayers of a-Ge:H/a-GeN_x [101], a-Ge:H/a-SiN_x:H [103], a-Si:H/a-Ge:H [104] MLs and a-Se in a-Se/a-CdSe [100, 105], and a-Se/a-As_2S_3 MLs [106]).

The crystallization process in progressively annealed a-MLs has been investigated using differential scanning colorimetry, small- and high-angle X-ray diffraction (SAXRD and HAXRD), as well as high-resolution transmission electron microscopy (HRTEM) and Raman scattering techniques. Earliest investigations of thermal properties of a-MLs (Se/As_2Se_3) [72] performed using differential scanning colorimetry showed a different annealing behavior in pure Se thin films having a thickness of 2 μm and Se/As_2Se_3 MLs. In the temperature range 270 K–470 K, an exothermal peak of crystallization and two endothermal peaks of glass transition and melting were observed in Se thin films. In Se/As_2Se_3 MLs with Se layer thickness <30 nm, no crystallization peak was observed in this temperature range. This was the first indication for some increase in the crystallization temperature of two-dimensional amorphous films. Later, detailed investigations were performed on chalcogenide [88, 95, 99, 100, 105–110], a-Si [102, 111–113], and a-Ge [66, 101, 103, 104, 114, 115] based a-MLs which proved the increase of crystallization temperature T_c. This T_c increase will be discussed in detail later. Furthermore,

upon rapid thermal annealing of a-Si/SiO_2 MLs, in which the a-Si layer thickness ranged from 4 nm to 25 nm, crystallization has been observed at temperatures 1070 K to 1120 K [63], while in a-Si single films, crystallization temperature is near 970 K [116]. Even at such high temperatures, a small amount of residual amorphous tissue (5–10% of the volume) remained in a-Si/SiO_2 MLs after this rapid thermal annealing. To achieve complete crystallization, an additional 30 min furnace annealing at 1320 K has been used [63], as the temperature was raised from 1070 K to 1320 K using a slow ramp of 10 K/min.

Nanocrystallite Shape and Size First studies of the shape of the Si NCs in nc-Si/SiO_2 MLs have shown [63] that nanocrystal are almost spherical with their packing density controlled by the thickness of SiO_2. Later HRTEM studies on the shape nc-Si/SiO_2 MLs [117, 118], as well as the results on nc-CdSe/SiO_x MLs [119], revealed an oval-like shape with the lateral dimension of nanocrystals exceeding the vertical dimension (see Fig. 2b). Transmission electron microscopy studies performed on Si/SiO_2 MLs have shown [117, 120] that nucleation starts in a-Si layers away from the interfaces. The growth of the crystalline nuclei is stopped by the interfaces, which accounts for the observed oval-shaped nanocrystals in ultra-thin nanocrystalline layers. A summary of the results on the relation between the initial thickness of amorphous layers and NC size indicates that the average vertical size of the crystals after conventional annealing is in good agreement with the thickness of the amorphous layers [63, 119, 121–123] for layers thinner than 7 nm. For thicker films, the nanocrystallite size is smaller than the thickness of the initial amorphous layers [117]. Though a quantitative analysis of the nanocrystallite size distribution was not obtained, it has been seen that the difference between recrystallized spheres was not greater than a few monolayers. Here we would like to pay attention to an observation of NCs whose size was larger than layer thickness. In case of ultra-thin SiO_x layers of Si/SiO_x a-MLs (a-Si layer thickness $d = 2$ nm), it has been noted [33] that Si crystallites were larger than 4 nm. The formation of crystallites larger than the initial thickness of layers has been explained with the presence of overstoichiometric silicon in the SiO_x layers, which made possible the observed growth of large Si NCs.

Crystallization Temperature Summarizing the results on thermal crystallization of a-Si layers in a-MLs, one can see an increase of the crystallization temperature by approximately 300 K when the Si layer thickness was reduced to 2 nm [45]. A similar behavior has been reported for a-Ge based MLs. The crystallization temperature of thick a-Ge film is about 770 K, while 1.7 nm a-Ge layers did not show crystallization even after annealing at 1030 K [124]. A different approach has been applied in order to study qualitatively the T_c changes of ultra-thin a-Se layers in Se/CdSe a-MLs. The a-Se crystallization was realized by exposing MLs with a laser beam which is strongly absorbed. High-frequency (vibrational) Raman spectra were measured [100]. It has been observed that a gradual increase of laser power density caused crystallization of Se sublayers; in similar low temperature (25 K) experiments (using even higher laser power densities), there was no indication of substantial crystallization, implying that the latter is mainly a thermal effect. From the threshold for crystallization, it was obtained that crystallization of three-dimensional a-Se occurs at laser beam power density twice lower than that necessary for crystallization of 3.5 nm layers.

Some results on the T_c increase of crystallization temperature with decreasing a-Ge and a-Si layer thickness are summarized in Figure 3. It is seen that decreasing the layer thickness below 10 nm results in a strong increase of T_c. For a-Si layers in Si/SiO_2 MLs this increase has been fitted by the relation [117]:

$$T_c = T_o + \Delta T \cdot \exp(-d/C) \tag{1}$$

where the thickness of the Si layers is d and the parameters are $T_o = 988$ K, $\Delta T = 663$ K, and $C = 2.43$ nm. The second term in Eq. (1) represents the shift of the crystallization temperature. There might be an additional influence of the composition of the "high-temperature" layers which is expected to have an influence on the constant C. The observed T_c increase has been connected with an existing built-in strain on a-MLs. The different T_c reported at equal Si layer thickness can be accounted for [117] with uncertainties in the layer thickness and the accuracy (±25 K) of the crystallization temperature. In addition, it has been assumed that a thinner "high-temperature" layer may not be able to release the same built-in strain in the ML structure which may change T_c [125].

A general discussion from thermodynamic point-of-view of the crystallization process in a-MLs consisting of alternatively deposited amorphous semiconductors ***A*** and ***B*** has been made in [59, 105]. Both the layer thickness and the nature of constituent materials (heterointerface) have been shown to be key factors for determining the crystallization temperature. According to the well-known theory of the

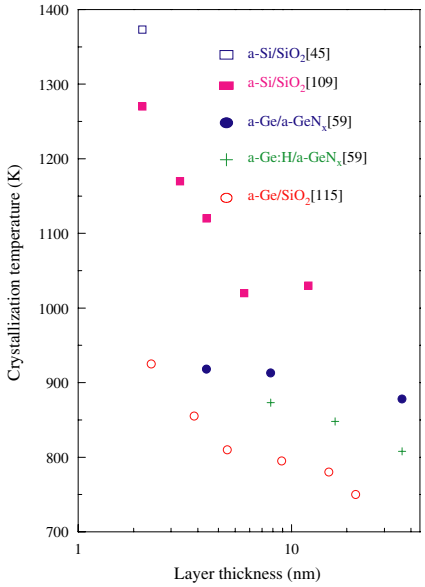

Figure 3. Crystallization temperature T_c of different Si- and Ge-based regular amorphous multilayers as a function of the layer thickness of the layers with lower T_c. A great T_c increase is seen in multilayers having layer thickness <10 nm.

homogeneous nucleation, crystallization of a total volume occurs only when the radius of crystalline nuclei (embryos) exceeds a critical value for the free energy of the system can be minimized. The crystallization temperature of an amorphous material is determined by the critical size $r_c = 2\gamma/\Delta G_v$, where γ and ΔG_v represent the interfacial free energy per unit area and the decrease of the bulk free energy per unit volume accompanied by the crystallization of super-cooled liquid. In the consideration of crystallization in a-MLs, the layer ***A*** was assumed to have a lower bulk crystallization temperature T_c than the material ***B*** and thickness smaller than the critical embryo radius r_c. For this reason, the crystallization nucleus formed in the material ***A*** were assumed, to a first approximation, to be cylindrical. Then, the free energy change upon crystallization is described as follows [66]:

$$\Delta G_{2D} = -\pi r^2 d\Delta G_v + 2\pi r^2 \Delta\gamma + 2\pi r d\gamma_{ac} \qquad (2)$$

where r is the radius of the cylindrical crystalline nucleus, ΔG_v is the decrement of the free energy per unit volume in amorphous-to-crystalline phase transformation, d is the layer thickness of the material ***A***, $\Delta\gamma = \gamma_{bc} - \gamma_{ba}$, is the increment of the interfacial free energy between material ***A*** and ***B*** per unit area when material ***A*** is crystallized, γ_{ac} is the interfacial free energy per unit area between amorphous and crystalline phase of the material ***A***, γ_{bc} is the interfacial free energy between the material ***B*** and the crystallized material ***A***, and γ_{ba} that between the material ***B*** and the initial amorphous material ***A***. ΔG_{2D} keeps increasing with r when $d < 2\Delta\gamma/\Delta G_v$, which means that crystallization never occurs. For $d > 2\Delta\gamma/\Delta G_v$

$$r_c = d\gamma_{ac}/(d\Delta G_v - 2\Delta\gamma) \quad \text{and}$$
$$\Delta G_{2D}^{\max} = \pi(d\gamma_{ac})^2/(d\Delta G_v - 2\Delta\gamma) \qquad (3)$$

Taking into account that $\Delta G_{2D}^{\max} \sim kT_c$ (k is Boltzmann's constant), the above relations show that T_c should increase with decreasing layer thickness for $\Delta\gamma > 0$, while T_c must decrease with decreasing d for $\Delta\gamma < 0$. It also predicts that not only the layer thickness but also the nature of the heterointerface affects T_c. The last prediction has been experimentally proven in Se/Se_xTe_{100-x} a-MLs. It has been shown [110] that crystallization temperature of a-Se layers in those MLs depends on the composition of Se_xTe_{100-x} layers. The results on a-Ge based MLs shown in Figure 3 are also in agreement with such a prediction.

Recently, a new model has been suggested [125] in which, in addition to the interface energies, the crystallization temperature of the thick amorphous layer, and the thickness of the layers, the melting point of the system was taken into account. In the framework of this consideration, the experimentally determined exponential increase of the crystallization temperature has been fitted by

$$T_c = T_{ac} + (T_{\text{melt}} - T_{ac})\exp(-d/C) \qquad (4)$$

where C has been found to be equal to 2.52–2.56 nm independent on the material (Si, Ge). In this model, it has been assumed that the crystallization nucleus is symmetrically embedded in the amorphous material between the interfaces and is cylindrical in shape. However, an additional spacing l has been introduced that corresponds to a finite separation of the nucleus from the boundaries represented by the second material ***B***. For $l = 0$, that is, the vertical nucleus size $h = d$, it has been assumed that a sharp interface is formed with the specific interface energy γ_{bc}. In the other limit of a very large l, the material ***B*** and nucleus are separated by two noninteracting well-defined interfaces, namely, the interface between the crystalline and amorphous phase of material ***A*** and the interface between the amorphous ***A*** and ***B***. For small l, the concept of an effective interface layer has been adopted and it has been assumed that a quasi-amorphous layer (called quasi-interface) is formed in the space between crystalline ***A*** and ***B***. The effective free interface energy γ_{bc}^{eff} is

$$\gamma_{bc}^{\text{eff}} = \gamma_{ac} + (\gamma_{bc} - \gamma_{ac})M \qquad (5)$$

where M is an effective order parameter which is normalized to unity for the real ***B***/crystalline ***A*** interface and zero for the amorphous/crystalline ***A*** interface. Under those assumptions, Eq. (2) becomes

$$\Delta G_{2D} = -\pi r^2 h\Delta G_v + 2\pi r^2 \gamma_{bc}^{\text{eff}} + 2\pi r h\gamma_{ac} \qquad (6)$$

and for the crystallization temperature, the following dependence has been obtained [125]:

$$T_c = T_{ac}\{1 + (\gamma_{bc} - \gamma_{ac} - \gamma_{ab})/\gamma_{ac}\exp(-d/4l_o)\} \qquad (7)$$

where T_{ac} is the crystallization temperature of a thick amorphous film ***A***, and l_o has been interpreted as an average screening or bonding length that is related to the range of interatomic forces typical for the crystalline ***A*** and ***B***. Through comparison with the empirical relation (4), which describes the experimental exponential increase of the crystallization temperature, the following relation has been derived [125]:

$$T_{\text{melt}} = T_{ac}(\gamma_{bc} - \gamma_{ab})/\gamma_{ac} \qquad (8)$$

According to the relations (4) and (7), the T_c increase in the limit $d \to 0$ is related to the difference in the specific interface energies of the interfaces between the crystalline and amorphous phases involved. The model yields a lower bound for the layer thickness below which no crystallization can occur in a-MLs. The value calculated for the Si/SiO_2 system is in good agreement with the experimental observation [125].

3.2.2. Laser-Beam Crystallization

Laser beam annealing of a-MLs under cw or pulse exposure has also been applied as an alternative of thermal crystallization, in order to produce nanocrystalline films [100, 103, 106, 109, 110, 121, 126–130]. In a series of studies on crystallization with an excimer laser of a-Si:H/a-SiN_x:H MLs [126–130], ability for fabrication of electroluminescence cells has been shown having visible light emission. This approach provides several advantages such as selected area processing, rapid crystallization, and avoidance of the surface contamination. It is also possible to crystallize a thin film while keeping the substrate temperature low enough to prevent its thermal damage.

The primary interaction between laser light and semiconductors is based on excitation of electrons and phonons [131]. The dominating interaction mechanisms depend on the laser parameters and the particular type of semiconductor, its microstructure (amorphous/crystalline), doping, etc. The interaction mechanisms may be thermal or non-thermal depending on the relative size of the thermal relaxation time and the time for structural rearrangements of material atoms or molecules. In most cases of semiconductor processing, the excitation energy is rapidly dissipated into heat (thermal laser processing previously mentioned). In spite of the thermal character, laser-driven processes may be quite different from those initiated by a conventional heat source. The laser-induced temperature rise can be localized in space and time. Temperature changes of more than 10^4 K can be induced in a small volume at a heat rating of 10^{15} K/s. For example, heat flow calculations have been performed for a-Si:H thin film for the case of single-shot laser annealing with an excimer laser [132]. It has been shown that the laser irradiation is able to melt and crystallize the film but even the melting process could not be described by pure heat flow calculation. It is interesting to note that the results of crystallization of a-Si:H thin films with a cw Ar^+ laser and a pilsed Nd:YAG laser have indicated [133] that the mechanisms of crystallization are different and, in particular, the pulsed crystallization is a nonthermal process. Another example of the complex interaction of the light with matter is laser-induced crystallization of a-Se. Polarization-dependent photocrystallization has been observed and though it seems to be optical in origin [134], an alternative, essentially thermal, mechanism has also been discussed [135].

Both thermal and pure photo-induced crystallization has been observed in a-MLs. Compositional and thickness dependent changes of the crystallization process in amorphous $Se/Se_{100-x}Te_x$ multilayers ($x = 7.5$, 15, and 30) have also been studied under light treatments [109, 110]. The treatments have been performed using the 647.1 and 530.1 nm Kr^+ laser lines. The thermal effect of the laser exposure has been investigated at room temperature in $Se/Se_{70}Te_{30}$ a-ML, using the red laser line (which is strongly absorbed by the $Se_{70}Te_{30}$ sublayers but weakly so in the Se ones), as well as on $Se/Se_{100-x}Te_x$ a-MLs using the green laser line [110]. In these experiments, it has been established that the threshold power for crystallization (and, hence, the crystallization temperature) of $Se_{70}Te_{30}$ sublayers increases with decreasing their sublayer thickness. The result is in accordance with those reported previously for a-Se [100, 106].

"Pure" photo-induced structural changes in $Se/Se_{100-x}Te_x$ a-MLs have been explored at a low temperature (38 K) at which thermally induced photo crystallization is not anticipated. It has been found [110] that exposure to the green laser line lead to an increase of the strength of photo-induced crystallization in $Se/Se_{100-x}Te_x$ a-MLs with increasing Te content, which is in agreement with previous reports on three-dimensional $Se_{100-x}Te_x$ alloys [136–138]. This result implied that there is no considerable change in Se-Se and Se-Te bond energies when a dimensionality reduction (from 3 to 2) takes place in the alloys. Furthermore, the thickness dependence of the strength of photo-induced crystallization was studied in $Se/Se_{70}Te_{30}$ a-MLs for which the strongest effect has been observed. A series of Raman scattering spectra measured with the laser beam focused on the same spot of each sample are shown in Figure 4. One can see that the intensity of the 237 cm^{-1} band, which corresponds to scattering from trygonal Se, and hence, the relative part of the crystalline phase in both $Se_{70}Te_{30}$ and Se layers increases when the time of preliminary exposure increases. A reduction of overall Raman intensity has also been observed. The latter has been ascribed to a deterioration of the ML structure and/or the surface quality of the sample due to crystallization. A conclusion has been derived [109, 110] that, as in the case of thermally induced crystallization, the rate of photo crystallization in $Se_{70}Te_{30}$decreases with decreasing sublayer thickness but the cause of this dependence in the case of photo crystallization is different from that responsible for thermal crystallization. The last suggestion is based on the mechanism of photo-induced crystallization developed for a-Se [134]. According to this model, the photo crystallization strength in a-Se is controlled by the production of electron hole pairs and not by the density of absorbed energy. This implies that structural disorder may play a significant role in the process of photo crystallization. Thus, the observed lower rate of crystallization in $Se/Se_{70}Te_{30}$ a-ML having thinner sublayers has been attributed [110] to a decrease in the lifetime and, hence, the concentration of photo-excited free carriers due to a disorder level increase. Moreover, in thinner sublayers, photo crystallization starts at a higher level of structural disorder and, hence, at the same light exposure, a longer time is necessary in order to achieve the same crystallization effect.

Laser annealing along with both previously described thermal post-treatment methods (furnace annealing and rapid thermal annealing) were applied for crystallization of a series of a-Si:H/a-SiN_x:H MLs [139]. It has been shown that when the thickness of a-Si:H layers is larger than 4.0 nm, the constrained a-Si:H layers were well crystallized by each of three methods. However, when the thickness of a-Si:H layers is smaller than 4.0 nm, the laser annealing method is the most advantageous for the formation of the nuclei and

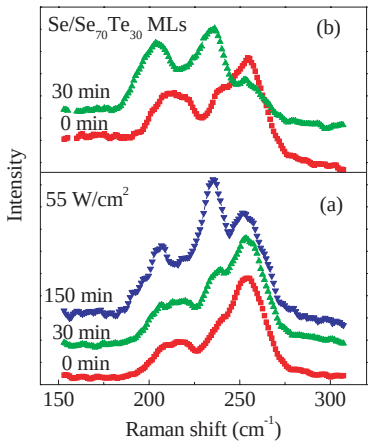

Figure 4. Raman scattering spectra of Se(4 nm)/$Se_{70}Te_{30}$ MLs having $Se_{70}Te_{30}$ layer thickness of (a) 3.5 nm and (b) 7.0 nm. The spectra were measured on a constant spot for each sample after a preliminary laser beam exposure (647.1 nm, 55 W/cm^2) for various times indicated in the figure.

crystallization of the samples compared to the other methods. Using laser annealing, ultra-thin a-Si:H layers can be well crystallized even when their thickness decreases down to 2.0 nm. In contrast, the nucleation become more difficult upon furnace annealing, so that few Si NCs can be formed by this method.

3.2.3. Crystallization Induced Changes

The crystallization of layers in a-MLs by annealing or laser exposure can cause a number of structural and mechanical changes. Among them are cracking [103], some increase in the magnitude of the internal strains [123], deterioration of the interface smoothness, ML periodicity [105, 140], ML surface [110], etc.

Laser power between 0.25 W and 3.0 W from an Ar^+ cw laser were used for crystallization of A-Ge:H/a-SiN_x:H MLs [103]. No visible changes or measurable signs of crystallization have been detected for MLs on crystalline silicon substrates. For multilayers on glass, however, changes have been observed. Even for powers below 1.0 W, some regions appeared "milky," caused by microscopic bubles that increased in density with power. For powers greater than 1 W, some rough and shiny areas appeared, corresponding to severe cracking and pitting when viewed through a microscope. The appearance of such mechanical defects can be avoided using slow thermal annealing [103].

As previously mentioned, in order to determine the average size of nanocrystals, X-ray diffraction and HRTEM studies are usually used. The Scherrer's equation

$$d_{NC} = \lambda/\delta 2\Theta \cdot \cos\Theta \tag{9}$$

is employed to a distinct band in the X-ray diffraction pattern of the sample in order to calculate the average nanocrystallite diameter d_{NC} (Fig. 5). Here, Θ and $\delta 2\Theta$ are the position and full width at half the maximum of the band. However, a discrepancy has been reported [119] between the average size of CdSe nanocrystals in nc-CdSe/SiO_x MLs determined with X-ray diffraction and HRTEM studies. It is known that the full width at the half maximum of X-ray diffraction peaks depends not only on the NC size but also on existing microstrains and deformations in the NC network. The observed discrepancy has been related to the existence of microstrains in the nanocrystals. Using relation [141]

$$(\delta 2\Theta \cos\Theta/\lambda)^2 = 1/d_{NC}^2 + 16\varepsilon^2(\sin\Theta/\lambda)^2 \tag{10}$$

and the average nanocrystallite diameter obtained from HRTEM, the approximate levels of the microstrains have been estimated assuming the CdSe NC size and strain (ε) distributions to be Gaussian. Values of around $20 \cdot 10^{-3}$ and $28 \cdot 10^{-3}$ have been obtained for nanocrystals having $d_{NC} =$ 10.0 and 5.0 nm, respectively. They are close to the values of $20–22 \cdot 10^{-3}$ calculated [142] for the CdSe layers of a free-standing CdS/CdSe superlattices with layers of equal thickness. A value of $\varepsilon \approx 49 \cdot 10^{-3}$ has been determined for nanocrystals having $d_{NC} = 3.0$ nm, which indicates that, as it might be expected, the level of microstrains rises with decreasing NC size. Several reasons can cause this strain. The surface-to-volume ratio increases with decreasing layer thickness and nanocrystallite size, which is correlated with a higher intrinsic stain and caused by bond-angle deviation. Some interface strain can originate from the difference in the thermal expansion coefficient of the two materials. There may be also an intrinsic component resulting from the volume shrinkage with the transformation of an amorphous region into a more dense crystalline material. Keeping in mind that both the particle size and the lattice strain have a different angle dependent influence on the Bragg diffraction linewidth, the particle size and strain can be separated by two-line Scherrer analysis as described in [143].

The internal strain distribution has also been studied in nc-Si:H/a-Si:H MLs [144] by analyzing the intensity and line widths of X-ray diffraction peaks in the low- and high-angle ranges and the obtained results have been compared with those from Raman scattering. The elastic tensile strain ε has been calculated approximately by using the X-ray diffraction angle of the (120) plane for Si single crystal ($2\Theta = 28.47°$), which was reduced to $2\Theta \approx 27°$ in MLs [145]. The relation

$$\varepsilon = (a - a_o)/a_o \tag{11}$$

has been applied, where a_o is the lattice constant of single crystal Si and a is the measured lattice constant of MLs due to the internal strain. The elastic tensile strain has also been estimated from the Raman scattering data using the relation

$$(\omega_c - \omega_s)/\omega_c = -\varepsilon(P + 2Q)/\omega_c^2 \tag{12}$$

where $P = 1.43\omega_c^2$ and $Q = (-1.89)\omega_c^2$ are the phonon deformation potentials of Si, ω_c is the frequency of the crystalline peak, and ω_s is the vibrational frequency of the shell region between the crystalline core and outer space in nanocrystallites [123, 146]. The effective strains obtained by both approached are about 5% for MLs with nc-Si:H layer thicknesses of 2.2 and 3.0 nm and a-Si:H thickness of 8 nm. The strain can partially be released by using high annealing temperatures [118]. A quasi-equilibrium annealing (with a rate of temperature increase of ~10 K/min) from 870 K to 1320 K has been proposed [63] to reduce internal strains and

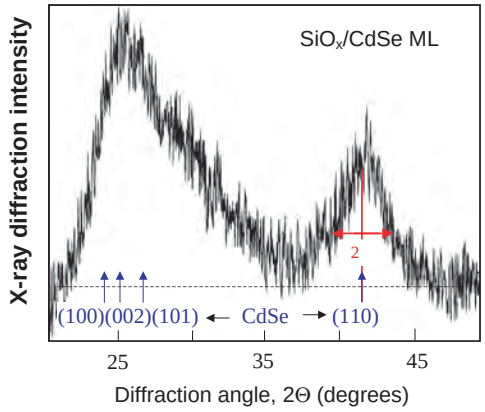

Figure 5. X-ray diffraction spectrum of a SiO_x(5 nm)/CdSe(5 nm) ML. The (100), (002), and (101) bands of wurtzite CdSe are not resolved while the (110) one is well resolved and can be used for determination of CdSe nanocrystallite size by applying Eq. (1); $\delta\Theta$ indicates full width at half maximum of the (110) band.

interface defect density upon rapid thermal crystallization of Si/SiO_2 a-MLs.

Small- and high-angle X-ray diffraction studies on a-Se/a-CdSe MLs, annealed at various temperatures for a long time (18 hr) have shown [105, 140] that the ML periodic structure vanishes upon annealing at 333 K (the glass transition temperature of a-Se is $T_g \approx 320$ K). Upon annealing at 363 K, a crystalline phase was evident by its main diffraction peak situated at $2\Theta = 29.6°$. Also, upon annealing at 720 K in a vacuum used for preparation of a-Si:H/nc-Si MLs [147], it has been seen that the layered structure is partially destroyed. This observation has been explained by the effusion and redistribution of hydrogen over the volume of the films. On the other hand, the SAXRD spectra of a-Ge:H/a-GeN_x MLs annealed at temperatures higher than the crystallization temperature of a-Ge (723 K) have proved that both the ML period and the interface quality did not change appreciably after the crystallization of a-Ge:H layers [101]. The HRTEM results on those MLs, as well as on other Ge-based a-MLs [67, 103], have displayed that a-Ge layers crystallized without disrupting the multilayer structure, and that after crystallization the interfaces were atomically smooth and uniform. It has also been established that in a-Si:H/SiO_2, a-Si:H/SiC_x, and a-Si:H/SiN_x [63, 121], as well as in SiO_x/GeO_y [148] MLs, both thermal and laser-beam crystallization of the a-Si:H and GeO_y layers do not destroy the regular periodic structure of multilayers. Finally, SAXRD studies of CdSe/a-SiO_x MLs, annealed at 673 K for 60 min [93], have shown that these MLs also exhibited a very good periodicity. The above short review of the results on the periodicity of various nanocrystalline/amorphous multilayers shows that the periodic structure of amorphous multilayers is resistant to annealing or laser beam illumination when the constituent material with the higher crystallization temperature has a rigid structure. In such MLs, the growth of semiconductor microcrystals in the "low-temperature" sublayers is restricted along the ML axes and, thus, crystallization does not destroy the ML periodic structure.

3.2.4. Material Intermixing

The furnace crystallization of sublayers from the "low-temperature" material in a-Ge and a-Si based a-MLs, requires quite high annealing temperatures (>770 K for a-Ge:H [1] and >970 K for a-Si:H [23]). At these temperatures, undesired interdiffusion and alloying of the constituent materials may take place at ML interfaces. In certain studies on annealing of a-Ge:H/a-GeN_x [101], a-Ge:H/a-SiN_x:H [103] and a-Ge/a-C [67] MLs alloying has not been observed. On the other hand, in a-Si:H/a-Ge:H MLs [111], the annealing at temperatures > 670 K leads to strong material intermixing, followed by the crystallization of the resulting silicon germanium alloy. Anisotropic Ge diffusion has been directly observed in SiGe/Si-strained superlattices [149] induced by nonuniform strain in SiGe/Si interface in the range 700–1000 °C. Additionally, it has been shown [150] that the Ge-Si interdiffusion increases by more than two orders of magnitude for stucked hut clusters and the degree of Si alloying in vertically aligned self-assembled islands increases with the number of stached layers. Interdiffusion has also been reported in annealed Si/SiC [112] MLs. A small region of mixed Ge-Si alloy at each interface has been observed in SiO_x/GeO_y MLs annealed 770 K [148].

Although thermal crystallization in chalcogenide a-MLs occurs at much lower temperatures than in a-Si- and a-Ge-based MLs, material intermixing has also been observed in MLs of various materials. The effect of annealing (at 340 K for 60 min) on photo and electrical conductivity, as well as on infrared absorption of As_6Se_{94}/Te, a-MLs has been studied in [70]. It has been observed that at the first step of the annealing process, a diffusion of Se atoms into Te sublayers occurred and As-Se/Se-Te a-ML formation took place. Further annealing leads to As-Se/As-Se-Te MLs formation. Systematic optical and electrical studies on photo- and thermo-induced changes of As_2S_3/Se, As_2S_3/Se_xTe_{1-x} ($0.1 < x < 0.5$), and $As_6Se_{94}/Se_{80}Te_{20}$ a-MLs have indicated [80, 81] that the periodic structure of these MLs was changed by thermal treatment and laser beam exposure due to the interdiffusion. It should be pointed out that in this group of MLs, the corresponding photo-induced changes of their optical parameters (absorption, refraction) can be successfully used for optical recording. Raman scattering measurements have been carried out on as-deposited and annealed at 670 K multilayers of ZnSe/CdSe [151]. It has been shown that $Zn_xCd_{1-x}Se$ interface regions were formed during sample preparation and a gradual change in the composition is characteristic for these regions. Raman spectra of ZnSe/CdSe MLs annealed at 670 K for 60 min are displayed in Figure 6. It can be seen that the intensity of the band at around 225 cm^{-1} (it is due to scattering from $Zn_xCd_{1-x}Se$) is rather high. This indicates that large $Zn_xCd_{1-x}Se$ interface regions exist in annealed samples. The result has been explained assuming diffusion of Cd atoms from CdSe into ZnSe. It has been shown in this study that when the nominal thickness of CdSe layers is very small, taking advantage of material alloying at the interfaces, it is possible to produce $Zn_XCd_{1-X}Se$ nanoparticles in a ZnSe matrix by means of thermal evaporation of CdSe and ZnSe in vacuum.

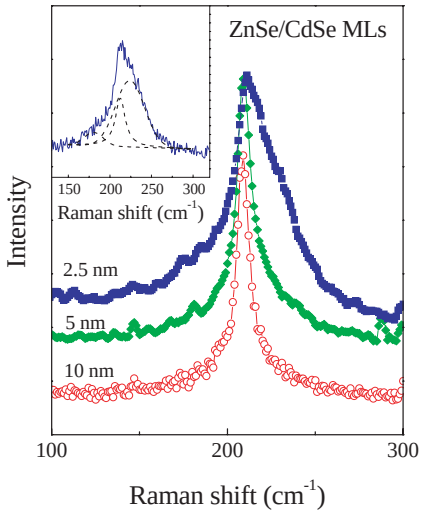

Figure 6. Raman scattering spectra of ZnSe/CdSe MLs with layer thicknesses indicated in the figure. The 647.1 nm line of a Kr^+ laser was used for the excitation. Inset: Raman spectrum (solid line) fitted to one Lorentzian peaked at 212 cm^{-1} and two Gaussians at 180 cm^{-1} and 225 cm^{-1} (dashed lines).

Various results obtained under annealing of different amorphous MLs may be understood if one keeps in mind that several competitive factors can affect material intermixing and alloying at the ML interfaces. Diffusion coefficients of the atoms of each constituent material in the other one, and the possibility for alloying of both materials (i.e., the correlation between the magnitudes of the bond energies in the constituent materials and their alloy) could be among them. Hence, various approaches may be applied in order to avoid the layer intermixing. One of them is the selection of proper pairs of materials; the data reviewed imply that semiconductor/semiconductor oxide (or nitride) pairs are better than semiconductor/semiconductor ones. This suggestion is motivated by the results for nc-CdSe/SiO_x [152], nc-Ge/a-GeN_x [101], and nc-Ge/a-SiN_x [103] MLs, in which no alloying has been observed and the considerable alloying reported for nc-CdSe/ZnSe, nc-CdSe/GeS_2 [151, 153], nc-Ge/a-Si:H [111], etc. The second approach, which may be applied to avoid thermally induced sublayer intermixing, is the application of combined photo-thermal or "pure" photo-induced crystallization processes. As previously described [79, 86], a considerable diffusion of Se and Te takes place in chalcogenide materials upon long-time furnace annealing even at considerably low temperatures. In Se-based MLs, one may use the fact that "pure" amorphous selenium and, particularly, selenium-tellurium alloys exhibit strong photo thermally-induced crystallization at room temperature. Moreover, they crystallize under laser beam exposure at fairly low temperatures (<100 K), at which the thermally induced atomic diffusion is extremely slow. Thus, using photo crystallization at room and low temperatures, it is possible to make optical recording in amorphous chalcogenide MLs with minimum alloying at the ML interfaces. It has been shown [103] that crystallization of a-Ge in a-Ge:H/a-SiN_x:H MLs is a type of explosive process, caused by the high stress of the a-Ge:H, which is triggered by laser heating. In this situation, crystallization occurs for a very short time and no interface alloying has been detected. All given examples indicate that special attention should be paid to material intermixing, in particular, when furnace long-time thermal crystallization of a-MLs is applied, As for the short-time crystallization procedures (rapid thermal annealing and laser annealing), it seems that they do not deteriorate the interface quality and ML periodicity very much.

All silicon and germanium-based multilayers described in Section 3 are listed in Table 1 along with the techniques applied for their preparation and crystallization of the layers with the lower T_c. This information for chalcogenide-based MLs considered in Section 3 is summarized in Table 2.

4. DISCONTINUOUS NANOPARTICLE LAYERS

4.1. Nanostructured Composites

Fabrication of semiconductor nanoparticles is very important for realization of new functional quantum devices [154]. Various techniques, such as doping in glasses, epitaxial nanocrystal growth, gas evaporation, cosputtering, laser ablation, colloidal methods, ion implantation, etc. have been applied [144 and references therein] for fabrication of nanoparticles. They can be produced as nanophase powders or nanostructured composites. The latter have two main advantages to the nanophase powders: they ensure a good mechanical stability and keep nanoparticles from the influence of the surrounding ambient. Bulk composites of $CdSe_xS_{1-x}$ semiconductors and silicate glasses (so-called semiconductor-doped glasses) have been the first to focus much interest with their high-optical nonlinearity [156–158] and quantum-size changes of the electronic structure [32, 35]. Thin films of CdS [152, 159, 160], CdSe, and CdTe [161] dispersed in high-frequency sputtered SiO_2 have also been prepared as counterparts of the doped glasses. In those bulk samples and thin films II–VI, semiconductor nanocrystals have been grown in a diffusion-controlled phase decomposition of oversaturated solid solution. That process is carried out at high temperatures ($T > 900$ K) for several to 100 hr [159]. Silicon nanoparticles in Si-rich silicon oxide films are also produced by high-temperature annealing ($T > 1170$ K) in an inert atmosphere [162–170]. In this approach, the average nanoparticle size could be tuned either by varying the annealing temperature or by changing the excess silicon content in the deposited films. Recent investigations have shown that very high photo conductivity can be obtained in hydrogenated amorphous silicon films containing a small volume fraction of nanocrystalline silicon inclusions [171]. However, even playing with the deposition parameters, it is rather difficult to control the size, amount, and spatial distribution of those nanocrystallites.

Systems based on metallic clusters encapsulated in an insulating or semiconductor matrix have also attracted considerable interest with their interesting optical properties [172], as well as with the appearance of switching effects in nanodisperse metals [173–175]. A somehow similar effect has been intensely investigated in metal/a-Si:H/metal sandwich structures [176–178] and MLs having discontinuous metal layers [179]. Multilayer systems of amorphous silicon and metals have been used as mirrors for soft X-ray radiation [180], X-ray detectors [181], and position sensors [60]. It has also been demonstrated that a-Si/Mo and a-Si/Ta MLs exhibit very interesting features such as linear lateral photo voltage [182] and giant current fluctuations [179] when the metal layers are discontinuous. Similarly, to the fabrication of semiconductor-doped glasses, the common method to prepare materials consisting of nano-sized metallic clusters embedded in insulating matrix is cosputtering or coevaporation of the metal and insulator on a suitable surface. The cluster sizes are controlled by varying the substrate temperature and/or post-growth annealing.

4.2. Preparation of Discontinuous Layers

An alternative approach for preparation of nanostructured composites is to use sequential vapor deposition of semiconductors (metals) and insulating (semiconductor) materials. The Stranski-Krastanow self-organized epitaxial growth of III–V [183] and, more recently, II–VI semiconductor nanocrystals [184, 185] in strained systems has attracted much attention. This mechanism takes place on the smooth surface of a crystalline material, but it can explain the nanocrystal growth observed on a rough surface [180, 185–189]. This nonepitaxial self-organized nanocluster formation has

been used for fabrication of nanoparticle layers buried in thin film matrices. It occurs on the rough surface of amorphous, thin films deposited by means of physical evaporation, sputtering, or glow-discharge techniques.

4.2.1. Metal Nanoparticle Layers

Metal (Mo,Ti,V)/a-Si ML systems (also called composite films) have been prepared by magnetron sputtering of both materials or by an rf glow discharge deposition of a-Si and thermal evaporation of metals [180, 186]. Discontinuous metal sublayers were formed by interrupting the growth process before the stadium of coalescence at a nominal layer thickness of around 1 nm. The thickness of a-Si layers was 100 nm. Scanning force microscopy measurements of surface topography revealed metal clusters with diameters of the a-Si:H surface roughness (2–8 nm). These clusters were arranged in chains up to several hundreds of nanometers in length. Cross-section TEM micrographs showed island-type metal layers having a typical thickness of 10 nm. It has been assumed that metal clustering is supported by the existing valleys of the a-Si:H surface structures. As in MLs with continuous layer, an material mixing has been observed at the interface. It is interesting to mention the observed asymmetry of the mixing. The mixed interface region from the growth of the metal on Si has significantly greater thickness ($\sim$10 nm) than that (a few nanometers) from the growth of the Si on the metal.

Nanoparticle layers of Ga, with relative low-size dispersion ($\leq$20%) and regular shape of a truncated sphere, have been produced by thermal evaporation of Ga on 5 nm thick SiO_x films. Metal particles were formed in the liquid state by a self-organization process [189, 190], which is related to the partial wetting character of Ga with respect to the insulator [190]. The melting point of Ga in nanoparticle layers is considerably lowered with respect to the bulk materials and it is liquid at room temperature [191].

Self-organized growth has also been observed on deposition of cobalt on alumina [192–195]. Multilayers were

prepared by sequential rf sputtering of Co and Al_2O_3 at room substrate temperature. It has been shown [193, 194] that nearly spherical crystalline Co clusters with diameters ranging from 0.8 nm to 4.5 nm were formed when nominal deposited Co thickness increases from 0.2 to 1 nm. The Al_2O_3 layer thickness was several nanometers. The metal nanocluster formation has been discussed in terms of a large difference of surface energies of the transition (and noble) metals and insulators [196]. Additionly, cross-section TEM of Co(0.7 nm)/Al_2O_3(3 nm) MLs has shown [195] an ordered structure (seen in a given range of thicknesses), which consists of Co clusters with a diameter of 3 nm, whose vertical arrangement from plane to the plane is not random but shows an *additional* self-organization related to topology reasons [195]. When Co is deposited on Al_2O_3, clusters are formed that display the in-plane order. The next Al_2O_3 layer is assumed to wet perfectly this Co island-type layer being undulated. During the next Co deposition, cluster formation takes place preferentially in the hollows of the wavy Al_2O_3 surface. The periodic repetition of this phenomenon is considered to be the origin of the self-organized Co growth observed. The last result illustrates that in contrast to a codeposition method, the multilayer approach allows preparation of composite structures in which the size and spacing of the clusters can be controlled directly by varying the thickness of the layers. If this fabrication method can be extended to ferromagnetic alloys, it might open a new route for the fabrication of advanced magnetic recording media.

As previously discussed, at semiconductor/semiconductor interface, significant material intermixing may take place which can strongly effect ML properties. Similarly, in a metal/oxide structure, one should pay attention to possible reactions at the interface. X-ray photoelectron spectroscopy has been used to probe metal (Au, Ag, Mg, Mg-Ag alloy)/AlO_3 interface structures. It has been found [197] that there is no chemical reaction at (Au, Ag)/AlO_3 interfaces, while there is a significant reaction/diffusion at (Mg, Mg-Ag alloy)/AlO_3 ones. The reaction involves formation of Mg and metallic Al and then followed by metallic Mg diffusion to the interface.

4.2.2. Semiconductor Nanoparticle Layers

Preparation Semiconductor nanocrystals (quantum dots) of ZnCdSe has been grown by molecular beam epitaxy on a ZnSe crystalline surface which was intentionally roughened [198]. High-resolution transmission electron microscopy studies have shown that the vertical size of nanoparticles was significantly smaller than their in-plane size and, also, the size distribution of those dots was rather wide.

Another technique has been developed [97, 188, 199–201] for fabrication of CdSe nanoparticle layers buried in amorphous thin film matrices. Consecutive deposition of ultra-thin films of thermally evaporated CdSe on a relatively rough surface of the matrix material (SiO_x, GeS_2, ZnSe) has been applied. When developing this technique, it has been taken into account that during the nonepitaxial growth of thin films, the top surface of these films is rough with amplitude of this roughness varying with the deposition techniques. In case of thermal evaporation of materials, this amplitude is $\sim d^{1/2}$ (d-film thickness) [202] and, hence, the thicker the thermally evaporated layer, the greater its surface roughness. Multilayer of consecutively deposited SiO_x (GeS_2, ZnSe) and CdSe layers were fabricated in which the SiO_x thickness d_{SiO_x} was 20 times greater than that of CdSe layers d_{CdSe}. One can expect that CdSe layers will be discontinuous rather than continuous. A schematic diagram of such a ML structure is shown in Figure 7. Cross-section high-resolution electron microscopy measurements have revealed [97, 199, 200] that, indeed, CdSe does not form a continuous layer. Instead, nearly spherical CdSe nanoparticles partly isolated, and partly in contact among each other, are disposed in a composite SiO_x-CdSe "sublayer" of up to 10 nm in thickness (Fig. 8). It should be pointed out that nanoparticles are not grown in the surface valleys but their spatial distribution follows the morphology of the surface underneath. The great width of the CdSe nanoparticle spatial distribution also indicates that they should not be formed only in the surface valleys. The results indicate that the surface roughness favors the self-organized formation of CdSe nanoparticle layers rather than the growth of continuous thin films.

High-density Si nanoparticles have been successfully grown on Si_3N_4 and SiO_2 thin film surfaces by hot-wire CVD using disilane, in which Si atoms were generated on a heated tungsten filament [203]. A highest density of 1.1×10^{12} cm^{-2} has been achieved with corresponding average nanoparticle size of about 5 nm. Sandwich-structured thin films of silicon nanoparticles embedded in Al_2O_3 matrices have been prepared by pulsed laser beam evaporation [203]. It has been found that the sharpness of the Si/Al_2O_3 interface depend strongly on annealing conditions.

The described approaches of production of nanoparticle layers buried in a thin film amorphous matrix makes possible the reproducible fabrication of nanocrystals for shorter times and at considerably lower annealing temperatures than those usually used for the nanocrystal growth in

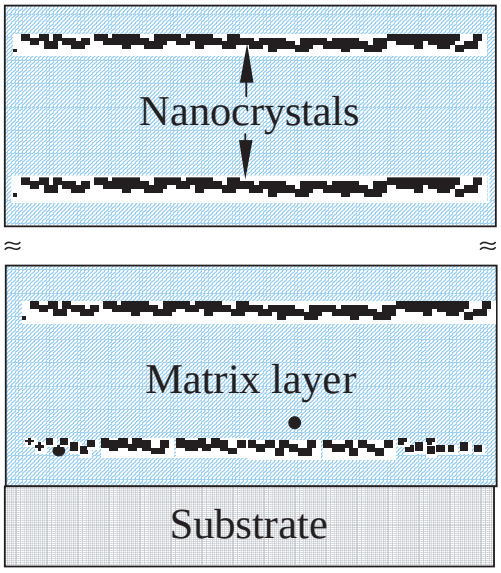

Figure 7. Schematic presentation of a semiconductor-matrix composite film in which the nominal semiconductor layer thickness d_s varies between 1 and 6 nm and the matrix layer thickness is $d_m = 20\ d_s$.

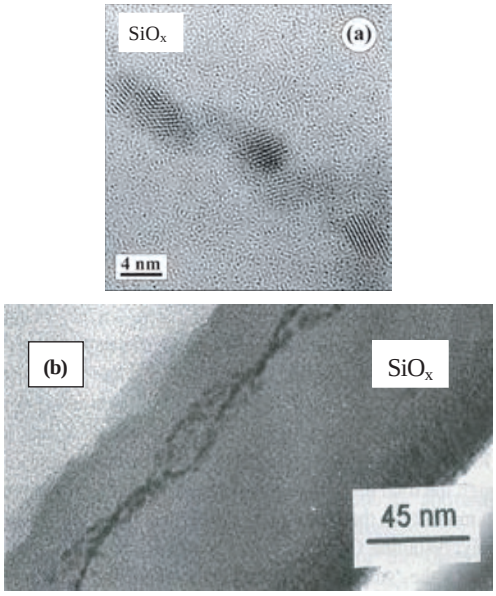

Figure 8. Cross-section view of the spatial arrangement of CdSe nanoparticles in as-deposited three layer structures SiO_x(40 nm)/CdSe(2 nm)/SiO_x(20 nm) at high (a) and low (b) magnification. The spatial distribution of the nanoparticles follows the surface morphology of the SiO_x layer.

semiconductor-doped glasses and their thin film counterparts. This technique, if applicable, can be very useful, especially for semiconductors such as Se, which form nanocrystals of very different sizes in the standard procedure of crystal growth in a diffusion-controlled phase decomposition of oversaturated solid solution.

Size Distribution and Structure A deeper inspection of the buried CdSe nanoparticles by high-resolution electron microscopy have shown [199] that nanoparticle crystal lattice is randomly oriented. Occasionally, deviations from the spherical shape have been observed indicating the effect of particle interaction by coalescence. The average size of CdSe NCs was estimated from the (119) band in the X-ray diffraction patterns of samples with various nominal CdSe sublayer thicknesses employing Scherrer's Eq. (9) and the values obtained were close to the nominal thickness of deposited CdSe layers. On the other hand, HREM evaluation of the particle sizes yielded a mean diameter, which is more than twice greater than the nominal layer thickness of deposited CdSe. Keeping in mind the above discussed reason for this discrepancy (internal strains and deformations), a value of $\varepsilon \approx 49 \cdot 10^{-3}$ has been determined for nanocrystals having $d_{NC} = 3.0$ nm, which indicates that as it might be expected, the level of microstrains rises with decreasing NC size.

The changes upon annealing of the SiO_x-CdSe samples at 670 K have been studied by a cross-section HRTEM [199, 204]. It has been observed that after annealing at 670 K, crystal lattice of the CdSe nanoparticles remains oriented randomly, but their sizes increase a little and the spherical appearance is improved. From the high-resolution imaging of lattice plane fringes and by comparison of the diffractograms of both images, it has been estimated that the crystallinity of the CdSe nanoparticles is improved upon annealing. Values of 0.12 and 0.15 have been obtained for η/d_{NC} ratio in as-deposited and annealed SiO_x(20 nm)/CdSe(1 nm)/SiO_x(20 nm) structures, respectively, (where η is half the width at half the maximum of the size distribution). In annealed SiO_x(40 nm)/CdSe(2 nm)/SiO_x(20 nm), $\eta/d_{NC} \approx 0.21$. This nanocrystallite size distribution is compatible and even slightly narrower than those reported for CdS [205] and Ge [206] nanocrystals grown in SiO_2 matrix during the annealing of thin films of CdS-doped silica and $Si_{1-x}O_xGe_y$, respectively.

One important observation from the HRTEM micrographs is the high density of planar lattice defects in both as-deposited and annealed films. These defects could be among the reasons for the great difference in the average nanocrystal sizes obtained from the X-ray diffraction patterns and those seen in HRTEM micrographs. This raises the question for the lattice type present in the nanoparticles. Usually, CdSe is described by the hexagonal wurtzite B4 type, which was found also for CdSe nanoparticles from HRTEM studies [207, 208]. On the other hand, it is known that in the nanoscale range II–VI, semiconductors tend to change rather easily from the wurtzite to the cubic zincblende B3 type and vice versa [209, 210]. This transition and the corresponding stacking disorder have been rated by measuring the lattice fringe spacings of a number of particles [204]. It has been observed that in as-prepared samples (deposited at room substrate temperature), CdSe particles display a predominantly wurtzite lattice type, while in the annealed structures (at 670 K), CdSe particles of the sphalerite lattice type have been frequently seen. For the as-deposited nanoparticle layer, three-quarters of the particles reveal spacings of the hexagonal and one-quarter spacings of the cubic or both lattice types. For the annealed structures, however, it has been found that approximately one-half of the particles reveal spacings of the cubic and another half spacings of the hexagonal or both lattice types, respectively. It is important to notice that in three-dimensional CdSe films deposited, the situation is just the opposite. The films deposited at low substrate temperatures ($T < 370$ K) show predominantly sphalerite structure. The annealing of three-dimensional films at 670 K converts their structure to wurtzite type. This difference in the behavior of three-dimensional and zero-dimensional CdSe is most likely due to surface-induced changes in bond strength in the nanoparticles.

Mechanism of Semiconductor Nanoparticle Formation As discussed in Section 2, at the first stage of thin film deposition, the formation of embryos takes place, which depends on the temperature, chemical nature, structure, and clearness of the substrate surface [202]. In particular, the presence of steps on the substrate surface induces an increase in the embryo concentration at these steps. It has also been shown [211] that the curvature and stress at a rough or even disordered surface, strongly affect reaction rates at solid interface as they create different environments at different reaction sites. The sequential vapor deposition of two materials, which have been used for preparation of CdSe nanocluster layers, has been also applied for nonepitaxial growth of nano-sized metallic clusters embedded in insulating matrix. Several assumptions have been previously mentioned for the mechanism of the metal nanoparticle formation. It has been assumed [186] that the existing valleys

of the thin film a-Si:H surface support clustering of Mo and W. Also, the cluster formation at most of the transition and noble metals on insulator has been attributed [196] to the large difference of surface energies. The partial wetting character of Ga with respect to SiO_x has been considered [190] as responsible for the formation of liquid Ga nanoclusters on the "smooth" surface of SiO_x ultra-thin films. The cross-sectional electron micrograph of SiO_x/CdSe multilayers have shown [95, 96] that when in the SiO_x/Ga MLs the ultra-thin metal layers are replaced by CdSe semiconductor layers, the latter is continuous rather than "island" type. However, when the SiO_x (GeS_2, ZnSe) surface is "rough," CdSe particle formation takes place, as the spatial distribution of nanoparticles follows the surface morphology of the SiO_x (GeS_2) films. This implies that different mechanisms should be responsible for the metal and semiconductor nanoparticle formation. Obviously, the assumption for difference of surface energies cannot explain deposition of continuous CdSe layers on a relatively "smooth" surface and discontinuous ones on a relatively "rough" surface. In addition, one could not expect the same partial wetting character of CdSe with respect to SiO_x, GeS_2, and ZnSe.

The HRTEM and X-ray diffraction results showed that the surface roughness of SiO_x layers in the SiO_x/CdSe MLs having layer thicknesses <10 nm is relatively small. Therefore, it has been assumed [95] that a homogeneous embryo formation takes place at the first stage of CdSe deposition on the "smooth" SiO_x surface. A gradual increase of the nanoparticle size and coalescence as well as new embryo formation can be expected further; CdSe layers become continuous at a nominal thickness ≥2.5 nm. The observed spatial distribution of the CdSe NCs in the composite films indicates that surface roughness plays an important role in the CdSe nanoparticle formation. It has been suggested [199] that at the very beginning of CdSe deposition on a "rough" oxide or chalcogenide surface embryos were formed at those surface positions at which the curvature and lattice stress are the greatest. The relatively narrow size distribution implies that further CdSe deposition does not create new embryos but leads mainly to an increase of the nanoparticle size. As the positions with great surface curvature and lattice stress are disposed accidentally, some embryos are created rather closely and, for this reason, some nanoclusters are in contact.

In the end of this section, we would like to pay attention to several slightly different applications of the multilayer approach. The first one is a size-controlled nc-Si synthesis, which has been recently realized in SiO/SiO_2 MLs [212, 213]. Thermally induced phase separation has been applied in order to grow Si NCs in the SiO layers. By this technique, a separate control of crystallite size and density is possible. This approach allows fabrication of Si nanocrystals of a well-defined size and rather high density, which is very important for fabrication of light-emitting devices. Germanium island (6–7 nm in diameter) formation with a high density (2×10^{12} cm^{-2}) has been reported [214] on ultra-thin SiO_2 films. It is important that each dot in this multilayer structure had a boundary with the SiO_2 film and, also, with a Si spacer layer.

Another application of the multilayer approach is in preparation of metal-doped films using metal dissolution in ammealed MLs [215]. Multilayers have been prepared by alternative metal (Ag) and chalcogenide ($As_{33}S_{67}$) vapor deposition in vacuum. Such MLs have shown a greater sensibility to illumination and a larger photo-dissolution rate in comparison to the conventional double-layer structure $Ag/As_{33}S_{67}$. The ML structure has been used to fabricate a phase grating for operation in the infrared region. Furthermore, Mo/Si MLs deposited using electron beam evaporation were used to study the formation of silicides at high temperatures [216]. It has also been demonstrated [217] that the introduction of SiO_2 layers in the interface of Mo/Si multilayers was quite effective in improving the heat stability of the MLs. An asymmetric SiO_2 layer thickness of 0.5 and 1.5 nm has been found to be most favorable at the Si-on-Mo interface an Mo-on-Si interface, respectively.

All multilayers described in Section 4, which contain discontinuous metal or semiconductor nanoparticle layers as well as techniques used for their preparation, are listed in Table 3.

Table 3. Multilayers with discontinuous metal or semiconductor layers.

Discontinuous layer/matrix	Preparation technique
Co/Al_2O_3	radio frequency sputtering [193–195]
Ga/SiO_x	thermal evaporation [190]
Mo/a-Si:H	radio frequency sputtering [186]
Ti/a-Si:H	radio frequency sputtering [186]
V/a-Si:H	thermal evaporation of V, glow discharge a-Si:H [186]
Ti/a-Si	[60]
CdSe/a-SiO_x	thermal evaporation [97, 98, 188, 199, 201]
CdSe/a-GeS_2	thermal evaporation [97, 98, 200, 201]
CdSe/ZnSe	thermal evaporation [97, 98, 201]
a-nanoparticle-Si/SiO_2	hot-wire CVD [202]
a-nanoparticle-Si/Si_3N_4	hot-wire CVD [202]
a-Si/Al_2O_3	laser beam evaporation [203]
SiO/SiO_2	thermal evaporation, high temperature annealing [213, 214]

5. CONCLUDING REMARKS

The results described in this article show that preparation of high-quality amorphous multilayers and superlattices and proper post-treatment can be applied for fabrication of semiconductor and metal nanoparticle layers buried in various thin film matrices. The production of amorphous multilayers is realized mainly by using vapor deposition techniques that are widely available, inexpensive, and do not require rather long times for sample deposition. In addition, the application of the step-by-step deposition approach ensures good periodicity and abrupt interfaces of the multilayers. Vapor deposition techniques have the following advantages:

1. The size of nanoparticles can be effectively controlled by predesigned layer thickness during sample deposition.
2. Surface contamination of nanoparticles, which significantly affects their electronic structure, photoluminescence, etc., is avoided.
3. The whole ML structure has a high stability.

However, using the described multilayer approach, it should be kept in mind that while at semiconductor-oxide (nitride, organic) interfaces, material intermixing is negligible, it might be rather strong at semiconductor-semiconductor interfaces. Such intermixing may affect many properties of materials comprising semiconductor-semiconductor interfaces and should be taken into account in all research and application studies.

The success in fabrication of continuous and discontinuous nanoparticle layers in multilayer structure makes possible fundamental investigations in the field of the classic and quantum physics. A great number of new phenomena have been observed that raise new questions for discussion [32, 96, 218]. The observed new size-related properties of these materials allow a number of applications in opto-electronics (light-emitting devices, color filters, photoresistors, etc.), nonlinear optics (transducers, optical keys, waveguides, etc.), and solar energy conversion. The possibilities for xerographic applications and information processing and storage are also subjects of investigations.

GLOSSARY

Continuous nanoparticle layer A layer consisting of densely packed nanoparticles, which are in close contact.

Discontinuous (island type) nanoparticle layer A layer consisting of nanoparticles, a part of which are isolated while others may be in contact with each other.

Multilayer A film consisting of three or more thin layers.

Nanoparticle Crystalline or amorphous particle of a given material and varying shape having a nanometer size in all dimensions.

Periodic (regular) ML A ML built of two kinds of alternating amorphous or/and crystalline thin layers. Each kind of layers is characterized by constant thickness.

Superlattice A periodic ML having ultra thin parallel layers and smooth interfaces.

ACKNOWLEDGMENTS

The author thanks all colleagues from her laboratory as well as Associate Professor C. Raptis from the National Technical University of Athens, Greece, and Dr. H. Hofmeister from the Max-Plank Institute, Halle, Germany, who work with the author on preparation and/or investigation of multilayer structures including nanoparticle semiconductor layers. Dr. Nesheva is also very grateful to the Royal Society for granting collaborative studies in the field with Dr. C. Main and Dr. S. Reynolds from the University Abertay Dundee, Dundee, United Kingdom.

CONTENTS

1. INTRODUCTION

Polymeric nanocomposites can be considered an important category of organic-inorganic hybrid materials, in which inorganic nanoscale building blocks (e.g., nanoparticles, nanotubes, or nanometer-thick sheets) are dispersed in an organic polymer matrix [1, 2]. They represent the current trend in developing novel nanostructured materials. When compared with conventional composites based on micrometer-sized fillers, the interface between the filler particles and the matrix in a polymer nanocomposite constitutes a much greater area within the bulk material (Fig. 1) and hence influences the composite's properties to a much greater extent, even at a rather low filler loading [3].

From the literature, it is somewhat ambiguous who proposed the term "nanocomposites" for the first time. Different authors gave different opinions [4–6]. Nevertheless, the definition of "nanocomposites" is generally accepted without any argument. That is, it refers to materials consisting of various (two or more) solid phases with different compositions or structures, where at least one dimension is in the nanometer range. It has become familiar worldwide nowadays, especially because of some successful commercial products based on these materials, such as air intake covers and bathroom deodorizers. As far as polymer nanocomposites are concerned, not so many results have been published (Fig. 2), despite a large interest in them. However, polymer nanocomposites have been investigated for a long time, even though the technical term has only recently become popular. For example, extensive studies of carbon black-filled rubbers began before the mid-twentieth century [7]. Semicrystalline polymers can also be considered in some sense another example of nanocomposite materials. They consist of crystalline lamellae (typically 10 nm in width and thickness) dispersed in an amorphous matrix [8].

The recent interest in polymer nanocomposites is based on new achievements expected from their nanostructure, such as unusual mechanical, optical, and magnetic properties. A new degree of freedom for the development of advanced materials with enhanced performance becomes available in this way. In addition, the push for polymer nanocomposites arises from the facts that (1) polymers are still easily processible in many different ways, even with nanoscale solid fillers and (2) nanoparticles are provided by a polymer matrix with a high resistance to any chemical attack. In this way, the unique properties of nanosized objects can be combined with the qualities of a polymer matrix, to fit the requirements of specific applications in diverse areas (Table 1). Examples of polymer nanocomposites include biomimetic ceramic/polymer composites [33, 34], nonlinear optical metal colloid/polymer nanocomposites [35], and intercalated clay/polymer nanocomposites [36, 37].

Numerous procedures for the preparation of polymer nanocomposites have been proposed [38, 39]. They can

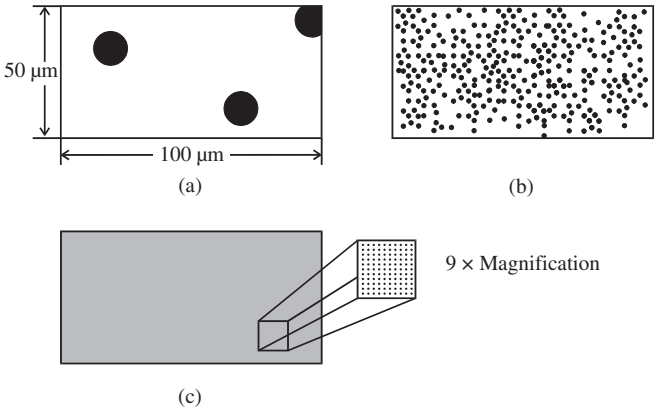

Figure 1. Schematic drawings of the microstructural appearance of typical particulate vs. fine particulate vs. nanoparticulate composites based on electronic microscopic observations. (a) 3 vol.% of particles with 10-μm diameter (2.86 particles within a volume of 50,000 μm^3). (b) 3 vol.% of particles with 1-μm diameter (2860 particles within a volume of 50,000 μm^3). (c) 3 vol.% of particles with 0.1 $\mu m = 100$-nm diameter (2.86 million particles within a volume of 50,000 μm^3). Reprinted with permission from [3], M. Z. Rong et al., *Polymer* 42, 3301 (2001). © 2001, Elsevier Science.

be basically classified in form of the following approaches: (i) direct incorporation of nanoscale building blocks into a polymer melt or solution [22, 40–42]; (ii) *in-situ* generation of nanoscale building blocks in a polymer matrix (e.g., vacuum evaporation of metals, thermal decomposition of precursors, reduction of metal ions through electrochemical procedures, etc.) [15, 43, 44]; (iii) polymerization of monomers in the presence of nanoscale building blocks [45, 46]; and (iv) a combination of polymerization and formation of nanoscale building blocks (e.g., sol–gel method, intercalation of monomers into a layered structure followed by polymerization, etc.) [47–50]. The key issue of these techniques lies in the fact that the geometry, spatial distribution, and volume content of the nanofillers must be effectively controlled through adjustment of the preparation conditions so as to ensure the structural requirements of nano-

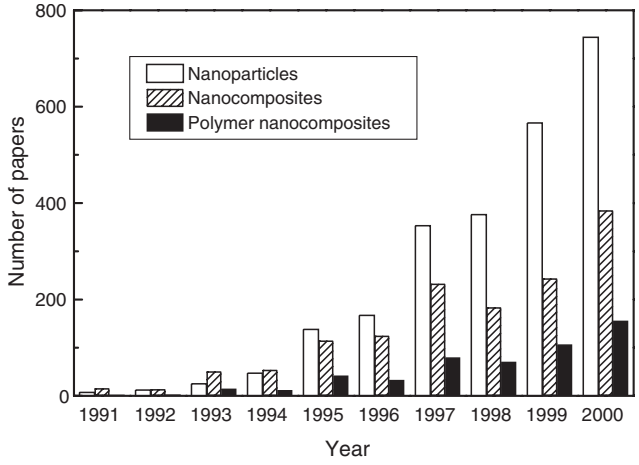

Figure 2. Number of papers published in the period 1991–2000 related to nanostructured materials. Data taken from EI Compendex.

Table 1. Potential applications of polymer nanocomposites based on their specific properties.

Properties	Examples of probable applications	Ref.
Catalytic	Long-life nanocatalysts	[9–12]
Mechanical	Strengthened and toughened polymers	[13, 14]
Magnetic	High-density storage elements, electromagnetic interference shielding materials	[15–18]
Electric	Low-cost conductive coatings, nonlinear resistors, electrostatic discharging filaments, electromagnetic interference shielding materials	[19–21]
Optic	Nonlinear optic materials, optical waveguides, photoelectric materials	[15, 22–26]
Thermal	High thermal conductive materials, low-temperature sintered materials	[19, 27]
Others	Sensors, biomimetic materials, wear-resisting materials, etc.	[28–32]

composites stated above. An ideal nanocomposite should be free of any agglomerates, should contain an optimum filler content, and should maintain at the same time the physicochemical characteristics of its individual components [27]. It is believed that the development of a mixing process for a stable, homogeneous dispersion of the nanophases is crucial for producing a uniform and void-free microstructure in polymer nanocomposites.

It is the aim of this chapter to provide a review of the main results achieved in the preparation and the mechanical behavior of nonlayered, nanoparticle-filled thermoplastic nanocomposites, as manufactured according to the first way (i) cited in the last paragraph. Thermosetting polymer-based composites, like nano-TiO_2/epoxy [51], carbon nanotube/epoxy [52], nano-SiO_2/unsaturated polyester [53], and nano-SiO_2/cycloaliphatic bisepoxide, with the use of an aqueous sodium silicate solution as a starting material [54], are excluded from the main concerns here. Instead, large-scale and low-cost production routes as well as a broad applicability of thermoplastic nanocomposites, intended to be used as structural materials, shall be considered. This can be achieved best by the employment of commercially available, nonlayered nanoparticles and by the use of blending techniques already widely used in the plastics industry.

From an examination of the literature, however, it was surprisingly found that works in this respect are relatively less documented. No global study of such systems has been carried out so far. Most of the papers dealing with thermoplastic systems as candidates for mechanical applications discuss intercalated and exfoliated (i.e., layered) nanocomposites. This phenomenon might be related to the shortcoming of the mixing dispersion method as characterized by the difficulties in (a) breaking up premade nanoparticle agglomerates, and (b) homogeneously arranging individual particles in a polymer matrix. Although great efforts have been made to solve these problems, techniques with sufficiently wide applicability are not yet available. As implied by the statistics in Figure 2, the development of nanocomposites and polymer nanocomposites is growing

moderately, presenting a striking contrast to the case of nanoparticles. This means there is a real need for a revolutionary breakthrough in making and utilizing polymeric nanocomposites.

2. SURFACE MODIFICATION OF NANOPARTICLES

Composite technology is aimed at producing a combination of properties that cannot be achieved with either of the constituents acting alone. Composition, component properties, microstructure, and interactions are the main factors determining the characteristics of composite materials. As compared with the other factors, interactions in composites play the most important role. Two basic types of interactions must be considered: particle–particle and particle–matrix interactions [55]. The effect of the former usually decreases the composite's performance, whereas that of the latter leads to the development of an interphase with properties different from those of the components.

It is known that the interaction between neighboring particles is governed by the competitive contributions made by attraction and repulsion due to van der Waals and electrostatic forces [56]. With decreasing particle size, a reduction in repulsion is much more significant than the decrease in attraction. As a result, attraction between the particles plays the leading role under a certain critical particle diameter. It accounts for the strong tendency of nanoparticles to aggregate.

The structure of a nanoparticle assembly may be classified according to the terminology used in the powder industry. That is, the ultimate primary particles (the smallest particulate pieces) exist in both strongly and weakly bound structures, which are commonly referred to as aggregates and agglomerates, respectively [57]. Agglomerates consist of an assembly of aggregates and have a larger, often more open structure. They behave like a single particle and can be disrupted by considerable force.

In a recent report by Pukanszky and Fekete [58], the forces acting on particulate fillers incorporated in a polymer (fluid or melt) are discussed in detail based on the works of Kendall [59] and Adams and Edmondson [60]. Although many types of forces (e.g., viscous, capillary, electrostatic, etc.) have certain effects, the adhesive force, F_a, which acts as an attractive force, and the hydrodynamic force, taking the role of a separating force, F_h, are the most important ones:

$$F_a = 1.5\pi W_{ab} R \tag{1}$$

$$F_h = 6.12\eta R^2 \dot{\gamma} \tag{2}$$

where R denotes the radius of the particles, W_{ab} is the reversible work of adhesion between the solid and the fluid, η is the viscosity of the fluid, and $\dot{\gamma}$ is the applied shear rate. It was revealed that agglomeration is determined by the relative magnitudes of attractive and separating forces. The predominant factors that influence the homogeneity of composites are the size of the particles, their surface tensions, and the shear forces acting during their homogenization [61]. It should be noted that the interparticle interaction might easily prevail over the shear force and favors the development of agglomerated structures in the case of smaller particles such as nanoparticles. Hence surface modification of the particles becomes critical to minimizing particle–particle interaction and enhancing particle–matrix interaction in composites.

In general, particulate surface modification can be carried out by utilizing physical and chemical interactions between particles and modifiers. The resulting bonds are often a mixture of secondary and chemical bonds. A great understanding of (a) treatment techniques, (b) interfacial characterization, and (c) the effect of interphase on composite properties has been acquired for composites incorporating inorganic fillers [62]. In the following, attention is focused on specific surface modification methods that have been intentionally used to introduce organic coatings onto nanosized filler surfaces.

2.1. Treatment by Physical Interaction

After physical treatment, inorganic fillers can be covered with either low-weight (through a surfactant) or high-weight organic molecules (through an encapsulation with polymer). Since secondary forces (like van der Waals, hydrogen, and electrostatic forces) can theoretically produce an adhesion of 7.0×10^2 to 7.0×10^3 MPa, in comparison with chemical bonds possessing specific adhesive forces of 7.0×10^3 to 7.0×10^4 MPa, the effect of surface modification based on physical interactions is, however, less significant than that of a chemical treatment.

2.1.1. Surfactant

Usually a surfactant contains one or more polar groups and a long aliphatic chain. The principle of surfactant treatment is the preferential adsorption of a polar group of a surfactant to the high-energy surface of a filler by electrostatic interaction. Ionic bonds can also be formed under certain circumstances. A typical example can be cited regarding the surface treatment of $CaCO_3$ with stearic acid [63], which is necessary when producing nano-$CaCO_3$. Stearic acid or its ammonium salt can be added directly during the precipitation step of $CaCO_3$. Electron spectroscopy for chemical analysis (ESCA) studies carried out on the surface of $CaCO_3$ covered with stearic acid showed that ionic bonds have been established between the surfactant molecules and the filler surface (Scheme 1). A further proof of the specific character of the above treatment is supplied by the fact that talc and silica absorb a significantly smaller amount of stearic acid at a unit surface than $CaCO_3$. Evidently, the lack of ionic bonding formation results in a much lower amount of the proportionally bonded molecules. Nevertheless, even for the treated $CaCO_3$, the particles still exist in the form of agglomerates because the interparticulate attraction is far beyond the obstructive effect resulting from the surfactant.

$$CaCO_3 + RCOOH \longrightarrow Ca(OH)(OOCR) + CO_2$$

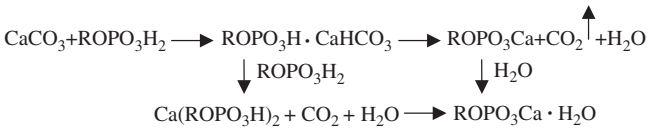
Scheme 1

Papirer et al. related the absorbed amount of stearic acid to the equilibrium concentration of the solution by establishing adsorption isotherms [64]. The quantity of stearic acid

retained by the solid was determined either from the change in concentration of the supernatant solution or directly by analyzing the recovered solid. The physisorption isotherm of stearic acid on $CaCO_3$ (50–100 nm) at 30 °C was found to follow a type II behavior, corresponding to a multilayer adsorption. After extraction of the treated particles with hot toluene for 24 h, the chemisorption isotherm was found to be a Langmuir-type one, which confirms the formation of a monolayer of stearic acid on the surface of $CaCO_3$. The monolayer (100% coverage) suggests a ratio of stearic acid of about 8% by weight. As the surface area of $CaCO_3$, calculated on the assumption of a cross-sectional area of stearic acid of 0.21 nm^2, is 35 m^2/g (in excellent agreement with the value obtained from N_2 adsorption), it was concluded that the stearic acid molecules are fixed perpendicular to the solid surface.

It should be noted that the shield made of C_{18} alkyl chains on the filler surface leads to a reduced surface energy. Contact angle measurements revealed a drastic decrease in surface energy with increasing degree of surface coverage by stearic acid. Before the treatment, $CaCO_3$ possesses a high energy surface. Both the dispersive (γ^d) and the polar (γ^p) components of its surface energy are higher than 50 mJ/m^2. When the particles were covered by a monolayer of stearic acid, the surface energy went down to 22 mJ/m^2, coinciding with the value published for pure stearic acid.

Alkyl dihydrogenphosphate, containing functional groups such as olefine, chloro, methacryloxy, and mercapto, is another kind of effective surface modifier of calcium carbonate fillers [65, 66]. It was shown that alkyl dihydrogenphosphate molecules can react with $CaCO_3$, resulting in a dibasic calcium salt of phosphate. The products are deposited on $CaCO_3$ and provide the surface of $CaCO_3$ with a certain hydrophobicity (Scheme 2), as indicated by its good dispersibility in mineral oil [64]. Relatively larger groups in the phosphates (like octyl dihydrogenphosphate, 3,7-dimethyl-6-octenyl dihydrogenphosphate, etc.) help to enhance the conversion of the agent through a lower hydrophilicity. Furthermore, a treatment with alkyl dihydrogenphosphates always results in an increase in the specific surface area of the treated particles. This can be ascribed to surface erosion and/or calcium salt formation.



Scheme 2

Zhou and co-workers modified nanosized Y-TZP powders (10–20 nm, consisting of 97 mol% ZrO_2 and 3 mol% Y_2O_3) with adipic acid and stearic acid, respectively (Fig. 3) [67]. A covalent bond was established by the chemical reaction between the surface hydroxylic groups and the acid groups of the surfactants. Fourier transform infrared (FTIR) spectroscopy proved that a monolayer of aliphatic chains was coated on the Y-TZP particulates, since the peak representing free carboxyl was no longer detectable. As a result, the flowability of the powders was improved because of the change of their surface polarity.

Yoshihara reported the application of hydrophilic dispersants of two-component structures (oxyethylene chains and acidic groups) for the preparation of a stable ultrafine particle dispersion (UFP) (chemical composition unknown, having hydrophilic and cationic nature, 120 nm in size) [68].

The results indicated that the interparticle attraction was reduced because of an adsorbed layer of dispersant on the surface of UFP by a hydrophilic interaction. On the principle of acid–base interaction, the oxyethylene chains might permeate the interface of the UFP agglomerates, and acidic groups contribute to hydrogen bonds and cationic hydroxyl groups on the UFP. Table 2 lists the effect of different dispersants on the average particle size of UFP. Obviously, the effect of the dispersants is not enough to separate the agglomerates completely. Furthermore, it was found that these dispersants could be easily desorbed from the UFP surfaces with the addition of small amounts of H_2O to the dispersion, leading to an increase in the average particle size. That is, reagglomeration occurred with increasing H_2O.

Table 2. Structure of dispersant and average particle size of UFP.

	Reactive dispersant	Particle size[a] (nm)
A:		250
B:		200
C:		195

[a] Dispersal conditions: UFP, 10.0 g; dispersant, 1.0 g; diethylene glycol dimethyl ether, 16.5 g; paint shaker, 3 h.

This dispersion system can be illustrated by the correlation among the three components in Figure 4. One of the major problems of the system is that the affinity of the dispersant for the UFP surface is lower than that of H_2O.

To solve the problem, grafting of a polymer to surface hydroxyl groups of the UFP was conducted to inhibit H_2O absorption and reagglomeration of the particles (Fig. 5). Figure 6 demonstrates the concept related to the application of grafting polymer to form hydrophobic layers that have an affinity for the dispersant. It can be expected to obtain a stable dispersion due to an improvement of interaction between the grafted UFP and the dispersant interface. The feasibility of the above proposed approach was subsequently demonstrated by an examination of the stability of the dispersion of poly-(dimethylsiloxane)-grafted UFP in diethylene glycol dimethyl ether. That is, a stable dispersion was kept even after 30 days in the case of polymer-grafted UFP, whereas the untreated UFP was completely precipitated after 1 week.

2.1.2. Encapsulation with Polymer

Encapsulation with preformed polymers or *in-situ* formed polymers can also promote the surface hydrophobicity of inorganic fine particles. In this case, the surface feature of the treated particulates is different from that of surfactant-treated versions because both the surface interaction and the morphology of the encapsulating polymer are more complex.

Hyperdispersant, which has been successfully used to treat inorganic dyestuffs in the paint industry (some of which fall into the category of nanoparticles), is a macromolecular dispersant [69]. Similar to surfactants, polymeric dispersants consist of two major components. One is a functional group, like -OH, $-NH_2$, $-NR^{3+}$, -COOH, $-COO^-$, $-SO_3H$, $-SO^{3-}$, or $-PO_4^{2-}$, which helps to anchor dispersants to the particle surface through hydroxyl and electrostatic bonds. The other is a soluble macromolecular chain, like polyolefine, polyester, polyacrylate, or polyether, which is appropriate for dispersion in different media of low to high polarity. In comparison with traditional surfactants, hyperdispersants have the following advantages: (i) they are anchored to the particles' surface more strongly than are surfactants and hence can hardly be desorbed; (ii) the long polymeric chains

can interfere with the reagglomeration of the particles more effectively; (iii) their specific molecular structures, characterized by an A-B or B-A-B block copolymer type, ensure the efficiency of particle isolation and avoid bridging between particles through an identical soluble chain. When nanoparticles are treated, however, it should be noted that hyperdispersants can only encapsulate nanoparticle agglomerates and can hardly penetrate the agglomerates, because of their long macromolecular structure.

In the presence of silica colloid, Yoshinaga and coworkers utilized radical polymerization of vinyl monomers, such as styrene, methyl methacrylate, and 2-hydroxyethyl methacrylate (HEMA), initiated by 2,2′-azobis (2-amidinopropane) dihydrochloride (AAP), to produce SiO_2/polymer composites with a retained particle size of 470 nm [70]. Since the surface of silica colloid particles possesses negative charges on the electric double layer, the initiator AAP can be concentrated, resulting in free radicals on the silica surface. It is thus expected that an efficient polymerization of vinyl monomer would take place.

The binding between the *in-situ* formed polymer and the silica surface is driven by an electrostatic attraction. It was found that the solvent used during polymerization was an important factor influencing the percentage of the attached polymer. At an initial stage, polymerization of vinyl monomers occurred first on the silica surface, leading to a certain degree of hydrophobicity. This simultaneously promoted aggregation of the polymer chains to be formed in the ethanolic bulk solution because of the poor solubility of the polymer in an ethanol-rich solvent. In this context, a solvent with lower miscibility for the polymer should facilitate the attachment of the macromolecular chains to the particles.

Hasegawa and co-workers proposed an encapsulation process capable of uniformly covering fine inorganic powders of submicron size with a filmy polymer [71]. The encapsulation of barium sulfate (0.6 μm) and calcium carbonate (0.4 μm) was attempted by a soapless emulsion polymerization of methyl methacrylate in water (in the presence of the inorganic powders). The encapsulation status of the particles with the polymer formed varied considerably with the species of the initiator and the reaction atmosphere. When potassium persulfate (acting as an initiator) and nitrogen were used, the fine powder surface was partially covered by polymer particles that were the same size as the powder particles. In addition, many polymer chains did not adhere to the powder surface, meaning that the monomers were not used effectively to cover the powders. In the case of a redox initiator under an air atmosphere, however, the powder surface was well encapsulated with a film-like polymer layer. It was believed that the formation of a large number of oligomers with short alkyl chains at an earlier stage of reaction should be responsible for the above difference. On the basis of this mechanism, the authors suggested that the addition of an extremely small quantity of a certain surfactant to the reaction system prior to the polymerization would facilitate the polymerization on the powder surface.

Du et al. [72] demonstrated that when a seed emulsion polymerization was carried out in the presence of nanoparticles, a core-shell structure can be obtained, in which the inorganic particles stay in the middle layer while the polymer is located at inner and outer layers. For the system containing Fe_2O_3 nanoparticles (3–5 nm) and styrene/acrylic acid/butyl acrylate (St/AA/BA) latex particles, for example, the size of the resultant composite microspheres is 80 nm. Changes in the infrared absorption band of carbonyl groups indicated a strong interaction between Fe_2O_3 nanoparticles and the surface groups of the seed latex particles.

Nanoparticles covered by a polymer layer can also be obtained during the manufacture of nanoparticles. For instance, nanocrystalline titania coated with poly (methacrylic acid) (PMAA) was prepared by microwave-induced plasma [73]. Such an *in-situ* treatment is characterized by high effectiveness and homogeneity (Fig. 7). Transmission electron microscopy (TEM) observation showed that the titania particles (rutile in majority with a few anatase) were 10–25 nm in diameter, with a 7-nm-thick PMAA layer.

During the synthesis of metallic and semiconductive particles, polymeric materials are frequently employed as particle stabilizers to prevent agglomeration and growth of the particles. In the present case, however, existing nanoparticle agglomerations must be separated in advance, that is, before encapsulation with a polymer in solution can take place. This means that, under these circumstances, particle deagglomeration, electrostatic stabilization of the solvent, and the interpenetration plus electrostatic stabilization of the polymer play an important role. Gonsalves and Chen illustrated the above points when preparing highly loaded AlN/polyimide nanocomposites (Fig. 8) [74]. In their work, *N*-methylpyrrolidinone (NMP) was used as a solvent, functioning as a medium for the deagglomeration of the nanoparticles and their stabilization through electrostatic interactions. With the addition of poly(amide acid) (PAA), the nanoparticles were further deagglomerated and stabilized through both steric and electrostatic stabilization. Acting as a polyelectrolyte, PAA tends (a) to diffuse into the pores of the secondary structures of the AlN nanoparticles and (b) to be absorbed by the particle surfaces. To prevent any possible destabilization of the homogeneous suspension system, a rapid precipitation method making use of different nonsolvents and suspension/nonsolvent ratios should be used. For the AlN/PAA system, triethylamine was considered the best choice because it completely precipitated out of the composite phase of the suspension.

2.2. Treatment by Chemical Reaction

As a surface treatment through chemical reaction can lead to much stronger interactions between modifiers and nanoparticles, much more attention has been paid to this area. In general, a chemical treatment can be divided into two aspects. One deals with the use of lower weight molecules, such as coupling agents, and the other with a grafting of polymer chains. In comparison, chemical techniques are more complicated than physical treatments because physical and chemical absorptions as well as polymerization of the modifiers are involved in the former. As is often the case, a three-dimensional multilayer structure forms on the solid surface, which is somewhat difficult to control and optimize.

2.2.1. Coupling Agent

A variety of coupling agents, such as silane, titanate, zirconate, etc., have been used to improve the adhesion between inorganic fillers and organic matrices. Extensive information on reaction mechanisms and effects of coupling agents is available for microfillers, but less is available for nanoparticles. Actually, there is no evident difference between these two kinds of particles regarding the reaction mechanisms, except that the coupling agents can hardly penetrate nanoparticle agglomerates.

Most commercially available silanes contain three ethoxy or methoxy groups and a linear alkyl chain attached to a single silicon atom. A typical structure of a common silane can be written $RSiX_3$. The functional group X reacts with hydroxyl groups on the filler surface, while the alkyl chain, capped with a reactive group such as amino, vinyl, or methacryloxy, may react with the matrix polymer. Hydroxyls or absorbed water from the inorganic surface can serve to hydrolyze the silane agent. The silanol moieties readily condense to form siloxane bonds that can result in a linear, branched, or cross-linked polysiloxane structure. It is clear that in the case of trifunctional silane, a three-dimensional siloxane multilayer forms on the solid surface, which remains even after extensive washing in boiling water [75]. However, only a portion of X groups in grafted silanes can interact with the particle surface or with other X groups of the reactant because of a relatively low concentration of surface hydroxyls (1–2 OH/nm^2). As a result, a fraction of X groups remains, and these residual groups can influence the properties of both the covering material and the final polymer matrix. The whole process is dependent on the synthesis and treatment conditions.

To illuminate the effect of a silane coupling agent treatment, fumed silica is taken as an example in the following discussion. A structural hierarchy exists for fumed silica, based on four levels [76, 77]. The first level represents the tetrahedrons of SiO_4, which, in turn, form amorphous and almost spherical primary particles of 5–50 nm (second level) containing 10^4 or more SiO_2 units. These particles, linked by -Si-O-Si- bridges (maybe partially) or intermolecular bonds (such as hydrogen bonds), build up relatively stable aggregates (100–500 nm) (third level). Last, the aggregates give rise to loose and relatively unstable agglomerates (>1 μm) (fourth level) due to intermolecular polar and electrostatic bonding effects. The existence of this structural hierarchy of fumed silica can, of course, influence the effect of the surface modifier on the structural features and other characteristics of the silica dispersions in different ways. In other words, after a certain pretreatment, the observed particle size distribution depends on the transformation state between the agglomerates and the aggregates; the latter can be decomposed during pretreatment and subsequently rearranged through different dispersion processes.

Gunko et al. [78] studied the features of fumed silica coverage with silanes from both experimental and theoretical aspects. It was found that a modification with the use of methacryloyloxymethylenemethyl diethoxysilane (MMDES), 3-methacryloyloxypropyltrimethoxysilane (MAPTMS), and 3-aminopropyltriethoxysilane (APTES) strongly changed the ξ(pH) potential. The quantity and the structure of the modifiers controlled the particle size distribution in an aqueous suspension. MMDES gave better results in comparison with its mixture with APTES or with pure MAPTMS, when considering the reduction in particle (agglomerate) size of modified silica at a modifier concentration of over 0.05–0.2 mmol/g. Depending on the pretreatment conditions, grafted silanes can reduce the hydrophilic properties of silica to different extents.

The silylation procedure can be distinguished simply by examining whether the reaction system contains water or an organic agent. In the case of organic silylation, a very high surface concentration of silane molecules would be obtained because the hydroxyl groups on the inorganic particles serve as reactive groups and are involved in grafting organic molecules. However, it should be noted that the chemical reaction of these hydroxyl groups might be selective. Moreover, some chemicals would compete with silane. Baraton and co-workers [79] studied the grafting of hexamethyldisilazane (HMDS) on nanoalumina (100 m^2/g) and nanotitania (50 m^2/g) through *in-situ* FTIR. The results indicated that the reaction of HMDS with different hydroxyl groups on the nanoparticles is selective. Moreover, Si-OH groups can be generated by oxidation of the particles. When acetic acid, which has a strong affinity for hydroxyl groups, was added to these modified surfaces, a partial or total displacement of the grafted HMDS occurred, and indicating selectivity.

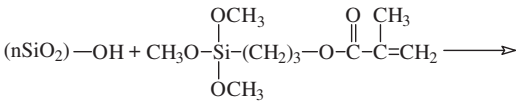
2.2.2. Grafting Polymerization by Chemical Methods

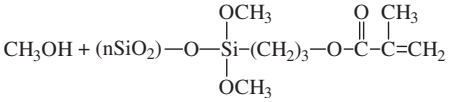
Grafting polymeric molecules to inorganic particle surfaces has some advantages over modification by low molecular surfactants or coupling agents. Polymer-grafted particles can possess desired properties through a proper selection of the species of the grafting monomers and the grafting conditions.

A series of works has appeared in this field of growing interest for purposes of improving the dispersibility of the nanoparticles in solvents and their compatibility in polymer matrices. The grafting polymerization was conducted mostly via two routes: (i) monomers are polymerized from active compounds (initiators or comonomers) covalently attached to the inorganic surface, and (ii) ready-made polymers with reactive end-groups react with the functional groups on the particles. The latter benefits the control of the molecular weight of the grafting polymer. So far, many grafting techniques, such as chemical grafting, irradiation grafting, and

mechanical grafting, have been applied to the modification of nanoparticles. Moreover, various kinds of initiation or polymerization processes, including radical, anionic, and cationic polymerizations, were also undertaken in the grafting investigations.

Grafting from Double Bonds on Particles Espiard and Guyot [80] studied grafting from silica particles with the use of radical processes in an emulsion. The particle surface was first covered with a silane coupling agent containing a polymerizable group (i.e., methacryloxypropyltrimethoxysilane, MPTMS) (Scheme 3). Then the modified silica was engaged in the emulsion polymerization of ethyl acrylate. It was proved that a part of the polymer could be covalently grafted to silica only if the latter has been functionalized. The grafting process took place mostly in the early stage of the polymerization according to the results of the grafting kinetics. The silane-treated silica particles were actually slightly agglomerated when dispersed in water. Their mean diameter amounted to 37 nm, whereas that of the initial particles was only 12–13 nm. The interstitial volume inside these particle agglomerates made it possible to partly locate the polymer there.





Scheme 3

From the surface density of silane molecules on silica and the amount of grafted polymer, the average number of monomer units in a grafted polymer molecule between two grafting points can be estimated, assuming full consumption of the anchored methacrylate. It was found that the estimated value of that number does not exceed 15. This means that the grafted polymer is very close to the particle surface, with rather short loops between the grafting points (Fig. 9).

Oosterling et al. [81] grafted polystyrene (PS) and poly(styrene-block-isoprene) to silica (average particle diameter, 12 nm; specific surface area, 200 m^2/g) by initiating immobilized double bonds on the silica surface with *t*-butylithium and then adding the monomers to the reaction suspension (Fig. 10). The functionalization of silica was done by reacting *p*(*m*)-vinylbenzyltrichlorosilane with the silica surface; however, only 58% of the hydroxyl groups on the silica were consumed (Fig. 11). Therefore, the reaction product had to be treated with HMDS to block the remaining hydroxyl groups, preventing them from interfering with the subsequent anionic polymerization. With the addition of two or more types of monomers one after another, an end-grafted block copolymer was created. The amount of the grafted polymer increases linearly with increasing monomer concentration, as was expected for the anionic polymerization. It appears that the increase in grafting polymer was

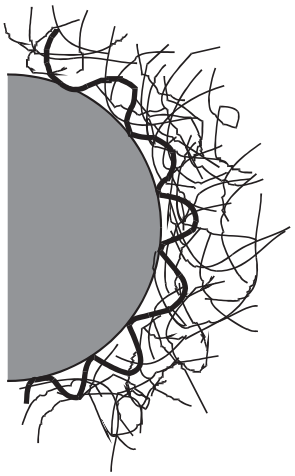


Figure 9. Schematic representation of polymer around a silica particle. Loops of grafted polymer are shown as thick lines attached to the silica, and nongrafted polymer chains are shown as thin lines. Reprinted with permission from [80], Ph. Espiard and A. Guyot, *Polymer* 36, 4391 (1995). © 1995, Elsevier Science.

completely due to an increase in the molecular weight and not to an increase in grafting density.

Isotactic poly(methyl methacrylate) (PMMA) covalently bound to silica (12 nm) can also be synthesized by an initiation of silica-bound methacrylate groups with phenylmagnesium bromide (Fig. 12) [82]. The grafted PMMA appeared to be highly isotactic and had the same molar mass distribution and tacticity as the polymer freely formed in solution. The grafted polymer led to a range of 0.30–0.47 g/g, but only about 0.15 g/g could be obtained if no

posttreatment with HMDS was applied to the functionalized silica.

Grafting Starting from the Initiator on Particles To obtain polymer-grafted inorganic particles with a higher percentage of grafting, it is preferred to initiate the graft polymerization from the initiating groups introduced on the particles because the grafted polymers can propagate directly from the particles' surface. In a series of articles, Tsubokawa and co-workers [83–88] systematically reported the grafting of various polymers to ultrafine silica and carbon black surfaces by polymerization, starting from the initiating groups previously introduced onto the surfaces. For instance, they have conducted anionic, cationic, and radical graft polymerization of various monomers initiated by potassium carboxylate, acylium or benzylium perchlorate, and peroxyester or azo groups already introduced onto ultrafine silica, respectively. In the following text, methods of introducing initiators onto inorganic particles and the resultant grafting polymerization efficiency will be reviewed briefly.

In consideration of the fact that an anionic ring-opening copolymerization of epoxides with cyclic anhydride can be initiated by potassium carboxylate, Tsubokawa et al. first treated ultrafine inorganic particles (silica (16 nm), titanium oxide (120 nm), and nickel zinc ferrite (15 nm)) with 4-trimethoxysilyl-1,2,5,6-tetrahydrophthalic anhydride (TSPA) to bring acid anhydride groups onto the surface of the particles [83]. Then these acid anhydride groups were neutralized by potassium hydroxide, leading to particles attached with -COOK groups. The results of the grafting of various polymers to the nanoparticles carrying the anionic initiators by the copolymerization of epoxides showed that high percentages of grafting were obtained in all cases.

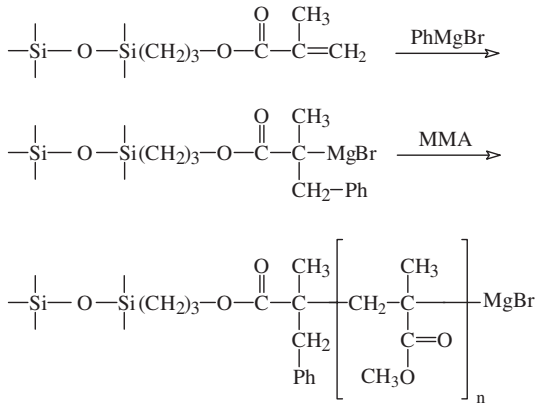

Figure 12. Grafting PMMA onto nanosilica. Reprinted with permission from [82], E. Schomaker et al., *Polym. Commun.* 29, 158 (1988). © 1988, Elsevier Science.

To generate cationic initiators on a silica surface, Tsubokawa et al. also introduced acid anhydride groups onto the particles with the use of TSPA [84]. After that, acyl chloride groups were obtained by treating the surface carboxyl groups with thionyl chloride. Eventually, the introduction of acylium perchlorate (APC) groups onto the silica surface (silica-APC) was achieved by the reaction of acyl chloride groups with silver perchlorate in nitrobenzene at room temperature (Fig. 13). The polymerization of styrene was found to be successfully initiated by silica-APC, and the grafting efficiency reached 64.5%.

As peroxide groups can effectively initiate grafting polymerization of vinyl monomers, Tsubokawa et al. [84–86] have made many attempts to introduce the groups of this kind onto silica (16 nm). In summary, three approaches proved to be feasible. The first one originates from acid anhydride groups that are introduced onto the silica surface by a reaction of silanol groups with TSPA. Then the peroxyester (POE) groups were introduced onto the silica surface by the reaction of surface acid anhydride groups with α, α-dimethyl(4-isopropylbenzyl)hydroperoxide (DIBHP) (Fig. 14). The second is related to the reaction of hydrogen peroxide with chlorosilyl groups, and the latter are introduced by the treatment of silica with thionyl chloride. Both diisopropylbenzene peroxide and *tert*-butyl peroxide groups can be obtained with this method. The third method utilizes a Michael addition reaction of *t*-butylperoxy-2 methacryloyloxyethylcarbonate (HEPO) with amino groups introduced on the silica surface to produce peroxycarbonate groups linked to silica. The experimental data revealed that all of the grafted silica initiated by the above peroxide groups on the treated silica produced a stable colloidal dispersion in organic solvents.

In addition to the peroxide group, azo is another radical initiator commonly in use. Usually it is introduced onto ultrafine particle surfaces in two ways. One deals with the reaction of 4,4′-azobis (4-cyanopentanoic acid) (ACPA) with a surface epoxide group [86], which is introduced by the treatment of the particles with γ-glycidoxypropyltrimethoxysilane (GPS) (Scheme 4). The other is related to the reaction of ACPA with a surface isocyanate group [87], which is introduced by treating the particles with 2,4-tolylene diisocyanate (TDI) (Scheme 5). In addition, by means of

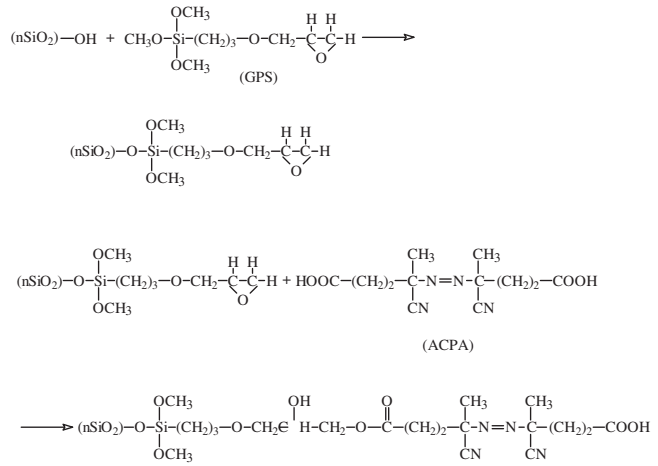
an amide bond established between ACPA and an amine-bearing silane coupling agent on silica, an azo initiator can also be immobilized on silica substrates [89].

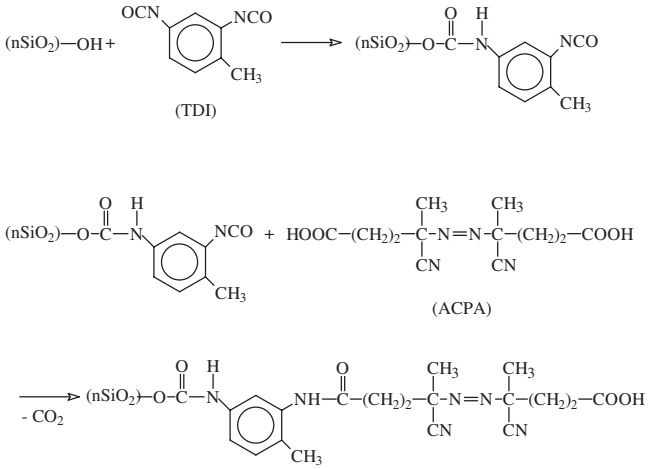
Various vinyl monomers, such as methyl methacrylate, styrene, acrylonitrile, and *N*-vinylcarbazole, were found to be effectively grafted to inorganic particles (silica (16 nm), titanium oxide (120 nm), and ferrite (15 nm)) initiated by the attached azo groups. Needless to say, these polymer-grafted nanoparticles produced stable dispersion in organic solvents. Furthermore, the dispersion of polymer-grafted ferrite in organic solvent was found to behave like a magnetic fluid.

In fact, the azo groups introduced onto inorganic particles can also initiate graft polymerization by a photoirradiation technique [88]. Furthermore, the percentage of grafting by photografting polymerization is much higher than that initiated by thermal decomposition [86], indicating that the blocking effect of surface radicals by the grafted polymer chain is considerably reduced. In the process of photopolymerization at room temperature, the propagation rate of polymer radicals is smaller than that during the thermal polymerization at 70 °C. The surface radicals and the parted free radicals have the same chance to react with the monomers. However, in the thermal polymerization system, the formation of ungrafted polymer by free radicals preferentially proceeds with the progress of polymerization.

Tsubokawa et al. revealed that a redox system consisting of ceric ion and silica particles carrying reducing groups, such as alcoholic hydroxyl, amino, and mercapto, is also capable of initiating a radical polymerization (Fig. 15) [90]. The introduction of alcoholic hydroxyl groups onto



Scheme 4



Scheme 5

the surface can be achieved by the treatment of the silica with 3-glycidoxypropyltrimethoxysilane (GPS) under acidic conditions in water. Amino and mercapto groups are introduced by the reaction of surface silanol groups with 3-aminopropyltriethoxysilane (APS) and 3-mercaptopropyltrimethoxysilane (MPS), respectively (Fig. 16). The initiating ability of the redox system changes with the reducing activity of the reducing groups on the silica surface in the following order: alcoholic hydroxyl < amino < mercapto.

Based on the above-mentioned redox systems, polyacrylamide (PAAM) was grafted to silica particles, and the grafting percentage reached about 25% [90]. It was found that both carbon and oxygen radicals can initiate the polymerization (Fig. 16). Since PAAM chains grafted to the silica surfaces interfere with the aggregation of the nanoparticles, the dispersibility of the modified silica in water was remarkably improved.

Shirai et al. proved that haloalkyl groups introduced onto ultrafine inorganic particles can serve as a coinitiator for free radical grafting polymerization based on the interaction with transition metal carbonyls [91]. In their work trichloroacetyl groups were first introduced onto the surface of TiO_2/Si-R-OH through the reaction of the surface alcoholic hydroxyl groups with trichloroacetyl isocyanate. The radical grafting polymerization of vinyl monomers was successively initiated by a system consisting of $Mo(CO)_6$ and TiO_2/Si-R-$COCCl_3$. The percentage of grafting and grafting efficiency of the graft polymerization initiated by this coinitiation system are

much higher than those initiated by azo groups, because of the absence of fragment radicals.

It is worth noting that a proper selection of polymer species, along with a control of molecular weight and density of the grafted chains, is needed in all cases to obtain desired properties of polymer-grafted particles. Therefore, factors including types of initiator, monomer concentration, polymerization temperature, etc. should be considered comprehensively.

For example, the molecular weight of PS grafted to silica obtained from radical graft polymerization was found to be much higher than that from cationic graft polymerization (Table 3). The number of grafted PS in the radical polymerization, however, is much less than that in the cationic polymerization. The difference can be attributed to the initiation efficiency. That is, the initiation efficiency was lower in the former case because of the blocking effect of the previously formed polymer chains. In the cationic polymerization system, in contrast, the initiating efficiency was quite high but the chain lengths of the grafted polymer were rather short, as a result of chain transfer reactions of the growing polymer cation. On the other hand, the molecular weight of PS grafted to silica obtained from radical grafting polymerization initiated by surface azo and peroxyester groups decreased with decreasing monomer concentration and polymerization temperature. The former was assumed to be related to the reduction of the polymerization rate, whereas the latter was assumed to be related to the decrease in the number of propagating chains from the surface with a drop in polymerization temperature (Fig. 17) [92]. By means of a chain transfer agent, the molecular weight of grafted PS can also be controlled to some extent without lowering the number of grafted chains (Fig. 18).

Among various polymerization methods, a controlled/"living" polymerization technique appears to be optimal in

controlling the molecular weight, molecular weight distribution, and structure of the grafting polymer [93]. Recently von Werne and Patten reported a technique of atom transfer radical polymerization (ATRP) for conducting controlled/"living" radical polymerizations from the surface of silica nanoparticles [94]. For this research, two initiators were prepared: (3-(2-bromopropionyl)propyl) dimethylethoxysilane (BPDS), in which the secondary α-bromoester could function as a styrene or acrylate ATRP initiator, and (3-(2-bromoisobutyryl)propyl) dimethylethoxysilane (BIDS), in which the tertiary α-bromoester could serve as a methacrylate ATRP initiator. Two sets of silica particles were used in this study, 75-nm and 300-nm diameter particles, with different surface area-to-volume ratios (0.08 vs 0.02, respectively). A monolayer of the ATRP initiator was deposited on the silica nanoparticle surface by heating the siloxane initiator and nanoparticles in tetrahydrofuran

(THF) at 80 °C. The standard polymerizations of styrene and methyl methacrylate (MMA) were conducted by heating the initiator-functionalized silica with monomer, copper(I) bromide, ligand, and solvent at a temperature of 90–110 °C (typical conditions: temperature 110 °C, solvent *p*-xylene, $[\text{styrene}]_o = 8.73$ M, $[\text{CuBr}]_o = 61.6$ mM, $[\text{dNbipy}]_o = 116$ mM, and 1.00 g of SiO_2/initator). For the smaller (75 nm) silica nanoparticles, the grafting molecules of PS exhibited good molecular weight control (molecular weight polydispersity index <1.25), whereas PMMA grafting chains had higher molecular weight polydispersity index of about 2.0 under the same reaction conditions. When a small amount of free initiator was added to the polymerization solution, better molecular weight control was observed. Thus, the above difference should be induced by different termination modes during polymerization processes for PS and PMMA. In the case of larger (300 nm) silica nanoparticles, neither PS nor PMMA grafting molecules exhibited molecular weight control. This lack of control was ascribed to the very high initial monomer-to-initiator ratio. It should be noted that only about 25% of the initiator present on the nanoparticle surface can initiate the growth of chains because of the sterically blocking effect of growing chains on the accessing of the catalyst to the neighboring initiation sites. As a result, the experimental molecular weights were a factor of ~4 higher than would be expected based upon the polymerization conversion factored with the ratio of monomer to nanoparticle initiator content.

Tsubokawa and Yoshikawa [95] prepared silica particles grafted to various polymers with well-defined molecular weight and structure by termination of living polymer cations with the amino groups already introduced on the particles. The introduction of amino or *N*-phenylamino groups onto the silica surface was made by the treatment of silica with γ-aminopropyltriethoxysilane or *N*-phenyl-γ-aminopropyltriethoxysilane. It was found that these amino groups on silica can readily react with living poly(isobutyl vinyl ether) and poly(2-methyl-2-oxazoline). The percentages of amino and *N*-phenylamino groups used for the grafting reaction with living poly(isobutyl vinyl ether) were only 4.4% and 4.9%, respectively. This means that the surface amino groups were blocked by the neighboring grafted polymer chains.

Liu and co-workers [96] showed the feasibility of using diisocyanate as a coupling agent to introduce poly(ethylene glycol) (PEG) (weight averaged molecular weight = 1500) to the surface of nanoapatite particles. With the use of a monoisocyanate isocyanatoethyl methacrylate, the reactivity of the surface hydroxyl groups of nanoapatite was proved. The percentage of grafted polymer was about 20% by weight. The amount of hydroxyl groups of nanoapatite was decreased by 7.7% after a surface grafting reaction. Green et al. [97] found that the grafting of PEG to alumina powder (0.5 μm) can be obtained simply by heating the dispersion of alumina powder in a pure PEG melt. The amount of the grafted polymer is strongly dependent on temperature. Grafting from a solution of the polymer, instead of the polymer melt, was also found to be effective, and a poor dispersion medium is profitable to the grafting reaction.

2.2.3. Grafting Polymerization by Irradiation

The above-described methods of chemical grafting possess advantages in controlling the development and molecular weight of the grafting polymers. However, there are also some evident disadvantages. For example, most of the grafting reactions have to be performed in solvent, which causes environmental pollution, especially in the case of large-scale production. Furthermore, the chemical techniques are quite complicated in certain cases because more than two reaction steps and a posttreatment procedure are often needed. Thus, a simpler approach to grafting by irradiation became a focus of interest of several researchers.

Grafting of polymers to inorganic particles can be realized by γ-irradiation, but only a few papers have been concerned with nanoparticles. Fukano and Kageyama [98–105] published a series of works on irradiation-induced grafting polymerization of styrene and methyl methacrylate absorbed to several kinds of nanoparticles, including silica gel (SiO_2; specific surface area 480 m^2/g), white carbon (SiO_2, 180 m^2/g), silicic acid anhydride (SiO_2, 380 m^2/g), zeolite ($Na_2Al_2Si_3O_{10} \cdot nH_2O$, 116 m^2/g), and activated alumina (Al_2O_3, 153 m^2/g). They found that the amount of grafted polymer varies with the type of inorganic substrate, with a maximum of about 30%. In the case of substrates that are chemically identical, the amount of grafted polymer is proportional to the specific surface area of the particles. In the case of substrates with the same specific surface area, inorganic substances that contain aluminum as a component element are grafted more easily than those consisting of SiO_2 alone. Gel permeation chromatography (GPC) measurements indicated that both the grafted polymer and the homopolymer possess low- and high-molecular-weight chains. By studying the effect of inhibitors (*p*-benzoquinone and ammonia) on the ratio between the low- and the high-molecular-weight portions of the grafted polymer and the homopolymer, mechanisms involved in irradiation-induced polymerization were concluded. It was believed that the high-molecular-weight materials appear to have been generated by radical polymerization, whereas the low-molecular-weight polymers are formed as a result of cationic (for styrene-silica) and anionic (for methyl methacrylate-silica) polymerizations. Further studies revealed that the relative yields of the low- and high-molecular-weight parts of the grafted polymer and the homopolymer are a function of dose rate and irradiation temperature.

It should be noted that a postirradiation effect exists in certain cases when methyl methacrylate is grafted to MgO by simultaneous irradiation methods [106]. Such an effect is characterized by the appearance of long-lived radicals or ions, which might lead to a continuous polymerization, even when the system is away from the irradiation field. Certain measures should thus be taken to eliminate the remaining radicals and ions to stabilize the microstructure of the grafted particles.

Fukano and Kageyama have also tried the preirradiation grafting polymerization of styrene to silica gel surfaces [105]. It was found that both radical and cationic polymerizations took place to form grafting polymer and homopolymer in a way similar to that of the case of simultaneous irradiation.

To obtain a higher degree of grafting, Fukano and Kageyama conducted an irradiation grafting process under

high vacuum conditions (lower than 10^{-4} Hg) [98–105]. Actually, this is less convenient for industrial application. Therefore, Rong et al. developed another method in which strict irradiation grafting conditions, such as high vacuum and purification of monomers, usually required in the case of conventional particles, are no longer necessary [107]. Various polymers were grafted to the surface of silica nanoparticles through simultaneous irradiation (Table 4). The molecular weights (M_n and M_w) of both the grafted and the homopolymerized polystyrene obtained by irradiation with or without solvent are shown in Table 5. The higher M_n of the homopolymer, relative to the grafting polymer, could be ascribed to the stronger motional ability of nanoparticles compared with conventional particles, which made the chain termination between the two radicals easier. The results also showed a relative wide molecular weight distribution of PS in the system with the solvent; this is due to the fact that chain transfer from the radical to the solvent can easily take place. FTIR and ESCA were adopted to characterize the interaction between the nanoparticles and the grafted PS, demonstrating that PS is chemically connected with SiO_2 through Si-O-C and Si-C bonds.

2.3. Additional Remarks

Based on the above introduction about surface treatments for nanosized inorganic particles, it can be concluded that there is no evident difference between the treatments of microparticles and nanoparticles. However, some issues relating to the practical application of the modification approaches with respect to the specific structure and properties of nanoparticles should be emphasized as follows:

- A nanoparticle assembly usually possesses a hierarchy structure, starting from primary particles, via aggregates to agglomerates (in which aggregates are bound through hydrogen and electrostatic bonding forces). A surface modification may cause a splitting of agglomerates or aggregates to a certain extent according to the treatment conditions. However, the decomposed aggregates can get together once again when they are incorporated into a polymer matrix, because of the uneven coverage of the modifier molecules. Therefore, the eventual filler size and its distribution in the composites depend not only on the surface treatment but also on the compounding technique. Meanwhile, it should be kept in mind that primary particles in a premade nanoparticle assembly are hard to attain no matter what treatment is used.
- When compared with microparticles, nanoparticles, with their tremendous specific surface area, have a reasonably high surface activity and would lead to substantial chemical interactions, even in the case of a physical treatment. On the other hand, there are much greater difficulties encountered by surface modifiers in penetrating the tightly bonded nanoparticle agglomerates, especially for physical treatment methods such as surfactant treatment and encapsulation of polymer.
- Chemical treatment is more effective in promoting the miscibility between nanoparticles and polymers, but the penetration of nanoparticle agglomerates by reactive agents is still a problem. By comparison, infiltration of monomers followed by polymerization benefits the disintegration of the agglomerates.
- Morphologies of grafting or encapsulating polymer chains have scarcely been studied because of the limitation of characterization facilities. Research in this direction is of great importance for controlling the particle dispersion in the final matrix, because the morphology of the molecules surrounding the nanoparticles is closely related to the entanglement with the polymer chains of the matrix, especially for those nanocomposites produced by solution mixing. Therefore, the length of grafting or encapsulating chains, as well as the number and position of reactive groups, should be considered in detail to optimize the surface treatment effect.
- Most of the published works that deal with surface treatment of nanoparticles neglect the correlation between treating methods and structural details of treated nanoparticle agglomerates with their interfacial interactions, which occur when the particles are added to a polymer matrix. In other words, various surface treatments developed up to now only focus on treatment methods themselves. Their application in preparing nanoparticle-filled polymer composites has not been studied deeply. Therefore, in the following sections, microstructural effects of treated nanoparticles on the properties of the final nanocomposites

will be discussed mainly from the processing point of view.

3. COMPOUNDING AND MECHANICAL PERFORMANCE OF POLYMER NANOCOMPOSITES

3.1. Fundamentals of Agglomerate Dispersion in Polymers

Dispersive mixing in polymer-based particulate composites has an important technical meaning. The state of dispersion usually refers to the amount of unagglomerated particulates that are present in a compound. The number and nature of the dispersed solids have been shown to greatly influence the mechanical behavior of the composites. The appearance of nondispersed or reagglomerated clusters is detrimental to the uniformity of the ultimate properties of the products [108]. As this chapter deals with ready-made nonlayered nanoparticles that are used in the form of agglomerates, problems related to agglomeration and deagglomeration should be considered throughout the discussion. In particular, understanding the dispersion process and the relationships between processing conditions and quality and extent of dispersion are of practical interest.

3.1.1. Variation of Agglomerates during Mixing

During the compounding operation, the dispersion is generally achieved in four steps: incorporation, wetting, agglomerate breakup, and aggregate spatial distribution in a polymer matrix [109]. It must be ensured that the particulate fillers can be wetted and distributed before they can agglomerate. In the field of solid-liquid dispersion, a series of works have been devoted to the breakup of agglomerates. Agglomerate breakup occurs when hydrodynamic forces induced by the flow overcome the cohesion forces mentioned in the previous chapter. Consequently, the mixing intensity needed is strongly dependent on the affinity between the polymer matrix and the additives.

The mechanism of agglomerate dispersion in various media has been studied by several researchers. Two major types of cluster breakup have been identified; in particular, Parker et al. proposed the occurrence of (1) large-scale splitting, also called the rupture process, and (2) fine particle erosion [110]. Rwei et al. suggested the existence of critical conditions for the different dispersion mechanisms [111, 112]. Erosion, which is initiated at lower shear stresses, is characterized by a continuous detachment of small fragments from the outer cluster surface. The rupture mechanism is characterized by an abrupt splitting of the agglomerate into a small number of large aggregates; it tends to take place at relatively high shear stresses. Analysis of the evolution of carbon black agglomerates in the melts of PS and high-density polyethylene (HDPE) indicated that a coarse rupturing of the agglomerates occurred during the early stages of the dispersion. This was followed by a more gradual erosion of small aggregates from large fragments [113]. Pandya and Spielman investigated the rupture process of cohesive agglomerates and found that fragment size and configuration were affected by the shape and internal structure of the parent agglomerate [114]. Erosion of cohesionless clusters of spherical particles was studied by Mason et al.; they also modeled the effect of shear stress and particle size on the erosion rate [115, 116]. Shiga and Furuta suggested that the dominant mechanism of carbon black agglomerate dispersion in elastomers is the scraping of individual constituent particles from the surface of the agglomerates [117]. Most of the models based on experimental investigations show that the variation of the agglomerate size as a function of time follows a first-order kinetic law regardless of the matrix viscosities [112]:

$$\ln[R(t)/R_o] = Kt\dot{\gamma} \tag{3}$$

where $R(t)$ is the radius of the cluster at time t, R_o is the initial cluster radius, K is the erosion rate constant, $\dot{\gamma}$ is the applied shear rate, and $t\dot{\gamma}$ is a dimensionless erosion time (Fig. 19). It is believed that K is dependent on the flow geometry, the applied shear stress, and the cohesive strength of the agglomerate.

For a short erosion time, Eq. (3) leads to

$$[R_o - R(t)]/R_o = Kt\dot{\gamma} \tag{4}$$

In this case, the erosion kinetics was found to be independent of both the agglomerate size and the applied shear rate. When interfacial interactions between particulate agglomerates and the polymer matrix are taken into consideration, variation of the agglomerate size can be described by

$$[R_o - R(t)]/R_o = K'W_{ab}\mu\dot{\gamma}t/\tau_c \tag{5}$$

where K' is the erosion rate constant corrected for the work of adhesion, τ_c is the cohesive strength of the agglomerate, and μ is the fluid viscosity [118]. This model has been confirmed by the radius reduction of ultrafine TiO_2 agglomerates in linear low-density polyethylene (LLDPE) melts with shearing time.

Since particulate agglomerates have a permeable structure, they can be subjected to a fluid infiltration. The infiltration of a liquid polymer to a porous agglomerate

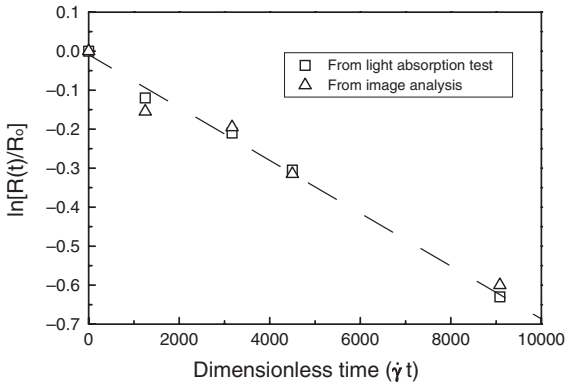

Figure 19. Carbon black agglomerate size reduction in PS melt as a function of dimensionless shearing time under a shear stress of 19,500 Pa. Reprinted with permission from [113], S. P. Rwei et al., *Polym. Eng. Sci.* 32, 130 (1992). © 1992, Society of Plastics Engineering.

corresponds to a transition from a dry agglomerate (pores filled with air) to a wetted one (pores filled with polymer melt). This process is driven by the capillary pressure (pressure difference across the interface between the two filling media) and the hydrostatic pressure, although the latter can be shown to be negligible compared with the former. Liquids characterized by a contact angle on particulate fillers of less than a critical value can infiltrate the agglomerates, provided the air displaced from the pores is allowed to escape. Otherwise, the air pressure inside the agglomerate rises to a point where it counterbalances the capillary pressure, and consequently the infiltration stops.

The presence of a liquid inside an agglomerate affects its cohesiveness. The creation of liquid bridges leads to a substantial increase in the tensile strength of moist agglomerates [119]. Calcium carbonate agglomerates, for example, were found to be strengthened by matrix infiltration during dispersion in polymer melts under simple shear flow conditions. Hence assessing the kinetics of matrix infiltration constitutes a valuable tool in the analysis of the dispersion behavior of fine particle agglomerates in molten polymers.

The role of matrix infiltration in the hydrodynamic dispersion of particulate clusters was highlighted during the study of the dispersion of carbon black agglomerates in liquid polymers. Yamada and co-workers investigated the dispersion mechanisms of carbon black agglomerates in simple shear flows. They found that the agglomerate erosion kinetics could be interpreted in terms of the degree of matrix infiltration and agglomerate permeability [120, 121]. The agglomerate dispersion behavior could be correlated with the ratio of the depth of the infiltrated layer to the square root of the agglomerate permeability, a characteristic length related to the thickness of the agglomerate region that can be drained by viscous flow.

According to the model proposed by Yamada et al. for the kinetics of agglomerate infiltration [122], it is assumed that matrix infiltration in spherical agglomerates occurs symmetrically, leading to an infiltrated outer shell of constant thickness and a dry core. The principle of a spherically symmetric infiltration has been confirmed experimentally by Bohin et al. by phase-contrast microscopy [123]. The kinetics of infiltration of $CaCO_3$ agglomerates by liquid polymers can be well described by the theoretical relationship based on Darcy's law [124]. Reducing the agglomerate radius, polymer viscosity, and/or agglomerate density leads to higher infiltration kinetics. A stearic acid surface treatment, for example, was observed to have a dramatic influence on the latter. Infiltration was much slower for the surface-coated $CaCO_3$ (80 nm) than for the untreated powder when other parameters were kept identical. It was suspected that the surface treatment could have affected the morphology and the packing characteristics of the nanoparticles.

3.1.2. Mechanical Deagglomeration

Intimate contacts (up to almost the molecular level) of the nanoparticles with the polymeric matrix are a prerequisite for the design of well-functioning nanocomposites. To satisfy this condition, a thorough homogenization of the components must be obtained. Winkler et al. [125] developed a theory for the deagglomeration of ultrafine particle clusters in fluid systems, using the mechanical forces in a dispersion machinery. They showed that the probability that filler particles are dispersed in a dispersion medium, ρ_T, is the product of two separate, partial probabilities: ρ_t, the probability with which the agglomerates encounter a potentially active dispersion site, and ρ_ε, the probability that enough energy per unit volume (energy density) is available to overcome the forces holding the agglomerates together. By applying their theory to dispersion experiments carried out in a bead mill and a high-speed impeller [126], the effective volumes per second (in which a dispersion of the agglomerates could take place) were found to be on the order of 1% of the total volume, and the transfer efficiency of the energy into the agglomerates was approximately 1% as well. According to these findings, it was suggested that the key to success for dispersing particles is to guide their agglomerates in a constrained path through well-defined zones of suitable energy densities. In addition, Winkler and Dulog found that the deagglomeration in most dispersion machinery is governed by the shear stress within the mill base [127]. This means that smearing-type mechanisms are far more important than smashing-type stresses for dispersions.

From a practical point of view, compounding polymers in their molten state with additives is generally achieved by various devices, like two-roll mills, internal mixers, single-screw extruders, and twin-screw extruders [128]. Two-roll mills and internal mixers are not suitable for production on an industrial scale. Single-screw extruders cannot provide sufficient homogenization. Corotating twin-screw extruders are therefore the most popular machines because of their continuous operation and high productivity. Both the screw and the barrel of the extruders are constructed from segments and can be assembled to produce the necessary conditions for efficient homogenization.

Fundamental dispersion studies have identified some useful rules for optimum compounder performance, for example [129–131]:

- Since dispersion is a phase reduction process, it pays to generate a well-mixed feed in the feeder train or feed section of the compounder.
- High stresses applied during melting are important and friction dependent, and care should be taken to reserve lubricating fluids, powders, and low melting solids for post-addition.
- Compatibilizers reduce the interfacial tension and result in dramatically improved dispersions.
- Solid particles in polymer melts break up like a fatigue failure, which accounts for the fact that there must be a minimum residence time established to achieve dispersion in addition to a minimum shear stress. Above the minimum residence time and minimum shear stress, the shear and time values are interchangeable in achieving the same dispersion effect.
- Shear yield stress of particle filled polymer melts increases with decreasing particle size.

When a twin-screw extruder is used, the effects of extrusion processing conditions on the final state of dispersion should be known in advance, so as to control the formation of agglomerates. Although most of the available literature is

actually based on the approaches developed for microcomposites, the original principles stated above might also be applicable to nanocomposites. This is due to the facts that (a) the size of the nanoparticle agglomerates also falls in to the micrometer regime, and (b) the initial particle size gives only slight differences in dispersion, as demonstrated by Ess and Hornsby in their paper dealing with $CaCO_3$ particles varying in diameter from 80 nm to 3 μm [132].

Ess and Hornsby discussed the dispersive mixture quality of $CaCO_3$-filled PP and PA 66 composites compounded by an intermeshing corotating twin-screw extruder. For the system under investigation, the zone of polymer fusion at the end of the first stage of the screw profile was identified as having a crucial influence on enhancing the filler dispersion because of the high levels of shear developed in this region. Furthermore, there was some evidence of filler agglomeration due to compactive forces in the solid bed formed before polymer melting. Compounding experiments, using pellets of $CaCO_3$ preconditioned under various pressure, temperature, and moisture conditions, indicated that too high values of these quantities gave a marked reduction in the degree of filler dispersion. These results therefore highlight the importance of controlling these variables (for example, in premixing operations) for an optimized filler dispersion.

Recently, Bories et al. made a study of this aspect by using polypropylene (PP) and $CaCO_3$ (0.7 μm) as the experimental materials [133]. They found that reducing the extrusion flow rate or increasing the rotation speed and barrel temperature can yield improved dispersion. Furthermore, the main concerns of their work were focused on twin-screw extruder design and its relation to particle agglomerate dispersion. Four different screw geometries were employed; each one had two separate kneading sections, referred to as the melting and mixing sections (Table 6). To evaluate the conditions that minimize the relative agglomerate fraction, the dispersion efficiency of the four different screw configurations was compared with the use of either hopper feeding or mid-extruder feeding of $CaCO_3$. As shown in Figure 20a, where the screw configurations have a common severe melting section and differ in the mixing section, better dispersions are achieved when PP and $CaCO_3$ are fed together at the hopper. It is possible that a distribution of the mineral can be achieved even during solid conveying before PP melting, leading to low levels of agglomeration. When feeding takes place at the primary hopper, the state of dispersion does not change significantly whether severe or gentle mixing sections are used downstream, indicating that the agglomeration/dispersion process is completed after the melting zone. The conclusions are quite different when feeding of $CaCO_3$ takes place at the mid-extruder. In this case, significantly higher agglomerate volume fractions are observed for the severe mixing zone, which includes a reverse element that is used to fill the mixing zone. This may cause additional agglomeration, since large undistributed mineral pockets can be rapidly compressed into agglomerates in this section.

Table 6. Summary of screw configuration severity.

Screw configuration	Melting section (first mixing section)	Mixing section (second mixing section)
1	+	−
2	+	+
3	−	+

When the screws have a common gentle melting section and differ in the second mixing zone severity (Fig. 20b), the best results are obtained by mid-extruder feeding. For both hopper and mid-extruder feeding, the best improvements are achieved with configuration 4, which has gentle melting and mixing zones. The use of a severe mixing section is detrimental for the dispersion in both configurations, leading to higher agglomeration levels. The effect of the second mixing zone is also observed, even when feeding of the $CaCO_3$ takes place in the primary hopper. This indicates that the dispersion process is not completed at the end of the melting zone, contrary to the observations with the severe melting section. The PP, being only partially molten in the melting zone, is still highly viscous at the mid-extruder position. This seems to be a good compromise. The polymer has sufficient fluidity to help in the wetting of the mineral while it is still viscous enough to generate high hydrodynamic stresses. Best overall results are thus obtained when the mineral is fed at mid-extruder with the gentlest configuration.

3.2. Polymer Nanocomposites Produced Through Different Mixing Techniques

3.2.1. Melt Mixing

Melt mixing is most commonly used because of its energy efficiency, operability, and environmental containment. The proven mechanisms for transporting viscous melts include drag and ram flow. Phase homogenization can be significantly improved through reorientation and gap flow in the mixer. The melt mixing dispersion process is controlled by the shear viscosity and elasticity ratios of the components and the deformation field generated by the operating condition and the mixer geometry. Although the publications dealing with direct incorporation of nonlayered nanoparticles into polymers are relatively few in comparison with those using intercalation of layered solids, most of the available papers in this field are based on the melt mixing technique.

Huang et al. mixed SiC/Si_3N_4 particles (20 nm) with low-density polyethylene (LDPE) with the use of a two-roll mill at 120 °C for 6–10 min, followed by compression molding at 170 °C under 70 MPa [134]. The nanoparticles were pretreated with a titanate coupling agent. For comparison, microscale $CaCO_3$ (1–3 μm)- and TiO_2 (0.3–0.8 μm)-filled LDPE composites were made in a similar way. Mechanical testing of the materials indicated that both impact and tensile strengths of LDPE were doubled when 5 wt.% nano-SiC/Si_3N_4 was incorporated, whereas neither $CaCO_3$ nor TiO_2 could provide any reinforcing effect. According to the melt flow rate measurements, a drastic drop was perceivable at a nano-SiC/Si_3N_4 loading of 5 wt.% (Fig. 21). It was believed that a strong interaction between the nanoparticles and the matrix was established at the very low filler content. In a latter report of Huang's group [135], nano-SiC/Si_3N_4 was employed to improve the mechanical performance of conductive polymer composites made of carbon black (CB)-filled chlorinated polyethylene (CPE)/polyvinylchloride (PVC). The relationships between mixing time for roll milling at 172 °C and strength properties were studied carefully (Fig. 22). It was found that a mixing over 9 min gave optimum results. Furthermore,

the addition of nano-SiC/Si_3N_4 reduced the melt viscosity of CB/CPE/PVC systems. Their data are an indicative of positive hybrid effects of nanoparticles. That is, a combination of different nanoparticles (like SiC/Si_3N_4 and CB in the present system) can yield a composite with performance and processability better than those of one containing only one type of particle. It manifests the feasibility of preparing polymer nanocomposites coupled with multiple functions (e.g., flame retardant, electroconductive, etc.).

To further improve the compatibility between nanoparticles and polyolefines, Xu et al. introduced into the treatment of nanoparticles a macromolecular coupling agent that contains hydrophobic carbon chains much longer than those found in conventional coupling agents [136]. In their work, $CaCO_3$ (50 nm) and HDPE were employed as the basic materials, and P403 macromolecular coupling agent and NDZ-101 titanate coupling agent were added to the nanoparticles for surface pretreatment, respectively. Rheological investigations of the composites at 200 °C indicated that the two types of coupling agents helped to reduce the apparent viscosity, especially under low shear rates. When the shear rate increased to 500 s^{-1} and above, the rheological behavior of the filled systems approached that of the neat HDPE. Considering that plastics are usually extruded under a shear rate of 10^2 to 10^3 s^{-1} and injection is molded under 10^3 to 10^5 s^{-1}, it was expected that the incorporation of the treated nano-$CaCO_3$ would not change the original processability of HDPE. With respect to the tensile properties [137], the addition of P403-treated $CaCO_3$ prominently improved the elongation to break of the composites, in comparison with NDZ-101-treated $CaCO_3$/HDPE (Table 7). However, the nanoparticles treated with both coupling agents failed to enhance the strength of the matrix polymer.

Guo et al. compared the effect of various silane coupling agents on the melt viscosity of SiO_2 (20 nm)-filled PMMA composites with the use of a Haake rheometer (temperature 210 °C, rotor speed 60 rpm) [138]. As can be evaluated by the maximum torques and equilibrium torques shown in Table 8, the composites with the addition of A-174-treated SiO_2 had the highest flowability. Evidently, the compatibility between methacryloxypropyl segments of

A-174 and PMMA should be responsible for this. It is worth noting that the dosage of the coupling agent should not exceed a certain limit, otherwise the excess silane would act as an internal plasticizer, leading to reduced mechanical performance of the composites (Fig. 23). In the case of micrometer particulate-filled polymer composites, the optimum coupling agent/filler ratio can be estimated in terms of the so-called monomolecular layer approach [139]. It assumes an even coating of a monomolecular layer of a coupling agent on each particle. However, the experimental data of polymer nanocomposites indicated that the calculated optimum dosages are always noticeably higher than the actual ones [140, 141], manifesting the invalidity of the above theory on a nanoscale. Since the content of nanoparticles necessary to cause a consistent drop of viscosity of the polymer has to be higher than that usually adopted for coarse particulates, because of the high surface area of the nanoparticles, new rules should be determined. Levita et al. suggested a simple way to determine the appropriate amount of coupling agent by measuring the viscosity of a dispersion of nanoparticles in mineral oil (Fig. 24) [142].

In view of the fact that the polar groups in certain thermosetting resins strongly interact with active functional groups of fillers [143, 144], such as oxidized carbon fibers, and form coating layers around the filler particles [145, 146, 147], Jana and Jain expected that the polar reactive solvents could help dispersion and prevent agglomerate formation by nanoparticles [148]. They used epoxy as a processing aid and as a dispersing agent of fumed nanosilica in producing melt-mixed blends of polyethersulfone (PES). Epoxy component was polymerized after dispersion of the particles to recover the mechanical properties. It was found that strong interaction between the polar groups of epoxy and silanol groups on the surface of fumed silica helped dispersion of the particles into PES. The viscosity and processing temperature of the PES/epoxy/silica system were significantly reduced as compared with PES and PES/silica blends. Furthermore, improvement in barrier resistance to diffusion of solvents like methylene chloride, heat deflection temperature, and impact strength over neat PES was observed.

During preparation of micrometer particle-filled polymers, mixing dispersion of the fillers is usually completed by simply adding all of the ingredients of a certain proportion into the extruder. In the case of polymer nanocomposites, however, homogeneous dispersion of the nanofillers would be hard to achieve in this way because of their high surface energy and low volume fraction in the composites. Using a twin-screw extruder, Ren et al. produced a

$CaCO_3$ (80 nm)/PP nanocomposite master batch first and then compounded the master batch with the same PP to dilute the filler loading to a desired value [149]. They found that the homogeneity and the mechanical performance of the composites were much better than those of the materials prepared in one step. Recently, Zhang et al. reported similar results when studying the effect of macromolecular dispersant pretreatment of TiO_2 (20 nm), in combination with the master-batch approach, on the mechanical performance of high-impact polystyrene (HIPS) [150]. With a nano-TiO_2 content of less than 5 wt.%, not only the Young's modulus, the tensile strength, and the impact strength, but also the hardness of the composites could be enhanced. This might also act as a new solution for the improvement of the inherently poor resistance of HIPS to surface scratching. In another paper by Ren and co-workers [140], the authors evaluated the effect of a homemade phosphonate coupling agent. The treated nano-$CaCO_3$ can result in an increase in tensile and impact strength, whereas the untreated agents had nearly no reinforcing effect (Fig. 25). In addition to the effects of the surface modification of the nanoparticles, their results also showed the importance of the matrix toughness. As illustrated in Figure 26, a much more remarkable increase in impact resistance was observed in the J340-PP-based composites (a PP copolymer with higher ductility), but the same nanoparticles did not result in a similar improvement in the F401-PP homopolymer. It was suggested that the polymer to be toughened by nanoparticles should possess at least a certain toughness. This finding received experimental support from Wang et al., who mixed an elastomer with $CaCO_3$ (70 nm) into a PP matrix [151]. Both notched and unnotched impact strength values of the trinary blends were found to be much higher than those of the binary ones without the elastomer, at the same content of nanoparticles.

In most of the cases, as introduced above, people treated nanoparticles by using coupling agents or dispersants before the melt mixing procedure. However, since only the exterior nanoparticles of the agglomerates can take part in the reaction, split of the treated nanoparticle agglomerates during the subsequent compounding with polymers at high

temperature leads to an exposure and reagglomeration of the unreacted interior particles. As a result, these newly flocculated and loosely bound nanoparticle agglomerates can act as sites of stress concentration in the composites. To solve this problem, Wu and Ye followed a different route in hopes of stabilizing the split particles [152]. They first put HDPE in a two-roll mill, preheated to 150 °C. When the polymer was melted thoroughly, both $CaCO_3$ (40 nm) and stearic acid at a desired composition were incorporated. It was expected that (a) the dispersed nanoparticles in the polymer melt can be activated *in-situ* by stearic acid, and (b) the formation of larger nanoparticle agglomerates can be prevented accordingly. Microstructural observation of the fractured surfaces of the composites proved the feasibility of their idea. That is, nearly no nanoparticle agglomerates appeared when a proper dosage of the dispersing agent was applied. For the composites containing 20 wt.% nano-$CaCO_3$ prepared in this way, both impact strength and elongation to break of HDPE were increased by more than 100%.

By inferring that it might be impossible to pursue a nanoscale dispersion of nanoparticles in polymer melts characterized by a high viscosity, Rong et al. emphasized the enhancement of the inherently friable structure of nanoparticle agglomerates besides the formation of sufficient interaction between fillers and matrix by means of an irradiation grafting technique [107, 153]. The typical pregrafting of the nanoparticles proceeded by mixing the monomers with the particles and then irradiating the mixture under ^{60}Co γ-rays at room temperature. Although the processing viscosity of the grafted nanoparticles/PP was slightly higher than that of the untreated system (Fig. 27), it was still close to that of PP, implying that the processing variables can be the same as those set for manufacture of the neat polymer. To prepare polymer composites, the treated nanoparticles were compounded with PP on a lab-scale single-screw extruder at 200 °C. The experimental results exhibited that a simultaneous enhancement in stiffness, strength, and toughness of PP can be acquired by the addition of only a small amount of modified SiO_2 (7 nm) or $CaCO_3$ (60 nm) (Figs. 28 and 29).

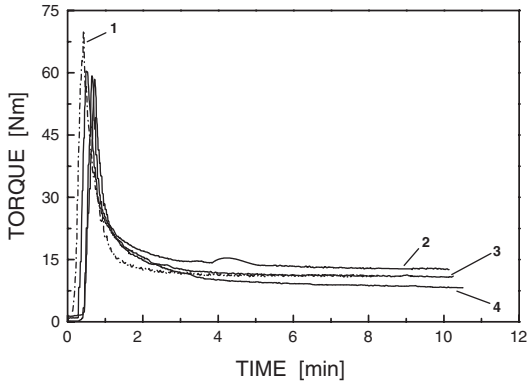

Figure 27. The torque–time curves of (1) PP (MI = 8.5 g/10 min), (2) SiO_2-g-PS/PP, (3) SiO_2-g-PMMA/PP, and (4) SiO_2 as-received/PP. SiO_2 content = 3.31 vol.%. Some researchers added nanoparticles without any surface treatment into polymers. For example, Schwartz and Bahadur directly blended γ-Al_2O_3 (33 nm) with polyphenylene sulfide (PPS) powder in an electric mixer for 60 s. The mixture was then compression molded in a die at 310 °C [154]. Flexural tests on the composites for 1, 2, 3, and 5 vol.% alumina nanoparticle proportions indicated that their flexural strengths were lower than that of the neat PPS. The strength decrease was attributed to the weakening inevitably introduced by the presence of the heterogeneous particles. However, untreated nanoparticles are not always bound to result in a negative influence. Sumita et al. used a two-roll mill to mix silica with different diameters (7, 16, and 40 nm, respectively) and PP at 180 °C for 15 min [155]. The mixture was then molded at 200 °C under a pressure of 10 MPa. It was demonstrated that 20 wt.% of the nanoparticles increased the tensile yield strength of PP by 55–75% and its Young's modulus by 35–69%, while micrometer-sized inclusions only marginally increased the yield stress and the modulus. In addition, the strength and Young's modulus increased with increasing nanofiller content and decreasing

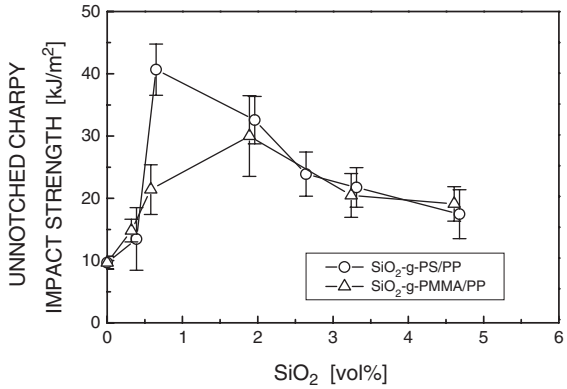

Figure 29. Filler content dependence of unnotched Charpy impact strength of PP (MI = 6.7 g/10 min)-based nanocomposites filled with various nano-SiO_2. Reprinted with permission from [107], M. Z. Rong et al., *Polymer* 42, 167 (2001). © 2001, Elsevier Science.

nanofiller size. They observed similar effects of the same nanoparticles in nylon 6 [156], PMMA [157], and PVC [158]. In the works of the authors, focused on the elastic performance of nano-SiO_2-filled PP [159] and LDPE [40], the above reinforcing behavior proved to be valid for different conditions. By comparing a modified expression, based on the dispersion strength theory, with the measured filler loading dependence of the yield stress, Sumita et al. were able to determine an aggregation parameter. It was thus concluded that the extent of nanoparticle aggregation did not increase in a polar matrix within a range of the filler volume fraction between 0 and 0.1. In a nonpolar matrix, however, the aggregation became larger with an increasing amount of particles. But this analysis has to be taken cautiously, since no direct microstructural investigation was conducted.

Landry et al. also mixed untreated fumed silica (7 nm) and molten polyvinyl acetate (PVAc) at about 100 °C for 20 min in a two-roll mill [160]. The mixture was melt-pressed at 100–120 °C to obtain thin, optically transparent composite films. At a filler loading of 18 wt.%, room-temperature tensile modulus and tensile stress of the composites were increased by 30% and 5%, respectively, but the elongation to break was reduced by a factor of 3.5, when compared with the neat PVAc control. The marginal improvement of the stiffness and strength was interpreted as a lack of a "percolated" SiO_2 network.

With an improved understanding of carbon nanotube properties and the continuous development of nanotube production and purification, there is an increasing in fabricating composites containing carbon nanotubes [161]. Cooper et al. assumed that the difficulty of producing well-dispersed carbon nanotubes in a composite is due to a phase separation of the carbon and polymer powders. The latter can occur as the result of sonication of a small amount of solid (carbon) in a comparatively large amount of liquid. The carbon nanotubes are more attracted to each other than they are to the larger volume of the liquid. To solve the problem, Cooper et al. suggested that the two solid phases of the composite should be combined in a relatively dry state [162, 163]. In this "dry" processing method, even though a very small amount of liquid is used to transfer sonication energy to the particles (carbon and matrix), there is only a low likelihood that the nanotubes will pass around the solid matrix particles to agglomerate together. Based on the above idea, multiwalled carbon nanotubes (MWNTs) and single-walled carbon nanotubes (SWNTs) were mixed by ultrasonication in a small amount of ethanol to achieve a homogeneous slurry of spherical PMMA particles (100–500 μm). The mixture was dried and mechanically mixed with an attritor operating at 2000 rpm. This mixing was followed by a kneading process at 170 °C, so that the matrix became a viscous mass. The final step of composite preparation was to extrude the premixture to orient the reinforcement and the polymer matrix in the flow direction. Tensile tests indicated that the Young's modulus of the MWNT composites was even lower than that of the neat PMMA. This was attributed to the fact that the inner nanotube shells were sliding past each other, thus preventing effective load transfer. This was confirmed by Raman spectroscopy, since no shift in the peak position of the A_{1g} Raman band for MWNTs was observed when a nanotube composite was deformed in tension [164]. Nevertheless, the impact resistance of the SWNT composites at a rather low filler content of 0.01 wt.% was about four times higher than the value of the matrix. It is believed that the high flexibility and elasticity of the nanotubes increase the fracture toughness of the composite by absorbing the impact energy.

Table 9 summarizes the polymer nanocomposites discussed in this section in terms of component species, filler treatment, and ultimate properties of the composites. It is seen that (a) $CaCO_3$ nanoparticles are the most frequently used fillers, and (b) a coupling agent treatment is the main way to enhance the interfacial interaction between the nanoparticles and the matrix polymers. This statistic seems to be similar to the classic situation of microscale particulate composites. Many techniques for modifying nanoparticles, as intensively reviewed previously, have not yet been applied to practical manufacture. In fact, incorporation of nanoparticles into polymers has scarcely brought about remarkable improvement in overall properties of the matrices in most systems investigated so far. Experience has shown that the reproducibility of performance enhancement is not always guaranteed. This means that mass production of composites is not yet available. Continuous efforts must be made to develop new techniques to bring the extraordinary characteristics of nanoparticles into full play in the plastics industry. Mechanically copying the common practice in the manufacture of microparticle-filled polymer composites would not result in a genuine polymer nanocomposite [165].

3.2.2. Solution Mixing

Solution mixing is a liquid-state powder processing method (particles in a polymer solution) that brings about a good molecular level of mixing, but at a cost depending on the solvent and its recovery. It is applicable to the polymers that can be dissolved or swelled by the solvent. Its advantages include large interface extension, improved interfacial bonding, low viscosity, fast solvent removal, easy casting, and high homogeneity of the ultimate composite materials.

Carotenuto et al. produced monolithic silica (356 nm)/PMMA nanocomposites through solution blending [166]. They mixed a silica/methoxy propylacetate suspension with a PMMA solution (50 wt.% polymer in methoxy propylacetate) and then sonicated the mixture for 5 min. The samples were centrifuged to remove bubbles and then dispersed into a mold. After being heated in a vacuum at 100 °C for 15 min, the nanocomposites were ready for use. The particle surface modification was obtained by treatment of the silica particles with an organic colorant (methyl red) at room temperature [167]. Electron microscopy indicated the formation of a polymer coating around the organically modified particles in the starting liquid precursor, and the resultant composites exhibited an excellent homogeneity. In contrast, the untreated SiO_2 formed a lot of agglomerates ($\sim$1 μm) in the matrix after evaporation of the solvent due to the weak hydrogen bonds between the methyl-ester groups of the polymer and the hydroxyl groups on the particle surface. A significant improvement of the Young's modulus was observed after the introduction of the nanofiller. The Vickers hardness of a composite with 50 wt.% silica was increased by 90%, and the glass transition temperature

[c] Single-walled carbon nanotubes serving as the fillers.

became 5 °C higher than the characteristic value of the pure PMMA.

With the same mixing technique, Carotenuto et al. prepared nanocomposites consisting of poly(methacrylic methylester) and monodispersed $Cu_2(OH)_2CO_3$ particles [168]. They found that the thickness of the polymeric layer around the particles increased with the polymer concentration. Hence it may be possible to manipulate the composite morphology and properties *in-situ* by changing the degree of wrapping of the organic molecules on the inorganic filler particles.

Because of the high mobility of nanoparticles in a polymer solution, composites with specific spatial distribution of the nanoparticles can thus be made, based on the self-organization process. Hamdoun et al. prepared stable solutions of polystyrene-polybutylmethacrylate P(S-b-PBMA) diblock copolymer (M_W = 82,000, molecular weight polydispersity index = 1.05) and γ-Fe_2O_3 (3.5 nm) in toluene [169]. To acquire good solubility, the nanoparticles were precovered by a PS layer of short chains (M_W = 13,000). Eventually, a thermodynamically stable nanocomposite was obtained in three steps: (i) mixing of the two solutions; (ii) spin-coating the composite solution on a solid substrate; (iii) annealing the resulting film at 150 °C under vacuum, until a quasi-equilibrium self-organization was reached. Microscopic observation revealed a periodic arrangement of the particles in the polymer matrix, which reproduces the ordered arrangement of the copolymer mesophase. It is expected that the macroscopic properties of the composite could reflect both the physical properties characteristic of the nano-objects and those that are specific to the large mesh periodic structure of the matrix.

During a series of works by Shang et al. focusing on the effect of interfacial bonding on the mechanical performance of particulate filled polymer composites [41, 170, 171], a silica/ethylene vinyl acetate (EVA) composite system was manufactured by means of a solution mixing technique. The silica particles, either 600 nm or 14 nm in diameter, were modified by a thermal treatment at different temperatures or by a thermal treatment combined with a chemical treatment with trimethylchlorosilane. Then the particles were incorporated into the EVA/benzene solution. For the coarser silica composite solutions, a magnetic stirrer was used to improve the particle dispersion. For the finer particles, sonication was employed instead. Benzene was chosen as a solvent because it is a good and nonpolar solvent for EVA copolymer. The silica particles were expected to be well distributed in the polymer solution since the solvent

induces optimal polymer chain length expansion that stabilizes the silica powders in solution [171]. The tensile strength values of the composites indicated that the SiO_2 (600 nm)-filled versions had a lower tensile strength than the unfilled EVA, suggesting that the particles had a weakening effect. In contrast, the composites filled with SiO_2 (14 nm) were stronger than the matrix polymer. Within the lower loading range of SiO_2 (14 nm), the tensile strength of the composites increased with increasing volume fraction of filler, reaching a maximum at around 4 vol.%. The composites retained their higher tensile strength compared with the unfilled polymer up to 15 vol.% of filler [41]. On the other hand, the Young's moduli of the composites increased with a rise in the content of either SiO_2 (600 nm) or SiO_2 (14 nm) [170]. For identical filler volumes, the SiO_2 (14 nm) composites were stronger than the SiO_2 (600 nm) ones, owing to the fact that the fine particles have more surface area available to bond and adsorb matrix polymer. These bonded and adsorbed polymer chains become stiff as a result of a loss in flexibility.

To diminish mixing problems and to improve the dispersion of fine particles in polymers, Vollenberg and Heikens combined solution mixing and melt mixing when preparing alumina-filled composites [172]. They first made master batches containing 30 vol.% of alumina beads (35 nm and 400 nm in diameter, respectively) by adding the particles to the polymer solutions. Having been stirred for a few hours, the mixture was poured onto a large surface, allowing the evaporation of the solvent overnight. The master batches were then dried at 100 °C under vacuum. Finally, the unfilled polymers were mixed with the master batches on a two-roll mill to obtain the desired composites. The polymers employed in their work were PS, styrene-acrylonitrile copolymer (SAN), and polycarbonate (PC). The solvent for the former two polymers was ethylene acetate, and methylene chloride was used to dissolve the latter one. Similar to the case stated above, the Young's moduli of the composites appeared to be dependent on the particle size. At a constant volume fraction of filler, the smaller alumina particles (35 nm) generated a more significant reinforcing effect than the larger ones (400 nm).

To compare the properties of nanocomposites, prepared through a sol–gel route, with particulate-filled systems, Landry et al. added nano-SiO_2 (7 and 14 nm, respectively) to a 10 wt.% solution of PVAc in tetrahydrofuran (THF) and mixed them for several hours [160]. The solution was then cast in a Teflon mold, yielding opaque, broken pieces of the composites. Eventually, transparent nanocomposite films were obtained by melt-pressing the substance at 100–120°C. Tensile testing indicated that below the glass temperature, T_g, of PVAc, the solution-mixed samples possess properties similar to those of the melt-mixed ones (see last section). At a temperature higher than T_g, however, the solution-mixed composites decayed rapidly, in sharp contrast to the rubber-like plateau of the *in-situ* composites extending to about 300 °C. Again these observed differences were attributed to the differences in particle–particle connectivity.

Shaffer and Windle fabricated carbon nanotube composite films by carefully mixing aqueous poly(vinyl alcohol) (PVA) solutions with catalytically grown carbon nanotube dispersions followed by subsequent casting and controlled water evaporation [173]. The electrostatically stabilized dispersion of carbon nanotubes in water was produced when the nanotubes had been pretreated by a suitable oxidation [174]. Successful preparation depended crucially on maintaining stable colloidal mixtures of nanotubes and polymer. Dynamic mechanical analysis of the composites suggested that the presence of carbon nanotubes stiffens the material, particularly at high temperature, and in some cases retards the onset of thermal degradation. The authors concluded that carbon nanotubes might not ideally be suited to a straightforward reinforcing role, but that they could find application as a modifier for polymers, particularly as an improved matrix for conventional fiber composites for service at high temperatures.

3.2.3. Miscellaneous Mixing Techniques

Thermal spraying seems to be a viable solution to the processing limitations of conventional techniques for polymer nanocomposite manufacturing, such as the use of a high working temperature for melt mixing and solvents for solution mixing [175]. This is particularly true for the preparation of nanocomposite coatings. During a thermal spray process, materials, in powder, wire, or rod form, are heated, accelerated, and propelled by a high-temperature jet through a confining nozzle toward a surface. The individual molten or softened droplets impact, spread, cool, and solidify to form continuous coatings. Material heating, quenching, consolidation, and posttreatment are thus combined in a single step. The important benefits of using a thermal spray process for making polymer nanocomposites include the following: (i) powdered polymers are heated only to a temperature at which the particles are viscous enough to spread because of the high kinetic energy; (ii) good dispersion of nanoparticles is achieved by the high velocity; (iii) processing without the use of a volatile solvent is possible.

Schadler et al. employed a high-velocity oxy-fuel (HVOF) system to thermally spray SiO_2/nylon 11 nanocomposite coatings [175]. The particles (7 and 12 nm in diameter, respectively) were pretreated to be either hydrophobic or hydrophilic, respectively. To avoid powder segregation in the jet due to differences in powder size and density, the nylon and silica particles were dry ball milled together for 48 h, resulting in a gradient shell of embedded silica particles near the surface of the nylon powder particles. By optimizing spray parameters such as nozzle design, spray distance, oxygen-to-fuel ratio, powder feed position, and substrate cooling, dense coatings with relatively uniform particulate distribution were achieved. Compared with neat nylon, scratch resistance improved by 30% and wear resistance improved by 55%. Silica particles with a hydrophobic surface led to better mechanical properties than those with a hydrophilic surface.

Recently Petrovicova et al. characterized the changes that the above silica reinforced nylon 11 underwent during thermal spraying and their influence on the final polymer morphology and coating performance [176, 177]. Agglomerates of silanated silica, on the order of 50 nm in size, were observed in the nanocomposites, whereas the agglomerates of untreated silica and hydrophilic silica were on the order of 100 nm. Reinforcement of the polymer matrix, for

example, in the case of a 15 vol.% silanated silica-filled nanocomposite, resulted in an increase of up to 205% in the dynamic storage modulus (Table 10). At temperatures above the glass transition temperature of nylon 11, the storage modulus of a 15 vol.% hydrophobic silica nanocomposite was higher than that of the unfilled version by up to 195%. An increase in matrix crystallinity was assumed to be the predominant cause of the enhancement of the mechanical properties.

Unlike conventional dispersive mixing at a temperature above the melting point or the flow temperature of the polymer matrix, mechanical alloying, which compounds the components at room temperature through mechanochemical effects, is an effective route for producing polymer composites with sufficiently high interfacial adhesion. The process is a high-energy ball-milling one in which the repeated fracture and welding of powder particles, arising from ball-powder collision events, allows true alloy powders to be formed from mixtures of elemental powders [178, 179]. It appears to be very promising because it offers the possibility of mixing two ordinarily immiscible materials, and no coupling agents or other surface treatments are needed, in principle.

So far, very few results have been reported that deal with mechanical alloying of polymer nanocomposites. Hu et al. applied mechanical milling to the preparation of composites consisting of carbon nanotubes (20 nm in diameter) and an ultra-high-molecular-weight polyethylene (UHMWPE) [180]. Having been milled for 2 h, the mixture of carbon nanotubes and the micron powder of UHMWPE was homogeneous. At a filler loading of 1 wt.%, the impact strength of the composites increased by a factor of 43% compared with the value of the unfilled UHMWPE. Electron microscopic observations of the fractured surface indicated that a resin layer (15–20 nm thick) was wrapped around the nanotubes, suggesting a good adhesion between the fillers and the matrix formed during mixing.

Table 10. Dynamic storage modulus G' of thermally sprayed nanocomposite coatings.

Silica content (vol.%)	Silica surface	Polymer matrix	G' at 30 °C (GPa)	G' at 70 °C (GPa)
0	—	D-60[a]	0.65	0.36

Chen et al. found that α-Fe_2O_3 nanoparticles (10 nm) were generated in the ball milling process of a Fe_3O_4/PVC system in the presence of air [181]. With the use of Mößbauer spectroscopy, it was revealed that PVC powders were partially degraded because of mechanical milling and became reactive on their surface. α-Fe_2O_3 nanoparticles were the products of activated PVC and Fe_3O_4. The authors also found that Mößbauer scattering, characteristic of interfacial interactions between Fe_3O_4 and PVC, appeared even in the case of argon protection.

4. MECHANISMS FOR PROPERTY IMPROVEMENTS

4.1. Interfacial Interaction

An extremely high surface area is one of the most attractive characteristics of nanoparticles because it facilitates the creation of a great amount of interphase in a composite. Introduction of nanoparticles into a polymer changes the intermolecular interaction of the matrix [182]. As estimated by Reynaud et al. [5], an interphase, 1 nm in thickness, represents roughly 0.3% of the total volume of the polymer in the case of microparticle-filled composites, whereas it can reach 30% of the total volume in the case of nanocomposites. Therefore, the nonnegligible contribution made by the interphase provides diverse possibilities for performance tailoring.

To study the influence of the interphase on the properties of polymer composites, two groups of models have been proposed. The first one assumes uniform properties of the interphase [183–185], and the other assumes nonuniform properties [186, 187]. It seems that the nonuniform models of the interphase are limited to relatively large particles. For nanoparticles, the interphase region is on the order of some nanometers [188]. In this context, it is reasonable to assume that the physical properties of the interphase in nanocomposites are either uniform or nearly uniform [189].

The nature of interfacial interactions is a function of atomic arrangement, molecular conformation, chemical composition, morphology, and diffusivity of the filler and the matrix [190]. Usually the strength of the interaction is created by primary bonds (e.g., ionic, covalent, and metallic) and/or secondary bonds (e.g., hydrogen bonds and van der Waals forces) [54]. With respect to the mechanisms responsible for interfacial adhesion in microcomposites, numerous theories have been studied, including adsorption and wetting, electrostatic attraction, chemical bonding, interdiffusion, mechanical interlocking, etc. However, only a few papers have discussed the interfacial effects of nanocomposites because the importance of the materials began to be recognized just in recent years.

According to the theory of interdiffusion, two surfaces in contact with each other can build up adhesion by the mutual diffusion of the molecules of the interacting surfaces. The bond strength is dependent on the amount of molecular entanglement, the number of molecules involved, and the strength of the bonding between the molecules. The interphase thus formed has a substantial thickness, and its chemical, physical, and mechanical properties are different from those of the filler and the matrix. Kendall and

Sherliker demonstrated for nanosilica/polyethylene composites the presence of "bound polymer," which cannot be removed by solvent extraction from the filled material [188]. It was suggested that there are two interfaces; one is between the filler and the bound polymer, and a second interface occurs between the bound polymer and the soluble polymer. The latter acted as a weak point, embrittling the matrix through the reduced entanglement resulting from the surface assymmetry. To overcome this problem, increasing the molecular weight of the matrix polymer to produce a better physical entanglement across the second interface proved to be effective [188, 191].

In fact, the expectation that a sufficiently long surface chain, extending some distance from the filler, would strengthen the interfacial bonding [191] was further confirmed by Rong et al. for nanoparticle-filled PP [107]. They introduced macromolecules with a molecular weight of around 10^4 onto nano-SiO_2 (7 nm) through irradiation grafting. Although the monomers of the grafting polymers should have different miscibilities with PP, all of the grafting polymers, except PEA, exhibited a reinforcement effect on the tensile strength of the nanocomposites (Table 11). These results contribute to a further understanding of the modified nanoparticles and their role in the composites. That is, interdiffusion instead of a miscibility of the grafting polymer segments with the polypropylene molecules, and entanglement between the grafting polymer and the matrix, dominate the interfacial interaction in the nanocomposites. This leads to the conclusion that a PP matrix with a higher molecular weight should entangle even more effectively with the nanoparticles agglomerates, thus leading to a higher tensile strength increment. The experimental data of the authors for PP with different molecular weights support this estimation.

In a recent report on grafted nano-SiO_2 particle-filled PP composites studied by atomic force microscopy (AFM) [192], it was shown that PP molecules are able to immigrate into the nanoparticle agglomerates in the molten state of PP (Fig. 30). An interdiffusion and entanglement between the molecules of the grafting polymers and the matrix can thus take place outside and inside the nanoparticle agglomerates. Moreover, Shumsky et al. [193] measured the viscoelastic behavior of the nanocomposites employed in [107] in the molten state. Drastic changes in the pattern and broadening of the relaxation times spectra to longer relaxation times for the composites were attributed to the onset of plastic yielding of a spatial network of the filler particles grafted with macromolecular chains, preceding the macroscopic melt flow. The results of this study can be regarded as experimental evidence for a shear-resistant, stiff spatial structure of filler particles coated with a polymer boundary layer in the melt phase of a nanocomposite with relatively low filler content. Landry et al. also proposed the existence of a nanosilica network in PVAc-based composites [160]. The chains of PVAc are strongly adsorbed to and entrapped in the silicate network, as suggested by a high plateau modulus above T_g, a broadened distribution of relaxation times at T_g, a diffuse interface between silica and PVAc, and a high level of hydrogen bonding.

Kunz and co-workers studied the distributions of colloidal gold nanoparticles (20 nm) in poly(2-vinylpyridine) (PVP), at the surfaces of PS and PVP, and at the interface between PS and PVP [194]. Contrary to the results obtained for PS surfaces, it was found that the particles adsorb strongly to the PVP surface, even at temperatures at which gold particles are quite mobile. A striking manifestation of slow dynamics at the gold/polymer interface is the pinning of gold nanoparticles to an interface between PS and PVP. The effect can be explained by the formation of loops between different portions of an effectively grafted PVP chain. PS chains are linked to the gold particles by the entanglements they make with these loops.

Espiard et al. further described the details of molecular entanglements at the interfacial region of a nano-SiO_2 reinforced poly(ethyl acrylate) (PEA) film to explain the improved mechanical properties [195]. The nanoparticles used in their work were pretreated with silane carrying a polymerizable methacrylic group, which furthermore served as a nucleating agent in an emulsion polymerization of ethyl acrylate monomers [80, 196]. It was found that grafting of ethyl acrylate to the treated nano-SiO_2 particles took place in the earlier stage of the polymerization. As a result, the polymer that had not been grafted participated in two kinds of entanglements. One involved polymer molecules coming from different particles. Entanglements are formed during the coalescence process of the film formation. The other involved both the nongrafted polymer and the tight loop system formed around the particles by copolymerization of the methacrylic groups of the coupling agent and the growing polymer. Upon elongation of the film, the set of entanglements involving the loops is expected to remain, whereas the nongrafted polymer can be elongated extensively and

quasi-reversibly up to near the rupture process, which occurs when the first set of entanglements disappears.

The above-cited works imply that the interfacial interaction in nanocomposites is often a combination of different effects, like adsorption, chemical bonding, interdiffusion, etc. It is hard to treat the problem based on a single mechanism. Shang et al. proved the existence of intermolecular forces between the silanol groups of the nanosilica filler and the carbonyl groups of the EVA matrix [41]. A reduction in the amount of surface hydroxyl groups of nanosilica results in a weaker interfacial bonding. Within the nanocomposites of SiO_2/EVA, more EVA molecules are adsorbed and coupled through entanglements other than direct hydrogen bonds to the silica surface [170]. In the course of rheological measurements at 150 °C, the adsorbed polymer gradually loses its entanglements through decoupling at the silica surface with a rise in the testing frequency [171].

Since many of the thermoplastics, serving as matrices in nanocomposites, are semicrystalline (with properties that are strongly related to the crystalline characteristics), effects of a heterogeneous nucleation exerted by the nanoparticles would significantly influence the microstructure of the matrix polymers. This in turn affects the mechanical performance of the nanocomposites. In a work on nanosized carbon fiber reinforced polyether polyurethane, Xu and co-workers detected two melting peaks of the matrix polymer in the composites, instead of a single melting peak of the polymer without a nanoparticle reinforcement [197]. Ren et al. measured the melting behavior of a $CaCO_3$ (80 nm)/PP nanocomposite in comparison with that of the neat PP [149]. They found a minor melting peak corresponding to the β-phase PP at 150.6 °C in addition to the main endotherm at 165 °C typical for the α-phase PP (Fig. 31). Since impact strength and toughness of β-PP exceed those of α-PP because of β-to-α or a β-to-smectic transition during the deformation [198, 199], an appearance of β-phase in PP should account for the improvement in ductility of the nanocomposites.

In general, γ-quinacridone is the most widespread highly active β-nucleating agent. Some two-component compounds obtained by the reactions of organic acids with $CaCO_3$ can also serve as β-nucleators [200, 201]. Moreover, Liu et al. indicated that certain inorganic nanoparticles like Y_2O_3 (20 nm) are able to induce β-crystallites in PP [202]. At an Y_2O_3 content of 1 wt.%, the melting enthalpy of β-PP approaches 3/4 compared with that of α-PP [203]. Nevertheless, the role of nanoparticles in modifying the crystallization habit remains unclear because research groups

have obtained different results. Wu and Xu examined the crystallization behavior of SiO_2 (20 nm)/PP/ethylene-propylene-diene monomer (EPDM) terpolymer [204]. Nano-SiO_2 was found to increase the crystallization temperature and crystallization rate of PP and to reduce the spherulite size. However, there was no trace of a β-phase PP. Similarly, Rong et al. demonstrated that both the untreated and treated nano-SiO_2 have some nucleation influence on the crystallinity of PP [107]. Except for this effect, the difference between the nanocomposites and the neat PP could not be detected during the nonisothermal and isothermal crystallization measurements (Tables 12 and 13). Therefore, the reinforcing and toughening effects of the modified nanoparticles could not be attributed to the slight variation in matrix microstructure.

4.2. Quantitative Considerations

Although there are quite a lot of theories for the mechanical properties of composite materials, usually they do not offer a general solution. In the case of nanocomposites, for example, in which the nanofillers are used to modify the properties of the polymer matrix at a rather low filler concentration, it is sometimes rather difficult to describe the performance by using the theories for conventional polymer composites [205]. Specified models have to be worked out as a result. Nevertheless, nanocomposites are a rather new member of the family of composite materials, and for the moment continuous efforts are needed to collect as much information as possible about their deformation behavior and damage processes. We are far from the stage of concluding theoretical estimations with adequate applicability and predicability. Instead, analyses of case studies would help to establish a knowledge path and a frame of methodology for dealing with a quantitative description of the mechanical role of nanoparticles in composites.

4.2.1. Stiffness

The rule of mixtures is a general approximation of the description of the mechanical behavior (especially elastic behavior) of composites. It gives upper (Eq. (6)) and lower (Eq. (7)) bounds to their mechanical response:

$$E_c = \phi_m E_m + \phi_f E_f \tag{6}$$

$$E_c = E_m E_f / (\phi_m E_m + \phi_f E_f) \tag{7}$$

where E_c is the modulus of the composites, E_m and E_f denote the moduli of the matrix and the filler, and ϕ_m and ϕ_f symbolize the volume fraction of the matrix and the filler, respectively. As a matter of fact, Eqs. (6) and (7) are based on a strong interfacial adhesion and rigid spherical reinforcement, respectively. The main reinforcing mechanism is attributed to the efficiency of the load transfer from the matrix to the filler. It was found that the moduli of most particulate filled polymers lie between the two limits [206]. On the other hand, Kerner's equation was derived from a basic consideration of mechanical properties of a composite at moderate concentration [207]. For low filler content, Nielsen's modification of Kerner's equation is more applicable because the maximum packing of the fillers, interfiller interactions, and the mechanical coupling of the matrix and filler are taken into consideration [208, 209]:

$$E_c = E_m(1 + AB\phi_f)/(1 - B\psi\phi_f) \tag{8}$$

where A accounts for the contribution of the interfacial interaction and factors like filler geometry, B represents the relative stiffness of the two components, and ψ is dependent on the filler packing fraction.

Predictions of nanocomposite moduli based on the above equations were made by Petrovicova et al. [177]. The experimental results indicated that all of the nano-SiO_2/nylon 11 nanocomposites exhibited a modulus higher than that calculated by the rule of mixtures. Although the data for most of the nanocomposites closely fit Eq. (8) for $A = 3 - 4$, there was a large deviation for the 2.4 vol.% filled composites, manifesting the extraordinary reinforcing tendency of the nanoparticles. It was believed that the lower values of A were due to an improved spatial distribution of the silica in the matrix.

As a result of the unsatisfactory agreement between the Kerner equation and the measured data, Kryszewski and Bak [189] assumed that some volume of the surrounding

matrix becomes immobilized as a result of interfacial binding, giving rise to an effective increase in the size of the nanoparticles. The effective volume fraction of the partially immobilized material ϕ_e is given by [210]

$$\phi_e = \phi_f(1 + \Delta R/R)^3 \tag{9}$$

where R stands for the radius of nanoparticles and ΔR is the increment of the effective particle size. By replacing ϕ_f with ϕ_e in Kerner's equation for a Poisson ratio of 0.5, the elastic modulus of nanocomposites can be described as

$$E_c = [1 + 2.5\phi_e/(1 - \phi_e)]E_m \tag{10}$$

A comparison between the testing data of nano-palladium (1–2 nm)/PMMA and Eq. (10) indicated a good agreement, provided $\Delta R = 2.25$ nm. This suggests that the effective radius of the immobilized matrix environment could be much greater than that of the nanoparticles. The stronger the interfacial interaction is, the thicker is the interlayer [171]. Similarly, Sumita et al. studied the energy dissipation of PP-based nanocomposites under the circumstances of dynamic mechanical testing [159]. According to the concept of the effective volume fraction of the dispersed phase, which assumes that the "immobilized" matrix associated with the interphase does not contribute to energy loss, they yielded an expression for the relative loss modulus,

$$E_c''/E_m'' = 1/(1 - \phi_e) \tag{11}$$

where E_c'' and E_m'' represent the loss moduli of the composites and the matrix, respectively. By substituting the measured values of E_c''/E_m'' into Eq. (11), one can obtain ϕ_e. The data showed that the effective volume fraction increased with increasing filler content and decreasing filler size.

In fact, most of the current theories valid for conventional composite systems assume an isotropic and homogeneous matrix filled with spherical particles. In this context, Young's moduli of the composites should be independent of the dimension of the dispersed phase. The local stresses in these composites under load are only dependent on the ratio of the distance between the particles of the dispersed phase and the dimensions of these particles. This ratio is often a constant in the case of a certain volume fraction of the dispersed phase and a certain spatial distribution of the particles. Evidently, this is not the case, especially when nanoparticles, characterized by high surface area, are incorporated. Therefore, the commonly accepted theories have to be modified in the case of nanocomposites, as shown by the above-mentioned works. Vollenberg and Heikens treated this problem in another way [172]. They clearly demonstrated the considerable dependence of Young's modulus on filler size (ranging from 35 nm to 100 μm); it was indicated that effects like adsorption of additives, particle size distribution, dewetting, and matrix morphology cannot explain the phenomenon well. The remaining explanation is that the solidification of the matrix is locally activated at a free filler particle surface, leading to a particular morphology of the polymer surrounding the filler particles, such as segmental orientation and improved packing in the neighborhood of the filler surface. For nanoparticles, the interparticle distance is so small that a homogeneous matrix material of a higher modulus polymer is reasonably assumed to be created, as supported by the results of annealing and solid-state nuclear magnetic resonance experiments [211].

It is also of importance to note that the formation of a relatively compliant layer at the interface tends to hinder a complete stress transfer under low stress and thus masks the stiffness of the nanoparticles. Table 11 gives evidence of such a masking effect provided by grafting polymers (PBA, PVA, and PEA, for example) on various nanoparticles. In this or a similar case, the above-discussed relationship between composite modulus and effective volume fraction of the interphase, consisting of an immobilized matrix polymer, is no longer applicable.

To avoid complicated geometric effects in composite materials, Shang and co-workers proposed a thermodynamic model based on the work of adhesion [170]. It was hypothesized that the interfacial bond strength can be quantified

by this parameter. The rationality of this assumption lies in the breakdown of the interface interaction required to do certain work. Accordingly, Young's modulus of a composite at a given filler loading is written as a function of the work of adhesion, W_a:

$$E_c/E_{co} = \exp\{-K_{E_c}[(1/W_a) - (1/W_{ao})]\} \qquad (12)$$

where E_{co} is the modulus of the composite with the weakest interfacial bond, W_{ao} is the work of adhesion of the composite with the weakest interfacial bond, and K_{E_c} is a constant, independent of the filler volume content and experimentally determined from the slope of log E_c versus $1/W_a$. When the Young's modulus of a composite with its corresponding W_a is known, Eq. (12) can be used to predict the Young's modulus of another composite with another W_a but with the same filler content. Results from SiO_2/EVA composites verified that Eq. (12) leads to good agreement for both, composites filled with micro- and nanosized particles. Furthermore, the data indicated that the composites that incorporated smaller particles have a higher K_{E_c} value. Since the K_{E_c} values show how the Young's modulus changes with W_a, the dependence of K_{E_c} on particle size proves that the effect of the interfacial bond on Young's modulus depends on filler particle size.

4.2.2. Strength and Fracture Toughness

The theories for the strength properties of filled systems are less developed than those for the modulus. In particular, only a few reports deal with the exploration of fracture mechanisms of nanocomposites where changes in the nature of crack propagation are believed to be one of the main mechanisms responsible for the strengthening effect [212]. In the case of poor bonding between the filler particles and the matrix, the tensile strength of a composite is usually reduced, with the filler content ϕ_f following a power law [213–216],

$$\sigma_c = \sigma_m(1 - \alpha\phi_f^n) \qquad (13)$$

where σ_c and σ_m are the strengths of the composite and the matrix, respectively; the constants α and n depend on the shape of the particles and their arrangement in the composite. This means that the strength of the composite cannot be greater than that of the unfilled version because the filler particles do not bear any fraction of the external load. However, this contradicts the results of the nanocomposites described in previous sections.

When the bonding between fillers and the matrix is strong enough, as suggested by Jancar and co-workers [217], the tensile strength of a composite can be 1.33 times as high as that of the matrix polymer:

$$\sigma_c/\sigma_m = 1 + 0.33F(c)\phi_f^2 \qquad (0 < F(c)\phi_f^2 \leq 1) \qquad (14)$$

$$\sigma_c/\sigma_m = 1.33 \qquad (1 < F(c)\phi_f^2) \qquad (15)$$

where $F(c)$ is proportional to the average yielded area per particle. In this case, an overlapping of stress concentration fields around the particulate fillers is responsible for shear yielding of the matrix [218]; the latter can be considered the dominant energy dissipation mechanism. Figure 32 illustrates good regression results in terms of Eqs. (14) and (15), demonstrating that a "perfect" adhesion is associated with the PP-based nanocomposites when $\phi_f > 0.65$ vol.% [3]. It should be noted that the equilibrium relative strength is about 1.15 but not 1.33, which can be attributed to the low ductility of the matrix polymer employed. When the filler content exceeds the critical value of 0.65 vol.% (i.e., $F(c)\phi_f^2 = 1$), the corresponding $F(c)$ can be estimated to be around 2.4×10^4. Considering the fact that $F(c)$ characterizes the rate of increase in connectivity of yielded microzones around individual particles [75], one might conclude that the reinforcing effect generated by the nano-SiO_2 particles here is far superior to that induced by conventional particles. For example, the $F(c)$ values for $CaCO_3$ (10 μm in diameter)-filled PP composites range only from 3 to 5 [217]. In addition, the greater value of $F(c)$ is also indicative of a strong interfacial interaction in the nanocomposites.

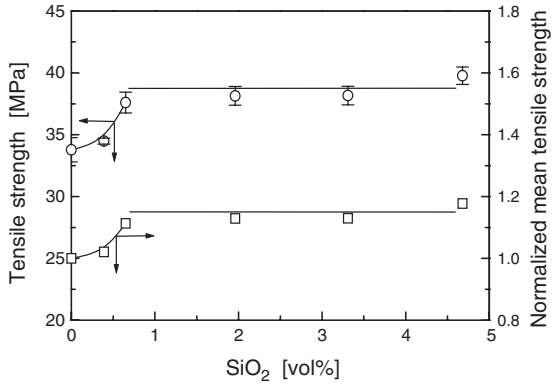

Figure 32. Tensile strength of SiO_2-g-PS/PP nanocomposites as a function of SiO_2 content. The lines represent the results of curve fitting in terms of Eqs. (14) and (15). Reprinted with permission from [3], M. Z. Rong et al., *Polymer* 42, 3301 (2001). © 2001, Elsevier Science.

Pukanszky et al. developed, alternatively, a semiempirical correlation for describing the composition dependence of the tensile yield stress in heterogeneous polymer systems [219]:

$$\sigma_c/\sigma_m = (1 - \phi_f)\exp(B\phi_f)/(1 + 2.5\phi_f) \qquad (16)$$

where B is a parameter related to the components' interaction. It is given by

$$B = (1 + A_f\rho_f l)\ln(\sigma_i/\sigma_m) \qquad (17)$$

where A_f and ρ_f are the specific surface area and the density of the filler, and l and σ_i are the thickness and yield stress of the interphase. By using Eq. (16) and the measured mechanical performance, Fekete et al. calculated a series of B values [220]. It was shown that the correlation of B versus A_f is linear up to a specific surface area of about 7–8 m^2/g as predicted by Eq. (17), but it becomes independent of A_f at higher values. The deviation from the prediction was attributed to the formation of particle agglomerates. With agglomeration, the surface area for interphase formation no longer changes with increasing A_f. Clearly, an examination of the linear relation between B and A_f based on Eq. (17) can reveal the homogeneity of the nanocomposites of interest.

Shang et al. also took the interfacial interaction into consideration when discussing the tensile strength of SiO_2/EVA composites [170]. Similar to the description of the modulus in Eq. (12), the dependence of tensile strength on the work of adhesion can be written as

$$\sigma_c/\sigma_{co} = \exp\{-K_{\sigma_c}[(1/W_a) - (1/W_{ao})]\} \quad (18)$$

where σ_c is the tensile strength of a composite with W_a at the interface. σ_{co} is the tensile strength of the composite with the weakest interfacial bond W_{ao}. When the tensile strength of a composite and its corresponding W_a are known, Eq. (18) can predict the tensile strength of another composite of a certain filler loading, even if the fillers have different W_a values. K_{σ_c} is the slope of log σ_c versus $1/W_a$ and depends on both silica particle size and volume fraction. The experimental results reflected that the K_{σ_c} values increased as the filler content increased, especially for the composites with coarser particles. It was thus suggested that for the tensile strengths of the nanosilica composites, the interfacial bond strength has a more pronounced effect on the composites filled with larger filler particles than on the composites with fine particles. The effect of W_a on the tensile strength is dependent on both particle size and volume fraction, but the Young's modulus depends only on filler size.

Sumita et al. observed that the shear yield stress for the composites filled with nanoparticles increases with increasing filler content and with decreasing filler size, whereas the value for the composites filled with micron-sized particles decreases with filler content [155, 156]. Considering that the dependence of reinforcing and antireinforcing effects on filler size and volume fraction can be explained by the dispersion strength theory, Sumita and co-workers proposed a modified equation as follows:

$$\tau_c = \tau_m(1 - \phi_f^{2/3}) + Gb/\{dk(d)[(4\pi/3\phi_f)^{1/3} - 2]/2\} \quad (19)$$

where τ_c and τ_m are the shear yield stresses of a composite and its matrix, G is the shear modulus, b is the Burger's vector, d is the diameter of a particle, and $k(d)$ is an aggregation parameter. It suggests that under the same filler content, smaller nanoparticles result in a more remarkable reinforcing effect. For the micron-sized particle-filled composites, the second item of Eq. (19) is negligibly small. The experimental results of nano-SiO_2 incorporated PP and nylon 6 exhibited a good agreement with the calculation with Eq. (19) [155, 156].

Xiong et al. concluded that the influence of particle size on the composite strength can be depicted more clearly by a simple empirical expression. The authors studied the mechanical performance of ultrafine Al_2O_3/PS composites prepared through bulk polymerization in the presence of filler particles [221]:

$$\sigma_c = 35\{1 + [2.71/(1 + R)]\} \quad (20)$$

where the units of σ_c and R are MPa and μm, respectively. The authors showed that particles with radii smaller than 0.5 μm can bring about significant reinforcing effects.

Based on the methodology of structural elements, Ovchinskii et al. developed a computer simulation model and algorithms for simulating the processes of failure of fibrous nanocomposites [212]. An account was made of the scale effect of the strength of the superthin fibers, which was associated with a change in not only their lengths but also their diameters. Analysis of the modeling results showed that the increase in the strength of the examined composites was obtained by employing superthin fibers, which was more efficient than increasing the fiber volume content.

The fracture toughness of $CaCO_3$ (70 nm)-filled PP was studied by Levita et al. [142]. It was found that the critical stress intensity factor remained almost unchanged in the lower filler concentration range (5 vol.%). Different behaviors were observed at higher loadings, depending on the surface treatment. There was a monotonic decrease in the case of untreated fillers, whereas for modified fillers a well-defined maximum at 10 vol.% was observed. As a coupling agent, stearic acid was more efficient than titanate. No difference between the two treatments was found at higher concentrations. Usually the fracture properties of particulate composites can be explained by the model of crack pinning [222]. It is assumed that the crack front is characterized by a line tension (energy per unit length), so that lengthening this line increases the energy associated with the crack. When the crack encounters an array of impenetrable particles it is arrested (pinning) and a higher tension is required to release the crack. Lange and Redford related the fracture energy of a composite, G_c, with the line tension, T [223]:

$$G_c = G_m + 3\phi_f T/2d(1 - \phi_f) \quad (21)$$

where G_m is the fracture energy of the matrix. To account for the influence of particle size, an empirical factor, $F(d)$ $(0 < F(d) < 1)$, has been introduced [224]. At low concentration Eq. (21) thus becomes

$$G_c = G_m + 3\phi_f F(d)T/2d \quad (22)$$

By examining the $F(d)T$ values as a function of particle size, Levita et al. pointed out that $F(d)T$ is very small for finely sized particles. That is, the pinning contribution proved to be negligible. A particle can only interact with a crack if its size is greater than a certain length that characterizes the crack. Instead, interfacial debonding that reduces the local stress was attributed to the main factor responsible for the toughening effect.

Studies on the filler loading dependence of the toughness of SiO_2/PP nanocomposites showed that the maxima in impact strength and fracture toughness appeared already at very low filler loadings (<1 – 3 vol.%) [107]. This is the opposite of the optimum loading conditions known for conventional particle-filled systems. Although the typical size of the modified nanoparticles at the above-mentioned filler content range varies between 100 and 150 nm (as found by TEM observation), the distances between individual particles and therefore the interparticle ligament thicknesses are still much larger than those found in toughness-optimized conventional particle-filled systems [225]. Therefore, the considerable toughening effect perceived at such a low filler loading in the nanocomposites implies that the mechanisms involved should be different from those used as a basis for the single-percolation concept of Wu [226], which has been proved to be well applicable to conventional particulate-filled polymer composites.

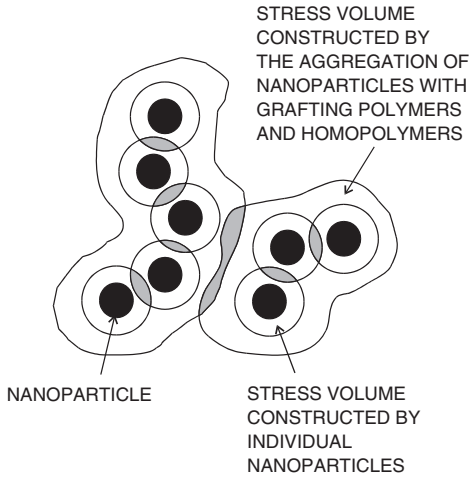

Figure 33. Hypothetical model of a nanocomposite with superposed stress volumes.

To overcome this problem, a hypothetical model of double percolation was suggested [3]. It was assumed that a double percolation, characterized by the appearance of connected shear-yielded networks throughout the composite, might be responsible for the performance enhancement at low nanofiller loading. This means one is dealing with (i) a percolation of shear yielded zones inside the dispersed phases (i.e., SiO_2-g-PS agglomerates, consisting of nano-SiO_2, the grafting PS on SiO_2, and the homopolymer derived from the grafting styrene monomer) due to the superposition of stress volumes around the nanoparticles, and (ii) a percolation of shear-yielded zones throughout the matrix resin due to the superposition of stress volumes around the dispersed agglomerates (Fig. 33). Provided these two percolation processes take place almost simultaneously, the eventual percolation threshold should be equal to the product of the individual percolation thresholds, in accordance with the scaling theory [227]. As a result, a rather low filler content is sufficient to bring about a significant improvement of the nanocomposites' performance. In fact, the concept of a so-called double percolation or multiple percolation has been successfully used in designing very low filler-loaded conductive polymer composites [228]. It should also be applicable to the description of critical transitions in other disordered systems with randomly geometric structure. In addition to the quantitative analysis provided in [3], fractography of tensile-fractured surfaces of the nanocomposites also give supporting evidence, as illustrated by the closely packed concentric matrix-fibrillated circles around particle-like objects (Fig. 34).

5. CONCLUSION

Nanocomposites represent a new prospective branch in the huge field of polymer materials science and technology. Though they have not yet been thoroughly studied, they show promising results in many aspects. To improve their competitiveness in the market, direct mixing of nanoparticles and polymers by existing blending techniques proved to be a possible breakthrough as long as the fillers are suitably pretreated. In contrast to the composites filled with microparticles, nanoparticles might permit simultaneous enhancement of the modulus, strength, toughness, and thermal deformation temperature of polymers without affecting the thermoformability under a rather low filler loading [3]. In addition, the rheological performance of the melts of the nanosystem is similar to those of the unfilled versions. As a result, the density, cost, and gloss of the final products are nearly not influenced, providing broad applicability in a variety of processing and manufacturing.

To truly ascertain the present and future potential applications of polymer nanocomposites, considerably more research and development needs to be done. The following issues in particular have to be borne in mind:

- What are the theoretical upper limits of the mechanical properties of a polymer nanocomposite?

So far, the reported increment in strength and toughness of nanocomposites (including intercalated and exfoliated nanocomposites) relative to the properties of the matrices is less than one order of magnitude, regardless of how the composites were prepared. It strongly indicates the necessity of establishing a framework that is able to quantitatively predict the reinforcing effects of nanoparticles as well as of new compounding techniques. These are the prerequisites for further development of the nanocomposites.

- How does the interphase influence the mechanical performance of a polymer nanocomposite?

In fact, this question is closely related to the previous one. When the reinforcing fillers reach a nanoscopic size, the mechanical properties of the nanocomposites should be governed almost entirely by the interface, and the bulk properties play a secondary role [5]. As the nanofillers might have the same size as the segments of the surrounding polymer chains, the classic models are no longer valid.

- What kind of surface treatment is most effective for purposes of separating nanoparticle agglomerates and improving filler/matrix interfacial adhesion?

It seems to be somewhat difficult to simultaneously meet both demands. Actually, no matter what methods have been used to date, a uniform dispersion of nanoparticles on a

nanometer scale is hardly obtained throughout the composites when it is done by the direct addition of premade nanoscale fillers to a thermoplastic matrix. Therefore, in addition to a continuous study of novel dispersion techniques and compounding facilities, research interests should also focus on developing surface treatments capable of giving full play to the reinforcing effect of nanoparticulate fillers, even though a homogeneous dispersion in the matrix is not available.

- What is the optimum phase morphology of nanocomposites, and how can this morphology be obtained by choosing proper processing conditions (including surface treatments of nanoparticles and mixing variables)?

Self-organization and self-assembly have been successfully adopted in the construction of well-defined discrete nanosystems, with a physical oriented performance toward certain functions [19, 229, 230]. Comparatively speaking, the effect of the spatial distribution of nanoparticles or nanoparticle agglomerates on the mechanical properties of nanocomposites has not yet been understood, to say nothing of the effects of the adjustment of the microstructural arrangement.

- Are there any relationships between the species of the nanoparticles and the improvement in mechanical performance of the nanocomposites?

The study of PP-based nanocomposites demonstrated that SiO_2 and $CaCO_3$ have similar strengthening and toughening effects [153]. It seems that a proper interfacial bonding, which facilitates (i) stress transfer between the matrix and the nanoparticles and (ii) plastic deformation of the matrix, is a very important issue. If this is the case, however, it is somewhat difficult to understand the positive synergistic effect provided by ultrafine $CaCO_3$ and talc [231], which cannot perform well when used individually in reinforcing HDPE.

- What are the applications for which only nanocomposites are competent?

The superiority of a new material should be expressed by its unique technical importance. For example, Al_2O_3 is not a suitable filler in the microscale particulate form for wear-resisting composites because of its angularity and thus its propensity to damage the counterface. However, the material in the nanoscale particulate form has much lower angularity and, therefore, is not that abrasive [154].

To have an idea of the prospects of the nanocomposites, a brief survey of the history of the development of intrinsically conducting polymers might be enlightening. Much of the early research on conducting polymers was spurred by their potential application as replacements for existing metals and semiconductors. However, with many years of intensive development activity, it seems that many of the proposed applications for these materials were rather optimistic and have not yet become possible. With growing experience, a number of more realistic applications have now emerged that tend to exploit the novel features associated with conducting polymers rather than those properties that are readily obtainable in traditional materials [232]. Similarly, the future commercial success of polymer nanocomposites might also require a careful consideration of other technological and economic aspects besides their mechanical role.

GLOSSARY

Agglomerates Weakly bonded particle clusters.

Aggregates Strongly bonded particle clusters.

Compatibility Miscibility on a molecular scale.

Composites A material consisting of two or more components, which largely retain their identities and yet result in many properties that cannot be achieved with either of the constituents acting alone.

Copolymer A polymer in which chemical combination exists in the main chain between two polymers $[A]_n$ and $[B]_n$. A copolymer can be a block copolymer [AAA...] [BB...] or a random copolymer ABAABAB, the latter having no long sequences of A or B units.

Crystallization of polymers The macromolecular chains fold in a regular manner forming ordered structure.

Dispersion Break up of agglomerated particles and separation of the resulting fragments to a point where reagglomeration will not occur.

Failure In a tensile stress-strain experiment, the sample is elongated until it breaks. Stress-strain studies are usually relatively slow, of the order of mm/s. Impact strength measures the material's resistance to a sharp blow, typically m/s. In both stress-strain and impact studies, energy is absorbed within the sample by viscoelastic deformation of the polymer chains, and finally by the creation of new surface areas.

Glass transition A transition describing the change between glassy and rubbery states in polymers. At the glass transition temperature, the amorphous portions of a polymer soften. Carried out under ideal conditions, glass transition is a type of second-order transition.

Graft Long macromolecular chains of a polymer are chemically attached to the base material.

Initiation Radical chain polymerization is a chain reaction consisting of a sequence of three steps-initiation, propagation and termination. The initiation step is considered the production of free radicals by any one of a number of reactions. The initiation involves the addition of this radical to the first monomer molecule to produce the chain initiating species.

Interface A surface formed by a common boundary of filler and matrix that is in contact with and maintains the bond in between. A polymer composite interface consists of a polymer and a nonpolymer. Usually the nonpolymer is a solid phase such as glass, carbon, or boron fibers, steel, or particulates such as calcium carbonate or titanium dioxide. In such a case the polymer cannot interdiffuse into the nonpolymer surface but may bond and adhere to it.

Monomers Small molecules that combine with each other to form polymer molecules.

Polymer A long molecule containing atoms held together by primary covalent bonds along the molecule. When one speaks of polymers, one is concerned with materials whose molecular weights may reach into the millions.

Polymerization Reactions by which the monomers combine building up macromolecules.

Thermoplastics Linear or branched polymers, that is, uncrosslinked ones, which soften, melt and flow upon heating. Almost all of the polymers produced by chain polymerization are thermoplastics. There are only a relatively few such polymers which are crosslinked.

Wetting Polymer wets the filler and squeezes into its void spaces, such that losse filler particles disappear and air introduced into the compound by entrapment in the filler agglomerates is replaced.

Young's modulus A parameter characterizing stiffness of materials, which relates the stress to the strain for uniaxial tensile or compressive loading.

Nanoparticles as Drug Delivery Systems

Jörg Kreuter

Johann Wolfgang Goethe-Universität Frankfurt, Frankfurt, Germany

CONTENTS

1. INTRODUCTION

One of the primary objectives in the development of drug delivery systems is the controlled delivery of a drug to its site of action at an optimal rate [1] and in the most efficient way possible. Targeting a drug to its site of action would not only improve the therapeutic efficacy but also enable a reduction in total dose of the drug which must be administered to achieve a therapeutic response, thus minimizing unwanted toxic effects. This concept of site-specific or targeted delivery was already envisioned by Paul Ehrlich around the early 1900s when he proposed the idea of the concept of the "Zauberkugel" (English: magic bullet).

One possibility to reach this goal may be drug delivery by nanoparticles. Chiefly due to their small particle size below 1 μm, these drug delivery systems offer various advantages for many medical and veterinary applications [2, 3]. This particle size enables intravenous and intraarterial injection since particles of this size can easily traverse even the smallest blood capillaries with inner diameters of 3–8 μm [4]. A small particle size also minimizes possible irritant reactions at the injection site [5, 6].

2. DEFINITION OF NANOPARTICLES FOR PHARMACEUTICAL AND MEDICAL PURPOSES

Nanoparticles for pharmaceutical purposes are defined by the *Encyclopedia of Pharmaceutical Technology* [7] as solid colloidal particles ranging in size from 1 to 1000 nm (1 μm). They consist of macromolecular materials and can be used therapeutically as drug carriers, in which the active principle (drug or biologically active material) is dissolved, entrapped, or encapsulated, or to which the active principle is adsorbed or attached. This definition was already formulated earlier in a number of reviews [1, 3, 6, 8] and includes monolithic nanoparticles with drug dispersed in the polymer network or dissolved in the polymer in form of an amorphous solid solution (Fig. 1a) as well as capsules with a shell-like wall (Fig. 1b). It also includes for instance nanoparticulate adjuvants in vaccines. This definition does not include solid lipid nanoparticles which are produced from lipids [9–11]. Nevertheless, solid lipid nanoparticles are described in Section 4.9.

3. HISTORICAL

In the late 1960s and early 1970s Professor Peter Speiser at the ETH (Swiss Federal Institute of Technology) in Zürich realized Paul Ehrlich's idea and developed the first nanoparticles for drug delivery purposes [12–14]. These first nanoparticles were produced by emulsion polymerization of acrylamide crosslinked with *N*,*N*′-methylenebisacrylamide in hexane.

Independently, Zolle et al. [15] and Scheffel et al. [16] used another process, denaturation of albumin dissolved in water and emulsified in hot cottonseed oil, to produce nanoparticles. $^{99m}TcO_4^-$ was bound to the nanoparticles, and these particles were used for radioimaging of the lungs after intravenous injection.

Later the albumin nanoparticles were also used for drug delivery. Kramer [17] incorporated the anticancer drug mercaptopurine into these particles using the method of heat denaturation (Section 4.5).

The first successful drug targeting with nanoparticles was then performed by Widder and Senyei [18–22] by

incorporation of magnetite particles into similar albumin nanoparticles and the employment of a magnetic field. These authors substituted mercaptopurine by the more efficient anticancer drug doxorubicin. Couvreur et al. [23–25] later could demonstrate that nonmagnetic nanoparticles also could accumulate in certain solid tumors and thus were able to substantially enhance the therapeutic efficacy of anticancer drugs such as doxorubicin or dactinomycin. This accumulation of the nanoparticles in these tumors probably was due to the enhanced permeability and retention effect (EPR effect) first described by Maeda and Matsumura [26] (see Section 6.1.1).

The latest important steps in the improvement of drug targeting with nanoparticles were the development of long circulating nanoparticles by the covalent linkage of polyethylene glycol (PEG) chains to poly(lactic-co-glycolic acid) (PLGA) [27] or to poly(alkyl cyanoacrylate) nanoparticles [28, 29] and the targeting of drugs to the brain across the blood–brain barrier [30].

4. PREPARATION METHODS FOR NANOPARTICLES

Several methods exist for the manufacture of nanoparticles. Table 1 lists the most important manufacturing methods. A very comprehensive compilation of preparation methods is given in the book *Colloidal Drug Delivery Systems* [6]. Only a few new considerably different manufacturing methods have been developed since the publication of this book; these include the above-mentioned methods to produce particles with covalently attached PEG chains and methods to attach linkers for drugs or targeting moieties. Following, the most frequently used preparations are briefly described.

4.1. Emulsion Polymerization

Emulsion polymerization in a continuous aqueous phase [33–93] is one of the most frequently used methods to produce nanoparticles. This method has a number of advantages. It represents a rapid production method that can rather easily be scaled up [7, 31]. The most important advantage, however, is that no organic solvents at all or well tolerated solvents like ethanol [64] are employed during this procedure.

To produce nanoparticles by emulsion polymerization a sparsely soluble monomer is dissolved in the aqueous phase. Additional monomer above its solubility may be added. This additional monomer can be stabilized by addition of emulsifiers (hence the name "emulsion polymerization") and then is present in emulsifier micelles or in larger emulsion droplets. However, the presence of an emulsifier is not necessary and does not influence the kinetics of this process [32–35]. The polymerization is initiated by radicals. These may be generated by the decay of initiator molecules such as potassium peroxodisulfate [35], which decays into two radicals upon heating, or by high energy radiation, such as γ-irradiation [37], ultraviolet, or strong visible light. The particle size as well as the molecular weights increase with increasing monomer concentration and decreasing initiator concentration [35, 36]. The polymerization is terminated by collision of two radicals or by two oppositely charged ions. The radicals or ions can be micro- or macroradicals and small ions or polymer ions, respectively. The termination can occur in the surrounding phase before phase separation or within the particles when two unterminated growing oligomer or polymer molecules meet [34, 38].

The heterogeneity in termination is one of the reasons polymerization of the poly(alkyl cyanoacrylates) is a rather complex procedure [54–57]. Poly(alkyl cyanoacrylates) have the advantage that they belong to the most rapidly biodegradable polymers. The polymerization of the poly(alkyl cyanoacrylates) is initiated by bases, specifically by the OH^- ions present in water. Actually, the pH has to be reduced below pH 3 in order to form nanoparticles. Above this pH the cyanoacrylates polymerize to large lumps. The pH may have to be even further reduced if basic components, for instance basic drugs, are present in the polymerization medium. On the other hand the water also generates the terminating species (i.e., H^+). For this reason the molecular weights of the poly(alkyl cyanoacrylates) in the nanoparticles are rather low [57] for instance compared to poly(methyl methacrylate) nanoparticles [36], and the influence of the monomer concentration on particle size is relatively small [54–56]. An increasing pH generally reduces the particle size, but again the situation is rather complex, and the pH influence is not very pronounced. Other components that are present in the polymerization mixtures such as drugs or stabilizers may have a much greater influence on the particle size and on the molecular weight [94, 95]. The presence of stabilizers tends to increase the molecular weights. The stabilizers, especially macromolecular stabilizers, which are present during polymerization are to a certain degree intermingled with the polymer network, most likely on the particle surface, but are not covalently bound to the polymer [96].

Nanoparticles also may be produced in a continuous organic phase. Solvents such as hexane, cyclohexane, isooctane, chloroform, and others were used. Polyacrylamide nanoparticles thus produced were among the first nanoparticles [12–14]. Later this process also was adapted for the production of poly(alkyl cyanoacrylate) nanoparticles [97–99]. However, the employment of organic solvents creates toxicological and environmental problems. For this reason, these processes are less useful.

Table 1. Preparation methods.

Method	Polymer	Ref.
Emulsion polymerization in a continuous aqueous phase	Poly(methyl methacrylate)	[33–43]
	Poly(methyl methacrylate)-copolymers	[44–53]
	Poly(butyl cyanoacrylate)	[30, 54–69]
	Poly(isobutyl cyanoacrylate)	[23–25, 70–81]
	Poly(hexyl cyanoacrylate)	[82–85]
	Poly(isohexyl cyanoacrylate)	[74–78, 81, 86–93]
Emulsion polymerization in a continuous organic phase	Poly acrylamide	[12–14]
	Poly(alkyl cyanoacrylates)	[97–99]
Interfacial polymerization	Poly(isobutyl cyanoacrylate)	[101–104, 107–112]
	Poly(isohexyl cyanoacrylate)	[105–107]
Solvent evaporation	Poly(lactic acid) and Poly(lactic acid-co-glycolic acid)	[115–143]
	Poly(ε-caprolactone)	[119, 128–130]
	Poly(ß-hydroxybutyrate)	[137, 138]
Solvent deposition or nanoprecipitation	Poly(lactic acid) and Poly(lactic acid-co-glycolic acid)	[145–148, 151, 154–157]
	Poly(ε-caprolactone)	[148–150]
	Eudragit®	[148, 154]
	Poly(ß-malic acid-cobenzylmaleate)	[152]
	Cellulose acetate phthalate	[153]
Preparation of nanoparticles in an oil emulsion	Albumin	[158–171]
	Gelatin	[172, 173]
	Chitosan	[174]
Desolvation of macromolecules	Gelatin	[178, 181, 184, 192–195]
	Albumin	[178, 182, 183, 187–191, 192–197]
	Cellulose	[186]
PEGylated nanoparticles	Poly(lactic acid) and Poly(lactic acid-co-glycolic acid)	[27, 200–205]
	Poly(alkyl cyanoacrylates)	[28, 29, 208–212]
	Albumin	[213–215]
Other methods	Polyglutaraldehyde	[216–218]
	Starch	[221]
	Polyacryl dextran	[222]
	Polyacryl starch	[223–226]
	Alginate	[227, 228]
	Chitosan	[229–231]
	Poly(ethylene imine)–fatty acid complexes	[232]
	Cholesterol–pullulan copolymers	[233, 234]

Emulsion polymerization is thermodynamically controlled. For this reason the particle size distribution generally is rather small.

4.2. Interfacial Polymerization

Interfacial polymerization occurs between two partners of a polymerization reaction that are soluble in two different immiscible solvents. The classical interfacial polymerization partners are hexamethylene amine, which is soluble in water, and a bifunctional acid chloride, for instance sebacyl chloride dissolved in chloroform or another organic solvent. The two bifunctional components react at the interface between the two liquids under formation of HCl yielding a polymer film, in the case of the above partners the producing Nylon® 6–10. This process was one of the first used to make microcapsules [100].

In order to make nanocapsules this process has to be modified. Significant amounts of a water soluble organic solvent—mainly ethanol is used—have to be present in the organic phase to help the dispersion of the organic phase in the aqueous medium. Poly(alkyl butyl cyanoacrylate) nanocapsules thus are produced by dissolution of the cyanoacrylate monomers in a mixture of ethanol and Miglyol® 812 or 829, or benzyl alcohol [101–107] plus drug. This mixture then is added slowly through a thin tube to an aqueous solution of a surfactant leading to the formation of a nanocapsule with a wall. Wall formation was demonstrated by electron microscopy [102, 105]. It is conceivable that this wall forms by polymerization of the cyanoacrylate

monomer present in the organic microemulsion droplets at the interface to the aqueous medium upon contact with the OH^- ions present in the surrounding water.

Chouinard et al. [107], however, argue that the polymer is already formed in the organic phase due to the nucleophilic character of ethanol and is then precipitated at the interface after emulsification in the aqueous phase similarly to the solvent deposition process described in Section 4.4.

Interfacial polymerization also can be carried out in an outer organic phase yielding nanocapsules with an aqueous core [111, 112]. In this case a 20% aqueous ethanol solution containing the drug is added to a surfactant containing (20%) Miglyol® 812 solution and finely dispersed by stirring. Isobutyl cyanoacrylate monomer is then added leading to the formation of nanocapsules within 4 h by interfacial polymerization. The nanoparticles are then separated from the organic phase by ultracentrifugation and resuspended in an aqueous medium.

4.3. Solvent Evaporation

Solvent evaporation is a classical method to produce microcapsules of the monolythic type [113, 114]. The manufacturing method can be modified to produce nanoparticles. In contrast to the *in-situ* polymerization processes mentioned in the previous sections, for solvent polymerization, a preformed polymer is used, usually poly(lactic acid) or poly(lactic-co-glycolic acid) [115–135, 139–144] or poly(ε-caprolactone) [119, 128–130]. The ratio between poly(lactic acid) and poly(glycolic acid) governs the biodegradation rate. The polymer is dissolved in an organic solvent. The drug also is contained in this solvent and may be present in the form of a solution or a fine dispersion, or it may be dissolved in water and then emulsified in the organic medium. As the next step, this organic solution or mixture is emulsified in an aqueous medium to form a O/W (oil in water) emulsion. After emulsification the organic liquid is evaporated under reduced pressure or by spray drying. This then leads to the formation of the solid polymer particles.

In order to form nanoparticles by the solvent evaporation process, compared to normal microcapsules much larger amounts of emulsifiers such as poloxamers [115], poloxamines [135], polysorbates [115, 132, 133], sodium lauryl sulfate [115], sodium dodecyl sulfate, poly(vinyl acetate) [118], poly(vinyl alcohol) [120, 124–126, 131], albumin [121–126], gelatin [117, 127], etc., plus the employment of high sheer homogenizers or extensive ultrasoniction are necessary in order to form the necessary small (nano)particle size. Since this process is kinetically controlled, the resulting particle size distribution is much broader than after emulsion polymerization. Besides the poly(lactates) other polymers have been used for this process including polyacrylates [136], ethyl cellulose, and poly(ß-hydroxybutyrate) [137, 138]. Some of the latter polymers, such as Eudragit® RL or RS and ethyl cellulose, even did not require the use of additional emulsifiers or surfactants due to their amphiphilic properties [136]. In some cases a water soluble organic solvent such as acetone may be added which aids in dispersion of the polymer. If these amounts are relatively minor [139–142] the formation of rather homogeneous monolithic particles prevails; higher amounts lead to formation of nanocapsules. This process is called solvent deposition.

The solvent evaporation process also may be used to encapsulate materials in the form of a double emulsion [143]. A very good review about solvent evaporation and related processes is given by Arshady [144].

4.4. Solvent Deposition or Nanoprecipitation

Solvent deposition or nanoprecipitation describes the formation of nanocapsules or nanoparticles by dissolution of poly(lactic acid) or a poly(lactic acid)-copolymer in a water miscible organic solvent, such as acetone [145–147] or benzyl alcohol [148]. Again the drug is dissolved in or admixed to the organic solution. This mixture is then poured into a surfactant-containing water phase under moderate stirring. Surfactants that can be used include poloxamers 118, 407, poloxamine 904, 908, and 1504, or stabilizing hydrocolloids such as poly(vinyl alcohol) or gelatin. The aqueous phase turns opalescent due to the formation of nanocapsules [145]. The acetone or a similar water miscible organic solvent is then removed similarly to solvent evaporation. Besides polylactic acid and copolymers, other polymers such as poly(ε-caprolactone) [148–150], Eudragit® [148] or another methyl methacrylic acid copolymer [151], poly(ß-malic acid-cobenzyl maleate) [152], or cellulose acetate phthalate [153] can be used, and by using acetonitrile as the organic solvent even no surfactants are required [151].

The process of precipitation–solvent evaporation can be modified by addition of the organic phase into a electrolyte rich aqueous solution. The electrolyte leads to the salting out of the organic materials and to the formation of nanoparticles after addition of water which results in the extraction of the water miscible organic solvent [153–157].

The solvent deposition method also may be called nanoprecipitation, solvent displacement, or the precipitation–solvent evaporation method.

4.5. Preparation of Nanoparticles in an Oil Emulsion

One of the first methods to produce nanoparticles was the emulsification of an aqueous solution containing a dissolved macromolecule such as albumin [15–22, 158–171], gelatin [172, 173], chitosan [174], or a similar macromolecule together with the drug in an oil. The emulsion is then homogenized with a high sheer homogenizer or by ultrasonication and poured into hot oil leading to the denaturation of the macromolecules and the formation of solid nanoparticles. Alternatively to heat denaturation the particles also may be hardened at much lower temperatures, even at room temperature, by cross-linking with an aldehyde [20, 172, 174] or by gelation [172]. After solidification of the nanoparticles the oil is removed by washing with volatile organic solvents.

The particle size and the size distribution of the nanoparticles are influenced by the type of oil, macromolecule concentration, aqueous-to-nonaqueous phase concentration, emulsification temperature, and surfactant used [6, 7, 160–166]. The time lapse between emulsification and hardening must be kept to a minimum to prevent an increase in particle size and distribution [6, 7]. Like nanoparticle formation by solvent evaporation, nanoparticle production in an

oil emulsion is kinetically controlled and yields a relatively broad particle size distribution.

References [175–177] represent comprehensive reviews about these preparation methods.

4.6. Desolvation of Macromolecules

Another method in which preferentially natural macromolecules are employed is the desolvation of macromolecules [178–197]. Macromolecules swell in a good solvent. The better the solvent and the greater the dilution, the more the molecules will be expanded. The process is reversible upon addition of a desolvating agent (nonsolvent), or changes in charge, temperature, and pH. This latter process is commonly known as coacervation [180] which results in the formation of a new phase called coacervate. Most commonly used microcapsules are produced by this process.

Shortly before phase separation occurs, the molecules are in a tightly packed, rolled-up conformation. If this structure can be maintained by addition of cross-linking agents, mainly aldehydes, or by heat denaturation [194], nanoparticles are formed. The process can be monitored by turbidity measurements, because due to the rolling-up the turbidity goes through a minimum. Upon addition of more desovating agent the formation of a coacervate starts which results in a strong increase in the turbidity (i.e., in the amount of scattered light). The method of desolvation of macromolecules is mainly used to produce albumin or gelatin nanoparticles, but also cellulose particles have been produced [186].

One of the problems that arises especially with gelatin is the heterogeneity in molecular weights of the employed macromolecules. This can lead to a wide range in particle sizes and to the formation of large aggregates. Therefore this manufacturing method was recently optimized by the invention of a two-step desolvation process [192–195]. In this case, after the first desolvation step, the lower molecular weight macromolecule fractions in the supernatant are removed after separation by a variety of methods and the sediment is redissolved again. After a second desolvation step the particles are hardened with an aldehyde.

Nanoparticles produced by this method can be surface-modified by introduction of sulfhydryl groups [193, 195, 197]. These groups can then be used to introduce certain linkers and ligands, for instance avidin [193, 195]. The avidin can then be used further to couple a diversity of other biotinylated ligands with therapeutic or targeting properties.

4.7. Pegylation of Poly(lactic Acid) and Poly(alkyl Cyanoacrylate) Nanoparticles

Nanoparticles like other colloidal carriers are rapidly taken up by cells of the reticulo-endothelial system (RES), also referred to as the mononuclear phagocytic system, and are then removed from the bloodstream [189, 199]. As a consequence, they do not remain long enough in the circulation to be able to reach the desired target site (unless of course the target site is the RES). One possibility to prolong the circulation time is the so-called "stealth" approach, the covalent attachment of PEG chains on the polymer. This process is called PEGylation (or pegylation) of the particles. The PEG chains are protruding from the nanoparticle surface into the aqueous environment yielding a hydrophilic shield around the particles and minimizing the adsorption of opsonins, compounds from the bloodstream that trigger the endocytotic uptake by macrophages and other cells of the RES.

The first nanoparticles that were pegylated were poly(lactide) nanoparticles [27, 200–205]. To obtain a coating that might prevent opsonization and subsequent recognition by the cells of the RES, PEG is attached to the particles using amphiphilic diblock copolymers, PEG-R, where R is the biodegradable polymer, that is, poly(lactic acid) or poly(lactic-co-glycolic acid) copolymer [27, 200, 201]. The PEG-R copolymers can be formed by the direct reaction of the terminal amino group from the monoamine monomethoxy PEG with the reactive carboxyl end group of the poly(lactic-co-glycolic acid). They can also be synthesized by the ring-opening polymerization at 114 °C of lactide and glycolide in the presence of monomethoxy PEG by the use of stannous octoate as a catalyst [27]. Instead of poly(lactic acid) or poly(lactic-co-glycolic acid) poly(ε-caprolactone) can be used [202–204]. The PEG-R polymers have amphiphilic properties where PEG due to its good water solubility represents the hydrophilic and R, being not water soluble but very soluble in organic phases, represents the hydrophobic part. For this reason, nanoparticles can easily be formed by the solvent evaporation method using methylene chloride or ethyl acetate [27] or by the solvent deposition or solvent displacement method using acetone [201]. Due to its hydrophilicity the PEG part of the copolymer enriches on the polymer–water interface and after removal of the organic by evaporation [27] or solvent displacement [201] solid particles are formed. Therefore, with pegylated polymers generally no additional emulsifier is required. The production can easily be optimized and particles from 100 [27, 200, 201] up to 820 nm can be prepared with good reproducibility [205]. Instead of diblock polymers, it is also possible to use PLA–PEG–PLA [PLA = poly(lactic acid)] using the salting-out process [206].

By a similar method sulfobutylated poly(vinyl alcohol)–graft–poly(lactide-co-glycolide) nanoparticles using acetone and the solvent displacement method were produced especially for the delivery of proteins [207].

Poly(alkyl cyanoacrylates) belong to most rapidly biodegrading polymers and may be even more rapidly degrading then the poly(lactides) [25, 126]. For this reason also pegylated poly(alkyl cyanoycralate) nanoparticles were produced [28, 29, 208–212]. One method uses emulsion polymerization of isobutyl cyanoacrylate in the presence of methylated PEG (Me_2PEG) as described in Section 4.1 [208]. The authors claim that the PEG is covalently linked to the poly(isobutyl cyanoacrylate) by this method. Later poly(methoxy-polyethyleneglycol cyanoacrylate-co-hexadecyl cyanoacrylate) nanoparticles were produced [28, 29, 209–212]. The methoxy-polyethyleneglycol cyanoacrylate-co-hexadecyl cyanoacrylate is amphiphilic like the pegylated poly(lactides). Consequently, as with the poly(lactides) nanoparticles can be produced by the solvent evaporation as well as by the nanoprecipitation methods [29].

In addition to these artificial polymers, PEG-modified albumin nanoparticles were prepared using albumin PEG

conjugates, poly(thioetheramido acid)-poly(ethylene glycol)-grafted human serum albumin and methoxy poly(ethylene glycol)-grafted human serum albumin [213–215]. The surface modified albumin nanoparticles released a model drug, rose bengal, in the presence of the enzyme trypsin much slower than similar unmodified albumin nanoparticles, suggesting the existence of a steric hydrophilic barrier by the PEG on the nanoparticle surface that made the digestion of the particles more difficult [215].

4.8. Nanoparticles Made by Other Methods

Nanoparticles also may be produced by a variety of other methods. These include polyglutaraldehyde nanoparticles produced by polycondensation techniques [216–220], carbohydrate nanoparticles made directly from starch [221] or from polyacryl dextran or polyacryl starch [222–226], alginate nanoparticles [227, 228], chitosan nanoparticles made by electrostatic interaction and complexing methods [229–231], nanoparticles consisting of poly(ethylene imine)–fatty acid complexes [232], and nanoparticles formed by self-aggregation of cholesterol–pullulan copolymers [233, 234]. This list, however, is not complete.

4.9. Solid Lipid Nanoparticles

Limitations in drug loading, a potential immunogenicity, and/or a too slow biodegradation rate are some problems that may occur with some of the polymers used for the preparation of nanoparticles. For this reason nanoparticles made from lipids were developed. These nanoparticles were called solid lipid nanoparticles (SLNs). Again, Speiser [235] was one of the pioneers in this field.

One of the most frequently used methods for the production of solid lipid nanoparticles is dispersion of warm O/W microemulsions in water [236–240]. The lipid or lipid mixture is melted, and water, drug, and surfactants with the same temperature of the melt are added. The right composition of this mixture this results in the formation of a thermodynamically stable microemulsion. This microemulsion is then poured into a cold (2–3 °C) aqueous phase which leads to the solidification of the lipids and the formation of solid lipid nanoparticles. Emulsifiers and dispersing agents used for this process include lecithin, bile salts, and butanol. Even the incorporation of a water phase into the lipid phase under formation of a W/O/W emulsion as an intermediate step is possible [240].

Another possibility for the production of solid lipid nanoparticles is the preparation by high pressure homogenization [9, 241–246]. This process again is kinetically controlled. Using high pressure homogenization the SLNs can be made in two ways, by hot homogenization [9, 241, 242] and by cold homogenization [243, 246]. For both techniques the drug is dissolved or solubilized in the liquid lipid which was heated to about 5 to 10 °C above its melting point. For the hot homogenization process this mixture is added to an aqueous surfactant solution of the same temperature and subjected to high pressure homogenization and then cooled down to room temperature. The lipid crystallizes and forms solid lipid nanoparticles. For cold homogenization the lipid melt is supercooled with liquid nitrogen or dry ice and milled in the supercooled stage. The resulting particles of a size of approximately 50 to 100 μm are then dispersed in a cold surfactant solution and also subjected to high pressure homogenization.

4.10. Inorganic Nanoparticles

Inorganic nanoparticles made of silica also were produced and their body distribution was investigated [247, 248]. Fumed silica with particle sizes around 16 nm (Aerosil® 200) is a frequently used excipient for oral, dermal, and rectal dosage forms. However, the use of silica nanoparticles for parenteral application is limited or not feasible due to the nonbiodegradability of this material. It has to be mentioned that colloidal aluminum hydroxide, phosphate, and oxide are contained as adjuvants in a number of intramuscularly or subcutaneously administered vaccines.

5. CHARACTERIZATION AND PROPERTIES OF NANOPARTICLES

The main important feature of nanoparticles is their size which enables them to traverse blood capillaries and may help to reduce irritant reactions at injection sites [4–6]. Some of the most important analytical methods for physicochemical characterization, drug loading, drug release, and *in vitro* interactions with blood components and cells are described in Sections 5.1–5.4 and Section 6.1. Many critical reviews have appeared about the characterization and properties of nanoparticles [6, 7, 33, 249–251].

5.1. Physicochemical Characterization

The important methods for the physicochemical characterization of nanoparticles are listed in Table 2. These methods mainly are similar to other materials or to larger particles.

Table 2. Physicochemical characterization methods for nanoparticles.

Parameter	Method	Ref.

Some of the most frequently occurring problems are discussed in this section.

A special difficulty in nanoparticle characterization represents particle sizing. The method of choice for size and size distribution determination is photon correlation spectroscopy (PCS) based on laser light scattering because this method provides a rapid size analysis. However, this method is strongly influenced and skewed by larger particles present in the sample. Therefore, a confirmation of the particle size measurement by another method is advisable. Electron microscopy is especially optimal for this purpose. However, it has to be considered that for scanning electron microscopy a thin conducting layer has to be sputtered onto the sample. Since the thickness of this layer is not certain, errors in particle sizes may result [6, 7, 33]. Another excellent method for particle sizing is transmission electron microscopy. This method, however, is very laborious and enables only the analysis of small sample fractions. The same applies to scanning probe microscopy [27]. Transmission electron microscopy after freeze-fracturing [33] also enables the identification of nanocapsules. If this method is used for sizing it has to be taken into account that particles are not only fractured across the equator but also close to the poles of the particles which again skews the particle size analysis [35].

Four methods exist for the molecular weight determination of nanoparticles: gel permeation chromatography, mass spectroscopy, viscosimetry, and analytical ultracentrifuge. The results obtained with these methods may differ. Mass spectroscopy is mainly useful for smaller molecular weight nanoparticles such as the poly(alkyl cyanoacrylate) nanoparticles. For gel permeation chromatography [34, 35, 57, 90] and viscosimetry [38] the nanoparticles have to be soluble in a useful solvent. Moreover, often appropriate molecular weight standards for calibration are missing. Analytical ultracentrifuge analysis is very laborious and requires considerable expertise which is not available in most labs. None of these methods is very helpful for the molecular weight determination of nanoparticles made of cross-linked polymers which, therefore, is often impossible.

Nuclear magnetic resonance (NMR) was used to answer the question if components that were present during polymerization were covalently linked to the polymer. It was shown by this technique after repeated dissolution and precipitation steps that dextran present during polymerization of poly(alkyl cyanoacrylate) polymerization was not covalently linked to the cyanoacrylate polymer in significant amounts [96]. It was claimed, however, that methylated PEG was covalently linked to the cyanoacrylate after being present during polymerization [208]. However, this was not proven by repeated dissolution and precipitation. Hence it may be possible that the PEG chain are just entangled with the polycyanoacrylate chain network.

5.2. Drug Loading

The aspects of drug loading also are covered by a number of reviews [6, 7, 250]. Drugs may be bound to the nanoparticles by a number of ways: (a) incorporation into the interior of nanocapsules, (b) incorporation into monolithic nanoparticles in form of a solid solution or solid dispersion [253], (c) covalent binding [13, 14, 193, 195, 197], (d) electrostatic binding [48, 50, 52], and (e) surface adsorption [35, 254–256]. In most cases, the physicochemical properties of the drug determine the method of nanoparticle preparation and, hence, also the method of drug binding. Thermolabile drugs cannot be incorporated into nanoparticles produced involving heating. Hydrophilic drugs cannot be incorporated into hydrophobic nanoparticles without difficulties and vice versa. Consequently, in many cases drug loading is not sufficient.

Surface adsorption in general is governed by a Langmuir type of interaction [35, 254–256]. Surfactants generally reduce adsorption. In some cases, however, they improve adsorption [59, 257].

The precise determination of the drug content in certain cases may be a problem because of the colloidal nature of the carrier [7]. The problems involved have been reviewed in detail [258].

5.3. Drug Release

Drug release from nanoparticles generally is rather rapid, although also a very slow release has been observed [259, 260]. Again this topic was subject of number of reviews [6, 7, 250, 251, 258].

Release may occur by desorption of surface-bound drug, diffusion through the nanoparticle matrix or nanocapsule wall, matrix erosion, or a combined erosion–diffusion process [6, 7]. After injection into the bloodstream nanoparticles are rapidly opsonized by blood components [198, 261, 262] (see Section 6.1). This adsorptive blood component layer may strongly impede drug release.

In vitro drug release may be studied by a variety of methods [7]. Due to the small size of the nanoparticles the separation of the releasing particles from the rest of the sample represents a major problem. In principle this separation can be achieved in two ways, either by ultracentrifugation or by separation by a membrane, using for instance side-by-side diffusion cells with artificial or biological membranes, dialysis bags, ultrafiltration, and centrifugal ultrafiltration. All these techniques have the common disadvantage that a significant time lapse exists between immediate release from the particle and the time of sampling, because ultrafiltration, membrane diffusion, and ultracentrifugation are all time consuming processes. During this time lapse the release continues; therefore, it is not possible to obtain real time release rates. A very good alternative to study the release is the employment of substances that change their analytic profile, for instance color, by going from a hydrophobic into a hydrophilic environment when traversing from the particle surface into the release medium. Such a compound is the fluorescent marker Prodan®. This marker exhibits a hypsochromic shift from 424 nm in poly(lactate) to 512 nm in water [125]. Unfortunately, this method is compound specific and therefore can only be employed for model experiments.

Moreover, it has to be considered that in very many cases the *in vitro* release cannot be correlated with the *in vivo* situation [257].

5.4. Biodegradation

Biodegradation is a very important property of nanoparticles for most therapeutic uses, especially for parenteral administration (injection or implantation). Biodegradation has a profound influence on the drug release rate (see Section 5.3). In addition, with the possible exception of vaccines, the nanoparticle carrier material has to be eliminated rather rapidly to avoid an accumulation in the body.

Most natural polymers such as albumin, gelatin, or starch are biodegraded and eliminated rather rapidly due to enzymatic digestion [123–126, 263]. Poly(butyl cyanoacrylate) is also very rapidly biodegradable. It represents the most rapidly biodegrading artificial polymer. After 24 h already about 80% of the polymer is eliminated from body after intravenous injection of poly(butyl cyanoacrylate) nanoparticles [25]. The degradation and elimination of poly(hexyl cyanoacrylate) is considerably more slow [263–265]. Poly(alkyl cyanoacrylate) nanoparticles degrade in the body by enzymatic cleavage of the side chain ester bond, and the rate of this process depends on the ester side chain length [266–268]. The degradation was found to occur by surface erosion, because the particle size decreases immediately after incubation and does not show any lag period [269, 270]. Due to the low molecular weights of the poly(alkyl cyanoacrylates) [57, 94] the resulting water soluble polymer acid is the excreted rather rapidly from the body [6].

Poly(lactide) nanoparticles are rapidly degraded by enzymes, especially lipases [123–126]. Again this appears to be degradation on the surface comparable to the poly(alkyl cyanoacrylate) nanoparticles. Some coating materials, for instance poly(vinyl alcohol), largely prevent this degradation, since this coating material cannot be degraded by enzymes [124–126]. Therefore drug release from poly(lactide) nanoparticles coated with poly(vinyl alcohol) release occurs by diffusion only [125]. The degradation of the poly(lactide) nanoparticles from the surface contrasts the degradation process of the larger poly(lactide) microspheres ($\gg 1\ \mu$m) which degrade by hydrolysis and bulk erosion mainly from the center [271–273]. For this reason the particle size of microspheres changes very little during degradation for a considerable time.

Poly(methyl methacrylate) nanoparticles degrade very slowly over periods of years [274]. As a consequence, they are only useful as model particles or, more importantly, as adjuvants for vaccines, where a long persistence of the antigen and a long immune response are desired [39, 275, 276].

6. BODY DISTRIBUTION OF NANOPARTICLES

Although a small particle size also seems to be advantageous after localized administration [5] such as administration into the eye, injection or implantation into muscles, under the skin, joints, tumors, etc., the majority of nanoparticles are developed for intravenous injection or for oral administration. The small particle size enables a passage through even the smallest capillaries, and after oral administration they may enable a favorable gastrointestinal release for drugs with solubility problems or even an uptake through the intestinal mucosa [65, 82, 277–281]. Therefore, the investigation of the body distribution is of prime importance.

6.1. Body Distribution after Intravenous Injection

The main objective in the development of nanoparticles is drug targeting. As mentioned in the Introduction drug targeting enables high concentrations at the target site, that is, the desired place or action, whereas only little drug is distributed to the rest of the body. This can be done using the natural passive distribution pattern of the body for the carrier and therefore it is called passive targeting [7, 282]. However, the target sites that can be reached by this approach are very limited. Active targeting refers to the distribution achieved after the natural distribution pattern has been modified by alteration of the surface properties, binding of ligands, employment of magnetic nanoparticles, etc. For this reason, many more target sites can be reached or the drug concentrations at the target are much higher.

6.1.1. Passive Targeting

Nanoparticles are rapidly coated with blood components [6, 7, 198, 199, 249, 250] in the same manner as other colloidal carriers such as liposomes, microemulsions, erythrocyte ghosts, etc. This process is called opsonization. These opsonizing molecules trigger a rapid uptake of the colloidal drug carriers mainly by the sessile but also by the wandering macrophages of the RES [283]. As a consequence, shortly after intravenous injection of such carriers about 60 to 90% of the injected dose is distributed into the liver, 2–20% into the spleen, a varying amount into the lungs, and a smaller amount into the bone marrow [7, 198].

Some nanoparticles have the tendency to accumulate in certain solid tumors [25, 264]. This accumulation is due to the so-called EPR effect [26] that also can be observed with the other particulate colloidal carriers as well as with soluble macromolecules. The EPR effect can be attributed to two main factors [284–286]: First, the endothelium around the blood vessels in tumors often is very discontinuous and leaky and therefore allows the extravasation of larger particulates. Second, no lymphatic drainage exists in these tumors that normally would remove these particulates. However, in order to take good advantage of this effect, the particles have to stay long enough in the circulation to reach the tumor and must not be removed before by the macrophages. A prolonged circulation can be achieved by pegylation (see Section 4.7) or by coating with surfactants (see Section 6.1.2).

6.1.2. Active Targeting

Active targeting is much more difficult to achieve. A number of possibilities exist.

The first possibility that was employed was the alteration of the surface charge [287]. However, only a redistribution within the RES was obtainable.

Another approach is the incorporation of small (10–20 nm) magnetic Fe_3O_4 particles into the nanoparticle matrix [19, 19, 163–166, 174, 288–290] and the targeting by an external magnetic field. A localization in predesigned

areas of rat tails was possible with magnetic albumin nanoparticles, and very promising results were obtained with such nanoparticles in rats with a Yoshida tumor, a rat tail tumor [21, 22]. However, this tumor is located in a thin long extremity. It is much more difficult to focus the particles by a magnetic field deeper inside the body. For this reason, magnetic targeting so far has not found broad application.

An obvious drug targeting strategy would be the attachment of target specific ligands such as antibodies to the nanoparticles. This approach was attempted rather early [291–293]. One of the difficulties with this strategy is similar to the successful exploitation of the EPR effect, namely to obtain both a suitable coupling of the antibodies plus a sufficiently long enough circulation time to achieve high concentration at the target site. No successful targeting was achieved with nanoparticles with bound antibodies against an osteogenic sarcoma 788T in mice [294]. Instead the particles accumulated in the liver and the spleen to a higher degree than uncoated nanoparticles. Since antibodies are large proteins they may activate the removal mechanisms for foreign materials in the body. In addition, antibodies are very specific. For this reason the production of nanoparticles with bound antibodies on an industrial scale does not seem to be very feasible.

As previously stated, a prolongation of the circulation time of the nanoparticles is very desirable. One possibility to prolong this time is the so-called "stealth" approach, the covalent attachment of polyethylene glycol chains as described in Section 4.7. This largely decreases the adsorption of opsonins and very significantly reduces the uptake by macrophages [27–29, 200–215]. Another possibility to prolong the circulation time is the adsorption of surfactants on the surface of the nanoparticles [295–302]. Hydrophilc block copolymers, poloxamers (Pluronic®) and especially polxamines (Tetronic®), were able to considerably prolong the circulation time of model polystyrene and poly(methyl methacrylate) nanoparticles after intravenous injection to rats and rabbits. These surfactants adsorbed in the form of a monomolecular film coating the nanoparticles when added at a concentration of around 0.1%. Below this concentration, the particles behaved in their body distribution like uncoated particles whereas the body distribution changed very little above this concentration [302]. Other surfactants behaved differently and some yielded a higher accumulation in certain non-RES organs [299]. Polystyrene nanoparticles of a size of 60 nm coated with poloxamer 407, for instance, allowed a high accumulation in the bone marrow [303], and poly(butyl cyanoacrylate) nanoparticles coated with polysorbate 80 (Tween® 80) enabled the transport of significant amounts of a number of drugs across the blood–brain barrier (BBB) into the brain, both after intravenous injection [30, 66, 67, 304, 305]. Surface coating also plays a role in tumor targeting. Nanoparticles coated with different surfactants accumulated differently in different types of tumors [64, 306, 307]. It has to be mentioned that besides the surface coating, the nanoparticle material also plays a role in the body distribution obtained.

Both the prolongation of the circulation time as well as the enhancement in distribution into specific organs or certain tumors depend on the opsonins, complement [308], and other blood components which become adsorbed on the surface of the nanoparticles. The adsorption pattern of these blood components is governed by the surface properties of the nanoparticles [262, 309–311]. Depending on the surface properties, certain proteins are preferentially adsorbed after contact with the blood and some components will be enriched while others are reduced. Carriers with different protein adsorption patterns acquired following intravenous injection will interact with different tissue specific receptors or will be recognized by different macrophage subpopulations or different tumors. This adsorption pattern can be analyzed by two-dimensional polyacrylamide electrophoresis [262, 309–311]. Polysorbate 80-coated poly(butyl cyanoacrylate) nanoparticles for instance adsorb apolipoprotein E and/or B from the blood [312]. These apolipoproteins then seem to interact with the lipoprotein receptors on the brain blood capillary endothelial cells and thus are endocytosed by these cells leading to the above-mentioned delivery of drugs across the blood–brain barrier [68, 312].

6.2. Body Distribution after Subcutaneous and Intramuscular Injection

After subcutaneous and intramuscular injection, the nanoparticles remain at the injection site [274, 313]. After subcutaneous injection of ^{14}C-labelled poly(methyl methacrylate) nanoparticles, less than 1% of the dose distributed into the rest of the body.

6.3. Body Distribution after Oral Administration

The uptake of nanoparticles after oral administration has been studied in a number of investigations [278–281, 314–319]. A calculation of the total radioactivity excreted within 48 h after oral administration of ^{14}C-labelled poly(methyl methacrylate) nanoparticles via bile and urine amounted to over 10% of the administered dose [278]. Nevertheless, the radioactivity in individual organs was rather low. The highest concentrations were found in the liver, kidneys, muscles, and bone marrow [278, 280]. Up to 10% of the administered dose was found in the gastrointestinal walls. In general, gastrointestinal uptake of nanoparticles can occur by (a) a paracellular pathway, (b) intracellular uptake and transport via the epithelial cells lining the intestinal mucosa, and (c) lymphatic uptake via the M-cells and the Peyer's patches. Evidence exists for all three pathways, and the simultaneous existence of more than one pathway was reported [277]. Both surface properties [280, 318, 319] as well as the particle size [314] seem to play a role in the uptake pathway and in the amount of particles taken up. Concerning the influence of coadministered surfactants the results are contradictive; some studies suggest a reduced uptake [318, 319] whereas other investigators report a considerably enhanced uptake [280]. Again the different composition of the nanoparticle core between these studies might be responsible for the observed trend. Lymphatic uptake seems to be favored by hydrophobic particles [315–320].

7. APPLICATION OF NANOPARTICLES

Nanoparticles can be used as carriers for all sorts of drugs. The following section describes the most important applications.

7.1. Cancer

One of the most straightforward applications of nanoparticles is their employment in the targeting of anticancer drugs to solid tumors via the EPR effect (see Section 6.1.1). The accumulation of nanoparticles in certain solid tumors as well as the influence of the surface properties on this accumulation has been demonstrated in a number of studies [23, 25, 64, 306, 307].

The two cytostatic drugs of antibiotic origin, dactinomycin and doxorubicin, as well as another cytostatic, 5-fluorouracil, were among the first compounds that were coupled to nanoparticles and tested in animals using a variety of malignant experimental tumors [23, 24]. Dactinomycin bound to poly(alkyl cyanoacrylate) nanoparticles significantly reduced tumor growth. However, this beneficial effect was accompanied by a parallel increase in toxicity. The same was true with 5-fluorouracil nanoparticles [321]. In contrast, with doxorubicin the toxicity was significantly reduced compared to free drug [23], leading to an increased efficacy and safety [322]. In addition, doxorubicin bound to nanoparticles enabled an accumulation [25] and increased efficacy [323] in experimental lung and hepatic metastasis, which probably was due to the EPR effect. Moreover, in tissue cultures poly(alkyl cyanoacrylate) nanoparticles were able to overcome multidrug resistance [93, 324–326]. As stated above, nanoparticles have a tendency to be taken up especially by the macrophages of the RES [91]. This can explain why the drug efficacy after binding to nanoparticles was potentated by the activation of macrophages releasing cytotoxic factors such as NO, which resulted in increased cell death [327]. Because of the accumulation in the RES toxicological effects of the poly(alkyl cyanoacrylate) nanoparticles toward these organs were investigated [92, 328–332], and some toxicity was observed. However, this toxicity was largely reversible. Bone marrow toxicity was higher with poly(isohexyl cyanoacrylate) nanoparticles than with poly(isobutyl cyanoacrylate) nanoparticles [329]. This favorable toxicity led to the development of doxorubicin poly(isobutyl cyanoacrylate) and poly(isohexyl cyanoacrylate) nanoparticle preparations with bound doxorubicin for human application that were then subjected to a clinical trial [333, 334]. The doxorubicin-loaded nanoparticles exhibited a higher therapeutic index than free doxorubicin and also showed promise to overcome multidrug resistance. Although unexpected side effects such as fever, bone pain, or allergic reactions were noted, they were well tolerated and were all rapidly reversible [334].

An alternative to the binding of free doxorubicin is the coupling of this drug to dextran [335] or directly to poly(lactic-co-glycolic acid) [336, 337] and the incorporation of these conjugates in nanoparticles. An enhanced antitumoral effect also was observed with these preparations.

Other cytostatic drugs that have been bound to nanoparticles include mitoxantron [64, 306], cisplatin [338], and paclitacel [339, 340].

One strategy to increase drug delivery to a tumor is the attachment of antibodies as discussed in Section 6.1.2. Since antibodies are rather large and may encounter problems of immunogenicity after repeated injection, the attachment of receptor specific targeting moieties, such as vitamins and hormones, may be an alternative. The folic acid receptor, for instance, is such a target since it frequently is overexpressed on the surface of a variety of human cancer cells, especially ovarian carcinomas. For this reason, folic acid was coupled to poly(alkyl cyanoacrylate) nanoparticles and the specific interaction between these nanoparticles and the folate-binding protein was determined [341]. The analysis confirmed a specific binding of the nanoparticles to this protein which did not occur with nonconjugated nanoparticles.

Nanoparticles, therefore, are very promising for tumor targeting. Efficacy and toxicity depend strongly on the drug, the type of tumor [307], the surface properties, and the nanoparticle material used.

7.2. Antiinfective Agents

The treatment of intracellular infections often is difficult or impossible, since a number of drugs cannot reach certain target sites within these cells in which the microorganisms reside. Cells that frequently are infected and are inaccessible to a number of relevant antibiotics include phagocytic cells [6], such as the Kupffer cells in the liver, cells in the spleen, as well as circulating macrophages. Since nanoparticles are easily taken up by these cells, they are well suited for the delivery of antiinfective drugs to these cells. Possibilities for the targeted delivery of antibiotics by nanoparticles and liposomes have been reviewed recently [342].

The most promising results in treating such intracellular infections results were obtained with ampicillin bound to poly(isobutyl cyanoacrylate) and poly(isohexyl cyanoacrylate) nanoparticles [73, 86, 87]. Nanoparticle bound ampicillin was more effective against *Listeria monocytogenes* in mice at 20-fold lower concentrations than free ampicillin. The liver was free of bacteria 7 days after intravenous injection of the nanoparticle preparation. The bacterial count, however, increased again after this time. The nanoparticle preparation was similarly efficient against *Salmonella thyphimurium*. Although neither the liver nor the spleen was bacteria-free, all mice injected intravenously with the nanoparticles survived at an ampicillin dose that was 40-fold lower than required for free ampicillin.

Binding of primaquine to poly(isohexyl cyanoacrylate) nanoparticles also yielded a significant reduction in acute toxicity in mice and increased the life span of mice infected with *Plasmodium berghei* [343, 344].

A similar reduction of the toxicity was observed with dehydroemetine bound to poly(isohexyl cyanoacrylate) nanoparticles for the treatment of *Leishmania donovani* [345].

Other anti-infective agents that have been bound to nanoparticles include amikacin [62, 346], amphotericin B [142] ciprofloxacin [347], gentamycin [73], metronidazol [348], and the antiviral drug vidarabin [90]. Antiviral drugs against HIV (AIDS) are referred to in the next section.

7.3. AIDS

AIDS (acquired immune deficiency syndrome), an infection by the human immune deficiency viruses HIV 1 or 2, is mainly caused by infection of the T-helper cells and a subsequent breakdown of the immune system. While these cells die after infection, the virus can very well survive a number of other cells in the body, especially in macrophages. Since the macrophages easily take up nanoparticles, they are ideal delivery systems of anti-HIV drugs into these cells. The uptake of a variety of nanoparticles by HIV-infected and noninfected human macrophages was demonstrated *in vitro* [171, 187]. The uptake was even significantly higher in infected than in noninfected cells. No difference was observable between macrophages from infected patients and artificially *in vitro* infected cells [349]. Uptake also was influenced by the surface properties of the nanoparticles [187].

With the nucleoside analogs azidothymidine (AZT) and dideoxycytidine, the enhanced macrophage uptake only led to a small decrease in virus replication *in vitro* (macrophage cultures) because these drugs easily penetrate across cell membranes and get access to the cell interior [188]. In contrast, anti-HIV drugs such as the protease inhibitor saquinavir possess no or a very limited cell membrane permeability. Consequently this drug was already *in vitro* 10 to 20 times more efficient after binding to nanoparticles than with free drug or with a simple mixture of nanoparticles and free drug [83].

However, even with the drugs like AZT etc. that are able to penetrate cell membranes, binding to nanoparticles represents a major advantage. Cell cultures such as the macrophage cultures described above in most cases consist only of one cell type. The body, however, consists of numerous different cell types. Consequently, after intravenous injection to rats AZT bound to nanoparticles accumulated in the organs and cells of the RES that represented reservoirs for HIV, and, as a result, tissue concentrations in these organs were up to 20 times higher than with free drug [85, 86, 350]. Even after oral administration an enhanced uptake of nanoparticle bound drug AZT into these organs was observed [351].

7.4. Delivery to the Brain Across the Blood-Brain Barrier

The BBB represents an unsurmountable obstacle for a large number of drugs, including anticancer drugs, antibiotics, and a variety of central nervous system-active drugs, especially neuropeptides [352]. Nanoparticles coated with polysorbate 80 were shown to enable the delivery of a number of drugs across the BBB and to induce a significant pharmacological action [30, 66–68, 304, 305, 353–355]. Besides polysorbate 80, polysorbate 20, 40, and 60 also enabled this delivery, whereas with a variety of other surfactants no drug transport across the BBB was detectable [356]. The drugs that were delivered across the BBB with the polysorbate-coated nanoparticles include the hexapaptide dalargin [30, 66, 353] and another peptide, kytorphin [354], loperamide [67], tubocurarine [355], doxorubicin [304], and the NMDA-receptor antagonist MRZ 2/576 (8-chloro-4-hydroxy-1-oxo-1,2-dihydropyridazino[4,5-*b*]quinoline-5-oxide choline salt) [305]. Especially the results with the last two compounds are very promising: Doxorubicin seems to be very active against brain tumors but is not able to cross the BBB. After binding to polysorbate 80-coated nanoparticles drug concentrations in the brain were 60 times above the detection limit whereas all controls were below this limit [304]. No increase in doxorubicin toxicity appeared with these nanoparticles [69]. MRZ 2/576 is a potent but short acting anticonvulsant. Binding to the polysorbate-coated nanoparticles prolonged its action from 15 min up to almost 5 hours.

The mechanism for this drug delivery is not totally elucidated. *In vitro* an uptake of the polysorbate 80-coated nanoparticles but not of uncoated nanoparticles by endocytosis was observed in cultured human, bovine, rat, and mouse brain capillary endothelial cells [68, 357]. Only the polysorbate-coated nanoparticles adsorbed apolipoprotein E after incubation in plasma but not uncoated nanoparticles or those coated with the other surfactants. This apolipoprotein as well as apolipoprotein B but not other apolipoproteins also enabled a transport of significant amounts of the model hexapeptide drug dalargin across the BBB into the brain [312]. Both apolipoproteins are present in lipoprotein particles that are taken up by the lipoprotein receptors on the blood capillary endothelial cells of the brain. It is conceivable that the nanoparticles after injection into the bloodstream adsorb these apolipoproteins and thus mimic natural lipoprotein particles, leading to the uptake by these cells followed by drug delivery to the brain interior. Thus the polysorbate-coated nanoparticles would act as "Trojan horses." An alternative delivery mechanism, opening of the tight junctions between the endothelial cells, seems to be less likely since no major increase in the so-called inulin spaces was observed after intravenous injection [357], and no drug transport into the brain was observable with the other surfactants [54].

Transport of drugs across the BBB with nanoparticles was reviewed comprehensively in [352].

7.5. Oral Delivery

The basics for the employment of nanoparticles as oral drug delivery systems were discussed in Section 6.3 and are covered in a fundamental review [277]. Following, the oral delivery of a number of drugs is described.

7.5.1. Insulin

The oral delivery of the peptide insulin is a very important and yet unresolved issue in medicine since by this route of administration the presently necessary frequent injections can be avoided. Insulin is rapidly degraded in the gastrointestinal drug and therefore cannot be given in conventional oral dosage forms. Insulin can be encapsulated into poly(isobutyl cyanoacrylate) nanocapsules particles by the interfacial polymerization method described in Section 4.2 [101–103, 358–361]. The oral administration of these nanoparticles decreased glycemia in diabetic rats fasted overnight before dosing by 50–60% [103]. This effect lasted up to 20 days. Nonencapsulated insulin had no effect. In fed diabetic rats the nanoparticles yielded a 25% reduction in blood glucose levels only at high doses. Administration to different locations in the intestine exhibited a dependence of the glycemia on the administration

sites leading to 65% glycemia after administration into the ileum, 59% for administration into stomach, 52% into duodenum and jejunum, and 34% into colon [358]. Peak blood levels amounted to about 15 to 20% of the administered dose give parenterally [359]. *In vitro* investigations showed that the insulin is not chemically altered during nanoencapsulation [110]. The encapsulation into the nanoparticle process appears to protect the insulin against gastric degradations by enzymes. The interaction of nanoencapsulated insulin with insulin receptors *in vitro* was similar to that of native insulin regarding binding, negative cooperativity, and autophosphorylation [360].

7.5.2. Enhancement of the Bioavailability of Other Oral Drugs

The bioavailability and the drug action of a number of other drugs after oral administration also was improved considerably by binding to nanoparticles. The drugs showing an improved oral delivery with nanoparticles including vincamine [82], lipiodol [362], hydrocortisone [363], avarol [65], the anti-HIV drug azidothymidine, AZT [350, 351], the HIV 1 protease inhibitor CGP 57813 [156, 364], the peptide salmon calcitonin [365], and plasmid DNA, pCMV/ß-gal [366] as well as pCMVArah2 [367]. With indomethacin binding to nanoparticles did not result in an improved bioavailability after oral administration but rather in a reduction in side effects, and a prolonged action was observed [368, 369]. The most interesting results were those with avarol, where a nine-fold increase in bioavailability was obtained [65], and those with salmon calcitonin and plasmid DNA. Peptides as well as naked DNA are generally rapidly degraded in the gastrointestinal tract and they are poorly adsorbed.

Oral administration of salmon calcitonin bound to poly(*N*-isopropyl acrylamide) nanoparticles yielded a high hypocalcemic effect. The observed pronounced absorption enhancement by the nanoparticles probably resulted from both bioadhesion to the gastrointestinal mucosa and increased stability in the gastrointestinal tract [365]. Five days after a single oral dose of plasmid DNA, pCMV/ß-gal bound to fumaric acid-co-sebacic acid-polyanhydride nanoparticles was able to transfect cells in areas containing Peyer's patches [366]. Most of the transfected cells were located in the muscularis mucosae and adventita below these patches. Oral administration of pCMVArah2 complexed with chitosan to form nanoparticles resulted in transduced gene expression in the intestinal epithelium [367]. Mice receiving these nanoparticles produced secretory IgA and serum IgG2a. These results demonstrate that oral allergen-gene immunization with chitosan-DNA nanoparticles is effective in modulating murine anaphylactic responses and may be useful for treating food allergies.

The bioavailabiltiy after oral administration of drugs bound to nanoparticles may be further enhanced by the alteration of the surface properties [280]. Especially the coupling of tomato lectin seems to promising in promoting gastrointestinal uptake using nanoparticles [370].

7.6. Ocular Delivery

The efficacy of conventional ophthalmic dose forms is very poor because most of the instilled drug is drained away into the nose very rapidly, where it could lead to adverse effects. As a result, the bioavailability of eye drops is well below 5%. Therefore, an improvement in ocular delivery is very necessary. With gels and ointments the vision is strongly obstructed. Larger controlled or prolonged drug release dosage forms such as rods and microparticles can irritate the eye leading to an enhanced tear flow and a resulting increase in drug elimination by drainage. Due to their small size nanoparticles are much better suited for local delivery in the eye and a prolonged release. In addition, they possess slightly bioadhesive properties [371] which further can improve the ocular concentration of a variety of ophthalmic drugs. Nanoparticles with bound pilocarpine, one of the most important ophthalmic drugs, significantly increased the bioavailability of this drug, as determined by the intraocular aqueous humor drug concentration [60, 61]. This improvement led to a considerable prolongation in miosis time of over 30% and to an increase in intraocular pressure reduction from less than 5 to over 9 h; the latter action is representing the desired therapeutic effect. Besides the poly(alkyl cyanoacrylate) nanoparticles, cellulose acteate phathalate pseudolatex [372–374] and albumin [190, 191] nanoparticles were especially efficient in prolonging the action of nanoparticle-bound pilocarpine. The pharmacological action was further prolonged by the addition of bioadhesive polymers to the nanoparticle preparations [191].

Furthermore, the nanoparticles enabled a targeting to inflamed areas of the eye, away from inner eye segments where adverse effects could occur [189, 375]. This property makes them especially useful for the ophthalmic delivery of anti-inflamatory and anti-infective drugs.

Besides pilocarpine, other drugs that were bound to nanoparticles for ocular delivery include arecaidin propargylester [49], betaxolol [75], carteolol [376], metipranolol [377], hydrocortisone [189], amikacin [346], cyclosporine A [150], and progestereone [260]. The topic of ophthalmic application of nanoparticles also was covered in a review [378].

7.7. Delivery of DNA and Antisense Oligonucleotides

Another promising application of nanoparticles is their use as carriers for nucleic acids such as DNA and antisense oligonucleotides. A number of delivery issue requirements can be anticipated for genes and for oligonucleotides based upon their size, stability, the specific cell or tissue to be targeted, targeting concerns to specific tissues or cells, desired level of expression, and the potential for controlling that expression [379]. Some of these problems, especially issues of stability and targeting, may be overcome by the choice of an appropriate carrier. Viruses posses the ability to find their target cells and to permeate through cell membranes. However, large problems concerning immunological reactions were encountered with viral vectors. Therefore, nonviral delivery systems such as nanoparticles may be superior since they have the potential to be nonimmunogenic and stable *in vivo*.

The binding of these nucleic acid to the nanoparticle was achieved by three main strategies [380]:

1. The nucleic acids may be bound covalently either directly to the nanoparticles or better to hydrophobic linkers which than can be attached to the polymer surface by hydrophobic interaction [381]. Also binding via the avidin–biotin system is conceivable.
2. Cationic polymers such as cetyltrimethylammonium bromide (CTAB) [78] or DEAE-dextran [382] are attached to the nanoparticle surface. These polymers associate with the nanoparticle surface due to their amphiphilic character by intermingling with the nanoparticle polymer network when they are present during polymerization, or they can adsorb to the nanoparticle surface with their hydrophobic part. In both cases the cationic part of the molecules protrudes into the surrounding aqueous phase and the anionic nucleic acids bind to them by electrostatic interaction.
3. The nucleic acids may be incorporated into the nanoparticles. Although most nanoparticle polymer networks may be too tight to release the nucleic acids in a useful way [63], the incorporation into porous alginate nanosponges represents a promising approach [228].

The first experiments with plasmid DNA (pCAT-c and pUC-19 construct) bound to poly(butyl cyanoacrylate) nanoparticles [63] showed an excellent stability of the nanoparticle-bound DNA but no transfection in mice. The problems of plasmid encapsulation and release poly(lactide-co-glycolide) nanoparticles were studied in detail [383]. The most promising results for using nanoparticles were obtained with the chitosan [367] and the fumaric acid-co-sebacic acid-polyanhydride nanoparticles [366] which enabled the transfection of certain cells in the gastrointestinal region after oral administration as described in Section 7.5.2.

Silica nanoparticles also were used as carriers for plasmid DNA [384]. However, due to the nonbiodegradable and inorganic nature of these particles they may be less acceptable for administration to humans.

Antisense oligonucleotides are single-stranded short RNA or DNA fragments that are able to block the function of certain complementary sequences in mRNA or in genes. In the case of RNA this is achieved by mRNA Watson–Crick pairing thus inhibiting mRNA translation. This process is called translational arrest. DNA inactivation can occur by formation of a triple helix through Hoogsteen interaction. By employing the antisense strategy, certain genes or RNA function can be blocked thus preventing the replication of viruses or the proliferation of tumors by blocking oncogenes. The higher the number of bases the better the target specifity, but the more difficult it is to reach the target site.

The binding of antisense oligonucleotides to nanoparticles leads to a very pronounced protection against inactivation of the oligonucleotides by RNAses [51–53, 78, 79, 81, 88, 89, 382, 385–388]. The nanoparticles also improved the transport into the cell interior compared to free oligonucleotides and reduced or inhibited mRNA translation and gene expression. However, frequently oligonucleotides with a scrambled base sequence that was not complimentary to the sequence of the target nucleic acid and hence should not bind to the target also showed considerable inhibitory activity. This was observed for instance with an oligonucleotide designed to bind to the initiation site of the gag gene region of HIV 1 (GEM91) [387]: The encapsulation of this oligonucleotide into poly(lactic acid) nanoparticles and addition of these particles to HIV 1-infected CEM cells led to a strong inhibition of the viral production. Nanoparticle-entrapped random order gag oligonucleotides, however, were similarly effective.

Pharmacokinetic investigations in mice showed an increased accumulation of the nanoparticle-bound oligonucleotides in the liver reducing their distribution into the kidneys and bone marrow [79, 81]. The particles could partially protect the oligonucleotides against degradation in the plasma and in the liver for 5 min, whereas free oligonucleotide was totally degraded at the same time [79]. With alginate nanosponges 10-fold higher oligonucleotide concentrations were obtained in the lung than with poly(isobutyl cyanoacrylate) nanoparticles [81].

Poly(alkyl cyanoacrylate) nanoparticles were efficient against a tumor expressing the ras oncogen [89]. Oligonucleotides with bound antisense oligonucleotides directed to a point mutation in codon 12 of the Ha-ras gene were injected subcutaneously into nude mice. This point mutation leads to changes in cellular proliferation and induces the tumorigenic properties. The nanoparticle-bound oligonucleotides markedly inhibited Ha-ras-dependent tumor growth.

Whereas in most studies the oligonucleotides were attached to the nanoparticle surface and may be released prematurely, interfacial polymerization (see Section 4.2) allowed encapsulation into poly(isobutyl cyanoacrylate) nanocapsules [111, 112]. This may further improve the stability and the delivery of the oligonucleotides to the target cells.

7.8. Peptides and Proteins

The number of peptide and protein drugs is increasing steadily since they are becoming more and more assessable by using genetic engineering technology. However, their stability in body fluids, especially in the gastrointestinal tract, often is very low. In addition they often encounter difficulties in traversing membranes in the body. Peptides and proteins mostly bind rather well to nanoparticles, which can enable an improvement in the stability as well as in the transport across membranes and into specific cells.

The possibility of using nanoparticles to enable the oral delivery of the peptides insulin [103] and salmon calcitonin [365] and the transport of dalargin [30, 66] and kytorphin [354] was already shown and discussed in Sections 7.5.1 and 7.4, respectively.

The model protein bovine serum albumin (BSA) was incorporated into poly(lactic-co-glycolide) nanoparticles and their loading and release properties were investigated [389]. The release rate was fairly constant after an initial burst release and was enhanced by the incorporation of poloxamer 188, reaching approximately 100% with this preparation after 30 days. Other peptidic substances that were bound to nanoparticles include growth hormone releasing factor (hGRF) [77, 390], gangliosides [391], and granulocyte-colony stimulating factor (G-CSF) [392]. The stability of

these factors was increased and their release could be modulated. Poly(isohexyl cyanoacrylate) nanoparticles were able to maintain rather constant plasma levels of this drug for over 24 h after subcutaneous administration to rats. In contrast, with the same dose of free GRF plasma levels about 7 times higher appeared after 2 min that deceased rapidly, and no GRF was detectable any more after 100 min [390]. Mice experiments were conducted with rhG-CSF bound to poly(isohexyl cyanoacrylate) nanoparticles by addition after 8 h after start of the polymerization. However, no increase in short-term effects was observable after intravenous injection of the nanoparticle preparation compared to free (rhG-CSF) [392].

7.9. Vaccines

A large number of reviews have appeared on the subject of using nanoparticles as delivery systems and adjuvants for vaccines [393–397].

Poly(methyl methacrylate) nanoparticles were shown to be very good adjuvants for a number of antigens [40, 43, 275, 276, 398–402]. Antigens may be incorporated into these nanoparticles by polymerization in the presence of the antigen by gamma irradiation at low temperatures, or they may be adsorbed to previously polymerized particles [30, 35, 403]. Adsorption to previously polymerized particles also allows the employment of heat polymerization since most antigens are heat sensitive. The adjuvant effect depended on the particle size as well as on the hydrophobicity. The adjuvant effect increased with decreasing particle size [40, 398] and with increasing hydrophobicity [276, 400, 402]. Poly(methyl methacrylate) nanoparticles were superior to the conventional aluminum adjuvants which are the most frequently used adjuvants for human vaccination. The nanoparticles induced a good neutralizing antibody response against influenza [30] and good and long lasting protection [276, 399]. They were especially effective for subunit vaccines [275]. Poly(methyl methacrylate) nanoparticles not only yielded an excellent adjuvant effect but also increased the stability of the vaccine considerably [276].

Besides influenza [30, 275, 276, 399] and the model antigen BSA [40, 400], poly(methyl methacrylate) nanoparticles also were excellent adjuvants for HIV 1 and HIV 2 [43, 401]. A study involving a total of 24 different adjuvants demonstrated that the antibody response was dependent on the specific adjuvant used [402]. Different adjuvants led to large differences in antibody titers against the different antigenic components contained in the vaccines.

Poly(methyl methacrylate) nanoparticles are well tolerated by the body after subcutaneous injection. They are very slowly biodegradable [274] which is very beneficial because this enables a prolonged antigen presentation to the immune system of the body.

In addition, nanoparticles may be useful for oral vaccination. As mentioned in Section 7.5.2 oral administration of plasmid DNA (pCMVArah2) bound to nanoparticles produced secretory IgA and serum IgG2a [367]. Such nanoparticles may be useful for treating food allergies.

8. CONCLUSIONS

Nanoparticles represent very diverse colloidal drug delivery systems for a number of drugs, including nucleic acids and peptides. They also are promising adjuvants for vaccines. Nanoparticles enable the drug targeting to many solid tumors and the delivery of a number of drugs across the blood–brain barrier. They can significantly enhance the oral bioavailability and prolong the action of ophthalmic drugs.

GLOSSARY

Active targeting Targeting of particulate or soluble drug carriers to special target sites in the body after altering the surface properties, incorporation of magnetite particles, binding of ligands, etc., whereas passive targeting refers to the natural body distribution of these carriers without these alterations.

Drug loading Drug binding or amount of drug bound to nanoparticles.

Nanoprecipitation Formation of nanoparticles by precipitation of a water insoluble polymer dissolved in a water miscible organic solvent upon addition to water.

Solvent deposition Synonym to nanopreciptation.

Nanoparticles for Live-Cell Dynamics

Xiao-Hong Nancy Xu, Rudrax N. Patel

Old Dominion University, Norfolk, Virginia, USA

CONTENTS

1. INTRODUCTION

Noble metal nanoparticles have been widely used as nanoprobes to determine the receptors on the cell surface using transmission electron microscopy (TEM) since the 1970s [1, 2]. Because cell death occurs under the vacuum of TEM, no kinetic information on the interactions between the nanoparticles with live cells was learned. As detection means have advanced, nanoparticles have been used for ultrasensitive sensing of biomolecules (DNA, proteins) in buffer solutions [3–7], and, most recently, nanoparticles have been used as nanoprobes to measure the real-time size transformation of membrane pores in live cells [8, 9]. Nanoparticles prepared with semiconductors and polymers have also been widely explored for the study of biomolecules in buffer solution [10, 11] and in live cells [12–15].

Recent developments in nanoscience and nanotechnology demonstrate the possibility of transforming biological and material research. For instance, the nanometer-scale, size-dependent, optical properties of noble metal nanoparticles have the potential to lead to new techniques for real-time live-cell imaging with sub-100-nm spatial resolution and millisecond to femtosecond time resolution. These unique capabilities could revolutionize our fundamental understanding of such important phenomena as membrane transport, protein dynamics, protein–protein interactions, and intracellular and intercellular signaling in live cells. Numerous approaches have been reported for exploring the inherent promise in the application of nanoparticle optical principles to biological problems. This review presents an overview of the research on the dynamics of biological processes in live cells or live organisms (e.g., microtubules) using nanoparticles. Three major nanoparticles, including noble metal nanoparticles (Au, Ag), semiconductor quantum dots (QDs), and fluorophores incorporated with polymer matrix nanoparticles (FluoSphere beads, PEBBLES), have been used for the study of the dynamics of biological processes in live cells and will be the focus of this review. We offer a brief summary of past and current research on this topic and provide a future outlook of this subject.

2. SYNTHESIS AND CHARACTERIZATION OF NANOPARTICLES

2.1. Noble Metal Nanoparticles

The synthesis of Au and Ag nanoparticles [16, 17] and silver-enhanced gold nanoparticles (SEGNPs) [8, 18] has been well described. Typically, the sizes of Au and Ag nanoparticles were governed by controlling the ratio of $HAuCl_4$ or $AgNO_3$ to reducing agents (trisodium citrate or tannic acid). Various sizes of SEGNPs were prepared using small colloidal gold-nucleating cores (6 nm) and a commercially available silver enhancement kit [8, 18]. These nanoparticles have their unique surface plasmon resonance characteristics and show a size dependence of absorption bands and surface plasmon resonance spectra [18–21]. Thus, these nanoparticles have been widely characterized using TEM, ultraviolet–visible (UV–vis) spectroscopy, and dark-field microscopy and spectroscopy (Fig. 1). These nanoparticles have been offered as nonbleaching multicolor optical probes for real-time tracking of cellular events for an unlimited time frame (hours/days).

The optical properties (colors) of Au and Ag nanoparticles are attributable to the surface plasmon resonance of the nanoparticles and depend on the size and shape of the nanoparticles and the dielectric constant of the embedding medium of the nanoparticles as described by Mie theory with quasistatic regime [19–21]. Unlike the bulk plasmon, the surface plasmon of nanoparticles is directly excited by propagating light waves (electromagnetic waves). This allows the nanoparticles to absorb and scatter specific wavelengths of light selectively. Therefore, one could tune the color of the nanoparticles by carefully selecting the nanoparticle

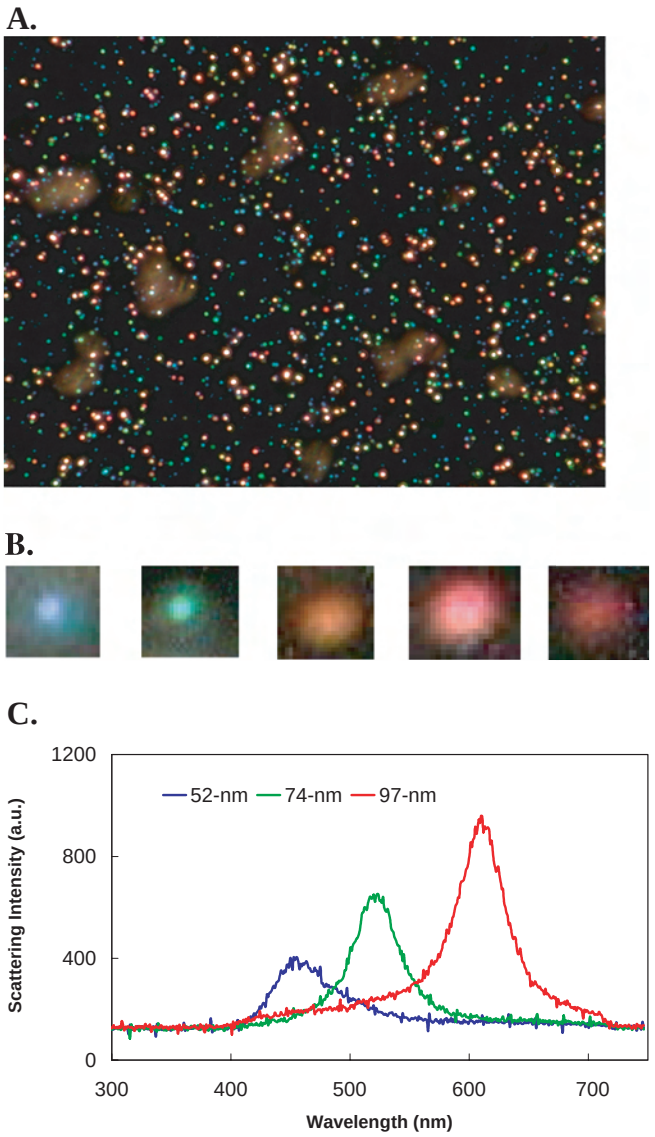

Figure 1. Representative full frame of real-color images of SEGNPs (A) and close-up real-color images (B) and surface plasmon resonance spectra (C) of single SEGNPs with sizes of 52 nm (blue color), 74 nm (green color), and 97 nm (red color) [8]. The sizes of the nanoparticles were characterized using TEM (JEOL). The images (A–B) and spectra (C) were recorded using a dark-field microscope equipped with a color digital camera (Coolpix 990) and LN-back-illuminated CCD camera coupled with SpectraPro-150 (B), respectively. These data demonstrate that it is possible to simultaneously size the nanoparticles using their colors while following the membrane transport in real time. The optical images of nanoparticles look larger than their actual sizes because of the optical diffraction limit (~200 nm). Reprinted with permission from [8], X.-H. Xu et al., *Nano Lett.* 2, 175 (2002). © 2002, American Chemical Society.

sizes and maintaining the nanoparticle shape (sphere) and embedding medium at a constant. These unique properties allowed qualitative analysis of these multicolor nanoparticles and demonstrated the possibility of distinguishing in real time the different sizes of nanoparticles in solution using dark-field microscopy and spectroscopy (Fig. 1). These nanoparticles have served as multicolor nanoprobes for measuring the real-time size transformation of membrane transporters and membrane permeability (Figs. 2–5). The optical properties of nanoparticles are preserved after functionalization of the surface of Au and Ag nanoparticles using biological molecules (antibodies) [22, 23]. These labeled nanoparticles have been used to follow the motion of single components on live cells [24–26] and to measure the real-time dynamics of ligand–receptor interactions on live cells (Fig. 5) [22, 23]. Taken together, these unique properties show the possibility of using nanoparticles for the study and characterization of molecular channels, the following of membrane pump machinery and assembly, and the interaction of several functional protein molecules on/in living cells simultaneously.

Au nanoparticles attached with fluorophore molecules (fluorescein derivatives) have been developed for the study of the flux rate of nitric oxide (NO) in live cells [14]. The orientation of fluorophore molecules on the surface of Au nanoparticles changed in the presence of NO in live cells. This led to a change in fluorescence intensity of the fluorophore molecules. This sensing scheme is based on the fluorescence spectroscopic properties of fluorophore molecules on Au nanoparticles rather than the optical scattering properties of the nanoparticles themselves. Thus, this type of nanoparticle is unable to resist photobleaching.

2.2. Semiconductor Quantum Dots

Semiconductor (CdSe) QDs 1–10 nm in diameter have been synthesized [27, 28]. The methods for the synthesis of the QDs have been continuously improved [29]. Water-soluble QDs are now commercially available and have been prepared by capping CdSe QDs with ZnS and silica-coating the CdSe/ZnS [10, 11, 30–32]. These QDs offer narrow, tunable, symmetric fluorescence emission spectra and are relatively photochemically stable. The emission wavelengths of the QDs show size dependence [27–34]. The sizes of these QDs are comparable with the sizes of proteins. In addition, the fluorescence emission of the QDs allows them to be visualized inside live cells more easily and clearly than that of the surface plasmon resonance of Au and Ag nanoparticles. Nevertheless, QDs are not as photochemically stable as noble metal nanoparticles. It is evident that the emission intensity of the QDs decreases substantially after labeling with biological molecules (e.g., antibodies) [11]. This affects the sensitivity of the QDs for bioanalysis. Furthermore, QDs suffer an on–off blinking phenomenon that may an obstacle for their use as effective probes for real-time dynamics measurements in live cells. Moreover, the toxicity of the QDs may become a major obstacle to be studied and overcome before they become popular nanoprobes for the study of live-cell dynamics and disease diagnosis in humans.

2.3. Polymer-Based Fluorophore Nanoparticles

Nanoparticles prepared by the incorporation of fluorophores with a polymeric matrix have been developed to circumvent the drawbacks of bare fluorophore molecules for the study of the dynamics of subcellular events in live cells [14, 15].

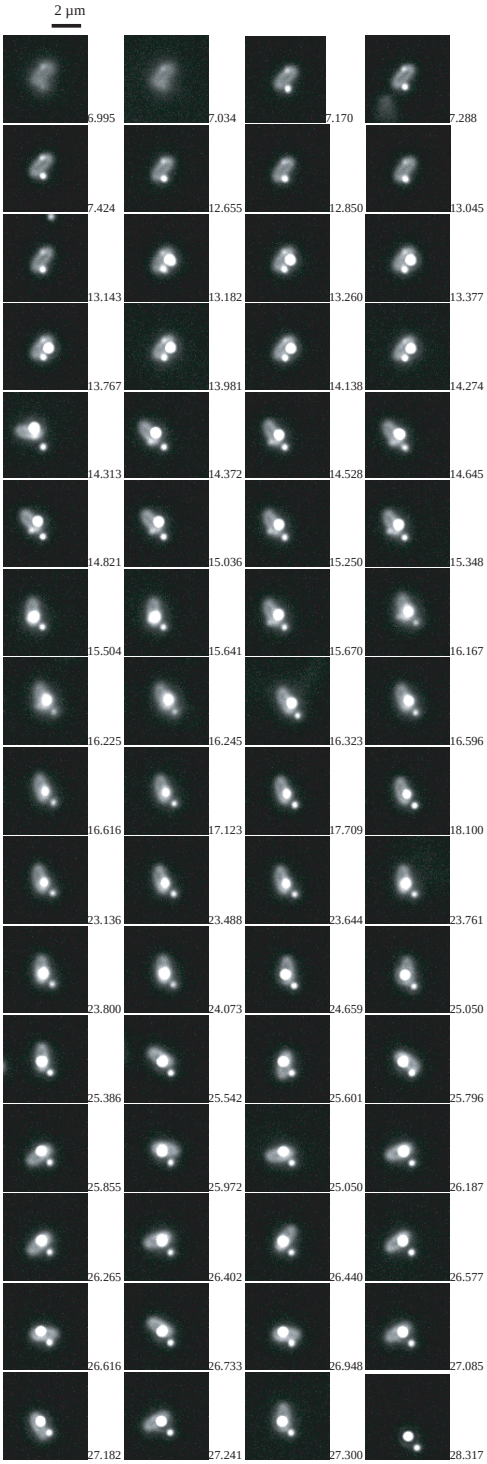

Figure 2. Representative snapshots of ΔABM cell uptake and efflux of SEGNPs using dark-field microscopy through a coverslip with a 100 × objective, equipped with a PID 1030 × 1300-pixel CCD camera (Micromax, 5 MHz-Interline), at 100 ms exposure time with a temporal resolution of 1.17 s [8]. The time shown in each image represents real time with 1 min as a unit. A blue nanoparticle (∼50 nm in diameter) participated in several uptake/efflux events in the ΔABM cell: first uptake at 7.170 min with efflux at 14.313 min; second uptake at 25.050 min and efflux at 25.386 min; third uptake at 25.601 min and efflux at 25.855 min; fourth uptake at 26.948 min and efflux at 27.085 min; and fifth uptake at 27.182 min and efflux at 27.241 min. The bright yellow particle was taken up at 13.182 min and extruded at 28.317 min by the same ΔABM cell. This yellow particle (∼80 nm) is larger than the blue nanoparticle (∼50 nm) and therefore appears brighter. The larger size made it harder for the nanoparticle to enter the cell. The cellular membrane absorbs and scatters the light. This leads to a reduction in the illumination intensity inside the cell. Thus, the nanoparticles look significantly dimmer inside the cells than outside the cells. This allows us to distinguish if the nanoparticles are inside or outside the cells. The nanoparticles appear to stick out of the cellular membrane. This is because the size of the nanoparticles and the thickness of the cell membrane are under the optical diffraction limit and the nanoparticles scatter light much more efficiently and appear brighter than the cell membrane. The gray scale was set at 262–500 electron counts. The color of the nanoparticles was directly observed and confirmed with spectroscopy. Samples were prepared by directly mixing 20 μL of the cell solution (10 × dilution of absorbance at 600 nm = 0.1) with 20 μL of a 2.60-pM SEGNPs solution. The timer was started at the point of mixing. Reprinted with permission from [8], X.-H. Xu et al., *Nano Lett.* 2, 175 (2002). © 2002, American Chemical Society.

Two primary types of fluorophore polymer-based nanoparticles are fluorescence FluoSphere beads (20–100 nm) [35] and PEBBLEs (probes encapsulated by biologically localized embedding) (20–200 nm) [14, 15]. Like fluorophores, these polymer-based fluorophore nanoparticles use the fluorescence properties of fluorophores as sensing elements and hence are unable to overcome the inherent photobleaching of fluorophores even though the inner reference (free fluorophores) has been used to deduct the possible photobleaching of the fluorophores. This affects the sensitivity, stability, and lifetime of these nanoparticles. Thus, in general, these nanoparticles have a shorter lifetime than that of QDs and Au and Ag nanoparticles.

FluoSphere beads are prepared by loading polystyrene nanospheres with a variety of fluorescent dyes. These fluorescence nanospheres provide emission spectra ranging from the near ultraviolet to the near infrared and are able to be used in multicomplex analysis [35]. These nanospheres are also easily functionalized for sensing the specific target molecules. This property circumvents the limitation of reactive dyes that easily disrupt the function of biomolecules upon conjugation. Furthermore, these fluorescence nanospheres offer highly intensive fluorescence emission and can be visualized at the single-nanoparticle level. These nanospheres also provide a longer shelf life and can be monitored for a longer lifetime than free fluorophore molecules in solution. Moreover, the polymeric matrix protects the embedded fluorophores from nonspecific interactions and reduces the toxicity of the fluorophores to live cells.

PEBBLEs have been prepared by incorporation of fluorescence indicators with a polyacrylamide matrix and have been used to measure ion flux rates in live cells as described by Kopelman and co-workers [14, 15]. Unlike fluorescent indicators, the fluorophore molecules in PEBBLEs are protected by the polymeric matrix in order to avoid the interaction of fluorophore molecules with proteins in live cells and to eliminate the possibility of false results and the toxicity of dyes. This approach allows the dyes to stay in the live cells for a relatively longer time and to be used for monitoring the dynamics of ion fluxes in live cells more effectively.

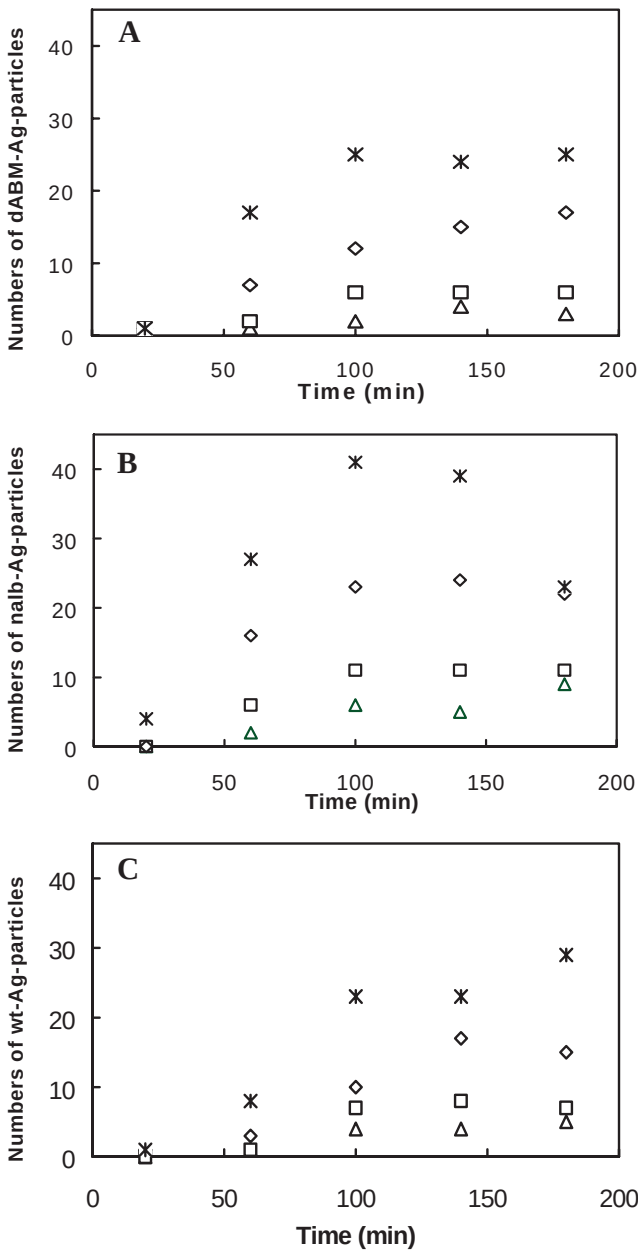

Figure 3. Representative plots of the number of cells with SEGNPs versus incubation time: (A) ΔABM, (B) nalB-1, (C) WT [8]. Samples were prepared by incubating the cell solution (absorbance at 600 nm = 0.1) with the nanoparticle solutions at 0.26 (Δ), 0.52 (□), 1.30 (◇), and (*) pM in a vial while the timer was simultaneously activated. At each corresponding time, a sample of 40 μL was transferred to the microchamber and imaged directly by dark-field microscopy using a CCD camera and color digital camera (Fig. 2). Ten images taken from each sample similar to those shown in Figure 2 were analyzed by counting the number of cells with and without nanoparticles. The total number of cells analyzed for each cell type was 400. Reprinted with permission from [8], X.-H. Xu et al., *Nano Lett.* 2, 175 (2002). © 2002, American Chemical Society.

3. DYNAMICS OF LIVE CELLS

The study of the dynamics of live cellular membranes using single-particle tracking (SPT) has been described in several excellent review articles [36–39]. The use of nanoparticles as probes for the study of the real-time dynamics of subcellular events can be tracked back to the 1980s, when Nuydens and co-workers demonstrated the detection of microtubule-dependent intracellular motility using 20- to 40-nm Au nanoparticles through NANOVID (nanoparticle video ultramicroscopy) [40]. Nuydens and co-workers explored the application of Au nanoparticles for the study of molecular biology by the conjugation of Au nanoparticles with specific ligands. They demonstrated that Au nanoparticles conjugated with ligands could be used to determine the intracellular motility, cell membrane dynamics, receptor translocation, internalization, and intracellular routing [41]. These pioneering efforts realized the potential of nanoparticles as an essential tool for the study of live cells. Nuydens and co-workers provided a new and improved automatic technique for the study of intracellular mobility of live cells using the latest tracking algorithms and image processing hardware of that time [42]. They found the results collected from live-cell experiments in astonishingly close agreement with the experiments in a buffer solution containing microtubules and a kinesin-like protein extract. The development of this technique led to the successful determination of distributions of jump time, jump velocity, stop time, and orientation of the Au nanoparticles in PTK-2 cells [42]. They demonstrated that it was possible to monitor the lateral diffusion and the rearward movements of cellular protein toward the boundary between lamelloplasm and perinuclear cytoplasm in live cells using Au nanoparticles with a velocity of 0.5–1 μm/min and a diffusion coefficient of 0.1–0.2 $\mu m^2/s$. Inspired by this work, Sheetz and co-workers developed the techniques to study the motion of motor molecules and membrane proteins in live cells using nanoparticles [43–45]. By the 1990s, these techniques have been advanced to record the reorganization of individual components on live cells [45].

Since then, an array of nanoparticles, including noble metal nanoparticles and polymer-based nanoparticles incorporated with dyes, has been developed for the study of the dynamics of biochemical events in live cells. Kopelman and co-workers studied the kinetics of calcium release in live cells using nanoparticles prepared by the incorporation of the polymer matrix with fluorescent indicators (PEBBLEs) [14, 15]. They also developed Au nanoparticles attached with fluorescent dyes (fluorescein derivative) and then used these labeled nanoparticles to measure NO release in macrophages [13]. Recently, Xu and co-workers (our research group) applied the new approaches for the study of the dynamics in live cells using the unique properties of Ag and Au nanoparticles [8, 9]. We directly measured the real-time transformation of the size and dynamics of single-living-membrane transporters using nanoparticle optics and single-live-cell imaging [8]. The unique optical properties of the Ag nanoparticles allow us to monitor in real time the size transformation of the single-membrane transporters of live cells at a nanometer resolution and a millisecond temporal resolution using dark-field microscopy and spectroscopy. We also studied the ligand–receptor interaction on a single live cell in real time using SEGNPs [22].

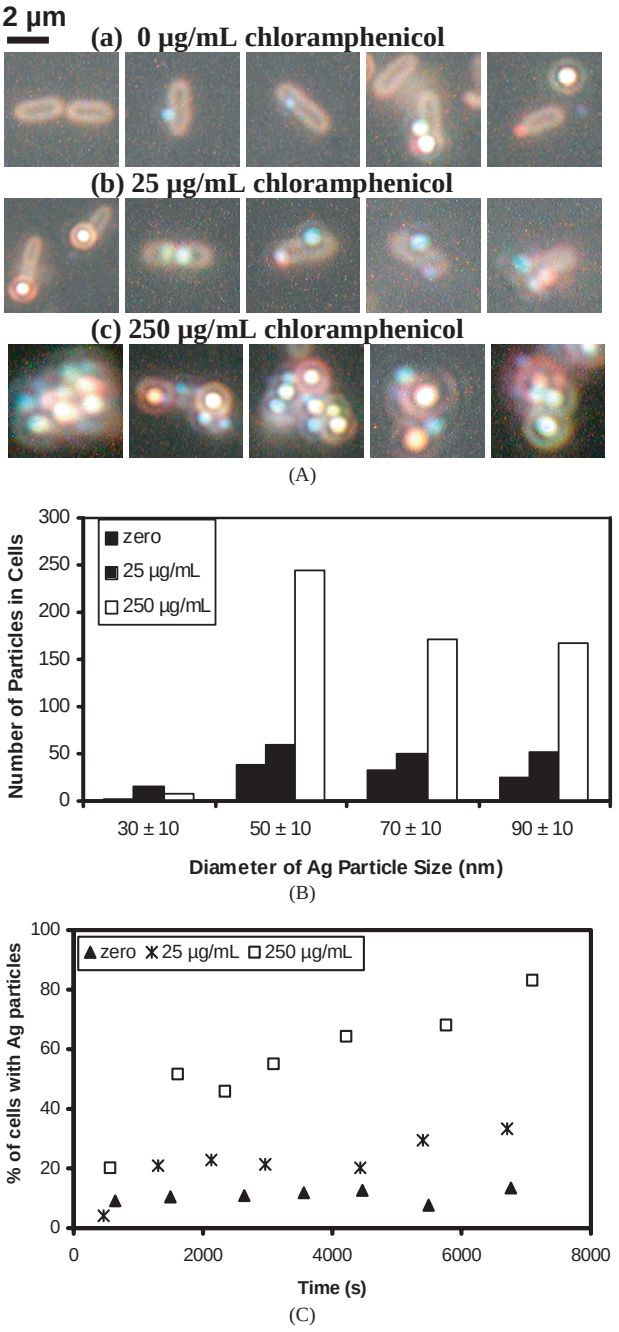

Figure 4. Direct observation of real-time size transformation of membrane pores (permeability) in WT cells [9]. (A) Representative optical images (a–c) of single cells (WT) recorded by the CCD and digital color camera through a dark-field optical microscope for 2 h. The single cell was selected from approximately 60 cells in the full-frame images. The solutions containing the WT cells ($A_{600nm} = 0.1$), 1.3 pM Ag nanoparticles, and (a) 0 μg/mL, (b) 25 μg/mL, (c) 250 μg/mL chloramphenicol, were prepared in a vial and imaged in a fresh microchannel every 15 min. (B) Representative histograms of Ag nanoparticles in WT cells versus sizes of nanoparticles acquired from 70 images (~4200 cells), recorded for 2 h, showing a great number of larger nanoparticles were presented in the membrane at the higher concentration of chloramphenicol. The solutions were the same as those in (A). (C) Representative plots of percentage of WT cells with Ag nanoparticles versus time from solutions in (A). Images for each solution were acquired at each particular time and about 600 cells were analyzed for each point.

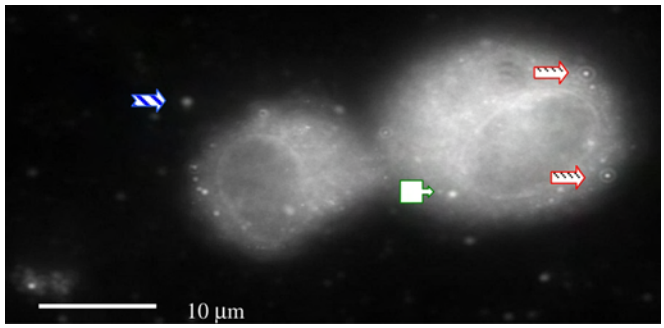

Figure 5. Real-time images of single IgG molecules binding with single ZZ-T (ZZ is a short derivative of protein A) anchored on single live fibroblast cells (L929) cultured directly on a microscope coverslip [22, 23]. The interaction of single IgG with ZZ-T on live-cell surfaces was monitored in real time. (a) Binding IgG (), (b) unbound IgG (), (c) already bound IgG ().

Nanoparticles have been developed as delivery systems and imaging probes at a brisk pace in recent years. Many researchers have described the development of nanoparticles for the study of microtubules [39, 46–48]. The relative motions of the microtubules have been measured using Au nanoparticles labeled with monoclonal tubulin antibodies [47]. These tools have been extended to study the motor-driven microtubule transport, measure the forces required for ligand–receptor interactions, and monitor the kinetics of ligand–receptor interactions on the surface of the microtubules [47, 48]. Semiconductor QDs have also been used to study ligand–receptor interactions in buffer solution and have shown a great potential for use as probes for the study of the kinetics of interactions in live cells [10, 11].

In summary, the study of the dynamics of subcellular events in live cells using nanoparticles has drawn much attention and appears to have gained momentum in recent years as research in nanoscience and nanotechnology progresses.

4. APPLICATIONS OF LIVE-CELL DYNAMICS

4.1. Intracellular Cell Motility

Nanoparticles have been used to study and characterize motion in the cytoplasm or cellular membrane of live cells. The nanoparticles have been designed and conjugated with a specific antigen or antibody to monitor the motion of specific components on the membrane of live cells [24–26]. The movement of these nanoparticles was detected and followed using a video camera as the nanoparticles moved along with the components of interest and left their discerning motility path [40, 41]. Colloidal Au nanoparticles were very popular for such studies because individual nanoparticles could be followed for an extended length of time to obtain real-time mobility using dark-field optical microscopy. Single Au nanoparticles were directly visualized by optical dark-field microscopy using a video camera [49, 50]. The mobility of Au nanoparticles has been studied in PTK-2 cells [42].

The motion of single Au nanoparticles has been determined using algorithms and image processing hardware

[42]. Typical patterns of saltatory and Brownian motion were taken into account for statistical analysis. Saltatory movement was characterized by long jumps (>1 μm) and long stop times (2–5 s), whereas Brownian motion was characterized by small elongations and no stop times [51]. These criteria allow one to continuously update the distributions of the jump time, jump velocity, jump direction, stop time, and orientation on the coordination matrix. If the next direction lay within 30° of the former direction, it was considered to be linear saltatory motion, whereas if that was not the case, the former motion was considered to be a finished saltatory motion. The jump time was used to determine whether the nanoparticles were participating in energy-demanding [adenotriphosphate (ATP) utilizing movement] saltatory movement. If the motion was not saltatory, then it was determined to be Brownian random motion. The diffusion coefficient was used to assign the movements of the nanoparticles in Brownian random motion.

Bare metal nanoparticles or metal nanoparticles labeled with fluorescent dyes have been used as probes for the study of intracellular cell motility [40–42, 49, 50, 52]. Furthermore, these nanoparticles conjugated with antibodies, receptors, and proteins have been employed to determine the motility characteristics of the corresponding components on the surface of live cells or inside the cells [24–26]. This technique provides the mobility features of individual nanoparticles and allows a large group of single nanoparticles to be monitored in real time simultaneously. Unlike classical fluorescence recovery after photobleaching (FRAP) techniques that offer the average motion of a number of components [53], nanoparticles were used to study individual cellular components. Thus, the subtle and heterogeneous spatial differentiation of the motion is unmasked.

Recently, FluoSphere beads (20 nm) labeled with a Fab fragment of monoclonal antibody (W6/32) have been developed and used for the study and characterization of the motion of MHC (major histocompatibility complex) class I molecules on the surface of HeLa cells [52]. The labeled FluoSphere beads were tracked in real time using high-sensitivity fluorescence microscopy. The spots recorded at 4-s intervals by fluorescence microscopy were connected to deduce the path of mobility (Fig. 6). Typically, a higher mobility was observed from bare metal nanoparticles and a lower mobility was observed from nanoparticles incorporated with fluorescence dyes or polymer based because bare nanoparticles have less interaction with biological entities.

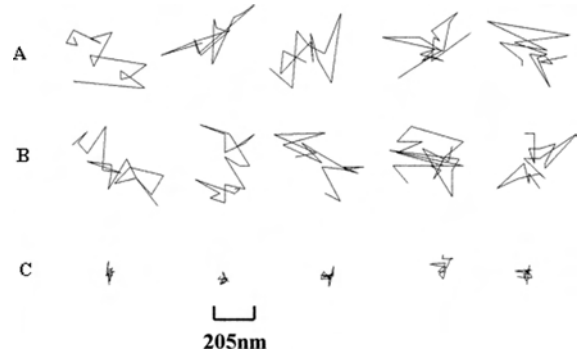

Figure 6. Tracks generated by MHC class I molecules on the surface of HeLa cells obtained using high-sensitivity fluorescence imaging [52]. The tracks of MHC class I were obtained using 20 nm FluoSphere beads labeled with PE-Fab, CML 100-Fab, and CML 30-Fab. Representative samples of the tracks obtained using PhyE-Fab (A) and CML 100-Fab (B) on cells and PhyE-Fab (C) on poly-L-lysine-coated microscope slides. Anomalous diffusion patterns were deduced from these tracks generated by linking the spots obtained at approximately 4-s intervals. Reprinted with permission from [52], P. Smith et al., *Biophys. J.* 76, 3331 (1999). © 1999, Biophysical Society.

4.2. Cell Motility

Motility and migration of cancerous cells lead to metastases and the formation of secondary tumors. Cell motility is correlated with the metastases of the cells and has been studied using phagokinetics tracks [54, 55]. Several methods have been developed to record the phagokinetic tracks of cells [55–59]. One method, based on real-time observation of phagokinetic tracks of cells, has been developed, in which single live cells are passed over a layer of markers and ingest the markers and hence individual cells leave behind a trail of blank spots that automatically register the area that the cells traveled through [55]. These trails reflect the phagokinetic tracks of cells. The advantage of this method is that it provides a rapid and automatic method for the study of cell motility that reflects both temporal and spatial information of the individual paths. The selection of markers for this method has been difficult because these markers have to be able to be uniformly coated on the surface, be ingested rapidly by cells, and endure long luminescence. Organic dyes are rapidly bleached and are unable to serve as markers. Au nanoparticles have served as the markers in this method for the study of phagokinetic tracks of cells. Due to the low-sensitivity detection means, larger Au nanoparticles (150 nm) have been used as markers for this method and hence it suffers severe drawbacks such as the lack of uniformity in both the film of Au nanoparticles and the sizes of Au nanoparticles. As ultrasensitive detection means advance, smaller Au and Ag nanoparticles (10–20 nm) will be used to circumvent these problems.

Recently, relatively photochemically stable luminescence probes, semiconductor QDs ($CdSe/ZnS/SiO_2$)(4–8 nm), have been used to study the motility of live cells [12]. These QDs are stable and soluble under physiological buffer conditions and have been used as efficient light emitters for a variety of applications [27–34]. Thin layers of QDs were deposited on a collagen-coated tissue culture substrate and then the cells were seeded on the substrate [12]. The cells and QDs were monitored in real time by using confocal fluorescence microscopy or multiphoton microscopy. As the cells migrated and ingested the QDs, the cells freed the immobilized QDs and created a trail of blank spots that clearly revealed the cell migration paths (Fig. 7). Thus, the migratory paths of tumors and normal cells were assayed simultaneously at millisecond temporal resolution. This allowed the cell motility to be calculated and the metastases of the cells to be studied. QDs have been conjugated with a wide variety of molecules for the detection of targeting molecules. Moreover, the emission spectra of QDs are size dependent [27–34]. These unique features of QDs have empowered

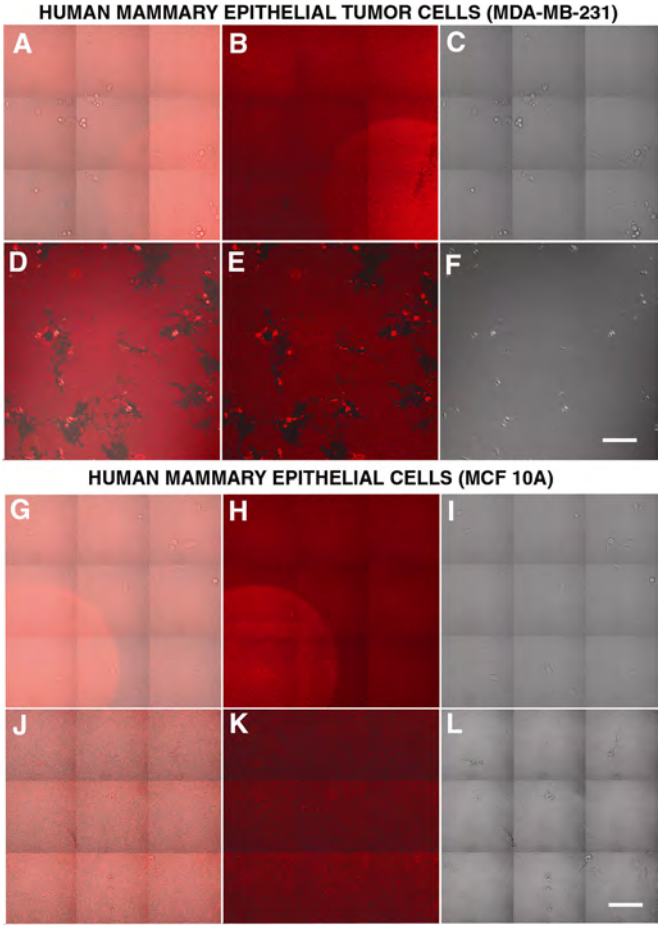

Figure 7. Migratory paths of the tumor cells determined by differential interference contrast (DIC) and fluorescence confocal microscopy [12]. Migratory paths of the tumor cells could be determined by engulfment of QDs. Human mammary epithelial tumor cells, MDA-MB-231 (A–F), and nontumor cells, MCF 10A (G–L), were grown on collagen that had been coated with a thin layer of silanized, water-soluble, red fluorescent semiconductor QDs. The merged images (A, D, G, J) show that the cells and the layer of QDs beneath the tumor cells (B) and nontumor cells (H) were fairly uniform. After 24 h, (i) the large clearings in the QD layer were observed around the tumor cells (D, E), but not around the nontumor cells (J, K). (ii) Tumor cells filled with QDs offered intensive bright fluorescence (E), whereas nontumor cells did not provide fluorescence (K). (iii) Some tumor cells were crawling into the underlying collagen and these tumors were less distinct in the DIC image (F). The images were collected using fluorescence confocal microscopy to examine QDs (B, E, H, K) and using DIC optical microscopy to visualize the cells (C, F, I, L) where the images were collected at the optical section to show the layer of QDs. The scale bar was 200 μm. The results show that the tumor cells are more motile. Reprinted with permission from [12], W. Parak et al., *Adv. Mater.* 14, 882 (2002). © 2002. Wiley–VCH.

multicomplex analysis in buffer solution [60, 61]. This offers the possibility of the measurement of cell motility and the detection of a group of specific proteins simultaneously in real time using QDs. This also makes it feasible to study cell motility in three dimensions if the different sizes of QDs in a vertical gradient are prepared in extracellular matrix media. Studies of this kind will surely advance our understanding of cell motility and metastases.

4.3. Single-Membrane Transporters

Multidrug extrusion systems have been reported for both prokaryotes and eukaryotes [62–64]. Membrane permeability and active extrusion systems appear to play a crucial role in universal cellular defense mechanisms. For instance, the efflux pump of *Pseudomonas aeruginosa* can extrude a variety of structurally and functionally diverse antibiotics [62]. It is very likely that membrane proteins are triggered by substrates to assemble membrane transporters optimizing for the extrusion of encountering substrates. Thus, the study of the real-time size and the dynamics of membrane transporters will lead to a better understanding of the multidrug resistance mechanism.

X-ray crystallographic methods have been used to determine the sizes of membrane transporters and the cellular transport mechanism. This method is limited by the difficulties of crystallization of membrane proteins and this method cannot provide the real-time dynamics of live cells [65–69]. The metal nanoparticle with the help of molecular dynamic microscopy solves this problem to a large extent [8]. The optical properties of the noble metal nanoparticles (SEGNPs) are attributed to its surface plasmon resonance and show size dependence [19–21]. Thus, we used the color index of nanoparticles as the size index to study the real-time size transformation of membrane transporters in live cells (Figs. 1–3). The sizes of the nanoparticles transported through the live-cell membranes can be measured by directly visualizing the color of individual nanoparticles, which are correlated with the size of the nanoparticles. This study has demonstrated that nanoparticle optics showed the possibility of real-time live-cell imaging with sub-100-nm spatial resolution and millisecond time resolution. Furthermore, unlike conventional fluorescent dyes or QDs, noble metal nanoparticles resist photobleaching and blinking. These unique features allow these nanoparticles to be used for continuously monitoring the size transformation of membrane transporters and efflux dynamics in live cells for an unlimited time. Nanoparticle optics is superior to TEM and scanning probe microscopy (SPM) for the study of subcellular dynamics in live cells because TEM cannot provide real-time measurements of dynamics events in live cells and SPM offers lower temporal resolution and cannot monitor nanoparticles inside live cells or many single nanoparticles simultaneously.

Three strains of *P. aeruginosa* [70–72], wild-type (PAO4290, a wild-type cell level expression of MexAB-OprM), ΔABM (TNP076, deletion of MexAB-OprM, derivative of PAO4290), and nalB-1 (TNP030#1, overexpression of all MexA, MexB, and OprM, derivative of PAO4290), have been constructed and studied. The MexAB-OprM membrane pump was used as a working model. We investigated the roles of these membrane proteins on the extrusion system by measuring the sizes and dynamics of substrates (nanoparticles) transported by mutants of overexpression or deletion of these subunits. The sizes of single substrates (nanoparticles) transported through live-cell membranes were measured by directly visualizing the color of the individual nanoparticles and hence the sizes of the extrusion pump were determined in real time at the nanometer scale (Figs. 1–3).

Based on random-walk theory [73, 74], the transport of nanoparticles through the live-cell membrane (in a buffer solution, on the cell membrane, and inside the cells) was determined [8]. Representative snapshots of real-time images of single nanoparticles transported across live-cell membranes in Figure 2 shows all three strains of *P. aeruginosa* were uptake and efflux both blue ($\sim 50 \pm 5$ nm) and green ($\sim 70 \pm 5$ nm), and, occasionally, yellow nanoparticles ($\sim 75 \pm 5$ nm). The red nanoparticles ($\sim 95 \pm 5$ nm) tended to remain outside the cells on the cell membranes and were rarely observed inside the cells (Fig. 2). These results suggest that the membrane of three mutants of *P. aeruginosa* permeated and extruded substrates up to 80 nm in diameter.

The accumulated nanoparticles by cells showed time and concentration dependence (Fig. 3). The uptake and efflux dynamics of nanoparticles by three mutants of *P. aeruginosa* differ at 100 min of incubation time. A greater number of nalB-1 cells took up and retained nanoparticles during the first 100 min in comparison with ΔABM (MexAB-OprM-deficient mutants) and WT. At 100 min, nalB-1 cells began to extrude the nanoparticles and the number of cells with nanoparticles decreased whereas ΔABM and WT have distinguished uptake and efflux characteristics. The observation of uptake and efflux of nanoparticles by ΔABM implies that nanoparticles (substrate) may trigger the assembly of membrane transporters optimized for the extrusion of encountered substrates.

This work demonstrates the possibility of real-time tracking of membrane permeability and the observation of pump machinery of single live cells at the single-extrusion-pump level and may lead to a better understanding of multidrug resistance and designing of pump inhibitors. Furthermore, alternative molecular pump designs may be explored so that pumps may one day be engineered to selectively transport specific molecules into and out of live cells for a variety of applications (e.g., intelligent drug delivery).

4.4. Membrane Permeability and Efflux Mechanism

Real-time size transformation of membrane pores (permeability) and efflux kinetics in three mutants of *P. aeruginosa*, WT, nalB-1, and ΔABM, have been directly observed in the presence of 0, 25, and 250 μg/mL chloramphenicol using nanoparticle optics and single-live-cell imaging. The membrane permeability in *P. aeruginosa* (WT, nalB-1, ΔABM) increased as the chloramphenicol concentration increased from 0 to 250 μg/mL and as the incubation time increased (Fig. 4), indicating the real-time size transformation of membrane pores (permeability). The results suggest that the mechanism of multi-antibiotic resistance may include the induction of transformation of membrane permeability and intrinsic efflux pump machinery. This work constitutes the first direct observation of the size transformation of membrane pores (permeability) and the interplay of membrane permeability and efflux kinetics in real time at single-live-cell resolution and offers the new possibility of advancing the understanding of multidrug resistance. This study demonstrates the possibility of using nanoparticles for the study of the real-time transformation of membrane permeability in eukaryotic cells (tumor) for better understanding of multidrug resistance. We are currently developing nanoparticle optics for the study of the real-time transformation of electropermeabilization [75, 76] for a better understanding of the effect of radio frequency (RF) and electric fields on membrane permeability.

4.5. Ligand–Receptor Interactions

The kinetics and binding of the ligand–receptor interaction on live cells play an important role in a variety of crucial biological events, such as immune regulation pathways. The motions of receptors on live cells using Au nanoparticles labeled with ligands have been studied previously [24–26]. We have recently developed and applied multicolor SEGNPs and real-time diffusion single-nanoparticle/single-cell microscopy for the measurement of single ligand–receptor interactions on live cells [22, 23]. We directly observed single IgG molecules labeled with single SEGNPs binding with single antigen molecules (ZZ-T) anchored on single living cells.

The ZZ is a derivative of protein A [77] that is renowned for its specific powerful binding with IgG, which serves as an invaluable molecular linker for a variety of immunoassays and affinity chromatography. This ZZ protein implies dramatic potential to build a specific molecular architecture on synthetic and natural membranes for a variety of applications (e.g., sensor, separation, nanoassemble) and can serve as a model for fundamental thermodynamics and kinetics studies at living interfaces. The ZZ-T was constructed by fusing the ZZ protein with a transmembrane domain (T) of diphtheria toxin [78–80]. Soluble protein molecules were fused with the T domain and then the T-domain fusion proteins were anchored to the membrane by triggered pH change from pH 7.4 to 5.0. The anchoring process was easily controlled and occurred rapidly.

We have anchored ZZ-T onto live cells and studied the binding of IgG (immunoglobulin G) with the ZZ-T (fusion protein) on live cells [22]. The SEGNPs were prepared and labeled with the IgG. The binding of IgG-SEGNPs with ZZ-T anchored onto live cells has been directly measured in real time as shown in Figure 5 [22]. The bound and unbound IgG-SEGNPs were distinguished using the diffusion distances of SEGNPs. The unbound probe created a large diffusion image and appeared dim because the intensity of the nanoparticles within the exposure time is distributed over each pixel of the entire diffusion area. The bound probe shrank to a single pixel of CCD resolution and appeared as a single bright spot because the bound probe on live cells would not move around and hence a single pixel collected all scattering intensity during the entire exposure time. The blank control experiments of ZZ-T-anchored cells incubated with nanoparticles or cells in the absence of ZZ-T incubated with IgG-SEGNPs showed no significant binding [22]. This study demonstrated that the nanoparticles can be used to monitor in real time the interactions of ligands with receptors on live-cell surfaces, which will lead to a better understanding of cellular events for a variety of applications (e.g., vaccine and drug design).

Other fusion proteins, T-hIL-2 and T-mIL-3, have also been constructed by fusing human interleukin 2 (hIL-2) and murine interleukin 3 (mIL-3) to the C terminus or N terminus of the T domain [78]. We are currently measuring the real-time binding kinetics and affinity of single anchored T-IL-2 (ligand) with IL-2R (receptor) labeled with nanoparticles on single live cells under RF radiation and electric fields using single-nanoparticle/single-cell microscopy. We aim to investigate whether the binding kinetics and affinity of single IL-2 (ligands) with single receptors (IL-2R) are altered by RF radiation and electric fields due to the possible changes in the dipoles of the ligands and receptors. This study will lead to a better understanding of the mechanisms of radiotherapy and electrotherapy.

4.6. Chemical Analysis

Changes in intracellular ion concentration accompany a variety of biological processes in live cells, including transport, signaling, and enzyme function. A few ions (proton and calcium) are very important in cellular functions. The ion flux has been measured by monitoring the emission intensity of the fluorophore indicators associated with intracellular ion concentrations. This study led to a better understanding of cellular events. The major drawbacks of such fluorophore indicators were that they interacted with the proteins in the cell and gave false results [81–83]. In addition, these dyes were toxic to cells and were rapidly extruded out of the cells. This limited the observation period. Moreover, these fluorescent dyes were distributed throughout the entire cell and created a huge background noise. Nanoparticles prepared by incorporating fluorescent dyes with a polymer matrix were proven to circumvent many of these problems [14, 15]. The PEBBLE sensors (20–200 nm) were prepared by incorporation of fluorescent dye molecules into the pores of the polymer matrix. The polymer matrix provided a protective coating for the dye molecules. This minimized nonspecific binding and eliminated the toxic effect of the dyes. Hence, it improved its application for real-time cellular studies. Multiple-dye PEBBLE sensors have been prepared by the integration of more than one type of dye in the polymer matrix [14, 15]. Some of these dye molecules were used as a real-time reference. Another advantage of PEBBLE sensors is that these sensors are small enough to be biocompatible and yet large enough to be retained in the cytoplasm with no leakage out of the cells for days [14, 15].

These nanoparticles enable us to study the rate of ion release in real time, which reflects specific cellular events. For example, the rate of calcium release from the mitochondria of C6 glioma cells and SY5Y neuroblastoma cells has been studied by stimulating the mitochondrial permeability transition (MPT) with varying dosages of *m*-DNB (*meta*-dinitrobenzene, a neurotoxicant). The exposure to *m*-DNB resulted in the uncontrollable release of calcium associated with the onset of MPT. The increase in intracellular calcium led to cell apoptosis. It was found that these two types of cells had different resistance and sensitivity to *m*-DNB (Fig. 8). The fluorescence intensity of the calcium-green family of dyes increased as the calcium concentration increased (Fig. 9). The change in calcium flux was

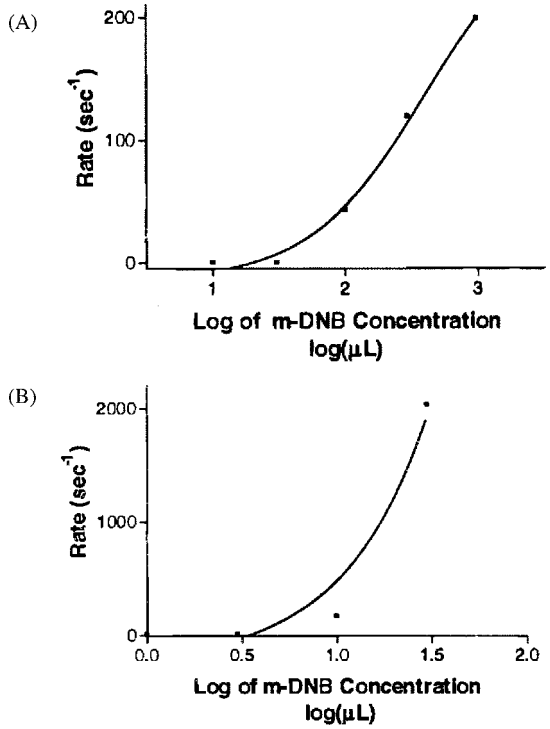

Figure 8. Direct observation of calcium release from the mitochondria of C6 glioma cells [14]. Representative plots of rate of calcium release from the mitochondria of C6 glioma cells (A) and the mitochondria of SY5Y neuroblastoma cells (B) versus the dose of *m*-DNB (*meta*-dinitrobenzene, a neurotoxicant) used to stimulate the mitochondrial permeability transition (MPT) measured by a fluorometer. Fluorescent nanoparticles (PEBBLEs) were prepared by incorporation of the dyes with the polymer matrix (polyacrylamide). Reprinted with permission from [14], H. A. Clark et al., *Anal. Chem.* 71, 4831 (1999). © 1999, American Chemical Society.

determined by measuring the changes in fluorescence intensity of the dyes embedded in the polyacrylamide matrix. These PEBBLE sensors have been used to measure the intracellular calcium fluxes in single live cells using confocal microscopy and to monitor bulk cells in real time using fluorescence spectroscopy via a fluorimeter.

Unlike PEBBLE sensors, Au nanoparticles attached with fluorophores (fluorescein derivatives) have been developed for the real-time study of NO release in macrophages [13]. The NO sensor was prepared by attaching a difluorofluorescein derivative onto Au nanoparticles [13]. This sensor measured the real-time release of NO from macrophages when macrophages were activated by LPS (lipopolysaccharide) and IFN-γ (interferon-γ). The difluorofluorescein derivatives attached perpendicularly on Au nanoparticles changed the orientation to the parallel position on the Au nanoparticle in the presence of NO. This led to a change in the fluorescence intensity. This change was used to detect the release of the NO from the live cells. Moreover, this sensor was stable toward the superoxide and hydrogen peroxide that are the byproducts of the action of LPS and IFN-γ on the cell. The advantages of these nanoparticle sensors offer a new opportunity for the study of real-time dynamics of ion flux in live cells.

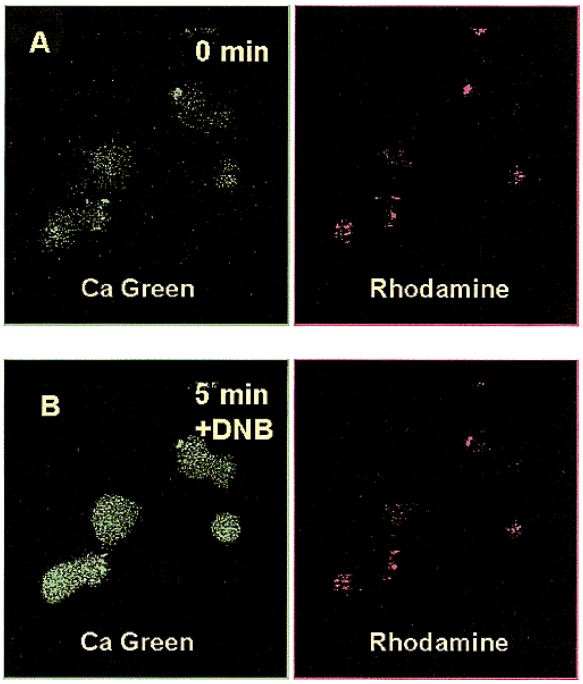

Figure 9. Direct observation of calcium release in SY5Y neuroblastoma cells. Laser scanning confocal microscopic images of *m*-DNB-stimulated calcium release in SY5Y neuroblastoma cells lipofected with calcium/sulforhodamine 101 PEBBLEs. Neuroblastoma cells were incubated in Dulbecco's phosphate buffered saline supplemented with glucose (0.5 g/L) at 37 °C and treated with 10 μM *m*-DNB. Calcium green and rhodamine fluorescence were monitored at time 0, prior to the addition of *m*-DNB (A) and 5 min following addition (B) [14]. The fluorescence intensity of the calcium green increased, which indicated that the calcium concentration level increased. As expected, the internal standard remained constant. 5. SUMMARY

Nanoparticles have shown great potential for the study of the dynamics of biological processes in live cells at the nanometer spatial resolution and millisecond time resolution. A new era in the study of the dynamics of biological events in live cells using the unique properties of nanoparticles and rapid ultrasensitive detectors (CCD cameras) have just begun. As we navigate through the wonderland of nanoscience and nanotechnology, the most noteworthy research topics surrounding the study of live-cell dynamics using nanoparticles are envisioned to be the following: (i) New tools for the nanofabrication and characterization of nanomaterials will continuously emerge and hence more new nanomaterials and new properties of nanomaterials will be discovered. Thus, more types of nanoparticles (e.g., magnetic nanoparticles, carbon-tube nanoparticles, chemically and biologically modified nanoparticles) for the study of specific biological processes (e.g., signal transduction) will be developed. (ii) Nanoparticles have been widely used as nanosensors to quantitatively and qualitatively determine species (DNA, protein, chemicals) in buffer solution [3–7, 84]. Future research will focus more on the study of biocompatible nanosensors and delivery of these nanosensors into live cells or into living organisms [85] to sense the desired biomolecules (e.g., tumor markers) for monitoring the onset and development of diseases and for understanding unclear biological mechanisms. (iii) As technologies advance, more sensitive and rapid detection means will be available. The combination of rapid and ultrasensitive detection means with unique characteristics of the nanoparticles, including nanosensing [84], multicomplexing [60, 61], nanometer resolution [9, 10], and photostability, will make real-time study of biological mechanisms at the single-molecule level feasible and hence advance our understanding of biological phenomena in real time at the nanometer scale and molecule level. We will be able to understand when and where the crucial biological events are taking place in live cells and what molecules are involved in these processes. An approach of this kind will certainly revolutionize our understanding of biology and related science and engineering. (iv) The development of nanoparticles for the study of the dynamics of biochemical events in live cells will also open up new opportunities for the study of the interactions of nanomaterials with live organisms at the molecular level. New research areas on the study of the assembly of new materials using the unique properties of live organisms for the development of self-repairing intelligent materials or the assembly of live organisms using the self-assembly of nanomaterials will appear. These research fields will revolutionize the biological sciences, materials sciences, and every aspect of science and engineering. The bright future of the exploration of live cells using nanoparticles is certain and will surely exceed our current imagination and expectation.

GLOSSARY

Charge-coupled device (CCD) A photodetector used in digital camera systems for sensitive detection of photos.

Dark-field microscopy A microscopic method that creates the dark background and the bright object with a high contrast between the object and the surrounding field [73].

Deoxyribonucleic acid (DNA) A macromolecule consists of one or two strands of linked deoxyribonucleotides.

Differential interference contrast microscopy (DIC) A microscopic method derives contrast in an unstained specimen from differences in index of refraction of specimen components [73].

Fluorescence The emission of light by a substance immediately after the absorption of energy from light of usually shorter wavelength.

Fluorescence recovery after photobleaching (FRAP) A technique to observe and quantify the movement of molecules by loading fluorescent tagged molecules, bleaching the fluorescence of a defined region of the specimen, and recovery of fluorescence in the bleached area based upon the mobility of the fluorescent molecules.

Human interleukin 2 (hIL-2) A cytokine that stimulates the immune system.

Interleukin 2 receptor (IL-2R) The protein has specific binding affinity with interleukin-2.

Metastases Pathogenic microorganisms or cancerous cells transmitted from an original site to one or more sites elsewhere in the body.

Mouse interleukin 3 (mIL-3) A peptide cytokine that stimulates haemopoiesis and activates mononuclear phagocytes and B and T lymphocytes.

Nanoparticle video ultramicroscopy (NANOVID) Tracking of the trajectories of individual microscopic particles attached to relevant molecules using optical microscopy equipped with video camera [40].

Nitric oxide (NO) A colorless gas, an important nitrogen compound, plays numerous biological roles in living organisms.

Probes encapsulated by biologically localized embedding (PEBBLES) The polymer-based fluorophore nanoparticles prepared by incorporation of fluorophores with a polymeric matrix [14, 15].

Pseudomonas aeruginosa (P. aeruginosa) A gram-negative bacterium that resists to a wide spectra of structurally and functionally unrelated substrates and is the epitome of an opportunistic pathogen of humans.

Quantum dots Inorganic nanocrystalline particles made from semiconductor materials.

Scanning probe microscopy (SPM) An experimental imaging technique maps the surface at (near) atomic resolution by scanning the surface of the sample using a sharp probe.

Silver enhanced gold nanoparticle (SEGNP) The surface of gold nanoparticles is coated with a thin layer of silver to increase the intrinsic optical dielectric constant of nanoparticle and enhance the detection sensitivity [8, 18].

Single particle tracking (SPT) A method to track the trajectories of individual microscopic particles attached to relevant molecules.

T domain: Transmembrane domain of diphtheria toxin.

Transmission electron microscope (TEM) An imaging technique takes advantage of shorter wavelengths of electrons to increase magnification and resolution.

T-ZZ A short derivative of protein A fused with amino-terminal of transmembrane domain of diphtheria toxin.

ZZ A short derivative of protein A.

ZZ-T A short derivative of protein A fused with carboxyl-terminal of transmembrane domain of diphtheria toxin.

ACKNOWLEDGMENTS

We are indebted to all the students of the Xu group for their contribution to the development of nanoparticles for the study of live-cell dynamics. We thank Taiji Nakae (Tokai University School of Medicine, Japan) for three strains of *Pseudomonas aeruginosa*. The support of this work in part by the NIH (Grant RR15057-01), DOD (Grant AFOSR-MURI), and Old Dominion University, in the form of a start-up grant, is gratefully acknowledged.

Nanoparticles in Nanostructured Polymers

Lyudmila M. Bronstein

Indiana University, Bloomington, Indiana, USA

CONTENTS

1. INTRODUCTION

Nanostructured materials containing metal or semiconductor nanoparticles present an exciting area of nanoscience and nanotechnology as particle incorporation allows imparting unique properties to polymeric materials: catalytic, optical, magnetic, etc. If the polymeric matrix is already nanostructured before nanoparticle formation (i.e., contains domains of different chemical nature divided by interfaces), this reflects a further degree of nanostructural organization. Normally, the presence of such nanostructures in polymer systems (presence of interfaces) allows one to carry out a subtle control over nanoparticle growth, particle size distribution, and particle surface interactions. The above characteristics are most important in determining properties of these nanomaterials and their possible applications. Narrow particle size distribution is crucial in developing well-defined materials for any application, as optical, magnetic, and even catalytic properties strongly depend on the precise control over a particle size. This particular field of science began developing about 10 years ago when papers dealing with nanoparticle formation in microsegregated block copolymers and block copolymer micelles were first published. Nowadays this field is characterized by an avalanche of publications and fast progress in discovery of new materials. Varying the polymer systems and different approaches in nanoparticle formation, nanoparticles of various size and shape, nanotubes, nanofibers, and other nanoinclusions can be obtained in polymer nanoenvironment.

The structure of this review article is the following. All methods of nanoparticle formation in nanostructured polymers will be combined into three groups depending on the medium: nanoparticle formation (i) in solid nanostructured polymer materials, (ii) in pores or cavities of nanometer size located in polymers (this makes polymers nanostructured), (iii) and in solutions of nanostructured polymers. Each type of polymeric nanoenvironment is characterized by particular features which will be thoroughly discussed. Characterization methods most commonly used for studying nanostructured polymers containing nanoparticles will be described. At the end, the properties of nanostructured polymeric systems with nanoparticles will be briefly described.

2. SYNTHESIS

2.1. Solid Nanostructured Polymers

2.1.1. Microsegregated Amphiphilic Block Copolymers

An important feature of amphiphilic block copolymers is their ability to microsegregate in bulk due to incompatibility of the blocks [1–3]. Yet, for interaction with metal compounds, a chosen block (where particles will be formed) of diblock or triblock copolymer should contain functional groups. Materials of this kind can be obtained using several avenues: (i) by copolymerization of organometallic monomers with a regular monomer followed by further transformations to obtained nanoparticles in a single block, (ii) by interaction of metal complexes with functional groups of block copolymers in solutions followed by microsegregation of organometallic block copolymers in the film or in bulk, and (iii) by incorporation of organometallic compounds directly into the already preformed microdomains of the block copolymer film. Inclusion of metal complexes in di- and triblock copolymers may strongly change the properties of the corresponding blocks and influence the

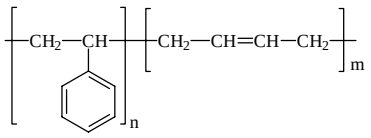
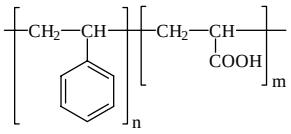
Volume 7: Pages (193–206)

Flory–Huggins interaction parameter χ_{AB}. This influence can be especially pronounced for nonpolar flexible blocks, such as polyisoprene (PI) or polybutadiene (PB), due to the appearance of polar groups and change of chain conformation. The representative example is introduction of $Fe(CO)_3$ groups in the PB block of polystyrene-*block*-polybutadiene (PS-*b*-PB-*b*-PS, Kraton, 30 wt% PS) block copolymer due to formation of π-conjugated diolefin complexes [4].



(PS-*b*-PB)

This significantly increases adhesion of polymer film to polar surfaces (metal, glass), increases rigidity, and decreases the mobility of the PB block, though the basic morphology of this material ("cylinders in continuous phase") did not change. Similar stability of the morphology was observed also for highly asymmetric diblock ionomers where a short block (polyacrylic acid, PAA) forms spherical microdomains inside the matrix of the major component (PS) [5].



(PS-*b*-PAA)

Neither incorporation of Cd^{2+} ions nor formation of CdS nanoparticles changes the block copolymer morphology. On the contrary, the morphology of triblock copolymers strongly changed when metal complexes are introduced in the middle block [6]. If noticeable influence of metal incorporation on block copolymer morphology is rather rare, the opposite influence (i.e., the influence of nanostructures and interfaces between block copolymer domains or free surfaces of thin films) plays an important role in nanoparticle formation within such domains. Growth of Ag [7], Pd [8], and other nanoparticles inside the microsegregated layers is limited by the thickness of the layer (Fig. 1). In so doing, penetration of metal nuclei or growing particles in the adjacent nonpolar layers is negligible. If a similar particle synthesis is carried out in the thick homopolymer films, uncontrolled particle formation with broad particle size distribution is observed [7]. On the other hand, if the thickness of the film of metal-containing homopolymer diminished to the block copolymer lamellae size (about 100 nm), the free surface of the thin film behaves similarly to the interface between block copolymer domains [7].

2.1.2. Polyelectrolyte Multilayers

Such nanostructured systems are obtained by deposition of polyelectrolytes (PE) on oppositely charged supports followed by further deposition of oppositely charged (toward first layer) polyelectrolytes with a formation of multilayer polyelectrolyte systems [9]. These systems strongly resemble thin homopolymer films and lamellar block copolymers, as

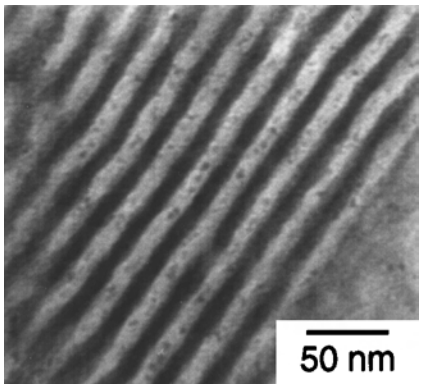


Figure 1. TEM image of the PI-*b*-P2VP/$Pd(acac)_2$ system obtained after the reduction and further stained by OsO_4 vapor. The dark and bright phases are PI lamellae stained by OsO_4 and unstained P2VP lamellae, and dark dots are the Pd nanoparticles in the P2VP phase. Reprinted with permission from [7], J. F. Ciebien et al., *New J. Chem.* 22, 685 (1998). © 1998, American Chemical Society.

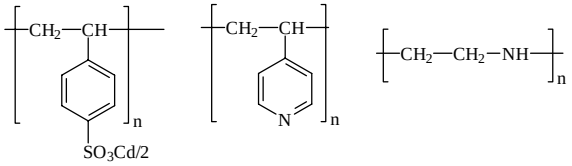
the interfaces between polyelectrolyte layers limit the migration of ions to the adjacent oppositely charged layer and metal nanoparticle formation. As support, not only flat surfaces but also various nanoparticles can be used. Such supports allow one to obtain core–shell materials or hollow spheres after further treatment (for example, dissolution of a core at certain conditions) [10, 11]. Each individual polyelectrolyte layer can serve as a nanoreactor.



(CdPSS) **(P4VP)** **(PEI)**

Reference [12] describes preparation of CdS nanoparticles in the material which originated from alternate deposition of cadmium polystyrenesulfonate (PSS) and protonated polyvinylpyridine [P4(2)VP] on quartz and other supports modified by protonated polyethyleneimine (PEI) (to charge the surface). Afterward the multilayer material was treated with H_2S which resulted in CdS nanoparticle formation within a polysulfonate layer. In some cases nanoparticles were prepared in the surfactant micelles to ensure better control over particle growth and then mixed with PE to form multilayer films with nanoparticles [13]. In the latter case, particles were formed outside of the nanostructured polymer layer (in surfactant micelles) so it falls out of the topic of this chapter. At the same time, taking into consideration recent discussion on the presence of a broad interface in polyelectrolyte multilayer films [14] (unlike amphiphilic block copolymers), one could consider incorporation of preformed nanoparticles being a viable approach to control particle size distribution. In the case of a broad interface, "nanoreactor" size strongly varies which can cause broader particle size distribution.

2.1.3. Polyelectrolyte Gel–Surfactant Complexes

Polyelectrolyte gel–surfactant complexes (PGSCs) are highly ordered systems which were extensively studied by theorists and experimentalists [15–18]. In these systems, surfactant molecules self-assemble and their ordering even exceeds the ordering of surfactant in the solutions [19]. As PGSCs contain a number of ions in well-ordered surfactant areas inside a weakly cross-linked gel, their replacement with ions of interest (transition metal ions) should offer the possibility of metal nanoparticle formation in a nanostructured medium. As found, metal ion uptake takes place when metal ions are oppositely charged toward polyelectrolyte charged groups [20–22]. In doing so, the incorporated metal compounds form clusters which are located between charged groups of a polymer chain and surfactant head groups. These clusters behave as nuclei for metal nanoparticle formation during reduction. If a fast reducing agent is used ($NaBH_4$), particles grow completely in an ordered environment. Moreover, as reported in [22], although particle growth decreases the degree of crystalline ordering in PGSCs, the ordering around growing particles even increases, which results in additional control over particle growth and a very narrow particle size distribution (Fig. 2). If reduction is carried out with a sluggish reducing agent ($N_2H_4 \times H_2O$), small clusters and ions migrate in unstructured areas of the gel where uncontrolled particle growth occurs. This results in large particles with a very broad particle size distribution. PE gels without internal nanostructure are also unable to control the particle growth.

2.2. Nanoparticles in Polymer Cavities

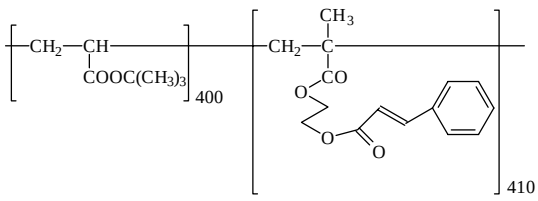
Existence of nanopores or nanocavities of a regular size and shape in polymer matrix creates interfaces between pore volume and polymer walls, thus creating nanostructures in polymers. These pores can be formed in polymers due to special conditions of polymer synthesis or polymer nature [23] and may serve as nanoreactors for particle growth; in this case, a particle size may be restricted by a pore size. This approach is very common for mesoporous solids where metal compounds are incorporated inside the pores and then nanoparticle growth is carried out within the pores [24, 25], but it is rather rare for polymers as the polymers containing regular interpenetrating cavities and pores are also uncommon. A detailed description of template synthesis of various nanoparticles (polymer, metal, metal oxide, etc.) in nanoporous membranes is given in a review article [23]. Here, porous alumina membranes are the most commonly used templates, although polycarbonate porous membranes were also described.

Two types of cavities will be considered here: (i) with and (ii) without any functional groups which might interact with metal compounds.

2.2.1. Nanoparticles in Nanoporous Polymers

The progress in nanoporous polymer synthesis was strongly inspired by the need for polymers with low dielectric constant [26] although in this case closed pores are required. Commonly this is achieved by templating over block copolymers with a thermally labile block. Another use of porous polymer membranes with open pores is metal deposition which is well described in [27].

An interesting example of a porous polymeric system is polymer microspheres containing PAA-lined channels which are most likely continuous [28]. These microspheres were prepared by ultraviolet (UV) crosslinking of poly(*t*-butyl acrylate)-*block*-poly(2-cinnamoyloxyethyl methacrylate) (P*t*BA-*b*-PCEMA) block copolymer micelles followed by hydrolysis.



(P*t*BA-*b*-PCEMA)

The microspheres were used for Pd nanoparticle formation that was performed by incorporation of the microspheres in the $Pd(NO_3)_2$ aqueous solution. Pd^{2+} ion uptake was 1 Pd ion per two carboxylic groups. To increase Pd loading, further Pd deposition during electroless plating has been used. This allowed an increase of Pd content to 27 and 63 wt% (from 13 to 14 wt%) which resulted in an increase of the Pd particle size. As the pores in the microspheres were comparatively large (~30 nm), they might provide restriction of the particle growth only at very high loading. In doing so, particles are getting so large that the advantages of the metal confinement are nearly lost (at least for catalytic applications).

Hyper-cross-linked polystrene (HPS) [29, 30] is another porous material of choice. This is a unique polymer network where pores form spontaneously during polymer synthesis. Due to its high cross-link density, which can exceed 100%, HPS consists of nanosized rigid cavities of comparable size in the 2–3 nm range. It is readily produced by chemically incorporating methylene groups between adjacent phenyl rings in dissolved polystyrene homopolymer or gelled poly(styrene-*r*-divinylbenzene) copolymer in the presence of ethylene dichloride. A unique feature of HPS is its ability to swell in a wide variety of different solvents, even thermodynamically poor ones (e.g., water). Such versatility greatly facilitates incorporation of various organometallic compounds into the nanostructured HPS matrix. Though HPS was known for absorption of heavy metal ions from solutions [31], the first use of HPS as a medium for metal nanoparticle formation was reported in 1999 [32]. Cobalt nanoparticles have been selected here due to the established [33] correlation between size and shape of Co particles and their magnetic properties, that is, their ferromagnetic resonance (FMR) spectrum characteristics. Particles measuring less than 1 nm in diameter are nonmagnetic, while those with diameters from 1 to 10 nm are superparamagnetic. Larger Co particles behave as ferromagnetic materials. Moreover, the width of the FMR signal (ΔH) for spherical particles depends on the size of the Co nanoparticles [33, 34], and the position corresponding to the zero signal (H_0) contains information regarding the shape of the Co nanoparticles. This allows one to determine the general size and shape characteristics of Co nanoparticles solely from FMR spectra.

Impregnation of HPS by either $Co_2(CO)_8$ in 2-propanol or the $[Co(DMF)_6]^{2+}[Co(CO)_4]_2^-$ complex in dimethylformamide (DMF), followed by thermolysis at 200 °C, results in the formation of discrete Co nanoparticles. The concentration and characteristics of such nanoparticles were investigated by X-ray fluorescence spectroscopy, FMR spectroscopy, and transmission electron microscopy (TEM). The FMR data confirmed the formation of spherical nanoparticles. At Co concentrations of 2–8 wt% the magnitude of the FMR linewidth reveals that the mean Co nanoparticle diameter is about 2 nm, which agrees well with the mean particle diameter discerned by TEM. An increase in Co content higher than 8 wt% is accompanied by an increase in mean particle diameter due to an increase in the population of large Co nanoparticles up to 15 nm across. Regulated nanoparticle growth over a wide range of Co concentrations is attributed to nanoscale HPS cavities, which serve to physically restrict the size of growing particles. It is noteworthy to mention that the HPS employed does not contain functional groups that could specifically interact with growing metal nanoparticles and stabilize them. In fact, the nanoscale cavities in HPS are anticipated to be highly interconnected and, therefore, should *not* hinder the migration of Co atoms or even small Co clusters. A steric limitation arising from the predominance of phenyl rings represents the most probable reason for controlled Co nanoparticle growth in HPS; phenyl rings may interact with metal surfaces and nonspecifically stabilize metal nanoparticles. If the Co concentration in a HPS-Co composite exceeds a saturation limit (at Co loadings in excess of 10 wt%), a few large nanoparticles grow. Their size might (i) correlate with the statistics of the pore size distribution of the HPS matrix or (ii) identify a metal-induced rearrangement of the HPS network.

As was shown by the example of Co particle formation, HPS is a robust and convenient nanostructured polymer matrix which might be broadly used for growth of catalytically active nanoparticles. Following this path, the authors [35] reported formation of Pt nanoparticles in HPS. Impregnation of HPS with tetrahydrofuran (THF) or methanol (ML) solutions containing platinic acid (H_2PtCl_6) results in the formation of Pt(II) complexes within the nanocavities of HPS. Subsequent reduction of the complexes by H_2 yields stable Pt nanoparticles with a mean diameter of 1.3 nm in THF and 1.4 nm in ML. As discussed above, for Co-containing HPS, the mean particle size was about 2 nm. This discrepancy in particle size can be explained by the different mechanisms of Co and Pt particle formation. As Co particles were formed at 200 °C, Co clusters could easily migrate between the HPS pores forming Co nanoparticles with the sizes matching the pore size. For Pt nanoparticles, H_2 reduction occurs at room temperature and migration of Pt clusters or atoms or Pt precursor molecules from pore to pore hardly occurs. This results in the formation of Pt particles with a size matching the size of Pt precursor (salt or complex) filling the pores [35]. Thus, for Co nanoparticle formation, HPS controls the particle size due to physical limitations of their growth by the pore size (2 nm). In the case of Pt nanoparticles, pores limit the amount of precursor filling the single pore so during reduction the precursor particle shrinks (density increases from Pt complex to Pt metal) to Pt nanoparticle (1.3 nm in diameter). In both ways, HPS provides strong control over nanoparticle growth. The simplicity of this approach makes this polymer system very attractive for broader use (semiconductor and other catalytic particle formation). The limitation of this system lies in the cross-linked nature of HPS, which does not allow film and coating formation. This limitation is of no concern from the viewpoint of catalytic materials (moreover, it can be used without support in heterogeneous catalysis) but strongly limits its prospects for HPS use for optical or magnetic materials. Another drawback of metallated HPS is an easy washing of the metal nanoparticles out of polymer in media where PS swells. So to prevent metal loss, HPS based catalysts should be used only in "poor" (for PS) solvents (water is the best).

2.2.2. Cavities of Nanostructured Polyoctadecylsiloxane

If the nanoporous polymer contains functional groups inside the pores, incorporation of metal compounds is facilitated and metal particle stability is enhanced. As an example, polyoctadecylsiloxane (PODS) containing nanocavities formed by a bisiloxane layer will be discussed here [36, 37]. This polymer is obtained by hydrolytic polycondensation of octadecyltrichlorosilane in water. As demonstrated in [36], the polymeric condensate consists of highly uniform, pillared microcrystallites in which the inorganic siloxy backbones form periodic layers, each containing a monomolecular layer of intercalated water, separated by crystalline assemblies of alkyl chains. These siloxy bilayers form nanocavities containing silanol groups. Being placed in an aqueous solution of metal salt, this polymer system absorbs salt into its

hydrophilic layer where, due to subsequent reduction, regularly spaced metal nanoparticles were formed [38, 39]. The incorporation of metal compounds in the nanostructured polymer containing siloxy bilayers is strongly determined by the type of metal compound. Planar ions ($PdCl_4^{2-}$, $PtCl_4^{2-}$) presumably driven by entropy are found to easily penetrate within thin layers of 2–3 nm in size. The entropy gain is provided by the hydrogen bond formation between the chlorine atoms of metal anions and the silanol groups so that each $PtCl_4^{2-}$ or $PdCl_4^{2-}$ ion replaces several water molecules. Subsequent reduction results in metal nanoparticles located in the siloxy bilayers (Fig. 3).

As shown by ASAXS and TEM, the sizes of the metal nanoparticles formed in the restricted environment of a siloxy bilayer do not depend on the reducing agent type, the metal compound loading, and the metal compound type. This points to a "cage" effect whereby the size of the cavity limits the particle growth. The increase in electron density upon nanoparticle formation permits direct visualization of these bilayers, as well as the individual nanoparticles residing within them (Fig. 4). In Figure 4 one can see that particles are located solely in siloxy bilayers. These nanoparticles measure about 1–2 nm in diameter and possess a narrow size distribution due presumably to volume availability within the ordered bilayers of PODS. Thus, the cavity size of the nanostructured polymer controls the nanoparticle growth. A modification of PODS with surfactants (cetylpyridinium chloride) or other long chain functionalized molecules allows immobilization of the metal ions both in the siloxy bilayer and in the hydrophobic part of the polymer. In this case, the reduction conditions still do not influence the particles growing in the siloxy bilayer but affect those located in the hydrophobic layers (no "cage" effect for the latter). Since the PODS nanostructure remains unaffected by the interaction with metal ions and reducing agents, this polymer seems to be robust enough to produce not only highly stable metal nanoparticles but also a nanostructured polymer containing regularly spaced nanoparticles. On the other hand, the amount of metal species being absorbed by the PODS cavities is very limited so the overall metal content is low. Another downside of this material is its insolubility in any media, preventing film formation.

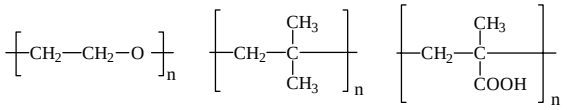
2.3. Solutions of Nanostructured Polymers

If nanostructured polymers are not cross-linked, they form stable colloidal solutions. These colloids (block copolymer micelles, dendrimers, microgels, etc.) play the role of nanoreactors for metal, metal oxide, or semiconductor nanoparticle formation.

2.3.1. Nanoparticles in Block Copolymer Micelles

Block Copolymer Micelle Cores Amphiphilic block copolymers form micelles in selective solvents (a good solvent only for one block); yet the size and shape of micelles depend on the block chemical structure, molecular weight of each block, and solvent type [1, 3]. If the micelle core consists of the block bearing functional groups (able to react with metal compounds, forming complexes or salts), such a core can be filled with a corresponding metal compound (by incorporating the metal compound in the block copolymer solution) and further can serve as a nanoreactor for nanoparticle formation. At the same time, the micelle core can be treated like a quasi-solid state, as the core-forming block is not soluble in a selective solvent. As such "functional" blocks, one may use polyvinylpyridines (P2(4)VP), polymethacrylic (PMAA) and PAA acids, PB, PI, and some others. Micelle corona should be formed by a block containing no functional groups but providing solubility and micelle stability in the respective solvent. These can be PS, poly(ethylene oxide) (PEO), polyisobutylene (PIB), etc.

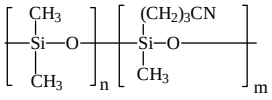


(PEO) **(PIB)** **(PMAA)**

Synthesis of metal or semiconductor nanoparticles in the cores of amphiphilic block copolymer micelles was reported almost simultaneously by several research groups [5, 40–43]. The Au, Pd, Pt, and other particle formation in block

copolymer micelles derived from PS-*b*-P4VP block copolymers showed that nanoparticle morphology strongly depends on the type of reducing agent. When a sluggish reducing agent is used, one nanoparticle per micelle ("cherrylike" morphology) can be formed if there is no exchange between micelles (for example, the micelle is cross-linked) [44]. Fast reduction leads to formation of many small particles per micelle ("raspberrylike" morphology) which is considered to be preferable for catalytic applications (Fig. 5) [45]. Using block copolymer micelle cores as nanoreactors allows synthesis of mono- and bimetallic nanoparticles; yet bimetallic particle morphology depends on a metal pair [46].

Co nanoparticles of different size and shape can be prepared either by incorporation of $CoCl_2$ in the PS-*b*-P2VP micelles followed by reduction or by thermal decomposition of $Co_2(CO)_8$ species embedded in the micelle cores [47]. Stable suspensions of superparamagnetic cobalt nanoparticles were prepared in poly(dimethylsiloxane) (PDMS) carrier fluids in the presence of poly[dimethylsiloxane-*block*-(3-cyanopropyl)methylsiloxane-*block*-dimethylsiloxane] (PDMS-*b*-PCPMS-*b*-PDMS) triblock copolymers as steric stabilizers [48].



(PDMS-*b*-PCPMS)

These copolymers formed micelles in toluene and served as nanoreactors for thermal decomposition of the $Co_2(CO)_8$ precursor. The nitrile groups on the PCPMS central blocks are thought to adsorb onto the particle surface, while the PDMS end-blocks protrude into the reaction medium to provide steric stability. The particle size can be controlled by adjusting the cobalt to copolymer ratio. TEM shows nonaggregated cobalt nanoparticles with a narrow size distribution and the particles are evenly surrounded with copolymer covering.

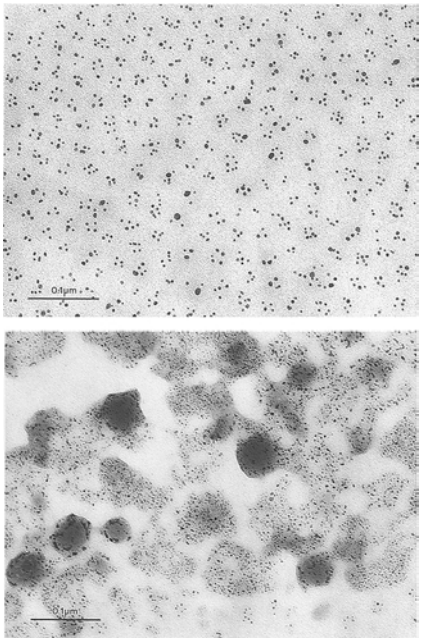


Figure 5. Electron micrographs of Pd colloids synthesized in PS-*b*-P4VP block copolymers via reduction with hydrazine (top) and $NaBH_4$ (bottom). Reprinted with permission from [45], M. V. Seregina et al., *Chem. Mater.* 8, 923 (1997). © 1997, American Chemical Society.

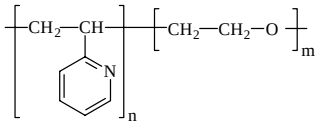
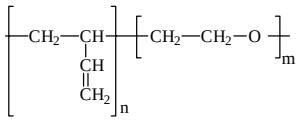
Formation of iron oxide particles in cross-linked block copolymer micelles is described in [49]. A polyisoprene-*block*-poly(2-cinnamoylethyl methacrylate)-*block*-poly(*tert*-butyl acrylate), PI-*b*-PCEMA-*b*-P*t*BA, forms spherical micelles in THF/hexane mixture with 65% volume fraction of the latter. The micelles consist of a PI corona, a solvent-insoluble PCEMA shell, and P*t*BA core. Their structure is locked in by photo-cross-linking the PCEMA shell to yield nanospheres. Similar to core cross-linking, this approach prevents exchange between micelles. The nanospheres were made water-dispersible by hydroxylating the PI double bonds. The core was made compatible with inorganic species by removing the *tert*-butyl groups of P*t*BA. The possibility of using such nanospheres as nanoreactors for inorganic nanoparticle preparation was demonstrated by incorporating iron salt and formation of iron oxide magnetic particles in the cores. However, this approach seems to be far too complex for magnetic particle formation as more robust and simple approaches can be used.

All the above examples describe nanoparticle formation in block copolymer micelles in organic solvents. Such examples are numerous, as many amphiphilic block copolymers form micelles with functionalized core in the organic medium. The choice of block copolymers for aqueous medium is very limited and metal particle formation is normally more complicated as the pH of the medium should be taken into consideration. A few examples of such block copolymers include P2VP-*b*-PEO and PB-*b*-PEO [50, 51]; yet the former block copolymer micellization depends on pH [52]. At pH below 5 P2VP-*b*-PEO becomes molecularly soluble in water. Nevertheless, lowering the pH of the P2VP-*b*-PEO micellar solution after incorporation of metal compounds or metal nanoparticle formation does not result in micelle decomposition, though micelles become less dense. In the case of PB-*b*-PEO, micelles formed in water are very dense, so they successfully fulfill two roles: they serve as nanoreactors for Pd, Pt, and Rh nanoparticle formation and as metal-particle-containing templates for mesoporous silica casting.



(P2VP-*b*-PEO)



(PB-*b*-PEO)

If the P2VP block is a middle block in PS-*b*-P2VP-*b*-PEO triblock copolymer, the "layered" well-defined micelles are formed in water with the PS core, P2VP shell, and PEO corona [53]. Here gold nanoparticle formation was carried out in the P2VP shell serving as a nanoreactor. As the shell is formed by the pH-sensitive P2VP block, according to the author's opinion this system can be useful for encapsulation and/or release of active species. However, one should remember that after metal particle formation this block loses its ability to dissolve at low pH [50]. So this property

can be used if no nanoparticles providing quasi-cross-linking are formed in the P2VP shell.

An original approach to form spherical assemblies of CdS-containing block copolymer reverse micelles in aqueous solution was reported in [54]. These stable assemblies were formed by slow addition of water to mixtures of the reverse micelles formed by PS-*b*-PAA and single PS-*b*-PAA chains. The structures are large compound micelles (LCMs) with quantum-confined CdS nanoparticles dispersed throughout a spherical PS matrix, which is stabilized in water by a layer of solubilized hydrophilic chains. The size of the CdS particles (approximately 3 nm) is determined by the ionic block length of the block copolymer forming the reverse micelle. LCM formation is dependent on the amount of added stabilizing copolymer. This method allows one to transfer the CdS nanoparticles formed in the micelle cores in organic medium to aqueous medium without loss of stability and particle aggregation.

Block Copolymer Micelle Coronas Nanoparticle synthesis can be carried out in the corona of amphiphilic block copolymer micelles. However, if the corona is functionalized, addition of metal salt can result in immediate formation of large aggregates and their precipitation so such a synthesis can be performed only in very diluted solutions. If the corona does not contain groups able to coordinate with metal compounds, particle stabilization is realized solely due to hydrophobic interactions with the hydrophobic core. This scenario was followed when synthesis of Pd, Pt, Ag, and Au nanoparticles was performed in aqueous solutions of PS-*b*-PEO and PS-*b*-PMAA by reduction of the corresponding salts in block copolymer solutions [55, 56]. As reported, this results in the formation of nanometer sized colloidal particles. As stabilization of these particles is provided due to hydrophobic interactions with the PS core, the stability of such systems cannot be satisfactory. At the same time, accessibility of particles in the micelle coronas can be favorable from the viewpoint of catalytic properties.

To improve stabilization in the micelle coronas, the authors [57–59] suggested using hybrid micelles consisting of PS-*b*-PEO and surfactants. It was expected that surfactant hydrophobic tails should be embedded in the PS core while surfactant head groups will be located on the micelle core surface or in its vicinity. As shown in Figure 6, exchange of surfactant counterions for ions of interest (Pt, Pd, or Rh) ought to allow saturation of the core with the given ions.

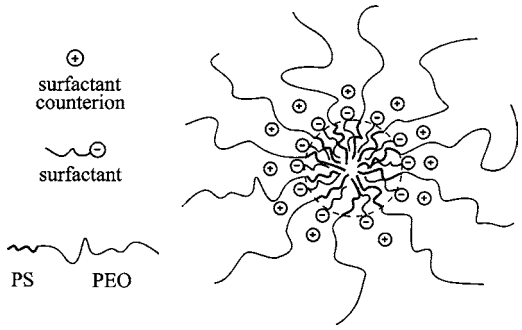


Figure 6. Schematic image of the hybrid PS-*b*-PEO/SDS micelle. Reprinted with permission from [58], L. M. Bronstein et al., *J. Colloid Interface Sci.* 230, 140 (2000). © 2000, Academic Press.

Dynamic light scattering (DLS) and sedimentation in an ultracentrifuge showed that incorporation of positively or negatively charged surfactants results in increase of size and weight of micelles and micellar clusters up to a certain surfactant concentration (which is different for different surfactants). Further increase of surfactant loading (as a rule, above critical micelle concentration for surfactants) results in a moderate decrease of micelle size and weight. By ^{1}H nuclear magnetic resonance, incorporation of surfactant leads to strong increase of mobility of the PS core which proves comicellization of block copolymer molecules and cationic or anionic surfactants. Ion exchange of surfactant counterions in the PS-*b*-PEO/CPC system for $PtCl_6^{2-}$ or $PdCl_4^{2-}$ ions results in saturation of micellar structures with Pt or Pd ions. Subsequent reduction of metal-containing hybrid micellar systems PS-*b*-PEO/CPC/MX_n with $NaBH_4$ or H_2 results in the formation of metal nanoparticles mainly located within the micelles. Morphology and stability of Pd and Pt nanoparticles synthesized in these systems depends on the metal compound loading and the type of a reducing agent. $NaBH_4$ reduction leads to decomposition of micellar clusters and formation of micelles with embedded nanoparticles. These systems display exceptional stability (for years) if metal salt loading does not exceed 1.24×10^{-2} M. Hydrogen reduction results in metal nanoparticle formation both in micelles and micellar clusters so stability of colloidal solutions is provided when metal salt concentration does not exceed 3.36×10^{-3} M. As found, nanoparticle size does not depend on the reducing agent type (contrary to the nanoparticles formed in other block copolymer solutions [42, 50]) but depends on the metal type [57–59]. This could be governed by strong interaction of surfactant head groups with growing nanoparticles.

When the targeted metal can be obtained only as a cation, the hybrid micellar system should include anionic surfactant: sodium dodecylsulfate (SDS) or SDBS. For one, using Rh cations $[Rh(Py)_4Cl_2]^+$, Rh nanoparticles with a diameter of 2–3 nm have been formed in the PS-*b*-PEO/SDS solutions. As seen from the above, incorporation of surfactants in the block copolymer micelles containing no functional groups allows reliable stabilization of metal nanoparticles of 2–6 nm in size. The disadvantage of these systems is the lack of direct methods to vary the particle size.

Micelle Formation via Complexation If both blocks of the corresponding block copolymer are soluble in the particular solvent, nanostructurization can occur due to complexation of the functional groups of the one block with a metal compound. First this phenomenon was described in [60] for the PS-*b*-PB molecular solution in toluene when micellization occurred due to formation of Pd and Pt π-complexes with double bonds. Another example is PS-*b*-P2VP which was molecularly dissolved in a good solvent for both blocks, THF, and subjected to interaction with cadmium ions [61]. It resulted in the formation of aggregates of single micelles called compound micelles. The growth of CdS nanoparticles is confined to the core of single micelles after introduction of hydrogen sulfide gas into the solution. UV-visible spectroscopy, fluorescence spectroscopy, and transmission

electron microscopy were employed to characterize the CdS nanoparticles. UV-visible absorption spectra show that larger nanoparticles are produced at lower 2VP:Cd^{2+} molar ratio, i.e. at higher Cd^{2+} loading. UV-visible absorption spectra and fluorescence spectra both indicate that with decrease of block copolymer concentration in THF, the size of the CdS nanoparticles decreases; that is explained by decrease of the micelle size. Thus, nanoparticle characteristics are dependent on numerous parameters.

If both blocks of a block copolymer are hydrophilic, the block copolymer gives a molecular solution in water. Again, if one of the blocks is inert and another contains functional groups, which are able to interact with metal compounds, their addition leads to micelle formation.

PEO-*b*-PEI was employed for synthesis of metal nanoparticles in aqueous medium using the idea described above [62, 63], as PEI easily interacts with metal compounds due to coordination [64]. This results in aggregation of the PEI block and micelle core formation, while PEO forms a corona and ensures colloidal solubility. Such micelles also provide control over particle nucleation and growth (similar to amphiphilic block copolymer micelles), although micellar and metal particle characteristics are more dependent on the reaction conditions: micelle formation is induced solely by metal compounds and micelle core densities are low. Metal ion reduction leads to metal nanoparticle formation. In so doing, PEO-*b*-PEI micelles remain intact, while changing their hydrodynamic parameters. This gives evidence of strong interaction of the PEI units with metal nanoparticle surface. Metal nanoparticle morphology here can be affected in the same way as in amphiphilic block copolymer micelles by varying the reducing agent type and the metal compound loading along with varying the pH.

The same block copolymer was successfully used for stabilization of CdS nanoparticles [65]. CdS nanoparticles had a well-resolved cubic structure and were monodisperse. The CdS nanoparticles showed a very good resistance against oxidation for months due to their polymer environment. The particle size was controllable in the range between 2 and 4 nm by adjusting the polymer concentration and choice of the solvent.

The ability of PEO-*b*-PMAA to control inorganic morphologies was applied recently to synthesis of silver nanowires [66]. Yet here a block copolymer was used both as a directing and reducing agent. The authors suggest that formation of double hydrophilic block copolymer complex micelles may play an important role in the directed aggregation growth of the silver nanowires. $CdWO_4$ one-dimensional nanorods with diameters of 2.5 nm were obtained in the presence of a similar double-hydrophilic block copolymer: PEO-*b*-PMAA and its partially phosphonated analog [67]. The $CdWO_4$ species formed in block copolymers showed highly increased fluorescence efficiency.

2.3.2. Nanoparticles in Polyelectrolyte Microgels

Microgels are gel spherical particles having diameters in a nanometer range [68, 69]. Cross-linking grants stability of their sizes and properties while their size ensures formation of colloidal solutions. When these microgels are formed by polyelectrolytes, they contain charged groups which are prone to ion exchange. Charged groups also provide solubilization in water. This allows one to consider microgels as nanoreactors for controlling the nanoparticle growth. Gold nanoparticle formation was studied in microgels based on sulfonated PS [70]. Morphologies of nanoparticles formed are strongly determined by the degree of microgel cross-linking. The higher the cross-linking density, the higher the probability of the formation of spherical particles embedded in the microgels. The type of reducing agent is the other key factor. As found, fast reduction ($NaBH_4$) in water results in small gold nanoparticles (4.5 nm) located in microgels. If $NaBH_4$ is added in alkaline solution (0.1 N NaOH), it slows the nucleation down: this results in 7 nm nanoparticles forming long "threads." Yet only 20% of microgels contain nanoparticles. So slow nucleation allows Au clusters and ions migrate out of ordered microgel areas where aggregation easily occurs. High resolution TEM shows that particles grow from one nucleus and microgel environment governs the particle shape. So here microgel provides a "cage" effect although the "cage" is elastic (not rigid as for HPS). In a similar fashion Pd and Pt nanoparticles have been grown in microgels. These metal-particle-containing microgels were used as co-templates (along with amphiphilic PS-*b*-PEO block copolymers) for mesoporous silica formation [71]. Here microgels play a dual role: they are nanoreactors for metal particle formation and pore-forming templates when mesoporous silica is formed.

2.3.3. Nanoparticle Formation in Dendrimers

Metal particle formation in dendrimers can be treated as an intermediate case between particle formation in the nondense block copolymer micelle cores and in the polymer cavities. Most commonly used and studied dendrimers (commercially available) are poly(amidoamines) (PAMAM), the structure of which is presented in [72]. Varying dendrimer size (dendrimer generation) and metal compound loading, one can vary the size of nanoparticles. For the first time dendrimers were used for stabilization of gold and silver nanoparticles with subsequent self-assembling of metal-containing dendrimers on the surface with monolayer formation [73]. Later [74] PAMAM dendrimers with terminal hydroxyl groups were used as templates and stabilizers for controlled synthesis of monodisperse catalytically active nanoparticles. This was achieved by sorption of metal ions inside the dendrimers. The driving force for metal species incorporation is formation of metal complexes with amino groups. Subsequent reduction results in the formation of metal nanoparticles encapsulated in dendrimers; yet the nanoparticle size is exactly determined by the amount of metal atoms loaded in the dendrimer. Deficiency of metal exchange between dendrimer molecules provides very narrow particle size distribution and subtle control over nanoparticle growth. These metal-containing dendrimers are water-soluble and very stable (no precipitation is observed for months). It is considered that a metal particle is formed in the cavity of the dendrimer. This location provides a certain stabilization of the particles, although a "cage" effect (restriction of the particle growth by the cavity size) is not realized. On the other hand, the presence of functional groups (amino groups) allows additional stabilization

of nanoparticles. Metal particle formation resembles the growth of nanoparticles in the cross-linked cores of block copolymer micelles when exchange between micelles does not occur. If PAMAM contains surface (terminal) amino groups, exchange between dendrimer molecules results in a situation when gold particle growth depends on the ratio of amino group/metal compound [75]. As might be expected, it also resulted in a broader particle size distribution than for PAMAM with terminal hydroxyl groups.

Dendrimer generation is an important factor influencing the particle characteristics [76]. Formation of gold colloids upon reduction of a gold salt precursor in charged PAMAM served as a model reaction to study the influence of reaction conditions and dendrimer generation on the resulting nanostructures [77]. Characterizations by TEM, small-angle neutron scattering, and SAXS show that the gold particles are formed inside the dendrimer and located offset from the center (probably in a dendrimer cavity) (Fig. 7). Lower generation dendrimers aggregate while stabilizing metal nanoparticle growth. Dendrimers of generation 6–9 can template one gold nanoparticle per dendrimer molecule, the size of which is well controlled by the number of gold atoms added per dendrimer. These data well agree with those described in [74]. For generation 10, multiple smaller gold particles per dendrimer were observed and dendrimers aggregated (Fig. 8). In [78] new dendrimers, poly(propyleneimine) dendrimers with stearyl end groups, combining both hydrophilic and hydrophobic moieties were used for metal particle formation. These dendrimers form inverse micelles in toluene. While the initial dendrimers have a spherical structure with a collapsed core, solubilization of metal salt hydrate leads to the formation of cylindrical multidendrimer structures with swollen, metal-salt-filled dendrimer cores. When the gold salt inside the dendrimers is reduced to form colloidal particles, the cylindrical structure breaks up and spherical nanoparticles are formed. Yet the particle sizes are larger than would be expected if the gold salt loading of one dendrimer formed one particle, indicating that the ions from several dendrimers are combined. In the author's opinion, these dendrimer-stabilized metal colloids represent hybrid structures that have potential importance as selective catalysts and in the formation of composite materials with special optical properties. On the other hand, the nanoreactors formed by aggregation of dendrimers with formation of dendrimer micelles are less defined and more complex than simple block copolymer micelles. So advantages of such amphiphilic dendrimers are not evident.

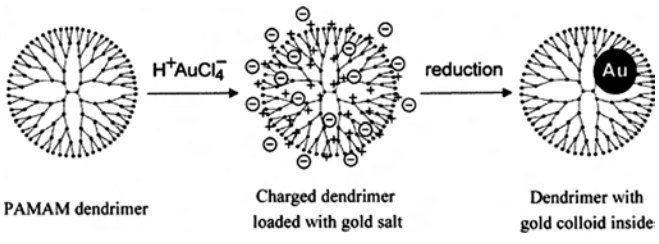

Figure 7. Dendrimer nanotemplating in aqueous solution. In a first step, the dendrimer is loaded with a precursor salt ($H^+AuCl_4^-$), resulting in a charged dendrimer with the precursor as counterions. In a second step, the chemical reduction is performed which yields a colloid inside the dendrimer. Reprinted with permission from [77], F. Gröhn et al., *Macromolecules* 33, 6042 (2000). © 2000, American Chemical Society.

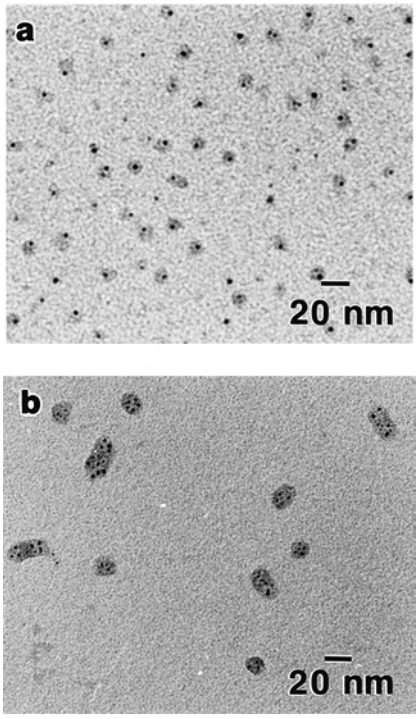

Figure 8. (a) TEM of gold containing G8 PAMAM dendrimer obtained for 1:1 loading and slow reduction. (b) TEM of gold containing G10 PAMAM dendrimer obtained for 1:1 loading and slow reduction. (In both cases the dendrimer has been stained with phosphotungstic acid and appears gray while nanoparticle appears black.) Reprinted with permission from [77], F. Gröhn et al., *Macromolecules* 33, 6042 (2000). © 2000, American Chemical Society.

Along with metal particles, a number of semiconductor particles—CdS [79–81], CdSe [82], and complex core–shell CdSe/ZnS [80]—were successfully prepared in dendrimers. As found in [80], the absorptive and emissive properties of the CdS/PAMAM (hydroxylated) systems are a function of the generation of the dendrimer which is related to the dependence of nanoparticle size on dendrimer generation and the dependence of optical properties on semiconductor nanoparticle size. Additionally, the numerous reactive groups on the surface of the dendrimer can be used to make the composites soluble in essentially any solvent, including water. The luminescence properties of these and other semiconductor nanoparticle/dendrimer nanocomposites will be described below.

3. CHARACTERIZATION

Characterizing nanostructured materials, one faces two challenging tasks: to access nanoparticle characteristics and to get information on nanostructured polymers. Fulfilling these tasks requires using a combination of several modern techniques. The choice of the method is mainly determined by the condition of a polymer matrix (solid state or solution). The following paragraphs give a short description of the major techniques used in characterization of nanostructured polymers with nanoparticles.

Transmission electron microscopy (with magnification 100,000–150,000) is a powerful tool to characterize nanostructured materials with nanoparticles as it allows accessing particle characteristics (size, particle size distribution, particle location) as well as polymer material parameters. Using designated software to process TEM images allows estimation of nanoparticle size and particle size distribution. If one deals with solutions of block copolymer micelles or dendrimers, the TEM sample can be prepared by simply placing a drop of the diluted solution on the electron grid. Micelle or dendrimer size can be obtained from the TEM micrographs along with particle characteristics [42, 43, 74]. Solid materials are normally embedded in the epoxy resin which is then cross-sectioned to allow one to prepare a thin slice. In this case TEM examination allows one to discern the microphase size and shape either in block copolymer bulk or in other solid biphasic materials [7, 38]. The nanoparticles or metal salts in these microphases play the role of staining agents, improving the visualization of the material structure. As seen from the sections above, this method is very commonly used.

One of the key advantages of scanning TEM compared to TEM is that the beam damage is limited to the scanned area since only part of the image is exposed to electrons. This feature can be especially valuable for polymeric systems. Other advantages are high resolution of particle imaging and the possibility of using subnanometer probe and high angle annular dark field (Z-contrast) imaging [83]. Despite these advantages this method is not yet widely used for studying the nanostructured polymers with nanoparticles.

High resolution TEM allows one to obtain more detailed information on nanoparticle size and structure [84, 85]. Along with that, distinguishing the shape of nanocrystals permits conclusions on the nucleation and growth mechanism [70].

Powder X-ray diffraction (XRD) is the convenient method to obtain a mean particle size of crystalline particles [45, 86]. Normally, the corresponding Bragg peaks appearing in the XRD profile allow quantitative assessment of a mean particle size, but no reliable information can be obtained on particle size distribution. Besides, this method cannot be applied to amorphous particles.

Small angle X-ray scattering can be used to characterize the nanoparticles within the nanostructured polymers as well as the nanostructured materials [20, 78]. It allows one to obtain particle size and particle size distribution if the ordered polymer structure does not obscure the assessment of the particle characteristics and does not change polymer ordering during incorporation of metal nanoparticles. In the latter case, ASAXS can be used [22, 39]. Here, the polymer matrix structure does not influence the scattering of the particles as the difference scattering (obtained via subtraction of the scattering curves at the different energies near the adsorption edge of the corresponding metal) is used. Both SAXS and ASAXS can be used for solids and solutions.

Extended X-ray absorption fine structure (EXAFS) and X-ray absorption near-edge structure (XANES) spectroscopies are other methods of choice to characterize nanoparticles and their environments. EXAFS and XANES measurements on the reduced poly(propylene imine) dendrimers with diaminobutane core containing Cu nanoparticles provided additional information on the possible encapsulation of the Cu nanoclusters by the dendrimers and corroborated TEM data [87]. Though these methods are becoming widely used for other types of nanostructured systems (for example, for mesoporous materials with nanoparticles [88]), only a few nanostructured polymers were analyzed in this way. The probable cause of such limited use is the complexity of these methods especially when they are applied to complex nanostructured polymer–nanoparticle systems.

Optical methods (UV absorption and luminescence) are widely used for characterization of the size and size distribution of semiconductor (quantum dots) and some metal (Au, Ag, Cu, etc.) or metal oxide nanoparticles as these parameters determine the optical response [89]. At the same time these methods allow one to characterize the optical properties of nanoparticles [80].

The above methods are designed mainly for particle characterization though TEM and SAXS are also useful for nanostructured polymer description. Other valuable methods for characterization of solutions of nanostructured polymers are DLS [80, 90], static light scattering [91], and sedimentation in an ultracentrifuge [57, 63]. All these methods allow one to obtain sizes of block copolymer micelles, microgels, and dendrimers. Sedimentation in an ultracentrifuge also allows one to distinguish between "empty" polymer nanostructures and those filled with nanoparticles [70].

4. PROPERTIES AND APPLICATIONS

The type of particles embedded in the polymeric materials mainly determines the properties of these materials and their feasible application. Unique properties of nanoparticles can be explained by their huge surface areas and high fraction of surface atoms. This fact is responsible for electron transfer which makes electronic and other properties dependent on the particle size. Both surface area and changed electronic properties are important in catalysis. Electron and spin confinement determines unique optical and magnetic properties of nanoparticles. As discussed in the Section 1, nanoparticles impart their properties to polymeric systems where nanoparticles were grown. In turn, polymers modify the particle surface, often dramatically changing the properties of nanoparticles. Altogether, chemical structure of the polymeric system (functionality and nanostructure) and particle characteristics basically furnish the interface properties and overall material properties [92].

In the following sections, a brief review of the major properties of nanostructured polymers with nanoparticles is presented.

4.1. Catalytic Properties

A majority of noble and transition metal nanoparticles are catalytically active in a number of reactions. Most of the articles dealing with catalytic properties of nanoparticle-containing nanostructured polymers present studies on catalytic hydrogenation of various substrates, as this is an easily available test of catalytic activity. For example, hydroxyl-terminated PAMAM dendrimers containing Pd

nanoparticles showed high catalytic activity in alkene hydrogenation in water [93]. Moreover, the catalytic activity might be controlled by changing the dendrimer size (generation). In the author's opinion, the dendrimer works as a "nanofilter" with a controllable mesh size.

Block copolymer (PS-*b*-P4VP) micelles in organic solvents bearing mono- or bimetallic nanoparticles displayed a high selectivity and activity in hydrogenation of dehydrolinalool to linalool (fragrant substance) [46]. The authors showed that modification of Pd nanoparticles with a second metal alters the electronic properties and surface geometry of the nanoparticles and, as a consequence, catalytic activity. Very high selectivity was provided due to modification of nanoparticle surface with pyridine units of the core-forming block.

Pd nanoparticles stabilized by the above block copolymers were also employed for Heck reaction: cross-coupling of alkylhalides and alkenes [94]. These systems showed reactivity similar to traditionally used Pd complexes but with much higher stability.

Pt nanoparticles formed in HPS [35] were successfully used for direct catalytic oxidation of L-sorbose to 2-keto-L-gulonic acid (vitamin C precursor). Here the catalytic activity and selectivity strongly depend on both the particle size and particle composition. The highest selectivity was obtained for the complex $Pt^0/Pt^{II}/Pt^{IV}$ nanoparticles with a mean diameter of about 1.8 nm obtained *in-situ* during the induction period of catalytic reaction.

So, in general, catalytic properties of such systems depend on the particle size, particle composition, and the type of surrounding polymer system.

4.2. Magnetic Properties

Magnetic properties of particles strongly depend on the particle size: with decrease of the particle diameter, the nature of magnetism changes: ferromagnetic particles become superparamagnetic (do not show hysteresis) and these properties are temperature-dependent. If magnetic particles are formed inside a polymer matrix, magnetic nanocomposites have unique properties and can be used for development of new magnetic and magnetooptical devices [95]. Magnetic measurements are often used for materials containing magnetically active particles to elucidate their composition and structure. In this way, Co nanoparticle formation in the PS-*b*-P4VP micelles and HPS was followed with FMR [32, 47]. In the PS-*b*-P4VP micelles Co nanoparticles were generated by two methods: by reduction of micelles loaded with $CoCl_2$ or by thermal decomposition of $Co_2(CO)_8$ in micellar solutions of these block copolymers [47]. In both cases Co nanoparticles are effectively stabilized by the block copolymer matrix and do not aggregate. For $CoCl_2$, the formed particles have a diameter below 1 nm. Thermal treatment of such dried polymers at 200 °C for 2 h leads to spherical particles of 3–5 nm in size. The polymeric hybrid materials containing the latter particles display remarkably high values of magnetization at rather low Co contents in the polymer (i.e., a tenfold increase of the specific magnetization was obtained). $Co_2(CO)_8$ as a precursor results in more complex behavior. The shape and size of the Co nanoparticles formed by thermolysis can be controlled by the ratio of 4-VP/Co. Both superparamagnetic and ferromagnetic materials can be prepared. For ferromagnetic samples, coercive force is in the range 250–475 Oe depending on the Co content and block copolymer characteristics. Co nanoparticles formed in the PS-*b*-P4VP micelles display remarkable stability under air (FMR signal remains unchanged for months); this confirms strong adsorption of pyridine units on the nanoparticle surface.

Co nanoparticles prepared in triblock copolymer, PDMS-*b*-PCPMS-*b*-PDMS (see Section 5.1.1), showed superparamagnetic behavior; however, some degree of surface oxidation was observed over time, resulting in a decrease in magnetic susceptibility [48].

A novel approach to preparation of magnetic polymeric nanoparticles by synthesis of the magnetite core and polymeric shell [using methacrylate and hydroxyethyl methacrylate (HEMA)] in a single inverse microemulsion was reported in [96]. The polymeric shell size was controlled in the range 80–320 nm by varying the size of the microdroplets. The technique of synthesizing a core and a shell in a single microemulsion has improved the particle structure and size distribution and allowed formation of the particles, made of a superparamagnetic magnetite core coated with a polymeric shell of PMA-*co*-PHEMA random copolymer. Magnetite concentration achieved 3.3 wt%. In a modification of this technique reported in [97], magnetite particles coated with PMAA showed ferromagnetic behavior with coercive force of 50 Oe.

4.3. Optical Properties

UV and luminescence spectra of CdS nanoparticles synthesized in G4 PAMAM with hydroxyl and amino groups [98] showed that the dendrimer stabilizes nanoparticles so their optical properties differ from the CdS bulk. Although dendrimer macromolecules filled with nanoparticles are prone to aggregation, storage at low temperature (−10 °C) prevents the aggregation and solutions retain their photoluminescent properties. The dot–dendrimer nanocomposites can be captured in a SiO_2 sol–gel matrix to yield a stable, bright blue-emitting glass [79].

Similar to dendrimers, Huang et al. [99] prepared CdS-containing nanocomposites using branched PEI as polymer stabilizer. These nanocomposites also demonstrated blue emission but with lower quantum yield. The authors believe that high local concentration of nitrogen atoms (in dendrimer or PEI) is responsible for formation of small well-defined particles.

Semiconductor nanoparticles can be doped with a second metal which strongly modifies the optical properties. Reference [100] reports synthesis of ZnS (doped with Mn and Tb) in microphase-segregated films of diblock copolymers containing carboxylic groups in one block. These films demonstrated emission which is characteristic for doping ions.

A remarkable nanocomposite was prepared by incorporation of CdTe nanoparticles in thin films made by layer-by-layer assembly of an anionic polyelectrolyte with poly(*p*-phenylene ethynylene) backbone (aPPE) and poly(allylamine hydrochloride) polycation [101]. Tethering of CdTe was accomplished by using poly(ethyleneglycol)

(PEG) chains with two reactive termini such as *t*-BOC-NH-PEG-COO-NHS. As found, luminescence spectra after incorporation of particles displays a new peak at 600 nm, identical to the emission peak of CdTe dispersions. Yet the excitation spectrum of CdTe-PEG-aPPE registered at 600 nm reveals a strong new band at 400 nm, which matches the absorption band of aPPE LBL films. This indicates that the light quanta emitted by the nanoparticles originate from the light absorption of the polymer film. The average separation distance between the nanoparticles tethered to the LBL films can be changed by altering the dielectric properties of the solvent affecting PEG tether coiling (water/alcohol mixture). CdTe-PEG-aPPE is an example of an organized nanoparticle system with tunable optical coupling.

4.4. Sensor Properties

Chemical sensors are an important area of the nanoparticle application. Normally, to make a viable device, nanoparticles should be located in a thin film. Polymers are good candidates for nanoparticle stabilization as they easily form films, although particle interaction with polymer functional groups can influence negatively the sensitivity of the sensors. CdS/dendrimer nanocomposites with a range of concentrations of the photoluminescent semiconductor nanocluster and the dendrimer were prepared in methanol and 1:9 methanol:water solutions and used for detection of cyanoacrylate ester fumed and unfumed fingerprints on polyethylene and aluminum foil [102].

Vossmeyer et al. [103] showed that the disulfide-functionalized polyphenylene dendrimers are well suited to layer-by-layer fabrication of gold nanoparticle/dendrimer composite films. During film deposition the dendrimers interact with nanoparticles and form homogeneous and mechanically reinforced films with a good control over the film thickness. When using a film as a chemiresistor sensor device, high sensitivity to vapors of toluene and tetracyanoethylene was observed but its sensitivity to humidity was negligible. The short response times, the high sensitivity to volatile organic compounds, and the low sensitivity to humidity make the material a promising candidate for sensor applications. However, complex response characteristics indicate that the overall sensing mechanism involves several processes and more robust systems should be found.

Another interesting possibility for application of nanoparticles formed in nanostructured polymers is nanolithography. Adsorption of block copolymer micelles containing Au nanoparticles on different substrates (GaAs- or InP-based semiconductor wafers, glass) allows formation of monomicellar films and using these films for nanolithography [104].

5. CONCLUSIONS

The previous sections clearly show that a number of polymeric systems containing nanostructures can provide stabilization of nanoparticles and tailor nanoparticle size, size distribution, and shape. The polymer nanoenvironment also changes the nanoparticle properties via modification of the nanoparticle surface with polymer chains. All of the above allow development of a number of sophisticated polymer nanocomposites with tunable properties and promise for important applications. The area of their possible function determines the prospect for the development of each particular system. For heterogeneous catalysis, nanoporous functionalized polymers with nanoparticles seem to be most promising and robust materials in a number of catalytic reactions, especially if pore size and functionality can be tailored. For solution applications, most promising are block copolymers and dendrimers with nanoparticles. Moreover, block copolymer micelles can form films of various thickness (by spin coating) which is especially important for optical, magnetic, and sensor applications. Both block copolymer and dendrimers can be adsorbed on the surface in a regular manner which is promising for nanolithography. At the same time, one can expect a vigorous development of this field for years to come so new polymeric systems better able to control nanoparticle formation and properties will be developed.

GLOSSARY

Nanocrystal Nanosized crystal.

Nanoenvironment Environment in nanometer scale.

Nanoparticle Particle of nanometer (10^{-9} m) size.

Nanoreactor Nanostructured inhomogeneity in the material where nanoparticles are formed (for example, nanopores or block copolymer micelles).

Nanostructure Structural inhomogeneity of nanometer size.

Nanostructurization Formation of nanostructure.

Nanopinning in High-Temperature Superconductors

J. Horvat

Institute for Superconducting and Electronic Materials, University of Wollongong, New South Wales 2522, Australia

CONTENTS

1. INTRODUCTION

High-temperature superconductivity is one of the most studied phenomena in the last 20 years. This is because of its potential to bring the fascinating world of superconductivity into our everyday life. However, soon after the discovery of high-temperature superconductivity [1–4], it became clear that two main obstacles have to be overcome: vortex pinning and grain connectivity. Improvement of vortex pinning in *high-temperature superconductors* (HTSs) is in the domain of nanotechnology, because of their special intrinsic physical properties. This chapter outlines improvement of vortex pinning in HTSs by introduction of nanosize *pinning centers*.

Because of the wide range of intended readership, the contribution will begin with a simple description of basic principles of superconductivity and vortex pinning. The focus will gradually shift to more specific topics, intended for more advanced readers.

2. SUPERCONDUCTIVITY

We are taught in school that all processes in everyday life are associated with the dissipation of energy. For example, driving a car, more energy is spent than required for mere movement of the car. This is because some of the energy obtained by burning the gasoline is dissipated into the environment through imperfect efficiency of the engine, friction of wheels, and air resistance to the car. Similarly, transport of electrical current through a wire is associated with energy loss. This is due to interaction of the electrons traveling through the wire with the atoms in the wire, whereby they give some of their energy to the atoms, heating up the wire. This phenomenon is called electrical resistance. Wherever we look around us, there is abundance of examples like this. However, superconductors are an exception, they do not exhibit electrical resistance [5–7]. Electrical current flows through superconductors without any loss, until it reaches a critical value. So are they not subject to the same physical laws as all the other phenomena around us? The answer to this can be found in the laws of quantum mechanics.

Quantum mechanics is a branch of physics applicable to atomic and subatomic particles. One of its main postulates is that the energy of these particles can have only certain discrete values [8–11]. The quantum state of a particle, or a system of particles, with the lowest allowed energy is called the ground state. The energy of a particle in the ground state can change only by an amount equal to the difference between the energy of higher lying states and the ground state. Therefore, there is a minimum energy required by the particle in the ground state in order to attain a state with the nearest higher energy level. On the other hand, it cannot transfer its energy to its surroundings, because it is already in the state with the lowest allowed energy level. These principles are vital for understanding the superconductivity and consequently for developing the idea of vortex pinning by nanoparticles in high-temperature superconductors.

The first model explaining superconductivity was the Bardeen–Cooper–Schriefer (BCS) model [12, 13]. It described superconductivity as a quantum state where electrons or holes form Cooper pairs. By pairing, they attain a lower energy level and they are in the ground state. The nearest available state is of a higher energy and there is an energy gap between these two states. When in the ground state, the charge carriers cannot exchange energy with their environment, as long as the energy of the environment is lower than this energy gap. Because of this, they can transfer electrical current through a wire without heating it up (i.e., there is no

Encyclopedia of Nanoscience and Nanotechnology
Edited by H. S. Nalwa
Volume 7: Pages (207–218)

electrical resistance in this wire). However, if thermal energy of the environment is high enough to overcome the energy gap, the Cooper pairs will be broken up and the charge carriers will attain quantum state with a higher energy level. The temperature at which this occurs is called the critical temperature (T_c). BCS theory predicts that the energy gap is actually 3.52 times the thermal energy at T_c, which is close to the value for most of the known superconductors.

All this implies that the superconducting state is a state of lower energy than the resistive state. Therefore, this is a stable state of the materials exhibiting superconductivity and transition into the resistive state requires input of external energy.

Another characteristic property of superconductors is that they screen out the external magnetic field, so that the field $\mathbf{B} = \mu_0(\mathbf{H} + \mathbf{M})$ is zero inside the superconducting volume [5–7]. Here, **B**, **H**, and **M** are vectors of the net magnetic field (also called magnetic induction), external field, and magnetization, respectively. $\mu_0 = 4\pi \times 10^{-7}$ T^2 m^3/J is the permeability of vacuum. This occurs because the magnetic field would otherwise break up the Cooper pairs and the total energy of the system would be higher if the field penetrated superconducting volume. Superconductors are divided into two groups, in regard to their response to external magnetic field. The type I superconductors screen out the external field completely, for small magnetic fields. This is accomplished by maintaining persistent supercurrent near the surface of the superconductor. These supercurrents produce internal field (or magnetization **M**), which cancels the field **H**. For higher fields, the thickness of the layer carrying the supercurrents gradually increases and superconductivity is finally broken down at a field called the critical field H_c.

The type II superconductors behave the same way as type I, up to the first critical field, H_{c1}. For higher fields, they are in a mixed state. Here, the field penetrates the superconductor in the form of thin filaments, called magnetic vortices [14] (Fig. 1). Each vortex carries magnetic flux of one flux quantum: $\Phi_0 = 2.067 \times 10^{-15}$ T m^2. The vortex consists of a core, which is in nonsuperconducting state. The diameter of the core is equal to the *coherence length*, ξ. Magnetic flux inside this core is screened out from the rest of the superconducting volume by persistent supercurrents, circulating the core. The value of the supercurrents decreases exponentially with the distance from the vortex center, with characteristic length scale equal to the London penetration depth, λ. This is mirrored in exponential decrease of **B** with distance from the core (Fig. 2). As external field increases, more magnetic vortices move into the superconductors from its surface. The overall screening around the whole of the superconductor, similar to the type I superconductors, still persists in the mixed state. When the external field reaches a value called the second critical field, H_{c2}, superconductivity is broken down.

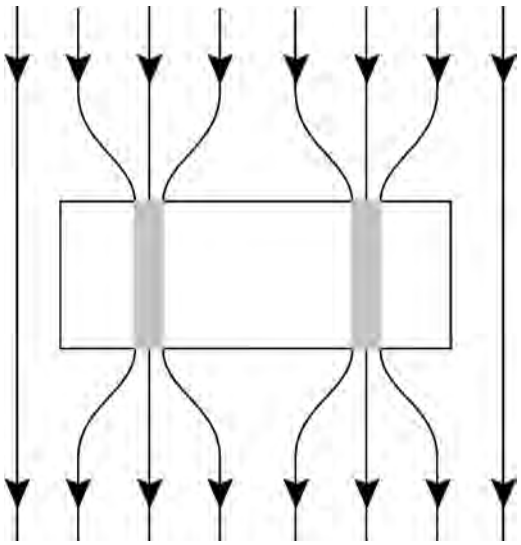

Figure 1. Schematic drawing of the field entering the type II superconductor through magnetic vortices (shaded).

3. VORTEX PINNING

In a perfect superconducting crystal, the vortices make a vortex lattice. The position of each of the vortices is defined by the repulsive force between them. When a current driven by external source is applied to this crystal, the vortices will be subjected to Lorentz force, because they carry a magnetic moment. Because of this, they will move through the crystal, exiting it on one side, whereas new vortices will be entering it on the other side, so that the total number of vortices in the crystal is always the same. The average Lorentz force per unit volume of the crystal is [15]

$$\mathbf{F}_L = \mathbf{J} \times \mathbf{B} \tag{1}$$

where **J** and **B** are spatially averaged transport current density and magnetic field inside the crystal, respectively.

Movement of the vortices is associated with a change of magnetic flux in and around the vortices [16]. This creates electromagnetic force that drives the supercurrents into the resistive core of the vortices. In effect, some of the Cooper pairs are broken down and the charge carriers interact with the crystal lattice, resulting in dissipation of their energy and electrical resistance. According to Bardeen and Stephen [16], about half of the dissipation occurs within the vortex core and half in the transition region just outside the core. This means that a perfect superconductor in the mixed state

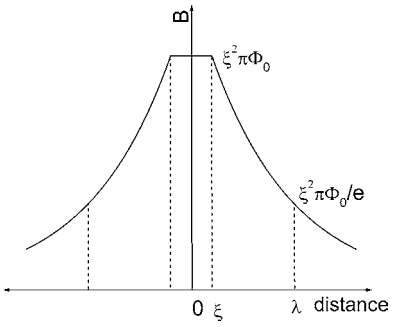

Figure 2. Spatial variation of **B** around a magnetic vortex. **B** is constant inside the nonsuperconducting core of radius of the coherence length ξ. It decreases approximately exponentially with distance outside the core, with the decay length equal to London penetration depth λ.

will exhibit electrical resistance regardless of the value of the transport current.

If, however, the superconducting crystal has defects in its structure, there will be local variations in the superconducting properties. This will result in energetically favorable sites for magnetic vortices, where they will be pinned down. Such sites are called the *pinning centers*. With the vortices pinned, there is again no electrical resistance in the superconductor. However, when applying too large a magnetic field or transport current, Lorentz force on the vortices will exceed the pinning force of the pinning centers. This will set vortices to motion again, and resistance will occur. The current at which the resistance just starts occurring is called the *critical current*, I_c. Additionally, if the thermal energy is higher than the pinning energy, vortices can also escape from the pinning centers. The thermal energy is proportional to temperature T,

$$E_{\text{th}} = k_B T \tag{2}$$

where k_B is the Boltzman constant. Because of this, I_c will become zero for certain combinations of magnetic field and temperature, for which vortices are just released from the pinning centers. They are called *irreversibility field* (H_{irr}) and *irreversibility temperature* (T_{irr}), respectively. Because $T_{\text{irr}} < T_c$ and $H_{\text{irr}} < H_{c2}$, electrical resistance in type II superconductors can occur even when they are still in the superconducting state. Values of H_{irr}, T_{irr}, and critical current density (J_c) are defined by the vortex pinning.

3.1. Mechanisms of Vortex Pinning

Magnetic vortices themselves are associated with variation of superconductivity in them. The core of the vortices is in nonsuperconducting state and carries a magnetic flux. Since the superconductivity is suppressed in the core, its volume is in a state with a higher energy than the superconducting matrix. The energy of the core per unit length is [17]

$$E_{\text{core}} = \frac{H_c^2}{2\mu_0}\pi\xi^2 \tag{3}$$

where $H_c = \Phi_0/(2\pi\xi\lambda\sqrt{2})$.

The core is surrounded by circulating supercurrents. The magnetic energy associated with the currents per unit length of the vortex was estimated as [17]

$$E_{\text{mag}} \approx \frac{H_c^2}{2\mu_0} 4\pi\xi^2 \ln\kappa \tag{4}$$

where $\kappa = \lambda/\xi$ is the Ginzburg–Landau parameter.

As the vortices move through the superconducting crystal with defects, they will encounter places in the crystal with suppressed superconductivity. The total energy of the whole superconducting system is then minimized. This is because vortices themselves are associated with suppression of superconductivity. Occupying a volume in the crystal where superconductivity is also suppressed, the net increase of energy due to the presence of the vortices is lower. Because of this, vortices will be pinned at such pinning centers. There are different types of basic interaction between the vortices and pinning centers.

3.1.1. Core Interaction

Pinning via *core interaction* occurs due to minimization of the core energy of the vortices when they encounter pinning centers [17, 18]. The vortex core energy saved when a vortex encounters a pinning center depends on the geometry of the pinning center and degree of suppression of the order parameter. Pinning force of a pinning center depends on the gradient of the energy variation within the pinning center. If the pinning center is much larger than the vortex core (i.e., ξ), it will be a weak pinning center. This is because the energy of the vortex will change very gradually as it passes the pinning center. On the other hand, if it is much smaller than ξ, it cannot contribute substantially to lowering the energy of the system and the energy gradient is again small, even though the variation occurs on a much smaller scale. Therefore, the most effective pinning centers are of the size of ξ.

3.1.2. Magnetic Interaction

When a vortex approaches a defect in the crystal, its circulating current and associated magnetic fields are redistributed because of the inhomogeneities around the defect. This is reflected in a change of magnetic energy of the vortex. Numerous reports have shown that this interaction can result in vortex pinning [19–21].

3.1.3. Interaction through Variation of Elastic Energy

Superconductivity is associated with small changes of volume ($\Delta V/V \approx 10^{-7}$) and elastic constants ($\Delta K/K \approx 10^{-4}$) of the crystal lattice [17] Because of this, the nonsuperconducting core of magnetic vortices will have different crystal lattice parameters and elastic constants. Consequently, they will behave like inclusions in the superconducting matrix, producing permanent elastic stress field around the vortices. This field will interact with crystal imperfections, which can result in pinning of the vortices [22–25].

3.2. High-Temperature Superconductors

High-temperature superconductors consist of metal-oxide layers, stacked atop each other along the crystalline *c*-axis [26, 27]. There are currently more than 100 known HTS systems. Critical temperature of different HTS spans from below 20 K for $Bi_2Sr_2CuO_6$ [28] or $(Nd_{0.925}Ce_{0.075})_2CuO_{4-\delta}$ [29] to 164 K for $HgBa_2Ca_2Cu_3O_{8+\delta}$ at high pressure [30]. Critical temperatures and coherence lengths of some HTSs are given in Table 1. For comparison, the highest values of T_c for classical superconductors are 23.2 K for Nb_3Ge [50, 51] and 18 K for Nb_3Sn [52].

A common feature of all HTSs is CuO_2 layers situated in the crystalline *ab*-plane (there are some exceptions, for example, $Ba_{1-a}K_aBiO_3$ with T_c of 32 K [53–56] and $YSr_2Ru_{1-b}Cu_bO_6$ with T_c of 60 K [57]). It is generally accepted that the primary sites of superconductivity in HTS crystal structure are these CuO_2 layers [27, 58–60], even though there are some other views, too [61]. While CuO_2 layers are a good conducting medium, the oxide layers between CuO_2 are poor conductors. This results in anisotropic superconducting properties of HTSs. The values

Table 1. Critical temperature (T_c) and in-plane (ξ_{ab}) and out-of-plane (ξ_c) coherence lengths of some high-temperature superconductors.

Superconductor	T_c (K)	Ref.	ξ_{ab} (nm)	ξ_c (nm)	Ref.
$YBa_2Cu_3O_7$	92	[31, 32]	1.2–1.8	0.2–0.3	[43–47]
$DyBa_2Cu_3O_7$	89	[33]			
$Bi_2Sr_2Ca_2Cu_3O_{10}$	110	[34]	0.63–2.9		[35, 36]
$Bi_2Sr_2CaCu_2O_8$	85	[37]	2–4	0.04	[38, 39, 48, 49]
$HgBa_2CuO_{4+\delta}$	97	[30]	2.1	1.2	[40]
$HgBa_2CaCu_2O_{6+\delta}$	128	[30]	1.7	0.4	[41]
$HgBa_2Ca_2Cu_3O_{8+\delta}$	135	[30]	1.5–2	0.19	[40–42]
$Tl_2Ba_2Ca_2Cu_3O_z$	125	[29]			

Note: All values given in the table are measured at atmospheric pressure.

of ξ and λ in the crystalline *ab*-layer are very different from the ones along the crystalline *c*-axis. For example, $\xi_a \approx \xi_b \approx$ 1.2–1.8 nm and $\xi_c \approx 0.2$–0.3 nm for $YBa_2Cu_3O_7$ superconductors (Table 1) [43–47, 62]. Technologically most important HTSs are currently $YBa_2Cu_3O_7$, $Bi_2Sr_2Ca_2Cu_3O_{10}$, and $Bi_2Sr_2CaCu_2O_8$, with anisotropy increasing in the same order.

The small coherence length of HTSs is a major cause for poor connectivity between the HTS crystals. This severely limits transport of the superconducting current through macroscopic conductors made of HTSs. The grain connectivity is still a major obstacle for wider introduction of HTSs in practical applications. Complexities of grain connectivity are beyond the scope of this chapter; detailed reviews can be found elsewhere [63]. The problem of grain connectivity was most successfully solved for $Bi_2Sr_2Ca_2Cu_3O_{10}$. It is produced in the form of kilometer-long wires [30], which can be used for electric cables, transformers, electrical motors, and generators. A weak point of this superconductor is strong suppression of its intracrystalline J_c by magnetic field. In contrast to this, J_c of $YBa_2Cu_3O_7$ crystals is much less sensitive to magnetic field; however, the grain connectivity is a serious problem. Current research efforts are aimed at developing thick films of $YBa_2Cu_3O_7$ with good grain connectivity over a large length. It is predicted that they will replace $Bi_2Sr_2Ca_2Cu_3O_{10}$-based wires in about 10 years.

3.2.1. Magnetic Vortices in High-Temperature Superconductors

The anisotropy in HTSs is reflected in a special structure of magnetic vortices in them. They are described as a pancake-shaped structures residing in CuO_2 layers, with weak connection between the pancake vortices in the neighboring CuO_2 layers (Fig. 3) [64, 65]. The higher the anisotropy of the superconductor, the weaker this connection. Because of a slight anisotropy in the *ab*-plane, the shape of the pancakes is elliptical. The vortex core is of the size of ξ_a and ξ_b in the direction of *a*- and *b*-axes, respectively. The screening currents circulate the core over the length scale of λ_a and λ_b in the direction of *b*- and *a*-axes, respectively.

The density of the vortices depends on magnetic field, because each of the vortices carries one magnetic flux quantum Φ_0. At elevated fields, the density of the vortices is high and they closely approach one another. Because of this, there is a strong interaction between the pancake vortices in each CuO_2 layer in high magnetic fields. In contrast to this, magnetic field strongly suppresses the interaction between the pancake vortices in neighboring layers [65].

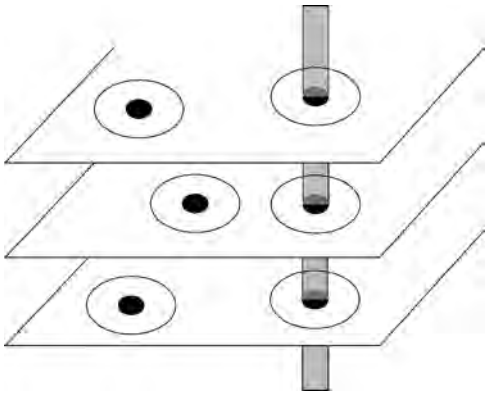

Figure 3. Schematic drawing of pancake vortices in high-temperature superconductors. The nonsuperconducting core (solid ellipse) of the size of coherence length ξ is surrounded by screening currents (open ellipse) that decay with the distance from the core, with a characteristic decay length λ. The diagram is not to scale, because $\xi \ll \lambda$ for high-temperature superconductors. The planes represent the CuO_2 layers. There is only weak interaction between the pancake vortices in neighboring layers and therefore there is almost no correlation of the distribution of pancake vortices in different layers. The shaded area is a columnar defect, which pins down the pancake vortices in different CuO_2 layers along a straight line.

This makes it very difficult to suppress the vortex motion. If there is no strong interaction between the vortices, pinning of one of them will not prevent the others from moving. Introducing the pinning center for each of the vortices is not a viable solution, because the large density of defects in the crystal would destroy the superconductivity in it. The only feasible way is to strengthen the interaction between the pancake vortices. By pinning one pancake vortex in an array of strongly interacting vortices, the unpinned vortices will be tied to the pinning center via this interaction.

3.2.2. Pinning Force in High-Temperature Superconductors

The magnetic energy of the vortices is larger than the core energy by a factor $4 \ln \kappa$ [Eqs. (3) and (4)]. The value of κ for high-temperature superconductors is of the order of 10^3–10^5, implying that the core energy of the vortices is much smaller than the magnetic energy. However, the pinning force depends on the gradient of the pinning energy. The core energy of the vortex changes on the length scale of ξ, and magnetic energy changes on the length scale of λ. Therefore, the gradients of the core energy and magnetic energy are proportional to $1/\xi$ and $1/\lambda$, respectively. This leads to the ratio of the core to magnetic pinning force as

$$\frac{F_{\text{core}}}{F_{\text{mag}}} \propto \frac{\kappa}{\ln \kappa} \tag{5}$$

Because for high-temperature superconductors $\kappa \gg 1$, F_{core} is always much larger than F_{mag}. Pinning force due to the variation of the elastic energy is negligible compared to F_{core} and F_{mag}.

In order to counteract the effect of magnetic field on J_c of high-temperature superconductors, the pinning force has to be larger than the Lorentz force. From this argument if follows that the only effective way of doing so is to improve the vortex pinning by introducing the pinning centers of the size of ξ. The value of ξ in high-temperature superconductors is less than ~10 nm [49–49, 66], which shows that nanosize pinning centers have to be employed in improvement of the critical currents in high-temperature superconductors.

4. NANOSIZE PINNING CENTERS

Nanosize pinning centers have two main advantages over the larger pinning centers. First, they provide a strong pinning force, because their size is comparable to ξ. Second, the volume with suppressed superconductivity is minimized, enabling introduction of a large number of pinning centers without significant degradation of superconductivity of the crystal. These pinning centers can be of spherical or columnar shape, each of them having different pinning properties. They are generally introduced into superconducting crystals by irradiation or doping by nanoparticles.

4.1. Irradiation Defects

Charged elementary particles or heavy ions interact with the atoms of superconducting crystals, transferring some of their kinetic energy to these atoms. If the transferred energy is larger than threshold energy, defects are formed in the crystal. Because each of the defects is formed by individual accelerated particles, the defect size is on the scale of 10 nm. Therefore, these defects are comparable in size to ξ, making them strong pinning centers. The type of defect depends strongly on the type and energy of irradiation.

4.1.1. Heavy Ion Irradiation

Accelerated heavy ions can interact with the target HTS crystal via elastic collisions with the target atoms or via inelastic interaction with the crystal lattice, resulting in ionization or excitation of electron states of the crystal. The type of the incurring damage will depend on the rate of energy loss, dE/dx, of the ions as they penetrate the crystal.

For low-energy ions, elastic collisions dominate, resulting in displacement of atoms from crystal lattice and pointlike defects. For high-energy ions, inelastic collisions dominate. Experiment shows that the inelastic collisions with high-energy ions can result in amorphous columnar tracks in HTSs [67]. The diameter of the tracks is about 10 nm and the length is tens of μm. An important parameter defining the formation of the columnar defects is the electronic energy loss, also called electronic stopping power, S_e. It is defined as the energy transfer into the electronic excitations of the target atoms per unit length along the ion path through the target crystal: $S_e = -dE_e/dx$. The value of S_e depends on the type of the target crystal, type, and energy of the ion and direction of the irradiation in regard to the crystal structure. It can be approximated as [68]

$$S_e = \frac{2h^3}{m_e \pi^2 e^2}\left(\frac{2E}{M}\right)^{1/2} Z^{2/3} \sum_i n_i Z_i^{1/3} \tag{6}$$

where Z and Z_i are respectively the atomic numbers of the incident ions and various target atoms, E is the energy of incident ions, n_i is the number of the target atoms of type i per unit volume, M and m_e are respectively the mass of the incident ion and electron, h is the Planck constant, and e is the base of natural logarithms.

Formation of amorphous columnar defects is described by the thermal spike model [69–72]. Because columnar defects are formed as a consequence of electronic excitation by the heavy ions, there has to be a mechanism of the transfer of this energy to the crystal lattice. The thermal spike model does not explain the nature of these interactions; however, it explains formation of the columnar defects in a thermodynamic approach. The energy transfer from the heavy ions to the electronic excitations occurs on a much smaller time scale than the subsequent transfer of this energy into the thermal energy of the crystal lattice. This heats up the crystal on a very localized scale around the atom targeted by a heavy ion. The heat is then diffused to the rest of the crystal on a larger time scale than the energy transfer to the crystal lattice, until the thermal equilibrium is reached.

Because of the transfer of the energy from the heavy ions to the electrons and to crystal lattice on a subsequently increasing time scale, a sudden localized increase of temperature occurs around the target atom of the crystal. For the value of S_e higher than a threshold value S_{e0}, the crystal lattice melts in much localized volume along the ion track. Because the diameter of the molten volume is very small (of the order of a nanometer), this heat is diffused through the crystal lattice quickly enough to freeze the molten volume without allowing recrystallization. Consequently, a track of amorphous material is formed in the crystal, which is not superconducting.

High-resolution electron microscopy analysis suggests that there are five ranges with different types of the damage, depending on S_e [67, 73–75]. Below S_{e0}, the damage occurs only due to the elastic collisions. For higher values of S_e, small spherical amorphous defects were observed along the ion track. These defects become elongated for yet higher S_e. For still higher S_e, discontinuous amorphous cylinders were observed along the ion track. For the largest values of S_e, continuous columnar amorphous cylinders were observed along the whole of the ion tracks. The values of S_e separating different ranges depend on the properties of the ions and target.

The thermal spike model gives a relationship between S_e and the track diameter. For the ion beam directed along the c-axis of the crystal, the amorphous track is of circular cross-section with diameter [68]

$$d = \left(\frac{4S_e}{\pi e C \Delta T_m}\right)^{1/2} \tag{7}$$

where C is the heat capacity per unit volume and ΔT_m is the difference between the melting and ambient temperature when the ion travels along the a- or b-axis of the crystal. If the ion travels along the a- or b-axis, the amorphous track is

of elliptical cross-section. The elliptical axes in the *ab*-plane and *c*-axis are respectively [68]

$$d_{ab} = d\left(\frac{D_{ab}}{D_c}\right)^{1/4} \tag{8}$$

$$d_c = d\left(\frac{D_c}{D_{ab}}\right)^{1/4} \tag{9}$$

Here, $D_{ab} = \sigma_{ab}/C$ and $D_c = \sigma_c/C$, with σ_{ab} and σ_c being the thermal conductivity in the crystalline *ab*-plane and along the *c*-axis, respectively. The value of d increases with the energy of the heavy ions via S_e and ΔT_m in Eq. (7).

4.1.2. Neutron and Proton Irradiation

Neutrons are electrically neutral particles and they do not have significant interaction with the electrons. They interact with the nuclei of the atoms in crystalline lattice. The maximum energy transferred to a crystal atom in elastic collision with a neutron is [76]

$$E_t = \frac{4m_n M}{(m_n + M)^2} E_n \tag{10}$$

where m_n and M are respectively the mass of neutron and target atom and E_n is the incident neutron energy. Neutron irradiation produces defects, with values of E_t ranging from the displacement threshold energy for different crystal lattices (~20 eV) to well above 100 keV.

For low values of E_t, point defects are produced. However, for roughly $E_t > 30$ keV, cascade defects are observed. When a high-energy neutron collides with an atom, E_t may be much higher than the threshold energy for the displacement of the atom. The high-energy displaced atom will cascade with other atoms in the crystal, displacing them, too. Cascade collisions will occur, eventually transferring the energy to the crystal lattice. This increases the temperature of the lattice beyond the melting point. A fast cooling follows, due to the small size of the molten volume, resulting in amorphous defects in the crystal. The size of these defects is 2–30 nm and it increases with the neutron energy [77–80]. The cascade defects are of irregular shape and are generally larger than the columnar defects obtained in heavy ion irradiation [81]. As opposed to the point defects, they are not annealed out at 300 °C [78].

Protons are charged particles and when accelerated to 800 MeV, they can also produce columnar tracks [82], similar to the heavy ions. Low energy protons (3 MeV) produce point defects, which have different pinning properties [83].

Neutron and proton irradiation can also be used for introduction of defects in inelastic interactions with nuclei in crystalline lattice [84, 85]. These interactions can provoke a nuclear reaction of the atoms in the crystalline lattice, or dopants. The products of the reaction are high-energy charged particles, which produce columnar tracks along their paths. The diameter of the tracks is typically less than 10 nm. These tracks are randomly orientated and they have proven to provide vortex pinning that is stronger than pinning on parallel columnar tracks [86, 87].

4.1.3. Electron Irradiation

High-energy electrons can be accelerated to energies of ~30 MeV [88]. Most of their energy is transferred to the superconducting crystal via electronic excitations of the target atoms. However, the energy of the electrons is too small to produce amorphous tracks of the type of heavy ion irradiation in this process. A small part of their energy is transferred to the crystal via elastic collisions with the atoms. It is estimated that about 40 eV is transferred to the target atom per elastic collision [88], which is of the order of the threshold energy needed to displace the target atoms from HTS crystal. Because of this, electron irradiation can produce only point defects [89] in the crystal, which do not contribute significantly to the vortex pinning [90, 91].

4.1.4. Columnar Defects

High-resolution electron microscopy examinations of heavy-ion irradiated HTS crystals showed a qualitative agreement with the thermal spike model [68]. $YBa_2Cu_3O_{6.3}$ and $Bi_2Sr_2Ca_2Cu_3O_{10}$ superconductors were irradiated with Au^{24+}, Ag^{21+}, Cu^{18+}, and Si^{13+} ions of 300, 276, 236, and 182 MeV, respectively. The energy loss was respectively 34.8, 23.8, 13.4, and 3.8 keV/nm. Only Au^{24+} ions produced continuous amorphous columns along the whole of their tracks. Each Au^{24+} ion produced a single columnar defect. However, only 50% of Ag^{21+} ions produced continuous columnar defects. Cu^{18+} ions produced only occasional columnar defect, whereas no columnar defects were observed for Si^{13+} ions. There was a threshold energy loss, below which no columnar defects were observed, for both types of superconductors. The cross-sectional area of the columns was circular for the ion beam directed along the crystalline *c*-axis, whereas it was of elliptical shape with the ion beam along either the *a*- or *b*-axis [68].

Continuous columnar defects introduced by heavy ions with energies higher than several hundreds of MeV are the best pinning centers in HTSs because they are about the size of ξ and they effectively tie together pancake vortices in different CuO_2 layers along a single straight line for each pinning center (Fig. 3). As opposed to the point defects, every pancake vortex along the line is pinned down. Thus pinned pancake vortices effectively behave as a vortex line. This is energetically more favorable than a stack of weakly coupled pancake vortices pinned randomly by point defects. The pancake vortices would meander inside the crystal from one point defect to the other, and the magnetic flux would occupy a larger volume in the crystal than a straight vortex line pinned by a columnar defect. Therefore, columnar defects provide the largest net pinning force. In addition, pancake vortices of such vortex lines cannot be individually excited away from the pinning site by thermal excitation. Consequently, pinning by columnar defects will be effective at high temperatures, which is not the case with the pointlike pinning centers. Improvement of the vortex pinning by columnar defects is the largest for HTSs with the highest anisotropy, because they exhibit the weakest interlayer coupling between the pancake vortices.

Improvement of J_c by introduction of columnar pinning centers has been observed for many HTSs [92–96]. Columnar defects were especially effective for highly anisotropic

HTSs. Irradiation of $Bi_2Sr_2CaCu_2O_8$ with 502 MeV ^{127}I ions resulted in the highest reported increase of J_c, up to 1000 times, as measured at 30 K and field of 2 T [97]. J_c for less anisotropic HTSs is usually improved 4–100 times, depending on the temperature, field, and HTS involved (Fig. 4) [83, 91].

To show that the improvement of J_c was indeed due to columnar defects, $YBa_2Cu_3O_7$ crystals were irradiated with 580 MeV $^{116}Sn^{30+}$ ions at an angle of 30° to the crystalline c-axis [98]. Field dependence of J_c was measured with the field oriented at 30° and −30° to the c-axis. A much higher value of J_c was obtained when the field was parallel to the ion beam, because vortices were pinned more effectively when aligned along the columnar tracks produced by the ion beam.

Improvement of J_c with the introduction of columnar defects is reflected in the increase of the values of H_{irr} and T_{irr}, which form the *irreversibility line* in the (H, T) diagram. Above the irreversibility line, J_c is negligibly small. Measurements of the irreversibility line for $YBa_2Cu_3O_7$ crystals showed that irradiation with 5.3 GeV Pb ions to a fluence of 7×10^9 ions/cm^2 produces a dramatic shift of the irreversibility line to higher fields and temperatures (Fig. 5) [99]. Experiments with 580 MeV Sn ions showed similar but less pronounced effects [98]. A strong increase of H_{irr} and T_{irr} was also obtained by irradiation of more anisotropic $Bi_2Sr_2CaCu_2O_8$ with 230 MeV Au^{14+} ions [95] and 6 GeV Pb ions [100].

Another important feature of pinning by columnar defects is that they give strong improvement of J_c at high temperatures, above $T = 0.5\ T_c$. While irradiation of $YBa_2Cu_3O_7$ crystals with 580 MeV Sn ions produced a drastic increase of J_c at 77 K (Fig. 4), point defects introduced by 3 MeV proton irradiation gave much weaker improvement of J_c at this temperature, especially at high fields [83].

Introduction of columnar defects is accompanied by an increase of the effective pinning energy of the crystal [101]. This in contrast to radiation induced point defects, which do not affect the pinning energy substantially [91, 102].

4.1.5. Splayed Defects

Theory shows that it is better to introduce columnar defects that are not parallel to each other, but splayed randomly in many directions [86, 103–107]. The most efficient way

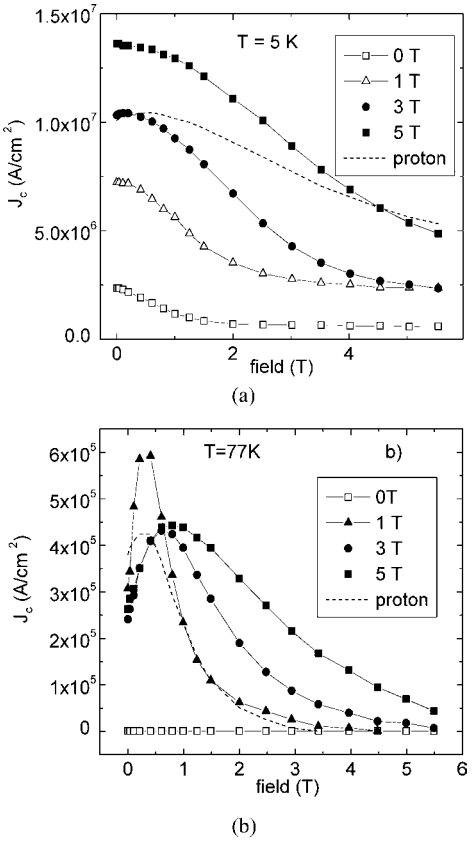

Figure 4. Critical current for $YBa_2Cu_3O_7$ crystals irradiated with 580 MeV Sn ions along their crystalline c-axis. The density of the defects produced is equivalent to trapping the magnetic vortices whose net magnetic field would correspond to the numbers indicated in the figures (each vortex carries magnetic flux $\Phi_0 = 2 \times 10^{-15}$ T m^2). Field dependence of J_c for the crystals irradiated with 3 MeV protons is shown for comparison. The temperature at which J_c was measured was (a) 5 and (b) 77 K. B* 44, 7167 (1991). © 1991, American Physical Society.

to introduce the splayed columnar defects is to instigate nuclear fission of small number of atoms in superconducting crystal. This can be achieved by doping an HTS with small amount of ^{235}U and then irradiating it with thermal neutrons [84, 108, 109]. ^{235}U is split into two fission products with energies of about 100 MeV each [110]. Because of the relatively low energy of the fission products, discontinuous columnar defects are obtained [111]. These defects are randomly splayed in the crystal. They produce an increase of J_c of 10–20 times for $Bi_2Sr_2Ca_2Cu_3O_{10}$ and shift of the irreversibility line to higher fields and temperatures.

Another way to introduce the splayed defects by fission fragments is irradiating $Bi_2Sr_2CaCu_2O_8$ that contains ^{209}Bi with 0.8 GeV protons [87, 112]. Irradiating ^{209}Bi with neutrons triggered nuclear fission. Typical fission products are 80 MeV Xe and 100 MeV Kr, which produce splayed discontinuous columnar defects of diameter up to 7 nm. A strong improvement of irreversibility line and J_c was observed, which was better than for the parallel columnar defects. The improvement was observed at all temperatures and fields. Similar results were obtained with neutron irradiation of lithium-doped $Bi_2Sr_2CaCu_2O_8$ [113]. There, neutron irradiation caused nuclear fission of Li atoms.

The effect of the splayed columnar defects on vortex pinning can be most effectively studied by rocking the HTS crystal upon high-energy heavy ion irradiation [114, 115]. As opposed to the defects introduced by fission products, the direction of the columnar defects can be easily controlled in this way. Increase of J_c by 14 times was obtained when irradiating $DyBa_2Cu_3O_7$ crystal at 45° and −45° to its surface, as compared to the parallel ion tracks with the ion beam perpendicular to the crystal surface [114]. The optimum splay angle for $YBa_2Cu_3O_7$ crystal was found to be ±5° with respect to the axis perpendicular to the *ab*-plane, with magnetic field oriented along this axis (i.e., at 0°) [116]. After irradiation with splay angle of ±5°, J_c increased respectively 10 and 10^4 times at temperatures of 5 and 77 K. With different splay angles, the increase was up to several times lower. However, splaying of the columnar defects seems to be much less effective for more anisotropic HTSs, like $Bi_2Sr_2CaCu_2O_8$ [100, 107]. This was attributed to the more pronounced pancake structure of magnetic vortices in highly anisotropic HTS, and increase of the diameter of columnar tracks by tilting the track away from the crystalline *c*-axis [100] [Eqs. (7)–(9)].

4.1.6. Point Defects

Point defects are introduced by low-energy particles (ions, protons, neutrons, electrons), which have low stopping power in HTS crystals. A common property of the pointlike pinning centers is that they generally improve J_c at temperatures lower than 0.5 T_c [88, 90, 91]. At higher temperatures, the improvement is insignificant. The pinning energy of these defects differs very little from the energy of the defects already in the crystal before the irradiation [91, 102]. Therefore, J_c increases because of the increased density of the pinning centers with the irradiation.

As opposed to the columnar pinning centers, the irreversibility line does not change with introduction of pointlike pinning centers. The irreversibility line for 3 MeV proton irradiated $YBa_2Cu_3O_7$ crystals was found to be independent of the proton fluence, even though J_c was improved by more than 10 times at 77 K [83]. On the other hand, irradiation of $Bi_2Sr_2CaCu_2O_8$ with 400 MeV oxygen ions resulted in only a slight shift of irreversibility line to higher values of fields and temperatures [117]. This is consistent with the dependence of the type of damage track on the energy loss [68]. Protons of 3 MeV produce point defects, which do not affect the irreversibility line. On the other hand, light oxygen ions produce a small number of columnar tracks, together with point defects, affecting the irreversibility line slightly.

High-energy neutrons and protons can produce cascade defects, which have vortex pinning properties somewhere between the point and columnar defects. Irradiation of $YBa_2Cu_3O_7$ crystals with 3 MeV protons resulted in defects, 30% of which were cascade defects [83]. J_c increased by an order of magnitude at both 5 and 77 K, whereas the pinning energy increased by only 25%. The irreversibility line, however, did not change. Irradiation of $YBa_2Cu_3O_7$ crystals with fast neutrons ($E_n > 0.1$ MeV) resulted in point and cascade defects. Value of J_c increased by an order of magnitude, at both low and high temperatures [77, 78, 80]. As opposed to the point defects, the cascade defects could not be annealed out at 300 °C [78]. The irreversibility line was also shifted to higher values of field and temperatures. Irradiation of $HgBa_2CuO_{4+\delta}$ [118] and $HgBa_2Ca_2Cu_3O_{8+\delta}$ [119–121] with fast neutrons ($E_n > 0.1$ MeV) also resulted in an increase of J_c, H_{irr}, and T_{irr} at low and high temperatures.

4.2. Doping with Nanoparticles

Doping with nonsuperconducting nanoparticles is another way to introduce pinning centers into HTSs. This way is more practical than the irradiation techniques, from the point of view of large-scale applications of HTSs. This is because irradiation techniques would be difficult to employ in industrial size applications. The nanoparticles have to satisfy certain criteria to be acceptable as pinning centers. Their presence should not affect the formation of the superconducting phase. They should not agglomerate in the superconductor, ensuring that the nonsuperconducting inclusions are of the size of ξ. The molten precursors for the superconductor should adhere to the surface of the nanoparticles, to ensure their incorporation into superconducting crystal. As with the irradiation-induced defects, the pinning properties depend on the shape of the particles.

4.2.1. Spherical Particles

Pinning centers formed by spherical particles incorporated into superconducting matrix have pinning properties similar to discontinuous defects introduced by irradiation. Chemically stable compounds are used, such as MgO [122, 123], ZrO_2 [124], and SiC [125]. They were incorporated into $Bi_2Sr_2Ca_2Cu_3O_{10}$, $Bi_2Sr_2CaCu_2O_8$, and $YBa_2Cu_3O_7$ superconductors, respectively. SiC nanoparticles were also used for doping of silver-sheathed $Bi_2Sr_2Ca_2Cu_3O_{10}$ tapes [126, 127]. Spherical particles of diameter about 20 nm were thoroughly mixed with precursor powder for production of HTSs. The superconductor was formed in thermal treatment, in which a liquid phase occurred before the formation of the superconductor. Because the liquid adhered to

the surface of the nanoparticles, they were incorporated into the superconducting crystal. Increase of J_c with this doping was usually less than 10 times at 5 K, whereas there was no significant increase at high temperatures [128]. The doping levels were generally kept below 5% by weight.

Doping of $YBa_2Cu_3O_7$ with SnO_2 and CeO_2 particles resulted in a moderate increase of J_c [129–131]. However, using nanosize particles did not have any advantage over the micrometer-size particles [129]. This was attributed to poor adherence of the molten phase of the superconductor to these particles.

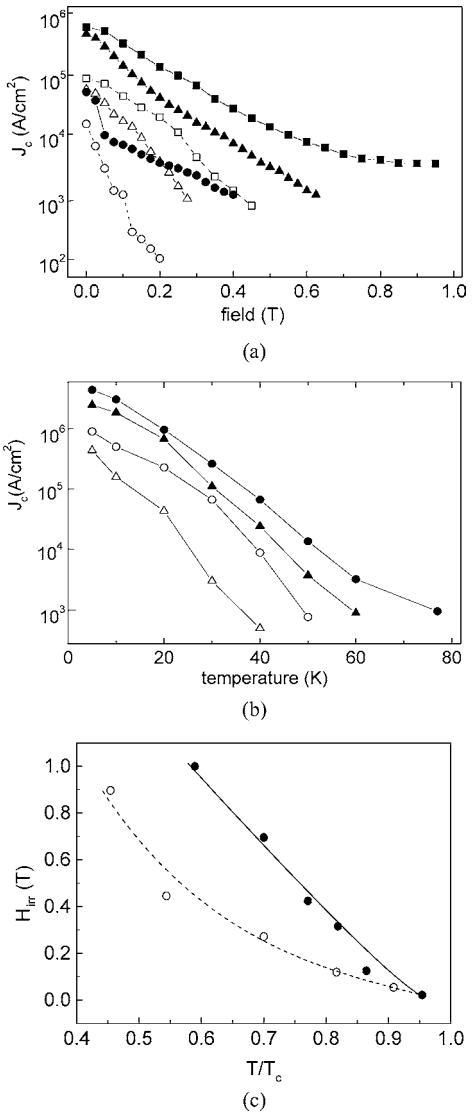

Figure 6. (a) Field dependence of critical current density for $Tl_2Ba_2Ca_2Cu_3O_z$ high-temperature superconductor doped with MgO nanorods. Measurements at 50, 60, and 90 K are represented by squares, triangles, and circles, respectively. Open and solid symbols represent J_c before and after introduction of MgO nanorods. (b) Temperature dependence of the critical current density for the same samples. The field was 0.5 and 0.8 T, represented by circles and triangles, respectively. (c) Irreversibility line for the same samples. Open and solid symbols represent the data before and after doping with MgO nanorods, respectively. Reprinted with permission from [133], P. Yang and C. M. Lieber, *Appl. Phys. Lett.* 70, 3158 (1977). © 1977, American Institute of Physics.

4.2.2. Nanorods

Incorporating nonsuperconducting particles in the shape of nanorods should produce extended pinning centers resembling continuous columnar defects introduced by high-energy heavy ion irradiation. Nanorods of MgO were used for improving the vortex pinning in $Bi_2Sr_2Ca_2Cu_3O_{10}$, [132] $Bi_2Sr_2CaCu_2O_8$ [128], and $Tl_2Ba_2Ca_2Cu_3O_z$ [133] superconductors. The diameter of the nanorods was 5–50 nm and length was about 2 μm. They were orientated preferably along two directions in the crystal: parallel and perpendicular to the crystalline c-axis [128].

Doping increased the value of J_c about 10 times, at all temperatures (Fig. 6) [128, 132, 133]. The increase was more pronounced at higher fields and temperatures. The values of J_c depended approximately inversely on the diameter of the nanorods. The irreversibility line was shifted to higher fields and temperatures with the doping (Fig. 6). All this is consistent with the pinning by columnar defects. Further proof for that was doping of $Bi_2Sr_2CaCu_2O_8$ with MgO nanoparticles of spherical shape [128]. This resulted in an increase of J_c only at temperatures lower than 25 K, consistent with point-defect pinning.

$Bi_2Sr_2CaCu_2O_8$ was also doped with *carbon nanotubes* [134, 135]. The carbon nanotubes consisted of one or more cylindrical shells of graphite. Their outer and inner diameters were respectively 2–20 and 1–3 nm. Their length was several micrometers. Embedding the nanotubes into $Bi_2Sr_2CaCu_2O_8$ gave increased vortex pinning at temperatures lower than 53 K. This increase of pinning was ascribed to the nanotubes, which are of size and shape comparable to the irradiation induced columnar defects.

Needle-shaped particles of CuO were also incorporated into $Bi_2Sr_2CaCu_2O_8$ [136]. The CuO particles were of diameter of about 50 nm and length 3 μm. J_c increased by more than an order of magnitude at 30 K and $H > 0.2$ T (Fig. 7). Such large improvement of J_c was attributed to the small size of the particles and even distribution within the crystal.

5. CONCLUSION

Strong improvement of vortex pinning in HTSs can only be achieved by introduction of pinning centers smaller than 10 nm. For pinning centers of spherical shape, J_c improves substantially only at temperatures lower than about 0.5 T_c and the irreversibility line does not change significantly. Pinning centers in the form of continuous columns improve J_c at all temperatures and significantly shift the irreversibility line to higher fields and temperatures. These pinning centers are especially effective if they are oriented randomly in the superconducting crystal.

Nanosize pinning centers have been introduced into HTSs by irradiation and doping with nanoparticles. The strongest improvement of the vortex pinning was achieved by swift heavy ion irradiation, upon which continuous columnar defects were formed in HTS crystals. The most successful doping technique was utilization of MgO nanorods.

GLOSSARY

Coherence length Characteristic length scale over which the charge carriers within Cooper pairs can still interact with each other.

Cooper pairs Charge carriers paired together by exchange of a phonon. They are basic blocks of superconductivity.

Critical current Maximum current through a superconductor that still does not produce dissipation of energy.

Flux quantum The lowest possible value of magnetic flux. Any change of magnetic flux occurs stepwise, in multiples of the flux quantum.

Irreversibility line Field and temperature above which the critical current is zero.

ACKNOWLEDGMENT

Many thanks are due to my wife, Greer Taylor, for her help with preparation of the figures.

Nanopipes in Transition Metal Nitrides

Daniel Gall

Rensselaer Polytechnic Institute, Troy, New York, USA

CONTENTS

1. INTRODUCTION

Transition metal (TM) nitrides are well known for their remarkable physical properties including high hardness and mechanical strength, chemical inertness, and electrical resistivities that vary from metallic to semiconducting. As a result, they are widely studied and have become technologically important for applications such as hard wear resistant coatings on cutting tools, as diffusion barriers in microelectronic devices, and as corrosion and abrasion resistant layers on optical components. Transition metals from the left side of the periodic table, including Sc, Ti, V, Cr, Y, Zr, Nb, Hf, and Ta, form nitrides with a B1–NaCl structure [1, 2]. The excellent mechanical properties of these materials are due to strong covalent–ionic bonds between the TM and N ions resulting from the fully occupied N 2p bands [2, 3].

The chemical bonding in NaCl structure transition metal nitrides occurs along perpendicular $\langle 100 \rangle$ directions. This strong bonding directionality results in dramatic changes in surface atom mobilities as a function of crystalline facet orientation, leading to a range of highly anisotropic effects including strong preferred texture development in polycrystalline thin films, anisotropic microstructures, and orientation-dependent properties including hardness, wear strength, adhesion, chemical inertness, and diffusion.

Recent advances in the growth of single crystalline layers of NaCl structure transition metal nitrides have shown that these highly anisotropic effects cause another remarkable feature: Epitaxial layers exhibit, due to atomic shadowing from kinetically roughened periodic surface mound structures, arrays of self-organized rectangular 1-nm-wide nanopipes. These nanopipes are open "holes" that extend through the entire layer thickness along the [001] growth direction. Their high degree of self-organization, due to kinetic faceting, leads to extremely high aspect ratios on the order of 1000. This, in turn, offers tremendous potential for technological applications in a wide range of fields including nanoelectronics, single molecule chemistry, sensors, and integrated low-dimensionality devices.

This chapter summarizes current understanding for the growth of such nanopipes, the underlying physical properties of their formation, and methods to control their shape, size, and separation. The first section reviews recent findings describing the atomistic processes that govern the growth of transition metal nitrides, including the effects of anisotropic surface diffusion, atomic N flux, adatom potential energies, and ion irradiation. This is followed by a discussion on the key processes leading to nanopipe formation, that is, kinetic roughening, surface morphological evolution, and atomic shadowing. The last section describes the actual growth on nanopipes, strongly utilizing the concepts described in the preceding sections, and provides insight into nanopipe manipulation.

2. ATOMISTIC PROCESSES IN THE GROWTH OF TRANSITION METAL NITRIDE LAYERS

Transition metal nitride layers are typically grown by reactive sputter deposition, where the metal atoms, emanating from the sputter source, impinge on the substrate from the gas phase while the nitrogen supply is provided by a N_2 atmosphere. The microstructure of the deposited layers defined by their density, texture, strain, grain sizes, and surface morphology, determines performance, usefulness, and lifetime of the coatings for a given application. A dramatic example of this microstructure–property relationship has been demonstrated by Chun et al. [4–7] who investigated the effect of crystalline texture of TiN layers in microelectronic applications. They found that TiN diffusion barriers with

Volume 7: Pages (219–227)

111 texture, that is, layers in which the crystalline grains are oriented such that the ⟨111⟩ direction is perpendicular to the substrate surface, exhibit a break down temperature of 450 °C, whereas 001-oriented layers are stable up to 560 °C, a technologically very relevant improvement.

Texture evolution in NaCl structure transition metal nitrides has been studied widely and the results of these investigations provide insight into the atomistic processes that govern layer growth. During the initial stages of growth, primarily 001- and 111-oriented grains nucleate with approximately equal number densities [8, 9]. However, grain growth rates are a function of crystalline orientation. This leads, with increasing film thickness, to the development of strong preferred layer orientation that is either 001 or 111, depending upon film deposition conditions, [4, 8–11]. A model system to study the competition between 111- and 001-oriented grains is the growth of ScN on single crystal MgO(001) substrates. While both layer and substrate crystallize with a cubic structure, there is a 7% lattice mismatch between MgO (a_o = 4.213 Å) and ScN (a_o = 4.501 Å), leading to two possible orientations for ScN nuclei. ScN grains can grow with 001 orientation and a cube-on-cube epitaxial relationship with $(001)_{ScN}||(001)_{MgO}$ and $[100]_{ScN}||[100]_{MgO}$. Alternatively, 111-oriented grains also nucleate with local epitaxy. In that case, strained triangular unit cells of the ScN (111) planes mesh with the squares of the MgO(001) surface, resulting in an epitaxial relationship with $(111)_{ScN}||(001)_{MgO}$ and $[11\bar{2}]_{ScN}||[110]_{MgO}$. Exactly these two grain orientations are observed experimentally by a combination of X-ray diffraction ω-2θ scans and pole figures, as well as electron diffraction patterns from ScN/MgO(001) layers grown in pure N_2 discharges at 750 °C [12]. Cross-sectional transmission electron microscopy shows that these layers exhibit a columnar microstructure. Both grain orientations nucleate with approximately equal volume fractions. However, the width of the 001 columns, which have broad bases and peaked tops, decreases with increasing layer thickness, and they are overtaken by columns with 111 orientation. Thus, the preferred orientation evolves toward a purely 111 texture within ≈40 nm as the 001 grains grow out of existence.

The lowest surface energy face for cubic TM nitrides is the (001), because metal–nitrogen bonds are along perpendicular ⟨100⟩ directions. Hence, 001 is expected to be the preferred orientation under growth conditions where adatom mobilities are sufficiently high to favor crystallites bound by low-energy planes. However, the described result from ScN, together with reports on TiN [8], $Ti_{0.5}Al_{0.5}N$ [13], and TaN [14], all indicate the opposite trend. Thus, the eventual dominance of the 111 versus 001 texture during competitive columnar growth must be due to kinetic limitations during film growth rather than thermodynamic driving forces, as described in the following argument.

An adatom on a (111) surface has three backbonds to N surface atoms and consequently a low potential energy and small surface mobility. In contrast, adatoms on (001) surfaces, with only one N backbond diffuse at much higher rates and may cross a grain boundary to a 111-oriented grain. Thus, adatoms that are stochastically deposited near grain boundaries and, through surface diffusion, sample sites on both sides of the boundary have a higher probability of becoming incorporated at the low-diffusivity (111) surface, which provides the more stable, lower potential energy sites. Conversely, adatoms on high-diffusivity planes have larger mean free paths with correspondingly higher probabilities to move off the plane and become trapped on adjacent grains. The consequence is a net adatom flux from the 001- to the 111-oriented grains, leading to the 111 grains overgrowing the 001 which die out.

This argument is consistent with detailed *ab initio* density functional studies of adsorption and binding energies of adatoms on TiN(001) and TiN(111) [15]. Calculated adsorption energies for Ti adatoms are 3.30 and 10.09 eV, with activation barriers for surface diffusion of 0.35 and 1.74 eV, on TiN(001) and TiN(111), respectively. Thus, Ti adatoms are much more stable and have a much lower surface mobility on 111- versus 001-oriented grains. Atomistic Monte Carlo simulations for face centered cubic metal film growth [16] indicate a trend similar to that reported for the growth of transition metal nitrides. The higher-energy surface emerges as the preferred orientation, primarily due to kinetic limitations.

In summary, the texture of transition metal nitride layers gradually evolves toward 111, due to a combination of a large cation surface diffusion length on the (001) surface combined with a considerably lower adatom potential energy on the (111) versus the (001) surface, leading to a net flux from 001- to 111-oriented grains. However, this effect can be totally reversed by high-flux ion irradiation during growth, as described in the following paragraphs.

Magnetically unbalanced magnetron sputter deposition methods have been developed to investigate plasma–surface interactions during film growth [17]. In such experiments, an external magnetic field is used to shape the plasma near the substrate, resulting in an increase by up to 2 orders of magnitude in the ion flux incident at the growing film with essentially no effect on the sputtered atom flux. The primary advantage of this technique is that it allows independent control over ion energy, determined by the substrate bias, and ion flux. It has been applied to the growth of polycrystalline and single-crystal transition metal nitride layers with dramatic effects on microstructural evolution and texture [8, 9, 13, 14, 18, 19]. For example, TiN layers grown at 350 °C with low ion-to-Ti flux ratios, $J_{N_2^+}/J_{Ti} \leq 1$, and low ion energies $E_i = 20$ eV exhibit 111 texture. However, increasing $J_{N_2^+}/J_{Ti}$ to ≥ 5, with all other deposition parameters remaining constant, results in 001 texture [8, 9], a total reversal. Very similar results are also reported for δ-TaN [14] grown in mixed Ar + 15% N_2 discharges and an ion energy $E_i = 20$ eV. Films grown with high ion-to-Ta flux ratios $J_i/J_{Ta} \geq 7.4$ exhibit a complete 001 texture while those grown with low ion flux ($J_i/J_{Ta} \leq 6.3$) have a strong 111 preferred orientation.

The energy E_i of the ions impinging on the surface during growth of transition metal nitrides, however, strongly determines their effect. Low E_i values ($\leq$15 eV) typically have no noticeable effect, $E_i \approx 20$ eV provides sufficient momentum transfer to alter surface kinetics, whereas larger energies, $E_i \geq 30$ eV, cause bulk defects and compressive stress. In the case of TaN, 8.5 eV is insufficient to observe an effect on texture evolution whereas $E_i = 30$ eV results in nucleation of a secondary hexagonal phase ε-TaN [14]. For ScN,

growth with $E_i = 13$ eV yields layers with mixed grain orientation, texture is controlled using 20 eV ions, and $E_i = 50$ eV causes high compressive stress due to the inclusion of N_2 gas bubbles in the ScN matrix [18]. The onset for ion irradiation-induced bulk defect formation in TiN is reported to occur at 43 eV with $T_s = 650$ °C [20]. Considerable amounts of N_2 bubbles form in TiN at $E_i > 300$ eV [21].

Several models have been proposed to explain the effect of ion irradiation on texture evolution in cubic transition metal nitrides. Pelleg et al. [22] and later Oh and Je [10, 11] proposed that the orientation of polycrystalline TiN films should initially be 001, corresponding to the lowest energy surface [21]. However, ion irradiation causes compressive stress, leading to preferred 111 texture, because the elastic modulus is lower in the [111] direction. The change in orientation in this model is driven by the film/substrate system, minimizing the total free energy.

However, investigations by Greene et al. [8, 9] mentioned above, showed that low-energy (20 eV) N_2^+ ions impinging on the layer surface during reactive TiN deposition have a dramatic effect on texture, without introducing strain. They therefore proposed a model in which texture evolution is determined by competition between thermodynamic and kinetic driving forces. The formation of 111 texture under low-flux conditions was ascribed to limited adatom mobilities on (111) surfaces, leading to larger cation residence times, and consequently, higher cation incorporation probabilities on 111- versus 001-oriented grains. In contrast, high-flux ion irradiation gives rise to increased surface diffusivity due to ion–adatom momentum transfer and therefore has an effect similar to raising the growth temperature. Thus, under high ion flux conditions, texture evolves toward the lowest surface energy, which is the 001 [21].

More recently, a detailed atomistic model has been proposed, based on results from density functional calculations [15]. Texture evolution toward 111 orientation has been ascribed primarily to the lower cation adatom chemical potential on the (111) surface, also related to the low surface mobility on 111 grains, similar to the argument of Greene et al. [8, 9]. However, it was found that the impingement of high-flux low-energy (~20 eV) N_2^+ ions on the layer surface results in the presence of excess atomic N on the (001) surface, due to collisionally induced N_2^+ dissociation. The atomic N reduces the Ti diffusion length, enhances the surface island nucleation rate, and lowers the Ti chemical potential on the (001) surface, leading to preferential growth of 001-oriented grains due to ion irradiation.

The change in texture from 111 to 001, mediated by ion irradiation-induced surface diffusion effects, also has a dramatic effect on layer microstructures. The limited adatom mobility on (111) surfaces of 111-textured layers leads to increased surface roughness and, due to atomic shadowing effects, underdense microstructures. Consequently, 111-oriented layers exhibit underdense columnar microstructures containing open grain boundaries and both inter- and intracolumnar voids. In contrast, the higher cation surface diffusivity on 001-oriented layers, obtained by growth with high ion-to-metal ratios, results in smoother surfaces and fully dense microstructures, which is generally preferred for applications such as hard corrosion-resistant coatings or diffusion barriers.

In summary, during the growth of transition metal nitride layers there are primarily two surfaces of importance, (111) and (001), which exhibit distinctively different growth kinetics. The (111) surfaces are under typical growth conditions fully N terminated [15], leading to low cation adatom potential energies and mobilities. In contrast, cations on (001) surfaces diffuse fast until they reach a step edge, surface island, or grain boundary or form an admolecule with a N adatom. The surface coverage of the latter can be altered by changing the flux of low-energy N_2^+ ion irradiation, which, in turn, allows control over growth kinetics and therefore microstructural evolution. The understanding of this anisotropy between (111) and (001) surfaces, together with kinetic surface roughening and atomic shadowing, is essential to the growth of nanopipes as described in the following section.

3. SURFACE MORPHOLOGICAL EVOLUTION

The development of nonplanar surfaces during transition metal nitride thin film growth results in surface mound structures that cause atomic shadowing which, under limited adatom mobility conditions, leads to the formation of voids, as described above, and more importantly, the formation of nanopipes, as described below. Surface morphological evolution, including surface diffusion, surface island growth and decay kinetics, and surface mound formation have been investigated for TiN(001) single crystal layers using *in-situ* scanning tunneling microscopy (STM) studies [20, 23–29].

Karr et al. [23] were the first to report *in-situ* STM results from TiN(001) surfaces that were grown on MgO(001) by reactive magnetron sputter deposition at 750 °C. Figure 1 shows the surface morphology of layers with thicknesses $t = 25, 50, 100$, and 230 nm. In all images, atomic height steps (0.21 nm) are clearly observable. The surface morphology on a large scale is controlled by a regular array of growth mounds, ~1 nm high, that are separated by a characteristic length d ~100 nm. The sequence of images indicates that both d and the vertical amplitude of the surface roughness A slowly increase with film thickness, indicating growth of the surface mounds in both lateral and vertical directions. The formation of the mounds is due to the asymmetry in the attachment of adatoms at ascending versus descending steps, which destabilizes growth on low miscut surfaces [20], and has been reported to lead to mound formation on both metal and semiconductor surfaces [30–32]. Although this process is well established, the reported roughening rates vary widely, with exponents ranging between 0.16 and ≈1 [23]. The roughening and coarsening rates for TiN(001) layer growth are within the range of rates reported for other materials and follow a power law with the exponent 0.25, that is, $d \propto h^{0.25}$ and $A \propto h^{0.25}$. Increasing the growth temperature does not affect the roughening exponent; however, it slightly increases d and decreases A [20]. Thus, the surface mounds become wider and less high at higher temperature, due to larger adatom diffusion lengths, similar to results from low-temperature growth of Ge(001) [33]. Ion irradiation during growth reduces the effective strength of the growth instability that drives the formation of growth

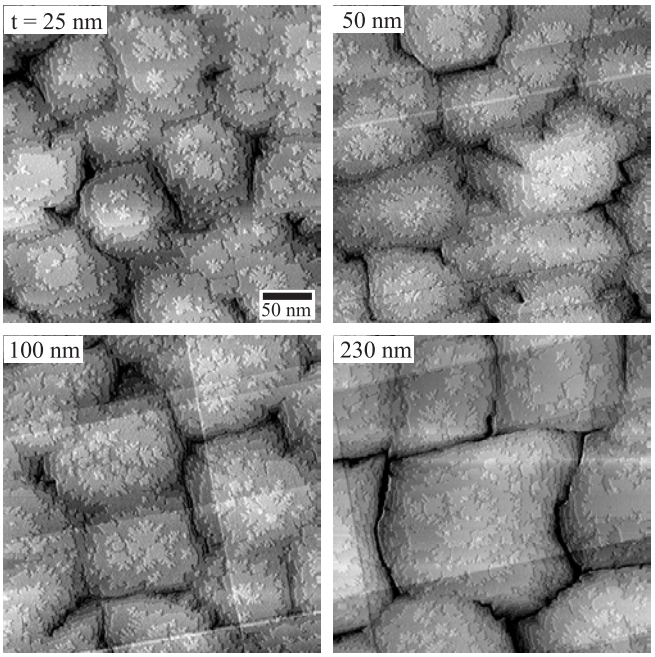

Figure 1. Scanning tunneling microscopy images of TiN(001) films grown on MgO(001) by reactive magnetron sputter deposition at $T =$ 750 °C as a function of film thickness $t = 25$, 50, 100, and 230 nm. mounds [20] and also reduces the diffusion length of Ti adatoms and consequently d, due to the presence of atomic N on the surface [15].

A study by Wall et al. [29] focused on surface diffusion and nucleation kinetics to develop a quantitative understanding of the relevant processes determining the surface morphological evolution of TiN(001). In this study, 0.3 monolayers of TiN were deposited on large, atomically smooth TiN(001) terraces. The resulting surface islands, which are one atomic step high, are dendritically shaped and increase in size with increasing temperature. The nucleation length L_n, which is defined as the characteristic separation between these islands, increases from 6 nm at 510 °C to 9 nm at 600 °C to 17 nm at 800 °C. These data, together with a derivation by Venables [34] showing the exponential growth of L_n versus T and the relationship between L_n and the surface diffusion, are used to determine the effective adatom surface diffusion activation energy for TiN(001), found to be $E_s = 1.4 \pm 0.1$ eV [29].

An alternative approach to studying surface diffusion and island kinetics was reported by Kodambaka et al. [25–28], who examined TiN(001) island decay kinetics by STM annealing experiments. The decay of islands in the presence of larger islands is due to coarsening (Ostwald ripening), as described by the Gibbs–Thompson equation showing that the equilibrium adatom concentration around an island increases with decreasing radius r. Small islands have a higher curvature and hence a higher two-dimensional spreading pressure than larger islands, resulting in the decay of the smaller and growth of the larger islands. Kodambaka et al. [26] modeled island decay, adatom diffusion, and adatom density distributions and extracted from the experimental data a value for the activation energy for adatom detachment plus diffusion of 3.4 ± 0.3 eV.

4. ATOMIC SHADOWING

Atomic shadowing, also termed self-shadowing, in the context of thin film growth refers to the part that the surface morphology plays in the capture probability of incident atoms from the gas phase. This is primarily due to surface mounds having a higher probability than surface valleys of capturing incident atoms, leading to an inequality in layer growth rates as a function of location on the surface. The development of surface morphology in the presence of atomic shadowing has been modeled by a variety of theoretical approaches [35–43].

The model by Karunasiri et al. [35] accounts for nonlocal atomic shadowing and surface diffusion and contains a Gaussian white noise term. They found that for small values of the diffusion constant, the growing layer surface develops a self-similar mountain landscape while larger diffusion values result in the growth of compact flat films. Bales and Zangwill [36, 37] showed that for the case of negligible surface diffusion, the maxima (i.e., surface mounds) flatten as growth proceeds while, in contrast, the minima steadily evolve toward grooves. Also, in the absence of diffusion, no characteristic length scale is favored, that is, self-similar starting surfaces result in self-similar final morphology, consistent with "cauliflower"-like morphologies observed experimentally [44]. However, when surface diffusion is present, that is, at growth temperatures that are a significant fraction of the melting point, smoothing of the surface occurs with a characteristic length scale, determined by the diffusion length. This smoothing is in direct competition to the destabilizing shadowing term, which causes groove formation.

The model by Guo and co-workers [38–40] shows that for low values of the angle spread of the incoming deposition flux $\theta_{\max} < 5°$, shadowing effects are minor and the surface simply roughens. However, larger $\theta_{\max}$ values result in columnar structures with deep grooves. Columns also coalesce or compete; for example, small columns are overshadowed and evolve into grooves. This column competition and coarsening follows a power law for which the exponent depends on $\theta_{\max}$, as shown by simulations by Krug and Meakin [41] as well as by Drotar et al. [42]. The combination of atomic shadowing with anisotropic material effects including surface free energies and/or surface diffusion is key to the development of texture evolution during polycrystalline thin film growth, as shown by a model of Karpenko et al. [43].

When the deposition flux occurs from oblique angles, atomic shadowing not only results in surface roughening or the formation of grooves but also can be used in a controlled manner to design well-separated complex three-dimensional nanostructures. This so-called glancing angle deposition (GLAD) technique exploits atomic shadowing to obtain layers with anisotropic microstructure and therefore anisotropic physical properties, including optical activity. This technique has been known for several decades [45, 46] but has gained considerable attention in more recent years due to the wide range of achievable nanostructures [47–70]. Atomic shadowing under limited adatom mobility conditions

results, if the growth occurs at glancing angles ($\alpha \gtrsim 70°$), in a microstructure that is dominated by well-separated columns, which themselves can exhibit complex shapes by virtue of substrate rotation during deposition [49]. The term columnar thin film (CTF) refers to such layers consisting of separated columns whereas sculptured thin films (STFs) are layers for which the columns themselves have an engineered complex structure. The porosity of the CTFs as well as the column tilt angle β increases with increasing deposition angle α. However, the porosity and β can be varied independently using controlled substrate rotation [51]. For example, if substrate rotation is fast relative to the time needed to grow a thickness comparable to the column width, columns grow straight (perpendicular to the substrate surface) although the deposition flux is at glancing angle [52].

A major application for STFs is optically active coatings [53]. Layers with tilted columns exhibit a strong dependence of optical transmission on the angle of incidence and polarization [54]. Biaxial films with large birefringence as well as thin film wave plates have been achieved using the GLAD technique [55, 56]. Layers containing helices act as helicoidal bianisotropic medium [57, 58]. They directly affect circular polarized light. For example, a circular polarization spectral hole filter can be realized by two structurally left-handed chiral STFs with a 90° twist between them [59, 60]. Regular arrays of columns are obtained using initial patterning of the substrate followed by GLAD. Such layers have potential applications as photonic crystals [52, 61, 62]. Columnar thin films also exhibit exceptional magnetic properties with possible applications in magnetic storage devices [63–66].

Shadowing effects during deposition at an oblique angle were also applied to grow Fe nanowire arrays on NaCl(110) templates [68], amorphous Si square spirals on colloid substrates [69], and nanoflowers using a periodic varying substrate rotation speed [70].

Glancing angle deposition was also studied theoretically with both analytical and numerical approaches [71–78]. These studies provided insight into the processes that determine the columnar microstructure of layers grown from oblique angles. There is a general consensus that deposition angle and surface diffusion are key parameters. Also, the column tilt angle β is smaller than the deposition angle α; however, the various studies do not agree on the exact form for the α versus β relationship and also indicate that material parameters like the crystal structure may be important.

5. NANOPIPES

Nanopipes have been first observed in single crystal ScN(001) layers [79], followed by reports on CrN [19], TaN [80], and $Ti_{1-x}W_xN$ [81]. ScN layers grown at $T_s = 800$ °C on TiN(001) buffer layers on MgO(001) exhibit a cube-on-cube epitaxial relationship with the substrate: $(001)_{ScN} \| (001)_{TiN} \| (001)_{MgO}$ and $[100]_{ScN} \| [100]_{TiN} \| [100]_{MgO}$, as determined by a combination of X-ray diffraction and transmission electron microscopy (TEM) analyses [79]. This is in contrast to the results mentioned above, showing that growth of ScN directly on MgO(001) leads to a polycrystalline film exhibiting a mixture of two grain orientations. The epitaxial ScN layers are in a mild state of in-plane compressive strain ($\varepsilon_\| = -0.8\%$), due to differential thermal contraction during cooling from the film growth temperature, because the thermal expansion coefficient for ScN, 4×10^{-6} K^{-1} [82], is much smaller than that for MgO, 1.3×10^{-5} K^{-1} [83].

A typical cross-sectional transmission electron microscopy (XTEM) image with a corresponding selected area electron diffraction pattern, in this case from an epitaxial 82-nm-thick ScN film deposited on a TiN(001) buffer layer, is shown in Figure 2. The 100 (Fig. 2a) zone axis diffraction pattern, obtained with a 0.4 μm aperture centered at the ScN/TiN interface, exhibits two sets of symmetric reflections characteristic of single crystals and separated by a distance consistent with the lattice constant mismatch between ScN and TiN. XTEM tilting experiments reveal an abrupt ScN/TiN interface, with misfit dislocations visible, at the position indicated in Figure 2b. The ScN layer appears defect-free (other than the presence of dislocations) up to a thickness t_c of ≈15 nm. Above the defect-free region, nanopipes with a width of ∼1 nm extend along the growth direction and continue to the free surface where they terminate at cusps. The apparent termination of some nanopipes below the surface in Figure 2b is due to a gradient in the thickness of the XTEM specimen, which is thinnest at the TiN buffer layer and thickest at the ScN free surface. The nanopipes exhibit contrast reversal in under- and overfocus imaging, indicating that they correspond to empty holes in an otherwise fully dense single crystal. The surface is relatively rough, exhibiting a periodic mound structure with an average mound height of ≈7 nm. Between the surface mounds are deep cusps, which connect to the nanopipes.

X-ray photoelectron spectroscopy (XPS) depth profile measurements confirm that the nanopipes are continuously open holes [79]. XPS shows that when the layers are exposed to an air atmosphere, the internal surfaces adsorb oxygen. That is, oxygen enters the layer from the surface through the cusps and adsorbs then at the exposed surfaces of the nanopipes. The nanopipe-free bottom of the layer, however, remains oxygen free.

The experimental results described above show that (a) nanopipes are not due to tensile stress, as could be imagined, because the presented layers exhibit even a slight compressive stress, (b) they do not form at the substrate/layer interface but develop after a certain critical thickness, (c) they

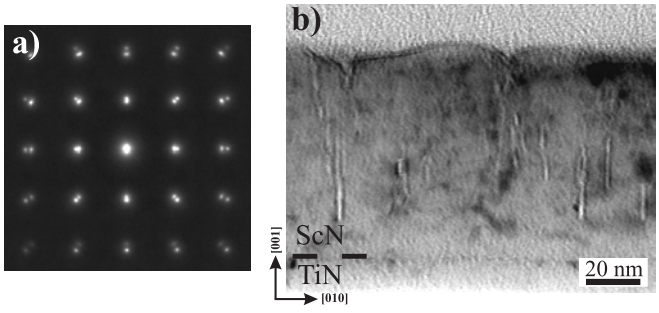

Figure 2. (a) Selected area electron diffraction pattern and (b) corresponding bright-field XTEM micrograph from an epitaxial ScN film grown on TiN/MgO(001). Reprinted with permission from [79], D. Gall et al., *J. Appl. Phys.* 86, 5524 (1999). © 1999, American Institute of Physics.

terminate at surface cusps, and (d) nanopipes provide a continuously open path trough the entire layer with exception of the nanopipe-free bottom. Based on these experimental observations, the following model for the nanopipe formation has been developed.

Initially the surface roughens kinetically to form a periodic mound structure [18], as illustrated in Figure 3a. Such mound structures are typical for films grown at temperatures that are low with respect to the melting point and have been observed in semiconductors [84–88] and metals [89]. The primary origin of kinetic roughening is the presence of Ehrlich–Schwöbel barriers [90] to the migration of adatoms over down-steps and/or deep traps at step edges on growing surfaces. This leads to a divergence in adatom flux and, hence, increased nucleation on terraces. Adatoms have a higher probability to be incorporated at ascending rather than descending step edges, which results in a net adatom flux toward surface mounds, giving rise to surface roughening and faceting during film growth.

When the mounds reach a certain height (Fig. 3b), roughening is exacerbated due to atomic shadowing from surface mounds. Sputter deposition typically results in a cosine distribution of the incoming atom flux with the highest flux at an azimuthal angle of 45° [16]. Atoms reaching the surface at non-normal angles have a higher probability to impinge on mounds than in valleys, leading to a decrease in the local deposition rate in the valleys which results in deep surface cusps (Fig. 3c). The surface around a cusp contains a high density of step edges or may even form (111) facets. Consequently, the adatom mobility around surface cusps is relatively low, as discussed above when diffusion on (001) and (111) surfaces was compared. Thus, surface diffusion is insufficient for filling of the trenches, leading to the formation of nanopipes as shown in Figure 3d.

The observation that nanopipes form only above a critical film thickness ($t > t_c \simeq 15$ nm) indicates that surface roughening occurs gradually during growth and a critical mound height, which depends on both the angular incident flux distribution and the adatom mobility, is required for maintaining continuously open nanopipe structures. Nanopipes elongate along the growth direction because the average direction of the incoming atom flux is normal to the layer surface. This directionality is drastically enhanced by the high adatom mobility on {100} surfaces, which causes nanopipes to be preferentially bound by {100} planes, as observed using plan-view transmission electron micrographs. An example is shown in Figure 4, taken from a

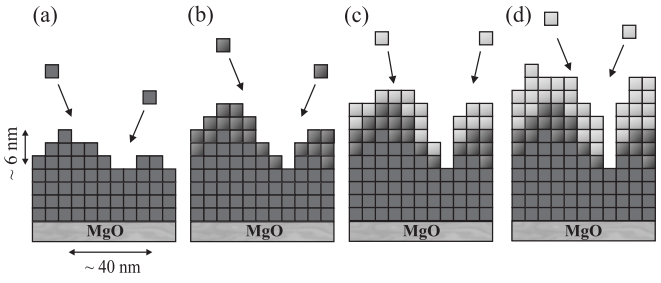

Figure 3. Schematic of nanopipe formation in single crystal transition metal nitride layers.

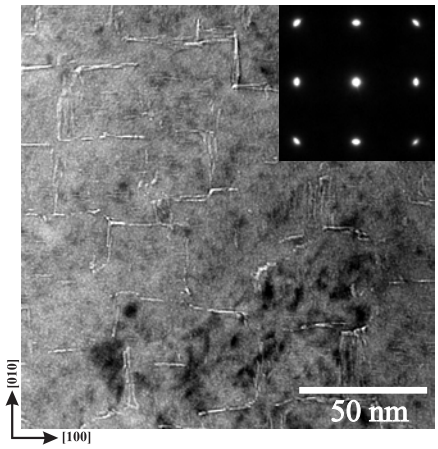

Figure 4. Plan-view TEM micrograph and corresponding diffraction pattern from a ScN(001)/MgO(001) layer showing the arrays of rectangular shaped nanopipes aligned along orthogonal ⟨100⟩ directions. Reprinted with permission from [18], D. Gall et al., *J. Appl. Phys.* 84, 6034 (1998). © 1998, American Institute of Physics.

ScN(001)/MgO(001) layer grown at 750 °C with $J_i/J_{Sc} = 14$ and $E_i = 20$ eV [18]. This plan-view sample was prepared by step-wise ion milling through the film from both sides. Thus, the micrograph is a plan-view from the center of the 345-nm-thick layer, showing a cross-section through the nanopipes, which are elongated along the growth direction perpendicular to the image plane. The nanopipes are rectangular in cross-section with a width of ~1 nm by 1–15 nm along orthogonal ⟨100⟩ directions. They are bound by high adatom mobility {100} planes. Their rectangular elongated shape is explained by their formation; approximately square-shaped surface mounds, with edges along low-energy ⟨100⟩ directions (i.e., along Sc-N bonding directions), adjoin along ⟨100⟩ with the development of valleys, which are consequently also elongated along ⟨100⟩. These transform, with increasing layer thickness, to deep cusps and ultimately nanopipes as shown in Figure 3. The square-shaped surface mounds, which have an average mound-to-mound spacing of 30 ± 5 nm, are centered between the nanopipes and their locations and shapes can easily be imagined when looking at Figure 4. Because the nanopipes are directly linked to the periodic surface roughness, they form a self-organized periodic array with, however, only very limited long-range order. Long-range order and complex nanostructures may nevertheless be obtained by initial patterning and controlled surface morphological evolution, as indicated in the conclusion/outlook section.

The nanopipe density can be controlled by ion irradiation during growth. This has been reported in a study on epitaxial CrN layers [19], which combined atomic force microscopy (AFM) and TEM to investigate the correlation of surface morphological evolution with nanopipe formation. Epitaxial CrN(001) layers of 0.5 μm thickness were grown at $T_s = 600$ °C by ultrahigh vacuum magnetron sputter deposition on MgO(001) substrates. Growth under typical conditions for magnetron sputtering, with an ion energy E_i of 12 eV and an ion-to-metal ratio $J_{N_2^+}/J_{Cr} = 1.7$, leads to a surface morphology that exhibits square-shaped growth mounds with edges predominantly aligned along low-energy

⟨100⟩ directions. Lateral mound sizes range from 130 to 300 nm with a surface width $\langle w \rangle$ of 1.80 ± 0.04 nm, an average peak-to-valley mound height $\langle h \rangle = 5.09 \pm 0.11$ nm, and an in-plane correlation length $\langle d \rangle$ of 208 ± 20 nm. However, growth at a high ion flux, $J_{N_2^+}/J_{Cr} = 14$, with all the other deposition parameters remaining, results in a strikingly different surface morphology. The growth mounds are much larger and elongated along ⟨110⟩, while they are dendritic in the orthogonal direction. Both the dendritic shape and the elongation along ⟨110⟩ indicate large surface diffusion lengths and a growth instability driven by the preferred adatom attachment at ascending versus descending step edges. The average mound height $\langle h \rangle = 2.52 \pm 0.03$ nm of samples grown with high ion irradiation flux is ∼2 times smaller than that for the $J_{N_2^+}/J_{Cr} = 1.7$ layer whereas the in-plane correlation length $\langle d \rangle = 520 \pm 100$ nm is 2.5 times larger. This results in a decrease of the average aspect ratio $\langle h \rangle / \langle d \rangle$ by a factor of 5 when $J_{N_2^+}/J_{Cr}$ is increased from 1.7 to 14.

These results from epitaxial CrN(001) layers show that increasing the incident ion-to-metal flux ratio during growth, using low N_2^+ ion energies, results in smoother surfaces with both smaller mound heights and decreased mound aspect ratios [19]. High-flux, low-energy, ion irradiation leads to higher adatom mean surface diffusion lengths and, consequently, larger surface features. In addition to larger adatom diffusion lengths on terraces, momentum transfer from low-energy ion irradiation increases the probability of adatoms crossing descending step edges. This contributes to the filling of trenches between growth mounds, thereby reducing atomic shadowing. The surface smoothing obtained at higher ion-to-metal flux ratios has important consequences on the formation of nanopipes, as described in the following.

XTEM investigations [19] show that CrN layers grown with $J_{N_2^+}/J_{Cr} = 1.7$ exhibit 1–5-nm-wide nanopipes along the [001] growth direction. The average lateral separation between nanopipes is 180 ± 40 nm, approximately equal to the growth mound in-plane correlation length $\langle d \rangle = 208 \pm 20$ nm determined by AFM. The nanopipes extend along the growth direction to the free surface where they terminate at cusps between growth mounds, suggesting, as discussed above, that the formation of nanopipes is directly related to the presence of the surface cusps between periodic growth mounds that cause strong atomic shadowing.

CrN(001) layers grown with $J_{N_2^+}/J_{Cr} = 6$ show a considerably different nanopipe distribution: The layers are defect-free (no nanopipes) over a thickness $t^* \simeq 250$ nm and exhibit a low nanopipe density at $t > t^*$. The nanopipes, as is the case for the layer grown at the low ion-to-metal ratio, have widths ranging from 1 to 5 nm. However, they are not continuous and appear and disappear along the growth direction. At even higher ion-to-metal ratios, $J_{N_2^+}/J_{Cr} = 10$ and 14, the nanopipe formation is nearly completely suppressed.

Therefore, the strong effects of low-energy N_2^+ ion irradiation during deposition on the surface morphology of CrN(001) layers also control the formation rate of nanopipes. Layers grown with low ion-to-metal ratios, $J_{N_2^+}/J_{Cr} = 1.7$, exhibit rough surfaces composed of growth mounds with relatively high aspect ratios and short in-plane coherence lengths which, within the experimental uncertainty, are equal to the measured average separations between nanopipes. For CrN(001) layers grown with medium ion-to-metal ratios, $J_{N_2^+}/J_{Cr} = 6$, the in-plane correlation length is larger, corresponding to a lower mound number density. This, in turn, results in a reduction in the nanopipe number density by more than a factor of 3 compared with CrN(001) layers grown with $J_{N_2^+}/J_{Cr} = 1.7$. In addition, nanopipes form only above a critical film thickness ($t^* \geq 250$ nm) and are found to be discontinuous along the growth direction. The rate of surface roughening occurs more gradually during growth with $J_{N_2^+}/J_{Cr} = 6$. Thus, at $t < t^*$, the mound aspect ratio is too small to provide sufficient atomic shadowing to form cusps and, hence, nanopipes. Even at $t > t^*$, the surface roughness is not adequate to sustain continuous nanopipe formation, leading to discontinuous nanopipes. At high ion-to-metal flux ratios, $J_{N_2^+}/J_{Cr} \geq 10$, layer surfaces are relatively smooth such that shadowing is negligible and essentially no nanopipes are formed.

6. CONCLUSIONS

Nanopipes in transition metal nitrides form due to atomic shadowing from a surface mound structure under limited adatom mobility conditions, as described in detail above. Nanopipe density, average spacing, and length can be controlled by thin film deposition parameters, including growth temperature, N_2 partial pressure, and ion irradiation energy and flux. This is due to changes in the surface morphology, which is primarily determined by surface diffusion and reaction processes on both (001) and (111). The surface mounds are roughly square shaped with edges along perpendicular ⟨100⟩ directions, leading to cusps, elongated along ⟨100⟩ directions, and the formation of nanopipes with rectangular cross-sections that are aligned along the [001] growth direction. The nanopipe width, 1 ± 0.5 nm, is determined by the angular distribution of the deposition flux, which controls the degree of shadowing, whereas the orthogonal elongation is defined by the width of the surface mounds. The average inter-nanopipe separation is equal to the in-plane correlation length and is therefore fully determined by the surface morphology.

While deposition parameters control the average distance between nanopipes by virtue of affecting surface diffusion processes and thus surface morphology, no long-range order of nanopipes has been achieved yet. However, various schemes could be envisioned that would provide the means for controlled nanopipe positioning. One approach would be to pattern the substrate before growth. The epitaxial transition metal nitride layer would then yield nanopipes that are positioned at the grooves of the initial substrate patterning. Although the patterning could be done with resolutions of ∼50 nm, the self-limiting shadowing processes would result in 1-nm-wide nanopipes. This corresponds to a self-organized feature size reduction by a factor of 50.

Further development of this technique could be envisioned. In particular, it should be possible to control the nanopipe width by glancing angle deposition techniques that directly affect the degree of atomic shadowing. In that way, arrays of nanopipes that exhibit a desired width can be synthesized. The width could even be varied as a function of layer thickness by simply changing the incidence angle of

the deposition flux. For example, if the deposition angle is increased for a short time during growth, the nanopipe width will be larger at this given layer height, leading to controlled in-plane nanochannel formation.

These advanced nanopipe-based structures have potential applications as templates for tunneling devices, sensors, and two-dimensional conductors. The nanochannels may be used for molecular transport and single molecule chemistry. Periodic arrays will be useful in optoelectronics and photonic materials. Other potential applications include magnetic storage, large surface area devices, thermal barriers, and optical coatings.

GLOSSARY

Ab initio [Calculations] performed using only fundamental physical constants, that is, no experimental data or empirical numbers.

Atomic shadowing The effect that the surface morphology plays in the capture probability of incident atoms.

Epitaxy/epitaxial growth Thin film growth where the crystallographic orientation of the grown layer aligns with that of the substrate.

Glancing angle deposition (GLAD) Exploits atomic shadowing effects to create layers with columnar structures.

Nanopore Analysis of DNA

David W. Deamer, Stephen Winters-Hilt

University of California, Santa Cruz, California, USA

CONTENTS

1. INTRODUCTION

A nanopore is defined as a pore having dimensions in the range of 1–100 nm. A nanopore therefore admits particles of molecular size but excludes micrometer-sized particles such as bacterial cells. If the pore is produced in a very thin membrane, such as a lipid bilayer 5 nm thick, it becomes possible to detect polymeric solutes as individual molecules. A voltage is first established across the membrane, so that an ionic current (typically potassium and chloride in 1.0 M salt) is driven through the pore. Larger ionic solutes such as nucleic acid molecules can also be transported through the pore by electrophoresis. When a sufficiently large solute molecule enters the pore, a measurable decrease in ionic current (referred to here as a blockade) is produced that provides information about the molecule. The signal is captured and digitized, after which it can be computationally processed to characterize the particle. Important applications for nanopore analysis of polymers in solution include determinations of concentration, identity, and composition of the solute molecules.

The concept of using small pores to analyze particles of biological relevance was pioneered by Coulter [1] who showed that blood cells in saline suspensions could be detected as they were moved through a pore 100 μm in diameter by a pressure gradient. As each cell enters the pore it changes the resistance to the ionic current that passes through the pore. The change is related to the volume of the cell by the equation $\Delta g = 2\pi r^3 \sigma / L^2$, where r is the radius of the particle (with the volume of a spherical particle being a function of r^3), L is the length of the pore, and σ is the conductivity of the solution [2]. The resulting signals provide information about the cell number and cell volume. In a blood sample, cells such as red cells and leukocytes have different volumes, so that differential counts can be rapidly carried out. This information is useful in diagnosis of blood disorders, and commercial versions of the Coulter counter remain an important instrument in clinical laboratories.

Following the success of pore-based cell counters as analytical tools, interest turned to smaller pores that could be used to detect particles such as biological polymers. However, it is much more difficult to produce a pore in the nanoscopic size range, 2–3 orders of magnitude smaller than used by Coulter. Bean and co-workers [2–4] first used etched nuclear tracks for this purpose. When a high energy nucleus passes through a solid it typically leaves a "track" in which the structure has been chemically altered at the atomic level of structure. This track can later be etched by applying solvents that preferentially dissolve the damaged structures. Tracks are produced by natural radioactive decay in a substance, such as fission of a uranium nucleus present in silicate minerals, or by exposure to a radioactive source such as californium (Cf_{252}) that undergoes spontaneous fission. In the latter case the fragments can be collimated so that the resulting tracks are parallel. The tracks are then etched by exposure to solvents such as hydrofluoric acid or concentrated sodium hydroxide. (Nucleopore filters with pore sizes ranging from 50 nm to several micrometers are produced by

this process and are commercially available.) If mica etched with 49% HF is used, the pore size at initial breakthrough is approximately 6 nm, which then increases to micrometer size ranges after 30 minutes of etching. DeBlois et al. [4] showed that mica nanopores were sufficiently sensitive so that particles as small as viruses could be detected by the change in resistance as the particle was driven through the pore.

Although mica and polycarbonate films produce pores of controlled size, the pores are in fact tunnels through the relatively thick materials. This limits their resolution, because a globular particle spends time negotiating a tunnel of varying dimensions. Ideally a nanopore will be present in a film that is no thicker than the analyte to be measured. This is particularly true of linear polymers such as nucleic acids, in which the desired resolution is at the level of a single nucleotide.

2. BIOLOGICAL NANOPORES

In the 1970s, it became apparent that biological membranes of cells incorporate nanoscopic channels composed of proteins that are embedded in lipid bilayers. The function of the channels is to provide a gated pore that allows solutes such as sodium, potassium, and calcium ions to cross the otherwise impermeable lipid bilayer barrier that surrounds all cells. Artificial bilayers are readily produced by self-assembly of amphiphilic compounds such as phospholipids. For instance, bilayers of phospholipid 5 nm thick can be produced as membranes covering a 100 micrometer diameter hole in a thin plastic sheet. Such membranes have dimensions appropriate for nanopore analysis, provided that a pore can be produced in the bilayer.

Hladky and Haydon [5] showed that the bacterial antibiotic gramicidin spontaneously inserted into lipid bilayers and could form continuous channels that conducted ionic current. Gramicidin, with a pore diameter of ~0.4 nm, is the smallest useful nanopore. The gramicin pore contains a chain of approximately 10 water molecules that form a single hydrogen-bonded strand across the bilayer. In the presence of a voltage, the pore conducts an ionic current of a few picoamperes, the amplitude depending on the voltage and ion concentration. The gramicidin pore is too small to be used directly to detect solutes other than ions, but Cornell and co-workers [6] have shown that it can be used as a biosensor if it is coupled to a specific antibody. When a target antigen binds to the antibody, the ability of the gramicidin pore to conduct ionic current is inhibited. The reduction in current can then be used to estimate the presence and concentration of the antigen.

The fact that such pores could conduct polar and ionic solutes across a membrane suggested that a larger pore might be used to detect macromolecules in solution. This concept was first tested by Bezrukov et al. [7] who showed that ionic current through the alpha hemolysin pore was affected by the presence of polyethylene glycol (PEG). The current fluctuations appeared only at certain molecular size ranges: PEG molecules that were smaller or larger than the pore had little effect, while PEG in the size range of the pore (0.5–1.5 nm) produced large current fluctuations. This allowed the authors to conclude that PEG could enter the pore and affect ionic current. Because PEG has no net electrical charge, the molecules enter the pore by diffusion, rather than by an energy-dependent process. (See Bezrukov [8] for review.)

At about the same time, Walker and co-workers [9] demonstrated that the hemolysin pore could be modified to serve as a metal biosensor. In this work, the hemolysin was modified by introducing histidine for amino acids 130–134 in the central glycine-rich loop of the protein. The modified pore had a conductance that could be modulated by micromolar concentrations of ions such as zinc, suggesting that modified protein pores such as hemolysin could serve as sensitive metal ion sensors.

3. NANOPORES AS LINEAR POLYMER SENSORS

The next advance in nanopore analysis was to take advantage of the fact that larger ionized solutes could potentially be driven through the pore by an electrical field. This would be particularly important for analyzing linear polymeric solutes such as nucleic acids. The pore diameter permits nucleic acids to be translocated as single strands, rather than duplexes, so that a given strand passes through the pore in strict linear sequence. This fact led to the concept of nanopore sequencing, which depends on the possibility that each base in a nucleic acid strand will modulate the signal in a specific and measurable way. If so, the base sequence in a nucleic acid molecule could be determined at rates far exceeding those now possible.

The hemolysin toxin produced by *S. aureus* is a suitable nanopore because it self-assembles in lipid bilayers to form aqueous pores with diameters just large enough to translocate the nucleotides in a single strand of DNA or RNA (Fig. 1).The entrance to the head of the channel has a diameter of approximately 2.6 nm that contains a ring of lysine residues. The entry opens into a vestibule with an interior diameter of 3.6 nm that in turn leads to the pore's stem which penetrates the lipid bilayer. The average inside diameter of the stem is about 2.0 nm with a 1.5 nm constriction between the vestibule and the stem. This limiting constriction is composed of alternating lysine and glutamate residues, and the remainder of the stem is lined primarily with neutral residues except for a single hydrophobic ring of exposed leucine residues. The opening at the other end of the pore has a 2.2 nm ring of alternating lysine and aspartate residues.

To produce a nanopore, α-hemolysin subunits are introduced into a buffered solution that is in contact with a lipid bilayer which separates the solution into two compartments, designated *cis* and *trans*. This apparatus, in conjunction with a standard amplifier and software, provides rapid response times on the microsecond time scale and substantially lower noise than the larger planar lipid membrane commonly used in single channel research. The open channel of a hemolysin pore carries an ionic current of approximately 120 picoamps (pA) with an applied voltage of 120 millivolts (mV).

Kasianowicz et al. [10] first reported that addition of single-stranded nucleic acid homopolymers produced large numbers of transient ionic current blockades, suggesting that individual molecules were being translocated through the pore and blocking ionic current. Formal proof for this

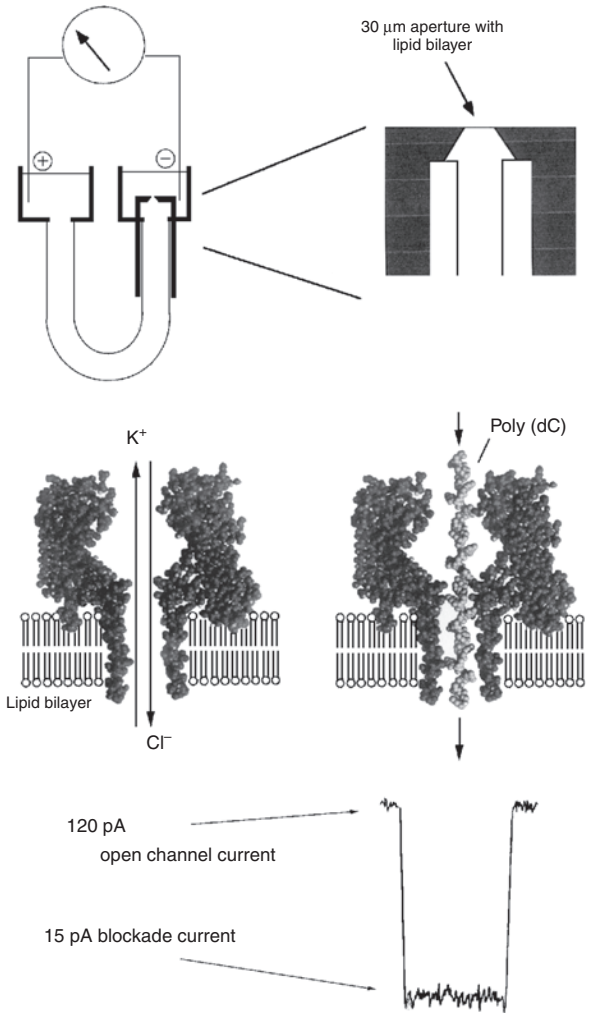

Figure 1. α-Hemolysin pore inserted into a lipid bilayer. The heptameric pore is illustrated in cross section, and a single strand of poly(dC) synthetic DNA is shown translocating from the top through the nanoscopic pore in the stem that penetrates the bilayer. The resulting ionic current blockade is shown at the bottom, with a duration of approximately 200 microseconds for a 100mer.

conjecture followed when it was demonstrated that the number of blockades was correlated with the actual number of single-stranded DNA molecules translocated through the pore [10]. The experimental approach involved a comparison of the ability of DNA as single-stranded (ssDNA) and double-stranded (dsDNA) molecules to pass through the pore. Quantitative PCR was then used to make a direct measurement of nucleic acids appearing on the *trans* side of the membrane, and the numbers were compared with the number of blockade events that occurred during the same time interval. Only ssDNA appeared on the *trans* side, and the ratio of single-stranded DNA molecules appearing on the *trans* side to the number of blockade events was close to 1. This observation permitted the conclusion that single-stranded nucleic acids were in fact translocated through the hemolysin pore, and that the resulting ionic current blockades could be used to gather information about single molecules.

4. BLOCKADE MECHANISM

The process by which an ionic current blockade is produced must entail three phases: capture, entry, and translocation. When a voltage of 120 mV is imposed on the pore, the resulting ionic current consists of potassium and chloride ions. If single stranded nucleic acids are present, a given molecule will occasionally diffuse into the small volume near the mouth of the pore. When the polymer enters the biased region, three outcomes are possible. The first is that the diffusing nucleic acid molecule simply collides with the pore mouth. During this collision, the ionic current may be interrupted for a few microseconds, but the duration and extent of this transient blockade is variable and largely independent of chain length.

The second possibility is that one end of the molecule partially enters the vestibule and remains for periods ranging from tens of microseconds to several milliseconds, after which it either diffuses out of the pore or is drawn completely into the pore stem. While the molecule occupies the vestibule it causes a partial blockade having a characteristic amplitude about half that of the full blockade.

The third possibility is that one end of the nucleic acid is drawn completely into the pore stem, where it produces a full blockade with a duration that is a function of chain length. Translocation occurs as a result of electrophoretic force acting on the anionic phosphate groups of the chain. The pore stem is only 5 nm long, but the nucleic acid strand can be up to thousands of nucleotides in length. Experiments with very short polynucleotides show that the electric field acts primarily on the 10–14 phosphate groups within the stem [11]. The resultant force of about 20–40 piconewtons is sufficient to drive the molecule through the pore with velocities that depend on the composition and secondary structure of the strand. Given the small aperture of the pore (1.5 nm), the polynucleotides must move as an extended linear polyanion. Meller et al. [11, 12] have undertaken detailed studies in which temperature effects on translocation are considered, as well as direct estimates of force acting on a DNA strand during translocation. (See Muthukumar [13] and Lubensky and Nelson [14] for discussions of the physics of polymer translocation through nanopores.)

5. PARAMETERS OF IONIC CURRENT BLOCKADES

The structural properties of the hemolysin nanopore shown in Figure 1 are relevant to understanding the mechanism of ionic current blockades. Here we will assume that the major component of the blockade occurs when a nucleic acid occupies the 5 nm long stem of the channel, and neglect contributions by the larger vestibule. The pore volume within the stem is 18 nm^3, and the average diameter is 2.0 nm, with a limiting aperture of 1.5 nm at the neck of the pore.

Three parameters provide information about the nature of the linear polymer passing through a nanopore. The first is blockade amplitude, which is best normalized and expressed as a fraction or percentage of the open channel current, I/I_o, where I is the blockade current and I_o is the open channel current. I/I_o has a characteristic value for many homopolymers of RNA and DNA, suggesting that

it will be an important analytical feature of nanopore technology.

Although several factors could conceivably contribute to blockades of ionic current, the simplest to test experimentally is that the fractional volume of a linear nucleic acid strand occupying a pore will reduce the number of ions available to carry current. The contribution of fractional volume of the molecule occupying the pore stem has been tested by investigating blockades produced by several polyanions that vary in molecular volume yet have approximately the same charge density of phosphate along the strand. These blockade amplitudes were then compared with the fractional volume of the pore stem occupied by the polymer, taking into account not only the molecular volume of the polymer but also water of hydration on the polymer and pore walls. The exact conformation of a single strand of DNA in the channel is unknown, but for the purposes of this calculation a conservative estimate is 0.34 nm per base, the repeat distance of bases in a double helix. About 15 nucleotides would then be in the pore at any given time during translocation. (The pore is defined here as the portion of the hemolysin channel that penetrates the lipid bilayer and does not include the larger volume of the vestibule and channel mouth.) Assuming that each monomer of the nucleic acid has four waters of hydration (60 total), and that a single layer of water is bound to the interior surface of the pore (320 total), approximately 70% of the available pore volume would be occupied by a single strand of oligo(dA).

Similar calculations were made for oligo(dC), for an abasic strand of nucleic acid, and for polyphosphate, both of which also produce measurable ionic current blockades [15]. The experimental values are in approximate agreement with the calculated values. From the results of this simple experiment, it can be concluded that blockade amplitude is largely a function of the fractional volume occupied by a linear polymer traversing a nanopore. The difference in total volume between purine and pyrimidine deoxyoligonucleotides in the α-hemolysin pore is only 0.3 nm^3, which represents a 6% difference in the volume occupied by the molecules in the pore after correcting for water of hydration. This difference is just barely detectable as an average signal over noise and is produced by multiple nucleotides occupying the length of the pore. It follows that an improved pore having a smaller limiting aperture than that of the α-hemolysin channel will probably be required for single nucleotide resolution in nanopore sequencing applications.

6. CORRELATION OF BLOCKADE PARAMETERS WITH POLYNUCLEOTIDE COMPOSITION

If blockades are caused by the transport of linear polynucleotides through the pore, their lifetimes should be proportional to the length of the polymer. This was tested for polyU, polyC, and polyA [10], and it was found that all three homopolymers exhibited a linear relation between chain length and duration of the blockade. Akeson et al. [16] went on to investigate the amplitude of blockades caused by homopolymers of RNA. The pattern of blockades caused by polyC was easily distinguished from the pattern for polyA, whether the polymers were examined separately or in a mixture. The channel current was reduced significantly more by polyC RNA (typically 95% blockades) than by polyA RNA (84% blockades), and the polyC blockades were shorter in duration, averaging 6 μs per nucleotide compared to 16 μs per nucleotide for polyA.

The fact that polyA and polyC could be distinguished by the nanopore suggested that a transition from polyA to polyC segments within a single RNA molecule should be detectable. An RNA was synthesized with the sequence $A_{(30)}C_{(70)}Gp$, which would be expected to produce a bilevel blockade. Such blockades were in fact commonly observed and interpreted to represent an initial blockade by polyC RNA (current reduced to 5% of open channel value) followed by polyA RNA (current reduced to 16% of open channel value).

The evidence presented by Akeson et al. [16] provided the first demonstration that modulations of ionic current during translocation of a macromolecule through a pore can be used to discriminate between components along its linear sequence. At first the greater blockade amplitude associated with polyC seemed paradoxical because adenine (a purine) is a larger base than cytosine (a pyrimidine). If the size of individual nucleotides within the RNA strands alone dictated blockade amplitudes of ionic current, the polyA blockade might be expected to have had a greater amplitude. The paradox was resolved when it was recalled that polyC forms a single-stranded helix with a 1.34 nm diameter [17] that can readily translocate through the pore as a helix. PolyA also forms a single-stranded helix, but with a diameter of 2.1 nm [18]. It therefore seems likely that polyA penetrates the pore only when the helical strand is partially unwound into an extended configuration, which also permits more ionic current to pass during a blockade. The additional energy required to unwind the purine bases is consistent with the significantly longer blockade duration associated with polyA strands.

7. NANOPORE ANALYSIS OF DNA AT SINGLE BASE-PAIR RESOLUTION

From the measured velocities of single stranded nucleic acid translocation through the hemolysin pore, it is clear that a major factor limiting resolution is the time available to detect current modulation by a single nucleotide. For instance, a single nucleotide in a DNA strand passes through the length of the pore in a few microseconds, a time interval that does not provide sufficient ionic current to distinguish between a purine base and a pyrimidine base in the total ionic current of a blockade. In order to demonstrate that increased time intervals may permit the sensitivity required for single base resolution, DNA "hairpins" can be used to keep a single molecule of DNA in the α-hemolysin channel for relatively long (millisecond) time intervals. Hairpins are sequences of single-stranded nucleic acids folded back on themselves to form hydrogen bonds between Watson-Crick base pairs [19, 20]. The entropy and enthalpy components of DNA hairpin formation are readily estimated, and the sequence can be designed so that only intramolecular interactions occur [21]. An extensively hydrogen bonded hairpin

structure can enter the vestibule of an α-hemolysin channel but would not be translocated through the pore until all the hydrogen bonds stabilizing the hairpin spontaneously dissociated.

The investigation reported by Vercoutere et al. [22] used a well-characterized DNA hairpin with a six-base-pair stem and a four-deoxythymidine loop. When captured within an α-hemolysin nanopore, this molecule caused a partial current blockade (or "shoulder") lasting hundreds of milliseconds, which was followed by a rapid downward spike. This signature was interpreted as an initial capture of a hairpin stem in the vestibule which produces the shoulder, followed by simultaneous dissociation of the six base pairs in the hairpin stem. The extended single strand can then traverse the pore and produce the spike. With this assumption, a series of blunt-ended DNA hairpins with stems that ranged in length from 3 to 8 base-pairs (bp) was found. It was found that each base pair addition produced a marked increase in median blockade shoulder lifetime, and a downward trend in shoulder current amplitude, from I/I_o equal to 68% for a 3 bp stem to I/I_o equal to 32% for a 9 bp stem (Fig. 2). These results demonstrate that single base pair resolution can be achieved by monitoring the duration and reduction of ionic current blockades as the hairpin stem extends further into the vestibule with each additional base pair.

8. CORRELATION OF BLOCKADE DURATION WITH FREE ENERGY OF DUPLEX STABILIZATION

In the experiments described, the standard free energy of hairpin formation was calculated and compared with the median duration of hairpin shoulder blockades [22]. The median blockade duration correlated remarkably well with the free energy of formation. This correlation would not be expected if the force generated by the electric field was simply unzipping the hydrogen bonded base pairs of the hairpin and drawing the molecule through the pore. Instead the hairpin remains in the vestibule until all of the hydrogen bonded complementary bases dissociate simultaneously, at which point the unwound DNA strand is drawn through the pore to produce the spike. The time required before the hairpin dissociates (the shoulder) is an exponential function of the number of base pairs in the hairpin structure and is directly related to the calculated free energy that stabilizes the hairpin. Note that this relation between free energy and blockade duration also extends to a single nucleotide mismatch in the hairpin, in which the AT pair is replaced by an AA pair. This reduces the median blockade duration from $\sim$1 second to 10 milliseconds, showing that the nanopore can distinguish two DNA molecules that differ by a single nucleotide.

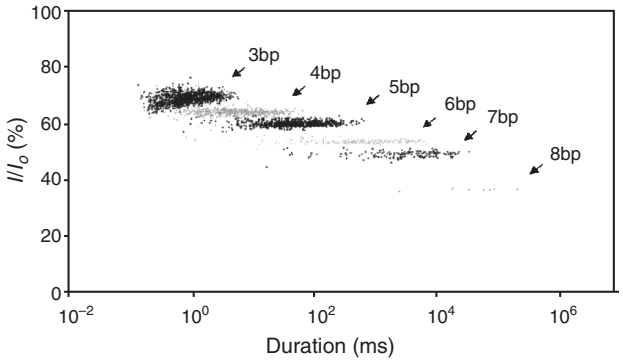

Figure 2. Nanopore resolution of single base-pair differences, illustrated as an event diagram for DNA hairpins with 3 to 8 base-pair stems. Each point represents the duration and amplitude of a shoulder blockade caused by one DNA hairpin captured in the pore vestibule. The duration of the 9 bp hairpin blockade shoulders lasted so long that a statistically significant number of events could not be readily obtained. Modified with permission from [22], W. Vercoutere et al., *Nat. Biotechnol.* 19, 248 (2001). © 2001, Nature.

These results illustrate the extraordinary ability of a nanopore to provide information about dynamic events occurring in single molecules. Furthermore, they demonstrate that ionic current blockades are sufficient to detect differences between DNA molecules at the single base-pair level, suggesting that a suitable nanopore may be able to resolve individual nucleotides.

9. NANOPORE ANALYSIS USING SEQUENCE-SPECIFIC DETECTION

Howorka et al. [23] found that it was possible to attach a single-stranded oligomer of DNA to hemolysin so that the vestibule contained a short sequence that potentially could bind to traversing DNA if complementary base pairing was possible. This remarkable feat of nanoengineering produced a biosensor that could detect specific DNA sequences with single base resolution. The principle underlying the function of this biosensor is that a traversing DNA strand binds to the tethered DNA in the vestibule by complementary base pairing and remains in the pore for a measurable amount of time. As a result, a distinctive two-part signal is generated, first by the duplex DNA that partially blocks the current, followed by a spike as the target DNA is released and passes through the pore stem. DNA that lacks the complementary base pairing passes through very rapidly without the partial blockade. The duplex lifetimes allow discrimination between short DNA strands that differ by only a single nucleotide so that duplex formation is inhibited. Because of this sensitivity, it was possible to determine the sequence of a codon embedded in the sequence of a single DNA oligomer covalently linked to the vestibule. These authors also used this approach to detect a mutation in the reverse transcriptase gene of the HIV virus.

10. COMPUTATIONAL APPROACHES TO ANALYSIS OF NANOPORE DATA

A key strength of nanopore detectors is that they not only detect and identify single molecules but can also analyze populations of single molecules. With signal processing and pattern recognition, this information provides an analytical tool based on a rapid sampling of channel current blockades. In recent work, a computational tool incorporating machine-learning methods has been used to perform signal analysis

and pattern recognition [22, 24]. Feature extraction methods, such as hidden Markov models (HMMs), offer a powerful and generic data-mining tool. For instance, labeling the HMM analyzed data-events, followed by support vector machine (SVM) discrimination, allows pattern recognition among thousands of individual blockade events. SVM is in many ways superior to neural nets, in that performance optimization is done with structural risk minimization (SRM). Due to their SRM constraint, SVMs are much less susceptible to overtraining, which permits a training process that is easily deployed and scalable.

Two hurdles must be overcome for successful signal processing by HMM and SVM approaches. At the earliest stage of the signal acquisition, ad hoc methods generally must be used. In recent channel current pattern recognition work, signal acquisition and primitive feature selection were performed by a time-domain finite state automaton (FSA) and a wavelet-domain FSA. The second hurdle is the data labeling needed for training the discriminator (supervised learning). In the case of nanopore experiments the labeling problem was solved by using training data drawn from operation with only a single type of analyte, so that all training events had the same label.

A primary computational goal of the blockade pattern recognition was real-time signal calling, in which event patterns are identified in less time than the duration of the measurement. This goal has practical use in detector operation in that extensive data capture is not required. In other words, detector data outflow does not exceed the throughput of the signal processing pipeline. In recent work involving 100 ms blockade signatures, it has been demonstrated that real-time signal calling is possible with an inexpensive PC using Linux (a free Unix-type operating system), and the C and Perl software packages.

11. SYNTHETIC NANOPORES FOR ANALYZING NUCLEIC ACIDS

Synthetic nanopores are now being tested that could have the potential to match or surpass α-hemolysin in detecting and analyzing nucleic acids in solution. In contrast to a labile protein in a delicate lipid bilayer, solid state nanopores should be mechanically robust, tolerate a broad range of temperatures, pH, and chemical conditions, and provide a low capacitance, low noise surface suitable for integrated electronics. Ideally, the fabrication process used to make the solid state nanopore should make it possible to easily control and vary pore dimensions so that these dimensions can be optimized for a particular application (e.g., probing single-stranded vs. double-stranded DNA).

Fulfilling these requirements is difficult because fabrication methods able to manipulate matter at nanometer dimensions have not been available. For example, single 3–5 nm holes in an insulating silicon nitride membrane can be made using an erosion process, such as reactive ion etching [25], but this method produced nanopores with a range of dimensions from 3 to 40 nm, only a few of which were of the desired dimension. Achieving greater reproducibility requires knowing precisely when to stop the erosion process. One approach that can reproducibly fabricate nanopores of a desired dimension is a feedback-controlled ion sputtering system that counts the ions transmitted through the gradually opening pore and extinguishes the ion sputtering erosion process at the appropriate time [26]. With feedback control, reproducibility does not depend on precisely matching all conditions and starting dimensions. Using this system, it is possible to routinely produce robust single nanopores with 2, 3, or 4 nm diameters. Such nanopores are capable of registering single DNA molecules that produce characteristic current blockade signals in much the same way as they do in the α-hemolysin pore [23].

12. FUTURE APPLICATIONS OF NANOPORE ANALYSIS

To summarize, single-base resolution in DNA or RNA remains the goal of investigators now working to establish nanopore sequencing, and several significant intermediate applications are now within reach. These include simple detection of DNA in microscopic volumes, as well as targeted molecular barcodes. Although nanopore analysis is just emerging as a new research tool, the rapidly developing technology has immense promise as an analytical method for measuring and characterizing linear polyions such as nucleic acids. The ability to detect and identify single nucleic acid molecules in solution has numerous applications, but these will be realized only if a stable inorganic nanopore can be developed. We are making significant progress toward this end, and as noted the first such nanopore based on silicon nitride has detected long double-stranded DNA molecules as they pass through. Assuming that a nanopore instrument can be commercially developed, the following applications appear to be feasible:

1. Measurement of nucleic acid concentration, for instance, during PCR amplification.
2. Identifying molecular species in solution. A nanopore in the size range of 4–6 nm diameter will be able to detect and perhaps identify individual soluble protein molecules.
3. Encoded polymers as molecular markers. Akeson et al. (unpublished results) have demonstrated that synthetic nucleic acids can be linked to a cleavable targeting agent and used to identify and quantify analytes in solution. After binding of the targeted marker to the analyte, the linker is cleaved and the nucleic acid marker is determined by its nanopore signal.
4. Hybridized DNA is readily distinguished from single stranded DNA by a nanopore of appropriate size.

GLOSSARY

Alpha hemolysin A toxin produced by Staphylococcus bacteria. Hemolysin assembles into heptameric structures in lipid bilayers and produces a nanopore approximately 2 nm in diameter.

Base pair In the double helical structure of DNA and RNA, the complementary bases hydrogen bond to from base pairs. A bonds to T (DNA) or U (RNA) and G bonds to C.

DNA hairpins Short strands of DNA ~ 10–50 bases in length with complementary base pair sequences at both ends are able to assemble into a hairpin-like loop. The ends of the loop form the double helix structure of DNA.

Hybridization When two strands of DNA with complementary base sequences come together in solution, they form a double helix. This process is called hybridization.

Lipid bilayer Amphiphilic molecules such as phospholipids self-assemble into biomolecular structures called lipid bilayers. Such structures represent the permeability barrier of all cell membranes, and can be used to support a nanopore such as hemolysin.

Nanopore A nanoscopic pore (1–100 nm diameter) in a thin membrane.

polyA, polyC, polyU When RNA is synthesized from a single species of nucleotide, it is called a homopolymer. PolyA, polyC, and polyU are abbreviations from polyadenylic acid, polycytidylic acid, and polyuridylic acid, all RNA homopolymers.

Polymerase chain reaction (PCR) A method for enzymatically amplifying DNA.

1. INTRODUCTION

Carbon material is a versatile substance because of its variety of bonding character. The typical allotropic forms are graphite and diamond, in which carbon element consists of sp^2 and sp^3 hybridization, respectively. In general, carbonaceous products categorized in the former carbon are obtained when many organic compounds and those of biological origin such as wood, peat, coal, and biomass are pyrolyzed in inert atmosphere at high temperature. The products contain a lot of elemental carbon and a small amount of oxygen, nitrogen, and so on.

Franklin classified the carbonaceous materials into two distinct groups (e.g., nongraphitizable and graphitizable carbon) on the basis of X-ray diffraction study [1]. Also hard and soft carbons are often referred to under another nomenclature, respectively [2]. The structural models proposed are represented schematically in Figure 1. Thereafter the great advance of the high resolution transmission electron microscope (TEM) has made it possible to visualize the more precise structure of the carbons. Jenkins and Kawamura observed TEM images of a glasslike carbon and illustrated a schematic model for the network of ribbon stacks, as shown in Figure 2a [3]. In addition Shiraishi proposed another model for nongraphitizable carbon (Fig. 2b) [4]. Figure 3 shows typical lattice images of nongraphitizable carbon from phenol formaldehyde resin and of graphitizable carbon from petroleum pitch coke. They reflect the skeleton of the hexagonal aromatic carbon layers [4]. The resin carbon does not form a structure like Figure 3d even at high temperatures like 3273 K, whereas the number of parallel layers increases considerably in the pitch carbon with heat treatment at much lower temperature, indicating a better graphitic structure.

It is said that such a structural difference originates both from the structure of the raw material and from the carbonization process: the cross-linking develops between the randomly oriented crystallites during carbonization of the resin leading to a rigid structure and to a charcoal which is hard carbon and has a well developed porous structure. On the other hand, the pitch proceeds in a liquid state during the carbonization around 627–773 K and aromatic hydrocarbons produced at this temperature range can arrange in parallel with each other to lead a formation of small spherical droplets with optical anisotropy called carbonaceous mesophase [5]. It has been shown that oxygen-rich precursors inhibit graphitization whereas high C–H ratios enhance the formation of a three-dimensional graphitic structure with less developed porous structure. The nongraphitizing carbon contains a large number of pores between small crystallites as can be seen from Figure 1a. Most of these pores originally included are located inside far from the surface. Thus, in order to generate the open pores on the surface of the particles, carbon atoms are partially burned off at high temperature using oxidative agents such as steam, carbon dioxide, and so on. The process and the resultant product are referred to as activation and activated carbon. Since most of the pores are mainly the spaces between a few stacked lamellae or crystallites, the pore shape in the carbon materials is basically of slitlike structure.

Activated carbon is one of the well-known porous substances and a collective name for a group of porous carbons. In 1911, Norit Company began the commercial production

of activated carbons from peat by steam activation. During the first decades of the last century, activated carbon was used mainly for the purification of products of the chemical, pharmaceutical, and food industries. Purification of drinking water was also an important application from the outset. In recent years, the production of carbon has been increasing for the prevention of environmental pollution and for meeting the constantly increasing demands for purity of natural and synthetic products [6].

Porous carbon materials have so far played an important role in many industries, including air and water purification, gas separation, catalysis, chromatography, and so on. However, there are numerous other potential applications in which materials with carbonaceous surfaces would be attractive, for instance adsorption of large hydrophobic molecules such as vita dyes, humic acids, dextrines, chromatographic separation, electrochemical double layer capacitors (EDLC), and lithium batteries. In these cases, the presence of wider pores, preferably mesopores, would be more advantageous to the adsorption of these large compounds.

To meet such requirements many novel approaches have been proposed to control pore structure and to produce different types of porous carbons. And it has been demonstrated that such porous carbons are very useful and exhibit outstanding performance in many new applications such as catalytic supports [7] and EDLC with very high power [8].

In the first section of this chapter the general definition of a pore in solid materials and the characteristics of the pores included in carbon materials are briefly represented to help readers understand the contents described in the following sections. Second, the importance of the nanopores in the carbons is pointed out and then special emphasis has been put on the novel preparations of nanoporous carbons and development of new utilization areas of these carbons. Throughout the chapter readers can survey the state of the art preparation and application for nanoporous carbons.

From this point of view carbon nanotubes and nanohorns are also promising materials because the pores have a unique shape and are more uniform than those in the conventional carbons.

Here the authors point out the importance of mesopores (or nanopores) in the porous carbons. All the micropore entrances in fibrous activated carbon [or activated carbon fiber (ACF)] can access the outer surface of the fiber, whereas most of the micropores existing in granular activated carbons are placed deep inside far from the surface of the carbon particles through the mesopores. Such a difference in the circumstance of the pores in fibrous and granular carbons is depicted in Figure 4. Of course, micropores are important to the adsorption ability of small molecules because most of the adsorption takes place in the micropores. In the case of granular carbons the species to be adsorbed have to approach to the micropores through meso- or macropores. In other words, these relatively large pores can serve as a passage for the transport of the adsorbates. In particular the presence and the quantity of the mesopore are very important in designing nanoporous carbons suitable for heterogeneous catalysis and supercapacitor applications.

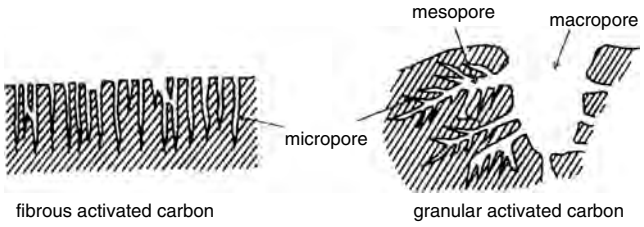

Figure 4. Structural models of pores in fibrous activated carbon and granular activated carbon.

2. CHARACTERIZATION OF NANOPOROUS CARBONS

2.1. Pore Definition

The general classification of pore in adsorbents is given according to the International Union of Pure and Applied Chemistry recommendation, dividing the size into the following groups (Table 1) [9];

- micropores: pore size <2.0 nm
- mesopores: pore size in the range of 2.0–50 nm
- macropores: pore size >50 nm

2.1.1. Micropores

A more precise classification of the micropores would distinguish two types of micropores, narrow and wide pores [10]:

- ultramicropores: pore size <0.7 nm
- supermicropores: pore size in the range of 0.7–2.0 nm

Micropores in porous carbons are very important for gas adsorption because their quantity and size are closely related to the specific surface area and the interaction with adsorbates. As a consequence of the overlapping of the adsorption potential of opposite pore walls, the filling of the microporosity corresponds to the initial steep portion of the adsorption isotherm at low relative pressure. The classification of adsorption isotherm curves will be explained in detail in Section 2.3.1.

Table 1. Classification of pore.

1. Classification by size (see text)
   - Micropore <2.0 nm
     Ultramicropore <0.7 nm
     Supermicropore 0.7–2.0 nm
   - Mesopore 2.0–50 nm
   - Macropore >50 nm
2. Classification by origin
   - Intraparticle pore: existing in crystallites
     Intrinsic pore: originated from crystal structure
     Extrinsic pore: induced by doping of foreign substances
   - Interparticle pore: generating by aggregation of primary particles
     Rigid pore
     Flexible pore
3. Classification by pore situation
   - Open pore: accessible to adsorbates
   - Latent pore: open, but very narrow so as to be inaccessible to adsorbates
   - Closed pore: isolated from surface and inaccessible to adsorbates

2.1.2. Mesopores

These pores with widths from 2.0 to 50 nm were previously named transitional pores, in which an adsorbate condenses in liquidlike state by capillary condensation and a meniscus is formed; as a consequence, a hysteresis loop often appears on desorption and its interpretation can lead to the distribution of mesopores in the carbon.

2.1.3. Macropores

Since these pores have widths exceeding 50 nm, they cannot be filled by capillary condensation. The limit of 50 nm is artificial and it corresponds to the practical limit of the method for the pore size determination based on the analysis of the hysteresis loop. These pores are not so important for the adsorption of gas and small molecules, but recently Toyoda and Inagaki have found that the macropores in exfoliated graphite have a high capacity for sorption of heavy oil [11]. In general, however, these large pores cause a decrease of the bulk density, one of drawbacks for transport usage such as natural gas storage vehicles [12].

The "nanopore" used in this chapter is not a formal nomenclature, but recently this word appeared in some papers as the importance of nanopores in the carbons is recognized [13–15]. The authors define it as pores covering the size dimension with a single nanometer ranging from larger micropores (1.0–2.0 nm) to smaller mesopores (2.0–10 nm). However, the size is not a restricted definition but has a certain range. Thus, in some cases we would include pores ranging from micropores to mesopores in the category of nanopores.

Pores in carbon can be further divided into the following two categories from a different point of view. The pore classification reported by Inagaki and Kaneko [16] is partially modified and shown in Table 1, together with the definition of pore size mentioned previously. The first category is separated into two groups (i.e., intra- and interparticle pore) by origin of the pore formation. The former, intraparticle pore, being present between particles (or crystallites), is further subdivided into two types of pore, intrinsic and extrinsic. The intrinsic pore originated from imperfection of the crystal structure itself, and the extrinsic one is induced by doping a foreign element such as boron or nitrogen. A typical example is the very narrow pore formed when a few layers stacked in graphite are expanded by intercalation. The interparticle pore can be classified into two pores due to the strength of the pores, hard and flexible pores. Most of the pores in the carbonaceous material (i.e., those in carbon aerogel) are hard because they are heat-treated at high temperature. But the pores formed by intercalation or those included in some original coals are considerably soft and easily deformed due to shrinkage at low temperature or they are destroyed by external forces. So when materials with such soft pores are employed for liquid nitrogen adsorption or mercury porosimetry experiments one should be careful of handling or data treatment.

In the second category pores are divided into open and closed pore. Pores measured by gas adsorption experiments are usually classified as open pores, but all of the pores by adsorption are not open, depending on the size of the probe molecule used. Very narrow pores, which the adsorbate molecules cannot access, fall into latent pores. Yoshizawa et al. have investigated accessible and inaccessible pores in microporous activated carbons by N_2 adsorption, density, and small angle X-ray scattering measurements [17]. The closed pores can be evaluated by TEM observation and small angle X-ray scattering which are described in the next section.

2.2. Characteristics of the Pores in Carbon Materials

As already mentioned in the Introduction, the small pores in carbon materials are spaces between stacked aromatic layers or interfacials/interstitials of the crystallites consisting of these stacked layers. Thus, it has been generally accepted that micropores in the carbonaceous materials like activated carbons possess slitlike structure (Fig. 1a).

The carbon nanotube was discovered by Iijima in 1991 [18]. Since a single walled carbon nanotube (SWNT) is composed of a monolayer graphene sheet rolled up into a long seamless cylinder, the substance has a structure of packed bundles of the tubes, in which the pores are located inside of the tubes as well as at intertubular channels. These pores shown in Figure 5 are of round shape, being considerably different from those in the conventional carbons [19]. In 1999 also Iijima et al. have found an analogous type of nanotube called a nanohorn, which was obtained by CO_2 laser ablation of a graphite rod [20]. TEM images of particles prepared suggest that each particle consists of a tubularlike structure with cone caps. Based on the TEM observation they proposed a model for the packing of carbon nanohorns in a dahlia particle [20]. Furthermore, Murata et al., have measured the N_2 adsorption isotherms of these nanohorns and reported geometrical models for the horn and its aggregate structure shown in Figure 6 [21]. Accordingly, these modern carbon materials have round-shaped pores, as easily supposed from the structure of Figures 5 and 6.

2.3. Analysis Method and Limitation

The major techniques to characterize pores in carbon materials are indicated in Figure 7, in which arrows give how much range the individual analytical technique can cover in the pore size included in the carbon. Each technique has various advantages and disadvantages as well as the limitation. A brief explanation and the limitation for each method are described.

2.3.1. Gas Adsorption

Gas adsorption is widely used as a standard method to analyze the porosity in carbon; the nitrogen adsorption/desorption isotherms are measured at the boiling point of liquid nitrogen. In recent years since almost all commercially available apparatus are equipped with computer-aided controller systems, one can collect isotherm data automatically. At the same time, pore characteristic parameters such as Brunauer, Emmett, and Teller (BET) surface area, pore

size distribution, and so forth can be easily obtained by computer analyzing programs.

Isotherm Curve The shape of the adsorption isotherm curve reflects the characteristics of the pore structure in the adsorbents. Thus, it is very important to understand the relationship between the shape of the isotherm curves and pore structure. Brunauer et al. classified the curves into five groups (i.e., Types I–V) shown in Figure 8 [22].

Type I Isotherm The main feature of Type I is a sharp increase in adsorption at very low relative pressure (p/p_0) and a following long horizontal plateau over a wide range of higher pressure. This type is also called a Langmuir curve after his detailed analysis [23].

In this curve a monolayer adsorption takes place at very low pressure, which is indicative of strong interaction between the gases introduced and the micropore surface. The isotherm of the Type I can be found in porous carbons with a very narrow range of micropores (e.g., ACF, in which there is an enhancement of adsorption potential).

Type II Isotherm The isotherm of Type II is associated with monolayer–multilayer adsorption on an open and stable external surface of a powder, which may be nonporous, macroporous, or even, to a limited extent, microporous. The curve can be seen when an energetic heterogeneity in the adsorbent–adsorbate interactions can exist.

Type III Isotherm The isotherm of this type is confined to a few systems, in which the overall adsorbent–adsorbate interaction is weak, in contrast to relatively strong adsorbate–adsorbate interaction. For example, isotherm curves of this type can be observed when steam is adsorbed on the nonporous solids with a hydrophilic surface like graphite. The monolayer density tends to be unevenly distributed on the adsorbent surface with a relatively high concentration of

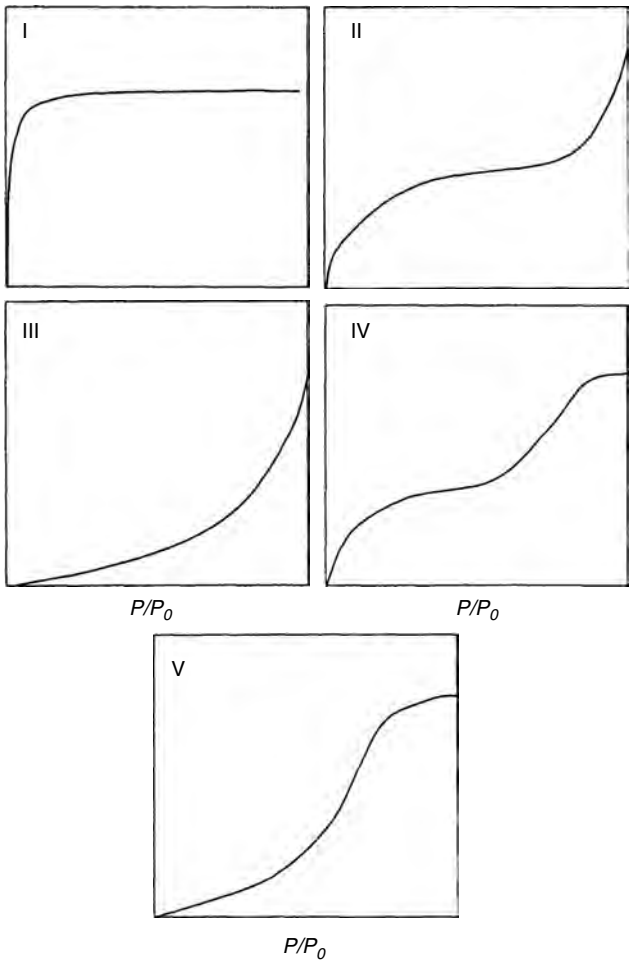

Figure 8. Shape of gas adsorption isotherms of Types I, II, III, IV, and V.

molecules located on the most active areas. As the pressure is raised the average monolayer concentration is increased, but before it can become closed-packed over the complete surface, the monolayer coverage is overtaken by a form of cooperative multilayer adsorption in which molecules are clustered around the most favorable sites.

Type IV Isotherm The isotherm curve can be observed in the case of porous solids with both mesopores and macropores, in which there are any interactions between adsorbent and adsorbate, being analogous to the behavior in the case of Type II. The typical example can be seen in the adsorption of nitrogen on activated carbons at 77 K. In general, the curves give a hysteresis loop between adsorption and desorption curves at relative pressure, $p/p_0 > 0.4$, which is due to the occurrence of capillary condensation at the adsorption into mesopores.

Type V Isotherm The appearance of the initial section of Type V isotherm is very similar to that of a Type III isotherm for a gas–solid system (e.g., water/carbon). In this case, however, the sharp increase in adsorption at higher p/p_0 is dependent on the pore size. For example, the ultramicropores in a molecular sieve carbon are filled with water at a much lower p/p_0 than are the wider pores in a supermicroporous carbon.

Surface Area In order to determine the surface area of porous carbons, the well-known BET method is always used as a standard procedure [24]. In principle, the BET method can be applied to isotherms of all types described previously, provided that there is no significant primary micropore filling contribution and that the structure of the completed monolayer does not vary from one surface to another.

Micropore Analysis Various procedures have been used to evaluate the micropore capacity for the experimental isotherm data, but in practice these are all empirical methods. Dubinin utilized the characteristic curve principle of the Polanyi potential theory [25, 26]. The fractional filling, n/n_0, of the micropore volume is expressed in the general form

$$n/n_0 = \exp -(A/E)^m$$

where m is a small integer, E is a characteristic free energy of adsorption for the given system, and A, originally termed adsorption potential, is the change in differential free energy of adsorption, viz.:

$$A = -RT \ln(p/p_0)^2$$

In this equation, R is a gas constant and in the special case of $m = 2$, the adsorption isotherm equation in linear form becomes

$$\log n = \log n_0 - D(\log p/p_0)^2$$

where D is a constant related to E. This equation is generally known as the Dubinin–Radushkevich (DR) equation. According to the DR equation, a linear relationship should be obtained between $\log n$ and $(\log p/p_0)^2$, with the intercept equal to $\log n_0$, the mciropore volume.

t-Plot and α_s Plot The t plot introduced by Lippens and de Boer [27] is one of the methods to compare experimental isotherms with the standard isotherm obtained on a suitable nonporous reference adsorbent. It provides a simple and direct method of comparing the shapes of the adsorption isotherms of the sample with that of the standard nonporous reference from which valuable information on the porous structure of the adsorbent can be obtained. The amount adsorbed on the porous adsorbent is plotted against t, the corresponding multilayer thickness of the standard nonporous solid. Actually the adsorption isotherms for a given adsorptive on different adsorbents may be superposed by plotting them in the reduced form, $t(n/n_m)$, against p/p_o. The backextrapolation to the ordinate of the linear portion of the plot gives a measure of the total micropore volume, whereas the slope of the linear section provides a measure of the more external area of the solid and the extrapolation to the origin of the initial part of the plot provides the total surface area.

The α_s method is another empirical approach for the determination of the microporosity [28]. The application of the method requires a standard isotherm of the adsorption (nitrogen in this case) on nonporous reference materials with a similar surface structure to the carbon under investigation. The amount adsorbed is plotted against the reduced standard adsorption (placing $\alpha_s = 1$ at $p/p_o = 0.4$).

In using both the t plots and α_s plots for the characterization of microporous carbons, one should understand that they are based on the assumption that adsorption in micropores is complete before it starts on the rest of the surface. Very often, however, depending on the pore structure of the carbon, there is a wide range of relative pressure where significant amounts of adsorption are occurring in both micropores and mesopores.

Mesopore Analysis The mesoporosity of the carbons can be evaluated by the analysis of the hysteresis loop observed on desorption, following the adsorption of vapors to initial relative pressure. The hysteresis loop results from the progressive condensation of the adsorbate in the pore, in the course of adsorption, with the formation of a meniscus. The vapor pressure above the meniscus decreases with the pore size, due to the small radius of curvature, and it follows that the smallest pores are desorbed last when the pressure in the vapor phase is reduced during desorption. The pore size distribution of mesopores can be calculated from the hysteresis loop by the computational techniques described in detail by Gregg and Sing [29]. The mesopore capacity is the amount adsorbed at the plateau of the Type IV isotherm (Fig. 8): to obtain the mesopore volume, it is assumed that the condensate has the same density as the liquid adsorptive at the operational temperature. There are various classical procedures for mesopore size analysis, such as the Barrett, Joyner, and Halenda method [30], the Cranston–Inkley method [31], and the Dollimore–Heal method [32, 33]. The details of these methods are given in each paper.

2.3.2. Analysis by Small-Angle X-ray Scattering

Since small-angle X-ray scattering (SAXS) occurs at the local electron density difference in materials, either pore or matrix can be scattered in principle. Therefore it provides averaged information over all pores regardless of their accessibility [34]. Recently, a pore characterization method which combines SAXS and N_2 adsorption with density data has been proposed and applied to pitch-based ACFs prepared with different activation extents [35]. The difference including inaccessible pores is successfully described among the ACFs by this method. In this section the SAXS results on the pore structure of carbon fibers prepared by a polymer blend are introduced as an example.

Fukuyama et al. applied the SAXS technique to evaluate the pore shape and size of the carbon fibers prepared from two kinds of polymers, in which one is phenolic resin as a carbon precursor, and the other is polystylene that disappears by pyrolysis, (e.g., a pore forming resin) [36]. Two kinds of samples heat-treated at 773 and 1273 K (sample A and B, respectively) were used for the measurements. The SAXS patterns are shown in Figure 9, where I and s are intensity in arbitrary units and a scattering parameter, respectively. In order to analyze the radius of gyration, R_g, in the pore by the Guinier and Fournet method [37], the regression lines to fit the experimental data of the lower s^2-region were drawn as shown in Figure 10. The values (R_g) of 7.1 nm for sample A and of 6.9 nm for sample B were obtained from the slop of the straight lines in the smaller s^2-region. The information on the shape of pores is included

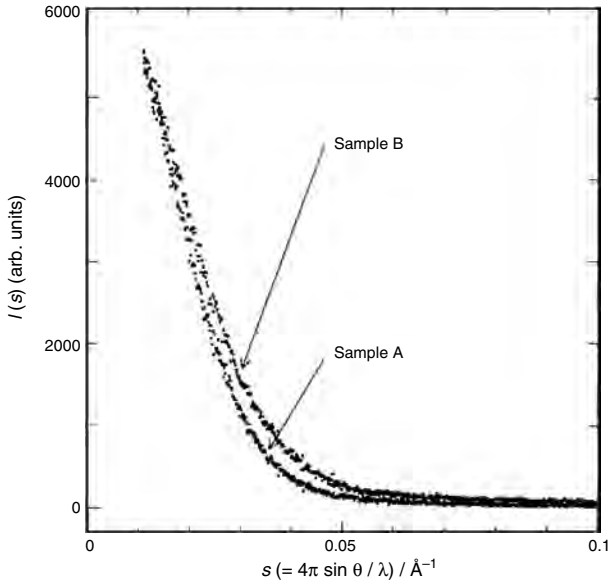

Figure 9. Scattering patterns of sample A (773 K) and sample B (1273 K). Reprinted with permission from [36], K. Fukuyama et al., *Carbon* 39, 287 (2001). © 2001, Elsevier.

in the scattering pattern in larger regions than the Guinier one [37]. Thus, they drew the cross-section plot given by the expression [38]

$$\ln(I(s) \cdot s) = \ln(I(0) \cdot s) - 1/2R_c^2 \cdot s^2$$

where R_c is a gyration radius of the bottom of the column. The R_c value of the pores from the slop if the plot of $\ln(I(s) \cdot s)$ vs s^2 forms a straight line (Fig. 11). From the

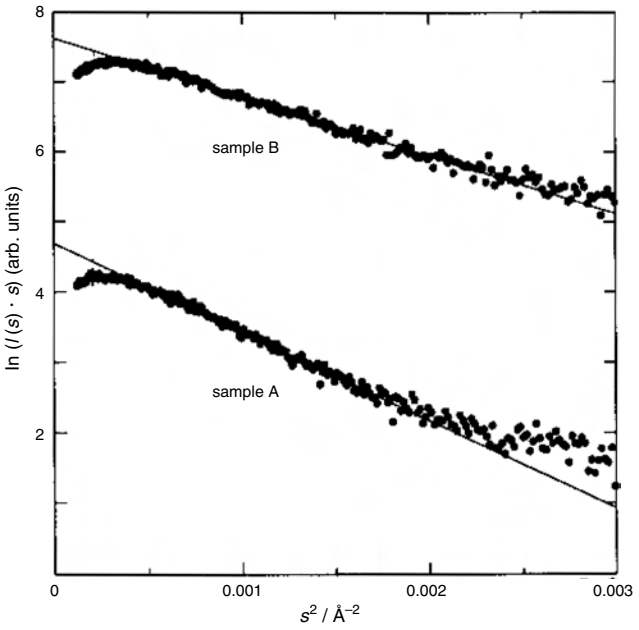

Figure 11. Cross-section plots. The plot for sample B is displaced by +3 unit for clarity. Reprinted with permission from [36], K. Fukuyama et al., *Carbon* 39, 287 (2001). © 2001, Elsevier.

following relation between R_c and radius of column bottom R, $R = \sqrt{2}\ R_c$, the value R can be calculated [38]. Also for the column with R and height L, the gyration radius R_c is given by

$$R_c^2 = (R^2/2) + (L^2/12)$$

Then, the values of L are determined as 17.4 and 19.2 nm for sample A and B, respectively. Table 2 and Figure 12 show the list of the results and the model of the pore structure in the carbon fiber heat-treated at 1273 K. Since the pore is elongated in the direction of the axis of a column and shrinks in the circle with heat treatment, the structural model is consistent with the results obtained by other methods.

2.3.3. Quantitative Analysis by TEM Observation

This method is useful for obtaining direct information on pore structure. Another advantage of this method is that a very small amount of the sample is enough for TEM observation. This tool has been used as a complementary technique for analyzing porous materials, because it gives only qualitative information on the pore character. However, recent advances in computer image analysis provide quantitative data on the pore structure.

Table 2. Structural parameters of sample A (773 K) and B (1273 K).

Sample	R_g^a (nm)	R_c (nm)	R (nm)	L (nm)	R_g^b (nm)
A	7.1 ± 0.3	5.0 ± 0.1	7.1 ± 0.2	17.4	7.2
B	6.9 ± 0.3	4.1 ± 0.1	5.8 ± 0.1	19.2	6.7

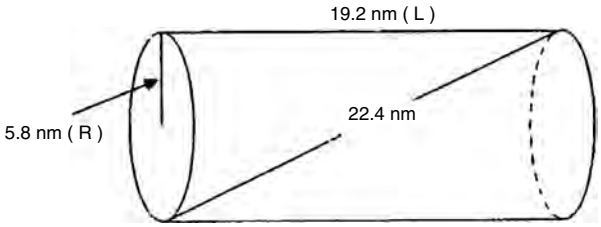

Figure 12. Structural model of pore in sample B (1273 K) based on the SAXS results. Reprinted with permission from the authors (Fukuyama et al.).

MacEnaney and Mays have applied quantitative microscopy or image analysis to the characterization of macropores by using as examples different types of porous carbon materials [39]. The principal advantage of the technique is an ability to evaluate both open and closed porosity. In addition, shape, location, and orientation of pores in the carbon matrix can be observed directly. It is also an advantage to be able to measure these parameters for different classes of macropores in a given porous body. The stereological problems of relating two-dimensional measurements to structural parameters of the three-dimensional material are a disadvantage, particularly when dealing with anisotropic and heterogeneous substances.

Here we introduce the analysis process of this technique and the results on the pore structure of ACF, which were carried out by Oshida et al. [40]. They used computer image analysis to improve the quantitative interpretation of the TEM images of ACF. Figure 13a shows the digitized picture of TEM images for the ACF sample obtained using an image scanner. The white parts correspond to the pores. The inset Figure 13b is the power spectrum of the fast Fourier transform of Figure 13a, and Figure 13c is the binary image of Figure 13(a) in order to clarify the pore images of the ACF. Finally the relationship of the pixel numbers in the outline (length of the peripheral of the binary images, X_N) against those inside the island (surface area of the pore, S_N) is shown in Figure 14. By using the following relation between X_N and S_N, $\log X_N = 1/2D \log S_N + A$, the fractal dimension (D) can be calculated to be $D = 1.74$, where A is a constant. On the basis of these results they proposed microscopic and macroscopic structural models for the pores in the ACF, as shown in Figure 15. The pores in the fiber connect together to form open pores, but the ultramicropores are isolated with each other. Consequently, this method is useful for the precise analysis of pore structure and will be more important with the advances of computer analysis.

2.3.4. Quantitative Analysis of STM and AFM Observation

Basically these methods are same as the analysis by TEM observation; the images obtained by scanning tunnel microscopy (STM) or atomic force microscopy observation (AFM) are treated statistically through computer analyses in order to evaluate the pore size distribution. Inagaki et al. applied the STM method to activated carbons from phenolformaldehyde resin particles and compared the pore size parameters obtained with those by the adsorption method [41–43].

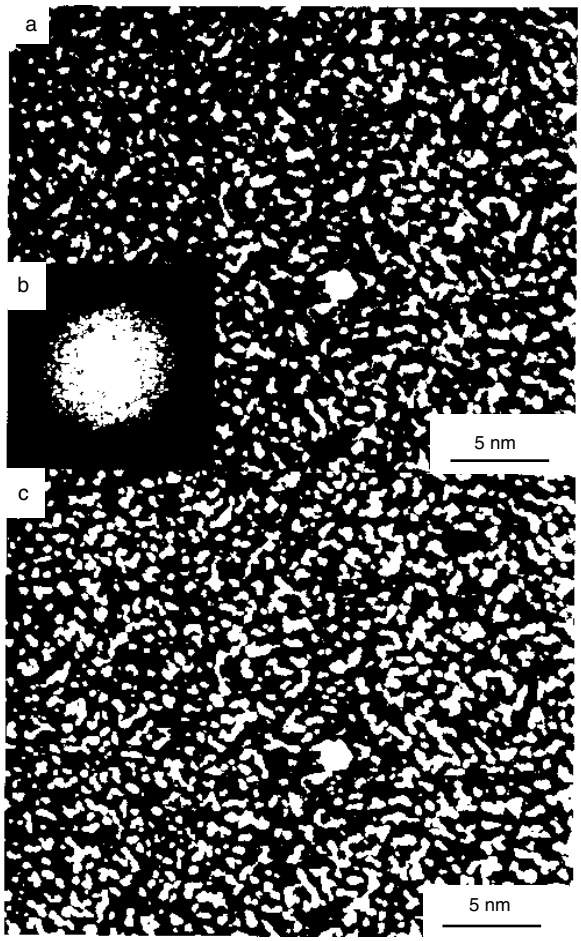

Figure 13. Digitized picture of a TEM image for ACF obtained using the image scanner. The inset (b) is the power spectrum of fast Fourier transform of (a), and (c) is the binary image of (a). Reprinted with permission from [40], K. Oshida et al., *J. Mater. Res.* 10, 2507 (1995). © 1995, Elsevier.

2.3.5. Quantitative Analysis of Scanning Electron and Polarizing Optical Microscopy Observation

The quantitative analysis of the pores is possible by scanning electron microcopy (SEM) or polarizing optical microscopy (POM) observation, but the magnification of these images is of μm order. Therefore these methods are effective for the macropore analysis, as is clear from Figure 7. For example, Inagaki and Suwa analyzed the macropore structure in exfoliated graphite by using SEM images [44]. Also the analysis of the pore in high density isotropic graphite was carried out by the POM method [45].

2.3.6. Mercury Porosimetry

Macroporosity and most mesoporosity can be assessed by mercury porosimetry, which is a simple technique based on the intrusion of mercury into the pores under the effect of pressure. The method can be used only when a sample to be measured has no wettability to liquid mercury. The range

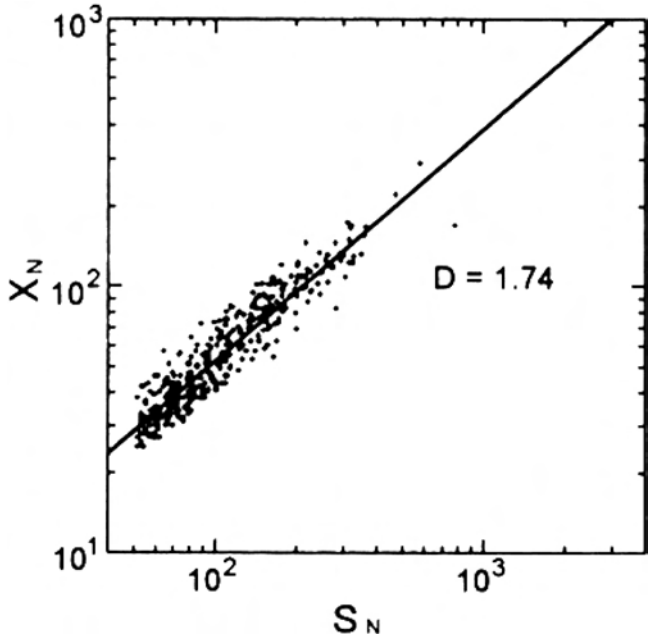

Figure 14. Plots of the pixel numbers in the outline of the binary images of ACF sample versus that inside the islands of the binary images (Figure 13c). Reprinted with permission from [40], K. Oshida et al., *J. Mater. Res.* 10, 2507 (1995). © 1995, Elsevier.

of mercury porosimetry extends from a pore size of about 7.5 nm at 200 MPa to 15 μm, the size of pores penetrated at atmospheric pressure. As pointed out in Section 2.1, when a soft sample with flexible pores such as a kind of raw coal is employed, one should be careful in the measurement.

3. PREPARATION OF NANOPOROUS CARBONS

3.1. Conventional Preparation Methods

3.1.1. Carbonization

A brief description of conventional porous materials, activated carbons, is given in this section. Activated carbons are the carbon materials that possess well-developed pores in their bodies as shown in Figure 16 [46]. Carbon materials are usually prepared by heating organic materials, such as plant-based substance, synthetic polymers, etc., at around 1273 K in nonoxidative atmosphere. This heat treatment process is called carbonization, which is a collective name for the reactions like dehydration, cyclization, aromatization, condensation, and dehydrogenation, resulting in the formation of graphitic structure. For the preparation of porous carbon materials, activation treatment is needed.

Activation is a process to introduce pores into carbon materials. This is usually divided into two categories, physical activation and chemical activation [46].

3.1.2. Physical Activation

This process is a gasification of carbons by gaseous oxides. In other words, partial oxidation can leave holes or voids in the materials depending on the extent of the reaction. Steam and carbon dioxide are exclusively used for this purpose, because the basic reactions for these gases are endothermic which enables fine control of the gasification [47]. In this sense, oxygen is not a good gasifying reagent, because the reactions between carbon and oxygen have large exothermic heat of reaction. Steam can gasify carbons above 1023 K, while carbon dioxide can activate carbons above 1123 K, reflecting the difference in the specific rate of reaction

Figure 16. A conceptual model of porous carbon. This is a three-dimensional representation of Figure 1a. Reprinted with permission from [46], R. C. Bansal et al., in *Active Carbon,*" Chapter 3. Dekker, New York, 1998. © 1988, Dekker.

between the gases (relative rates; $C + H_2O$: 3; $C + CO_2$: 1; $C + O_2 : 1 \times 10^5$) [48].

When carbon materials are exposed to activating gases, a two-stage pore formation process takes place reflecting the reactivity of the phases. In the first step the disorganized carbon is burnt out preferentially when the burn off does not exceed 10%. This results in the opening of the blocked pores. In the second stage the carbon of the aromatic ring system starts to burn, producing active sites and wider pores. In this way, a very complex and interpenetrating pore system is developed in the carbon materials. As the manner discussed previously, the pore size distribution is a function of the degree of activation. It is said that micropores are formed when burn-off is less than 50%, and macropores are introduced when burn-off is larger than 75%.

Physical activation can be accelerated and modified by the presence of metal elements. In the 1980s, Baker et al. conducted direct observations of catalytic gasification by using controlled atmosphere electron microscopy and found that transition metals made channels as they moved around the carbon matrices [49, 50]. This is the principle of conventional catalytic activation.

Oya et al. prepared the metal-containing ACFs, where the metal elements were introduced by mixing their complexes with phenol-formaldehyde resin [51, 52]. After spinning and stabilization, the raw fibers were subjected to carbonization and activation. Figure 17 shows the mesopore size distribution curves for the ACFs with manganese, zinc, copper, chromium, nickel, and iron. Introduction of Mn, Zn, and Cu gave no changes from the pristine fiber sample. Cr, Fe, and Ni showed various distribution curves (i.e., Cr enhanced the population of pores with 1–2 nm in radius, Fe formed mesopores spreading over the wide range of pore radius, and Ni gave a considerable development particularly in the 10–100 nm radius region).

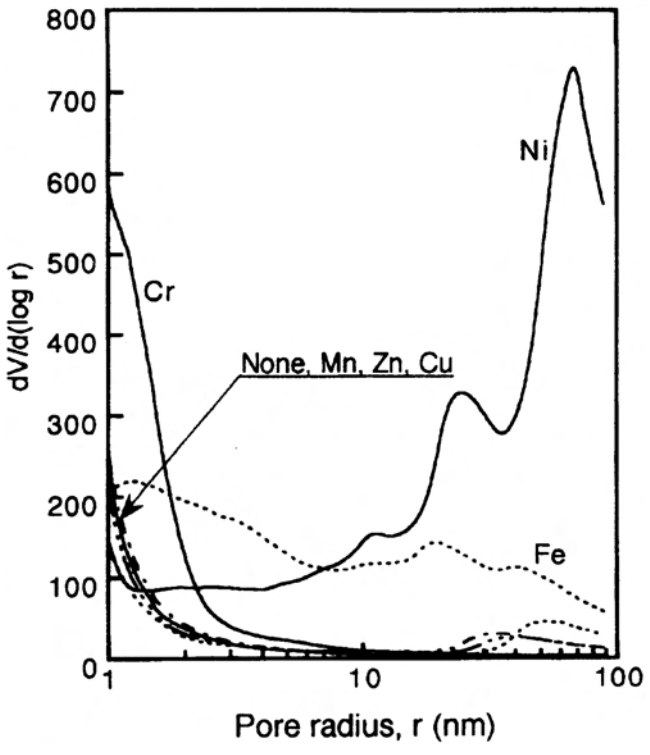

Figure 17. Mesopore size distribution curves of metal-containing activated carbon fibers. ACFs were prepared by spinning of metal compounds containing phenol-formaldehyde resin followed by carbonization and steam activation. Reprinted with permission from [52], J. Ozaki and A. Oya, *HYOMEN (Surface)* 35, 535 (1997). [in Japanese]. © 1997, Koshindo.

Tamai et al. reported that introduction of yttrium complex to a pitch finally gave mesoporous carbons [53, 54]. These carbons possess exclusively mesopores at a high rate such as 80% on surface area basis. They suggested the possibility of using these carbons for trapping large molecules such as vitamin B_{12} and humic acids in water. The formation of mesopores was attributed to the catalytic activity and to the movement of yttrium particles in the carbon matrix.

As seen the catalytic effects and the pore-size distribution are strongly dependent upon the kind of metal elements used as catalyst. Catalytic activation basically utilizes catalytic gasification, so that the differences in the effects should be attributed to the catalytic activity of each metal element. For further control of the pore size distribution, we have to understand the mechanism of catalytic gasification from the viewpoints of pore formation processes.

Metal elements can also be introduced by cation exchange. Nakagawa et al. studied the carbonization of styrene-based polymers with cation exchangeable sulfonic groups [55]. They introduced zinc, copper, calcium, and nickel into the polymer by cation exchange. When the exchanged cation was proton, the polymer shrank during carbonization at 1173 K and finally gave no pores in the carbon. In the cases of divalent or trivalent exchanged metals, carbonization resulted in the formation of micropores ranging 0.33–0.55 nm. The introduced cations have two roles in the pore formation. In the earlier stages of carbonization, the divalent or trivalent cations act as a bridging agent to resist shrinking against pyrolysis of the resin. Pores formed in these stages reinforced by metal-sulfide pillars as depicted in Figure 18. There seems to be an inconsistency between the pore size and the crystallite size of the metal sulfide crystallites.

Blending of iron compounds such as ferrocene with thermosetting resins like phenol-formaldehyde resin or furan resin resulted in the formation of mesoporous carbons. Ozaki et al. are interested in the microstructure and the electrochemical properties of the iron-containing carbons prepared from these mixture [56–59]. Figure 19 shows an electron micrograph characteristic of the iron-containing carbons obtained. Several tens of nanometers of iron particles were surrounded by partially ordered graphitic layers. Carbons containing such structures showed electrocatalytic activity comparable to a platinum electrode. Nitrogen adsorption study revealed that these iron-containing carbons included mesopores [59]. These mesopores may originate from the voids between the spheres shown in Figure 19.

3.1.3. Chemical Activation

Chemical activation includes degradation of raw materials with activating chemicals, such as zinc chloride, phosphoric acid, calcium chloride, etc. This method is usually applied to

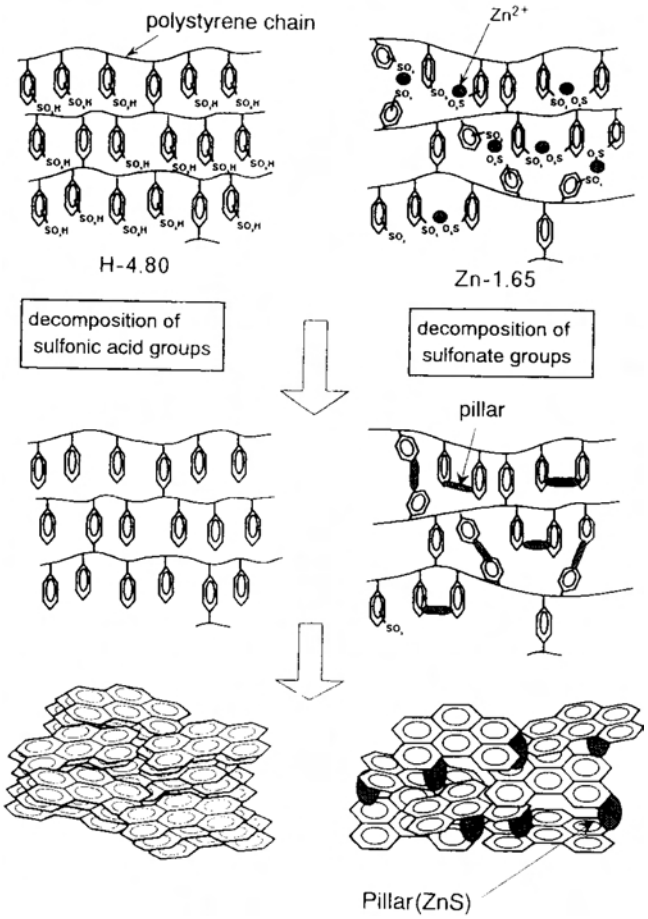

Figure 18. A mechanism for preparation of porous carbons from ion-exchange resins. The pillars are responsible for the formation of pores (right). Reprinted with permission from [55], H. Nakagawa et al., *Carbon* 37, 1455 (1999). © 1999, Elsevier.

wood origin materials, for example, sawdust [47]. Raw materials are impregnated with these chemicals and then heat-treated at elevated temperature ca. 673–1073 K. The main role of the activating reagent is to dehydrate and oxidize the chemical structure of the raw material. Such chemical alteration of the raw materials results in the suppression of tar formation and the promotion of carbonization. The temperatures required for chemical activation are normally lower than required for physical activation and hence we can obtain well-developed pores by using this method without worrying about pore shrinking at higher temperatures. In addition the pore size distribution strongly depends on the activator loading. Because of difficulties in scale-up and wastewater treatment, the chemical activation method is used only in restricted application fields.

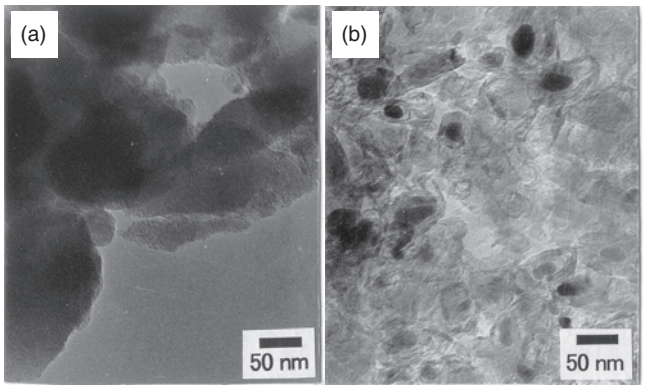

Figure 19. Transmission electron micrographs of the carbons (a) from pristine poly(furfuryl alcohol) and from a copolymer of vinyl ferrocene and poly(furfuryl alcohol).

Kadlec et al. reported that the shapes of the pore were different between the activated carbons obtained by physical and chemical activation processes [60]. The pores were usually bottle shaped in the case of chemical activation and cone shaped in physical activation. The bottle-shaped pores were attributed to the plastic state of the carbonizing materials, because of the low temperature activation (ca. 773 K). The gases released by thermal decomposition make hollows in the plastic material. When the gases escape from the hollow, small pathways would be created. That is why the chemical activation brings about a bottle-shaped pore. In the case of steam activation, there is a concentration gradient between the entrance of the pore and the central part of the pore. The gasification rate is higher at the pore entrance than at the pore center. Thus the conelike shape pore is likely created.

Activation by alkali metal salts should also be classified as a chemical activation. Heat treatment of raw materials mixed with excess amounts of alkali metal salts can provide activated carbon with specific surface area as high as 1000–4000 m^2/g. Weunerberg and O'Grady prepared activated carbons with high surface area from coal, coke, petroleum coke, and their mixtures by impregnating them with potassium hydroxide [61]. The mixture was first subjected to heat treatment between 573 and 723 K, and then to further heat treatment between 973 and 1123 K. The heat-treated samples were washed with water to remove the alkali metal, so that they gave activated carbons with surface area of 3000–4000 m^2/g for coke and of 1800–3000 m^2/g for coals. Schafer prepared activated carbons from a Victorian brown coal by adding potassium hydroxide [62]. The surface area of the activated carbon obtained was 1100–1500 m^2/g. Introduction of potassium hydroxide causes formaion of micropores, and the micropore volume is found to be a function of the potassium hydroxide loaded. For example, addition of 70% of KOH by weight to coal resulted in an increase in micropore volume by four times.

3.2. Novel Preparation Methods

Interest in mesoporous carbons has been growing recently instead of the traditional microporous carbons. This is probably for two reasons. One is increasing demand for the applications concerning liquid media, for example water treatment, EDLCs, and polymer electrolyte membrane fuel cells as described in Section 4. Another is interest in the preparation of ordered mesoporous materials stimulated by templated mesoporous silica.

Following are possible ways to prepare porous carbon materials stated by Ryoo et al. in their review [63]: (1) Deep activation, (2) utilization of metal catalysts, (3) coupling of physical activation and chemical activation,

(4) template methods, (5) carbonization of polymer gels, (6) polymer blend methods, and (7) multiwalled carbon nanotubes (MWNTs). The first three methods should be classified as conventional methods, as already mentioned. Of course physical activation still occupies an important position in practical meaning, so that much fundamental research on this subject is undertaken and published [64–67]. We will concentrate only on new preparation methods other than conventional physical or chemical activation methods. Taking into account the classification of Ryoo et al., the novel techniques were divided into five categories: (1) template methods, (2) polymer blend methods, (3) organic gel methods, (4) new methods for pore formation, and (5) utilizing MWNTs.

3.2.1. Template Methods

Template methods essentially consist of the following three steps: charging of organic materials into nanospaces of the template inorganic materials, carbonization of the organic–inorganic nanocomposites, and liberation of carbons by removing the template inorganic materials [68]. Knox et al. prepared mesoporous carbons by carbonization of phenolic resin impregnated silica gel or porous glasses followed by removing the inorganic templates [69–71]. This carbon is commercially available for column packing materials for liquid chromatography. Kamegawa and Yoshida also carbonized organic–silica composite and obtained carbon materials that can be swollen by contact with organic vapors [72, 73]. In this case, they made very thin organic layers that were fixed by estrification to the surface of template silica.

In the previous examples, the pores in the porous materials were utilized as templates, in other words, carbon precursors penetrated into the template's pores. There are examples including embedded templates. Hyeon et al. used a colloidal silica (ca. 12 nm in diameter) as a template to be embedded in the resorcinol resin [74]. They obtained carbons of which surface area, total pore volume, and mesopore volume were 950 m^2/g, 5.5 cm^3/g, and 4.8 cm^3/g, respectively, when the resorcinol/silica ratio was 7.5. Li and Jaroniec developed an imprinting method in which template silica particles were imprinted into mesophase pitch spheres [75]. In this case, carbonization and template removal were also included. This method gave a possibility of controlling the spatial distribution of the pores such as uniform distribution or biased distribution to surfaces depending on the extent of the imprinting depth into the mesophase pitch, as depicted in Figure 20. Kawashima et al. prepared mesoporous carbons from polymerized furfuryl alcohol in the presence of silica sol made by hydrolysis of tetraethoxysilane [76].

There are many attempts to use ordered inorganic materials as templates. Clays and zeolites form a class of porous materials with ordered pore structures defined by crystalline ordering. Kyotani et al. synthesized very thin carbon film by carbonization of the *in-situ* polymerized polyacrylonitrile or poly(furfuryl alcohol) in the interlayer space of a montmorillonite [77–79]. The obtained carbon was easily graphitized even though the carbon precursors were polymers that usually gave nongraphitizing carbons. Actually, this is the starting point of this type of study. Kyotani et al. tried to prepare carbon material with controlled pore distribution by using these microporous crystalline templates [80]. They could obtain high surface area carbon (2200 m^2/g) by using Y-zeolite as a template [81]. They also made another effort to fill the zeolite's pores with carbon as much as possible by utilizing both *in-situ* polymerization of furfuryl alcohol and chemical vapor deposition of propylene into pore spaces. The obtained microporous carbon had a periodical ordering of 1.4 nm, which is the same as the spacing of the 111 plane of Y-zeolite as shown in Figure 21.

Apart from the utilization of microporous inorganic material as template, two Korean research groups reported that they successfully prepared regularly ordered mesoporous carbons by using mesoporous silica as templates. Lee et al. used an aluminum substituted mesoporous silica, MCM-48, as a template [82]. Phenol and formaldehyde were polymerized in the template and subjected to carbonization and removal of template. The obtained carbon showed an X-ray diffraction pattern resembling the template. Electron microscopic analysis revealed that there were small pores of 2 nm in diameter separated by a carbon wall with a thickness of 2 nm. Ryoo et al. also reported the formation of highly ordered porous carbon by using the same mesoporous silica, MCM-48 [83]. However, they employed different carbon precursor materials, sucrose and sulfuric acid. Figure 22 shows the X-ray diffraction of the template (a), template with carbon (b), and carbon itself (c). Highly ordered pores can be observed in an electron micrograph presented in Figure 23. Recently Joo et al. compared the carbon precursor for the mesoporous silica templated carbon [84]. When furfuryl alcohol was used as a precursor, rodlike carbon was obtained, while in the case of sucrose with sulfuric acid, like Ryoo et al., pipelike carbon was obtained. They loaded platinum on the pipelike carbon and found that the activity for oxygen reduction in fuel cells was extremely high (100 A/g-Pt).

Alkaline metal amalgam or alkali metal can defluorinate poly(tetrafluoroethylene) (PTFE) to produce carbynelike structure (*sp*-carbon allotrope) and finely dispersed metal fluoride crystallites in the polymer matrix. Washing out the metal fluoride from the matrix promoted a transformation from *sp*-hybridization to sp^2-hybridization by a cross-linking reaction between the adjacent carbyne chains [85, 86]. Shiraishi et al. found that heat treatments after the reaction between PTFE and alkali metals can alter the pore size distribution of the resultant carbons, (i.e., higher heat treatment temperature above 623 K caused a formation of mesopores) [87, 88]. This was attributed to the crystalline growth of the alkali halides that are anticipated to be templates for pore formation.

Fenelonov et al. reported a unique example of the template method [89]. They used carbon black as a template and deposited pyrocarbon from C_1–C_4 gases at 1123–1223 K. Templates were removed by steam gasification. In this process, at first the most defected parts of pyrocarbon were gasified. When the formed pore reached the carbon black, a preferential gasification started as shown in Figure 24. A distinct feature of this carbon was high resistance to attrition and mechanical crushing. They anticipate that this carbon can be applicable to catalyst supports.

Although the obtained pore was classified as macropores, Zakhilov et al. prepared spatially ordered porous carbon material by using opal as template [90]. Figure 25 shows the micrographs of the obtained carbon material.

3.2.2. Polymer Blend Method

The polymer blend or polymer alloy method has been developed as a way to improve properties of polymers by blending other polymers. In this sense, the polymer blend is a kind of composite material. Polymer blends are divided into two categories depending on mixing levels. One is macroscopic blending and another is microscopic blending. Phase separated polymers are usually included in the first category and blends with compatibilizers, block co-polymers, and grafted co-polymers are included in the second category.

Pyrolysis behaviors of polymers are decided by the competition between scission of the polymer main chain and formation of cross-linking. Polymers with a tendency to main chain scission are unstable against heat treatment and therefore such polymers decompose without leaving carbon residues. Here these kinds of polymers will be referred to as pyrolyzing polymers. On the other hand, polymers with a tendency to form cross-linking can stand with the heat treatment and consequently leave carbon materials. Usually the latter category polymers are used as carbon precursors, and tentatively we call such polymers carbonizing polymers in this chapter.

Let us consider polymer blends between the pyrolyzing and carbonizing polymers. When we heat such a polymer blend for example up to 1273 K, theoretically we will have a porous carbon without further activation process, by leaving pores where the pyrolyzing polymer existed in the carbon matrix from the carbonizing polymers. If we control the distribution of the pyrolyzing polymer in the carbonizing polymer matrix, we will obtain carbon materials with controlled pores in them. This is the principle of the polymer blend method for preparing porous carbon materials as illustrated in Figure 26 [91].

Hatori et al. prepared a carbon from a polymer blend between polyimide and polyethylene glycol [92, 93]. In this

case, polyimide was the carbonizing polymer and polyethylene glycol was the pyrolyzing polymer. They successfully obtained mesoporous carbon of ca. 5 nm diameter. Takeichi et al. used co-polymers between amide and urethane [94]. In this case the former was a carbonizing and the latter was a pyrolyzing polymer, respectively. The carbon material obtained from this polymer was indeed porous; however, the pore size was as large as 10 μm. These could be classified as macropores.

Ozaki et al. tried to use the polymer blend method for preparing ACFs [91]. In this case, the materials for the blends were limited from the standpoints of spinnability, compatibility, and difference in the decomposition temperatures between the selected polymers. They chose novolac-type phenol-formaldehyde resin as the carbonizing polymer and poly(vinyl butyral) as the pyrolyzing polymer. Figure 27 shows the weight decrease during heat treatment. The pyrolyzing polymer [poly(vinyl butyral)] shows a steep decrease in weight between 573 and 673 K. The carbonizing polymer (phenol-formaldehyde resin) showed a stepwise weight decrease. The first weight decrease is observed at around 523 K followed by a greater decrease between 673 and 823 K than the former. The final weight loss of this sample was 40%. For a 1:1 polymer blend, the final weight loss was 73%, which is very close to the simple average of the weight losses of both component polymers. Pore size distributions for micropores and mesopores were obtained by N_2 adsorption and are presented in Figure 28. As can be seen, the carbon fiber made from the polymer had a suppressed micropore volume and an enhanced mesopore volume. However, the obtained increase in the pore volume was less than they expected. Ozaki et al. analyzed the details of the polymer blend by using Fourier transform infrared and TG-MS techniques [95]. They found that when the

two components were prepared, they chemically interacted, which inhibited the independent pyrolysis of each polymer resulting in insufficient pore development.

Yang et al. prepared size-controlled mesoporous carbon spheres from polymer blends of novolac-type phenolic resin and two pyrolyzing polymers, poly(ethylene glycol) (PEG) and poly(vinyl butyral) (PVB) [96]. They put only a small amount of pyrolyzing polymers (7.5 units of PVB and 15 units of PEG were blended to 100 units of phenol-formaldehyde resin on weight basis), and finally they subjected the carbonized materials to steam activation. The obtained activated carbons possess mesopores ranging 3–5 nm. Addition of ferrocene to the polymer blend could give additional larger pores (10–90 nm) to the polymer blend derived activated carbons.

If a pyrolyzing polymer includes metal precursor and is dispersed in carbonizing polymer matrix, we can expect a porous carbon material on which pore surfaces are deposited by metal particles. Ozaki et al. prepared platinum loaded carbon fibers with the same polymer combination as described previously [97, 98]. By comparing the platinum loaded carbon fiber with platinum loaded fibers prepared by a simple mixing method, the former gave a higher hydrogen adsorption ratio and showed platinum particles deposited exclusively on the pore wall by electron microscopic observation.

During carbonization unstable parts in carbon precursor materials are eliminated as volatile matters. Devolatilization can introduce voids or pores in the resultant carbons. Such a preparation technique can be included in the polymer blend method, as the raw polymers are designed to have carbonizing parts and pyrolyzing parts. Takakura et al. synthesized a series of triple bonds containing polymers, poly(phenylene butadiyne) derivatives as shown in Figure 29, and studied their pore structures [99]. The micropore volume was around 0.3 ml/g independent of the polymer; however, the mesopore volume varied from 0.01 to 0.47 ml/g. The highest mesopore volume was achieved on P3 structure in Figure 29. Furthermore, the mesopore size distribution was tremendously influenced by the kinds of side chain groups. They considered that mesopores were introduced by the elimination of side chain groups. There is another example of preparing porous carbons by modifying the original polymer structure. Lenghaus et al. prepared phenolic resin from

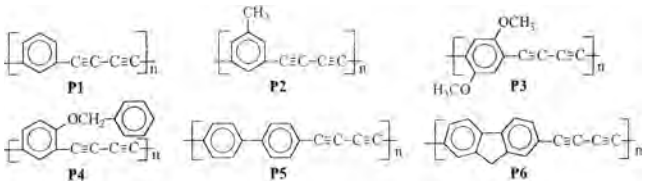

Figure 29. Structurally modified poly(phenylene butadiyne) polymers for carbonization. Reprinted with permission from [99], T. Takakura et al., in "Proceedings of the 28th Annual Meeting of the Carbon Society of Japan," Kiryu 2001, p. 208 [in Japanese] © 2001, Carbon Society of Japan.

alkyl-substituted phenols and studied the influence of these groups on the formation of porous structures [100]. By comparing the CO_2 and N_2 surface areas, para-alkyl substituted phenols gave wider micropores. Thus changing the substitution group will be a promising way of controlling the pore size, but we need to know the carbonization mechanisms of the parent polymers for designing the raw materials.

3.2.3. Sol–Gel Method

Preparation of mesoporous carbons by carbonizing organic gels was initiated by Pekala [101]. In his study, resorcinol was condensed with formaldehyde in alkaline solution. A schematic diagram of the resorcinol–formaldehyde (RF) gelation mechanism is presented in Figure 30. Resorcinol was first substituted with hydroxymethyl group by a catalytic action of alkaline reagent. The products condensed into surface functionalized polymer "clusters" that cross-link to form a gel. Pekala and co-workers carbonized the organic gel and found that the resulting carbon aerogel has high porosity (>80%) and a high surface area (400–900 m^2/g) [102]. The mesoporosity of the carbon aerogels can be ascribed to a network structure that was inherited from the original organic aerogel.

Tamon et al. conducted exhaustive studies on the relation between the porous nature of the carbon aerogels and their sol–gel conditions and showed that the pore size and the pore volume can be controlled by changing the mixing ratios of resorcinol, formaldehyde, water, and catalyst [103]. They tried to use freeze drying instead of supercritical drying for drying wet gels, because the former is more economical than the latter [104]. Hanzawa et al. conducted high temperature treatment of the carbon aerogel [105]. They found that micropores disappeared by 2273 K, but half of the mesopores could survive even after a heat treatment at 3073 K.

Resorcinol is not the only reagent for the preparation of organic gel. Gel formation was also observed for phenolic–furfural [106], melamine–formaldehyde [107], polyurethane [108], and mixed cresol–formaldehyde [109] systems. Finding cheaper raw materials and developing a cost-effective and time-saving drying method should be required for the practical uses of sol–gel carbons.

The application fields of carbon gels will be expanded, because the gels can be formed into desirable forms such as monoliths, wafers, films, spheres, and irregular powders [110]. In particular, monolith or film type carbon gels are suitable for electrochemical usage such as electrodes for EDLC [111, 112], for capacitive deionization [113], porous electrodes for fuel cells [114], and analytical electrodes [115].

3.2.4. Unique Pore-Forming Methods

In the traditional way to prepare activated carbons, pores are introduced by exposing carbons to oxidizing gases such as steam or carbon dioxide at elevated temperatures. Although the studies are not so many, there are unique activation methods such as electrochemical, supercritical fluid (SCF), and microwave assisted oxidation.

Electrochemical oxidation of carbon fibers has been employed to improve the shear properties of the fibers. Pittman et al. studied electrochemical oxidation of carbon fibers using the continuous operating system [116–118], as represented in Figure 31. The electroxidation apparatus permitted running carbon fiber tows through the U-tube using a motor and a set of gears. Carbon fiber from the incoming spool contacts the first rotating metal cylinder before going

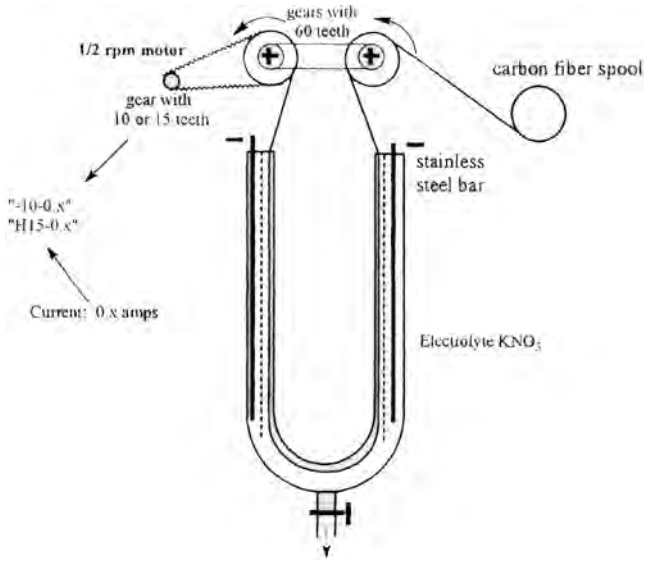

Figure 31. An apparatus for pore introduction to a carbon fiber by a continuous electro-oxidation of carbon fibers. Reprinted with permission from [116], C. U. Pittman, Jr., et al., *Carbon* 37, 85 (1999). © 1999, Elsevier Science.

through the entire U-tube and contacting the second rotating metal cylinder, where it is rewound. These two metal cylinders serve as the positive electrode. The two stainless steel bars in the U-tube act as the negative electrode. They used 1 wt% KNO_3 solution as electrolyte. By using adsorption, NaOH titration, and X-ray spectroscopy (XPS) techniques, electro-oxidation was an activation method that could introduce highly interconnected ultramicropores extending far below the depth probed by XPS.

SCFs have gaslike and liquidlike properties, such as high diffusion coefficients and low viscosities similar to gases, and excellent dissolving abilities. SCFs have now been used in extraction and separation fields. Recently, their unique chemical properties attracted people's attention for recycling plastics [119, 120] and decomposition of environmentally harmful substances. Applications of SCFs to materials processing are now studied, for example particle formation by rapid expansion of supercritical solution [121] and antisolvent deposition [122]. Li et al. conducted a study examining the feasibility of using supercritical water or carbon dioxide as the activating agent for carbon materials [123]. They employed vapor grown carbon fiber as the carbon material to be activated. After the treatment at 653 K and 250–320 kgf/m^2, surface areas of the carbon fibers were slightly increased from 9.29 to 15.85 m^2/g for water and to 13.64 m^2/g for carbon dioxide. Taking into account the critical points of water (T_c: 647 K, P_c: 22 MPa) and carbon dioxide (T_c: 304 K, P_c: 7.3 MPa), the treatments were done in the supercritical conditions of each substance. An enhanced effect was obtained for both media, if the carbon fibers were pretreated with nitric acid (i.e., they observed 35.27 m^2/g for water and 33.66 m^2/g for carbon dioxide). Adsorption abilities of the ACFs by means of supercritical treatments were studied for benzene and phenol, but a commercially available ACF showed the highest ability.

As microwave heating can give internal and volumetric heating, microwave-induced reaction is expected to proceed more quickly and effectively at a lower bulk temperature. Chars are reported to be a good receptor of microwave energy and may reach the minimum reaction conditions. Guo and Lau conducted a study on microwave induced CO_2 activation of an oil-palm-stone char [124]. A microwave power of 450 W was the minimum power required to cause any change from the viewpoint of volatile content and adsorptive properties such as BET surface area and pore volumes. Addition of CuO to the char induced a further activation resulting in the formation of a mesopore region, because the substance acted as a microwave receptor to increase the effective activating temperature.

Usually porous carbon material has inferior electrical conductivity to nonporous carbon materials produced at the same temperature. Lu and Chung developed a high surface area with high conductivities [125]. The idea of the preparation is to include a graphitization process. They examined the following methods to produce such carbons from PAN-based carbon fibers (specific surface area: 7 m^2/g), pitch-based carbon fibers (5 m^2/g), and vapor grown carbon fibers (54 m^2/g): (1) activating graphitized carbon after ozone treatment and (2) activating carbon that has not been graphitized, followed by graphitization and second activation. Both methods could increase porosity for all of the samples used here. In the case of method (1), the surface areas of the samples were ca. 400 m^2/g with resistivities of (2–4) $\times 10^{-3}$ Ω cm. On the other hand, method (2) produced porous carbon materials with 200–300 m^2/g with resistivities of (2–4) $\times 10^{-3}$ Ω cm. From the viewpoints of surface area development and economic merit, they favored method (1) for producing porous carbon materials with high conductivity.

3.2.5. Nanocarbons

This nomenclature has been widely used since an international symposium on nanocarbons was held in Nagano, Japan in November 2002. Inagaki and Radovic interpret it in terms of the structural and textural features [126]. They summarize the controlling factors for the production of various classic and new carbon materials containing the nanocarbons, as indicated in Figure 32. In regard to the pore structure, they explain that what are traditionally called microporous carbons in which the dominant pores are the so-called micropores, <2 nm, are increasingly being referred

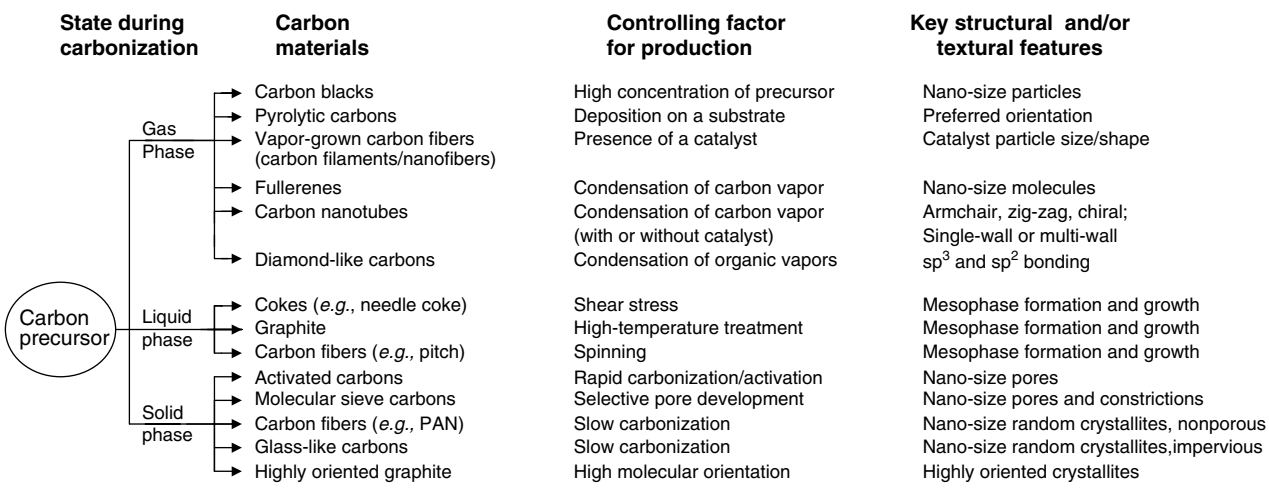

Figure 32. Controlling factors for the production of various carbon materials and the key points for their structural and/or textural features. Reprinted with permission from [126], M. Inagaki and L. R. Radovic, *Carbon* 40, 2263 (2002). © 2002, Elsevier Science.

to as "nanoporous" carbons, because the majority of the pores are of nanometer size. Also the category of nanocarbons is proposed on the basis of nanometer-scale structure and size of newly developed carbons, as illustrated in Figure 33. In this section we focus only on the carbon nanotubes in the nanocarbons.

Carbon nanotubes and their related materials are forming a new category of nanoporous materials. In 1997, Dillon et al. first clamed that SWNTs have a high reversible hydrogen storage capacity [127]. It was the start of the following a large number of studies on hydrogen storage. Here we will not review these studies, but we explain the overview of these materials from the viewpoint of pore structure. SWNT is a carbonaceous tube with a diameter of 1 nm and usually makes hexagonally packed bundles (Fig. 5). Figure 34 shows a configuration of H_2 molecules on carbon nanotube arrays by a Monte Carlo calculation [128]. It illustrates that H_2 molecules adsorb in the interstitial cavity and in inner-tube cavities. The attraction potential inside the tube is calculated to be larger because the curvature of the tube increases the number of nearest neighbor carbon atoms.

Eswaramoorthy et al. were interested in the adsorptive nature of carbon nanotubes without worrying about the surrounding graphitic layers [129]. So they conducted a study by selecting a SWNT rather than using a multiwalled carbon nanotube that was known to possess mesopores [130]. They prepared HNO_3-treated SWNTs as well and compared the adsorption nature of N_2 and benzene. The fact that the HNO_3-treated SWNT showed a larger amount of benzene and the calculation of the cross-sectional area of benzene lead them to conclude that the inner-tube space was also used for adsorption.

Barisci et al. studied the electrochemical nature of SWNTs from the standpoint of electrochemical capacitance [131].

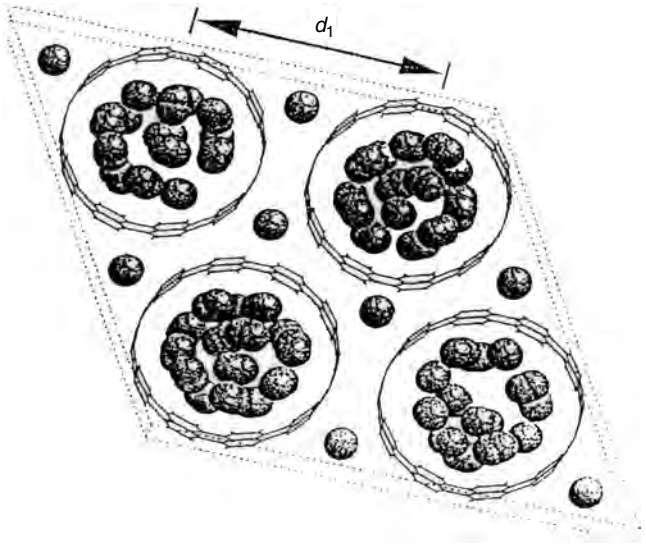

Figure 34. Configuration of hydrogen molecules in a bundle of single-walled carbon nanotubes. Reprinted with permission from [150], H. M. Cheng et al., *Carbon* 39, 1447 (2001). © 2001, Elsevier.

The capacitance of the nanotube paper (NTP) made from SWNTs was independent of the sizes of the cation or anion and of the voltage sweep rate for the measurements. These results indicated that the NTPs investigated are characterized by an interbundle open structure with relatively large pores that can be readily accessed by ions with a wide range of sizes and charges. Possibly, this is due to the pores being interconnected spaces in the entangled nanotube network rather than cavities and micropores as in other carbon materials.

The adsorption nature of SWNTs is not so simple as is judged from its appearance. It is important to modify the

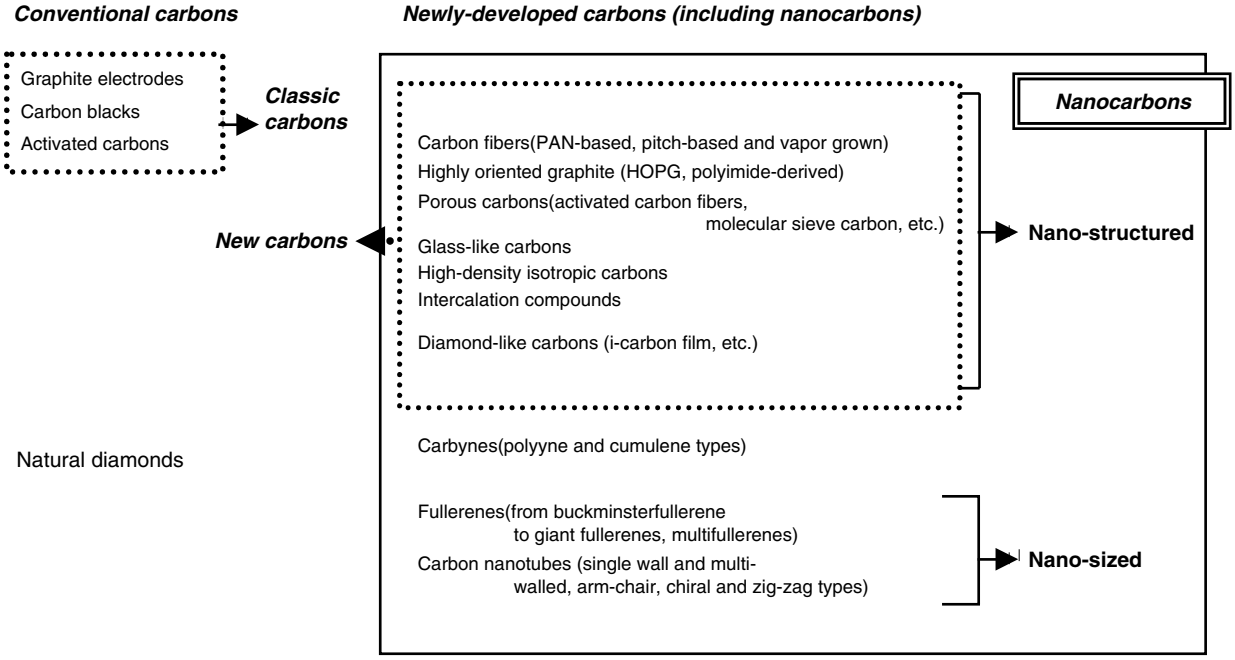

Figure 33. Proposed scheme for classification of carbon materials, including nanocarbons. Reprinted with permission from [126], M. Inagaki and L. R. Radovic, *Carbon* 40, 2263 (2002). © 2002, Elsevier Science.

higher order arrangement as well as the bundle structure and the inner-tube spaces depending on the applications of the SWNT. The situation of multiwalled carbon nanotubes seems more complex, because this substance is known to include mesopores.

4. APPLICATION OF NANOPOROUS CARBONS

4.1. Traditional Applications

Discoloration of sugar, air purification, removal of odor or toxic gases, water purification, gas separation, solvent recovery, etc. have been the traditional application areas of porous carbons. Most of these applications are based on the superior adsorption properties. Of course, the pore sizes of the activated carbons are different among the various applications by controlled production of activated carbons. Because the readers may find a suitable book for activated carbons that describes these historical usages of the activated carbons [132], we will review contemporary applications of porous carbons.

4.2. Nontraditional Applications

In recent days, we are facing many problems making our life dangerous and uncomfortable, such as pollution induced by highly toxic chemicals like dioxins or environmental endocrine disruptors (environmental hormones), air pollution caused by emitted gases from vehicles and industries, and shortage of energy and foods particularly in the developing countries. Political efforts are the main means to solve these problems; however, it is also important to provide techniques to back up the efforts. Porous carbon is now earning its good reputation as an agent to solve the problems due to developments in fine techniques and sciences to prepare the desired properties, as we have already learned in the previous section.

In this section, we will give a brief review of porous carbon application in the fields of gas storage, catalysts, removing harmful gases, electronics, and medicine.

4.2.1. Gas Storage

The target gases for storing are mainly methane and hydrogen.

Natural gas gathers attention as a clean energy source and is expected to be an automobile fuel [133]. Compression and liquefaction are the currently available techniques to store it and are called CNG (compressed natural gas) and liquefied natural gas (LNG), respectively. Gas is charged in a container at 25 MPa in CNG, so that the pressure resistance is required for the container and the valves, which lead to restricted application areas. In the LNG application, natural gas is liquefied at 111 K, which requires incidental facilities for lower temperatures. This technique is not also suitable for vehicle uses. ANG stands for adsorbed natural gas. In the ANG technique methane is usually adsorbed on a suitable adsorbent at a relatively lower pressure (3.5 MPa) at ambient temperature. The key for the practical uses of this technology is to find effective and cheap adsorbents. Activated carbons, porous polymers [134–137], silica gels, and zeolites [138–141] have been examined as candidates for the adsorbents.

As the critical point of methane is $T_c = 190.55$ K, $P_c = 4.595$ MPa, the substance is in the subcritical or in the supercritical states. Supercritical gases tend to selectively adsorb in the pores of which pore width is about 4–5 times the molecule size [133]. It is also well known that the equilibrium amount decreases with the increase in pore width. So the adsorbent should not have pores larger than 2 nm. Further the materials are required to be microporous with large density, because the adsorption ability is evaluated by the amount of adsorption per unit volume of the adsorbent rather than by the amount per weight of the material. The researchers are targeting the value of 150 V_m/V_a at 298 K and 3.5 MPa, where V_m and V_a stand for the volume of adsorbed methane and the volume of the adsorbent, respectively. The Gas Research Institute presented more severe conditions for practical automobile applications, 200 V_m/V_s (STP) and less than \$4.41 per a kilogram [142]. Preparing microporous carbon materials with high packing density at cheaper prices can satisfy these requirements. From a theoretical calculation, the adequate pore sizes are 1.12 [143] or 1.14 nm [144]. If the density of an adsorbent is 0.67 g/ml, which is a typical value for a monolithic carbon, the maximum methane uptake is estimated to be 220 V_m/V_a at 298 K.

The carbon materials that selectively possess micropores are ACFs. Alcaniz et al. examined ACFs with different pore characteristics prepared by different activating agents and conditions for methane storing ability [145]. They found that the methane uptake has a good relation between the micropore volumes and obtained the highest value such as 163 V_m/V_a for adsorption and 143 V_m/V_a for desorption of methane.

Coal, biomass, and used tires are cheaper raw materials for use in porous carbons for ANG. Sun et al. conducted a study with coal and found that KOH activated carbon has a larger methane uptake than the steam activated one on the weight basis, but the uptake by the steam activated one was larger than the KOH activated one, because of the smaller density of the KOH activated carbon [146]. Catula et al. found that the activated carbon made from peach kernel with zinc chloride activation showed a high adsorption ability for hydrocarbons [147]. MacDonald and Quinn extended the study to examine the methane storing ability by using phosphoric acid as an activator [148]. The methane storing ability was less than the master curve for other carbons. This was probably caused by the presence of abundant surface functional groups. Used tires seem to be a promising candidate for the adsorbents, but Muller et al. could obtain only a 47 V_m/V_a storing index [149]. As the utilization of waste materials is a very important subject of contemporary engineering, efforts like these must proceed.

Hydrogen must be the ultimate fuel for automobiles because it emits only water after combustion of the fuel. Whether the power generator is direct combustion or fuel cells, the common elemental technique is storing hydrogen. The US Department of Energy Hydrogen Plan has provided a commercially significant benchmark for the amount of reversible hydrogen adsorption [150]. The benchmark requires a system-weight efficiency (the ratio of stored hydrogen weight to system weight) of 6.5 wt% hydrogen and

a volumetric density of 62 kg-H_2/m^3. Three types of storing technology are considered: (1) cryogenic liquid hydrogen, (2) compressed gas storage, and (3) metal hydride storage technology. However, these approaches are not sufficient to satisfy the previous requirements [150]. Since Dillon et al. found the reversible hydrogen storage capacity for SWNT [127], many research groups started to conduct hydrogen storage experiments and have made some noticeable progress. The carbons examined for this approach were essentially so-called nanocarbons, like SWNTs, MWNTs, carbon nanofibers (CNFs), and nonstructured graphite. The amount of hydrogen adsorbed and the measurement conditions are listed in Table 3 [127, 151–165].

The results reported so far are varied and controversial due to poor or no reproducibility of the data. Recently David et al. measured the adsorption capacity using a variety of materials: carbon nanotubes, carbon aerogels, activated carbons, and so on. In the case of the nanotube samples all of the SWNTs and MWNTs tested showed poor adsorption values (less than 0.5 wt%) at 300 K and 10 MPa [166]. Also Takagi et al. reported the adsorption ability of hydrogen for ACF, a SWNT, and a zeolite [167]. In the study they improve the reliability of the data by confirming the reversibility between the adsorption and desorption at each equilibrium pressure. The values for the ACFs which showed a high adsorption amount in the samples, are around 0.2 wt% at 303 K and 3 MPa. At the moment, therefore, the capacitance level of hydrogen adsorption seems not to be so high, compared with the data listed in Table 3. In order to obtain accurate and reliable amounts of the adsorption, special attention should be paid to the preparation and purification of samples as well as the design of high pressure apparatus without leakage of hydrogen. Moreover, the adsorption mechanism of hydrogen in the nanoporous sites has to be elucidated for the improvement of the adsorption capacity.

Table 3. Summary of reported hydrogen storage capacities in nanocarbons.

Material	Amount of hydrogen storage (wt%)	Temperature (K)	Pressure (MPa)	Ref.
SWNT	5–10	133∼	0.04	[127]
SWNT	2–4	133∼	0.04	[151]
SWNT	4.2	R.T.	10–12	[152]
SWNT	0.9	295	0.1	[153]
SWNT	2.1	77	0.1	[153]
SWNT	8	80	12	[154]
SWNT	6.5	77	1.5	[155]
SWNT	0.05	296	3.6	[156]
SWNT	0.1	300∼	0.1	[157]
SWNT	1.6	R.T.		[158]
MWNT	3.4	290	10	[159]
MWNT	0.03	296	3.6	[156]
CNF	12.8	R.T.	11	[160]
CNF	ca. 5	300	10.1	[161]
CNF	1.2	296	10	[162]
CNF	0.7	R.T.	10.5	[163]
CNF	0.1	308	10	[164]
Nanostructured graphite	7.4	∼300	1.0	[165]

Note: R.T. is room temperature.

4.2.2. Catalysts

Application of porous carbon to catalyst is not a new and nontraditional example, but the surfaces of porous carbons still have unsolved problems particularly in the participation of surfaces to catalysis. So the topic concerning catalyst is also included in this section. A concise review is available for surveying the important research in the last two decades by Rodriguez-Reinoso [168].

The keywords to understanding the catalytic natures of carbon support are oxidation activity, electron transfer, high surface area, and spillover of hydrogen.

The oxidation ability of the carbon surface has been known and already used in flue gas desulfurization and denitrification reactions. Figure 35 shows a scheme for desulfurization on a carbon surface. The emitted SO_2 is adsorbed on the oxidation sites and then oxidized to SO_3 by the action of oxygen gas. The formed SO_3 is hydrated to sulfuric acid. Sulfuric acid first fills the micropores of porous carbon catalyst. After all of the micropores are filled with sulfuric acid, the reaction takes place on the macropore surface with lower reaction rate. Kisamori et al. claimed that the oxidation sites on the porous carbon are the surface defects induced by desorption of surface functional groups [169]. The desulfurization ability was not affected by surface areas of porous carbons, but porous carbons with higher nitrogen content showed excellent activity. The influence of surface treatments on the catalytic activity of carbon is an important topic in catalyst preparation [170–172]. Introduction of nitrogen onto the surfaces of porous carbons derived from a Victorian brown coal resulted in remarkable increases in the activity for both desulfurization and denitrification [173]. Kuhl et al. studied denitrification activity of sulfuric acid activated coke that was treated with ammonia [174]. They found that the denitrification activity increased when nitrogen was introduced in the range of 1–3%, and it saturated around 5%. However, the chemical structure and the mechanism of the introduced nitrogen are not clear.

Large surface areas of porous carbons have been used for catalyst supports. Porous carbon materials enable catalytic materials such as metals, metal oxides, and metal sulfides finely dispersed to exert high catalytic activity [168].

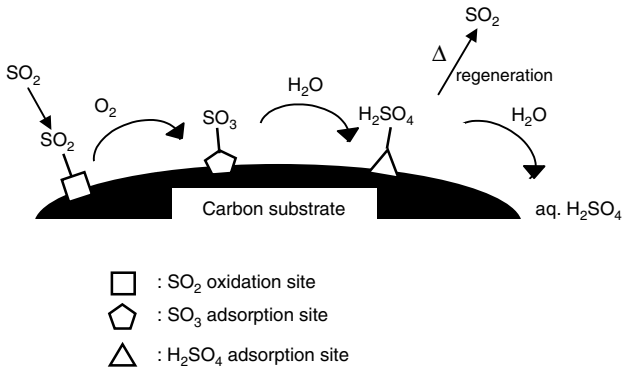

Figure 35. A schematic representation of desulfurization on a carbon surfaces.

Porous silica, alumina, and titania are more common catalyst supports, but the most striking difference of carbon supports from them is that we can anticipate electronic interaction between the supported metal and the carbon supports, because carbons are electronic conductors. An example can be seen in the Hoechst–Wakker reaction of ethylene to produce acetaldehyde. The catalyst, palladium chloride, is reduced when it is used for oxidizing ethylene and is regenerated by the presence of copper chloride. If palladium chloride is loaded onto a carbon support, the regenerating reagent is not required. This means that the surface of the carbon support promotes the reoxidation of palladium metal to form a continuous catalytic cycle. Similar electronic effects were also found for ammonia synthesis reactions.

Spillover is very interesting phenomenon involving platinum or nickel catalysts supported on carbon. Porous carbons do not adsorb hydrogen in the temperature range of room temperature to ca. 673 K, and uptake begins above 723 K gradually. On the other hand, the metal supported porous carbons adsorb hydrogen at temperatures as low as 473 K, and the adsorbed amount of hydrogen was 10^{21} atom/g-C, corresponding to the several tens or several hundreds times the amount of hydrogen which is expected from the metal loading [175]. This has been explained by the hydrogen transfer from the metal surfaces to the carbon surfaces as shown in Figure 36. The adsorbed hydrogen can easily be desorbed from the catalyst. In the figure dehydrogenation of hydrocarbon takes place on the carbon surface, and the removed hydrogen becomes spillover hydrogen. The produced olefin and hydrogen are effectively separated to inhibit recombination reaction.

4.2.3. Removing Environmentally Harmful Substances

Dioxins or environmental endocrine disruptors (environmental hormones) are emitted to environment which are too toxic and harmful and induce deformities or deaths, even with a very small quantity of these chemicals.

Dioxin is a collective name for chlorinated compounds including two benzene rings combined with ether linkage. The toxicity depends on the number and the substituted positions of chlorine on benzene rings. The optimum specification of the porous carbons for this purpose is as follows: pore size: 2–5 nm; specific surface area: >500 m^2/g; pore volume: >0.2 ml/g; particles size about 20 μm.

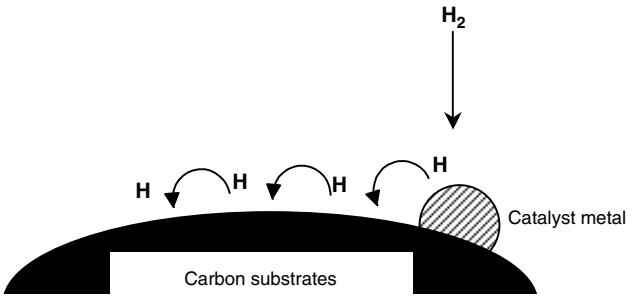

Figure 36. The concept of spillover of hydrogen in metal/carbon systems.

There are many chemical substances that are listed as environmental endocrine disruptors. Their removal by an adsorption technique is studied. Abe et al. studied the adsorption of 4-nonylphenol and bisphenol A on four types of activated carbons from different origins [176]. The porous carbons used there were particularly excellent adsorbents for bisphenol A by adsorbing up to saturation uptake even at concentrations as high as several mg/L.

In the practical situation for removing toxic substance from our environment, the concentration of the target molecules is very low as in the case of dioxin and furthermore the kinds of the suspicious molecules are various, which make the design of suitable porous carbon materials difficult. However, it is necessary to develop a design method for suitable porous carbon materials in order to protect our lives.

4.2.4. Electronics Uses

A battery is the most famous example of a carbon material for the electronic use. Graphite is used as an anode material in lithium ion batteries, and it shows a very close capacity to the theoretical capacity which is 372 mA hg^{-1} for this substance. On the other hand, some of the nongraphite carbons showed capacity exceeding the theoretical value. Tokumitsu et al. explained the high capacity on the basis of cavity model, in which lithium species are not only intercalated in carbon layers but also doped in cavities of which size was estimated as 0.5–1.5 nm by using a Fourier analysis of 002 diffraction profiles on an X-ray diffraction [177]. Although such carbons tend to show a large irreversible capacity, it is interesting to know the mechanism of lithium insertion and doping into these carbons from the viewpoint of structure of nongraphite carbons [178].

Carbons are also used in other battery applications, such as redox flow cells [179], zinc–air cells [180], etc. In polymer electrolyte membrane fuel cells (PEMFC), carbon materials are used in the gas diffusion electrode, bipolar plate, and the support for anode and cathode catalysts [124]. Three major barriers to technically overcome are developing bipolar plates, proton exchange membranes, and oxygen reduction catalysts. Because the working temperature for PEMFC is low as 353–373 K, the slow rate for oxygen reduction is the most serious problem. Usually porous carbon blacks are used as a catalyst support for platinum. In general carbon blacks with larger surface area can achieve a higher dispersion state of platinum, but we have to consider the pore structure of the carbon blacks, as it deeply affects the diffusion of oxygen gas and hydrogen ion. Sanyo Electric Co. Ltd. reported that carbon blacks with well-developed structure resulted in excellent oxygen diffusion. Matsushita Electric Co. Ltd. examined a number of carbon blacks and found that the carbon blacks that have a large amount of pores less than 10 nm are not suitable for the catalyst support. Carbon blacks for PEMFC applications are just for general use, so we need to develop a suitable carbon support. Iijima et al. recently found carbon nanohorns [20], which can be prepared just by laser ablation at room temperature. They showed a new type of carbon material especially for PEMFC application, as described in Section 2.2.

EDLC can be a complementary power source for secondary battery or internal combustion engines, because the

power density of EDLC is very high. This device is based on the electric capacity of the electrochemical double layer, which is formed at the interface of electrode and electrolyte. If the electrode is polarized positive, anions are attracted to the vicinity to the electrode surface. As a result opposite charges are aligned in face in a very short distance. This region is the so-called Helmholtz layer with a thickness of ca. 1 nm depending on the concentration of electrolyte. Hence the electric capacitance of the Helmholtz layer becomes considerably large. Porous carbon materials are commonly used for the electrodes of EDLC. As can be seen from the principle, the performance of the capacitor profoundly depends on the carbon pore structure. Yoshida et al. conducted a series of studies on the relation between the surface properties of the carbon electrode and the capacitance performances [181–183]. Their conclusion is as follows: increasing to pores larger than 2 nm leads to a good performance at lower temperature, and a smaller amount of surface functional groups is recommended for minimizing leak current. It is desired to prepare porous carbons with higher surface area and higher densities, but these requirements are oppositely demanding, so we must find an optimum pore structure for EDLC electrodes. Endo et al. also reported a morphological characterization and EDLC properties of activated carbons derived from a resin [184]. In this study they analyze the correlation between the capacitance and pore size distribution by a computer simulation. It would provide information on the relation between EDLC and ion-size related charge transfer solvation.

4.2.5. Electrochemical Application

Graphite is an anisotropic crystal, so that it has two types of surfaces. One is the basal plane normal to the stacking graphene sheets and another is the edge plane perpendicular to the basal plane. Kawakubo et al. demonstrated the difference in the activities between these crystal planes by using a redox reaction between ferricyanide and ferrocyanide [185]. Cyclic voltammograms of this study are presented in Figure 37. As can be seen in this figure, the edge plane of graphite is more active for electron transfer at the electrode/electrolyte interface than the basal plane of graphite. They also studied the electrochemical activity of the lead of mechanical pencils and found the anisotropic nature of the materials. Ozaki et al. prepared carbon materials by carbonizing poly(furfuryl alcohol), phenolic resin or a brown coal by mixing with iron compounds, and found that the obtained carbons showed electrocatalytic activity comparable to a platinum electrode [56–59]. They also found that the high electrochemical activity has a good relation between the formation of a special form of carbon, Ts carbon, of which the surface may be occupied by edge-plane-like structures.

Electrochemical separation or decomposition of impurities in water is another example of utilizing porous carbon materials in electrochemical applications. Capacitive deionization (CDI) of water is another application of the same principle as EDLC [113]. Figure 38 shows the principle of the CDI process for making fresh water from salty water. The striking difference of CDI from EDLC is that the electrolyte always flows through the cell. Electrodes for this application are usually made with ACFs, and sometimes with

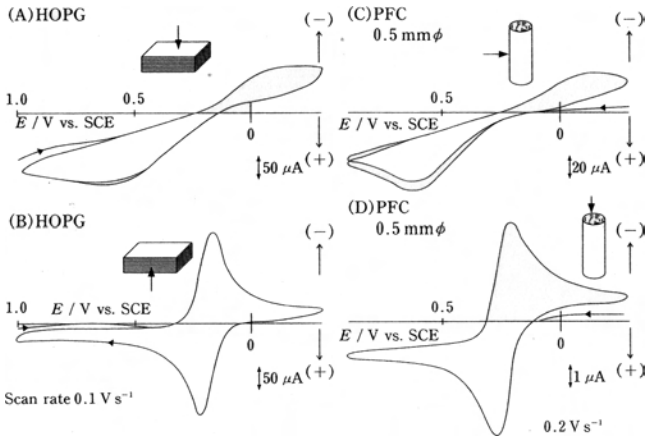

Figure 37. Cyclicvoltammograms for different carbon materials in a $Fe(CN)_6^{3-}$ aqueous solution. (A) and (B) Highly oriented pyrolytic carbons exposing different crystal surfaces. activated carbons with binders. Recent development of the sol–gel technique has enabled the preparation of carbon gels with desired shapes such as monoliths or films.

The flow-through-type electrochemical reactor is a very interesting application of porous carbon, although this is not so common in practical processes. Matsunaga et al. developed a flow-type reactor for electrochemical sterilization [186, 187]. This is based on their findings that applying 1.0 V of potential to the electrode could suppress the multiplication of bacteria on the electrode, and they could be taken off from the electrode by applying −0.8 V. By applying both voltages alternately, the multiplication of the bacteria was found to be considerably suppressed. They used ACF but changed to use titanium nitride as the porous electrode because of the lack of mechanical strength of the ACF.

There are several studies on electrochemical removal of pollutions from water or gases, such as dechlorination of organic compounds by using a flow-type reactor [188], electrochemical membrane separator of chlorine from gaseous hydrogen chloride wastes [189], and electrochemical

oxidation of bisphenol A [190]. These technologies are interesting and important not only from technical standpoints, but also an academic point of view of a coupling of catalysis and electrolysis occurring on carbon surfaces.

4.2.6. Medical Application

There are three main areas in the medical use of activated carbons: (1) as an oral adsorbent-antidote against acute poisoning; (2) for blood and other fluid purification using extracorporeal techniques; (3) as an odor adsorbing dressing for treatment of malodorous wounds [191]. The biocompatibility of the activated carbons with blood and so on is required for these uses. At the same time the presence of mesopores is of particular importance in order to remove large molecules such as proteins, circulating immune complexes, or endotoxin.

5. CONCLUSION

We reviewed the present status of the science and technology surrounding the nanoporous carbons. As a result it was recognized that the formation and the control of pore size ranging from micropore to mesopore are extremely important to meet the future demands for these carbons. While the improvement of the traditional preparation process is now being continued, new approaches to produce excellent porous carbons with outstanding properties, such as the template method, the polymer blend method, and the sol–gel process have been proposed and their performance of the products is being investigated by many researchers, as briefly described. In addition, the appearance of novel carbons such as carbon nanotubes brings about the stimulation and acceleration of the research activities in the carbon world, and at the same time the application field is expanded further. If the existing porous carbons such as activated carbons and ACFs would be examined thoroughly from the different points of view, they could play a more important role in the fields of environment, energy storage, catalysts, fuel cells, electronics, medical applications, and so forth.

GLOSSARY

BET surface area A popular surface area obtained from nitrogen adsorption isotherm, using a formula derived by Brunauer, Emmett, and Teller.

Carbon aerogel Mesoporous carbon spheres obtained by carbonization of organic gels which are dried at supercritical conditions.

Carbon fiber (PAN-based and pitch-based) Fibrous carbon materials obtained by carbonization of fibrous raw materials derived from PAN and pitch.

Electrochemical double layer capacitor (EDLC) A kind of capacitor utilizing the capacitance of electrochemical double layer formed near the electrode surface, showing extraordinarily high capacitance.

Mesophase pitch Optically anisotropic pitch due to liquid crystal nature.

Nongraphitizable and graphitizable carbons (hard and soft carbons) Type of carbon materials discriminated by the crystallinity after high temperature treatment (e.g., 3000 °C).

Polymer electrolytic membrane fuel cells (PEMFC) Type of fuel cell utilizing proton exchangeable polymer as an electrolyte of a fuel cell. It is expected to work at lower temperature than conventional fuel cells and to be utilized in domestic and on-board power generation in the near future.

sp, sp^2, and sp^3 Hybridizaton Electronic states of atoms determining molecular shapes. Carbyne, graphite, and diamond are available for carbon atom.

Supercritical fluid (SCF) A fluid at the state over its critical point, showing high solubility and low viscosity. It is also recognized as a new type of solvent for reactions.

Nanoporous Materials

Dongyuan Zhao, Chengzhong Yu, Haifeng Yang

Fudan University, Shanghai 200433, China

CONTENTS

1. INTRODUCTION

Porous materials are a family of excellent adsorbents, catalysts, supporting materials, ion-exchanging agents, and micro-reactors. Because of their open-framework structures and large surface areas (including internal and external surface areas), these porous materials have been widely used in the petroleum and chemical industries and in air separation [1, 2]. According to the definition of the pore size from the International Union of Pure and Applied Chemistry (IUPAC) [3], porous materials can be classified into three groups: microporous materials (<2 nm), mesoporous materials (2–50 nm), and macroporous materials (>50 nm). These three classes of materials can be included in the so-called nanoporous materials (1–100 nm), which are found to be more and more important in the applications of large molecular conversion, optic-electric devices, and other high-tech industries [4, 5].

Nanoporous materials can be amorphous, quasi-crystalline, or crystalline. Methods such as X-ray diffraction (XRD) and electron diffraction (ED) can be used to characterize these materials [1, 2]. The pore structure is one of the most important parameters for nanoporous materials and can generally be characterized by use of physical adsorption of the gas (such as N_2, Ar, organic molecules, etc.) or by a liquid pressure method (mercury extrusion). Amorphous and quasi-crystalline porous materials such as silica gels, aluminum oxides, and activated carbons have been widely used in industry as catalysts or the supports for catalysts. However, because these materials possess no long-range ordered structural regularity and they have disordered pore structures and widely distributed pore sizes, zeolite-type microporous materials have long been used as substitutes.

Nanoporous materials with long-range ordered structures are discussed in this chapter, and the focus is on the newly developed classes of mesoporous materials. Ordered macroporous materials developed recently will also be involved. At the atomic level, most mesoporous and macroporous materials are amorphous, but they have properties similar to those of crystalline materials because their uniform pore structures possess long-range order at the meso- or macroscales, which can be reflected by well-defined XRD and ED patterns.

2. MESOPOROUS MATERIALS

Some disordered mesopores can be generated during a dealumination process of zeolite molecular sieves, but the pore sizes and the quantity of mesopores are much dependent on such a dealumination process, and somehow it is uncontrollable [1, 2]. Some layered materials such as natural clays and metal phosphates can be used to prepare mesoporous materials with the use of large inorganic precursors such as polycations (e.g., Al_{13}, $[Al_{13}O_4(OH)_{24}(H_2O)_{12}]^{7+}$) or orthosilicates (referred to as pillars) to support the lamellar structures [6–10]. The final products are called pillared clays or pillared molecular sieves [10]. These lamellar structures include smectite, bentonite, montmorillonites, and

Edited by H. S. Nalwa
Volume 7: Pages (263–285)

zirconium phosphate, etc. The pillared clays were once important candidates for catalysis in heavy oil cracking at the end of the 1970s. However, later experiments revealed that the surface acidity of such materials was quite weak, and the catalytic activities were greatly decreased because of the carbon coke; moreover, the hydrothermal stability of such pillared clays was not good enough for use in the cracking process of the petroleum industry [11]. Although natural clays and metal phosphates are crystalline, the pillars within these layered materials are not uniformly distributed; thus the resultant mesopores are not ordered [5, 11]. In some cases, the pore size distribution of aluminosilicates synthesized by the sol–gel method under strict conditions is quite narrow, but the mesopores are still randomly packed.

In 1992, Mobil researchers reported the synthesis of ordered mesoporous aluminosilicates (denoted M41S) with the use of long-chain cationic quaternary ammonium surfactants as structure-directing agents [12, 13]. In fact, ordered mesoporous materials were already reported early in 1971 [14]. A group of French scientists utilized such long-chain quaternary ammonium cationic surfactants to adjust the surface area and pore diameter of silica gels. According to their patent [15], the resulting silica gel had a two-dimensional (2D) hexagonal structure similar to that of mesoporous silica MCM-41 reported by the Mobil Company [15]. Unfortunately, this patent has been ignored because no XRD or transmission electron microscopy (TEM) evidence was provided [15]. A Japanese group began to synthesize mesoporous materials before 1990 [16]; the cationic surfactants were also employed to synthesize pillared lamellar clay, kanemite. It was found that when a high concentration of NaOH was used, the structure of kanemite was destroyed; instead, a new type of ordered mesoporous material was obtained, which was known as FSM-16 in later literatures [17]. Since the TEM images provided and the mechanism were not fully understood in the original report [16], this contribution did not draw enough attention from the international scientific involved in research on zeolite molecular sieves community.

On the contrary, after the successful synthesis of lamellar MCM-22 molecular sieves [18–20], Mobil scientists continued to study the pillared structures of MCM-22. It was also found that at the beginning stage the lamellar structure of MCM-22 was destroyed, and afterward new ordered mesostructures were formed. Detailed and systematic work had been carried out after the initial observation; it was found that these mesostructures had structures similar to those of liquid crystals formed from the employed surfactant. Finally, a new family of mesoporous materials (M41S) was discovered, including MCM-41, with a 2D hexagonal honeycomb structure (*p6mm*); MCM-48, with a 3D bicontinuous cubic structure (*Ia3d*); and MCM-50, with a stable pillared lamellar structure [12, 13].

The structures of mesoporous silica M41S are schematically shown in Figure 1. It should be noted that MCM-50 materials are stable mesoporous silica materials and have a pillared lamellar structure (pillared by silicate agglomerate species hydrolyzed from tetraethoxysilane, TEOS) instead of an unstable, simple lamellar structure [21, 22]. Since the first report by the Mobil Company, mesoporous materials have drawn tremendous attention internationally from

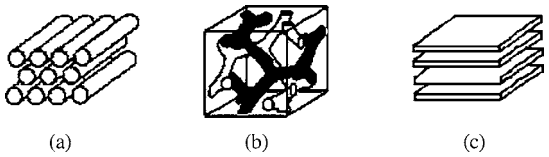

Figure 1. Schematic drawing of the pore structures of (a) MCM-41; (b) MCM-48; and (c) MCM-50.

researchers working on zeolite molecular sieves and in the materials research field. The success in the synthesis of mesoporous materials such as M41S is comparable to another great achievement with ZSM-5 zeolites in the 1970s, also by the Mobil Company [23]. Both materials have been synthesized by choosing organic structure-directing agents to control the pore size and shape of the resultant porous materials. The liquid-crystal-templating (LCT) mechanism in the case of mesoporous materials brings forward a true templating concept in the synthesis of porous materials; moreover, the restriction of the micropore (<1.2 nm) in the case of zeolite-type materials is no longer a problem [12, 13, 21, 22]: mesoporous materials with a uniform and controllable pore size between 1.5 and 40 nm offer new opportunities in many research fields in which large nanopore materials are essential.

The surfactants used in the synthesis of M41S materials were cationic quaternary ammonium salts with a hydrophilic headgroup and a hydrophobic long alkyl chain. In contrast to the organic templates in the synthesis of zeolite materials, the surfactants can generate complex supramolecular structures in aqueous solutions. At relatively low concentrations (>critical micelle concentration, CMC), the micelles can be formed, whereas at relatively high concentrations, liquid crystal phases are assembled. The surfactants and precursors of inorganic species cooperatively self-assemble into ordered composite mesostructures. This self-assembly process is similar to the formation of liquid crystals in solution. After the removal of surfactants, mesoporous materials are generated. The pore structure of mesoporous materials possesses long-range order, as reflected by well-defined XRD patterns at small angles ($2\theta = 2$–$8°$) (Fig. 2) [24], but the inorganic species (or inorganic wall) are amorphous; for example, a broad peak at $2\theta = 20$–$30°$ observed for mesoporous silica materials suggests that the silica walls are not crystalline [25–29].

3. FORMATION MECHANISM

In their early studies, Mobil scientists noticed that the formation of mesoporous materials is closely related to the assembly of traditional liquid crystals and biomineralization [12, 13]. The surfactants employed in the synthesis of mesoporous materials usually possess one or more polar headgroups and one long hydrophobic tail, whereas the lipid generally studied in life science has two hydrophobic tails. Traditional liquid crystals usually consist of one tail with a specific group (usually benzene groups). To explain the formation mechanism of MCM-41, the Mobil researchers first proposed a liquid-crystal-templating (LCT) mechanism [12, 13]. Based on high-resolution transmission electron

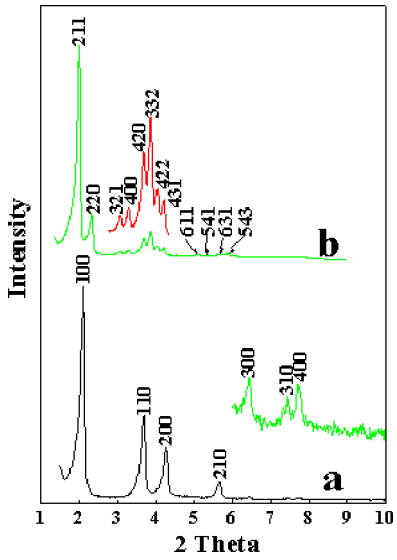

Figure 2. Representative XRD patterns of mesoporous materials. (a) Highly ordered MCM-41 prepared with cationic surfactant under basic conditions. (b) MCM-48 prepared with Gemini surfactant $C_{22\text{-}12\text{-}22}$ as a template at 100 °C.

microscopy (HRTEM) and XRD studies of MCM-41 materials [12, 13], which obtained results similar to those for liquid crystals formed in aqueous solutions, they proposed that the liquid crystal phase formed by the surfactants in aqueous solution was a template for the formation of an MCM-41 mesostructure. Mobil researchers suggested that the formation of liquid crystal phases of surfactants may occur (1) before and (2) after the addition of inorganic precursors [12, 13]. In this context, the LCT mechanism is "errorless," since there will be no other choices considering the formation of the liquid crystal phase.

When pathway (1) was utilized to explain the formation of mesoporous materials in aqueous solutions [12, 13], some conflicts occurred. In aqueous solutions, liquid crystal phases can only be observed at very high surfactant concentration. In the case of cetyltrimethyl ammonium bromide (CTAB), the hexagonal liquid crystal phase is formed when the concentration of CTAB is higher than 28 wt%, and the cubic phase occurs when the concentration of CTAB is higher than 80 wt%. On the other hand, MCM-41 can be synthesized at a very low CTAB concentration (~2 wt%) [24–28]. Even for the synthesis of cubic MCM-48 materials, the concentration of CTAB in starting compositions can be as low as 10 wt%. Later, Attard et al. prepared a liquid crystal phase by using surfactants and/or inorganic precursors under a nonaqueous phase [30]. With the use of this liquid crystal phase as a template, mesoporous materials were obtained. This observation supported the proposed pathway (1) by Mobil scientists; however, the formation of the liquid crystal phase prior to synthesis of mesoporous materials is somewhat difficult, and the synthesis of mesoporous materials strictly according to liquid crystal templating is not common in the literature [30].

Several formation mechanisms have been proposed to describe in more detail the synthesis pathway (2) where the liquid crystal phases are formed after the inorganic species were added. M. E. Davis et al. [25] suggested that surfactant molecules self-assembled into micelle rods first in aqueous solutions; these micelle rods could interact with inorganic silicate precursors and resulted in rod-like micelles of organic-inorganic hybrid composites that contained two or three layers of silicate oligomers (Fig. 3). These coated micelles agglomerated spontaneously to give a long-range ordered hexagonal mesostructure. After further condensation of silicates, the MCM-41 mesophase was obtained.

G. D. Stucky et al. proposed that the cooperative self-assembly of organic and inorganic species gave long-range ordered mesostructures [24, 27, 29]. Polymeric silicate anions interacted with the headgroups of cationic surfactants (Fig. 4) at the organic-inorganic interface; the charge density of the inorganic layer changed with the condensation of silicates and resulted in close packing of the long hydrophobic chain of the surfactants. The charge density matching between organic and inorganic species controlled the array of surfactant-inorganic hybrid materials. The pre-arrangement of organic surfactant molecules was not necessary in this mechanism. With the condensation of inorganic species, the charge density of the inorganic layer changed and the solid phase of the organic/inorganic composites was transferred. The final structure of the composite phase was governed by the extent of the reaction (the condensation of inorganic species) and by the charge density matching of surfactant/inorganic assemblies (Fig. 4).

Some questions may be argued with respect to Davis's mechanism. The length of the micelle rods is not uniform in solution; furthermore, long micelle rods must overcome a large energy gap to assemble into ordered organic-inorganic hybrid mesostructures. These facts contradict many observations; for example, the mesochannel of MCM-41 synthesized in the solution can be as long as several micrometers [31, 32]. In fact, at the surfactant concentration used to synthesize the mesoporous materials, the global micelles as well as rod-like micelles can be observed in solution; in this case, the composite phases other than hexagonal structures should coexist in the final products. Furthermore, this mechanism cannot be used to interpret the formation of cubic MCM-48 and lamellar mesostructured materials [24, 26]. Obviously, the limitation of Davis's mechanism restricted their general use in the synthesis of mesoporous materials. However, during the synthesis of mesostructured silica or germanium oxides, Yuan and Zhou [33] and Zhao et al. [34] observed that single rod-like inorganic or organic/inorganic materials could be obtained, suggesting that in some cases Davis's mechanism might be applicable.

The cooperative self-assembly mechanism proposed by G. D. Stucky et al. is quite general and thus has been accepted by most scientists. This mechanism can be widely used in different synthesis systems, and the general principle can be applied to the design of new materials.

Japanese scientists have proposed a lamellar transformation mechanism to explain the synthesis of mesoporous FSM-16 materials from kanemites [35]. However, this mechanism is restricted to specific conditions. From silicate oligomer precursors to the final hexagonal ordered mesoporous materials, the lamellar intermediate occurs only in a narrow pH range. Actually, it is not necessary to form the lamellar intermediate when the hexagonal mesostructure is assembled [24]. Furthermore, what is the difference in the structures between FSM-16 and MCM-41 materials has not been fully understood [36].

4. INTERACTION BETWEEN ORGANIC AND INORGANIC SPECIES

Considering the kinetic formation process of mesoporous materials, the total free energy change ΔG of such a process can be summarized by the contributions of the following interaction [26]:

$$\Delta G = \Delta G_{\text{Intra}} + \Delta G_{\text{wall}} + \Delta G_{\text{Inter}} + \Delta G_{\text{sol}}$$

where ΔG_{Intra} is due to interactions of organic and inorganic species, ΔG_{wall} is due to interactions between inorganic species, ΔG_{Inter} is due to organization of the organic surfactant molecules, and ΔG_{sol} is due to the chemical potential of the solutions during synthesis.

For the syntheses of mesostructures with a certain composition (such as silicates) in a given solvent system (usually aqueous solutions), the solution chemical potential ΔG_{sol} is similar and can be assumed to be a constant. Furthermore, at a given composition, concentration, pH, and synthesis temperature, ΔG_{wall} and ΔG_{Inter} may be varied within a small range, thus the formation of mesostructure is very dependent on the interaction of inorganic and organic species. G. D. Stucky et al. proposed a general synthesis pathway based on the charge density matching to minimize ΔG_{Intra} for a successful cooperative self-assembly process, that is, S^+I^+, S^-I^+, $S^+X^-I^+$, and $S^-X^+I^-$ (here S is the surfactant species; I is the inorganic species; and X is a counter-charged ion, such as Cl^-, Br^-, Na^+, or K^+) [24, 26]. With this concept, the synthesis of mesoporous materials was successfully carried out under acidic conditions; many mesoporous materials with new structures and new compositions have been synthesized [24, 26]. It is a real breakthrough that molecular sieves can be synthesized in acidic media.

It has been known that careful design of the headgroup of surfactant molecules is very important to the synthesis of mesoporous materials. During the formation of siliceous mesostructures under a basic condition, the inorganic precursors are negatively charged silicate oligomers (I^-); therefore, cationic surfactants such as long-chain quaternary ammonium salts should be used (S^+) to achieve a Coulombic interaction (S^+I^-) to form an ordered mesostructure. An example of S^-I^+ interaction is the synthesis of mesostructured alumina with anionic surfactants such as sodium lautyl sulfate and cationic inorganic species such as Al_{13} ($[Al_{13}O_4(OH)_{24}(H_2O)_{12}]7^+$), which has a Keggin structure similar to that of heteropolyoxometallates [37, 38]. Organic and inorganic species with the same charge can also be used to form mesostructures; however, counter-charged ions are necessary in such synthesis systems to balance the charge density, such as the $S^+X^-I^+$ ($X^- = Cl^-$, SO_4^{2-}, NO_3^-, etc.) and $S^-M^+I^-$ ($M^+ = Na^+$, K^+, etc.) synthesis pathways.

The S^0I^0 synthesis pathway was also proposed to explain the generation of mesoporous materials [39–43]. It was carried out at near-neutral conditions with the use of neutral organic amines or nonionic oligomeric surfactants (S^0) as templates. It should be noted that under such conditions both the inorganic and organic species are not strictly neutral, and hydrogen bonding may play an important role for these partially charged inorganic and/or organic species. Complexation may also occur, especially in the synthesis of nonsiliceous mesostructures; for example, niobium (V) ethoxides and long-chain alkyl amines can be used to form mesostructured niobium oxide [44]. Another combination is covalent bonding S-I interaction. For example, silicon-containing surfactants ($C_{14}H_{29}N(CH_3)_2$-$Si(OC_2H_5)_3Br$) can be used as a template in the synthesis of mesoporous silicate materials, with TEOS as a silica source (Fig. 4).

5. SYNTHESIS STRATEGY

5.1. *Hydrothermal* Synthesis

Mesoporous materials are usually synthesized by solution reactions under the *hydrothermal* conditions similar to those of zeolite molecular sieves. The synthesis undergoes a typical sol–gel process [24, 45]. Because the synthesis temperatures for mesoporous materials are relatively low (from room temperature to 100 °C), it is not the conventional hydrothermal synthesis. Mesoporous silica materials can be synthesized under basic media or strong acid conditions [24, 27]. Under alkaline conditions, due to the reversible polymerization of the silicate species [45], there is no limitation in selecting silica sources; therefore, all kinds of silica regents such as silica gels, silica sols, water glass, fused silica, and TEOS

can be used for the syntheses [12, 13]. Generally, NaOH, KOH, $NH_3 \cdot H_2O$, and organic amines can be used as the alkaline sources, and the best pH range is 11.0–11.5 [46–53]. In the reaction composites for preparing MCM-41 initially reported by the Mobil Company [12, 13], several types of mixing silica sources were employed; this might be attributed to the consideration of the amorphous inorganic walls of MCM-41. But later on, TEOS was found to be one of the most convenient and applicable silica sources [24, 27, 53]. MCM-41 with highly ordered hexagonal mesostructure is the most popular mesoporous material, which can be synthesized under a wide range of reaction conditions. High-quality mesoporous silica MCM-41 with a large pore size (>4 nm) can be obtained generally by recrystallization or mixed surfactant strategies [52].

Cubic bicontinuous MCM-48 is thought to be somewhat difficult to prepare. Since the first report of mesoporous silica materials by Mobil scientists in 1992, more than 4000 papers were published on the subject by the end of 2001. But the papers relating to MCM-48 are less than 10% of the total (<400 papers); the main reason for this is the difficulty of the synthesis of MCM-48. However, if the processing conditions are well controlled and the surfactant is properly selected (more specifically, the hydrophilic volume of the surfactant is relatively small), it is not hard to obtain cubic MCM-48 of high quality [52, 53]. It has been proved that TEOS is the best silica source for synthesizing MCM-48, and the reaction temperature is usually higher than 100 °C. Although R. Ryoo et al. reported that fused silica and other silica sources can also be used to prepare MCM-48, ethanol is still necessary [54]. Some successful examples of the synthesis of MCM-48 are as follows:

(A) Employing TEOS as a silica source; ethanol molecules produced during the hydrolysis reaction tend to invade the hydrophobic area of the surfactant micelle, leading to head volume expansion of the surfactant.

(B) Adding organic molecules with medium polarity, such as triethanolamine, to the synthesis system; these molecules are likely to stay at the outer fringe of the hydrophobic area of the micelles. In this way, MCM-48 can be obtained, even when sodium silicate is used as a silica source [55].

(C) Using special surfactants, such as Gemini surfactants, $C_{m\text{-}12\text{-}m}$ ($C_mH_{2m+1}N(CH_3)_2C_{12}H_{25}N(CH_3)_2C_mH_{2m+1}Br_2$) ($m = 12$–22) or CDBA ($C_{16}H_{33}N(CH_3)_2CH_2C_6H_5Br$); these surfactants contain the C_{12} long chain or benzene ring connected to the heads of the surfactants and have large hydrophobic volumes. Surfactant $C_{22\text{-}12\text{-}22}$ favors the formation of high-quality MCM-48, even at room temperature at low surfactant concentration (0.4 wt%) [52].

(D) Adding a small amount of negatively charged surfactants such as sodium lauryl sulfate. The ionic pairs generated by a part of positively charged and negatively charged surfactants are less hydrophilic and withdraw to the hydrophobic area of the micelles; therefore they can serve as cotemplates to form MCM-48 [56].

(E) A careful phase transformation from hexagonal MCM-41 at high temperature can also be employed to prepare cubic MCM-48 [53, 57–59].

Q. Huo et al. creatively found that high-quality mesoporous materials could be synthesized under strong acidic conditions [24, 27]. Hexagonal mesoporous material structures synthesized under acidic conditions with the use of cationic surfactant CTAB (which is also called SBA-3) are much different from MCM-41. There are many halogen ions (for example, Cl^-) in as-synthesized SBA-3 to counteract the charges of cationic surfactants. After calcination, the mesostructure (hexagonal) and chemical composition of SBA-3 are similar to those of MCM-41, but it is still unknown whether the inorganic wall structure is the same. More recently, it has been found that the walls of calcined SBA-3 have disordered micropores [60], and the reason for the generation of micropores is still unknown. Furthermore, the hydrothermal stability and the surface acidity after grafting of Al are quite different for SBA-3 and MCM-41.

Generally, TEOS is the only silica source used for the synthesis of mesoporous materials under acidic conditions, but recently it has been found that sodium metasilicate (Na_2SiO_3) can used as a substitute [61]. By fast acidification of Na_2SiO_3, low-polymerized silicate agglomerate species can be produced as well. Because of the acidic conditions, the polymerization of silicates is not reversible [45], and such oligomers are needed to act as the precursors to assembly of the mesostructure. Preparation of mesoporous materials under acidic conditions with a cationic surfactant as a template was usually carried out at room temperature, and high-quality mesoporous silica material can be produced within 3–5 min. After the precipitation of mesostructured silica, washing with water is not necessary because any extra species can be burned out in the late calcination process. With the use of large-head-group cationic surfactant, such as $C_{16}H_{33}N(C_2H_5)_3Br$ (CTEABr), as a template, a highly ordered mesoporous silica material, SBA-1, with a simple cubic structure (space group *Pm3n*) can be prepared under acidic conditions (Fig. 5) [24, 27].

A breakthrough for synthesizing mesoporous silica materials was the preparation of a new family of mesoporous silica, SBA-11, SBA-12, SBA-15, and SBA-16, with the use of nonionic alkyl poly(ethylene oxide) (PEO) oligomeric surfactants or poly(ethylene oxide)-*block*-poly(propylene oxide)-*block*- poly(ethylene oxide) (PEO-PPO-PEO) copolymers as the templates under acidic conditions [62, 63]. One of the most outstanding mesoporous silica materials is SBA-15, with its highly ordered hexagonal mesostructure (Figs. 5 and 6). The structural regularity of SBA-15 is better than that of MCM-41; the pore size is very large and tunable between 4.6 and 13 nm; the pore volume is between 0.85 and 1.3 cm^3/g. The thickness of the silica walls of SBA-15 is between 3.1 and 7.0 nm. The templates are triblock copolymers (such as P123, $EO_{20}PO_{20}EO_{70}$), have many oxygens in their composites, and therefore are easily removed [62, 63]. After calcination at 190 °C, about 99 wt% organic species can be decomposed, and after calcination at 450 °C, 100% templates can be burned off. Solvent extraction is another effective way to remove a template. In this way, the templates can be recovered and re-used to prepare SBA-15 with similar quality [62, 63]. The large-pore SBA-15 is

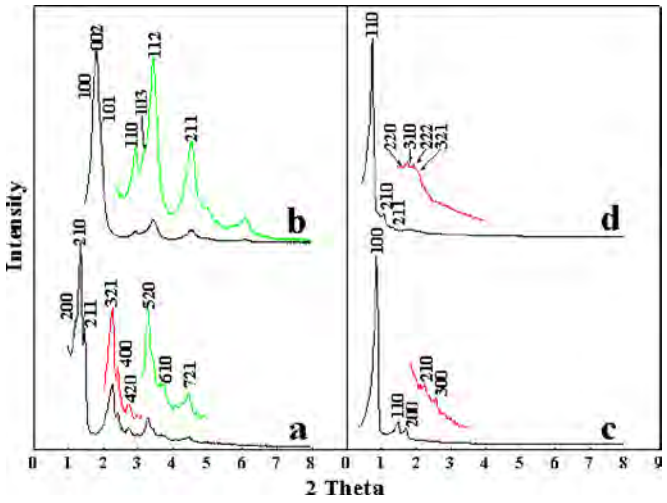

Figure 5. Representative XRD patterns of mesoporous materials. (a) SBA-1 prepared with cationic surfactant $C_{16}H_{33}N(C_2H_5)_3Br$. (b) SBA-2 prepared with Gemini surfactant. (c) SBA-15 prepared with triblock copolymer P123, $EO_{20}PO_{70}EO_{70}$, as a template at 100 °C. (d) SBA-16 prepared with triblock copolymer F127, $EO_{106}PO_{70}EO_{106}$, as a template under acidic conditions.

stable at high temperature and in boiling water. The structure of SBA-15 is still thermally stable after being calcined at 1000 °C for 24 h. Calcined SBA-15 can be stable after being heated in boiling water for more than 1 week. If a large amount of nonpolar organic compounds (for example, 1,3,5-trimethylbenzene, TMB, normally called organic-swelling agent) is added in to synthesis system, the products will be silica mesofoams [64]. The materials have a relatively narrow pore size distribution, and the pore size can be enlarged up to 40 nm; the pore volume can be as high as 2.5 cm^3/g (that is, the porosity is as high as 90%), which is comparable to that of silica aerosols. The silica mesoforms also have a high thermal stability (up to 1000 °C).

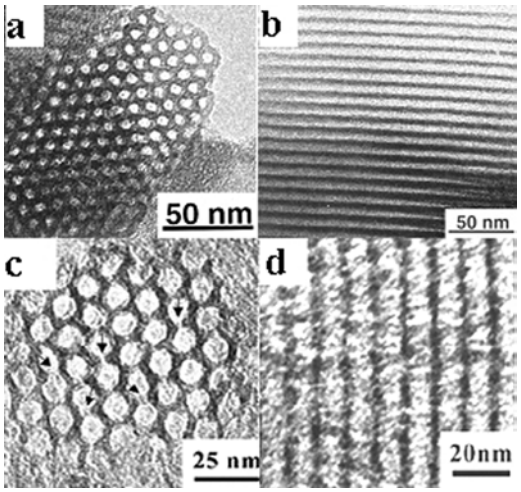

Figure 6. TEM images for (a, b) conventional mesoporous SBA-15 with a thick wall and (c, d) 3D SBA-15 with large mesotunnels on the wall. The images were recorded along the (a, c) [100] direction and along the (b, d) [110] direction.

In a similar synthesis system, different mesostructures can be obtained with different surfactants. For example, with $C_{16}H_{33}EO_{10}$ (Brij56), cubic SBA-11 (space group *Pm3m*) can be formed, whereas with $C_{18}H_{37}EO_{10}$ (Brij76), SBA-12 is obtained [63]. With the use of triblock copolymer with a high EO/PO ratio (such as triblock copolymer F127, $EO_{106}PO_{70}EO_{106}$, F98, $EO_{123}PO_{47}EO_{123}$, F108, $EO_{132}PO_{50}EO_{132}$) [65], highly ordered, large-pore cubic caged SBA-16 (space group *Im3m*) is produced (Fig. 5). Another example, FDU-1, is prepared with poly(ethylene oxide)-*block*-poly(buthylene oxide)-*block*-poly(ethylene oxide) (PEO-PBO-PEO) copolymer, B50-6600 ($EO_{39}BO_{47}EO_{39}$), which contains hydrophobic segment BO, $[CH_3C(CH_3CH_2)O]_n$ blocks [66]. With a block copolymer with a low EO/PO ratio such as L121, $EO_5PO_{70}EO_5$, unstable lamellar mesostructured materials are generally obtained. It has been suggested that the formation of the mesophase templated by block copolymers is processed through the $(S^oH^+)(X^-I^+)$ approach. With the addition of inorganic salts such as NaCl etc. to introduce Cl^- into the synthesis system, it takes less time for silica to precipitate and form a mesostructure [63, 67, 68].

Highly ordered mesoporous materials (SBA-15) have attracted more and more attention not only because they have high-quality structural regularity, thick inorganic walls, and excellent thermal and hydorthermal stability, but also because the template is economically cheap and nontoxic, and the synthesis is quite simple and reproducible [62, 63]. The pore size of the materials can be tuned easily through hydrothermal treatment; that is, a higher heating temperature achieves a larger pore size [62, 63]. More importantly, it has recently been revealed that the wall structure of SBA-15 is quite different from that of MCM-41. A large number of disordered micropores are distributed within the wall of SBA-15; even mesopores with diameters between 2 and 3 nm can be observed [69–71]. The detailed structure of these randomly distributed micropores is still unknown, but it is believed that these micropores may result from the partial occlusion of PEO segments into the inorganic walls during the synthesis process. In fact, this was already realized during the first synthesis of SBA-15 [62, 63]. When hydrothermally treated at high temperature, PEO segments of the triblock copolymers become more hydrophobic and draw back from the inorganic walls, which makes the core of the micelles of the triblock copolymers larger and results in the formation of SBA-15 with a larger pore size. The generation of the small number of mesopores on the silica walls of SBA-15 may not simply be attributed to the insertion of PEO groups in the inorganic walls; the transmutation of micelles during the hydrothermal treatment may be another important factor. The mesopores do not shrink because of the withdrawal of PEO segments from the walls at high temperatures; instead, such mesopores become larger. Zhao and co-workers have demonstrated a new method for the preparation of 3D SBA-15 (Fig. 6) [72]. TMB was added into the synthesis batch as soon as the SBA-15 embryo generated, followed by a hydrothermal treatment at high temperature (100–150 °C). With such a process, the core of the micelles, comprising the block copolymers and TMB, is swollen and breaks through the original micropore area of the silica walls, and finally large-sized disordered mesopores

(with diameters as large as 8 nm) are produced (Fig. 6). Almost no micropores were observed on the inorganic walls of these 3D SBA-15 materials, and all of the pores in the walls were large mesopores. N_2 adsorption/desorption isotherms show that because of the interconnection of the ordered channels by the mesopores on the walls, the calculated pore diameter can be as large as 22.8 nm, and TEM images confirm that the pore structure is like a 3D connected honeycomb (Fig. 6).

The existence of micropores on the silica wall of SBA-15 may favor their applications in catalysis and separation [73, 74]. The synthesis of ordered mesoporous carbon is especially advantageous because of this structural property [75–82]. But for some applications, these micropores are not required, and SBA-15 without micropores can be prepared via a nonaqueous system [65]. Conventional SBA-15 materials were also used as hard templates to synthesize semiconductor nanowires, and isolated nanowires can rarely be obtained [83–85].

5.2. Nonaqueous Synthesis

Nonaqueous synthesis is a convenient method for the preparation of ordered mesoporous materials, and this method has become more and more acceptable and profitable recently [86–90]. The nonaqueous strategy was first used by Brinker, an American sol–gel chemist, in the preparation of mesoporous silica films [91]. Zhao and co-workers further developed this method to synthesize large-dimension mesoporous silica materials [92, 93] and nonsiliceous mesoporous material [86, 90]. This nonaqueous synthesis method adopted in typical sol–gel chemistry proved to be successful, especially when the surfactant self-assembly was introduced into this system [45]. TEOS dissolved in the organic solvent (normally ethanol, tetrahydrofuran, acetonitrile) was prehydrolyzed with a stoichiometic quantity of water at a temperature of 25–70 °C with a small amount of acid (usually HCl) as a catalyst. Then low-polymerized silicate species that were generated by hydrolysis could interact with the surfactant. During the solvent evaporation, the silicate species further polymerized and condensed, forming the mesostructure due to the fast self-assembly of silicates and surfactants. Finally mesoporous materials can be obtained by calcination to remove the surfactants. Nonaqueous synthesis is a versatile method for preparing mesoporous films [91–97], monoliths [98–101], and spheres [102]. Compared with the "hydrothermal" synthesis method, nonaqueous synthesis is more convenient and faster. From the XRD patterns, the diffraction peaks at a relatively high angle range ($2\theta = 3$–$5°$) can hardly be observed for the mesoporous materials prepared by the nonaqueous method, and it seems that the regularity of mesostructures prepared by this method is poorer than that from the "hydrothermal" synthesis method. However, careful observations from TEM show that the structural regularity of the mesoporous materials prepared through the nonaqueous synthesis method is pretty good, and nearly all domains are highly ordered [65]. There may be fewer and broader diffraction peaks because the mesostructure forms too fast in the nonaqueous system, which may lead to nonuniformity of the silica gel particles. Furthermore, the surface area of the materials prepared by the nonaqueous route is lower than that prepared by "hydrothermal" synthesis. Although the recrystallization process can be used to improve the quality and increase their surface areas, why the surface area is so low is still unknown. In addition, another difference between the materials derived by nonaqueous synthesis and "hydrothermal" synthesis is that there are no or fewer micropores in the silica walls of the mesoporous silica products templated by the triblock copolymer, such as P123 under nonaqueous conditions. It is difficult to tune the thickness of the inorganic wall by the nonaqueous synthesis route compared with the preparation of SBA-15 by the hydrothermal method, and the maximum pore diameter that the block coploymers produced is achieved in nearly one step [92].

The nonaqueous synthesis strategy has proved to be one of the simplest and easiest methods for preparing 3D cubic mesoporous silica materials [65, 88, 89, 92]. With the use of block copolymers with long PEO segments, such as F127, F108, F98, or surfactant blends, mesoporous silica materials with a structure similar to that of SBA-16 (*Im3m*) can easily be synthesized [92]. Adding a small amount of organosilicates, for example, mercaptopropyltrimethoxysilane (MPTS), or a small amount of nonpolar organic molecules, for example, ethylbenzene, toluene, TMB, etc., at room temperature under acidic conditions, Zhao and coworkers have synthesized a bicontinuous cubic mesoporous silica material, FDU-5 [89], that has an *Ia3d* structure identical to that of MCM-48. The pore size (up to 10 nm) of the material is larger than that for that of MCM-48, and the pores of FDU-5 directly connect with organic function groups. These large-pore mesoporous silica materials (FDU-5) have been used as hard templates to prepare mesoporous carbon materials with a bicontinuous cubic structure (space group *Ia3d*) [89].

The nonaqueous synthesis route was further extended to prepare nonsiliceous mesoporous materials by Yang et al. [86, 90]. The synthesis process is quite simple. In general, metal halides, such as $NbCl_5$, $TiCl_4$, $AlCl_3$, $SiCl_4$, and so on, were dissolved in ethanol, and then, after the addition of block copolymer surfactants, mesostructures could be obtained by completely evaporating the solvent at 40–60 °C. Mesoporous materials can be obtained via removal of the surfactants by calcination at 300–450 °C. The materials prepared by this method were thermally stable (generally stable at ~500 °C), and the pore size distribution was relatively uniform, but the surface area was relatively low (<200 m^2/g) [86, 90]. It is proposed that this synthesis method is a sol–gel process with an acid-controlled mechanism. MCl_x can react with ethanol by alcoholysis reaction and produce intermediate $M(OEt)_nCl_m$ species that have a low polymerization speed; then mesostructure is formed by slow hydrolysis with the moisture in air [86, 90]. The coordination bond between the oxygen atoms of block copolymers and the metal ion is believed to be important to the formation of final organic/inorganic composite mesostructures.

Since the interaction between inorganic species is less considered, mesoporous oxide materials such as ZrO_2 and Nb_2O_5 and some metal oxides containing mesoporous silica are ordered, and some others are disordered mesostructures [86, 90]. Recently Zhao and co-workers demonstrated a new

"acid-base pair" concept, in which the interaction between inorganic species is considered and the inorganic sources can be classified into acids or bases by fundamental chemical principles. With the selection of proper inorganic precursors by this concept, a large family of mesoporous metal oxides, metal phosphates, mixed metal oxides, mixed metal phosphates, and metal borates can be successfully prepared. For example, highly ordered hexagonal (*p6mm*) and cubic mesoporous $TiPO_4$ can be obtained (Fig. 7) by this route. The materials obtained have a uniform composition distribution and are thermally stable (>700 °C in general) and highly ordered, and the pore size distribution is very narrow (FWHM < 3 nm).

5.3. Synthesis Rules

In general, the phase of mesoporous materials is very dependent on some factors such as reaction temperature, the concentration and the packing parameter of the surfactant molecules, and so on. It was assumed that the mesostructure is determined only by the concentration of the surfactant, and this observation is based on the fact that the hexagonal liquid crystal phase is first formed at low surfactant concentration, whereas the transformation from the hexagonal to the cubic mesophase occurs at higher concentrations. Later, the packing parameter (g) was proposed as a guideline to predict and explain the formation of the mesoporous product phase [29].

In $g = V/a_0 l$, V represents the hydrophobic volume of the whole surfactant molecule; a_0 represents the effective area of the surfactant head group, and l is the length of the surfactant chain. Although it is the result of a simple geometric computation, the value of g can well describe the type of liquid crystal phase formed under specific conditions. As for the synthesis of mesoporous materials, it can enlighten us about how to control the reaction conditions and parameters to obtain the expected mesophase. Moreover, it provides an excellent explanation of the experimental phenomena observed. When g is smaller than 1/3, caged SBA-1 (*Pm3n*, cubic) and SBA-2 ($P6_3/mmc$, 3D hexagonal) form. When g is between 1/3 and 1/2, MCM-41 (*p6mm*, 2D hexagonal) forms. When g is between 1/2 and 2/3, MCM-48 (*Ia3d*, cubic) forms. When g is near 1, a lamellar mesostructure can be formed.

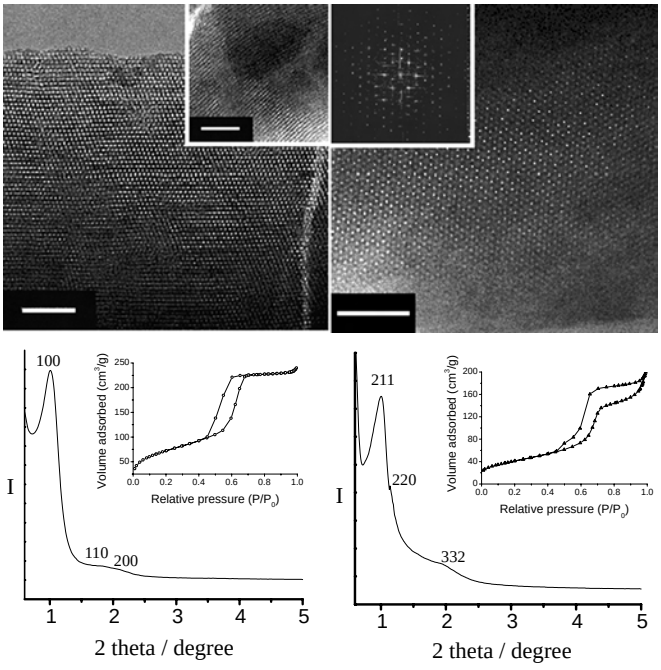

Figure 7. Structural characterizations of mesoporous titanium phosphate (TiPO). (a) TEM images (viewed from [110] and [100] directions). (b) TEM image, Fourier diffractogram (both from the [111] direction). (c) XRD, N_2 sorption curves of 2D hexagonal mesoporous TiPO. (d) XRD, N_2 sorption curves of bicontinuous 3D cubic mesoporous TiPO.

Under similar synthesis conditions, the influence of the reaction conditions and the inorganic species is nearly the same for the cooperative assembly of the surfactant-inorganic species. In this case, the properties of the surfactant (geometry, charge, and structure) have a large effect on the assembly of the inorganic-organic mesostructure; therefore different mesophases can be obtained with the use of different surfactants. In other words, the mesostructure of the products can be controlled by the selection of proper surfactants or the addition of auxiliary agents that have an influence on the packing parameter of the surfactants [24, 27, 52]. Some examples are shown as follows:

(A) Cubic SBA-1 can be prepared directly by alkyltriethylamine ($C_nH_{2n+1}N(C_2H_5)_3Br$, n = 10–18) [52], because the g value is decreased by the large head group of the surfactants. The lamellar mesostructure can be directed by bi-tail surfactants (e.g., $(C_{12}H_{25})_2N(CH_3)_2Br$) because they have a large hydrophobic part. The g value increases with the V value.

(B) The length of the hydrocarbon chains of the surfactants has a little influence on the mesostructure formed. The reason for this is that the value of V/l undergoes almost no changes with different lengths of hydrocarbon chains; that is, the g value does not change. But when the hydrocarbon chains are long enough (e.g., longer than 20 carbon atoms), the carbon chains can be wound, and thus the V value increases a little while l decreases, and the g value increases. Therefore, the lamellar mesostructure can easily be templated by surfactants $C_nH_{2n+1}N(CH_3)_3Br$ (n = 20, 22).

(C) The Gemini surfactant $C_{m\text{-}s\text{-}m}$ is a kind of special surfactant and consists of two head groups connected by a hydrocarbon chain. Controlling the length of the hydrocarbon chains can vary the area of the surfactant head groups. For example, with the surfactant $C_{16\text{-}s\text{-}16}$, $C_{16}H_{33}N(CH_3)_2(CH_2)_sN(CH_3)_2C_{16}H_{33}Br_2$ as a template under base conditions, when s is changed from 2 to 12, the product obtained was transformed from the lamellar to the hexagonal phase (MCM-41), and the final products (when s = 12) were cubic mesophase (MCM-48).

(D) Many experimental phenomena, including the influence of the organic additives on the synthesis, the mesophase transformation, and so on, can be explained based on the g value [103].

Although the g value is a wonderful parameter for the evaluation of the mesoporous product phase and explains well the experimental phenomena observed from cationic surfactants, somehow it does not apply very well to block copolymer synthesis systems. Recently, we found that the critical micelle concentration (CMC) of block copolymer surfactants is a powerful criterion for the experimental design of the synthesis of ordered mesoporous materials. When the CMC of the block copolymer is below 20 mg/liter at room temperature, the template is ready to synthesize ordered mesostructures. When the CMC is approximately between 20 and 300 mg/liter, some strategies can be used to decrease the CMC to give ordered mesostructures, such as increasing the temperature and/or ionic strength of the reaction liquors. When the CMC is further increased (>300 mg/liter), it will be difficult to make ordered mesostructures.

5.4. Secondary Synthesis

Besides the above-mentioned direct synthesis methods, secondary synthesis is also one of the most important synthesis strategies [104, 105]. To increase the wall thickness or local structure regularity, secondary synthesis, that is, grafting or recrystallization, must be employed. For example, MCM-41 can be stabilized in boiling water by the reaction of MCM-41 and $AlCl_3$ [106]. Compared with the matrix, the materials after the treatment have better mechanical and hydrothermal stability. This may be attributed to the improvement of wall thickness and internal silica linkage, and mend of some structural defects. After water vapor treatment at high temperature, the materials still have a strong Bronsted acidity on the surface.

Recrystallization can make the structural regularity of mesoporous materials more perfect and ordered; however, only a few research groups have comprehended this trick. Most researchers have employed hydrothermal treatment to improve the structural regularity [52]; to be specific, the solid mesoporous materials obtained at room temperature were put into an autoclave within the mother solution, where they underwent hydrothermal treatment at high temperature (100–150 °C). Differing from the above treatment, the recrystallization process includes the addition of water to an as-synthesized mesoporous material, which is then heated at 100 °C in neutral medium for several days (about 1 week). The quality (structural regularity, thermal stability, etc.) of the materials can obviously be improved after this treatment; sometimes the pore size can also be increased. Moreover, secondary synthesis is also a good method for preparing mesoporous material-doped transition metals [49, 50].

Another secondary synthesis method has been demonstrated by Zhao and co-workers to synthesize a highly ordered hexagonal mesoporous silica structure with the use of a nonionic oligomeric surfactant with long hydrophilic chains [104]. This process involved the adsorption of an extra silica source (TEOS) into the directly synthesized products and secondary hydrolysis process in either base or acidic media. The treatment resulted in great improvement of the ordering and hydrothermal stability of the mesoporous silica materials. Similar secondary synthesis procedures have recently been applied in the synthesis of high-quality mesoporous films [105].

6. THE DIFFERENCES WITH TRADITIONAL ZEOLITES

There are many differences between mesoporous materials and traditional zeolite molecular sieves. As far as the structure is concerned, the differences are:

(A) Different crystallinity. Mesoporous materials are imperfect crystals, and at the atomic level they cannot be defined as crystals.

(B) Structure codes. Each of the zeolite structures is given a structure code by the International Zeolite Association (IZA). For example, the code of zeolite faujasite Y is FAU [107]. But for mesoporous materials, it is difficult to give an IZA structure code, because there are so many differences in properties between the mesoporous materials with identical structure and composition.

(C) Building blocks. The traditional zeolite molecular sieves are mainly constructed by tetrahedrons (TO_4), but the inorganic walls of the mesoporous materials are amorphous, and many coordination types, such as TO_6 and TO_5, are allowed as the building blocks to construct a mesoporous material structure.

(D) From the viewpoint of the atomic level, the connections between the inorganic species of the frameworks for mesoporous materials are relatively weak. For example, the four corner points of the silicon-oxygen tetrahedron are not necessarily connected with other tetrahedrons.

(E) In general, mesoporous materials (especially silica) are not stable in water (referred to as "hydrothermally" unstable). After being heated for 6 h in boiling water (100 °C), calcinated MCM-41 becomes amorphous and loses its structural regularity [63, 108]. Al-containing MCM-41 is more stable than pure silica MCM-41 in hot water [106]. Mesoporous silica materials synthesized with nonionic oligomeric surfactants or block copolymers (SBA-11, -12, -15, -16) are far more stable and can retain their structure after being heated in boiling water at least for 10 days. People have recently tried to increase the framework stability by various methods, including the use of zeolite precursors as the inorganic sources [109–112]. It should be noted that stability in boiling water is not true hydrothermal stability. The true hydrothermal stability should be studied under the treatment with 100% water vapor at 600–800 °C. Until now, no detailed paper on the hydrothermal properties of mesoporous materials has been reported [112]. But based on the current literature, the structure of mesoporous silicates (or aluminosilicates) is destroyed after 100% water vapor treatment for 4 h at 800 °C [112].

As far as the synthesis is concerned, there are also many differences between mesoporous materials and traditional zeolite molecular sieves. First, the synthesis temperature is much lower for mesoporous materials. In general the temperatures vary from room temperature to 80 °C, and mesoporous materials can even be prepared at −20 °C [113, 114]. From this point of view, the synthesis method employed

for mesoporous materials is not the classical hydrothermal synthesis technology. The hydrothermal treatment temperature for mesoporous materials is normally lower than 160 °C (commonly 80–150 °C) even after these materials precipitate (this means the mesoporous materials have been formed), otherwise, crystalline microporous material zeolite can be formed at high temperature (>150 °C) [113]. Second, the formation rate of mesoporous materials is very fast. Mesostructure forms in several minutes, even in several seconds. In contrast, it generally takes several hours or days to prepare microporous zeolite materials. Third, the inorganic walls of mesoporous materials are amorphous; therefore their composition can be varied, and the inorganic framework does not have to be composed by tetrahedron building blocks. In this context, mesoporous materials can be made up of any inorganic elements. Because of this consideration, large amounts of nonsiliceous mesoporous materials, metal oxides, metal sulfides, metal phosphates, and even metal mesostructure have been prepared. Fourth, mesoporous materials can be synthesized under true nonaqueous conditions, such as preparing mesostructure through rapid solvent evaporation, with alcohol as a solvent. However, molecular zeolite sieves are still synthesized in pseudononaqueous conditions [115]. A little water is necessary for the formation of zeolite structure. Sometimes the structure of zeolite crystals may be destroyed by completely evaporating the solvent in an autoclave. Fifth, the morphology of mesoporous materials is relatively easy to control. In some cases, the morphology obtained is not related to the mesoporous material structure. Mesoporous materials can be prepared with a morphology of spheres [97, 116–120], fibers, and so on.

7. COMPOSITION

Metal doped mesoporous silica materials have attracted considerable attention because they show potential applications as hosts, adsorbents, and catalysts [73, 74]. Substituted MCM-41 and SBA-n mesoporous materials can be prepared by direct hydrothermal synthesis. The content of doped metals for substituted MCM-41 and MCM-48 prepared by direct synthesis is usually below 10 wt%. Mesoporous TiO_2 [88, 121], ZrO_2 [122], Al_2O_3 [111, 123], Ga_2O_3 [38], $AlPO_4$ [49, 124], $TiPO_4$ [125], and some other nonsiliceous materials have been synthesized as well. In addition to the previously described nonsiliceous materials prepared via the nonaqueous synthesis route, many cases have been reported for the preparation of nonsiliceous materials in aqueous solution, normally with long-chained organic amines or cationic surfactants as the templates. Most of these products are unstable; additional methods should be employed to stabilize the resultant mesostructures.

Adding a large amount of doped metal ions into a synthesis batch for mesoporous silica materials can result in a severe decrease in the mesostructural regularity of the materials. In fact, a large amount of transition metal ions can be introduced into mesoporous materials by a secondary synthesis that is similar to the impregnation method for preparing catalysts. Because the inorganic walls of mesoporous materials are amorphous, it is meaningless to try to determine whether the substituted atoms are in the inorganic framework of mesoporous materials. There is almost no doping quantity limitation for secondary synthesis. Based on currently published papers, the differences in some properties between the doped metal mesoporous materials prepared by the direct method and those prepared by the secondary method are not clear. For example, Al-MCM-41 prepared by secondary synthesis shows a better stability and surface acidity than that from direct synthesis. Heteropolyoxometallates, $H_2W_{12}PO_4$, can be incorporated into a mesoporous material (SBA-15) to prepare a good solid acid catalyst. When the doped amount is higher than 150 wt%, the crystalline phase of $H_2W_{12}PO_4$ cannot be detected by X-ray diffraction (XRD).

Mesoporous carbons are a kind of new nonsiliceous material discovered recently by Korean scientist R. Ryoo and co-workers [75–82]. The materials have an ultrahigh surface area (as high as 2500 m^2/g) and a very large pore volume (up to 2.25 cm^3/g) [126], which makes them promising materials for catalyst supports, hydrogen storage, and electrodes, and therefore they attract much attention [127, 128]. With ordered mesoporous silica materials as the templates, amorphous carbons can be incorporated into their channels, and ordered mesoporous carbon can be obtained after removal of the silica framework by HF or NaOH. The carbon materials have a structure that is a replica of their silica templates, which means the two materials belong to the same space group, but the pores and frameworks are inversed from that of the mesoporous silica. A series of mesoporous carbons have been prepared and named CMK-n (carbon materials of Korea). Mesoporous carbon derived by SBA-15 has a 2D hexagonal mesostructure (*p6mm*) and is called CMK-3. Because of the micro- and mesopores in the inorganic wall of SBA-15, after removal of silica, amorphous carbons filled in the micropores act as pillars to support the carbon rods formed in the 1D channel of SBA-15; therefore a hexagonal mesostructure is constructed. Mesoporous carbon templated by bicontinuous cubic MCM-48 is called CMK-1 or CMK-5. Because of the 3D interconnected pore structure of MCM-48, the CMK-5 obtained (CMK-1) is composed of continuous amorphous carbon frameworks, and the space group is a little different from that for MCM-48. Ordered mesoporous carbon cannot be templated by MCM-41, and only amorphous carbon nanorods or nanowires can be obtained. Because MCM-41 prepared under base condition has a solid inorganic wall without micropores, the pillars that support the carbon rods cannot be formed like that in the case for SBA-15, and after the removal of silica, the carbon rods or wires will be disassembled. The pore size control of mesoporous carbons is relatively difficult, and mesoporous silica with large pores may not produce large-pore mesoporous carbon. The only way to accomplish this is to control the wall thickness through different kinds of mesoporous materials. Recently, Ryoo and co-workers employed SBA-3 as a template, which has a few micropores on its inorganic wall, and successfully prepared mesoporous carbon with a small pore size [60]. Y zeolite was also used as a template to synthesize nanoporous carbon molecular sieves by a similar method [83].

There are several alternative methods for incorporating carbon into the channel of mesoporous silica materials,

mainly including chemical vapor deposition (CVD) [82] and the solution method [75–82]. The former is relatively difficult to control, while the latter is more effective. In a typical synthesis, sucrose or furfural alcohol is employed as a carbon source by impregnation. Carbonization was carried out at 90 °C with concentrated H_2SO_4. The mesopores of the template can be completely filled with the carbons by the process described above, repeated one or two times. After removal of silica by HF or NaOH, mesoporous carbon is obtained. Attention has to be paid to this step to ensure that the silica is completely removed.

At present, the synthesis of spherically structured mesoporous carbon has encountered difficulty. With mesoporous silica with a cage structure as a template, the windows connecting the cages are too small (the entrance size is smaller than 4 nm), so the replicas of carbon spheres are not well connected and easy to take apart; therefore the resulting mesoporous carbon is poorly ordered. Zhao and co-workers found recently that 3D spherically structured carbons can be synthesized by caged cubic mesoporous silica materials with large entrance sizes, which are synthesized by using high-temperature hydrothermal treatment in the presence of inorganic salt and nonpolar organic molecules (such as TMB).

Ryoo and co-workers carefully coated the walls of the channels of SBA-15 with a layer of amorphous carbons through a well-controlled process and obtained ordered carbon tubes after the removal of silica. This new interesting carbon material is thermally stable because the carbon rods, like pillars, support the tube (Fig. 8). What's more interesting is that the material has bimodel pore size distribution, namely two sets of mesopores with uniform pore size distribution.

Mesoporous carbons are very stable, and their structural regularity is retained even after calcinations at 1600 °C (in an inert atmosphere). Still, mesoporous carbon is difficult to graphitize. Although the partly ordered lamellar structure of graphitized carbon can be observed in some small domains, a material with a complete graphitized structure has not been obtained yet, and scientists are endeavoring to achieve this target.

8. FUNCTIONALIZATION

Mesoporous silica materials can easily be functionalized since their inorganic walls have abundant hydroxy groups that easily react with active organic groups such as R-Si(OEt)$_3$, R-SiX$_3$ (X = halide Cl, Br, etc.) [129–133]. The organic compounds commonly used for the functionalization are listed below. The functionalization can be attained by a simple process. In general, calcined mesoporous silica was heated in a vacuum at 100–130 °C to remove adsorbed water and then reacted with active organic compounds in an inert solvent (benzene, toluene, or cyclohexane). After filtration, the functionalized mesoporous silica product was obtained. The functionalization not only can change the hydrophilic/hydrophobic property of mesoporous materials (functionalized organic compounds are normally hydrophobic), but also takes the function of organic groups in catalysis, luminescence, separation, and sorption of heavy metal ions in environmental application. J. Liu and co-workers found that mesoporous silica materials functionalized with a mercapto group have excellent sorption ability for heavy metal ions and can be applied in wastewater treatment [134–136].

Another functionalized process is the direct synthesis method, in which a silica source with organic functional groups, such as $(EtO)_3Si\text{-}R$, is added directly to the silica sols of the synthesis batch [133, 134]. Because the R group cannot connect with the other tetrahedral silicate species, the quantity of the organic functional group introduced into the materials is limited. The structural regularity of the functionalized mesoporous material products is good enough when the $(EtO)_3Si\text{-}R/TEOS$ ratio is less than 10% (the largest ratio should be lower that 20%). There is still no clear determination of the differences, if any, between the functionalized materials obtained with the direct method and secondary synthesis.

Recently, Inagaki and co-workers synthesized a new kind of organic-inorganic periodic mesoporous organosilica (PMO) hybrid material with R-bridged (R represents organic function groups) organosilane $(EtO)_3Si\text{-}R\text{-}Si(OEt)_3$ as a silica source [137–140]. Different from the above functionalized mesoporous materials, the organic groups are located in the middle of the inorganic walls. Both ends of the silicate precursor molecules are able to hydrolyze and polymerize and do not affect the formation of the inorganic framework. One hundred percent of $(EtO)_3Si\text{-}R\text{-}Si(OEt)_3$ can be used as a silica source in the synthesis of mesoporous materials [141, 142]. However, it should be pointed out that the length of the hydrocarbon chain cannot be too long (shorter than C_6), otherwise ordered PMO would not be obtained. The organic function group in PMO is thermally stable (normally to 400 °C), so it is easy to remove the surfactants by either calcinaion or extraction. The PMO obtained has a high surface area (>800 m^2/g) and a large pore volume (>0.7 cm^3/g). What is more noticeable is that when benzene-bridged organosilane was used as a silica source, the resulting PMO has a crystal-like wall structure and the benzene groups can stack in a layered structure (~6 Å) by π-π interaction (Fig. 9) [138]. These ordered organic-inorganic hybrids further assemble to form an ordered mesostructure, which turns into a kind of hierarchically ordered PMO with considerable potential applications.

9. PORE SIZE

The methods used to tune the pore size of mesoporous materials are mainly as follows:

(1) Hydrothermal treatment: the higher the temperature, the larger the pore size [24, 63].

(2) using alternative surfactants [52, 63]. In general, the pore size of mesoporous materials is determined by the volume fraction of the hydrophobic part of the surfactant/inorganic composite micelles [63]. As for cationic surfactants, the longer hydrocarbon chain yields a larger pore size [12, 13]. However, it is not unlimited; when the hydrocarbon chain is longer than C_{22}, the surfactants are insoluble in water and cannot be used as templates for the synthesis of mesoporous materials. As for block copolymers, the pore size of mesoporous materials is determined by the molecular weight of the hydrophobic block. It seems that a larger molecular weight yields a larger pore size, and the pore size is not related to the total molecular weight of the block copolymers. Sometimes, using mixed surfactants as the templates can increase the pore size.

(3) Adding an organic swelling agent [12, 63]. This is an effective method of increasing mesopore size. In the synthesis of mesoporous materials with block copolymers under acidic conditions, the pore size can be as large as 40 nm when TMB is added as an organic swelling agent. Mobil Company scientists have claimed [12, 13] that the mesopore size of MCM-41 can reach 10 nm when CTAB is used as a template and TMB is added. It is noted that generally the structural regularity is decreased by the addition of TMB. The pore size of ordered SBA-15 can be increased to 20 nm [72]; for MCM-41 materials the upper limit is 6 nm, otherwise the ordered structure will be mostly destroyed. Nonpolar organic molecules, such as toluene, benzene, xylene, cyclohexane, and long-chain hydrocarbons, can be used as

organic additives to increase the pore size. Based on current reports, TMB is one of the most effective organic additives.

Sorted by the pore size of the products, the methods for achieving pore sizes are as follows:

2–5 nm: utilizing surfactants (including long-chain cationic quaternary ammonium surfactants and neutral organic amines) with various chain lengths as templates [39].
4–7 nm: employing long-chain quaternary ammonium surfactants as the templates and high-temperature hydrothermal treatment [52, 143].
5–8 nm: using cationic quaternary ammonium surfactants and adding organic swelling agents (TMB, middle, or long-chain amines) [144].
2–8 nm: utilizing nonionic oligomeric surfactants as the template [63].
4–20 nm: utilizing block copolymers as the template [62, 63].
4–11 nm: secondary synthesis (water or amines postsynthesis treatment) [144].
10–40 nm: utilizing block copolymers as templates and adding organic swelling agents (TMB) [62–64].

10. CHARACTERIZATION

Because of the potential applications of the mesoporous materials in advanced technologies such as catalysis, separation, microreactors, electronics, electrodes, microdevices, sensors, and so on, all kinds of modern characterization techniques, including XRD, TEM [82, 83, 145, 146], physical adsorption [69, 70, 81], ultraviolet diffuse reflectance spectroscopy (UV-DRS), solid-state nuclear magnetic resonance (solid-state NMR) [99], electron spin resonance (ESR) [57, 147, 148], X-ray photoelectron spectroscopy (XPS), etc. have been used to characterize the structure and formation mechanism of mesoporous materials. The most effective and essential methods are XRD, TEM, N_2 adsorption isotherm, and solid-state NMR.

10.1. XRD

It is very hard to obtain large single crystals of mesoporous materials (currently, the size of single-crystal mesoporous silica is between 1 and 2 μm); therefore, powder XRD is one of the most effective tools for characterizing mesoporous materials. Because mesoporous material structures have long-range periodicity and a large cell parameter, the diffraction peaks are usually observed at low angles (2θ is normally in the range of 0.8–8°). Measurement of low-angle XRD patterns must be carried out with caution. It is suggested that narrow slit setting, low X-ray power, and slow scan speed are the recommended measurement conditions; otherwise, artificial diffraction (or reflection) peaks will be observed, which often cause the wrong assignment of the periodicity of mesoporous materials. The limit of low-angle XRD that can be measured may be as small as $2\theta = 0.4$–0.5, depending on the type of XRD machine and measurement conditions; however, the absolute value obtained at such a low angle, even it is a true diffraction peak, may cause a relatively large error because no standard materials can be used to adjust the XRD machine at small angles. If necessary, a small-angle X-ray scattering technique should be employed to collect more accurate data at low angles. It is relatively easy to confirm a known mesophase from XRD patterns. Typical XRD patterns of some mesostructures are shown in Figures 2 and 5. Through simple comparison of XRD patterns and d values, generally, a known mesophase can be confirmed. It should be noticed that the errors for d values in a small angle range are relatively large; therefore, in addition to XRD patterns, the ratios of those precisely measured d values should also be in accordance with the known mesophases. To solve the structure of a new mesophase from the XRD pattern is a tough job. In addition to the errors of small-angle XRD, there are normally less than three diffraction peaks in the XRD patterns of the mesoporous materials. Therefore it is difficult to determine the space group from the indexation of XRD diffraction peaks of the mesoporous materials. However, it is possible as well to get information on space groups by the combination of high-quality XRD diffraction peaks with the liquid crystal phase of the surfactant. It is necessary to understand the new mesostructure of a material utilizing XRD combined with HRTEM images [145, 146]. Furthermore, a coarse judgment of the quality and structure regularity can be made by using the XRD peak width and relative intensity. Similarly, it should be noticed that XRD peaks are caused only by periodic crystal structures and represent the aggregate of the whole sample. Amorphous materials have no diffraction peaks and do not influence the XRD peaks. In other words, XRD measurements could not provide us with any information about the amorphous matters. Comparison of the periodicity of the materials by the relative intensities of the diffraction peaks should be made very carefully, because the intensity is always related to the measurement conditions.

10.2. TEM

Electron microscopy is one of the most important modern techniques for characterizing the geometry, periodicity, pore morphology, etc. of mesoporous materials [145, 146]. In addition, HRTEM can also provide information about superlattices, defects, twin growth, and breaking edge analysis for mesoporous materials.

Analysis of TEM images is always complicated. Artificial images and incorrect indexation often take place. To obtain more information on mesoporous materials, it is necessary to combine TEM results with electron diffraction analysis and XRD patterns. It should be noted that TEM data provide only local periodicity and structure information in small domains and cannot give us information for whole samples, whereas XRD can give information for whole bulk samples. TEM can be used to analyze the structure of mesoporous materials. Terasaki has made an excellent contribution in this field [83, 145, 146]. He and co-workers obtained high-quality images of mesoporous materials by defocus TEM, combined with XRD and N_2 sorption isotherm results; in this way they creatively established the energy distribution model. With this model they effectively resolved several mesoporous material structures, such as SBA-1, SBA-6, SBA-16, etc. (Fig. 10). Recently they found a novel method for resolving the structure of molecular sieves by TEM, which was expected to provide more useful tools for structural characterization in the field of molecular sieves [146].

10.3. Physical Adsorption

Physical adsorption is also one of the most effective modern tools for the characterization of the pore structure of mesoporous materials. Based on the shape of the isotherms and hysteresis loop, pore structures, including micro-, meso-, macropore, cylindrical pore, bottle-like pore, and so on, can be obtained. Pore size distribution, pore volume, and surface area can also be calculated. The probes used are usually Ar and N_2 molecules. Because the atom diameter of Ar is smaller than that of N_2, the measurement error for the pore size from Ar is smaller [12, 13]. Unfortunately, liquid Ar is not conveniently available. N_2 sorption measurements are more convenient to carry out. A typical curve for mesoporous materials is the IV type sorption isotherm. The steeper the adsorption volume change is, the more uniform the pore size distribution is. Mesopore size is generally calculated from the adsorption branches of the isotherms, and the window size of the pore is calculated from the desorption branches. Typical N_2 sorption isotherms of mesoporous silica materials are shown in Figure 11. Pore structure can be roughly judged from the shape of the hysteresis loop. MCM-41 or SBA-15 has cylindrical pores, and therefore their window sizes are the same as their mesopore diameters. The hysteresis loop is parallel and belongs to the H_1 type; therefore, the pore diameters calculated from desorption branches are the same as those from adsorption branches (Fig. 11). Cubic mesoporous materials with caged structures have small windows (smaller than 4 nm) [145]; therefore an H_2 type hysteresis loop is observed. Because of the physicochemical properties of N_2, the hysteresis loop always ends near the point of $P/P_0 \sim 0.4$. Several models, such as BJH (Barrett-Joyner-Halenda), HK (Horvath-Kawazoe), and BdB (Broekhoff-de-Boer), can be used to calculate the pore sizes and their distribution. The BJH model is mostly utilized by mesoporous material researchers. For a simple comparison, the BJH model is advisable, but some problems have been observed when this model has been used to calculate the pore sizes. The pore diameters calculated from the adsorption branches for cylinder pore MCM-41 or SBA-15 are not the same as those from the desorption branches, and the 4V/A value is not equal to the radius of the cylinder. It was found recently that the pore size calculated from the BdB model is more exact and is in agreement with that from other characterization

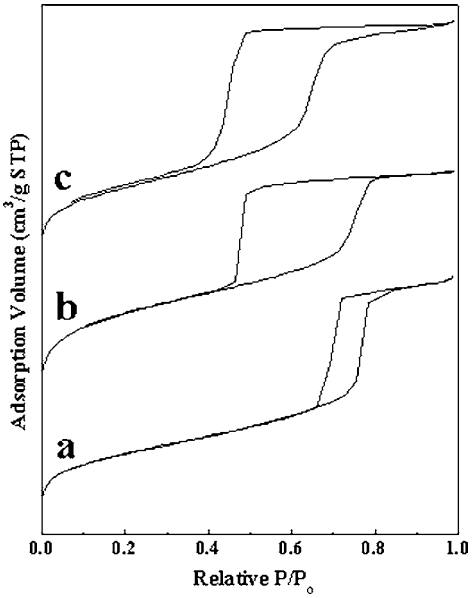

Figure 11. Typical nitrogen sorption isotherms of mesoporous materials with different pore structures. (a) SBA-15. (b) SBA-16. (c) SBA-1.

results [149]. In the past, because there have been no reference samples for the measurements of mesopore sizes, adsorption models and theories have been difficult to prove. The appearance of periodic ordered mesoporous materials such as SBA-15 and MCM-41 has made it possible to further develop the adsorption theory. Theoretically considered, pore diameters smaller than 300 nm can be measured by N_2 isotherms, but the practical error is large when the pore diameter is larger than 100 nm or even 50 nm. Pore diameters larger than 100 nm are normally measured by mercury extrusion. In fact, other adsorption probe molecules with different dynamic diameters, such as water, alcohol, *n*-hexane, cyclohexane, and aromatic hydrocarbons, can also be used in the measurement of pore diameters, which can provide an applicable pore diameter.

10.4. Solid-State NMR

Solid-state NMR is an important technique as well for learning about the framework structures of mesoporous materials [99]. Because the walls of mesoporous silica materials are amorphous, typical ^{29}Si-NMR spectra show fairly broad peaks, which include Q^2, [$=$Si(OH)$_2$], Q^3, [$\equiv$Si—OH], Q^4, [Si(—O)$_4$], at the chemical shift between -90 and -110 ppm. The quantity of hydroxy groups on the frameworks of mesoporous materials can be evaluated from the ratio of $Q^2/Q^3/Q^4$. Generally, the smaller the quantity is, the higher the thermal stability and hydrothermal stability are. Sometimes the evaluation is not correct. For example, compared with calcined MCM-41, calcined SBA-15 has a larger Q^3/Q^4 ratio because abundant micropores are located on the silica walls and result in a larger number of hydroxy groups, but the hydrothermal stability (heating in boiling water) of calcined SBA-15 is higher than that of MCM-41.

^{27}Al-NMR, ^{1}H-NMR, and ^{13}C-NMR [99] can also be applied to the characterization of mesoporous materials.

It has been known that the resonance peak for the tetrahedral Al species appears at 50 ppm and that for octahedral Al near 0 ppm. Though it cannot be concluded that octahedral Al species are not located on the inorganic framework (because the inorganic walls of mesoporous materials are amorphous), it is reasonable to believe that the octahedral Al species are located on the surface of the walls of the mesoporous materials. The formation mechanism of mesostructures and the interaction of organic species (surfactants) with inorganic species can also be studied by 2D-NMR [99].

11. MORPHOLOGY

Mesoporous materials can be synthesized in either basic or acidic conditions. In basic conditions, the Coulombic interaction between organic templates and inorganic precursors is relatively strong; furthermore, the silica walls are robust, therefore the morphology of the resulted mesoporous materials is quite rigid and in some cases sharp polyhedrons are obtained [82]. Under acidic conditions, hydrogen bonding is relatively weak, and the hydrolysis and condensation of silica species can be controlled efficiently by adjusting the temperature, pH, ionic strength, etc. In this way, combined with emulsion chemistry, mesoporous materials with fiber, film, monolith, and sphere morphologies, even mesoporous silica single crystals, have been obtained.

11.1. Fibers

Mesoporous fibers can be prepared by two methods. One synthesis approach is growth in a solution [150–152]. The synthesis of mesoporous silica fibers has been carried out at the interface of oil (long alkyl chain alcohols or hexane) and aqueous solutions (i.e., CTAB acidic solutions) when TEOS was used as a silica source [151]. The oil is not necessary when tetrabutylorthosilicate (TBOS) is used as a silica source. Under static conditions, mesoporous silica fibers can be obtained from the aqueous phase that are 1–10 μm in diameter and 100 μm to 5 cm in length (Fig. 12) [150, 151].

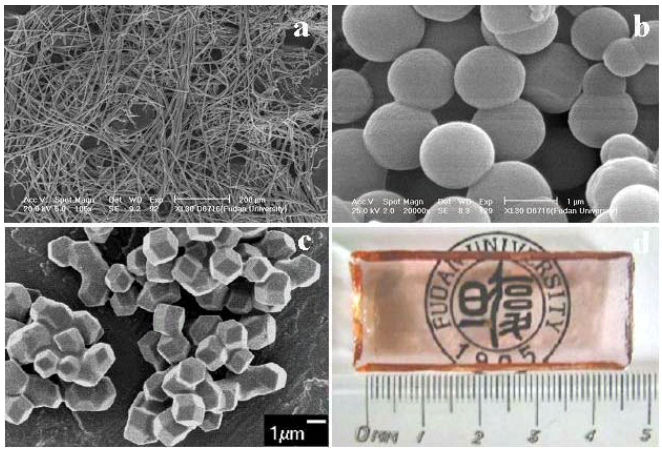

Figure 12. Selective SEM images of mesoporous materials synthesized with different morphologies. (a) Fibers. (b) Spheres. (c) Single crystals. (d) Monoliths.

For the pore structure of hexagonal mesoporous silica fibers synthesized by this method, it was once suspected that the hexagonally arrayed channels are parallel to the long axis of the fibers. Recent results suggest that the mesopores in such fibers run in a circular direction around the axis. The solution growth method has been successfully applied to the synthesis of SBA-15 fibers, with triblock copolymer P123 as a template and TMOS (tetramethoxysilane) as a silica source [93, 152]. The fast precipitation of products together with stirring is essential to the formation of mesoporous fibers [126]. Moreover, the mesoporous channels of the SBA-15 fibers obtained proved to be parallel to the long axis. Another approach to synthesizing mesoporous fibers was simply performed by drawing fibers from concentrated gel solutions [153]. These fibers do not have a well-defined mesopore orientation because the formation is too fast.

11.2. Films

Continuous and crack-free films with accessible mesopores may offer important potential for use in separation, adsorption, and electronic/optical applications. Generally dip-coating or spin-coating methods were utilized to synthesize such mesoporous films by an evaporation-induced self-assembly process [91–93]. The substrate at which the film is grown is an important factor. Yang et al. first reported the synthesis of a hexagonally ordered mesoporous thin film at a cleaved mica substrate with the use of an acidic aqueous mixture of CTAC (cetyltrimethyl ammonium chloride) surfactant and TEOS; TEM revealed that the pore channels were parallel to the mica surface [94]. A later report by Yang et al. demonstrated that ordered mesoporous silica films could be formed at the interface of air and water without a solid substrate [95]. Other research revealed that mesoporous thin films could be grown at a hydrophobic interface such as carbon, instead of commonly used hydrophilic substrates such as mica and glass slides [154].

Similar to what has been observed in the synthesis of powder samples, the choice of the structure-directing agents may result in the variation of the structure and pore size of mesoporous films. Stucky and co-workers reported the synthesis of 3D hexagonal mesoporous thin films with the use of Gemini surfactants as the templates, in which the *c* axis of the oriented film is perpendicular to the substrates [93, 96]. Using the block copolymers as the templates, the same group reported that highly ordered, large-pore, 2D and 3D mesoporous silica and transitional metal oxide films can be synthesized [90, 92]. By changing the silica source, Brinker and co-workers reported the synthesis of highly ordered hybrid mesoporous films [97].

11.3. Monoliths

Mesoporous silica monoliths with enhanced elasticity and ductility could be synthesized with block copolymers as the templates in a nonaqueous solution based on the sol–gel process [87]. A representative SEM image for mesoporous silica monolith templated by triblock copolymer is shown in Figure 12. Such rigid and transparent monoliths have potential uses in optics. Organic molecules such as butanol, pentanol, hexanol, or octane can be used as the cosurfactants

to control the mesostructure and the pore size of the final monolith products [98]. Zhao et al. synthesized 3D sponge-like macro- and mesoporous silica monoliths by employing the phase separation of concentrated salt solutions in the presence of block copolymer surfactants [93]. The hierarchical pore structures may be important for mass transportations in catalysis and separation. It is noted that cationic surfactants such as CTAB can also be used in the synthesis of silica monoliths.

Normally, the formation of crack-free mesoporous monoliths is too slow; it takes several days to a month [99, 100]. To solve this problem, recently we demonstrated a method in which liquid paraffin medium protected against solvent evaporation to quickly yield transparent, crack-free, large, highly ordered mesoporous monoliths. This method is quite simple; it just includes covering an inert layer liquid of paraffin as the morphology "protector," to reduce the damage caused by the internal pressure gradient. By accelerating the evaporation process of a silica gel by inert liquid paraffin with heating, the processing period is shortened to within 8 h [101].

11.4. Spheres

With a similar method for synthesizing mesoporous powders, mesoporous silica spheres with different diameters (Fig. 12) can be formed under either basic or acidic media [97, 102, 116–120, 155–157]. The key factors are stirring rate, silica source, and basic source. Marble-like mesoporous silica hard spheres ~1 mm in diameter can be prepared by using CTAB as a template [116]. It is essential for successful synthesis to use TBOS as a silica source. The stirring rate can be used to control the sizes of such spheres. These mesostructured silica spheres may be readily applied as catalysts when metal ions such as Cu^{2+} are doped into the frameworks. Under acidic conditions, Schacht et al. synthesized hollow spheres with 2D hexagonal and 3D hexagonal mesostructured shells, with the use of emulsion templating [117]. With ammonia as the base, uniform mesoporous silica spheres with a diameter size of 1–10 μm can be prepared with CTAB as a template [118, 155–157]. In the presence of dimethyl formamide (DMF) as a cosolvent and CTAB as the structure-directing agent, Luo et al. synthesized mesoporous spheres with a controllable nanometer scale (80–800 nm) [118]. A fast aerosol method has been developed by Brinker et al. to synthesize mesostructured spheres with hexagonal, cubic, and vesicle structures; the whole process can be completed within 6 s [102, 119]. Zhao et al. have synthesized hollow spheres with ultralarge mesopore (50 nm) wall structures by reverse emulsion templating [120]. Millimeter-size SBA-16 spheres have been synthesized in the same group with the use of block copolymers as the templates in the presence of inorganic salts such as NaCl. The salts can improve the structural regularity of mesoporous spheres [158].

11.5. Mesoporous Crystals and Polyhedrons

Mesoporous materials possess no short-range order on the atomic scale but obvious order on the mesoscopic scale. Unlike microporous materials that usually show well-defined crystal morphology in accord with their atomic order, it is unusual to synthesize mesoporous materials with crystal shapes [159]. A general method for growing crystal-like mesoporous materials has not been reported yet. The static condition is one of the keys to yields of crystal-like materials [151]. Kim and Ryoo first reported the synthesis of MCM-48 crystals (*Ia3d*) with a truncated rhombic dodecahedral shape [160]. Guan and Sayari et al. have reported the synthesis of hybrid cubic mesoporous crystals (*Pm3n*) with a well-defined decaoctahedron shape [161]. SBA-1 (*Pm3n*) has also been synthesized with crystal morphologies with a large number of facets [114]. In the above cases, ionic surfactants have been utilized to synthesize mesoporous crystals. An exception has been reported by Zhao and co-workers; cubic mesoporous silica single crystals (Fig. 12) have been synthesized with the use of a commercial non-ionic block copolymer as a template under acidic conditions [68]. This is achieved by using inorganic salts to increase the interaction between silicate species and non-ionic block copolymers. These single crystals possess exclusively uniform rhombdodecahedron shapes (~1 μm) with ~100% crystal yield and uniform large pores (up to 7.4 nm). The mesopore array in each crystal face is resolved by TEM, further confirming that these crystals are perfect single crystals with a body-centered cubic space group (*Im3m*) [68].

11.6. Other Morphologies

By careful choice of the pH of the reacting systems, MCM-41 materials have been synthesized with a tubules within tubules (TWT) morphology [162, 163]. With neutral double-head amines, $C_nH_{2n+1}NH(CH_2)_2NH_2$, as the templates, mesostructured silica vesicles can be obtained that are hydrothermally ultrastable (the structure is retained in 100 °C water for 150 h) [164].

12. MECHANICAL PROPERTIES AND APPLICATIONS

12.1. Mechanical Properties

Mechanical stability is an important property of nanoporous materials, which normally act as adsorbents or catalysts for most practical applications. Before the processes of adsorption and catalysis reaction, the fine powders obtained are routinely compacted at high pressure into pellets. High mechanical stability is a critical requirement for conserving the pore volume, surface area, and pore diameter of the original material. Studies of the mechanical properties of mesoporous materials have been carried out by several groups, especially on some important materials such as MCM-41, MCM-48, and SBA-15 [165–171]. The experiments were performed by treating the mesoporous samples with different external pressures and then characterizing their structure by XRD or NMR and adsorption properties by N_2, subcritical organic agents (benzene, *n*-heptane, or cyclohexane), or mercury porosity [165–171]. Broad X-ray diffraction peaks and weak adsorption capacities are always observed for the mesoporous materials after they have been compressed [165–171]. For MCM-41, the

BET surface area and pore volume decreased considerably with increasing pressure to 86 MPa, and the material was essentially destroyed at 224 MPa [165]. MCM-48 possessed better mechanical stability than MCM-41, possibly because of the 3D structure. Its adsorption capacity was affected by mechanical compression between 20 and 400 MPa before the material was finally destroyed at a high pressure (480–600 MPa) [167]. However, other research results have suggested that there are no remarkable changes in the mechanical stability of mesoporous materials such as MCM-41, MCM-48, HMS, FSM-16, KIT-1, and SBA-15 at relatively low pressures; all materials collapsed at a maximum pelletizing pressure of 450 MPa [169].

12.2. Catalysis

Zeolites have led to a brand new concept of "size- and shape-selective catalysis" in the petroleum industry; however, the pore size of zeolites is too small to process large molecules such as heavy oil. Mesoporous materials with a large pore size may favor the diffusion rate for large molecules and decrease the second cracking; therefore, the catalytic properties of mesoporous aluminosilcates in cracking and the hydrogenation process have been studied extensively.

In addition to the application of petroleum cracking, mesoporous materials showed excellent catalytic activity in many typical reactions, such as oxidation, acid catalysis, and hydroxylation. Bekkum et al. used nanoporous materials (HMCM-41) as catalysts in acid catalytic reactions such as acylation of 1-naphthol [172, 173]. It was found that HMCM-41 shows a much higher catalytic activity and selectivity (up to 99%) compared with HY zeolites. Sodium ion- or cesium ion-exchanged MCM-41 showed a high selectivity and catalytic activity for Knoevenagel and aldol condensation reactions, and cesium-doped MCM-41 was a good basic catalyst and displayed high activity in the Michael addition [174]. Since mesoporous aluminosilicates show mild surface acidity, improvement of the surface acidity of mesoporous materials by loading is necessary for the application of acidic catalytic reactions. Kozhevnikov et al. loaded heteropolyoxometallate acid, $H_3PW_{12}O_{40}$ (PW), into MCM-41 materials to obtain a PW/MCM-41 catalyst that exhibited shape selectivity and higher reaction activity than H_2SO_4 or bulk PW [175]. Corma and co-workers prepared NiMo/MCM-41 catalysts [12 wt% MoO_3, 3 wt% NiO] and found that such materials showed much higher activities for the hydrocracking of vacuum gas oil compared with amorphous silica-alumina and USY zeolites [176]. The large pore size and high surface area of mesoporous MCM-41 materials are important in the above-mentioned catalytic reactions.

Nanoporous materials can also be used as supports in the famous Ziegler-Natta polymerization. Woo and O'Hare showed that the polymers obtained have a high density and a large particle size [177, 178]. In 1999, Kageyama et al. synthesized 2D hexagonal mesoporous fibers and used them as a catalyst for the polymerization of ethylene [179]. The products are polyethylene nanofibers with diameters between 30 and 50 nm and an average molecular weight over 6,000,000, which is ten times larger than that of conventional polyethylene. It is believed that this polymerization was carried out in 1D mesoporous channels, and the morphology of the polyethylene is very dependent on the shape of the channels of supporting mesoporous materials. This achievement has led to the new idea that researchers might develop a new catalytic process for nanoporous materials.

12.3. Optics

Nanoporous materials have long, straight nanochannels and may be used as waveguides in optics. Marlow et al. have coated mesoporous fibers with laser dye molecules and found that the fibers obtained can emit light parallel to their longitudinal axis with amplified intensity [180]. The results imply that the fibers have resonant structure and can be used as laser materials such as optical waveguides. Yang et al. have prepared patterned mesoporous oxide materials with a low refractive index by combining micromolding, polystyrene sphere templating, and cooperative assembly of inorganic sol–gel species with amphiphilic triblock copolymers [181]. The resulting materials show hierarchical ordering over several discrete and tunable length scales ranging from 10 nm to several micrometers, which may be useful for constructing an optic loop. Wirnsberger et al. also coated optical fibers with mesostructured silicate film containing laser dye molecules. Emission with a low valve value and signal amplification has been observed when the functionalized fibers were activated by laser [182]. It is expected that the new composite can be used as a sensor to detect the gas molecules that are absorbed in the mesopore channels. Dag et al. have prepared silicon nanoclusters with a size of about 1 nm on mesoporous films by low-temperature CVD [183], which possessed luminescent life at about the microsecond level, much less than that of general porous silicon. Researchers hoped that this material could be used in silicon-based diodes. More recently, Karen et al. synthesized Eu^{3+}-doped mesoporous TiO_2 films with cubic structures and found that the films were intensively luminescent [184].

12.4. Nanoreactors

A challenge in material science is to control the size and shape of compounds at the nanometer scale. It is certain that mesoporous materials with ordered pore structures and defined pore connectivity can be utilized as ideal nanoreactors to confine the growth of nanomaterials. Yang and co-workers prepared uniform Ag nanorods with 5–6-nm diameters by the pyrolysis of $AgNO_3$ in the 1D ordered mesopore channels of SBA-15 [185]. In work similar to this, Stucky and Ryoo have used mesoporous silica SBA-15 and MCM-41 as hard templates to prepare metal Pt, Ag, and Au nanorods [186–188]. Mesoporous silica FSM-16 [189] and HMS [190] can also be used as hard templates to prepare metal Ag, Rh, and alloy Pt-Rh nanorods. Moreover, with this hard template approach, binary sulfides such as CdS and PbS have been used to fill in the nanoreactors of mesoporous materials, which resulted in the formation of uniform CdS and PbS nanoparticles and nanorods [191, 192].

12.5. Other Applications

Researchers found that mesoporous silica materials functionalized with MPTS can selectively absorb heavy metal ions such as Hg^{2+}. Instead the absorption amount of Cd^{2+}, Pb^{2+}, and Zn^{2+} ions etc. is quite low [193, 194]. The results suggest that these functionalized mesoporous materials are expected to be used in the treatment of wastewater in the nuclear industry. Dai et al. have grafted multiorganic functional groups to mesoporous SiO_2 materials and found that the resulting materials can be used as an adsorbent to selectively separate some heavy metal ions [195]. Such mesoporous materials are also attractive candidates for hosting large molecules, including proteins. When the pore size was varied and the surface silanol groups were derivatized, proteins of different sizes with mesoporous silicate materials were specifically selected [196]. The sequestration of anionic proteins (conalbumin, M_W 77,000; chicken egg ovalbumin, M_W 44,000; and soybean trypsin inhibitor protein, M_W 14,000) from aqueous solutions by 3-aminopropanetri(ethoxy)silane (APTS) functionalized SBA-15 and MCF, as well as the release of the sequestered proteins with an increase in the ionic strength, has been reported [196]. In such a procedure, both size exclusion and ion-exchange chromatography techniques are employed, suggesting the potential application of the nanoporous materials as chromatography in a protein separation. With the modification of SBA-15 with dimethyloctadecylchlorosilane, the nanoporous material has been successfully used as a high-performance liquid chromatography substrate to separate biomolecules, including peptides and proteins (lysozyme, bovine serumin, myoglobin, and ovalbumin).

13. MACROPOROUS MATERIALS

Ordered macroporous materials with a pore size in the range of the wavelength of light have unique optical properties and are the best photonic crystals [197, 198]. Unfortunately, a lot of problems are crearted by using colloidal microspheres as the templates to prepare this kind of photonic crystal. The sizes of the macroporous materials are still not large enough to serve as a photonic crystal. Normally, three methods can be used to synthesize ordered macroporous materials:

(1) The sol–gel templating method. With the use of uniform-sized polystyrene spheres (PS spheres) as the templates, and the impregnation of inorganic sol into the voids between the close-packed PS spheres, after a sol–gel process and calcinations for removing templates, ordered macroporous materials with a 3D spherical pore (large cage) structure can be obtained (Fig. 13). The pore size can be tuned at the range of 50–500 nm by varying the diameter of the PS spheres. With this method, macroporous SiO_2 [199], TiO_2 [200], ZrO_2, and Al_2O_3 [201] materials have been synthesized. These macroporous materials have uniform pore diameters and normally a face-centered cubic (fcc) or hexagonal close packing (hcp) pore structure. The surface of emulsified PS microspheres (diameter in the range of 50–500 nm) can be modified to negative charges (sulfates) or positive charges (amines) [202]. In this way, the inorganic sols will easily to fill up the voids of charged and closely packed microspheres. The key point of the technology is to pack the ordered arrays of the colloidal microspheres. Closely packed PS spheres can be achieved by evacuation, sedimentation, capillary extrusion, and flat pattern. As well, SiO_2 colloidal spheres can also be used as the templates for synthesizing ordered macroporous materials. Compared with PS spheres, SiO_2 colloidal spheres have better thermal stability, and, combined with the chemical vapor deposition (CVD) technique, they can be used to prepare macroporous materials with a high melting point, such as C [203], Si [204], SiC [205], and so on. In addition, silica spheres can also be used in the synthesis of macroporous materials with organic macromolecular networks. With the combination of electrodeposition, metal, metal alloy, semiconductor sulfides, and selenite macroporous materials have been successfully synthesized (Fig. 13) [206]. In addition, the zeolite nanoparticles can also be used as the precursors for synthesizing macroporous materials with zeolite crystal frameworks. Meso-macro hierarchical ordered porous materials can be prepared as well.

(2) Solid template method. Macroporous silica materials can be orientationally mineralized on bacteria thread [207]. With this method, porous meso-macro materials can also be obtained. The macropores are paralleled long channels, pore diameters are in the range of micrometers, and the wall thickness is 50–200 nm.

(3) Using surfactant-oil emulsion as the template. In the sol–gel process, with the emulsion formed by a surfactant with oil or water as a template, an ordered macroporous material can be synthesized by deposition of inorganic oxides on the external surface of the emulsion droplets. The pore diameter is in the range of 50 nm to several micrometers. The emulsion drops produced by oil and formamine have uniform sizes, which are suitable for use as the templates and can be stabilized by PEO-PPO-PEO block copolymer surfactants. Ordered macroporous SiO_2, TiO_2,

CMK-3	SBA-15	*p6mm*	4.5	[76]
CMK-4	MCM-48	*Ia3d*	3	[82]
CMK-5	SBA-15	Hexagonal	2 and 4[a]	[77]

[a]The material has two sets of pores.

and ZrO_2 materials have been successfully synthesized by this method [208]. With the use of the liquid drops of some inorganic salts like NaCl, KCl, and NH_4Cl, meso-macroporous silica membranes can be prepared [67]. Their macro-pores are not uniformly distributed and can be tunable in the range of 500 nm to 5 μm, but these meso-macroporous silica membranes show great potential applications in catalysis and separation [67].

14. CONCLUSIONS

The surfactant templating approach can be used to prepare highly ordered nanoporous materials with variable compositions. Nanoporous materials have long-range periodic pore 2D or/and 3D structures at the nanoscale, narrow pore size distribution, and extra large surface areas. Despite the great advances that have been achieved in nanoporous materials, some challenges remain to be further explored. From the point view of synthesis and future applications, it is very important to synthesize ordered nanoporous materials with crystalline frameworks, especially if the pore system is more than 1D and the structure exhibits thermal and hydrothermal stability. For energetic considerations [213], the thermodynamic barriers in the assembly process contribute little to the difference in frameworks between traditional crystalline zeolites and amorphous mesoporous materials, hence the dynamic behavior of formation of mesoporous materials and the limitation of the surfactant assembly pathway. For example, the hydrothermal temperature in the synthesis of mesoporous materials is normally lower than that in the synthesis of microporous materials; the surface charge density of structure-directing agents in the former case is usually much lower than in the latter case.

Another challenge facing the nanoporous materials community is to step from laboratory studies to industrial applications. This is even more important for the continuing study of mesoporous materials. It has been ten years since the report of mesoporous materials by Mobil scientists, and the application potential of such materials has been widely studied in catalysis, separation, and optics, and for nanoreactors, low dielectric constant materials, and sensors. Forthcoming commercialized mesoporous materials and related applications (1, see http://www.schumacher.com/products/DESCRIP/CHEM/Meso.htm for details; 2, see [214]) will stimulate more research interest in this area, and much more exciting developments in nanoporous materials will be delivered.

GLOSSARY

Hydrothermal synthesis Synthesis processes under a certain pressure (1–100 MPa) and a certain temperature (100–1000 °C), utilizing the chemical reaction in the liquid.

M41S A family of ordered mesoporous aluminosilicates discovered by Mobil researchers in 1992.

Macroporous material Porous materials with a pore diameter larger than 50 nm.

Mesoporous material Porous materials with a pore diameter in the range of 2–50 nm.

Microporous material Porous materials with a pore diameter smaller than 2 nm.

Nanoporous material Porous materials with a pore diameter at the nanometric scale.

Self-assembly A coordinated action of independent entities under distributed (i.e., noncentral) control to produce a larger structure or to achieve a desired group effect. It is a method of constructing devices and machines whose dimensions are measured in nanometers (units of 10^{-9} m or millionths of a millimeter). The technique works by simulating the way in which biological systems build molecules, viruses, cells, plants, and animals.

Sol–gel process A versatile solution process for making ceramic and glass materials involving the transition of a system from a liquid "sol" (mostly colloidal) into a solid "gel" phase by hydrolysis and polymerization of molecules or ions.

Structure-directing agent Structure-directing additives, often organics or polymers, in addition to the constituent-building units, which may be inorganic compounds. This template can serve to fill space, balance charge, and direct the formation of a specific framework. In this early context, "templating" and "structure-directing" were synonymous.

Surfactant Also known as a surface-active agent, a soluble compound that reduces the surface tension of liquids or reduces interfacial tension between two liquids or a liquid and a solid.

CONTENTS

1. INTRODUCTION

One of the most widely used classes of inorganic powders is ceramic powders. Some conventional applications such as pigments, catalysts, abrasives, polishing agents, and lubricants contain ceramic powders. An additional area of application includes provision of precious materials for electrical and electronic devices such as capacitors, piezoelectric transducers, and thermistors just to name a few [1]. Furthermore, ceramic powders are also applied as mechanical, structural material for engine components, cutting tools, and catalytic converters. Additionally, coatings to enhance corrosion resistance, thermal barrier, and electrical insulation are well-known areas for the use of ceramic powders.

Beside ceramic powders, there is a need for organic powders in the life-science industry for medical and cosmetic applications. A further large-scale application is the area of pigments and paints for the automotive industry, for household utensils, and in the furniture industry [2]. New developments in this area concern the application of polymer powders in aqueous or solvent-containing dispersions for paint and coating purposes.

One of the most common processes for powder production is the precipitation of the powders in large stirred tanks. This process allows the cost-effective production of powders with a wide variation of chemical composition in huge quantities. In the future there will be an increasing need for nanoparticles with well-defined size, such as for the construction of electronic devices with unique properties

concerning optical band gap [3]. As these properties are ultimately determined by the physical size and shape of the crystallites, new processing routes for powders are required.

Supersaturation, the driving force for precipitation, is caused by feeding a second reactant, and crystallization frequently starts in an uncontrolled way at the feeding point of one of the reaction partners. In batches, these processes regularly happen because the reaction solution added makes contact with the full concentrated solution of the second reaction partner and reacts immediately [4]. Additionally, industrial crystallizers provide extremely unequal flow conditions, with local velocities, shear rates, and energy dissipation rates varying by orders of magnitude throughout the vessel [5]. Many extremely irregular small crystals are created resulting in the formation of particles with a very wide range of the particle size distribution [4]. Furthermore, the scale-up from a small laboratory vessel to a large production tank is often costly, time-consuming, and a loss of powder quality is observed. In several cases, this scale-up failed [6].

To overcome these drawbacks it is necessary to improve the mixing quality of the reactants to achieve a homogeneous distribution of the compounds in the reactor and to install a continuous process. Hence, the residence time of the particles in the reactor can be controlled and optimized for the application. Additionally, for an enhanced throughput, the number of the continuously working reactors can be increased, and the highly risky scale-up step can be avoided.

A recent concept for powder production is based on the combination of microreaction technology with a tubular reactor. Micromixers are well known for their highly efficient, fast, and homogenous mixing of gases [7] and liquids [8]. Two of the most common concepts are based on multilamination, for example realized in interdigital mixers, or split and recombined of fluid flows [8]. Multilamination is a simple and reliable concept, as it relies only on alternatingly arranged lamellae. Two fluids are divided in several substreams of thicknesses beyond 100 μm in such a way that regular and alternating lamellae of the two different fluids are obtained. For fast mixing, these lamellae can be focused geometrically in a special chamber by a factor of 50 or more so that mixing within a few milliseconds can be achieved [9].

In this context, it should be mentioned that the expression " microreactor" is not well defined, for example comprising microchips, complete table-top units, large reactors of shoe-box size, or smaller ones of match-box size. In this review article, " microreactor" is used as term for a chemical reactor of undefined size that contains components with microstructured channels or tubes in the microscale. In general, the width of such channels is in the micrometer range, mostly between 50 to 500 μm [8]. In the field of powder technology, the term " microreactor" is sometimes used in a completely different way, referring to supramolecular aggregates or so. "Micelles" [e.g., 10, 11] or "spherulites" [12] in microemulsions or miniemulsions [13] as well as salt particles in a modified aerosol decomposition process [14] were also named " microreactors." It is beyond the scope of this review to include the above-mentioned methods for the generation of nanoparticles.

In general, the use of microreactors has the advantage over conventional reactors of fast and homogenous mixing [8, 15] of the reactants as well as efficient heat transfer, which allows fast heating and cooling cycles [16] and isothermal reaction conditions [17]. Additionally, continuous operation of the reactors can be achieved. In recent years, different microcomponents were developed for operations mixing [8, 15] and heat exchange [18] as well as whole reaction systems for chemical synthesis for thermal [17], heterogeneous catalysis [19–21], photochemical [22, 23], and electrochemical [24–26] processing. Additionally, the small internal dimensions of the reaction channels (width below 200 μm) allow one to perform reactions in the explosion regime [27, 28], which conventionally are not possible. For example, the direct fluorination of toluene with elemental fluorine selective to monofluorotoluenes was demonstrated using a falling film microreactor [29]. Hence, microreactors are now well established in the fields of gas, gas/liquid, and liquid phase reactions. In this review, the novel approach using microreaction technology for the production of micro- and nanopowders is described.

2. CONVENTIONAL CONTINUOUS PROCESS

A continuous production process can be achieved conventionally, such as with a continuous working crystallizer or with a reactor based on the concept of a "tubular reactor" [4]. For example, a special type of crystallizers allows the continuous precipitation and reaction crystallization in agitated crystallizers. For hydroxides, especially nickel hydroxides, spherical particles with a medium diameter larger than 10 μm can be produced. SEM photographs and diagrams of particle size distributions are given in [4].

3. STATIC MIXER-TUBULAR REACTOR SETUP

As mentioned in the Introduction, a first step to overcoming the drawbacks of stirred tank reactors is the use of a continuous operating tubular reactor equipped with a static mixer [30]. The static mixer contains bow-tie shaped helical static mixing elements with clockwise and counterclockwise orientations with an internal width of 14.3 mm. $BaTiO_3$ powder with a mean particle size of 80 nm and a specific surface area of 25 m^2/g was synthesized using this static mixer-tubular reactor setup [31]. An X-ray powder diffraction pattern shows that these $BaTiO_3$ particles are single phased. A 3 mol/l NaOH solution as well as a solution containing $BaCl_2$ and $TiCl_4$ with a molar ratio of 1:1.1 were mixed and reacted at 85 °C with an overall flow rate of 360 ml/min, leading to a production of 25 kg $BaTiO_3$ powder per day.

4. MICROREACTOR FOR THERMAL DECOMPOSITION OF A PRECURSOR

A nanoparticle microreactor [32] is a small-scale system capable of converting an aerosol precursor to solid particles. A liquid precursor is evaporated and transported with a carrier gas to a tube-type reactor (diameter = 2 mm, length = 400 mm). In this tube, the precursor is decomposed by heat

and the resulting particles are collected at the outlet of the reactor on a transmission electron microscopy (TEM) grid.

Titanium dioxide particles were synthesized by thermal decomposition of titanium tetraisopropoxide in a nitrogen carrier gas. 1 μl of the precursor was evaporated and subsequently decomposed in the reactor. After a run time of one minute, very small primary titanium dioxide particles with a mean size of 9.0, 20.6, and 31.7 nm could be obtained at a reactor temperature of 500, 700, and 1000 °C, respectively. The small size of the primary particles was explained with a dominating surface reaction at the wall. Increasing the tube diameter to 4 mm leads to larger particles, and the particle size decreases with increasing temperature. The latter result is comparable with the TiO_2 synthesis in a larger tubular flow reactor (tube diameter = 22 mm) [33].

5. MICROMIXER-TUBULAR REACTOR SETUP

The synthesis of cadmium sulfide nanoparticles in a micromixer-tubular reactor setup was reported recently [34]. In this setup, an interdigital micromixer [35] is used where the fluid streams of the two reactants are divided in 16 substreams each. Aqueous solutions of cadmium nitrate and sodium sulfide were delivered to the microfluidic channels at various flow rates (10–300 μl/min). The outlet flow was connected to a quartz flow cell, and the absorption spectra were obtained continuously. All judgments concerning the powder characteristics result from these absorption spectra: Miniaturizing the reaction volume is sufficient to lower the polydispersity of the crystallites, and increasing the volumetric flow rate leads to a further reduction of polydispersity.

6. SEGMENTED FLOW TUBULAR REACTOR (SFTR)

An innovative approach for the production of homogenous fine powders is the continuous operation in a plug-flow reactor, the segmented flow tubular reactor (SFTR) (see Fig. 1) [36]. This apparatus is mainly built from the components mixer, segmenter, tubular section, and separator. The two reactant solutions are mixed in the mixer, forming a supersaturated solution of the powder compound. In the segmenter, the reactant mixture flow is segmented by a nonmiscible fluid so that small volumes of about 100 μl are formed and guided through the tubular section. In the tubular section, the powder is precipitated in the small batch reactors. When those reach the end of the tubular section, the powder suspension is separated from the nonmiscible fluid, which is then recycled. Due to the defined mixing in the mixer and the defined residence time of the reaction solution in the tubular section, powders with narrow particle distribution are obtained. Examples of powders produced within the SFTR are given in the following sections.

In a reactor, the mixing conditions of the two reactants severely influence the resulting quality of the precipitated powder, especially the crystal morphology, the mean particle size, and the particle size distribution [e.g., 37, 38].

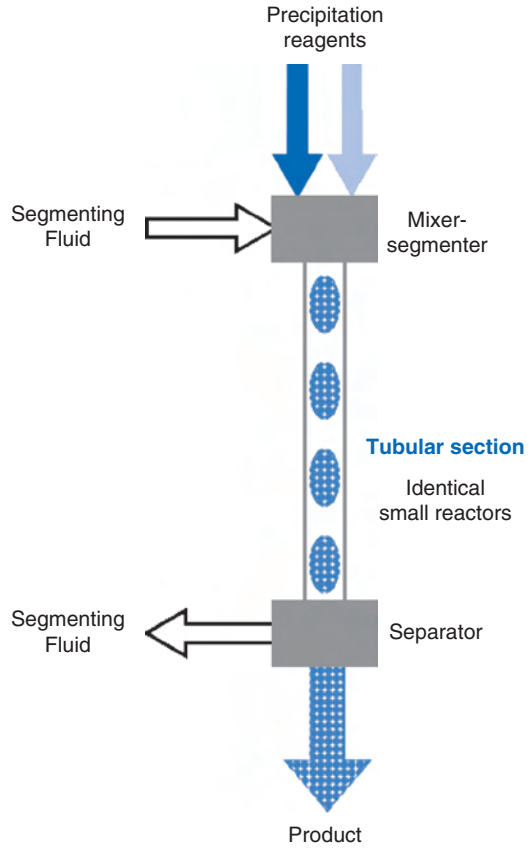

Figure 1. Scheme of the segmented flow tubular reactor (SFTR).

6.1. Hydrodynamics and Mixing Characterization of Micromixers

Microstructured mixers specially suited for the avoidance of fouling were evaluated as offering new means for chemical processes to benefit from micromixing physics. In the case of a residence time of the supersaturated solution in the mixer longer than the nucleation time of the powder, unwanted precipitation of the powder, so-called fouling, can occur in the mixer. For this purpose, new special-type micromixers, designed with regard to antifouling processing, were developed based on following concepts:

- Mixing in the segmenter outside the mixer ("chamber-free mixing") using an impinging-jet micromixer [39].
- Separation of the two reaction solutions by pure water ("delay-type mixing") [40, 41]. (Two different kinds of separation-layer mixers, "concentric" and "stacked," were developed, and their performance was investigated with the precipitation of calcium carbonate.)

Dependent on the flow rate, different types of flow patterns are found for the impinging jet mixers [39]. At low flow rates, the two fluids merge immediately after leaving the outlets, wet the mixer surface, and finally form droplets. At increasing flow rate, the frequency of the droplets increases and results in merging to a jet. The obtained "Y-type" stable jet at a standstill in the normal position is the preferred process regime (Fig. 2a). Increasing flow rate further yields

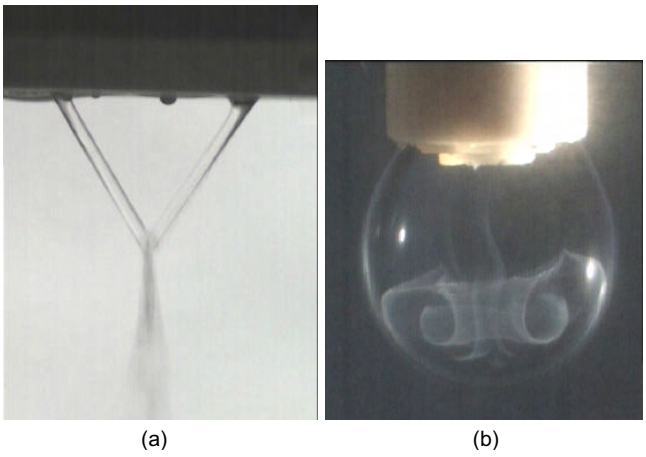

Figure 2. Hydrodynamics of (a) the impinging-jet and (b) concentric separation-layer micromixer.

a broadening of the jet, first termed "fan-shaped," thereafter "fanned-out" when broadening is intense. The stable "Y-type" process regime can be adapted to different flow rates by changing the width of the outlet hole. The mixing quality analyzed with competitive redox reactions, first applied by Villermaux et al. [42], increases with decreasing size of the outlet hole. The best results were obtained with the smallest openings of 350 μm.

Both droplet and jet operation are feasible with the concentric separation-layer micromixer. Two laminar flowing liquid shells surround a liquid core. This situation, however, is perturbed by a more intense mixing process when the three liquids enter the droplet end cap. Here, precipitation occurs (see Fig. 2b). By setting concentration and liquid flow rates, it is possible to avoid contact of the mixed flow with the mixer surface again. However, this generally seems to be more subtle as compared to impinging-jet operation. The mixing quality of the concentric separation-layer mixer is rather poor compared to the impinging-jet and stacked separation-layer micromixer.

In the case of the stacked separation-layer micromixer, the hydrodynamics in aqueous drops formed at the outlet of the rectangular mixing chamber were visualized by the formation of iron rhodanide. The photograph in Figure 3 shows the outlet of the mixer (top in picture) with a drop growing at the outlet and a second drop falling down. Contact of the two reactant solutions leads to the immediate formation of the red iron rhodanide immediately. Accordingly, the finding of a colorless solution inside the drop proves that no contact between the two aqueous reactant solutions (0.05 molar $Fe(NO_3)_3$ and 0.05 molar NaSCN) has taken place. The streamlines in the drop at the top in Figure 3 showed that the mixing has started. The homogeneous gray tone (in reality: red color) inside the second drop (Fig. 3) indicates that 0.4 s later the mixing is finished. By setting suitable flow rates (reactant solutions: 30 ml/h each; water: 200 ml/h), wall contact of the iron rhodanide can be avoided. The mixing quality of the stacked separation layer micromixer is good and increases with increasing water flow rate by a constant flow rate of the two reactants of 250 ml/h each. In the case of an overall flow rate of 1000 ml/h, the mixing quality is comparable with other micromixers such as the interdigital and caterpillar micromixer.

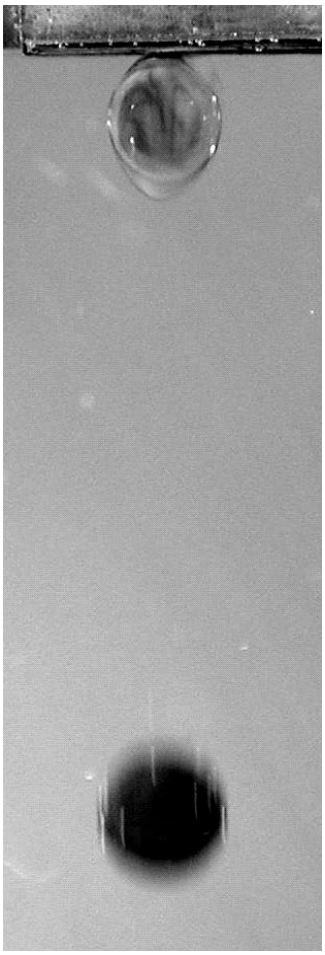

Figure 3. Photograph documenting the hydrodynamics in aqueous drops formed at the outlet of the stacked separation-layer mixer.

6.2. Numbering-Up Concept of the SFTR

For production purposes, the output of the reactor has to be increased. In highly nonlinear systems such as is given in precipitation reactors, scale-up is better ensured when all critical parts of the process are exactly the same at all scales [43]. Therefore, the concept of scaling by replication instead of the conventional scaling by dimensional changes was chosen to increase the productivity of the SFTR technique to avoid the drawbacks encountered with the scale-up procedure [44]. By this the productivity in terms of throughput is enhanced without changing the microfluidic flow properties at all. At present, a pilot plant with six parallel reactors is being built up. Each individual tubular reactor of the pilot plant SFTR is run with the some conditions as in the single-channel SFTR discussed above. The powder characteristics achieved with the continuous laboratory scale SFTR are expected to be maintained using the pilot plant SFTR. This pilot plant will be evaluated with the powder systems

calcium carbonate, barium titanate, and nickel manganese oxalate.

6.3. Nano- and Micropowders Produced within the SFTR

6.3.1. Calcium Oxalate: $Ca(C_2O_4)$

The precipitation of calcium oxalate serves as model system for mechanistic studies [45, 46] because of the different morphologies related to the three hydrates. Additionally, the understanding of the precipitation mechanism of calcium oxalate is important concerning the aim of prevention of the formation of renal calculi [47].

The mono-, di-, and trihydrate forms of calcium oxalate precipitate in the form of dendrites, bipyramids, and long platelets, respectively. These different morphologies are related to the three mineralogical phases [48], whereas in renal calculi the calcium oxalate monohydrate is the dominating morphology [49]. The proportion of calcium oxalate dihydrate (COD) increases with increasing supersaturation and decreases with the mixing time. It is proposed that a supersaturation limit for nucleation of the COD phase exists, and at low level of supersaturation, calcium oxalate monohydrate (COM) is formed [46].

In the case of precipitation in the SFTR equipped with a Vortex mixer, an additional type of aggregate could be achieved [47]. Key factor in the precipitation step is the mixing step influencing the morphology and the phase. The SFTR allows the observation of second-level aggregates, which are destroyed in a conventional batch reactor due to the shear forces induced by the impeller. The static flow conditions in the SFTR during the precipitation step result in an undisturbed formation of agglomerates [47].

6.3.2. Yttrium Barium Oxalate: $Y_2Ba_4(C_2O_4)_7$

Mixed yttrium barium oxalates are suitable precursors for the synthesis of the corresponding oxides through high-temperature pyrolysis. These mixed oxides are of interest in the area of high-temperature superconducting materials.

In a batch reactor under all investigated conditions, there is always a mixture of $Y_2Ba_4(C_2O_4)_7 \cdot 18_2O$ and $Y_2Ba_2(C_2O_4)_5 \cdot 8H_2O$ obtained [50]. The oxalate $Y_2Ba_4(C_2O_4)_7 \cdot 18H_2O$ is preferably formed at low temperature (30 °C) with fast addition of reactants, small volume of seed suspension, and a small mixing volume. At higher temperature (40 °C), slow reactant addition, high volume flow of the seed suspension, and a large mixing volume favors the formation of the mixed oxalate $Y_2Ba_2(C_2O_4)_5 \cdot 8H_2O$, which crystallizes in a pinacoidal shape. In contrast to the finding in the batch reactor, a selective synthesis of $Y_2Ba_4(C_2O_4)_7 \cdot 18H_2O$ could be performed using the SFTR. $Y_2Ba_4(C_2O_4)_7 \cdot 18H_2O$ forms octahedral crystals below 1 μm in size under the experimental conditions applied. The Ba/Y ratio is experimentally determined to 2.02, indicating that only this phase is precipitated. This result is in agreement with the X-ray diffractogram, which shows only the peaks that correspond to $Y_2Ba_4(C_2O_4)_7 \cdot 18H_2O$, and the peaks for the compound $Y_2Ba_2(C_2O_4)_5 \cdot 8H_2O$ are absent.

6.3.3. Zinc Sulfide: ZnS

Zinc acetylacetonate (0.05 mol/l) was mixed with thioacetamide (0.4 mol/l), which is thermally decomposed to form sulfide anions. In the tubular section, a reaction temperature of 80 °C and a residence time of 30 min was chosen. Comparable spherical nanoparticles were obtained performing the synthesis in a small-scale laboratory batch reactor and in the SFTR. The mean particle size was determined to be 120 nm with a span of 1.4 as well as the specific surface area (SFTR) of 90 m^2/g, and the powder obtained in a batch process was measured to a mean particle size of 90 nm with a span of 1.6 as well as specific surface area of 95 m^2/g. [51]. These investigations show that the ZnS nanopowders can be produced on a large scale by transferring the reaction from a small-scale laboratory batch reactor to a continuous process.

6.3.4. Yttrium Hydroxy Carbonate: $Y(OH)CO_3$

$Y(NO_3)_3$ (0.025 mol/l) and urea (0.75 mol/l) were mixed. In the tubular reactor the urea was thermally decomposed forming OH^- and CO_3^{2-} ions at a temperature of 95 °C. A residence time of 120 min and flow rate of 36 ml/h resulted in spherical particles of a mean size of 0.69 μm. The particles obtained from a small-scale batch process show nearly the same mean particle size of 0.67 μm [51]. In both cases a similar particle size distribution was obtained. The use of a mixer/tubular reactor setup without segmentation of the aqueous phase results in particles with a significantly larger varying particle size distribution.

6.3.5. Copper Oxalate: $Cu(C_2O_4)$

Copper oxalate was synthesized from $Cu(NO_3)_2$ and $Na_2(C_2O_4)$ aqueous solutions in a small-scale batch reactor as well as in the SFTR [36]. After the initial nucleation, two different growth processes, growth of crystallites and aggregation, were observed. The copper oxalate particles exhibit a rod- or cube-like shape. The single crystallites as well as the aggregates vary in size depending on the experimental conditions. At a high supersaturation level, the particle size distribution is narrower using the SFTR, while at a low supersaturation level the batch process delivers powder with a smaller particle size distribution. For production purposes, a high concentration of the reactants in water is preferable. Hence, running the system at a high supersaturation level is advantageous. In the case of copper oxalate synthesis, the type of the reactor has no influence on the powder morphology, in contrast to the addition of additives like hydroxymethylpropylcellulose, which induces a change of the powder morphology.

A further improvement of the favorable characteristics of the SFTR was expected when micromixers, instead of conventional Vortex or T-type mixers, are used. Hence, the SFTR was equipped with an interdigital micromixer. The resulting copper oxalate particles had a cushion-like shape and a mean particle size of 2.9 ± 1 μm [52].

6.3.6. Calcium Carbonate: $CaCO_3$

High-performance $CaCO_3$ powders are used for applications in paint, textile, plastic, adhesive, rubber, bioceramic, and paper industries [53]. Such industrial applications need

well-defined $CaCO_3$ powders with particles of defined crystallinity and morphology, uniform shape, and a narrow particle size distribution. These product properties are essential, and it is necessary to control such powder characteristics [54]. Furthermore, blocking free processing of $CaCO_3$ is a challenging task due to the low solubility of $CaCO_3$ in water. Hence, this reaction is an ideal candidate for fouling investigations [55].

Aqueous solutions of ammonium carbonate and calcium chloride were injected into the SFTR equipped with conventional "V"- or "T"-type mixers [53]. Alternatively, gaseous carbon dioxide or an aqueous solution of calcium hydroxide can be used as the calcium source. For comparison, in a small-scale laboratory batch reactor a mixture of micrometer-sized spherical and brick-shaped particles were obtained. These morphologies are related to vaterite and calcite crystals, respectively.

The formation of calcite or vaterite phases is strongly influenced by experimental conditions like temperature, pH value, the choice of reactants, reactant concentrations, use of additive, and the type of mixer. The competitive phase precipitation of calcium carbonate is very complex, and the synthesis of pure morphologies is only possible in a narrow process window.

Recently, it was reported [56] that the morphology of calcium carbonate can be selected by the use of seeds. In this case, the crystallographic structure of the seeds determines the structure of the powder: calcite seeds lead to calcite particles, whereas vaterite seeds result in the synthesis of a vaterite powder.

For these investigations calcium nitrate (20 mmol/l) and potassium carbonate (20 mmol/l) were used as reactants, and poly(acrylic acid) was added to stabilize the seeds in the reaction solution. Additionally, the SFTR was equipped with an impinging-jet micromixer. This new equipment and the more sophisticated reaction conditions allowed the synthesis of pure calcite powder of a rice-shaped morphology (see Fig. 4) with particles of a smaller order of magnitude (mean particle size = 0.4 μm) than described above and with a narrow particle size distribution (span = 1.06). The specific surface area was determined as being 35.2 m^2/g. In a 24 h continuous experiment, 25 L of a product suspension with 46 g $CaCO_3$ was produced. The calcium carbonate quality was constant concerning the parameters mean particle size, particle size distribution, specific surface area, and morphology. Furthermore, the synthesis of $CaCO_3$ in a small-scale laboratory batch reactor and in the SFTR results in the same powder properties. This allows the optimization of the reaction conditions in a small-scale batch reactor and, for production purposes, the transfer of these conditions to the continuous running SFTR.

Furthermore, computational fluid dynamics have been applied to investigate the mixing and segmentation conditions. Due to the short induction times (<50 ms), seeding has been applied to ensure a stable precipitation process in the SFTR. In the seeded precipitation of calcium carbonate, particles with a regular morphology and a smaller particle size compared to the unseeded case were obtained. Additionally, the predicted particle sizes show good agreement with the experimentally observed particle sizes [57].

6.3.7. Mixed Manganese Nickel Oxalate: $Mn_\alpha Ni_{1-\alpha}(C_2O_4)$

Ceramics made of mixed manganese nickel oxides have a negative temperature coefficient (NTC) and are used as NTC thermistors. The simple sintering of a mixture of the oxide powders is not sufficient to obtain a homogenous distribution of the metals in the ceramic. Hence, the electrical properties are unsuitable for industrial applications [58]. A suitable route to the nickel manganites is the thermal decomposition of the corresponding oxalates, which were synthesized by coprecipitation.

In an SFTR equipped with a "V"-type mixer, manganese and nickel nitrates as well as ammonium oxalate react to the nickel manganese mixed oxalates. Uniform and regular octahedral crystals with a monomodal particle size distribution were precipitated (see Fig. 5) [59]. The mean particle size was 12.5 μm with a span of 0.9. A continuous powder production with a rate of 3 g powder per hour over a period of more then 20 hours was achieved without change of the

Figure 4. SEM picture of a calcium carbonate powder with the SFTR.

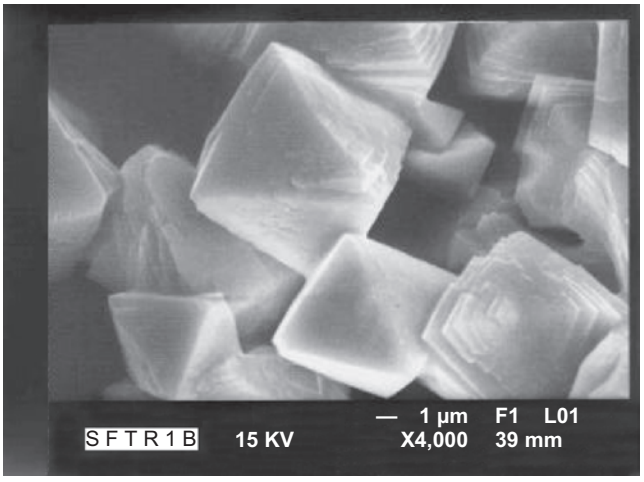

Figure 5. SEM picture of a mixed nickel manganese oxalate powder produced in the SFTR.

morphology of the particles, mean particle size, or size distribution. The corresponding synthesis in a small-scale laboratory batch reactor delivers particles with an irregular shape. The same mean particle size (11.9 μm) was observed, but the particle size distribution (span = 1.5) was significantly larger compared to the particles produced with the SFTR technique.

The above described SFTR process can also be used to produce a mixed nickel manganese cobalt oxalate of the composition $Mn_{0.5}Ni_{0.24}Co_{0.26}(C_2O_4)$. Homogenous and regular octahedral crystals with a mean particle size of 10.8 μm and a span of 0.84 were obtained. For comparison, the particles produced in a batch pilot reactor are irregularly shaped due to inhomogeneous crystal growth zones in the conventional batch reactor [58]. Consequently, the particle size distribution is enlarged (span = 1.31), whereas the mean particle size (10.4 μm) is comparable to the powder produced with the SFTR process.

6.3.8. Barium Titanate: $BaTiO_3$

Barium titanate is widely used in ceramic capacitors [60] as dielectric material in multilayer chip capacitors (MLC) due to the fact that the dielectric constant can be manipulated to increase capacitance. The higher dielectric constant ceramics usually have higher temperature and voltage sensitivity of capacitance. The future trend of MLC development goes in the direction of reduced layer thickness and increased number of layers; at present, layer thicknesses of 10 to 20 μm are common but will be decreased to approximately 2 μm. Recently, the area of application of ceramic capacitors is enlarged to switched mode power supplies (SMPS). Ceramic capacitors allow the design of smaller sized components for smaller package sizes in the SMPS itself [60]. An additional application for barium titanate is as a semiconductor material in PCTR (positive temperature coefficient of resistivity) devices [61, 62].

Barium titanate was synthesized in an SFTR equipped with a conventional "V" mixer or with a caterpillar micromixer. A solution containing $BaCl_2$ and $TiCl_4$ was mixed with a NaOH solution at room temperature. Subsequently, the precipitation of barium titanate occurs in the tubular section at a temperature of 80 °C to 95 °C. A residence time of about 20 min was achieved [63].

The mean particle size of barium titanate decreases with increasing concentration of the chloride solution. At the maximum reactant concentration, spherical particles of approximately 30 nm in size (SEM observation) were obtained [64]. This value is in good agreement with the surface area of 40 m^2/g and the crystallite size of 30 nm measured with X-ray diffraction. Figure 6 shows particles with a mean size of about 100 nm produced at a concentration of the reaction solution of 0.2 mol/l. At a chloride concentration of 0.062 mol/l, the mean particle size was determined as being 400 nm using a "V"-mixer and to 200 nm using a caterpillar micromixer, respectively.

For comparison, it should be mentioned that powders produced by hydrothermal methods can meet the requirements concerning the production of nanosized particles (30–60 nm), but this fine powder produced in a batch reactor suffers from an insufficient stoichiometric control and intensive agglomeration. The graph of the particle size distribution of fine commercial powders is given in [63]. Both commercial powders are composed of primary particles with a size of about 60 nm. The grade of agglomeration differs quite a bit so that 55% of the particles of one of the commercial powders is smaller than 100 nm, while only 25% of the other commercial powder particles are below a size of 100 nm.

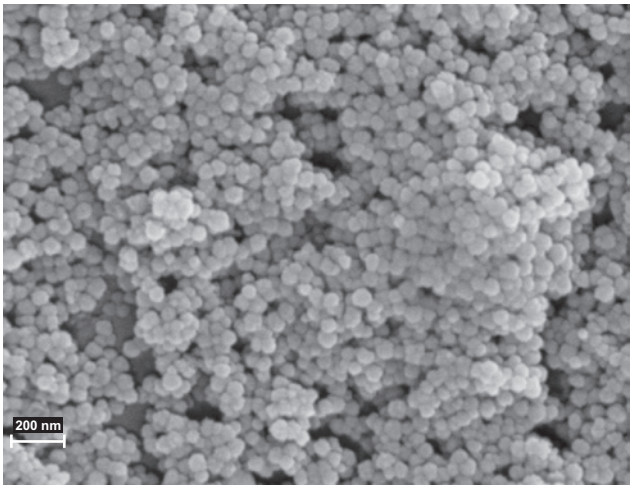

Figure 6. SEM picture of barium titanate powder produced with the SFTR.

The degree of agglomeration of $BaTiO_3$ powders was determined for the powder produced using the SFTR and was compared with powder produced according to the low temperature aqueous synthesis (LTAS) method in a 6-liter batch reactor [62]. Both reactors produce nanometer sized primary particles with a medium diameter of 23 nm for the SFTR and 30 nm for the LTAS system. Subsequent freeze drying and redispersion of these powders lead to agglomeration, but the SFTR powder is of superior quality compared to LTAS powder: 80% (57%) of the particles are smaller than 100 nm if produced with the SFTR (LTAS), respectively.

7. MICROJET REACTOR

The principle of this reactor is relatively simple: two reactant solutions were injected with high velocity (up to 1,000 m/s) into a reaction chamber through a small nozzle (between 100 and 1,000 μm), and colloids are formed in the surrounding gas [65, 66]. Fine spray is generated, which results in a fast and homogenous mixing in the fine droplets. The powder precipitates in these fine droplets immediately. Additionally, a gas stream is injected into the reaction chamber, which allows cooling of exothermic reactions. Furthermore, this gas stream removes the precipitated powder out of the reaction chamber completely.

One application of the MicroJet Reactor is the precipitation of organic pigments [67]. For example, the pigment tetrachloro copper phthalocyanine was precipitated in the MicroJet reactor. The mean particle size was determined as being 26 nm with a standard deviation of 11 nm and the specific surface area of 29.2 m^2/g. For comparison, the pigments

prepared in a conventional batch reactor are significantly larger (mean particle size of 34 nm with a standard deviation of 20 nm) and the specific surface area (12.6 m^2/g) is only 40% of the above mentioned value.

The pigments Yellow 12, Red 2, Red 146, and Yellow 191 based on an azo-group were synthesized and compared with pigments that were produced conventionally [68]. The first three pigments are used as offset printing colors, whereas Yellow 191 was investigated as a dye for poly(vinylchlorid) (PVC) foils. The printing colors synthesized using the MicroJet Reactor have a superior color strength, brightness, and transparency compared to conventionally synthesized pigments. In the case of Yellow 12, it has been reported [68] that the mean particle size is about 30% reduced compared to the commercially available pigment.

The pigment Yellow 191 was used as a dye to color a PVC foil. Using the pigment prepared with a MicroJet Reactor, the color strength was increased and the color distribution was more homogenous compared to the use of the conventionally produced pigment Yellow 191.

In an exploratory series of experiments, $CaCO_3$ powder was synthesized [69] using $Ca(NO_2)_3$ ($c = 40$ mmol) and K_2CO_3 ($c = 40$ mmol) aqueous reaction solutions. The concentration of the surfactant TWEEN 80 was varied from 0, to 0.05, to 0.5%. The SEM picture (Fig. 7) shows the powder produced without surfactant. The particle size was about 12 μm. The particle size decreases ($d = 6$ μm and 3 μm) with increasing concentration ($c = 0.05\%$ and 0.5%) of the surfactant. In the case of the high surfactant concentration, particles with an additional type of shape were formed. In all cases, the particles look homogeneous in size. Significantly smaller or significantly larger particles were not observed.

8. CPC REACTOR

Laboratory scale CPC microreactors are assembled of microstructured plates mounted together by metallic bonding [70]. Each plate has numerous parallel channels in the submillimeter range with a special function such as dividing reactants into substreams and guiding them into the reaction channels, collecting the substreams with the product and leading it out of the reactor, as well as guiding the heat exchanger liquid to maintain isothermal reaction conditions. In the reaction zone, the flow is laminar, and the residence time is in the range of some seconds at a flow rate between 20 and 80 ml/min.

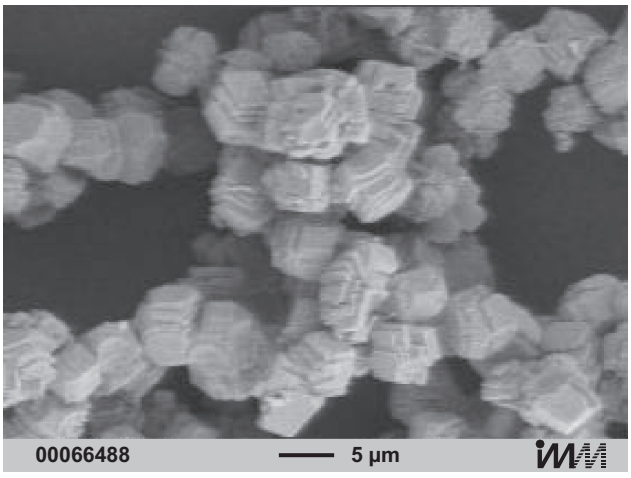

Figure 7. SEM picture of calcium carbonate produced with the MicroJet Reactor.

The pilot plant microreactor is based on a numbering-up concept. The reaction plate inside the microreactor was multiplied several times, and three of the reactors were integrated in one housing. Additionally, the dimensions of the reaction channels were slightly increased without changing the laminar flow regime or the mixing process. Also, in the pilot plant isothermal reaction conditions were maintained. With this pilot plant, a throughput of 500 ml/min reaction solution could be achieved.

Two different types of azo pigments were synthesized in a lab scale and pilot plant microreactor [71]. For pigment No. 2 the mean particle size (90 nm), is reduced drastically compared to the batch process (mean particle size: 600 nm), and a monomodal distribution (span of the particle size distribution = 1.5) is obtained instead of a bimodal distribution (span = 2) in the batch process. Beside these powder properties, the color properties could be dramatically improved as well. The color strength is increased by a factor of 1.49 using a microreactor compared to batch type synthesis. Additionally, the brightness and the transparency are enhanced by 6 steps on the glossier scale.

The estimated productivity of the synthesis of pigment No. 2 in the lab scale reactor is 1 t/a. To enhance this productivity to 10 t/a, a pilot plant, based on the numbering-up concept, was realized. This pilot plant runs several days successively with only cleaning steps of a few seconds every two or three hours having to be performed. The characterization of the pigments produced with the pilot plant shows the reproducibility of the powder characteristics found in the lab scale device.

9. SUMMARY

The production of powders using reactors equipped with microcomponents, named microreactors, is a rather new approach to obtain particles with defined morphology, small size, and, most important, narrow particle size distribution. Conventional stirred tank reactors suffer from mainly two disadvantages. First, the mixing of the reactants is ineffective and inhomogeneous, which results in a broad particle size distribution. Secondly, the scale-up procedure is rather risky because the powder quality is often different in a small-scale laboratory batch reactor compared to a large-scale production plant.

In contrast to the conventional reactors, all microreactors described here allow an intensive and, above all, homogenous mixing of the reactants. Furthermore, a continuous operation is achieved with a continuous flow of the reactant solution as well as a defined residence time of the precipitated powder can be performed. For production purposes, these operation conditions allow the numbering-up of the microreactor. This procedure avoids the risky scale-up step with all the drawbacks mentioned above.

Several examples of powders produced in different types of microreactors have been described. Ceramic powders such as barium titanate and calcium carbonate as well as

organic pigments are synthesized just to name a few. All together, these powders have a superior quality compared to batch-type synthesis. In most cases, small particles with a narrow particle size distribution as well as a defined morphology can be obtained. Additionally, organic pigments produced with a microreactor have superior color properties (such as brightness) compared to pigments produced in a conventional production process.

Despite the short time these microreactors have been used for powder synthesis, they are not only of scientific interest but also of industrial relevance. Pilot plants of different microreactors are currently being built and investigated. The first industrial production of powders with this new technology is expected to start in the near future [72]. These pilot plants will be able to produce several tons of powder per year in a reproducible high quality.

GLOSSARY

Impinging-jet micromixer Special type of micromixer where mixing is performed in a chamber outside the mixer ("chamber-free mixing").

Micromixer A special of microreactor for mixing purposes. In general, micromixers provide fast and homogeneous mixing.

Micropowder The mean particle size is in the range of 1 to 1000 μm. The powders dsecribed in this chapter have a size below 20 μm.

Microreactor Microreactor is used as a term for a chemical reactor of undefined size that contains components with microstructured channels or tubes in the microscale. In general, the width of such channels is in the micrometer range, mostly between 50 to 500 μm.

Nanopowder The mean particle size is in the range of 1 to 1000 nm.

Numbering-up For increasing the productivity of a production plant, numbering-up is a method of scaling by replication instead of the conventional scaling by dimensional changes, which is termed scale-up.

Pigment Solid particle of a dye.

Scanning electron microscopy (SEM) Technique for making enlarged pictures of objects with an electron beam. The resolution is enlarged compared to conventional light microscopy. Smaller objects can be seen.

Separation-layer micromixer Special type of micromixer were the two reaction solutions are separated by pure solvent ("delay-type mixing").

CONTENTS

1. INTRODUCTION

Nanoprecipitates and nanocavities can improve or degrade functional properties to a large extent. In particular nanocavities in low-k dielectrics affect the electronic properties of semiconductors that are employed in digital equipment [1]. In recent years a new era has emerged to control these defect clusters to provide novel functional properties. Examples are the metallic and semiconductor nanoclusters in optical materials, which enable one to tailor optical properties of the materials, with important applications, for example, in fiber optics. In silicon helium ion implantation induced nanocavities are used to getter metallic impurities in the design of devices, which does not allow one to use conventional gettering methods. This chapter aims at showing to what level this field of the design of nanocavities and nanoprecipitates has progressed. In all cases the precipitates are embedded in a matrix. This can be either a crystalline or an amorphous structure. The properties of the embedded precipitate or nanocluster depend for an important part on its surroundings, in particular on the interface between particle and the matrix. Furthermore, the shape and even the phase of the precipitate are determined by the surrounding medium. In the case of a crystalline matrix orientation relationships can exist, which cause crystalline alignment of the nanoclusters. This is in contrast to the other class of nanoparticles and assemblies of nanoparticles, which are grown in a liquid or gaseous medium and deposited as a layer on a substrate. In general, chemical growth modes give rather precise control over size. Implantation produced nanoparticles, which might be called a physical synthesis method, lack a narrow size distribution. However, certain tools are developed and will be developed in the future to narrow the size distribution or even create monodisperse particles. Also it has been suggested that a two-step process, where nanocavities are used as templates to nucleate and promote precipitate growth, offers new possibilities to create new types of precipitates. In principle, any atomic species can be implanted in any material. The starting point is displaced atoms, vacant lattice sites, and implanted atoms. Thermal annealing is used to remove the defects and promote clustering of the implanted atoms. Alloys and compound precipitates can be formed by multiple ion species implantation. A requirement is that all implanted species are poorly soluble in the matrix. Otherwise a homogeneous nucleation of the clusters will not occur.

Besides implantation methods, other methods exist, some of which have been known for more than 2000 years, to create metallic or other species in supersaturation in glassy materials. The methods consist of melting and quenching or reduction. Usually, these are bulk methods and graded layers cannot easily be produced. In this chapter we will restrict ourselves mainly to nanoprecipitates and nanocavities produced by ion implantation in crystalline media, notably single crystals of metal oxides and silicon. Production and optical properties of implanted metallic

and semiconducting particles in amorphous SiO_2 have been reviewed by Polman [2], and by Schultz and Lynn [3].

Besides well known techniques suitable to observe precipitates and nanocavities, like transmission electron microscopy, including all the analytical tools added to the electron microscope in the last decade, the less known positron annihilation techniques have been introduced to monitor precipitates and cavities. A positron is a positively charged particle that is repelled by nuclei. As a result it has a high preference for open volume. Because of the preference of positrons for open volume, that is to say, much more sensitive than electrons in electron microscopy, positron annihilation spectroscopy (PAS) has been developed over the last few decades into a successful nondestructive method for probing low atomic density regions (e.g., vacancies, clusters of vacancies, and nanocavities) in materials over a wide range of depths, from the surface to depths of hundreds of nm [3]. PAS can thus provide information that is complementary to the results provided by many other techniques for the examination of the chemical and structural properties of materials. Actually, a wealth of techniques is available for these latter purposes. Among them are Rutherford backscattering, nuclear reaction analysis, and secondary ion mass spectrometry, all of which are capable of depth profiling of impurity atoms [4]. Nevertheless, these techniques are not sensitive to the presence of open-volume defects. An indirect method for probing open volume is small angle neutron or X-ray scattering. Open volume is best probed by using probe particles that are trapped in the cavities. Suitable particles are gas atoms such as helium and hydrogen, or positrons. Other techniques using a probe atom are Mössbauer and perturbed angular correlation, but these are better suited for probing very small cavities (1–5 vacancies). The use of positrons as a probe has the advantage that the material is not damaged by the irradiation with the probe particles. A review on defect profiling by positrons and other techniques has been given by Dupasquier and Ottaviani [5]. Furthermore, PAS has been extensively applied to the study of thin films, layers of embedded nanoclusters, and interfaces [6]. In this chapter we confine ourselves to positron annihilation spectroscopy as a complementary technique to highresolution transmission electron microscopy.

In recent years, the development of radioisotope based monoenergetic slow positron (e^+) beams has led to the study of interesting surface and near surface phenomena in thin films and ion implanted materials [7]. By varying the initial energy of the implanted positrons one can study defects at different depths. The importance of depth-profiling studies becomes clear if one considers layered systems obtained by various deposition or implantation techniques. In these systems defects may appear at the interface of the layers because of low mobility of the deposited atoms. In some cases the layer becomes amorphous and will show many defects. The relatively low intensity of the radioisotope based slow beams was offset by the use of efficient solid-state detectors. The combination of depth profiling with the high-resolution two-dimensional angular correlation of annihilation radiation (2D-ACAR) method for the study of surfaces and layered systems, however, had to wait for the development of high-intensity slow positron beams. Nowadays, such beams are operational or under construction in several laboratories [8]. Depth profiling positron 2D-ACAR thin film studies have been performed for the first time at Brookhaven National Laboratory on the Si/SiO_2 system employing a strong ^{64}Cu source produced in a high-flux beam reactor [9]. The recent construction of a stable high-intensity reactor-based slow positron beam at the Delft 2 MW research reactor has proven to be successful [10, 11]. The beam called POSH ("POSitrons at the Hoger onderwijs reactor") has an intensity of $\sim 4 \times 10^8$ e^+/s. Numerous depth-profiling 2D-ACAR studies of various materials of great interest in materials science have been performed, (e.g., nanocavities in Si and MgO produced by ion implantation, metallic nanoprecipitates in MgO, SIMOX, low-k dielectric and silicon carbide thin films) [12–18].

The structure of this chapter is as follows. Section 2 presents a general introduction into positron physics, positron annihilation techniques, and intense positron sources. Further, some essential features of high-resolution electron microscopy are also presented. The new possibilities have been successfully applied to various types of materials, the results of which are collected in the subsequent Sections 3–7.

2. THEORETICAL BACKGROUND OF THE EXPERIMENTAL TECHNIQUES

2.1. Positron

The positron is the antiparticle of the electron. Hence, it has the same mass and the same spin (1/2), but opposite charge and magnetic moment. Dirac postulated the positron in 1930 as the "negative" energy extension of his theory of electron energy levels [19, 20]. Two years later Anderson [21] discovered the positron in his cloud chamber experiments. Positrons are unstable in matter where they annihilate with electrons predominantly via 2γ decay, both photons carrying energy of 511 keV. In rare circumstances (e.g., when a positron is in the vicinity of a heavy nucleus) the positron and the electron can undergo a 1γ decay process. The emission of more photons is also possible, but the probability of such an event is small (the ratio between the probabilities of 3γ and 2γ decay in metals is 1/371 [22]).

When a positron is injected into a material it interacts with its surroundings and rapidly loses its energy by ionizing collisions with atoms, collisions with conducting electrons, and phonon scattering, until it reaches thermal equilibrium. This process occurs within 10^{-11} s, which is short compared to the mean lifetime of the positron of the order of 10^{-9}–10^{-10} s [23]. This lifetime is so short that for realistic source strengths no more than one positron is present in the sample at any time. At room temperature the wavelength associated with a thermalized positron is usually one order of magnitude larger than the typical lattice parameter. Hence, in a solid the positron behaves like a delocalized Bloch wave, which in well-annealed crystals of metals and semiconductors exhibits maxima in the interstitial region due to core repulsion. In defective materials, however, the positron can be localized (trapped) in, or around, low-density regions such as vacancies, dislocations, and microvoids. As a consequence, the positron lifetime becomes longer and the

positron density is strongly enhanced at the position of a defect [24].

Positrons can be produced by the nuclear decay of isotopes or by pair production by high-energy gamma rays ($E_\gamma > 1.022$ MeV). Positrons emitted by a radioactive isotope (e.g., ^{22}Na, ^{58}Co, ^{64}Cu) have continuous energy distributions ranging from 0 to a few hundred keV. As a consequence, when positrons are implanted in a material, the implantation profile is broad, of the order of a few hundred micrometers. Because positrons are positively charged particles, they are repelled by the atomic cores, thus leading to the possibility of their ejection from a surface due to their negative work function ($\phi_+ < 0$). The positron work function for a solid is defined as the minimum energy required to remove a positron from a point inside the solid to one in the vacuum [3]. Owing to its interaction with the surrounding electrons, a positron can adopt an energy level that can be higher or lower than the energy level of the vacuum. As a consequence, the positron work function can be negative or positive in comparison to the electron work function, of which the latter is nearly always negative. The effect of positron ejection from a surface is used in the production of slow positron beams. Examples of surfaces that emit positrons are clean metal surfaces, for example, W(111), Ni(100), Cu(111), diamond, Si, SiC, GaN, or the surfaces of rare-gas solids.

2.1.1. Positronium

In some liquids and insulating solids, the positron can capture an electron prior to annihilation, forming positronium (Ps), a hydrogenlike positron–electron bound state with a binding energy in vacuum of ~6.8 eV. Predicted classically by Mohorovicic [25] in 1934 and quantum mechanically by Ruark [26] in 1945, the Ps atom was experimentally discovered in 1951 by Deutsch who found a long-lived component in a lifetime spectrum that was nearly independent of gas pressure [27].

The spectroscopic differences between Ps and hydrogen originate in the particle–antiparticle nature of Ps (equality of the positron and electron masses and of the magnitudes of their magnetic moments), which lead to the possibility of self-annihilation. The ground states of Ps consist of a singlet $^1S_0$ state ($S = 0; m_s = 0$) with the spins oriented antiparallel, called para-positronium (p-Ps), and a triplet $^3S_1$ state ($S = 1; m_s = 0, \pm 1$) with the spins oriented parallel, called ortho-positronium (o-Ps). Para-Ps has a lifetime in vacuum of ~125 ps and decays via two γ rays, while o-Ps has a lifetime in vacuum of ~142 ns decaying into three or more γ rays. In the absence of external electric and magnetic fields the relative amount of p-Ps:o-Ps formed is 1:3. In a low density gas the long-lifetime component approaches that characteristic of o-Ps, while at higher densities or in condensed matter the interaction of Ps with atomic electrons leads to a decrease in the 3γ decay mode associated with a shortening of the long lifetime. This decrease is due to the so-called "pick-off" process in which the positron of o-Ps annihilates during a collision with an atomic electron that has an antiparallel spin and thus annihilates via a 2γ process.

2.1.2. Magnetic Field Induced 2γ Annihilation

In the presence of an external magnetic field of flux density B the p-Ps state ($^1\Phi_0$) and the $m_s = 0$ substate of o-Ps ($^3\Phi_0$) are mixed in so-called ortho-like-Ps and para-like-Ps states [28–30],

$$\Phi_+ = \frac{1}{\sqrt{1+y^2}}{}^3\Phi_0 + \frac{y}{\sqrt{1+y^2}}{}^1\Phi_0 \tag{1}$$

$$\Phi_- = \frac{-y}{\sqrt{1+y^2}}{}^3\Phi_0 + \frac{1}{\sqrt{1+y^2}}{}^1\Phi_0 \tag{2}$$

with

$$y = \frac{x}{\sqrt{1+x^2}+1} \qquad \text{and} \qquad x = \frac{4\mu_B B}{\Delta E} \tag{3}$$

Here, μ_B is the Bohr magnetron and $\Delta E = 8.4 \times 10^{-4}$ eV is the hyperfine splitting between the p-Ps state and the o-Ps states. The annihilating rates of the new states are

$$\Gamma_+ = \frac{1}{1+y^2}\Gamma_3 + \frac{y^2}{1+y^2}\Gamma_1 \tag{4}$$

for ortho-like-Ps and

$$\Gamma_- = \frac{y^2}{1+y^2}\Gamma_3 + \frac{1}{1+y^2}\Gamma_1 \tag{5}$$

for para-like-Ps, where $\Gamma_3 = (142\ \text{ns})^{-1}$ and $\Gamma_1 = (125\ \text{ps})^{-1}$ are the annihilation rates of o-Ps and p-Ps, respectively. Both these new states can undergo 2γ and 3γ annihilations. Since Γ_1 is three orders of magnitude larger than Γ_3, even a weak magnetic field for which $y \ll 1$ causes a large fraction of ortho-like-Ps atoms to self-annihilate into 2γ. The annihilation characteristic of para-like-Ps for small y, however, is not so much affected by the magnetic field. This effect is called magnetic field induced o-Ps $\rightarrow$ p-Ps conversion or magnetic quenching of o-Ps.

Positronium annihilates subsequently with a characteristic signature and can be detected by studying the annihilation γ's in different manners: (i) by measuring the 3γ to 2γ yield ratio with a multiple-coincidence γ detector system, (ii) by measuring the positron lifetime, (iii) by measuring the energy spectrum of one of the annihilation photons, (iv) by measuring the momentum distribution of the electron–positron pairs, and (v) by studying the decrease in the 3γ yield due to the Zeeman mixing of Ps states when a magnetic field is applied [31–33]. In this chapter the attention will be focused on (iv).

Positronium is usually formed in regions with a low electron density such as gases or liquids. In gases Ps formation takes place by radiationless electron capture as long as the kinetic energy (T) of the positron is in the energy region $E_i - 6.8 \le T \le E_i$ [eV], called the Ore gap, where E_i is the ionization energy of the gas atom or molecule [22]. Ps can also be formed in some insulating materials and organic materials with large open volumes where an electron is captured in the ionization trail ("spur") created by the slowing down of the positron [34]. In these materials p-Ps still has a lifetime of 125 ps, but the lifetime of o-Ps is reduced to

a few nanoseconds owing to pick-off processes. Since the Pauli exclusion principle is not operative for a Ps atom (Ps is a boson), the Ps atom becomes quickly thermalized and thus resides near the bottom of its own band as a virtually momentum-free system. As a consequence, self-annihilation of Ps contributes a sharp peak in a 2D-ACAR spectrum. In metals and semiconductors, thermalized positrons annihilate from delocalized Bloch states without forming Ps.

With respect to the spatial extension of the Ps wave function (Ψ_{Ps}), two different types of Ps can be distinguished:

(i) *Localized Ps*, when $\Psi_{Ps}(\mathbf{r})$ extends over a region containing no, or only a few, atoms of the medium. Figure 1a shows the experimental 2D-ACAR momentum distribution of localized *p*-Ps atoms formed in radiation produced microvoids in vanadium.

(ii) *Delocalized Ps*, when $\Psi_{Ps}(\mathbf{r})$ extends over a region containing a large number of elementary cells of a crystalline solid. Figure 1b shows the experimental 2D-ACAR momentum distribution of delocalized *p*-Ps formed in an oriented crystal of SiO_2.

In some circumstances (e.g., when Ps is trapped in a large void) the positronium atom formed cannot lose its energy by collisions with atoms and molecules, thus remaining nonthermalized or "hot" Ps [12]. Also, when positrons are implanted at shallow depths in metals or semiconductors, emission of energetic Ps atom from the surface may occur [35, 36].

2.2. Positron Annihilation Spectroscopies

The positron annihilation process possesses a number of signatures that contain information concerning the system under investigation. Various experimental methods have been developed during the past decades to measure these signatures. In this section we shall discuss how and which information can be extracted from the experimental data.

There are three major positron techniques that use the annihilation photons in order to gain information about the electrons: (a) two-dimensional angular correlation of annihilation radiation, (b) Doppler broadening of annihilation radiation experiments, and (c) positron lifetime experiments. The first two techniques give information on the momentum distribution of electrons while the third one gives information on the electron density. Other techniques use different properties of the positron to probe material properties, (e.g., low-energy positron diffraction, positron channeling, positron annihilation induced Auger electron spectroscopy, but they are not the subject of this chapter [3, 37].

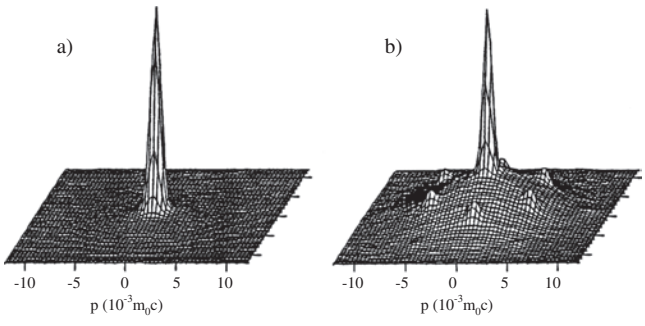

Figure 1. (a) Positronium localized in radiation produced microvoids in vanadium. (b) Delocalized positronium in an oriented crystal of SiO_2. Reprinted with permission from [5], A. Dupasquier and G. Uttaviani, in "Position Spectroscopy of Solids" (A. Dupasquier and A. P. Mills, Jr., Eds.), pp. 581–657. IOS, Amsterdam, 1995. © 1995, IOS.

A thermalized positron and an electron annihilate under emission of mostly two γ quanta. In the center-of-mass system of the annihilating particles the γ quanta are emitted in exactly opposite directions and the available energy of $2m_0c^2 - E_B$ (where $E_B = E_B^- + E_B^+$ denotes the binding energy of the two particles in the solid) is divided equally over the two quanta. In the laboratory coordinate system the momentum $\boldsymbol{p}$ of the two particles (largely determined by the electron, the positron being thermal) manifests itself in two different ways. First, the momentum component $p_{||}$ along the direction of γ-ray emission results in an energy shift $\Delta E = \pm 1/2\ p_{||}c$ of the energy of the γ quantum from its average value $m_0c^2 - 1/2E_B$. Since one half of the electrons moves toward the detector while the other half moves away from it, this shift results in a Doppler broadening by several keVs of the 511 keV line which can be measured with a solid-state detector [38]. Since the distance between the detector and the sample is usually very small the Doppler broadening experiment integrates over virtually all values of the transverse component of the momentum.

This transverse component can be measured (in one or two dimensions) in 1D- or 2D-ACAR experiment [39, 40]. In the laboratory system of reference, the directions of γ-ray emission differ from 180° by a small angle $\theta \sim p_\perp/m_0c$, typically of the order of 10 mrad and proportional to the component $p_\perp$ of the momentum perpendicular to the direction of γ-ray emission. In view of the smallness of θ the latter type of experiment requires large sample–detector separations in order to realize a good momentum resolution, and thus a strong radioisotope source or an intense positron beam is needed.

A third signature of the annihilation process is the positron lifetime, which is the inverse of the rate at which positrons annihilate. The lifetime depends on the density of electrons at the position of the positron. It can be measured in a delayed coincidence experiment in which the time interval is measured between the emission of a positron by the positron source and the entrance of a positron into the sample, and its subsequent annihilation. Finally, positrons diffusing back to the surface or trapped at the surface of the sample may be reemitted after having formed positronium, the hydrogenlike bound state of a positron and an electron. This so-called Ps fraction is usually not measured directly but derived in an indirect way from other measurements. In the following we shall examine the various signatures of the annihilation process more closely.

2.2.1. Two-Dimensional ACAR

The measurement of the angular correlation of the annihilation radiation is one of the means for studying positron annihilation in solids. This technique measures the angular deviation from collinearity of the two coincident annihilation photons. In the center-of-mass frame the total momentum

of the e^+–e^- pair is zero and since the energy and momentum before and after annihilation are conserved the two photons are emitted in opposite directions, each one having an energy equal to m_0c^2 (see Fig. 2a). In the laboratory frame, however, the e^+–e^- pair carries a total momentum **p**. Since the positron is thermal and annihilates mainly with weakly bound electrons, the momentum **p** is relatively small ($\sim 10^{-2}\ m_0c$) and, as a consequence, it will slightly change the picture found in the center-of-mass frame. Hence, the components of the momentum perpendicular to the photon emission axis, p_x and p_y, will generate small angular deviations from collinearity (see Fig. 2b) that can be written as follows

$$\theta \sim \sin\theta = \frac{p_x}{m_0c} \tag{6}$$

$$\phi \sim \sin\phi = \frac{p_y}{m_0c} \tag{7}$$

Figure 3 shows a schematic diagram of a typical 2D-ACAR setup. It consists of two large-area position sensitive gamma detectors, a central source–sample vacuum chamber, and data acquisition electronics. In the central chamber a positron beam is guided by an axial magnetic field to the sample of interest. The annihilation quanta are detected in the two detectors and the information concerning their individual points of arrival is converted by the acquisition electronics into (θ, ϕ) addresses, which are stored in an incrementally updated 2D discrete array. In this way one obtains the two-dimensional projection of the three-dimensional momentum density $\rho^{2\gamma}(\mathbf{p})$ [41],

$$N(\theta,\phi) = N(p_x, p_y) = \left(\int \rho^{2\gamma}(\mathbf{p})\, dp_z\right) \otimes R(p_x, p_y) \tag{8}$$

where p_x, p_y, p_z are the components of the total momentum **p** (p_z is not measured) and $\otimes R$ denotes the convolution with the 2D angular resolution $R(p_x, p_y)$ of the setup.

Typical resolutions obtainable are of the order of 1 mrad. The samples are usually oriented with one of their main crystallographic directions parallel to the integration axis of the setup. Figure 4 shows an example of a 2D-ACAR spectrum

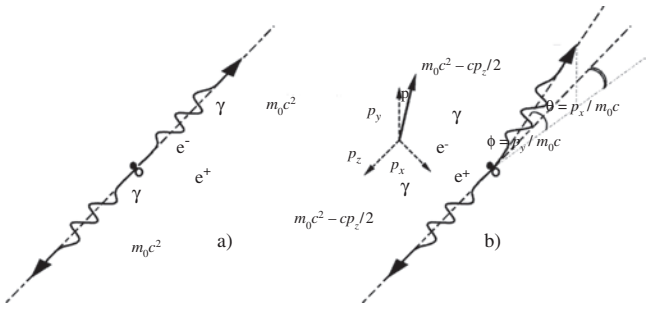

Figure 2. Two-photon annihilation process in: (a) center-of-mass frame; (b) laboratory frame.

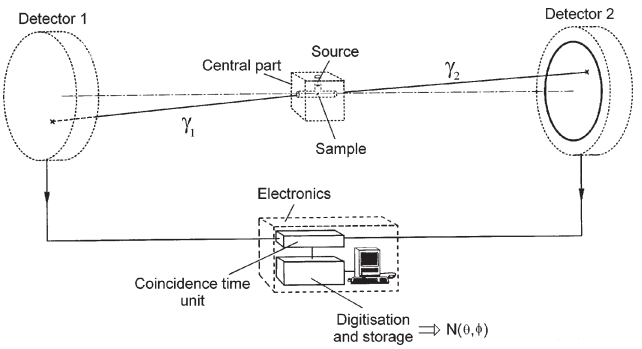

Figure 3. Schematic diagram of a typical 2D-ACAR setup showing the principal components.

for an oriented crystal of Si(100). The structure in the spectrum reflects the crystalline features of the momentum density of the electrons in Si. In the older 1D-ACAR method only one component of the total momentum was measured,

$$N(p_z) \sim \left(\iint \rho^{2\gamma}(\mathbf{p})\, dp_x\, dp_y\right) \otimes R(p_z) \tag{9}$$

where $\otimes R$ corresponds to the convolution with the one-dimensional angular resolution $R(p_z)$ of the setup. Since the 2D-ACAR method maps the momentum distribution of the electrons with a high-resolution, the method has important applications (e.g., Fermi surface topology).

The pioneering 2D-ACAR work with beams was performed in the 1980s in the laboratories of Lawrence Livermore (LLNL) and Brookhaven (BNL). The Livermore beam was made by moderation of high-energy positrons produced by pair production in a W target at the electron linac. The positrons were then moderated in a system of W vanes. The Brookhaven group used a slow positron source made by evaporating ~20 Ci of ^{64}Cu obtained by irradiation in the High-Flux Beam Reactor onto a single-crystal W(110) substrate, where it was annealed to form an epitaxial Cu(111) layer. This thin Cu layer emitted and simultaneously moderated the positrons into a monoenergetic beam of slow positrons. Both beams could be accelerated to obtain the desired incident positron energy.

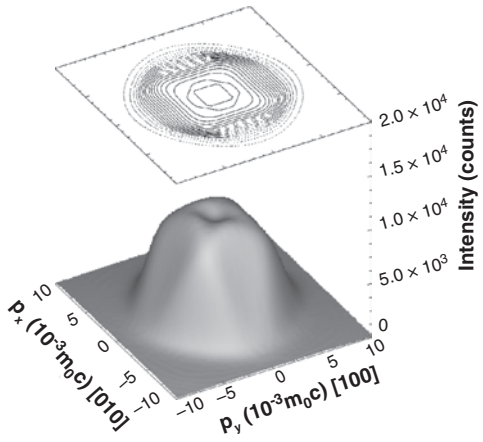

Figure 4. 2D-ACAR spectrum for Si (100).

These first 2D-ACAR experiments concentrated on the differences between the bulk and surface momentum distributions of single-crystal Al (BNL) [42–44] and Cu (LLNL) [45] samples and observed the momentum distribution of Ps emitted by the surface.

2.2.2. Doppler Broadening of Annihilation Radiation

In addition to the angular deviation of the annihilation photons, discussed in the previous section, there is a shift of the energy of the photons from its average value of 511 keV, caused by the component of the momentum parallel to the direction of γ-ray emission. The energy shift, δE, from 511 keV can be expressed by

$$\delta E = cp_z/2 \tag{10}$$

where p_z is the longitudinal component of the momentum of the e^+–e^- pair. Since one half of the electrons moves toward the detector while the other half moves away from it, the energy shift results in a Doppler broadening of the 511 keV line by several keVs, which can be measured by Ge detectors. The best detectors have a resolution of 1.1 keV at 511 keV which corresponds to a momentum of $4.3 \times 10^{-3}\ m_0c$. Owing to the small distance between the detector and the sample, the Doppler broadening experiment integrates over the transverse component of the momentum and the measured spectrum is a one-dimensional projection of the three-dimensional momentum density,

$$N(E) = N(p_z) \sim \left(\iint \rho^{2\gamma}(\mathbf{p})\, dp_x\ dp_y \right) \otimes R \tag{11}$$

where $\otimes R$ denotes convolution with the energy resolution of the Ge detector.

Figure 5 shows a typical Doppler broadening spectrum consisting of a broadened 511 keV peak. Due to the double integration and convolution with the resolution of the detectors the spectrum is smooth and featureless. However, one can derive valuable information from this spectrum by defining two regions of interest: the low-momentum central part corresponding to annihilations of positrons with valence electrons, and the high-momentum tails corresponding to annihilations with more tightly bound electrons (e.g., core electrons). Thus, one can characterize the shape of the 511 keV peak with the aid of two parameters, S and W, defined as [46, 47]

$$S = \frac{B}{A + B + C} \tag{12}$$

$$W = D + E + F + (F/D) \tag{13}$$

where A, B, C, D, E, and F are the areas of the energy windows defined in Figure 5. Therefore, the S parameter is more useful for monitoring the presence of defects in a material, while the W parameter gives the signature of that material. The parameter S gives the area under the central part of the profile, divided by the total area under the profile; thus a high value of S signals the presence of open-volume defects, whereas a "defect-free" sample will show a low value of the S parameter. The energy windows are set symmetrically around the center of the peak in such a way as to maximize the sensitivity to vacancies. Many workers use an S value of ~0.50. In order to make S parameter measurements in different laboratories easier to compare, the S values are usually quoted with respect to some standard material, often a highly perfect Si crystal. The orientation of this reference crystal and that of the crystal under investigation, if the latter also is a single crystal, should be specified, as the S parameter is an anisotropic quantity with the point symmetry of the crystal. The second parameter, W, gives the ratio between the area under the wings and the total area. The settings of the energy windows, which define the W parameter, differ more among different laboratories. Some workers choose their settings such that the value of W is approximately 0.25 of that of S, thereby obtaining a relatively high statistical precision, while others choose a lower fraction ($\leq$0.1) to increase the sensitivity to defects. As *areas under parts of the Doppler broadening profile give S and W parameters* they can be measured within a short time with a good statistical precision without putting high demands on the positron beam intensity. This makes this type of measurement highly suitable for defect investigations in which some parameter such as the positron energy, sample temperature, or previous heat treatment is varied.

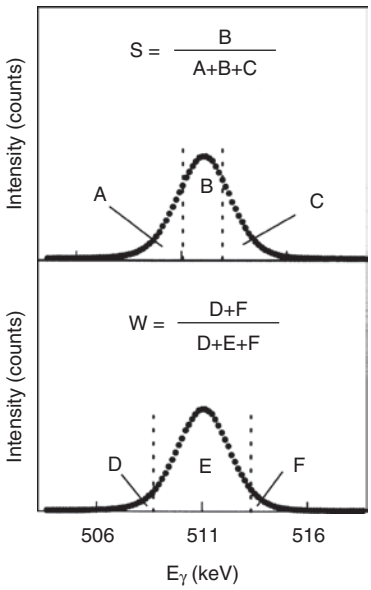

Figure 5. Definition of the S and W parameters in Doppler broadening spectrum.

In view of the positron affinity for open volumes, the Doppler broadening of the annihilation radiation technique in combination with slow positron beams has been extensively applied to the depth profiling of defects in materials [3, 6]. In these experiments the S and W parameters are measured as a function of the incident positron energy, E. The implantation of a slow positron beam can be approximated by a Makhovian profile [48],

$$P(z, E) = \frac{mz^{m-1}}{z_0^m} \exp\left[-\left(\frac{z}{z_0} \right)^m \right] \tag{14}$$

where m is a shape parameter usually set equal to 2 and z_0 is related to the mean implantation depth given by

$$\bar{z}\ [\text{nm}] = \frac{\sqrt{\pi}}{2} z_0 = \frac{\alpha}{\rho} E^n \tag{15}$$

Here ρ represents the density of the material in g/cm^3 and α and n are two material independent constants with values of 40 g cm^{-2} keV$^{-1.62}$ and 1.62, respectively.

The S vs E and W vs E curves for Doppler broadening data are analyzed with the aid of the VEPFIT program [49] that assumes the system studied to consist of a stack of different positron trapping layers, each layer being characterized by a thickness, an S parameter, and a positron diffusion length. The S parameter for a given energy E is then given by

$$S(E) = \sum_{i=1}^{n} f_i(E)\, S_i + f_{\text{surface}}(E)\, S_{\text{surface}} + f_{\text{bulk}}(E)\, S_{\text{bulk}} \tag{16}$$

where $f_i(E)$ is the fraction of positrons implanted at energy E which after thermalization and diffusion annihilate in the layer i, S_i denotes the corresponding value of the line shape parameter in layer i, and *bulk* and *surface* refer to bulk and surface contributions. Owing to the property of linearity of the S and W parameters, one can obtain a direct interpretation of the experimental results by plotting S and W data as a trajectory in an S–W diagram. In this case the running parameter is the positron implantation energy. The advantage of the S–W diagram is that it allows one to distinguish annihilations from different types of defects, which on the basis of the S and W parameter alone could not be detected. In a Doppler broadening measurement the sensitivity to annihilations with core electrons is reduced due to the relatively high background in the spectrum. However, this background can be reduced by placing a second Ge detector opposite the first one at the same distance from the sample [50]. In this way the peak to background ratio is improved by a factor of almost 1000 compared to a single detector system at the expense of much lower count rates.

2.2.3. Positron Annihilation Lifetime

In comparison with the previously discussed positron annihilation spectroscopies, which measure projections of the momentum density of positron–electron pairs, the positron lifetime technique measures the time difference between the emission of a positron and its annihilation with an electron of the material under study. In this experiment a positron source is used which by emission of a simultaneous γ ray provides a zero time signal at the moment at which the positron enters the sample. In conventional experiments ^{22}Na emits a 1.28 MeV γ ray simultaneously with the positron, which is used to trigger the lifetime measurement. In a beam with one or more moderation stages, accelerating and retarding sections, and particle transport over an often considerable distance this is, however, not a feasible option. Several methods have been developed to overcome this problem. Early experiments used the emission of secondary electrons released from the target surface by the entrance of the positron and detected with the aid of a microchannel plate. They achieved a time resolution of ~600 ps full width at half maximum (FWHM) [51]. The resolution is limited by positrons scattering off the sample surface and returning to it after some time and by the spread in response time of the detector. A different approach consists of "bunching" the beam [i.e., collecting the positrons in the beam in groups ("bunches") equally separated in time] and subjecting these groups to fields designed to achieve a degree of time focusing. Initial experiments along these lines produced resolutions of several ns FWHM [52, 53]. Further developments in Munich [54, 55] and Japan [56] resulted in pulse widths of 150 ps with pulse repetition rates of 10^5 Hz and a time resolution of ~200 ps which is comparable to that of good conventional lifetime circuitry. Also here backscattered positrons may interfere with the lifetime measurement, either by annihilations in the surrounding materials or by causing delayed start signals.

Typical values of positron lifetimes are 100–200 ps for bulk materials, corresponding to free-positron annihilation. When the size of the open volume is large enough to accommodate a Ps atom, the lifetime is considerably higher (~ns). The lifetime spectrum can be described as a sum of decaying exponentials,

$$F(t) = \sum_{i=1}^{N} \frac{I_i}{\tau_i} \exp(-t/\tau_i) \tag{17}$$

where N represents the number of different annihilation states, τ_i the lifetime of positrons corresponding to the state i, and I_i the intensity of that state. Contemporary positron lifetime setups commonly use nonmoderated ^{22}Na sources. Therefore the information extracted from a lifetime spectrum is only globally due to the uncertainty in depth at which the positrons annihilate. However, positron lifetime equipment combined with a slow positron beam is now operational or under construction in a few laboratories [57, 58].

2.2.4. Modeling of Positron Diffusion

In experiments where the energy of the implanted positrons can be varied (beam experiments) it is important to know the depth dependent concentration profile of the thermalized positrons. From the concentration one can calculate the number of positrons per unit of time that (i) is captured in defects and subsequently annihilates, (ii) annihilates in the bulk, and (iii) arrives at the surface. To this purpose the time-averaged positron concentration is derived from the balance equation

$$D\frac{d^2c}{dz^2} - \frac{d}{dz}(v_d c) + I(z) - \textstyle\sum_j k_j n_j c - \lambda_b c = 0 \tag{18}$$

where $c(z)$ is the depth dependent concentration, $v_d(z) = \mu E(z)$ is the drift velocity with μ the positron mobility and E the electrical field strength in the material (in particular for activated semiconductor devices), $I(z)$ is the positron implantation rate at depth z, $n_j(z)$ is the density of defects of type j, k_j is the specific capture rate for capture at defects of type j, $\lambda_b = \tau_b^{-1}$ is the annihilation rate in the bulk (τ_b is the bulk lifetime), and D is the positron diffusivity.

The various terms in Eq. (18) describe the following processes: *diffusion, drift, implantation, capture*, and *annihilation*

of the positron. It should be noted that this balance equation is equally valid for other mobile particles implanted in materials. The equation may also be used for hydrogen and helium in metals in which case the electric field drift term and the annihilation term should be omitted.

When there is a uniform concentration of defects n_t with specific trapping rate κ_t and the surface is located at a sufficient distance from the depth of implantation z_f, the solution will read

$$c(z) = c(z_f)\exp[-(z - z_f)/L_+] \tag{19}$$

where $L_+ = [D^+/(\kappa_t n_t + \lambda_b)]^{1/2}$ is the effective diffusion length (i.e., the averaged distance traveled by the positron before it is trapped or annihilated). From Eq. (19) the boundary condition at a large distance from the surface reads

$$\left[\frac{dc}{dz}\right]_{z=z_f} = -c(z_f)/L_+ \tag{20}$$

For the outer surface a similar boundary condition can be defined, but now the absorption length L_a instead of the effective diffusion length L_+ is involved

$$\left[\frac{dc}{dz}\right]_{z=0} = -c(z=0)/L_a \tag{21}$$

The stationary diffusion equation can be solved numerically and the solutions constitute the basis for the analysis of positron annihilation measurements with variable energy positron beams.

2.3. Intense Positron Sources

Positron spectroscopies for depth resolved material analysis, at the surface or near surface, require monochromatic positron beams. Low intensity ($<10^6$ e^+/s) positron beams based on commonly used radioactive isotope sources used in positron physics (^{22}Na, ^{58}Co) have been extensively applied to the investigation of surface or near surface material properties (e.g., surface structure or depth distribution of defects at surfaces and buried interfaces). Low-intensity beams are sufficient to perform many of the positron annihilation spectroscopies (e.g., Doppler broadening of annihilation radiation and positron lifetime), but the application of the 2D-ACAR method and positron microscopy to the study of surfaces and layered systems had to wait for the development of high-intensity slow positron beams ($\sim 10^8$ e^+/s). Nowadays, such beams in which positrons are created by pair production induced by high-energy γ rays are operational or under construction in several laboratories [8], and as these facilities are commissioned the number of applications of positron annihilation spectroscopies in the field of materials science will increase.

A slow positron beam system usually consists of the following components: (i) a primary positron source with a continuous energy distribution, (ii) a positron moderator located near the primary source, and (iii) a beam transport system. In order to increase the intensity of a slow positron beam one or more of these components will have to be improved. The beam transport systems are highly efficient so there is little room for improvement. The role of the positron moderator is to slow down the fast positrons [e.g., when fast positrons are implanted into a well-annealed sample, those within the diffusion length ($\sim$100 nm) from the surface can diffuse back and are ejected nearly monoenergetically as a result of their negative work function]. Typical moderating efficiencies are modest, of the order of $\sim 10^{-4}$–10^{-3}, and these limitations are based on the physics of positron interaction in the moderating system and the geometry of the moderators. The major factor to achieve intense slow positron beams is therefore the primary source strength, which has practically no physical limit. In the following, different approaches adopted at different laboratories to achieve strong sources of moderated positrons are presented.

2.3.1. Sources Based on Relatively Short-Lived Radioactive Isotopes

Reactor Based Sources A high-current positron beam can be achieved by activation of ^{63}Cu in a nuclear reactor to ^{64}Cu, which decays under the emission of a positron. Lynn et al. [59] built an intense beam relying on the activation of a strong (800 Ci) source of copper in the High Flux Beam Reactor at Brookhaven. The positron emitting ^{64}Cu, obtained via the nuclear reaction ^{63}Cu$(n, \gamma)^{64}$Cu, was evaporated onto a single-crystal W(110) substrate in an external vacuum system to provide a self-moderating copper film. The system has operated successfully for several years and has produced many useful data for atomic and solid-state physics including 2D-ACAR on thin films. Disadvantages were the operational efforts. Every three days the source had to be refreshed due to the 12.8 h decay time of the ^{64}Cu radioisotope.

Accelerator Based Sources Irradiation of materials with accelerator ion beams can produce intense positron emitting radionuclides [60]. An example is the irradiation of ^{12}C with a high current of low-energy deuterium ions, which produces ^{13}N. By interchanging the carbon target between the deuteron beam and a positron moderation stage an intense quasi-continuous slow positron beam can be obtained. Since compact linear accelerators are available, this technique is promising for producing inexpensive high-current positron beams. A first attempt to produce such a beam was undertaken at Brandeis University [8].

2.3.2. Sources Based on Pair Production

Pair production is the most commonly used method for producing high-current positron beams. When photons with energy higher than 1.022 MeV interact with the fields surrounding heavy nuclei (e.g., tungsten) that energy can be converted into e^+–e^- pairs. The probability of pair production increases when the photon energy increases. The fast positrons are then separated from the electrons and moderated in order to obtain an intense slow positron beam. Two primary designs are available: (a) linac based positron beams and (b) nuclear reactor based positron beams.

Linac Based Positron Beams Successful intense positron beams are linear accelerator (linac) based positron beams with intensities over 10^9 e^+/s. Positrons are generated in a high-Z target (e.g., tungsten) hit by high-energy (~100 MeV) electrons. Bremsstrahlung photon generation and subsequent pair formation yield fast positrons that can be moderated by tungsten foils. An example of such an intense positron beam was developed at the 100 MeV electron linac at Lawrence Livermore National Laboratory [61]. Other designs are available or under development at different laboratories [7]. Linac based positron beams are inherently pulsed. A quasi-continuous beam can be obtained by trapping the positrons from the linac in a magnetic bottle and then releasing them over the period between linac beam pulses.

Reactor Based Positron Beams The advantage of these beams is that they are practically continuous over time. Pair production can be obtained in nuclear reactors in two different ways: (i) *capture of high-energy gamma rays in thin tungsten moderator foil*s and (ii) *neutron capture of gamma rays from cadmium foils*. The latter is an alternative source of high-energy photons for pair production of positrons. It consists of the gamma rays generated when thermal neutrons are captured in cadmium foils via the nuclear reaction ^{113}Cd (n, γ) ^{114}Cd. Consequently, the gamma rays produce electron–positron pairs in tungsten foils. An intense beam facility based on neutron capture gamma rays is under development at the Research Reactor Munich [62].

2.4. Transmission Electron Microscopy

Transmission electron microscopy is a valuable tool to study defects because it allows for the observation and analysis of materials down to the (sub)nanometer scale. The resolution of a light microscope is limited to the order of a micrometer because of the wavelength of light; an electron microscope is limited by its lenses and stability and may reveal details down to the atomistic scale. The contrast is formed mainly by the elastic scattering of electrons with matter and can be used to obtain real-space as well as diffraction information. The inelastic scattering of some of the electrons can be helpful in obtaining chemical information from very small regions in the specimen. Magnetic lenses are used to focus the electrons and to a large extent the aberrations of these lenses still limit the resolution of the electron microscope. By reduction of the spherical aberration, an increase of the mechanical stability and the use of higher voltages (~400 kV) led to the development of the dedicated high resolution transmission electron microscope (HRTEM). With this type of microscope it is possible to observe the atomistic structure of crystalline solids in real space.

In a HRTEM a crystalline material under investigation is thinned to a thickness of a few nanometers in such a way that it becomes transparent for high-energy electrons. Electrons are then accelerated to typically 400 kV and focused on the specimen. The exiting electron wavefront is magnified and projected on a phosphor screen or a recording medium, which results in a projected 2D image of the atomic structure of the material. The technique of HRTEM originated in the technique of phase contrast microscopy, introduced by Zernike [63] for optical microscopy at the University of Groningen. In 1953 he received the Nobel Prize in physics for this invention. High-resolution TEM imaging is based on the same principles. Phase-contrast imaging derives contrast from the phase differences among the different beams scattered by the specimen, causing addition and subtraction of amplitude from the forward-scattered beam. Components of the phase difference come from both the scattering processes itself and the electron optics of the microscope [64]. Electron microscopy has been around for a number of decades but with ongoing development of the instrument the point-to-point resolution has now dropped well below 0.2 nm, making it possible to distinguish the atomic structure of many materials along low-index crystallographic directions.

A transmission electron microscope consists of an illumination system, specimen stage, and imaging system, analogous to a conventional light microscope. In this research two different electron microscopes are used, a JEOL 4000 EX/II (LaB_6, 400 kV) and a JEOL 2010F (FEG, 200 kV). Several textbooks and reviews have been written on the subject of (high-resolution) microscopy, sadly with different notation conventions. This text adopts the notation used in [64, 65]. Spence [66] has written a more in-depth description of imaging in HRTEM theory. Williams and Carter [67] have written a very clear and complete textbook on general aspects of electron microscopy.

The conventional way to generate electrons is to use thermionic emission. Any material that is heated to a high enough temperature will emit electrons when they have enough energy to overcome the work function. In practice this can only be done with high melting materials (such as tungsten) or low work function materials like LaB_6. Richardson's law describes thermionic emission as a function of the work function Φ and temperature T,

$$J = AT^2 e^{\frac{\Phi}{kT}} \tag{22}$$

with J the current density at the tip and A the so-called Richardson's constant, depending on the material used. In electron microscopes tungsten filaments were most commonly used until the introduction of LaB_6. These LaB_6 sources have the advantage of a lower operating temperature, which reduces the energy spread of the electrons and increases the brightness.

Another way of extracting electrons from a material is to apply a high electric field to the emitter that enables the electrons to tunnel through the barrier. Sharpening the tip may enhance the electric field because the electric field at the apex of the tip is inversely proportional to the radius of the apex,

$$E = \frac{V}{kR} \tag{23}$$

with k a correction factor for the tip geometry (usually $\approx$2). The advantage of this cold field emitter gun (cold FEG) is that the emission process can be done at room temperature, reducing the energy spread of the electrons. The small size of the emitting area and the shape of the electric field results in a very small (virtual) source size in the order of

nanometers with brightness that is three orders of magnitude higher than for thermionic sources. It is thus possible to focus the beam to a very small probe for chemical analysis at an atomistic level or to fan the beam to produce a beam with high spatial coherence over a large area of the specimen. The disadvantages of this type of emitter are the need for (expensive) ultrahigh vacuum equipment to keep the surface clean, the need for extra magnetic shielding around the emitter, and a limited lifetime.

Some of these disadvantages of cold FEG emitters can be circumvented by heating the emitter to moderate temperatures (1500 °C) in the case of a thermally assisted FEG or by coating the tip with ZrO_2, which reduces the work function at elevated temperatures and keeps the emission stable (Schottky emitter). This causes a doubling in the energy spread of the electrons and some reduction in brightness. The Schottky emitter is most widely used in commercial FEG-TEMs because of its stability, lifetime, and high intensity.

After leaving the electron gun the electrons are accelerated toward the anode and enter the column. Because the velocity of the electrons approaches the speed of light the wavelength of the electrons has to be corrected for relativistic effects

$$\lambda = \left(\frac{2m_0 eE}{h^2} \left(1 + \frac{eE}{2m_0 c^2} \right) \right)^{1/2} \tag{24}$$

For 400 kV electrons $\lambda = 1.64$ pm, which is much smaller than the resolution of any electron microscope because the resolution is limited by aberrations of the objective lens and not by the wavelength of the electrons. The electron beam is now focused on the specimen with the condenser lenses and aligned using several alignment coils. The function of the condenser lens system is to provide a parallel beam of electrons at the specimen surface. In practice this is not possible and the beam always possesses a certain kind of convergence when imaging at high resolution, usually in the range of 1 mrad for LaB_6 emitters and 0.1 mrad for FEGs.

After entering the specimen most of the electrons are elastically scattered by the nuclei of the atoms in the specimen. Some electrons are inelastically scattered by the electrons in the specimen. Compared to X-ray or neutron diffraction, the interaction of electrons with the specimen is huge and multiple scattering events are common. For thick specimens at lower resolutions an incoherent particle model can describe the interaction of the electrons with the specimen. However, with thin specimens at high resolution this description fails because the wave character of the electrons is then predominant. The electrons passing the specimen near the nuclei are somewhat accelerated toward the nuclei, causing small, local, reductions in wavelength, and this, in turn, results in a small phase change of the electrons. Information about the specimen structure is therefore transferred to the phase of the electrons.

Only elastically scattered electrons are of importance in formation of high-resolution images. The inelastic scattered electrons contribute mostly to the background of the image. These electrons can be removed by inserting an energy filter in the microscope between the specimen and recording device. Only the elastically scattered electrons are now used for the image formation. The energy loss spectrum of the inelastic scattered electrons contains valuable information about the chemical composition of the specimen. This information can be extracted by observing the electron energy loss spectrum or by filtering parts of the loss spectrum. The inelastic scattered electrons also produce Kikuchi lines in the electron diffraction pattern that are helpful for accurate crystallographic alignment of the crystals in the specimen.

To retrieve structural information on the specimen from the micrographs it is necessary to calculate the trajectory of the electron wave through the specimen. In kinematic approximation, multiple scattering of the electrons in the sample is ignored and this results in an undisturbed central beam. This approach already fails at a small thickness or a single atom. In dynamical calculations all the scattered beams and their mutual exchange of intensity during the course of multiple scattering in the specimen are taken into account. It is possible to do full dynamical calculations but these are soon limited by the available computing power. Using the fact that the vast majority of the electrons are scattered in a forward direction with small diffraction angles, Cowley and Moodie [68] devised the multislice approximation. Here the 3D crystal is divided into multiple thin slices perpendicular to the electron beam; in between the electron wave propagates. The incident electron wavefront intensity is described by a plane wave with wave vector k propagating *in vacuo*,

$$\begin{aligned} \Psi_0(\mathbf{r}) &= e^{-2\pi i \mathbf{kr}} \\ k = |\mathbf{k}| &= \frac{\sqrt{2meE}}{h} = \frac{1}{\lambda} \end{aligned} \tag{25}$$

with λ the nonrelativistic wavelength of the electrons. The refractive index in every slice depends on the position in the slice because the electrons will be accelerated toward the nuclei, whereby their wavelength is reduced. This phase change can be expressed by multiplying $\Psi_n(\mathbf{r})$ with a transmission function $q(x, y)$, assuming that the specimen acts as a pure phase object,

$$q(x, y) = e^{-i\sigma\phi(x, y)} \tag{26}$$

with $\phi(x, y)$ the projected potential distribution in the slice, averaged over the electron beam direction and $\sigma = \pi/\lambda E$ the interaction constant. Absorption is neglected in this approach, the so-called phase-object approximation. A further simplification can be made by only considering the first-order approximation of Eq. (26)

$$q(x, y) = 1 - i\sigma\phi(x, y) \tag{27}$$

This is known as the weak phase-object approximation in which the amplitude information is linearly related to the projected potential. The propagation between the slices, each of thickness δ, can be described by convoluting (26) with the Fresnel propagator,

$$p(x, y) = e^{-\pi i(x^2+y^2)/\lambda\delta} \tag{28}$$

and the emerging spherical wavefront is approximated by a paraboloidal wavefront.

The nth wave function can now be obtained by a convolution,

$$\Psi_n(x, y) = (\Psi_{n-1} \otimes p_{n-1}(x, y)) \cdot q_n(x, y) \tag{29}$$

with p_{n-1} the propagator from slice $n-1$ to slice n. In this way the exit wave computed can subsequently be used as input for the image formation calculations. Usually the convolution is done by a multiplication in Fourier space, which saves computing time. After the exit wave has left the specimen the electron wavefront has to be converted into an image. Because the exit wave mainly contains phase information, these phase differences have to be converted to intensities, much like the phase contrast microscope invented by Zernike [63]. The exit wave can be described in reciprocal space by performing a Fourier transform. The effect of the spherical aberration of the objective lens is that the electrons entering the objective lens at different distances from the optical axis are focused at different planes and also travel different distances, causing a phase difference for the different scattered electrons. The phase factor $\chi(U)$ describes the phase difference introduced by the defocus and spherical aberration,

$$\chi(U) = \pi\lambda\Delta f U^2 + \frac{1}{2}\pi C_s\lambda^3 U^4 \tag{30}$$

with Δf the defocus value of the objective lens, U the distance of the reciprocal lattice point from the optic axis, and C_s the spherical aberration. In reciprocal space this phase factor can be accounted for by multiplying the exit wave with $B(U)$, which is equivalent to a convolution in real space:

$$B(U) = \exp(i\chi(U)) \tag{31}$$

If the specimen behaves as a weak phase object only the imaginary part of $B(U)$ contributes to the intensity of the image, $T(U)$,

$$\begin{aligned} T(U) &= 2\,\sin(\chi(U)) \\ &= 2\,\sin\left(\pi\lambda\Delta f U^2 + \frac{1}{2}\pi C_s\lambda^3 U^4\right) \end{aligned} \tag{32}$$

which is usually referred to as the objective lens transfer function if the specimen behaves like a weak phase object. Only the real part is considered because the phase information from the specimen is converted in intensity information by the phase shift of the objective lens. In the microscope an aperture is inserted in the back focal plane of the objective lens that transmits beams only to a certain angle. This can be represented by an aperture function $A(U)$ which is unity for $U < U_0$ and zero outside this radius. When $T(U)$ is negative, the atoms in the specimen would appear as dark spots against a bright background and vice versa. For $T(U) = 0$ no contrast results. An ideal behavior of $T(U)$ would be zero at $U = 0$ (very long distances in the specimen) and $U > U_0$ (frequencies beyond the aperture size) and large and negative for $0 < U < U_0$.

The contrast of a high-resolution image depends strongly on the microscope settings and parameters. In practice, not all the information in $T(U)$ is visible in the image. This is caused by electrical instabilities in the microscope creating a spread of focus because of the chromatic aberration of the objective lens, which results in damped higher frequencies. Mechanical instabilities and energy loss due to inelastic scattering of the electrons by the specimen also contribute to the spread in defocus. The inelastic scattered electrons contributing to the image can be removed by inserting an energy filter in the microscope between the objective lens and the image recording media. Another factor that damps the higher frequencies is the beam convergence. Because the electron beam has to be focused on a small spot on the specimen there is some convergence of the beam present. This also affects the resolution because the specimen is now illuminated from different angles at the same time. These effects that affect the resolution can be represented by multiplying $\sin(\chi)$ by the damping envelopes E_α and E_Δ, which represent the damping by the convergence and spread in defocus respectively:

$$\begin{aligned} E_\Delta(U) &= \exp\left[-\frac{1}{2}\pi^2\lambda^2\Delta^2 U^4\right] \\ E_\alpha(U) &= \exp[-\pi^2\alpha^2(\varepsilon + \lambda^2 C_s U^2)^2 U^2] \end{aligned} \tag{33}$$

The resulting contrast transfer function (CTF) for the JEOL 4000 EX/II is plotted in Figure 6 with the damping envelops E_α and E_Δ. For higher frequencies the CTF is now damped and approaching zero. It becomes clear that defining a resolution for the HRTEM is not obvious. Several different resolutions can be defined as stated by O'Keefe [69]:

(1) Fringe or lattice resolution: This is related to the highest spatial frequency present in the image. In thicker crystals second-order or nonlinear interference may cause this. As the sign of $\sin(\chi)$ is not known there is in general no correspondence between the structure and the image. This resolution is limited by beam convergence and spread in defocus.
(2) Information limit resolution: This is related to the highest spatial frequency that is transferred linearly to the intensity spectrum. These frequencies may fall in a passband, with blocked lower frequencies. Usually this resolution is almost equal to the lattice resolution.
(3) Scherzer resolution or point resolution: This is the highest possible resolution when no lower frequencies are blocked or passed with opposite sign. This is the most relevant resolution definition because it results in a projected image of the specimen structure. The exact definition for the Scherzer defocus varies slightly in literature. In general, for images taken at optimum defocus of $(\frac{4}{3}C_s\lambda)^{1/2}$ the highest transferred frequency is equal to $1.51C_s^{-1/4}\lambda^{-3/4}[\mathrm{m}^{-1}]$.

In Figure 6 the CTFs of the JEOL 4000 EX/II, JEOL ARM 1250, and JEOL 2010F at Scherzer defocus are plotted with the damping envelopes. The CTF of the 2010F shows the rapid oscillations of the FEG due to higher spatial coherence. In this case there is a big gap between point resolution and information limit. For the ARM 1250 microscope at the Max Planck Institute für Metallforschung in Stuttgart the damping envelope is limited by the spread-of-focus and the point resolution is almost equal to the information limit. Using a FEG will not substantially increase the resolution here. Generally speaking, using a FEG in

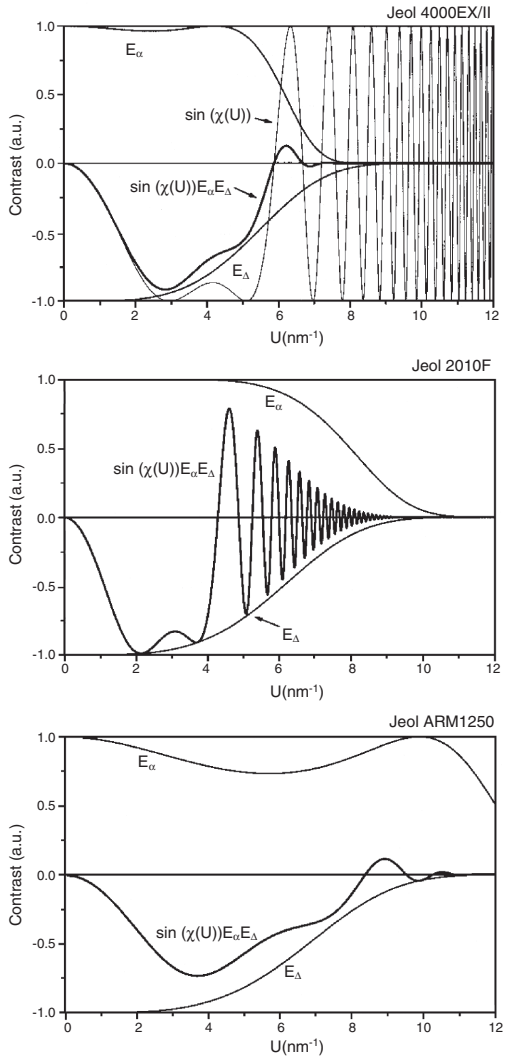

Figure 6. Contrast transfer functions (thick lines) and damping envelopes of the used microscopes at Scherzer defocus of 47, 58, and 51 nm respectively. Note the many oscillations in the CTF of the 2010F.

lower voltage ($\leq$200 kV) instruments helps to increase the information limit because in these instruments beam convergence dominates the damping envelope. With higher voltage instruments the higher acceleration voltage increases the brightness of the source and the damping envelope is limited by the spread of defocus. The spherical aberration of the objective lens can be lowered but generally at the expense of a decrease in tilt capabilities of the specimen. It is possible to compensate C_s by a set of hexapole lenses as suggested by Scherzer [70] in 1947 but it became feasible only recently due to the complex technology involved. Haider et al. demonstrated a C_s corrected 200 kV FEG microscope [71] in which C_s was set at 0.05 mm to reach an optimum between contrast and resolution. The point resolution of this microscope was now equal to the information limit of 0.14 nm. Successful application of this technology would put the limiting factors of the microscope at the chromatic aberration and mechanical vibrations that currently limit the resolution around 0.1 nm.

For correct interpretation of the structure the specimen has to be carefully aligned along a zone axis, which is done with the help of Kikuchi patterns and an even distribution of the spot intensities in diffraction. The misalignment of the crystal is in this way reduced to a fraction of a milliradian. Beam tilt has a more severe influence on the image because the tilted beam enters the objective lens at an angle that causes phase changes in the electron wavefront. To correct the beam tilt the voltage center alignment causes the acceleration voltage to be varied in order to find the center of magnification that is then placed on-axis. This alignment might not be correct due to misalignments in the imaging system after the objective lens. For better correction of the beam tilt the coma-free alignment procedure is necessary. This is done by varying the beam tilt between two values in both directions and optimizing the values until images with opposite beam tilts are similar. This procedure is only practically feasible with a computer-controlled microscope equipped with a charge coupled device camera and is not commonly used; instead, the voltage center alignment used could cause some residual beam tilt.

3. DEFECTS AND NANOCLUSTER ENGINEERING IN MgO

3.1. Introduction

Currently much research in the field of defect engineering is devoted to defects in magnesium oxide. Applications of MgO include the development of optical communications media [72] and the use of MgO in nuclear reactor fuels. An absorption band centered around 550 nm, known as Mie resonance, has been observed after Au/Ag implantation in a number of studies [73, 74]. Copper, silver, and gold are the most common metals used for ion implantation. The formation of metallic nanoprecipitates in MgO after implantation and subsequent annealing has been investigated for various annealing treatments using techniques such as Rutherford Backscattering Spectrometry/Channeling (RBS-C) and optical absorption spectrometry [75]. A related topic of research is the role of cavities in the material, which may act as gettering centers for implanted metal ions. Recently nanovoids in MgO have been created by helium implantation and subsequent annealing [76].

Here, we discuss investigations about the nucleation, aggregation, and dissociation of metallic nanoprecipitates and their possible interaction with vacancy-type defects. For this purpose, three complementary techniques were used. Positron beam analysis (PBA) is a very sensitive tool to monitor depth resolved vacancy-type defects [77]. RBS can provide information about the depth distribution of the implanted copper ions. Finally cross-sectional transmission electron microscopy (X-TEM) can provide information about the configuration of the metallic nanoprecipitates and vacancy-type defects.

Conventionally metal nanoclusters are formed after 1–2 MeV implantation followed by high-temperature anneals. An alternative way to form nanoclusters was studied in [78]. Prior to the metal ion implantation a chain of nanosize cavities was created as a result of 30 keV He^+

ion implantation followed by annealing. In the complementary TEM study [79] it was observed that the cavities are elongated in the [100] direction and have a rectangular form. Subsequently, Au ions were introduced by low-energy, 30 keV implantation. Then the samples were annealed to provide diffusion of the metal ions to the cavity layer. However, only a small fraction of Au reached the cavities located at a depth of about 200 nm. Most of the Au ions created a band of clusters close to the surface within the implantation range. In the present study MgO samples containing a band of nanocavities have been implanted with high-energy Au and Ag ions. The energies were chosen to introduce the metal ions directly in the vicinity of the cavity band. Single crystal MgO (100) samples with dimensions $10 \times 10 \times 1$ mm^3 were used. The samples were treated in the following way: The nanosize cavities were formed by 30 keV $^3He^+$ implantation followed by annealing in air at 1273 K for 0.5 h. After this the samples were implanted with 30 keV Au at room temperature (RT) and 1273 K. Another set of four samples with cavities was implanted with 600 keV Ag and 1 MeV Au ions at RT and at 873 K. After the implantation the samples were stepwise annealed in air in order to form the nanoclusters. The optical properties of the samples were studied by light absorption. The structure of the defects introduced by implantation was studied by X-TEM and PBA. A detailed description of the PBA technique is presented in Section 2 [51]. In short, with PBA the sample is probed by a monoenergetic beam of positrons with energies ranging from 0.1 to 25 keV, which correspond to typical depths from the surface up to 3000 nm. Annihilation of a positron with an electron at rest results in two photons of 511 keV each. If the electron has a nonzero momentum the energy of the photons is Doppler shifted resulting in a broader energy distribution. The energy spectrum of the 511 keV photon annihilation peak is characterized by two parameters: S and W (see also Section 2). The S parameter is defined as the contribution of the central part of the peak and is related to annihilations with valence or conduction electrons. The W parameter is defined by the contribution of the "wings" in the spectrum and is related to annihilations with high momentum core electrons. Thus, high S values are usually attributed to vacancy related defects where the chance for a positron to annihilate with a high-momentum core electron is low. Another contribution is positronium, which can be formed in cavities of nanometer size.

3.2. Results and Discussion

The bands of nanosize cavities and Au nanoclusters observed in X-TEM are shown in Figure 7. In this work an MgO sample containing a band of cavities at a depth of about 200 nm was implanted with 30 keV Au ions to a dose of 10^{16} cm^{-2}. The sample was subsequently annealed in air at 1273 K. It is seen that a band of nanoclusters is formed within 25–75 nm of the surface. The cavity layer formed prior to the Au implantation had developed into a band of elongated internal cracks during the annealing treatment. The cracks are presumably formed by merging a few adjacent cavities into one. Additionally, the Au implantation has created another band of rectangular nanosize cavities within the first 25 nm. The fact that the implantation

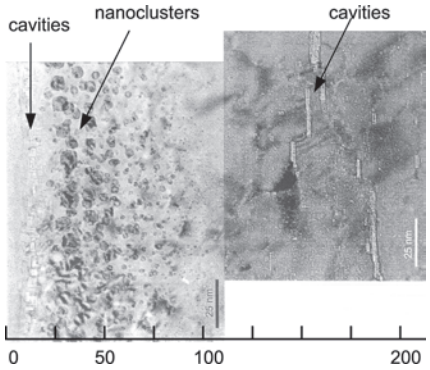

Figure 7. X-TEM picture of two bands of cavities and a band of nanoclusters obtained after a combination of 30 keV He and Au implantations and anneals discussed in the text. The depth location of the bands is shown in nanometers.

induced vacancies have agglomerated into cavities rather than escaping at the surface suggests a very short diffusion length within the damage region. The Au nanoclusters were later studied by X-ray diffraction (XRD) and X-TEM and were found to be semicoherent with the MgO host lattice [80].

In order to introduce the metal ions directly into the vicinity of the cavity band the implantations were carried out at energies which correspond to the depth of the original cavity band (i.e., 200 nm). Thus, the implantation energies for Au and Ag ions were 1 MeV and 600 keV, respectively. To enhance diffusion two samples were implanted at an elevated temperature of 873 K. The light absorption measurements performed directly after Au and Ag implantations are shown in Figures 8 and 9, respectively. For as-implanted samples an absorption peak at 560 nm is observed only in the case of RT implantation (curve a in Figure 8 and curve a in Figure 9). This absorption band has disappeared after the

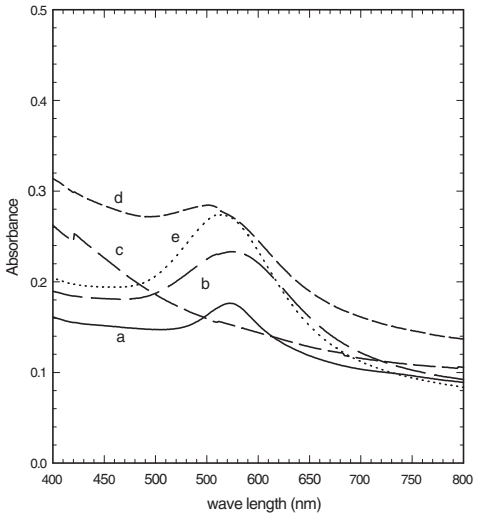

Figure 8. Light absorption measurements of the MgO samples after 1000 keV, 10^{16} cm^{-2} Au ion implantation: (a) as-implanted at RT; (b) implanted at RT and annealed at 1473 K, 23 h; (c) as-implanted at 873 K; (d) implanted at 873 K and annealed at 1473 K, 23 h; (e) implanted at RT and annealed at 1473 K, 22 h (no cavities).

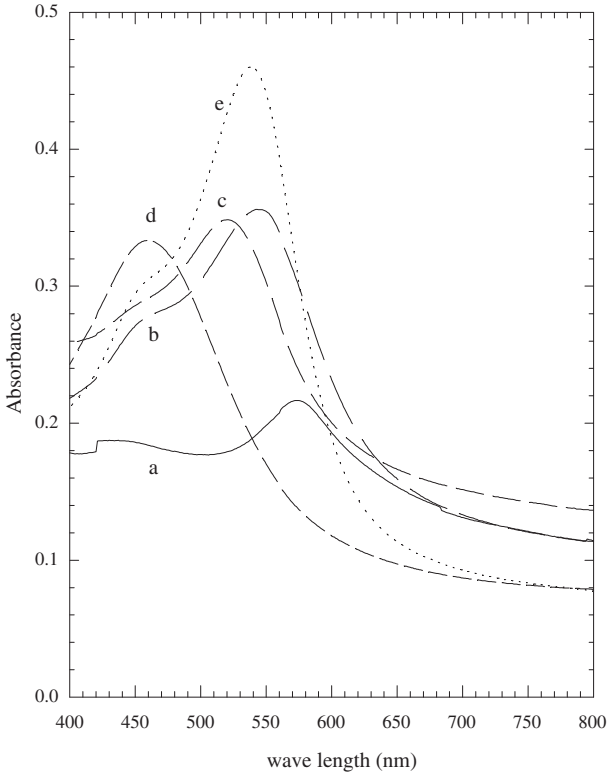

Figure 9. Light absorption measurements of the MgO samples after 600 keV, 10^{16} cm^{-2} Ag ion implantation: (a) as-implanted at RT; (b) implanted at RT and annealed at 1473 K, 23 h; (c) implanted at 873 K and annealed at 1473 K, 23 h; (d) implanted at RT and annealed at 1273 K, 5 h; (e) implanted at RT and annealed at 1473 K, 22 h [(d) and (e) contain no cavities].

samples were annealed at 873 K. That suggests that these absorption centers are introduced by the implantation and can be related to V-centers. During further anneals up to 1473 K nanoclusters are formed. Mie resonance peaks are observed at 570 nm for Au and at 540 nm for Ag. In the case of the Ag implantation another peak, located at 460 nm, can be observed. However, no evident enhancement of the metal nanocluster formation was observed in the samples containing nanocavities.

The evolution of the metal ion precipitation was also monitored with the help of PBA. The experimental data are presented on the *SW* map. As the positron implantation energy increases the experimental points form a path, which runs between a number of so-called cluster points. Each cluster point is related to a certain (electron) environment where positron annihilation takes place Thus, in Figure 10 four cluster points are identified (shown with open circles). For the case of the cavity containing sample (solid circles), the path runs first from the "surface" to the "MgO bulk"-cluster point. As the energy increases the positrons are implanted in the cavity layer and the *SW* path is deviated to the cluster point denoted as "cavities." At higher positron energies the data points tend to cluster around the "MgO-bulk" point again. After the sample was implanted with 1000 keV Au ions and annealed another cluster point ascribed to Au nanoclusters is observed. For the case of the Ag implanted sample (shown in Fig. 11) the

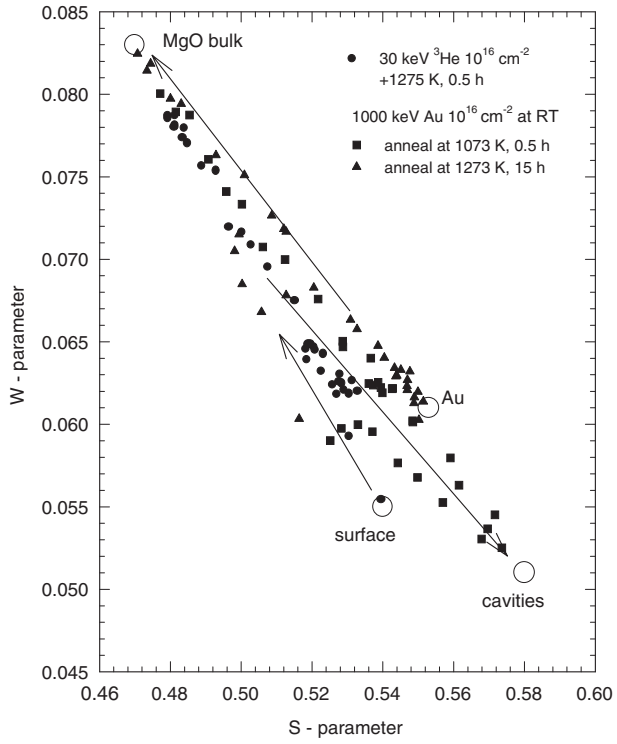

Figure 10. *SW* map of MgO with cavities implanted with 1000 keV Au and subsequently annealed at 1073 and 1273 K. Cluster points shown on the map with opened circles are related to positrons trapped at the surface, cavities, nanoclusters, and defect-free MgO bulk.

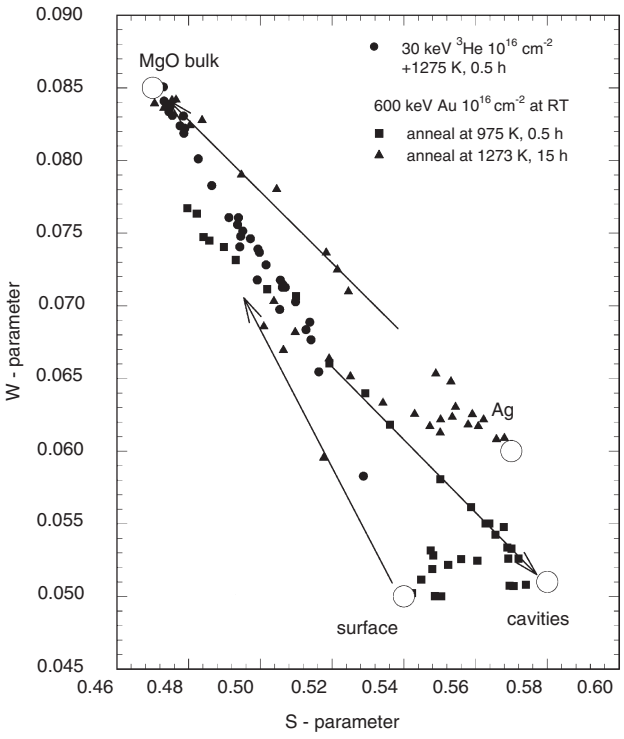

Figure 11. *SW* map of MgO with cavities implanted with 600 keV Ag and subsequently annealed at 973 and 1273 K. Cluster points shown on the map with opened circles are related to positrons trapped at the surface, cavities, nanoclusters, and defect-free MgO bulk.

cluster point ascribed to Ag nanoclusters is identified. Note that while the "cavities" and "MgO-bulk" cluster points in both cases are the same; the cluster points related to Au and Ag nanoclusters are different.

In order to obtain the depth location of the defected layers the *S* curves measured prior and after the metal ion implantations were analyzed with the program VEPFIT [49]. The *S* curve (a) ascribed to the original band of cavities was fitted with a model containing 3 layers: a layer of cavities between two layers of defect-free MgO matrix. The *S* curve (b) measured after the Au implantation was fitted with a five layer model: three defected layers (two with cavities and one with metal precipitates) and two defect-free layers. The results of the fit are shown in Figure 12. The stopping ranges of ions obtained by the TRIM [81] simulations are also shown for comparison. The implantation energies of He, Au, and Ag ions were chosen to yield the same implantation range. However, a discrepancy within 100 nm is observed between the predicted by TRIM ranges and the location of the defected layers obtained by VEPFIT. From the PBA studies alone, however, is difficult to say whether the metal ions have precipitated into a cluster or are still dissolved in the matrix. It can be concluded that nanosize cavities developed after He implantation were used as precursors for the precipitation of the metal nanoclusters. Metal ions were introduced by low-energy (30 keV) Au implantation and high-energy Au (1 MeV) and Ag (600 keV) implantations. In the case of low-energy implantation nanoclusters are predominantly formed within the implantation range close to the surface. In the case of high-energy implantation formation of the nanoclusters was observed by the presence of Mie absorption bands. However, the location of the nanocluster layer has yet to be identified.

Nanocluster sizes can be estimated using three different methods: using the Doyle formula for the broadening of the optical absorption peak associated with Mie plasmon resonance, using the Scherrer formula for the broadening of the Au and Ag XRD peaks, and from direct observation of TEM images. The average size and the size distribution are best determined from X-TEM. However, this technique often implies destruction of the sample and the specimen preparation is time consuming. Therefore, many authors working on annealing studies try to estimate the precipitate size from the broadening of the optical absorption peak that is present as a result of Mie plasmon resonance [82]. Here the Doyle theory [83] is used to estimate the nanocluster size during the annealing procedure. Alternatively, the size can be estimated from the broadening of the XRD diffraction peaks using the Scherrer formula [84]. Here, we compare the nanocluster size as obtained from the three methods mentioned. XRD and X-TEM are also employed in order to determine the coherency and the orientation relationship of the gold clusters with the surrounding matrix. The sample treatment data are listed in Table 1. In the Doyle theory, the free mean path of the electrons constituting the plasmon is limited by the size of the nanocluster. This allows estimation of the cluster size as [83]

$$D = 2\frac{v_F}{\Delta\omega_{1/2}} = 2\frac{v_F}{2\pi c}\frac{\lambda_{\max}^2}{\Delta\lambda_{1/2}} \tag{34}$$

Here D is the diameter of the precipitate (m), v_F is the Fermi velocity (1.39×106 m/s both for gold and silver [85]), $\Delta\omega_{1/2}$ is the FWHM of the peak when plotted as a function of the circular frequency ω (rad/s), c is the speed of light (m/s), $\lambda_{\max}$ is the position of the centroid of the peak, and $\Delta\lambda_{1/2}$ is the FWHM of the peak when plotted as a function of wavelength (m). The background in the optical spectra was fitted with an exponential function and the Mie plasmon resonance peak was fitted with a Gaussian. The FWHM of the Gaussian and the parameters mentioned were substituted in Eq. (34), yielding cluster diameters of 4.3 and 5.1 nm for the Au and Ag clusters, respectively. High-resolution XRD measurements were carried out on the MgO(002), (113), (004), and (024) diffraction peaks.

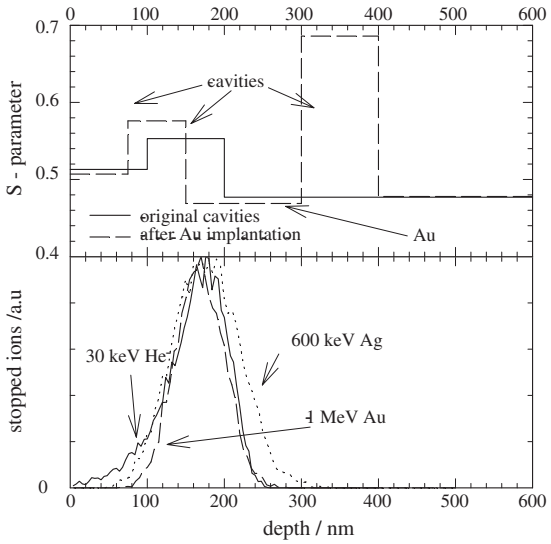

Figure 12. The results of the fitting performed with the VEPFIT program: Defect layers characterized by different *S* values are shown as a function of depth. Ranges of the implanted ions with the indicated energies are also shown in the bottom graph.

Table 1. Sample treatment and structural properties of the Au and Ag nanoclusters.

		MgO:Au	MgO:Ag
Sample treatment			
implantation		1 MeV, 10^{16} Au^+ cm^{-2}	600 keV, 10^{16} Ag^+ cm^{-2}
thermal anneal		1473K, 22 hrs	1473K, 22 hrs
Cluster size and shape			
optical abs. (Doyle)		4.3 nm	5.1 nm
XRD (Scherrer), (113) peak		4.0 nm ($K_w = 0.8290$)	9.8 nm ($K_w = 0.8863$)
XTEM	mean size	4.6 nm	11 nm
	distribution	2–14 nm	6–24 nm
	shape	spherical	octahedral
Lattice parameter *a*			
literature		4.078 Å	4.085 Å
misfit ($a_{MgO} = 4.212$ Å)		3.2%	3.0%
experimental *a* (XRD)		4.09 Å	4.12 Å
coherency strain $\varepsilon_{[100]}$ (XRD)		+0.4%	+0.9%

Figure 13a and b shows the contour plots of the (113) diffraction peaks of the MgO:Au and MgO:Ag samples. The $k_{[001]}$ axis corresponds to diffraction along the [001] crystal axis (perpendicular to the surface) and the $k_{[110]}$ axis corresponds to diffraction along the [110] crystal axis (parallel to the surface). The crystal structure of MgO, Au, and Ag is face-centered cubic (fcc) and their lattice parameters are listed in Table 1. Because the lattice parameters of Au and Ag are close to that of MgO, Au(113) and Ag(113) satellite peaks are observed near the intense MgO(113) peaks in Figure 13. The broadening of the MgO diffraction peaks is due to mosaic broadening (rocking curve). The Au and Ag satellite peaks were also found near the MgO (002), (004), and (024) diffraction peaks, clearly indicating a cube-on-cube orientation relationship with the MgO host matrix.

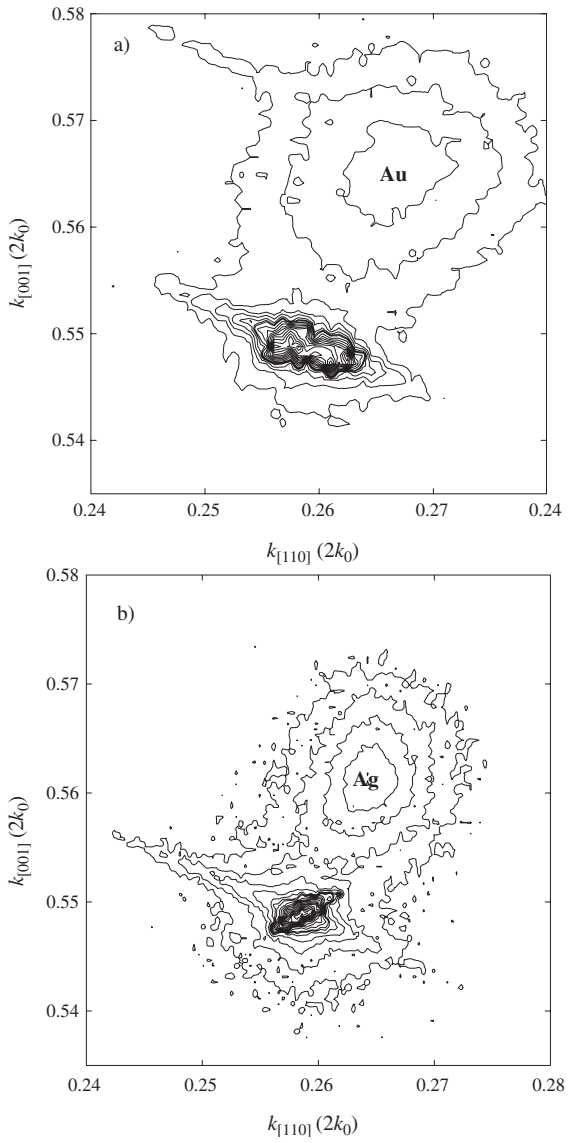

Figure 13. Reciprocal space plots of (a) the MgO(113) and Au(113) diffraction peaks of the MgO:Au sample and (b) the MgO(113) and Ag(113) diffraction peaks of the MgO:Ag sample. Units are in $2k_0 = 2/\lambda_0$.

The cluster size was estimated from the width of the (002) and (113) diffraction peaks using the Scherrer formula [84]

$$p = K_w \cdot \frac{\lambda_0}{\Delta\vartheta \cos \vartheta} = K_w \cdot \frac{2}{\Delta k\sqrt{h^2 + k^2 + l^2}} \qquad (35)$$

Here p is the precipitate size, defined as the cube root of the precipitate volume. Furthermore, λ_0 is the wavelength (1.540560 Å), θ is the position of the (hkl) diffraction peak, $\Delta\theta$ is the FWHM of the same diffraction peak, and Δk is the FWHM of the peak in reciprocal space in m^{-1}. The half-width Scherrer constant K_w depends on the shape of the nanocluster and—if the clusters are not spherically shaped—also on the *(hkl)* index of the diffraction peak [84]. The right-hand side of Eq. (35) is derived from Bragg's law, $\lambda = 2d_{hkl} \sin(\vartheta)$ and $k \equiv 1/d_{hkl}$. Here $d_{hkl} = d/\sqrt{h^2 + k^2 + l^2}$ where d is the lattice parameter of the material. k is the diffraction vector in reciprocal space and is commonly expressed in units of $2k_0 \equiv 2/\lambda_0$. The results of the Scherrer analysis are shown in Table 1. From the X-TEM results to be discussed, it was found that the shape of the Au clusters is spherical and the shape of the Ag clusters is octahedral. The corresponding values for the Scherrer constant K_w are listed in Table 1 and obtained from [84]. The cluster sizes were derived from the (113) diffraction peaks rather than from the (002) diffraction peaks, because the diffraction peaks of Au and Ag are better resolved from the MgO diffraction peak in the (113) case when compared to the (002) case. Therefore, the cluster sizes as obtained from the (113) are more accurate. From the positions of the Au(002) and Ag(002) peaks, the mean lattice parameter of the nanoclusters perpendicular to the surface was also calculated. It was found that the Au and Ag lattices are extended by 0.4% and 0.9%, respectively, in the direction perpendicular to the surface. This is probably caused by coherency strains, since the lattice parameters of Au and Ag are smaller than the lattice parameter of MgO (see Table 1). Calculation of the tensile strain from the (113) diffraction peaks yields the same result. The MgO:Au and MgO:Ag samples were analyzed with X-TEM. In the MgO:Au specimen, a band of Au clusters was found in a depth range of about 140–300 nm below the surface. Figure 14 shows a typical size distribution of the spherically shaped Au clusters. The size of the gold clusters varies from 2 to 14 nm with a mean size of 4.6 nm (average obtained from 40 clusters). Figure 15 shows a high-resolution TEM image of a few gold clusters. The cube-on-cube orientation relationship is clearly observable as the lines of the MgO lattice spacing continue in the Au nanocluster. X-TEM analysis of the MgO:Ag sample yields a depth range of 180–350 nm below the surface, a size distribution of 6–24 nm, and a mean cluster size of 11 nm (average obtained from 75 clusters). Here it was observed that the clusters have octahedral shapes except for the smallest clusters, which have spherical shapes.

In determining the mean cluster size, the Scherrer XRD method and the TEM observations are in excellent agreement. In the case of the Ag clusters, the Doyle optical method underestimates the cluster size, which might be attributed to additional broadening due to interface effects. Kreibig et al. [86] have shown that embedding of Ag nanoclusters in various matrices leads to additional broadening

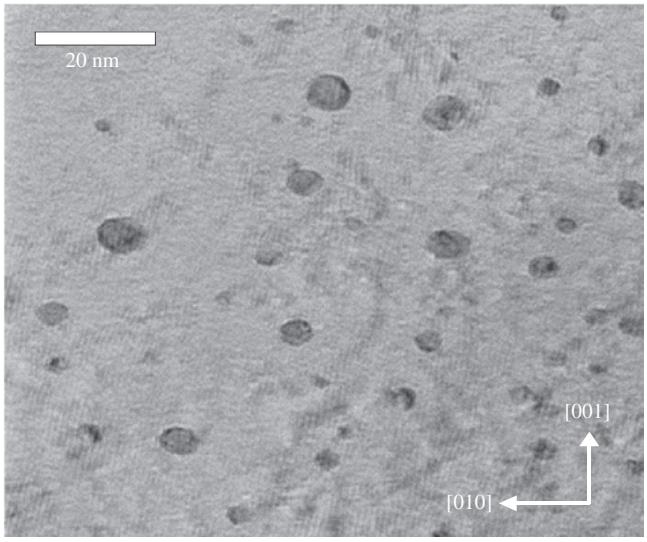

Figure 14. Bright-field TEM image of a part of the Au implanted layer showing a typical size distribution of spherically shaped Au clusters.

of the absorption peaks by a factor of 2 to 4 when compared to absorption peaks of Ag nanoclusters that are not embedded in a matrix, where the additional broadening is dependent on the embedding medium. Contemplating Eq. (34), additional broadening of $\Delta\lambda_{1/2}$ leads to an underestimation of the cluster size. XRD and TEM do not suffer from this artifact. However, both the Doyle method and the Scherrer method may suffer from the effect of size distribution, which, in general, also induces additional broadening.

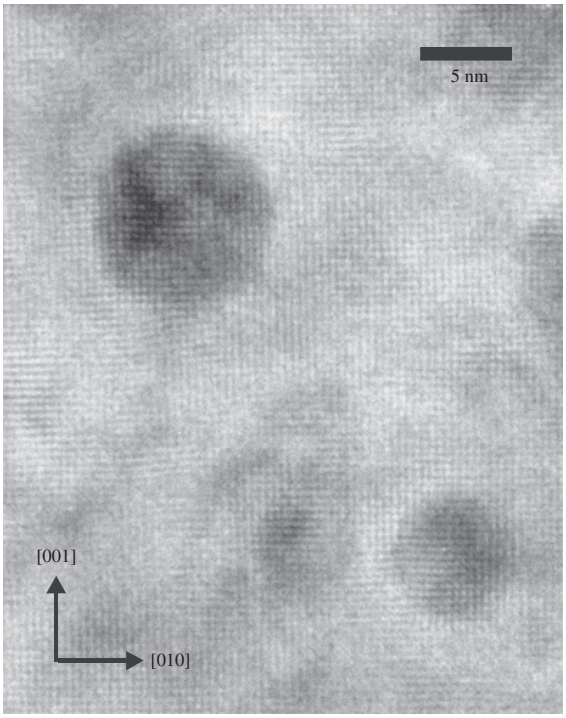

Figure 15. HRTEM image of a few gold clusters in a cube-on-cube orientation relationship with the embedding MgO matrix.

Nevertheless, the results shown in Table 1 show that the Scherrer method still accurately predicts the mean cluster size as observed by means of TEM. It was found here that of these three methods to determine the cluster size, the Doyle optical method is the least accurate. This is caused by the asymmetry of the absorption peaks, inaccurate background subtraction, and systematic underestimation due to interface effects. Scherrer XRD and X-TEM are both accurate methods to determine the mean cluster size, where X-TEM can also provide a good indication of the cluster size distribution. Considering that optical measurements take typically 10 minutes, XRD measurements a few hours, and X-TEM measurements about 3 days (including specimen preparation), Scherrer XRD is probably the best compromise. However, if one is interested mainly in the optical properties important for applications, optical absorption studies are indispensable. As shown in Figure 8 the absorption peak is a factor of 5 higher than in the case of RT implantations and the position of the peak is shifted to shorter wavelengths, $\lambda = 550$ nm. Moreover, in the case of the 1270 K implantation an extra peak at $\lambda = 800$ nm was observed. Assuming that the latter absorption peak results from the nanoclusters formed in the cavity layer the shift in the resonance wavelength can be explained by the elongated shape of the nanoclusters [87]. The photoabsorption measurements are summarized in Tables 2 and 3.

Besides Ag and Au, also copper ion implantation in MgO was studied. Two epipolished (100) MgO samples of size $1 \times 10 \times 10$ mm were implanted with copper ions at energy of 50 keV, sample 1 with a low dose of 1.0×10^{15} ions cm^{-2}, sample 2 with a high dose of 1.0×10^{16} ions cm^{-2}. In sample 2, nanovoids were present prior to copper implantation. These nanovoids were created by 30 keV implantation of 1.0×10^{16} He ions cm^{-2} and subsequent annealing at 1350 K [78]. After copper ion implantation, the samples were annealed isothermally and stepwise in air for 30 minutes, at temperatures of 550, 750, 1000, 1250, and 1350 K. After each annealing step, the samples were analyzed with the PBA technique using a 0–25 keV variable energy positron beam. After the 1250 K and 1350 K annealing step, the 1.0×10^{16} Cu cm^{-2} implanted sample 2 was analyzed using RBS-C. Finally, sample 2 was also analyzed with X-TEM after the 1350 K annealing step. A reference sample was present that underwent the same treatment as sample 2, except that no pre-existent cavities were present prior to copper ion implantation. The X-TEM result of sample 2 was

compared to an X-TEM analysis of sample 3. Sample 3 was implanted with 1.0×10^{16} Cu ions cm^{-2} at energy of 50 keV and was subsequently annealed only at 1250 K for 30 minutes. Sample 3 was used in another experimental series and the annealing took place in a reducing 5% H_2/95% Ar environment. However, the presence of a reducing environment only affects the relative areas of the (100) and (111) facets of the copper precipitate [88]. The sample treatment is listed in Table 4.

The PBA results for samples 1 and 2 are shown in Figure 16. The *S*-parameter corresponds to annihilation of positrons with conduction or valence electrons and is a strong indicator of open volume defects. On top of the figure a calculated depth distribution is shown of the copper ions after implantation and the depth distribution of implantation associated defects. These distributions were calculated with the TRIM code [81]. For comparison between the PBA data and the calculated TRIM data, the *S*-parameter has been plotted as a function of the depth in the material rather than as a function of positron energy. The depth has been calculated using the empirical relationship $\bar{z} = (\alpha/\rho)E^n$ with $\bar{z}$ the mean implantation depth in cm, E the positron energy in keV, ρ the density in g cm^{-3}, and α and n the empirical constants equal to 3.6×10^{-6} and 1.62, respectively [51].

It can be seen clearly that sample 1 (dose 1.0×10^{15} Cu cm^{-2}) results in a single layer at a depth of 0–40 nm under the surface with a quite high *S*-parameter value. These high values can only be obtained with large vacancy-type defects (size > 2–5 nm), where positronium can be formed. In this layer, nanovoids and presumably copper nanoprecipitates are present. In Figure 16, the same data are shown for sample 2 (dose 1.0×10^{16} Cu cm^{-2}). Here it can be observed that there are two peaks in the *S*-parameter graph, indicating that there are two layers of vacancy-type defects in the material, separated by a less defective layer. The formation of these two layers with vacancy-type defects does not depend on the presence of pre-existent cavities. The same PBA results were obtained for a reference sample that underwent the same treatment as sample 2 (implantation of 10^{16} copper ions cm^{-2} and annealing isothermally in air at temperatures of 550–1350 K), except for the fact that no preexistent cavities were present prior to copper ion implantation.

In both samples 1 and 2, the defects are located deeper in the material than predicted by TRIM. This might be the result of the long-range Coulomb interactions that are typical for ionic solids such as MgO. Furthermore, it can be observed that the pre-existent cavities present in sample 2 have been "washed out" by the copper implantation. The defects created by the copper implantation itself are thus dominant to the pre-existent cavities. The intermediate layer can be explained by assuming the presence of copper atoms, which decreases the *S*-parameter signal. An analysis of these PBA results has been performed by employing the positron beam analysis fitting program VEPFIT [49]. For sample 1, a three-layer model is used: first a layer with 0–40 nm depth representing the implantation area, a second layer with 40–130 nm depth representing a "tail" of defects stretching into the material, and the bulk as the third layer. For sample 2,

Table 4. Overview of sample treatment and main observations for three (100) MgO samples.

	Sample 1	Sample 2	Sample 3
Pre-existent cavities	—	1.0×10^{16} ^{3}He ions cm^{-2} and 1350 K annealing [76]	—
Implantation dose	1.0×10^{15} Cu ions cm^{-2} at an energy of 50 keV	1.0×10^{16} Cu ions cm^{-2} at an energy of 50 keV	1.0×10^{16} Cu ions cm^{-2} at an energy of 50 keV
Isothermal annealing	for 30 minutes at 550, 750, 1000, 1250 and 1350 K in air	for 30 minutes at 550, 750, 1000, 1250 and 1350 K in air	for 30 minutes at 1250 K in H_2/Ar gas
Positron beam analysis	• one single layer with vacancy-type defects	• implantation created defects are dominant to pre-existent cavities • two separated layers with large vacancy-type defects	—
RBS-C	—	• diffusion of copper into the bulk during annealing • copper atoms reach the cavities layers at depths over 100 nm • copper atoms epitaxial to the MgO lattice	—
X-TEM		• rectangular voids • no presence of copper precipitates	• copper precipitates next to small rectangular voids

Note: Not shown is a reference sample that underwent the same treatment as sample 2, except for the fact that no pre-existent cavities were present prior to copper ion implantation.

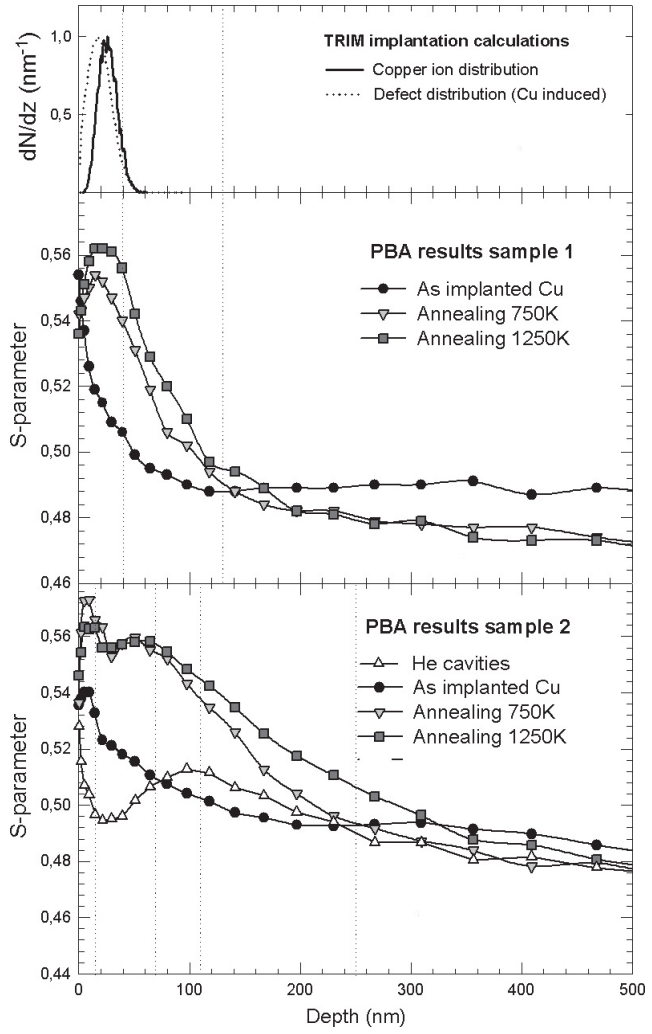

Figure 16. TRIM calculations and positron beam analysis results. Top: TRIM predicted depth resolved distribution of copper atoms and created defects after implantation. Center: *S*-parameter as a function of depth for sample 1 (dose 1.0×10^{15} Cu cm^{-2}) as implanted and after annealing at 750 and 1250 K. Bottom: *S*-parameter as a function of depth for sample 2 (dose 1.0×10^{16} Cu cm^{-2}) before implantation (with pre-existent cavities), as implanted with copper ions, and after annealing at 750 and 1250 K.

a five-layer model is used. The two peaks in the spectrum can only be ascribed to two highly damaged areas in the material, separated by a less defective layer. These are the first three layers, with boundaries at 0–15, 15–70, and 70–110 nm. Here again a "tail" of defects in the material is present from 110 to 250 nm and the fifth layer is the bulk. The *S*-parameters for each layer have been fitted and these values are plotted versus the sample treatment in Figure 17. In the five-layer model used for sample 2, the highly damaged layers 1 and 3 behave quite similar during the annealing procedure, while the intermediate layer 2 remains stable. This implies that the vacancy-type defects in layer 1 and 3 aggregate during the annealing process, and that these big vacancy-type defects are not present in the intermediate layer.

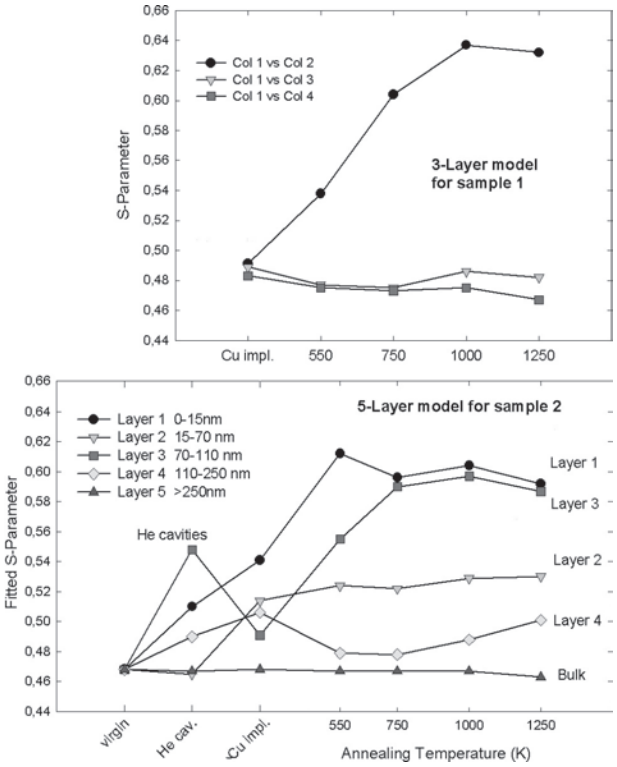

Figure 17. VEPFIT modeled *S*-parameters in each layer versus sample treatment. The "virgin" point is for clean unused MgO samples. Top: three-layer model for sample 1 (see text). Bottom: five-layer model for sample 2 (see text).

The high dose copper implanted sample was analyzed with RBS-C to observe the depth resolved distribution of the implanted copper atoms; the result is shown in Figure 18 and listed in Table 4. The first observation is that the copper atoms diffuse into the bulk during the annealing procedure. The total area under the signal is approximately equal

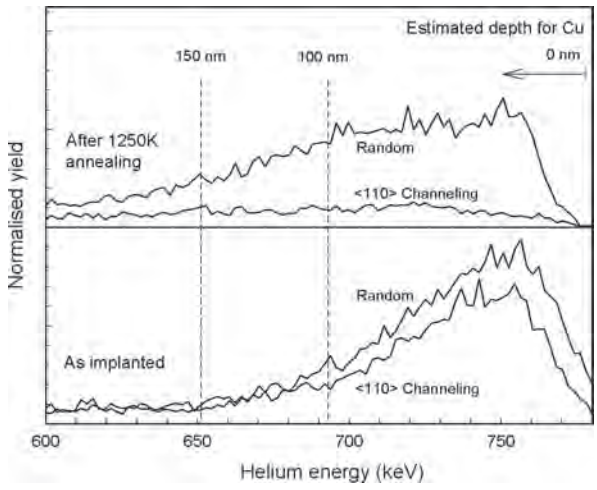

Figure 18. RBS-C results for the 1.0×10^{16} Cu ions cm^{-2} implanted sample 2, "as-implanted" and after the 1250 K annealing step. For both stages in the sample treatment, a random alignment (RBS) and a ⟨110⟩ alignment (channeling) are shown.

for the "as-implanted" and the "1250 K annealing" cases, indicating that the copper does not segregate at the surface. Combining this with the PBA results, the copper atoms have certainly reached the "deep" layer of nanocavities at depths over 100 nm. The second observation is that after the 1250 K annealing step, the copper atom lattice is epitaxial with respect to the MgO host lattice, as the signal is reduced to 20% when a channeling configuration is used. The X-TEM analyses that will be discussed show that copper nanoprecipitates are indeed epitaxial to the MgO host lattice.

From the previous discussion, it becomes clear that copper implantation and subsequent annealing cause a high concentration of defects that aggregate into bigger nanovoids. At the same time, the copper atoms diffuse into the bulk during the annealing process, with the copper atom lattice epitaxial to the MgO lattice. The question now arises as to what configuration the copper atoms are present during the various stages of the sample treatment. To answer this question, sample 2 was analyzed using X-TEM after the 1350 K annealing step. This result was compared to the X-TEM analysis of sample 3 that was implanted with the same dose of 1.0×10^{16} copper ions cm^{-2} but was annealed only once after implantation: at 1250 K for 30 minutes in a reducing environment. The results are displayed in Figures 19 and 20 and listed in Table 4.

Considering the X-TEM results of sample 2 (Fig. 20), it is clear that large cavities (size up to 20 nm) are present at a depth of 200–400 nm and that they are rectangularly shaped. The PBA results do not indicate large cavities at depths over 250 nm, possibly because of the low density of these defects. The rectangular shape of the cavities is probably due to the fact that the surface energy is lowest for the (100) face of MgO: the surface energy of the (100) face is calculated to be 1.2 J m^{-2}, and the surface energy of any other (faceted) MgO surface to be at least 1.8 J m^{-2} [82]. In sample 3 which was annealed at 1250 K in a reducing environment, nanovoids and copper nanoprecipitates coexist and do not form common clusters. Presumably there is a bias for copper

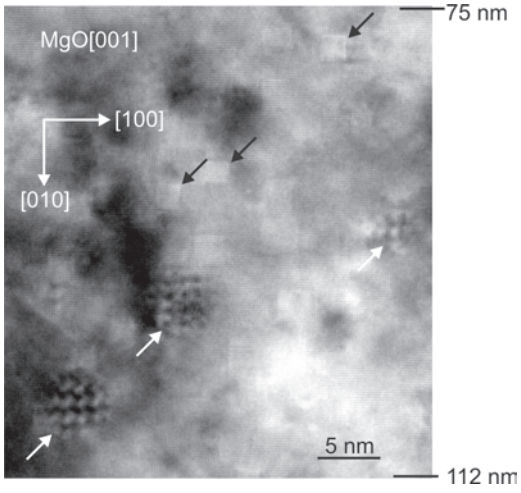

Figure 19. X-TEM result of sample 3 after the 1250 K annealing step. Copper precipitates (white arrows) are present next to small rectangular voids (black arrows) of size 2–3 nm.

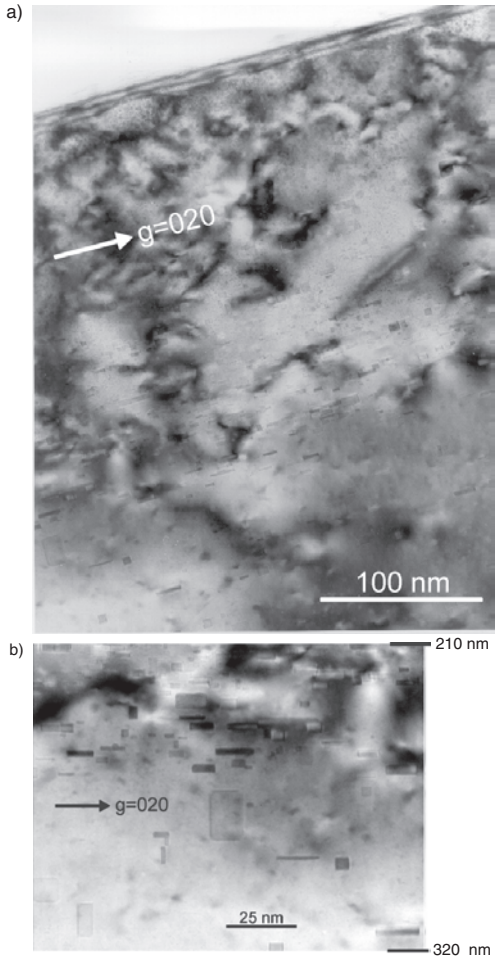

Figure 20. X-TEM result of a high dose implanted sample after one 1350 K annealing step. (a) Overview with surface (depth up to 400 nm). (b) Detail of rectangular cavities.

interstitial-type defects and vacancy-type defects to recombine. Furthermore, the copper precipitates seem to have a spherical shape but in fact the Cu//MgO interface consists of (100) and (111) facets [88]. In the 1350 K annealed sample 2 depicted in Figure 20 copper nanoprecipitates can no longer be found. Possibly the copper atoms are trapped at the internal surface of the nanovoids, although this cannot be put with certainty. An order-of-magnitude calculation on the X-TEM and RBS results yields that in the high-density void areas with a void fraction of 10^{-3}, less than 10% of the internal surfaces can be covered with copper atoms. The copper atoms might also be completely dissolved in the MgO lattice, replacing certain Mg atoms. This is in some concordance with results presented by Zimmerman et al. [82] on copper precipitates in MgO. These workers observed that the absorption peak disappeared after annealing at 500 K for 1 h, assuming dissociation of the copper precipitates. In this work, the dissociation of the copper precipitates occurs only after high temperature annealing. A feasible explanation for this discrepancy is that the formation and dissociation of metal precipitates depends on the annealing time and temperature as well as on the presence of a (non)reducing environment. The optical absorption spectroscopy technique

used by Zimmerman et al. was not used in this work because the implantation doses used are too low to produce significant absorption peaks.

The major conclusions that can be drawn from the above discussion are:

- A copper implantation dose of 1.0×10^{15} ions cm^{-2} results in a single layer of nanovoids; a copper implantation dose of 1.0×10^{16} ions cm^{-2} results in two layers of nanovoids. The defects induced by 50 keV implantation of 1.0×10^{16} cm^{-2} copper ions dominates the presence of pre-existent nanovoids at depths over 100 nm.
- The copper atoms diffuse into the bulk during annealing, reaching the nanovoid area at depths over 100 nm.
- Copper nanoprecipitates are epitaxial to the MgO host lattice and can coexist with nanovoids.
- Nanovoids formed in MgO are rectangularly shaped.
- After annealing at high temperature and/or for long periods of time the copper precipitates dissociate and resolve into the MgO host lattice

4. POSITRON CONFINEMENT IN EMBEDDED LITHIUM NANOCLUSTERS

4.1. Introduction

Metal and semiconductor nanoclusters are of interest because of their linear and nonlinear optical properties but also because of their electronic features as quantum dots [89–91]. The optical and electronic properties are strongly dependent on the nanocluster size, which is due to quantum size effects such as the confinement of surface plasmons and the discretization of energy levels below a certain cluster size. The engineering of quantum dots offers great opportunities for the future as the material properties, such as the bandgap and melting temperature of semiconductor clusters, can be tuned by varying the cluster size [92].

In this field positron confinement is a newly investigated type of quantum confinement in nanoclusters and can serve as a powerful tool to investigate the electronic structure of nanoclusters. Positrons are known as sensitive self-seeking probes of defects in materials and can provide detailed information on the electronic structure of defects or bulk materials [93, 94] such as the morphology of Fermi surfaces [95, 96]. The concept of positron confinement was introduced by Nagai et al. [97]. Under certain conditions, nanoclusters act as a potential well to positrons (i.e., the wave function of the positron is spatially confined within the nanocluster in three dimensions). A positron confined in a nanocluster will annihilate there and will thus provide unique information on the electronic and crystal structure of the nanocluster, which can be quite different from the bulk material of the atoms constituting the nanocluster. Previously, positron confinement in Cu nanoclusters embedded in Fe was investigated [97]. By analysis of the S and W parameters of the Doppler broadening curves (see Section 2) these authors found that, after thermal aging, approximately 90% of all positrons annihilate in the Cu nanoclusters while Cu makes up only 1.0 wt% of the Fe:Cu composite material. The positron confinement was confirmed by coincidence Doppler broadening (CDB) measurements and was ascribed to a difference in positron affinity between Cu and Fe of 1.0 eV. If the positron affinity of the cluster material is lower than the positron affinity of the host material, the cluster will act as a potential well to positrons, as will be explained in Section 4.2.

In this section positron confinement is discussed in Li nanoclusters embedded in monocrystalline MgO. In order to study the material properties of nanoclusters, it can be useful to embed nanoclusters in stable and inert ceramics such as MgO, which can be achieved by ion implantation and subsequent annealing [98]. It is expected that the wide bandgap material MgO (7.8 eV) does not interact with the electronic structure of metal and semiconductor clusters [98]. It is also optically transparent in a large frequency band, which facilitates optical studies. Furthermore, the high melting point of MgO (3070 K) allows a study of phase transitions of nanoclusters. The optical and structural properties of Li nanoclusters embedded in MgO have been investigated by photoabsorption spectroscopy, transmission electron microscopy, and electron diffraction [99]. It was found that small Li clusters (<20 nm) adopt the unusual fcc crystal structure while large Li clusters (>40 nm) adopt the regular body-centered cubic (bcc) crystal structure. This is a so-called extrinsic size effect: small Li clusters adopt a different phase in order to fit better in the MgO matrix. The lattice parameter of fcc lithium is closer to that of MgO, which reduces the formation energy of the MgO//Li interface. The fcc phase for bulk Li is otherwise only observed at low temperatures and high pressures [100, 101]. A similar effect was reported in the work mentioned previously [97] where the crystal structure of Cu nanoclusters embedded in Fe is expected, on the basis of lattice parameter similarity, to be bcc rather than fcc.

The nanoclusters shown in this section were created by ion implantation and subsequent annealing. It was shown previously in [102] that Doppler broadening PBA and 2D-ACAR measurements show a very high fraction of positron annihilations in Li nanoclusters, indicating possible positron quantum confinement. In the following we will first discuss the concepts of positron affinity and the positronic potential well. Furthermore, the positron affinities of MgO and fcc and bcc lithium are calculated in order to determine the drop of the positronic potential at the MgO//Li interface. The confinement of positrons in Li nanoclusters is discussed using the experimental and computational results.

4.2. Theoretical Methods and Concepts

As explained in Section 2 annihilation of positrons with electrons in solids yields information on the momentum distribution of these electrons. The electronic momentum distribution is reflected in the Doppler broadening of the 511 keV annihilation peak. Positron annihilation with low momentum valence or conduction electrons results in a small Doppler shift, contributing to the center of the peak. Annihilation with high momentum core electrons results in a large Doppler shift, contributing to the wings of the 511 keV annihilation peak. The shape of the 511 keV peak is characterized by the so-called S and W parameters [8]; see also section 2. When combined with a slow positron beam, this

method is called Doppler broadening positron beam analysis. The S and W parameters can be considered as a specific bulk property for every material. In the case of composite materials (e.g., metallic nanoclusters embedded in insulating oxides), the overall annihilation distribution can be modeled as a linear combination of the annihilation distribution of each of the composing materials. The S parameter of the composite material then equals

$$S_{\text{comp}} = f_{\text{cluster}} S_{\text{cluster}} + f_{\text{host}} S_{\text{host}} \tag{36}$$

where S_{cluster} and S_{host} are the bulk S parameters of the nanoclusters and the embedding material, respectively. f_{cluster} and f_{host} are the fractions of annihilation in the clusters and in the embedding host material ($f_{\text{cluster}} + f_{\text{host}} = 1$). Here it is assumed that the composite material is defect-free and that positrons do not annihilate at the cluster–host interface. Of course, the principle of superposition of annihilation distribution can be applied to other positron annihilation methods as well, including CDB and 2D-ACAR. Equation (36) applies to a "bulk" composite material. In the case of, for example, an ion-implanted layer investigated using a positron beam, the S parameter obtained at certain positron implantation energy consists of contributions from the surface and various layers,

$$S(E) = f_{\text{surf}}(E)S_{\text{surf}} + f_1(E)S_1 + f_2(E)S_2 + ::: + f_n(E)S_n \tag{37}$$

Here the material consists of n layers and the distribution of the fractions ($f_{\text{surf}} + f + ::: + f_n = 1$) depends on the positron energy E. Please note that Eq. (36) refers to defect (or material) fractions while Eq. (37) refers to layer fractions. Formulae analogous to Eq. (36) are valid for the W parameter. Fitting methods such as VEPFIT and SWAN [103] exist, which yield accurate values for the S and W parameters of the various layers and the fractions of Eq. (37) positrons annihilating in these layers as a function of positron implantation energy. This is achieved by solving the time-averaged diffusion equation [8]. Once the S parameter of a certain layer has been found using the VEPFIT code, Eq. (36) can be used in order to analyze further the defect fractions within that layer.

Assuming that the nanoclusters are homogeneously distributed, the annihilation fractions f_{cluster} and f_{host} are determined by the diffusion length of the positrons, the concentration of clusters, and the difference in positron affinity between both materials. Although the overall concentration of atoms constituting the clusters in the host material is usually small, the annihilation fraction in the clusters can be high with respect to the annihilation fraction in the host material when certain conditions with respect to the positron affinities are met.

Since the Fermi levels of the materials in contact become equal [104], the positron affinity is defined as [105]

$$A_+ = \mu_- + \mu_+ = -(\varphi_- + \varphi_+) \tag{38}$$

where μ_- and μ_+ are the electron and positron chemical potential, and φ_- and φ_+ are the electron and positron work functions, respectively. Values for the positron affinity are commonly expressed in eV and are negative for most materials. At the interface between two materials, positrons will encounter a potential step that is equal to the difference in the positron affinities of both materials [105]

$$\Delta E_+^{AB} = A_+^A - A_+^B \tag{39}$$

A necessary condition for positron confinement in a cluster (A) embedded in a host (B) is that $\Delta E_+^{AB} > 0$. Then the cluster represents a potential well for positrons. However, there must be at least one bound state in such a well, which determines the minimum size of the cluster. Assuming a spherical potential well this condition reads [105]

$$R > \frac{\pi\hbar}{\sqrt{8m_0\Delta E_+^{AB}}} \tag{40}$$

where R is the radius of the cluster and m_0 is the positron mass. In Figure 21, several possibilities for the positron potential energy as a function of the distance from the center of the nanocluster are plotted schematically. In Figure 21a, $\Delta E_+^{AB} > 0$. Here the nanocluster acts as a positronic potential well with depth ΔE_+^{AB}. Positrons can be confined in this nanocluster provided that condition (40) is satisfied. In Figure 21b, $\Delta E_+^{AB} < 0$. The nanocluster acts as a three-dimensional potential barrier and cannot confine positrons. Figure 21c shows a situation where the positron affinity of the nanocluster material is lower than the positron affinity of the host material, but positron confinement is unlikely as the positron is trapped at the interface. Often there is some lattice mismatch due to the different crystal structures of the cluster and the embedding matrix. At the interface, this may result in structural and electronic defects, which can act as a trap for positrons. In the case of, for example, a Si//SiO2 interface, there is evidence of preferential trapping at this interface [106].

Usually, the positron affinity is determined experimentally by measuring the electron and positron work functions

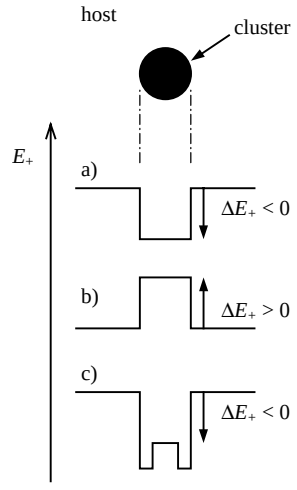

Figure 21. Diagram of the positron potential energy as a function of the distance from the center of the nanocluster. (a) Nanocluster acts as a positronic potential well with depth ΔE_+. (b) Nanocluster acts as a potential barrier with step size ΔE_+. (c) Positron trapping at defects at the cluster–host interface.

[107] [see Eq. (38)]. Alternatively, the positron affinity can be derived from the positronium formation potential ε_{Ps}, which can be determined experimentally as the negative of the maximum kinetic energy of positronium atoms ejected from the sample into vacuum. The positronium formation potential is related to the positron affinity as

$$\varepsilon_{Ps} = \phi_+ + \phi_- - 6.8\ \text{eV} = -A_+ - 6.8\ \text{eV} \qquad (41)$$

where 6.8 eV is the binding energy of the positron–electron pair constituting a positronium atom in vacuum. Two experimental time-of-flight studies on MgO [108] report positronium emission peak energies of 4.5 and 2.6 eV, respectively. Applying Eq. (41) then yields values for the positron affinity for MgO of −2.3 and −4.2 eV, respectively. Apart from the quantitative discrepancy, the interpretation of these results is complicated by the fact that the emission energy spectra are quite broad. Furthermore, the unknown binding energy of Ps at the MgO surface (MgO is too dense a material for Ps to be formed in the bulk) and the uncertainty about whether valence or conduction electrons participate in Ps formation obscure a direct translation to the positron affinity for MgO [108, 109]. Summarizing, determining positronium formation potentials at the surface of insulating oxides such as MgO is experimentally difficult, which results in the different values reported in the literature.

Therefore, we turn to *ab initio* calculations to determine the positron affinities. As the calculation of electron and positron work functions requires a careful treatment of the material's surface, we prefer to determine A_+ through the electron and positron chemical potentials [see Eq. (38)], the calculation of which is a standard procedure in "bulk" electronic structure computational methods. It should be noted that A_+ is a bulk characteristic of a material (see [94, 105] for details). For the calculation of the positron affinities and lifetimes in the materials studied [94] the linear-muffin-tin-orbital (LMTO) method was used within the atomic sphere approximation (ASA) [110, 111]. Within the framework of this method the crystal is divided into slightly overlapping spheres (called atomic spheres) centered at the positions of the nuclei. The sum of the volumes of the spheres is equal to the volume of the crystal. However, the rock salt structure of MgO is not as closely packed as the fcc and bcc structures considered for Li [112]. Therefore we had to introduce empty spheres [110] into the MgO lattice to describe properly the distribution of the electron and positron densities and potentials in the interstitial region. We considered the case where the empty spheres occupied 30% of the cell volume. In the following this case is referred to as MgO II, in contrast to MgO I where no empty spheres were included for comparison. Choosing the 30% filling with empty spheres leads to a reasonable overlap between neighboring Mg–O spheres in the MgO lattice [110]. The lattice constants a_0 used in our calculations are collected in Table 5. As for the positron calculations, in Li we used the parametrizations of the positron correlation potential and enhancement factor given by Boronski and Nieminen [113] within the framework of the local density approximation (LDA). The corresponding results will further be denoted as LDA, whereas the results obtained using the generalized gradient approximation [114] will be marked GGA. In the case of MgO we also employed the GGA, but instead of the LDA we made use of the so-called semiconductor (SM) and insulator (IM) models [115], which take into account incomplete positron screening in nonmetallic systems (i.e., systems having a bandgap; MgO is an insulator). A high frequency dielectric constant $\varepsilon_\infty = 3.0$ was employed in the SM and IM calculations. This constant was derived from the optical constants of MgO [116] in the visible spectrum $(n, k) = (1.73, 0.00)$ using the relationship $\varepsilon_\infty = n^2 - k^2$. Finally, the exchange-correlation potential for electrons parametrized according to Von Barth and Hedin [117] was used in the calculations of the electronic structure of MgO and Li.

Table 5. Structural data.

	Structure	a_0 (Å)	At. volume (Å^3)
MgO	rocksalt	4.212[a]	—
Li	fcc	4.40[a]	21.3
Li	bcc	3.51[b]	21.6

[a] From "Handbook of Chemistry and Physics," 56th ed., p. B-214. CRC Press, Boca Raton, FL, 1975.
[b] From [112].

For completeness, the positron lifetime (τ) in defect-free MgO and Li was calculated employing the well-known formula [94]

$$1/\tau = \pi r_0^2 c \int n_-(\mathbf{r}) n_+(\mathbf{r}) \gamma[n_-(\mathbf{r})] d\mathbf{r} \qquad (42)$$

Here, n_- and n_+ denote the electron and positron density, respectively, and γ stands for the enhancement factor describing the pile up of electrons around a positron (r_0 is the classical radius of the electron and c the speed of light). The form of γ within the LDA, GGA, SM, and IM approaches was used in the corresponding calculations. Other computational details are described in [118].

4.3. Experiments

Epi-polished monocrystals of MgO(100) of size $10 \times 10 \times 1$ mm^3 were implanted with 1.0×10^{16} cm^{-2} ^{6}Li ions at an energy of 30 keV. After the implantation the crystals were annealed in air in steps from room temperature to 1200 K. The annealing temperatures were 550, 750, 950, 1100, and 1200 K for periods of 30 min. Photoabsorption spectroscopy was used to detect Mie plasmon resonance due to the presence of lithium nanoclusters. Furthermore, the neutron depth profiling (NDP) technique, using the nuclear reaction $^6\text{Li}(n, \alpha)^3\text{H}$, was applied to determine the depth profile of ^{6}Li after the annealing steps. The results of these two methods have already been discussed in an earlier paper, which focused on the defect evolution during the annealing procedure [102]. In the present work we address the confinement of positrons in lithium nanoclusters, and therefore only the positron experimental techniques applied to the samples are presented.

After ion implantation and after each annealing step, the samples were analyzed with Doppler broadening PBA using a monoenergetic 0–30 keV positron beam. The energy resolution of the PBA setup is 1.2 keV. After the 950 K annealing step, one of the samples was also analyzed with 2D-ACAR.

The 2D-ACAR setup of the Anger-camera type is coupled to a high-intensity positron beam with a flux of 8×10^7 e^+ s^{-1}, allowing depth-selective 2D-ACAR [119]. The angular resolution of this system is 1.1×1.4 mrad^2. The sample measured with 2D-ACAR was identical to the other samples (which was ascertained by means of photoabsorption spectroscopy and PBA), apart from a 15-nm-thick layer of Al deposited on the sample surface after the 950 K annealing step to prevent buildup of electric charge. The 2D-ACAR distribution was collected at a positron implantation energy of 4 keV, which corresponds to a mean positron implantation depth at the center of the layer containing the lithium nanoclusters. This energy was chosen on the basis of depth profiling performed on the same sample by means of Doppler broadening PBA. Furthermore, an MgO bulk 2D-ACAR distribution was collected for reference purposes from an as-received sample of MgO(100). The use of a conventional ^{22}Na source in this latter measurement renders any surface effects negligible.

4.4. Results

4.4.1. Positron Beam Analysis

Figure 22 shows the *S* and *W* parameters as a function of positron implantation energy after lithium ion implantation and after annealing at the indicated temperatures. The solid lines represent the result of simulations performed with the VEPFIT code, as will be discussed. The *S* parameter shows a spectacular increase in the lithium ion implantation range (corresponding to a positron energy of 3–4 keV) after annealing at temperatures of 750 and 950 K. At higher annealing temperatures the *S* parameter in the ion implantation layer drops considerably and after annealing at 1200 K the peak almost disappears in this range. At larger depths (corresponding to positron implantation energies of 7–15 keV in Fig. 22), the *S* parameter drops below the bulk value of MgO (i.e., 0.468) after annealing at 1200 K. Such a drop of the *S* parameter below the bulk value of MgO as a result of ion implantation and subsequent annealing has not been observed before and we attribute this effect to positron annihilation in small Li-related defects, as will be discussed in more detail.

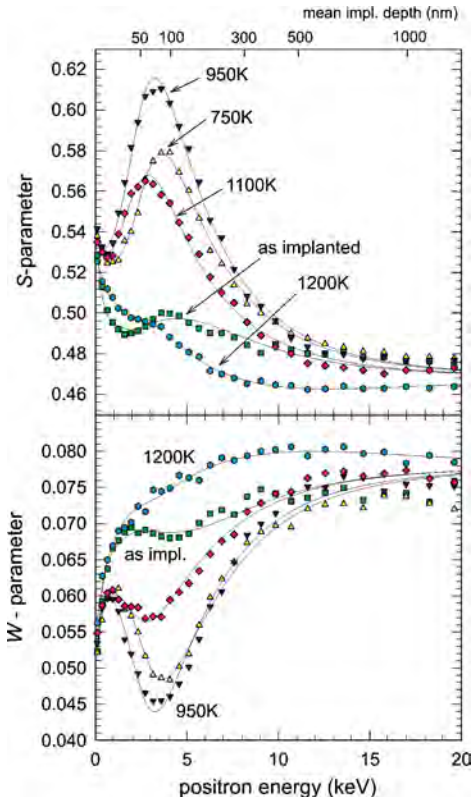

Figure 22. *S* and *W* parameters as a function of positron energy. The solid lines are the result of VEPFIT modeling.

The experimental *S* and *W* parameter curves shown in Figure 22 have been fitted using the VEPFIT code in order to gain more insight into defect evolution and in order to derive the contributions of the various layers to the annihilation distribution. A four-layer model was used. The principal defect types and the corresponding diffusion lengths that were used as input to the VEPFIT code are listed in Table 6. The choice for this model is mainly based on defect analysis performed on previously ion implanted MgO samples that were analyzed with techniques such as transmission electron microscopy, positron annihilation spectroscopy, and neutron depth profiling [120, 121]. In particular, there is a subsurface layer containing the ion-implanted species and the main implantation defects (layer 2). Dislocation loops are formed at smaller depths in the MgO top layer (layer 1) and below the ion implantation layer [120]. The presence of dislocation loops in MgO does not affect the *S* parameter significantly, but it does shorten the diffusion length compared to the bulk values. In the layer below the ion implantation layer (layer 3) there are not only dislocation loops but also a tail of implanted species as observed by NDP [102], possibly because of channeling effects. It was estimated that about 6% of the implanted species end up in this range. Due to the low atomic concentration of Li in this layer, we expect small Li-related defects rather than metallic Li clusters (see the discussion on the defect evolution of layer 3 in Fig. 22). The fourth layer is the MgO bulk. In order to monitor the defect evolution, the *S* and *W* parameters of layer 2 (ion implantation layer) and layer 3 (ion implantation tail) were fitted. The layer boundaries determining the position of the ion implantation layer have been allowed to relax as the *S* parameter peak shifts to somewhat lower positron energies when the annealing temperature increases (compare, for example, the 750 and 1100 K *S* parameter curves in Fig. 22). This might be due to a recombination of implanted lithium atoms and lithium clusters with vacancies

Table 6. VEPFIT model used to fit the *S* and *W* parameter curves shown in Figure 21.

	Depth (nm)	Diff. length (nm)	*S* par.	*W* par.	Description
Layer 1[a]	0–d_1	50	0.468	0.078	MgO top layer
Layer 2	d_1–d_2	15	fitted	fitted	MgO:Li
Layer 3	d_2–300	50	fitted	fitted	ion impl. tail
Layer 4	>300	100	0.468	0.078	MgO bulk

[a] In the case of the 1200 K annealing step, layer 1 was omitted ($d_1 = 0$).

and small vacancy clusters created by ion implantation. The main ion implantation damage is always located at slightly smaller depths than the range of the implanted ions.

The fitted curves are depicted as solid lines in Figure 22. The agreement with the experimental results is reasonable, considering the fact that the same model has been applied to all data sets. In the case of the S and W graphs corresponding to the 1200 K annealing step the MgO top layer was omitted since it was not possible to distinguish between the ion implanted layer and the MgO top layer. The fitted results yield boundaries d_1 and d_2 of the ion implanted layer of approximately 45 and 115 nm respectively, shifting to slightly lower values with increasing annealing temperature. The fitted values of S and W are presented in Figure 23b.

Figure 23 shows the S parameter plotted vs the W parameter. Every bulk material and every defect type has a characteristic S and W parameter. A few of these typical S, W combinations are indicated in Figure 23 with open circles and are called cluster points. The cluster points corresponding to pure MgO and bcc Li were determined experimentally from bulk samples of these materials. By plotting experimental or fitted S–W values in an S–W plot with, for example, the positron energy as the running parameter, the defect status at a certain depth in the material can be analyzed by means of comparison with the characteristic S–W cluster points for defects and bulk materials. In Figure 23a, the experimentally obtained S–W parameters are plotted with the positron energy as the running parameter. Figure 23b shows the S–W plot using the fitted S and W values for every layer with the annealing treatment as the running parameter. The main difference between the two plots is that in Figure 23a, all layers contribute to the experimental S–W points, while in Figure 23b the S–W parameters are layer-resolved with the aid of the VEPFIT code; that is, the S and W parameters corresponding to only one layer are shown [see also Eq. (37)].

Considering the defect evolution of layer 3 (ion implantation tail) in Figure 23b, it is clear that the S, W combination moves away from the bulk Li cluster point during the annealing procedure, while the NDP measurements show that a small fraction (approximately 6%) of the implanted Li atoms is present in this layer. Therefore, the Li atoms should be in an electronic state that is different from metallic bulk Li.

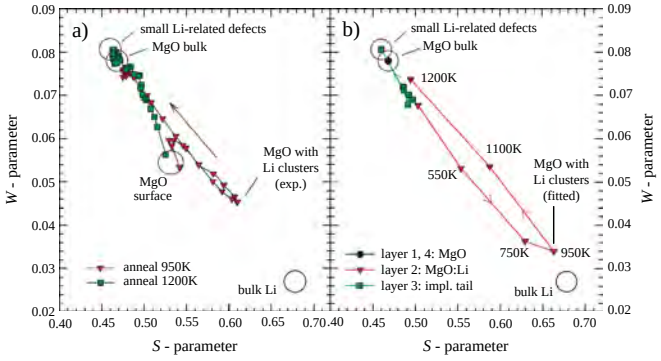

Figure 23. (a) SW plot with the positron energy as running parameter. The experimental data are plotted for the 950 and 1200 K annealing step only. (b) SW plot with the annealing treatment as running parameter. The fitted values are plotted for all four layers (see Tab. 6).

Research performed previously on Li-doped MgO crystals has revealed defect types such as Li_2O precipitates, isolated Li^+ ions, and so-called $[Li]^0$ centers [122]. These defects will yield S–W parameters that are quite different from bulk Li or bulk MgO. Another observation that can be made with respect to Figure 23b is that the S–W characteristic points corresponding to the ion implantation layer (layer 2) move roughly along the line connecting the MgO bulk cluster point and the bcc bulk Li cluster point. It is also clear that the experimental S–W point corresponding to MgO containing Li clusters after the 950 K annealing step in Figure 22a does not reach the fitted S–W combination of layer 2 (MgO containing lithium clusters) after the 950 K annealing step in Figure 23b. Due to the broadness of the positron implantation profile and positron diffusion processes, only a certain fraction of the positrons implanted at 3.5 keV (with a mean implantation depth that corresponds to the center of the implantation layer) annihilate in the MgO:Li layer. This is also clear from Figure 24 where the fraction of annihilations per layer is plotted as a function of positron implantation energy. It is found that 69% of the positrons with 3.5 keV implantation energy annihilate in MgO:Li (layer 2).

Calculation of the efficiency of positron confinement in Li nanoclusters using Eq. (36) requires numerical values for the S parameter of the composite MgO:Li material (i.e., the S parameter of layer 2), the S parameter of bulk lithium, and the S parameter of bulk MgO. The S parameter of the MgO:Li layer ($S_{MgO:Li}$) after the 950 K annealing step was found to be 0.662 by means of VEPFIT modeling (Tab. 6, Fig. 23b). The S parameters of bulk lithium and bulk MgO were measured using the same Doppler broadening PBA setup and were evaluated to be 0.678 for polycrystalline bulk bcc Li and 0.468 for monocrystalline bulk MgO. The measurement of the S parameter of bulk Li was carried out at a positron implantation energy of 27 keV. This energy is sufficiently high to make the contribution of the lithium oxide layer at the surface to the measured distribution negligible, which was ascertained by means of positron depth profiling. The S parameter for bulk lithium is much higher than the S parameter for bulk MgO. This is due to the rather

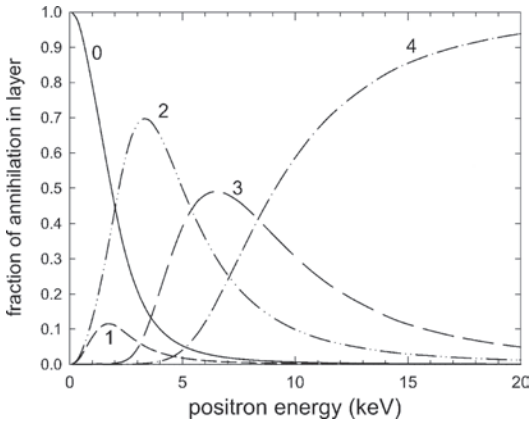

Figure 24. Layer fractions of the PBA sample as a function of the positron implantation energy. Annihilation fractions per layer were found by VEPFIT modeling of the PBA data obtained after the 950 K annealing step. The numbers indicate the layer number as listed in Table 6. Layer 0 is the surface (thermal and epithermal positrons).

small Fermi cutoff for metallic lithium of 0.58 a.u. [123] (equivalent to 4.2 mrad) while the window for the measurements of the S parameter is set at energies corresponding to ± 3.2 mrad. Consequently, most of the Doppler broadening curve falls within the window and the S parameter for lithium is therefore relatively high. This is also clear from Figure 25 where the experimentally obtained 511 keV annihilation peaks of bulk MgO, bulk bcc Li, and MgO:Li are displayed. The fraction of annihilations in lithium can be calculated rewriting Eq. (36) and using $f_{\mathrm{MgO}} + f_{\mathrm{Li}} = 1$

$$f_{\mathrm{Li}} = \frac{S_{\mathrm{MgO:Li}} - S_{\mathrm{MgO}}}{S_{\mathrm{Li}} - S_{\mathrm{MgO}}} \tag{43}$$

Here it should be realized that contributions from the surface and any other layers have already been filtered out by the VEPFIT code. Substituting the S parameters mentioned previously then yields a fraction of annihilations in lithium, f_{Li}, of $92 \pm 5\%$. This shows a very effective confinement of positrons in Li nanoclusters, which occupy only 1.3 at% of the MgO:Li layer. In the previous calculation, it is assumed that the S parameters for bcc Li and fcc Li do not differ significantly and that the S parameter of the lithium nanoclusters (without surrounding MgO) is similar to the S parameter of lithium bulk. A question that now arises is whether the positron is really confined within the Li nanocluster or whether it is trapped at the MgO//Li interface prior to annihilation.

4.4.2. 2D-ACAR

The 2D-ACAR (see Section 2) results are shown in Figure 26. Part (a) shows the anisotropic contribution [124] of the MgO bulk distribution (total number of counts 6.4×10^7) obtained from an as-received single crystal of MgO(100). Part (b) of Figure 26 shows the anisotropic part of the 2D-ACAR distribution obtained from a Li-implanted sample after annealing at 950 K (total number of counts 1.0×10^7). This distribution was collected at 4 keV positron

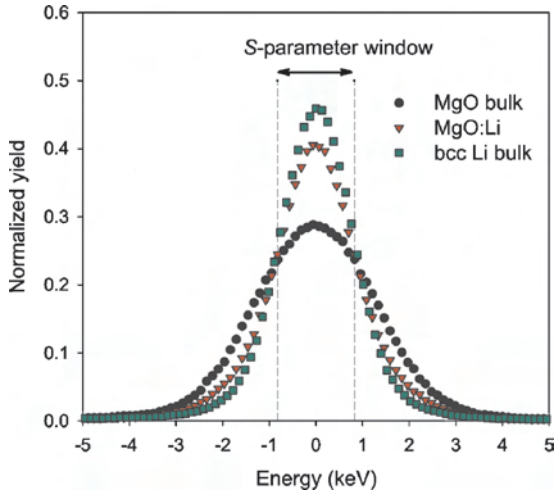

Figure 25. Experimentally obtained 511 keV Doppler broadening peaks for bulk MgO, bulk bcc Li, and MgO containing Li nanoclusters (after the 950 K annealing step).

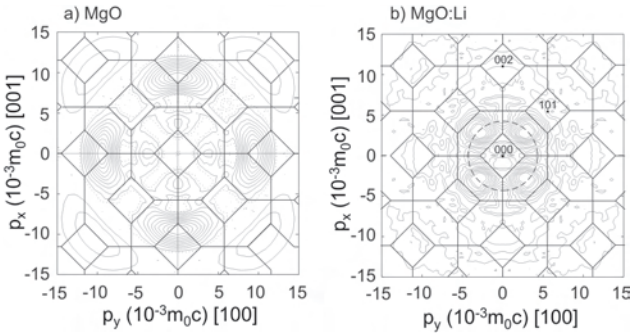

Figure 26. Anisotropic part of the [010]-axis projected momentum distribution obtained by 2D-ACAR measurements for (a) bulk MgO(100) and (b) MgO containing Li crystalline nanoclusters. The average Fermi cutoff for bulk Li of 4.3 mrad (see Section 4.2) is displayed as a dashed circle. The distributions have been symmetrized by reflection with respect to the (100) and (001) mirror planes. The contour interval is 10% (5%) of the peak height for solid (dotted) contours. The projection of the Brillouin zones is shown based on the lattice parameters of MgO (a) and fcc Li (b).

implantation energy, which corresponds to a mean positron implantation depth at the center of the lithium nanocluster layer (MgO:Li material). This energy was chosen on the basis of depth profiling performed on the 2D-ACAR sample by means of Doppler broadening PBA. Both distributions have been corrected for the difference in resolution between the directions parallel and perpendicular to the sample surface (1.1×1.4 mrad^2) and were symmetrized by reflection with respect to the (100) and (001) mirror planes. The anisotropy plot of the MgO:Li layer is strikingly different from the bulk MgO anisotropy plot. The bulk MgO anisotropy is still observable in Figure 26b, but another, very dominant anisotropic contribution is present in the central part of the figure. The major part of this contribution has a nearly perfect fourfold symmetry with peaks positioned near the Fermi radius of lithium. Therefore, we attribute the 2D-ACAR anisotropy in the center of Figure 26b to annihilation in bcc or fcc lithium clusters. Treilleux and Chassagne [112] found by means of electron diffraction and X-TEM analysis that, depending on the nanocluster size, metallic lithium nanoclusters in MgO can adopt either the fcc or a rotated bcc crystal structure. Whether the lithium clusters found in the 2D-ACAR distribution of Figure 26b are in the fcc or rotated bcc phase has not yet been established unequivocally. The fact that the anisotropic contributions displayed in Figures 26a and 13b both have the same symmetry and identical mirror planes shows that there is a distinct orientation relationship between the crystalline Li clusters and the MgO host matrix. Therefore, the lithium clusters will be coherent or semicoherent with the MgO crystal lattice. Comparing the ion implantation settings and annealing temperature used in this work with the experimental parameters of [112], the presence of fcc lithium is most likely. In that case, the lithium nanoclusters are in a simple cube-on-cube orientation relationship with the MgO host matrix. Cube-on-cube bcc Li is excluded by the anisotropy in Figure 26b as it would produce peaks along the $\langle 100 \rangle$ directions. The anisotropy in the central part of Figure 26b agrees very well with the results of preliminary calculations

performed on the momentum distribution of fcc Li using the KKR method. The free electron Fermi sphere for fcc Li ($a_0 = 4.4$ Å, cf. Table 5) is displayed in Figure 26b as a circle of radius 0.591 a.u., equivalent to 4.3 mrad. The peaks in the anisotropy then derive from bulges of the Fermi surface pointing toward the hexagonal Brillouin zone faces.

The fraction of positron annihilations in Li nanoclusters f_{Li} was also estimated from the 2D-ACAR distribution, using Eq. (36) in combination with a VEPFIT layer fraction analysis (giving the relative contributions of the layers to the annihilation distribution at a certain positron implantation energy). The fraction found (90%) was not significantly different from the one derived from the PBA results discussed in Section 4.4.1.

4.4.3. Positron Affinities

It was found that the fraction of annihilations in Li as deduced from the Doppler broadening PBA spectra is $92 \pm 5\%$ in the ion implanted layer. It will be shown that the effective positron confinement can be ascribed to the different positron affinities of MgO and Li. These positron affinities were calculated using the various models discussed in Section 4.2. The results of calculations of the positron lifetime, affinity, and electron and positron chemical potentials for Li are shown in Table 7. Very similar lifetimes and affinities are obtained for bcc and fcc Li. This is related to the fact that the atomic volumes of bcc and fcc Li are almost equal (Tab. 5). The affinities found are in good agreement with theoretical values from the literature [105, 125].

The electron and positron chemical potentials, positron affinity, and lifetime for MgO determined using three different models are given in Table 8. The IM and GGA approaches yield values for the bulk lifetime that are close to the experimentally obtained lifetime τ of 150–170 ps in MgO [126, 127], which is not the case for the SM results. We note that the incorporation of empty spheres into the MgO lattice (MgO II case) leads to a slight increase of the lifetime values because the interstitial space is better described compared to the case without empty spheres (MgO I). Table 8 also includes the calculated lifetimes by Puska et al. [115]. In the present work, the lifetimes found using the SM and the IM are somewhat higher and lower, respectively, than the values reported by Puska et al., while the same SM and IM models have been used. This is mainly due to a different treatment of the core electrons. In addition, the electron density of MgO in [105] was approximated by the superposition of atomic densities without consideration of the charge transfer between Mg and O atoms. Anyhow, it turns out that the semiconductor model does not describe reasonably the lifetime experiment (both in the present work and in [105]) so that we will not consider this model when calculating the difference between positron affinities of MgO and Li.

Table 7. Calculated positron lifetime, positron affinity, and electron and positron chemical potentials for bcc and fcc Li.

		LDA			GGA		
	μ_- (eV)	τ (ps)	μ_+ (eV)	A_+ (eV)	τ (ps)	μ_+ (eV)	A_+ (eV)
bcc Li	−2.8	299	−5.2	−8.0	283	−5.0	−7.8
fcc Li	−2.8	297	−5.3	−8.1	282	−5.0	−7.8

Table 8. Calculated lifetimes, positron affinities, and electron and positron chemical potentials for MgO without empty spheres (MgO I) and including empty spheres (MgO II).

	GGA				SM			IM		
	μ_- (eV)	τ (ps)	μ_+ (eV)	A_+ (eV)	τ (ps)	μ_+ (eV)	A_+ (eV)	τ (ps)	μ_+ (eV)	A_+ (eV)
MgO I	−2.9	139	−3.2	−6.1	121	−4.0	−6.9	141	−2.6	−5.5

MgO[a]					119			167		

[a] From [115].

The values of A+ presented in Table 8 depend obviously on the models used to calculate them. The lowest value comes from the SM, whereas the IM yields the largest value. Also, the affinity results depend slightly on whether the empty spheres are included or not. In the following considerations we will employ the MgO II case. The positronic energy step at the MgO//Li interface can now be calculated using Eq. (39). Combining the GGA and IM positron affinities for MgO II (Tab. 8) and the GGA results for bcc and fcc lithium (Tab. 7; LDA and GGA results differ only marginally), the positronic potential drop at the MgO//Li interface equals 1.8 eV using the GGA and 2.8 eV using the IM. Regardless of this uncertainty in the affinity difference, it is plausible to assume that clusters of Li in MgO act as positron traps.

In this context it is useful to mention recent work [118] in which the positron affinity was studied in several polytypes of SiC, which is a semiconductor. It was found that all theoretical approaches (GGA, SM, IM) overestimate (in magnitude) the positron affinity in SiC. This was ascribed to certain inadequacies in the theoretical description of both the electron and the positron part of the problem. Considering this conclusion and the aforementioned experimental values of the positron affinity for MgO [108, 109] it turns out that the values of A_+ calculated here for MgO are probably too large (in magnitude). Further theoretical and experimental work is therefore needed to clarify this point. A final remark in this section concerns the sensitivity of the values of the positron affinity with respect to the choice of the LDA exchange-correlation potential for electrons. In addition to the exchange-correlation potential of Von Barth and Hedin [117] we also examined the potential of Ceperley and Alder [128] as parameterized by Perdew and Zunger [129]. Surprisingly, the calculated positron affinities increase (magnitudes decrease) by about 0.5 eV in all cases presented in Table 7. The inspection of electron and positron chemical potentials leads to the conclusion that this effect can be attributed to the change of the electron chemical potentials only. It shows that, although the resulting difference of the positron affinity of MgO and Li remains unchanged, one has to be careful when comparing affinity results obtained using different exchange-correlation potentials for electrons (cf. [130]).

4.5. Discussion

This section shows a very high fraction of annihilations in lithium, indicating a very effective positron confinement in Li nanoclusters. Two aspects are important when considering the efficiency of positron confinement in nanoclusters: (a) the probability of trapping and reflection when a positron encounters a nanocluster acting as a potential well, and (b) the probability of reaching a nanocluster, assuming that the positron is thermalized in the embedding MgO material.

The kinetic energy of delocalized positrons is of the order of tens of meV, while the size of the potential step at the MgO//Li interface is a few eV (1.8 eV using the GGA and 2.8 eV using the insulator model). Thus, the depth of the potential well as determined by the difference in positron affinities is two orders of magnitude larger than the kinetic energy of the positron after thermalization. Therefore, when a positron is thermalized and diffuses within the embedding MgO, the probability of reflection when encountering the MgO//Li interface is negligible at room temperature. Every positron reaching a lithium nanocluster will thus be confined in that cluster. Once inside the cluster, the positron will be reflected at the walls. A necessary condition for the process described is that the size of the nanoclusters is large enough to accommodate at least one bound state. Applying the three-dimensional spherical well model with a finite potential, the critical radius is given by Eq. (40). Substituting a value of 1.8 eV for the depth of the potential well then yields a critical cluster diameter of 0.4 nm. As the confinement of positrons is quite obvious from the results described in Sections 4.4.1 and 4.4.2, the actual size of the nanoclusters will be larger than this value.

The probability of encountering a nanocluster is determined by the positron diffusion length and the concentration and spatial distribution of the Li clusters. Trapping of the vast majority of the positrons is only possible if the mean distance between the Li nanoclusters is smaller than the diffusion length for positrons diffusing in MgO within the MgO:Li layer. Here it is assumed that the positron is present in MgO after thermalization, as Li occupies only 3 vol% of the MgO:Li layer. In the diffusion-limited trapping model, described by Hautojärvi and Corbel [131], the diffusion to the defect is slow compared to the transition to the localized state. The depth of the nanocluster potential well is of the order of a few eV, so this condition is well satisfied. The possibility of detrapping is neglected. Assuming spherically shaped clusters, the fraction of positrons annihilating in the clusters is given by

$$f_{\mathrm{Li}} = \frac{\kappa}{\kappa + \lambda_{\mathrm{MgO}}} = \frac{4\pi r_{\mathrm{cl}} D_{+} c_{\mathrm{cl}}}{4\pi r_{\mathrm{cl}} D_{+} c_{\mathrm{cl}} + \lambda_{\mathrm{MgO}}} \tag{44}$$

where κ is the positron trapping rate with respect to the clusters (s^{-1}), λ_{MgO} is the annihilation rate in MgO (s^{-1}), r_{cl} is the radius of the cluster (m), c_{cl} is the concentration of clusters (m^{-3}), and D_{+} is the diffusion coefficient ($m^2\ s^{-1}$). The diffusion coefficient is related to the diffusion length L_{+} (m) and to the positron lifetime τ (s) as

$$L_{+} = \sqrt{D_{+}\tau} \tag{45}$$

By means of Eqs. (44) and (45), the fraction of annihilations in lithium clusters can be estimated. No detailed information is available on the size of the nanoclusters, so we perform an order-of-magnitude calculation. The mass density of bulk Li is 543 kg m^{-3}, so the 10^{16} implanted Li atoms occupy a total volume of 2.1×10^{-13} m^{-3} independent of the cluster size. If the radius of the lithium nanoclusters is, for example, 5.0 nm [112], the total number of clusters is 4.1×10^{11} and the concentration of clusters will be 5.8×10^{22} m^{-3} considering that all clusters are present in the ion implantation layer with a thickness of 70 nm (estimated from VEPFIT, Tab. 6) and an area of 1.0×1.0 cm^2. At this concentration, the average intercluster distance is 26 nm. The annihilation rate in MgO equals 6.5×10^9 s^{-1} as it is the inverse of the lifetime τ in MgO, 155 ps [126]. A value for the diffusion length for positrons in MgO of 50 nm can be assumed (equal to the diffusion lengths for layers 1 and 3 in the VEPFIT model). Substituting Eq. (45) into Eq. (44) and using the numerical values given previously, the fraction of annihilations in Li, f_{Li}, can be calculated. This yields a fraction of 90%, which agrees very well with the experimental results. Although the cluster size and the diffusion length are estimated, the calculation demonstrates that the annihilation fraction in lithium can be lower than 100% due to diffusion-related processes even if every positron encountering a nanocluster is trapped in that cluster. The calculated fraction is strongly dependent on the cluster size and the diffusion length. For clusters with a radius of 3–7 nm and a diffusion length of 50–100 nm, the trapped fraction varies from 82% to 99%.

Finally, the possibility should be discussed that positrons are not present in either MgO or Li but are trapped at the interface, corresponding to the situation depicted in Figure 21c. This phenomenon is observed, for example, for the Si//SiO_2 interface [132]. Open volume defects or lattice mismatch at the interface can induce positron trapping. No evidence of positronium formation was found in the analysis of the 2D-ACAR distribution, showing that large vacancy-type defects are not present. Positrons can also trap in interface defects that are too small for the formation of positronium. However, positron annihilation distributions corresponding to positron annihilation at interfaces usually bear characteristics of both materials. Thus, if positron trapping would occur at the MgO//Li interface, a considerably higher contribution from MgO to the Doppler broadening and 2D-ACAR distributions would be expected. Therefore, interface trapping in the case of the MgO//Li interface is not likely on the basis of these observations. On the other hand, the fraction of annihilations in Li nanoclusters might be influenced by local electric fields near the interface. These can be present as a result of charge redistribution associated with the equalization of the Fermi levels of MgO and Li in thermal equilibrium.

4.6. Conclusions

In this section it has been shown that positrons are very effectively confined in crystalline lithium nanoclusters that are embedded in MgO. The fraction of positron annihilations in lithium nanoclusters has been deduced by analysis of the Doppler broadening PBA spectra and found to

be $92 \pm 5\%$. This annihilation fraction is very high, considering the fact that the lithium content in the MgO:Li layer is only 1.3 at%. The anisotropic contribution of the 2D-ACAR distribution collected in the layer containing Li nanoclusters shows a fourfold symmetry (most likely indicating an fcc crystal structure) with peaks at positions near the average Fermi radius of lithium. This proves that crystalline bulk lithium is present. The symmetry of the 2D-ACAR anisotropic contributions also shows that the lithium clusters are coherent or semicoherent with the MgO host matrix. The difference in positron affinities of lithium and MgO yields a positronic potential step down at the MgO//Li interface. Therefore, the nanoclusters act as a potential well for positrons with a depth equal to the difference in the positron affinities. These positron affinities were calculated using the LMTO-ASA method, and values for the depth of the positronic potential well of 1.8 and 2.8 eV were obtained using the GGA and the insulator model, respectively. The depth of the potential well is so large that the trapping probability of positrons meeting a nanocluster is approximately equal to 1.

5. FORMATION OF SOLID Kr NANOCLUSTERS IN MgO

5.1. Introduction

Ion implantation of noble gas atoms in matrices offers the opportunity to create nanoclusters of van der Waals solids at room temperature, which is convenient for studying the optical and structural properties of these exotic materials. Here it should be realized that the material properties of small clusters (i.e., with sizes of a few nm or less) usually deviate from that of the bulk material. Apart from the fundamental interest in the material properties, a technological application of Kr implantation in MgO is the fabrication of ultrathin MgO slabs with a thickness of 100–200 nm [133]. Solid Kr clusters created by means of ion implantation were already observed in the metals Ti, Ni, Cu, Mo, and Au [134, 135] in graphite and Grafoil [136] and once in MgO [137]. The advantage of embedding the clusters in transparent materials such as MgO is that it facilitates optical studies. Most of the work mentioned concerns the analysis of diffraction patterns in TEM and X-ray absorption studies. Here, we discuss solid Kr clusters in the TEM in high-resolution mode, similar to the high-resolution work already performed on solid Xe clusters [138].

Apart from TEM, we also used optical absorption spectroscopy and Doppler broadening PBA [8] to follow the defect evolution in the sample. If positrons are effectively trapped in Kr nanoclusters, this allows investigation of the electronic structure of solid Kr by means of positron annihilation techniques. If the positron wave function is spatially confined within the nanoclusters in three dimensions, we speak of positron confinement [99, 139–141]. Kr is an important candidate for studying the effect of positron confinement because of the very low positron affinity of Kr [142], which means that the nanoclusters are very likely to act as a three-dimensional potential well to positrons. Positron trapping in solid Kr nanoclusters embedded in metals (Cu, Ni) was studied previously using various positron annihilation techniques [143, 144]. The main conclusion from these investigations is that positrons trap at the Kr–metal interface.

5.2. Experiments

Several epi-polished MgO(100) single crystals of size $10 \times 10 \times 1$ mm^3 were implanted at room temperature with 280 keV Kr ions to a dose of 3×10^{16} ions cm^{-2} and subsequently annealed in ambient air for periods of 30 min at temperatures of 900 and 1100 K, respectively. After ion implantation and after each annealing step, the evolution of ion implantation defects was monitored with optical absorption spectroscopy and Doppler broadening positron beam analysis using a monoenergetic positron beam with a variable acceleration energy of 0–30 keV. X-TEM was applied after the 1100 K annealing step. The TEM was performed using a JEOL 4000 EX/II operating at 400 kV (point-to-point resolution 0.165 nm; see Section 2). The specimen preparation is discussed elsewhere [79]. The sample treatment and main observations are listed in Table 9.

5.3. Results

First, results of optical absorption spectroscopy will be presented. Next, the X-TEM results will be shown, focusing both on the solid Kr nanoclusters and on the defects created in the MgO. Finally the result of positron beam analysis is shown as an additional method to obtain depth-resolved information on the defect evolution in the composite material during the sample treatment. Possible trapping in Kr nanoclusters is discussed in terms of the positron affinity.

5.3.1. Optical Absorption Spectroscopy

The results of the optical absorption spectroscopy are displayed in Figure 27. After ion implantation, two types of defects can be distinguished. At a wavelength of 570 nm, there is an absorption peak that can be attributed to V-centers (Mg vacancies) and at a wavelength of 250 nm; there is another absorption peak that can be attributed to F-centers (O vacancies) [145]. Both absorption peaks vanish after annealing at 900 K.

Table 9. Sample treatment and main experimental observations.

Sample treatment	
Ion implantation	3×10^{16} Kr ions cm^{-2} at an energy of 280 keV
Thermal anneal	at 900 K and 1100 K for a period of 30 min
Results	
Optical absorption	F- and V-centers present after implantation; dissociation after 900 K anneal.
X-TEM	Cubical, solid Kr clusters at 70–130 nm depth, cluster size 2–4 nm. Cubical nanovoids at 15–30 nm depth, cluster size 2–5 nm.
PBA	Defect agglomeration during annealing. High S parameter in nanovoids layer, S parameter in Kr cluster layer higher than that of bulk MgO and lower than the S parameter of MgO with defects.

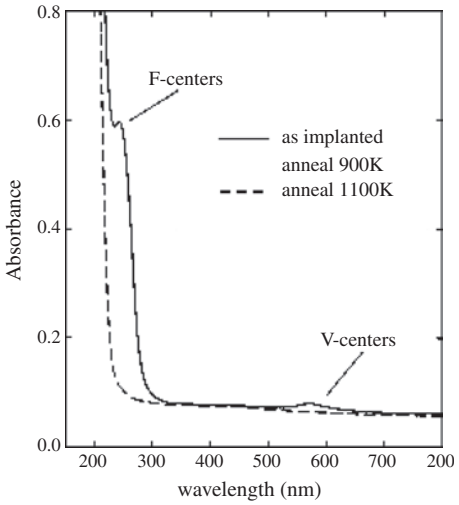

Figure 27. Optical absorption spectra of an MgO(100) crystal implanted with 280 keV 3×10^{16} Kr ions cm^{-2}, as implanted and after annealing in air at various temperatures.

5.3.2. Cross-Sectional TEM

X-TEM has been performed on a sample after the 1100 K anneal step. Figure 28 shows an overview image. The area between 70 and 130 nm depths is a subsurface layer that contains Kr nanoclusters. The rectangular area in Figure 28 (marked with the white brackets) is enlarged in the HRTEM image of Figure 29. Here the Kr nanoclusters can be clearly observed. The clusters are rectangularly shaped and the sizes vary from 2 to 5 nm. Moiré fringes are present due to the lattice mismatch between solid Kr and MgO. The morphology of the nanoclusters is determined by the interface energy corresponding to the various MgO//Kr interface facets; the

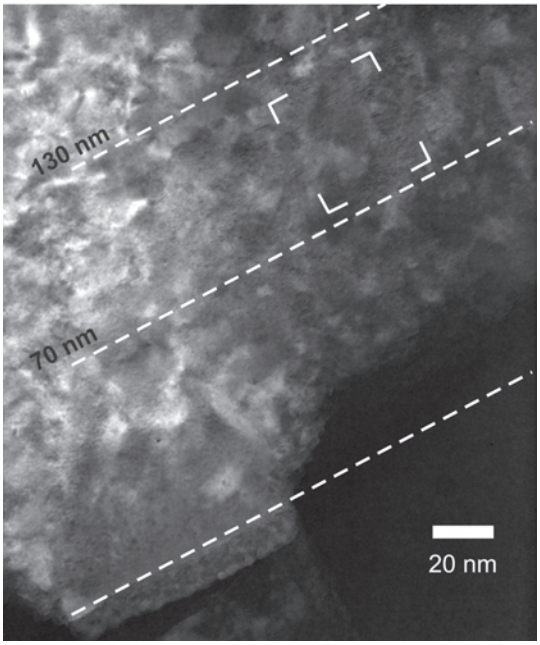

Figure 28. TEM overview image of Kr-implanted MgO. Solid Kr nanoclusters are observed in a band at a depth of 70–130 nm.

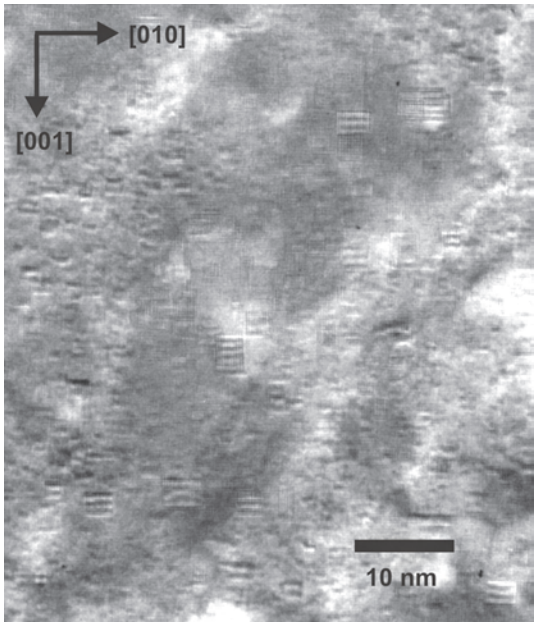

Figure 29. Solid Kr nanoclusters at a depth of 75–120 nm with Moiré fringes caused by the lattice mismatch between solid Kr and MgO.

shape of the cluster can be constructed using the Wulff diagram [146, 147] if the interface energies are known. In this particular case, it is clear that the {100} interface is energetically favored to the {110} and {111} interfaces. The interface energy equals the sum of the surface energies of MgO and Kr minus the work of adhesion:

$$\gamma_{\mathrm{MgO||Kr}} = \gamma_{\mathrm{MgO}} + \gamma_{\mathrm{Kr}} - W_{\mathrm{ad}} \tag{46}$$

Considering that the van der Waals bonding of the noble gas Kr atoms is very weak, the interface energy of Kr and the work of adhesion will be negligible with respect to the surface energy of MgO (i.e., by approximation the MgO//Kr interface energy equals the MgO surface energy). Watson et al. [148] calculated surface energies of 1.25 J m^{-2} for MgO {100}, 1.87 J m^{-2} for MgO{110}, and 2.5 J m^{-2} for MgO{111}. The last two values are valid for microfaceted surfaces, but the surface energies for unfaceted {110} and {111} MgO surfaces are even higher [148]. Considering the Wulff diagram the absence of the {110} facets in the rectangular Kr nanoclusters means that the MgO{110} surface energy should be at least $\sqrt{2}$ times larger than the MgO{100} surface energy, which is in agreement with the theoretical values given.

Figure 30 shows a magnification of the large cluster present in the center of Figure 29. There are 5 moiré fringes in 18 MgO lattice spacings. Because Kr exhibits an fcc structure in fcc host matrices [135] and the Kr clusters are in a cube-on-cube orientation relationship with the MgO, the following relationship can be used to calculate the lattice parameter of solid Kr, a_{Kr}

$$\frac{1}{d_{\mathrm{fringes}}} = \left| \frac{1}{d_{\mathrm{MgO}}} - \frac{1}{d_{\mathrm{Kr}}} \right| \tag{47}$$

With a lattice parameter a_{MgO} of 4.212 Å ($d_{\mathrm{MgO,\,200}} = 2.106$ Å), this yields $d_{\mathrm{Kr,\,200}} = 18/(18-5) \cdot d_{\mathrm{MgO,\,200}} = 2.9$ Å

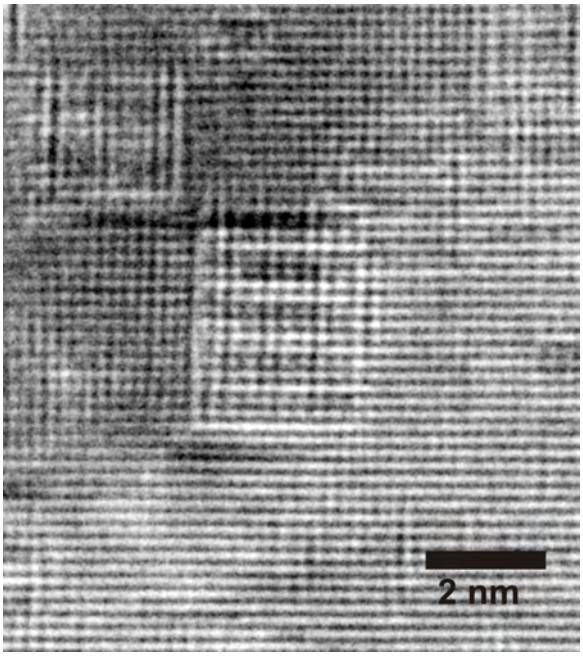

Figure 30. High-resolution TEM image of a solid Kr nanocluster (also present in the center of Figure 29). The lattice parameter of the solid Kr can be derived from the Moiré fringes (see text).

and thus the lattice parameter for solid Kr, a_{Kr}, equals 5.8 Å. This corresponds to the lattice parameter of frozen Kr at a temperature of 110 K [149]. In a similar fashion, the Kr lattice parameters in the other clusters present in Figure 29 can be analyzed and values of 5.3–5.8 Å are found. These values for a_{Kr} correspond reasonably well with the values of 5.0–5.5 Å reported in the literature [134, 137]. The important advantage of the use of moiré fringes in comparison with the experimental methods mentioned in the Introduction is that the lattice parameter can be determined for every Kr cluster separately. In Figure 31, the Kr lattice parameter is plotted as a function of the cluster size. It is clear that there is a positive correlation between a_{Kr} and the cluster size; the

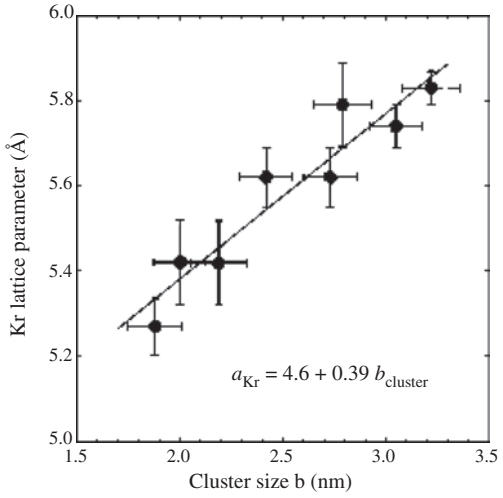

Figure 31. Relationship between the Kr lattice parameter and the cluster size.

straight line plotted in the figure is a linear least squares fit to the data. The cluster size (defined as the cube root of the nanocluster volume) cannot be determined accurately because the cluster dimension perpendicular to the plane in Figure 29 or 30 cannot be determined. Therefore, the cluster size was estimated as the square root of the cluster area that is visible in the figures. The lattice parameter in small clusters is smaller due to the higher pressure in small clusters. The lattice parameter can be related to the pressure using the Ronchi equation of state (EOS). A lattice parameter of 5.3–5.8 Å for fcc Kr corresponds to a molar volume of 22–30 cm^3. Using the EOS for solid Kr [150] at a temperature of 300 K, the pressure in the largest cluster is 0.6 GPa and the pressure in the smallest cluster is 2.5 GPa. These pressures are in reasonable agreement with the minimum pressure of 0.83 GPa that is necessary for the formation of solid Kr [137]. It is also in good agreement with the following equations, describing the relationship between pressure and interface energy. The energy of the cluster system is minimized when

$$dE = p\,dV - \gamma\,dS = 0 \quad \Rightarrow \quad \frac{dE}{da} = p\frac{dV}{da} - \gamma\frac{dS}{da} = 0 \tag{48}$$

For the case of a cube with size b, volume $V = b^3$, and surface $S = 6b^2$, it follows that

$$p = \frac{4\gamma}{b} \tag{49}$$

Since the interface energy is completely determined by the surface energy of MgO [see Eq. (46) and the previous discussion], the pressure in the cluster can be calculated. It should be realized that Eqs. (48) and (49) are only valid when the material is in thermal equilibrium (i.e., at the temperature at which the clusters were formed). The pressure and surface energy mentioned in Eq. (49) should therefore be considered at 1100 K. The MgO{100} surface energy at 1100 K is 1.17 J m^{-2} [151]. Using Eq. (49), a cluster size of 3 nm then yields a pressure of 1.7 GPa at 1100 K. How can this pressure be compared with the pressures of 0.6–2.5 GPa found in the electron microscope at 300 K? MgO is a rather incompressible material with a linear thermal expansion coefficient that varies with temperature. Over the temperature interval of 300–1100 K, the average linear thermal expansion coefficient a_{lin} is 12×10^{-6} K^{-1} [152]. Since MgO is very incompressible compared to Kr, we assume that the shrinkage of the cluster is completely determined by the MgO. With $a_{vol} = 3a_{lin}$, the change in volume of the cluster is 2.9%. Therefore, the molar volumes of 22–30 cm^3 as found at room temperature correspond to molar volumes of 23–31 cm^3 at 1100 K. Using again the Ronchi equation of state [150] but now for a temperature of 1100 K, we find pressures of 1.5–4.6 GPa. This is in good agreement with the pressure of 1.7 GPa that was found from Eq. (49).

Figure 32 shows an enlarged TEM image of the subsurface area down to a depth of 60 nm. It is clear that a band of rectangularly shaped nanovoids is present at a depth of 15–30 nm. These large vacancy clusters are 2–5 nm in size and are rectangularly shaped, similar to the nanovoids found previously in ion implanted MgO [153]. The rectangular shape is again caused by the different surface energies of

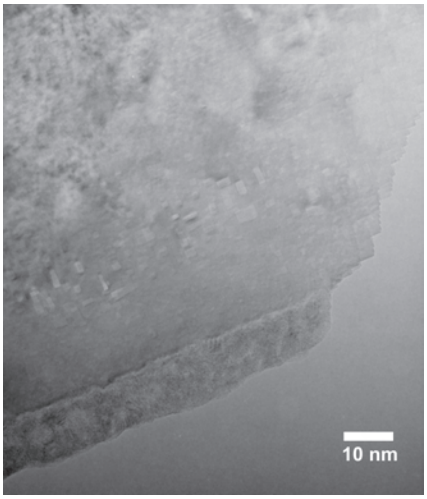

Figure 32. TEM image showing the vacancy cluster band located at a depth of 15–30 nm.

the various MgO facets (see the discussion on the rectangular shape of the Kr clusters). These voids are formed due to accumulation of vacancies created by the Kr implantation. It is, however, peculiar that this vacancy band is located so far away from the main Kr cluster band, because normally the damage depth distribution and the Kr depth distribution from the same implantation are overlapping to a large extent.

Figure 33 shows the Kr depth distribution and the damage created by ion implantation as simulated by means of the SRIM2000 code [83]. Here displacement energies of 55 eV were used for both Mg and O [154]. For the applied dose of 3×10^{16} ions cm^{-2}, the peak value of the Kr concentration is 4.1 at% and the peak damage level is 37 dpa (displacements per target atom). First of all, it is clear that the predicted Kr depth distribution is in excellent agreement with

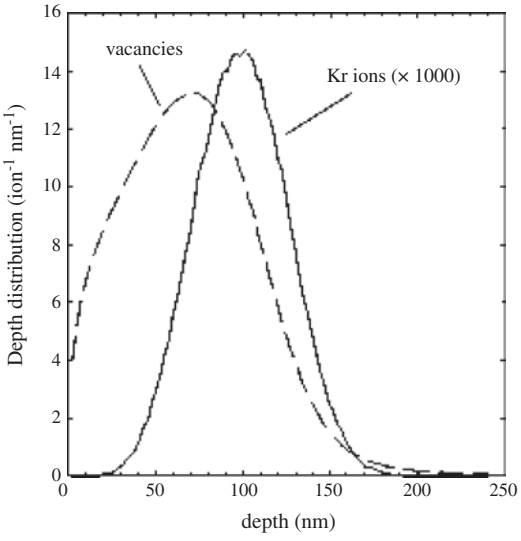

Figure 33. Kr depth distribution (after implantation, prior to thermal anneal) and damage depth distribution as calculated using the SRIM2000 code.

the location of the Kr nanocluster layer at a depth of 70–130 nm as observed by TEM in Figure 28. It is also clear that the predicted damage depth distribution is located shallower than the predicted Kr distribution. However, this does not explain the presence of a distinct vacancy cluster band at a depth of 15–30 nm as observed by TEM: in the SRIM simulation the vacancy and Kr distribution are not separated but overlap to a large extent. A possible explanation is that the vacancies and Kr atoms recombine at the intermediate depth range of 30–70 nm: the presence of Kr in the vacancy clusters slows down the mobility of Kr-filled vacancy clusters so that large vacancy clusters are not formed. At the same time, the concentration of Kr in this intermediate layer is not high enough to form solid Kr nanoclusters that are big enough to be observed by means of TEM.

5.3.3. Positron Beam Analysis

The defect evolution during the annealing procedure was monitored by Doppler broadening PBA [8]. Annihilation of positrons with electrons in solids yields information on the momentum distribution of these electrons. The electronic momentum distribution is reflected in the Doppler broadening of the 511 keV annihilation peak. Positron annihilation with low-momentum valence or conduction electrons results in a small Doppler shift, contributing to the center of the peak. Annihilation with high-momentum core electrons results in a large Doppler shift, contributing to the wings of the 511 keV annihilation peak. The shape of the 511 keV peak is characterized by the so-called *S* (shape) parameter, which gives the ratio of the number of counts in the center of the peak to the number of counts in the whole peak (see Section 2). By using a monoenergetic positron beam with variable energy, the *S* parameter can be recorded as a function of depth. However, at larger depths the depth resolution decreases due to broadening of the implantation profile of the implanted positrons.

The *S* parameter is displayed in Figure 34 as a function of positron implantation energy. The average positron implantation depth is indicated on top of the figure. The solid lines show the results of the VEPFIT simulation that will be discussed. It is clear that after implantation, the *S* parameter increases with respect to reference MgO in the ion implantation zone and it increases further after annealing at 900 and 1100 K over a wide range. The *S* parameter in ion-implanted MgO always increases after ion implantation due to the efficient formation of vacancy-type defects in the Schottky material MgO. It is observed that the *S* parameter increases after annealing at 900 K. Simultaneously, the optical F- and V-centers dissociate after annealing at this temperature as observed with optical absorption spectroscopy (see Fig. 27). This clearly indicates aggregation of vacancy-type defects (the larger the vacancy clusters, the larger the *S* parameter). The peak at 1.5 keV positron implantation energy in Figure 34 can be attributed to the presence of the vacancy cluster band that was observed with TEM in Figure 32. These voids are large enough to form Ps, a hydrogenlike bound state of a positron (e^+) and an electron (e^-). Positronium formation leads to a dramatic increase in the *S* parameter. In order to analyze the PBA results in more detail, the VEPFIT code [49] was used to find the

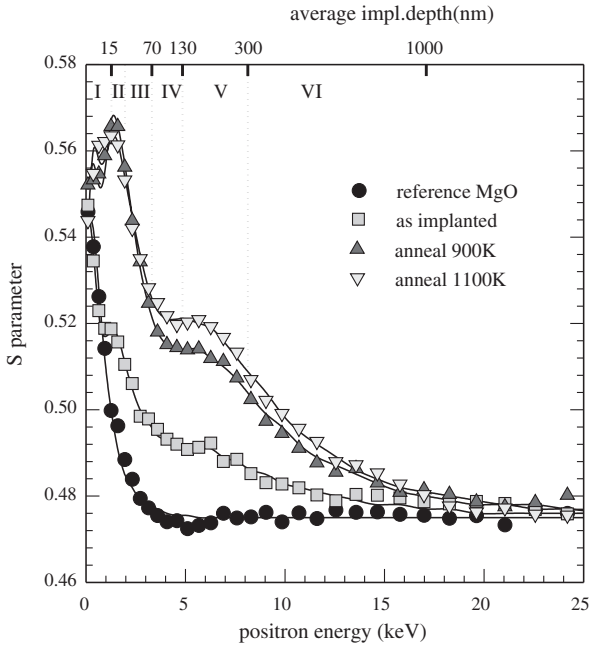

Figure 34. *S* parameter vs positron energy measured for reference MgO and for MgO:Kr after implantation and after thermal annealing treatments. The scale at the top of the graph indicates the average positron implantation depth. The Roman numerals are the layer numbers (see Table 10) and the solid lines are the result of VEPFIT fitting (see text).

S parameter corresponding to every defect layer. The *S* parameter found at a certain positron energy in Figure 34 consists of contributions of various layers due to the broadness of the positron implantation profile (which is increasing with increasing positron energy) and due to positron diffusion processes. The VEPFIT code takes these effects into account and yields the depth-resolved *S* parameters for every defect layer. Based on the TEM observations, a six-layer model was used as defined in Table 10. The chosen diffusion lengths are reasonable estimates. When considering the number of clusters in Figures 29 and 32, it is clear that here the diffusion length will be 5 nm or less. The layers and the corresponding depths are indicated at the top of the graph in Figure 34. Layer V with a depth of 130–300 nm is the so-called ion implantation tail. Due to channeling effects, the implantation damage in MgO extends much further than the maximum range as predicted by SRIM (Fig. 33) as this code assumes the atoms in the target material to be randomly distributed. Only for the *S* parameter curve of reference (nonimplanted) MgO, a single-layer model was used with the *S* parameter value of bulk MgO, 0.475.

Table 10. Model used for VEPFIT simulation.

Layer	Description	Depth (nm)	*S* parameter	Diff. length (nm)
I	MgO with defects	0–15	S_{def} (fitted)	5
II	nanovoids	15–30	S_{voids} (fitted)	5
III	MgO with defects	30–70	S_{def} (fitted)	5
IV	Kr clusters	70–130	S_{Kr} (fitted)	5
V	MgO with defects	130–300	S_{def} (fitted)	20
VI	MgO bulk	>300	$S_{MgO} = 0.475$	100

Note: The *S* parameters of layers I, III, and V are fitted with the same parameter.

The solid lines in Figure 34 are the result of VEPFIT fitting and it is clear that the model as discussed is well able to fit the experimental *S* parameter curves. Figure 35 shows the depth-resolved *S* parameters found using VEPFIT for the sample after the 1100 K annealing step (where X-TEM was also performed). As expected, the *S* parameter in the nanovoids layer (layer II) is rather high, 0.59. The *S* parameter in the layer with Kr nanoclusters (layer IV) is lower than that of the adjacent layers but higher than that of bulk MgO. This explains the "dip" in the *S* parameter curve in Figure 34 at 4.5 keV positron implantation energy. The fact that the *S* parameter in the layer with Kr nanoclusters is not much different from adjacent layers points to little interaction of positrons with Kr nanoclusters. The reason that the *S* parameter in the nanocluster layer is lower than in the adjacent layers (Figs. 34 and 35) is probably due to Kr filling of vacancy-type defects. Thus there are less open volume defects for the positrons to trap in and the value of the *S* parameter is closer to that of bulk MgO.

In order to investigate the behavior of positrons with respect to the nanoclusters in more detail, a 2D-ACAR (two-dimensional angular correlation of annihilation radiation) experiment was carried out on the nanoclusters after the 1100 K annealing step. 2D-ACAR allows a detailed investigation of the electronic structure of a material [155]. Experimental details of the setup can be found in Section 2 and [140], where positron confinement in Li nanoclusters in MgO is investigated. The positrons were implanted at 4.5 keV energy, corresponding to implantation in the center of the Kr nanocluster layer. No anisotropic contribution other that that of MgO could be observed in the 2D-ACAR spectrum after accumulation of 7×10^6 2γ-coincidence events [156] thus supporting the idea of negligible trapping

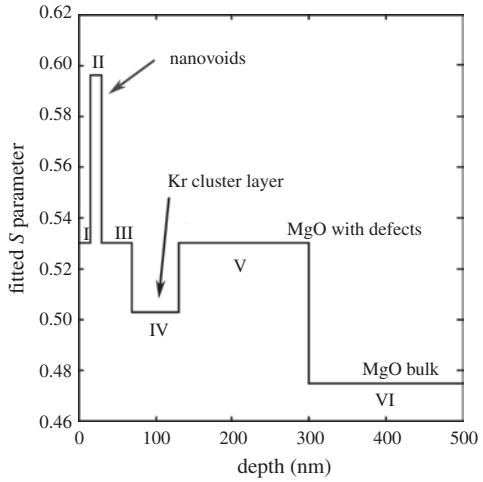

Figure 35. Depth-resolved *S* parameter as a function of depth in the sample after the 1100 K annealing step, as found using the VEPFIT code. The applied six-layer model is given in Table 10. The layers are indicated in Roman numerals.

in and interaction with Kr clusters. This is in contradiction with the expectation that positrons are very effectively trapped in Kr nanoclusters because of the very low positron affinity of solid Kr [142] compared to that of MgO [121]. So why do the Doppler broadening and 2D-ACAR results not give evidence of positron trapping in the Kr nanoclusters?

5.3.4. Positron Trapping and Positron Affinities

Whether positrons trap in nanoclusters is dependent on the positron affinity. First we deduce the definition of positron affinity for metals, following the derivation by Puska et al. [157]. Let us first consider Figure 36. Both the electronic energy levels and the positronic energy levels in the same material are defined with respect to the crystal zero (CZ). The crystal zero level is defined as the Coulomb potential far away from a single atomic sphere [158]. The electron chemical potential μ_- is defined as the energy difference between the top of the conduction band (coinciding with the Fermi level) and the crystal zero. The positron chemical potential μ_+ is defined as the energy difference between the bottom of the positron bands $E_{+,0}$ and the crystal zero. Both μ_- and μ_+ are usually negative. The electronic work function φ_- (positron work function φ_+) is the work to be done to bring an electron (positron) from the Fermi level (positron ground level) to vacuum. The surface dipole potential step Δ is the potential difference for electrons between the vacuum level and the crystal zero. Positrons experience the same potential step, but then with opposite sign: $-\Delta$. The following relationships hold:

$$\varphi_- = -\mu_- + \Delta \qquad \text{and} \qquad \varphi_+ = -\mu_+ - \Delta \tag{50}$$

When two metal surfaces are in contact, electrons will flow from one material to the other until the Fermi levels are aligned, thereby establishing thermal equilibrium. This situation is shown in Figure 37. The result is an interface dipole with potential difference $\Delta_{\text{align}}^{\text{METAL}} = \mu_-^A - \mu_-^B$. For positrons, this potential step is equal in magnitude but opposite in direction. The difference between the lowest positron energies of material A and B equals [157]

$$\Delta E_{AB,+}^{\text{METAL}} = E_{0,+}^A - E_{0,+}^B = \mu_+^A - \mu_+^B + \mu_-^A - \mu_-^B \tag{51}$$

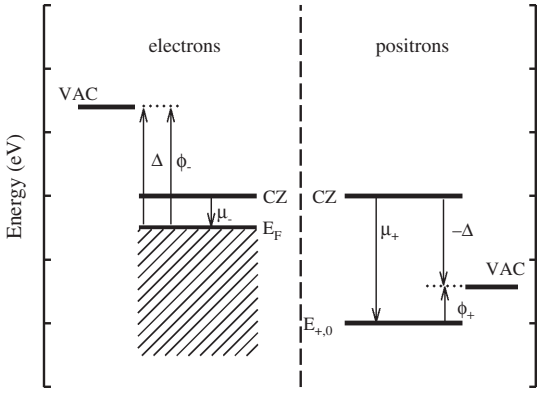

Figure 36. Schematic diagram showing the relevant electronic and positronic energy levels with respect to the CZ for the case of a metal.

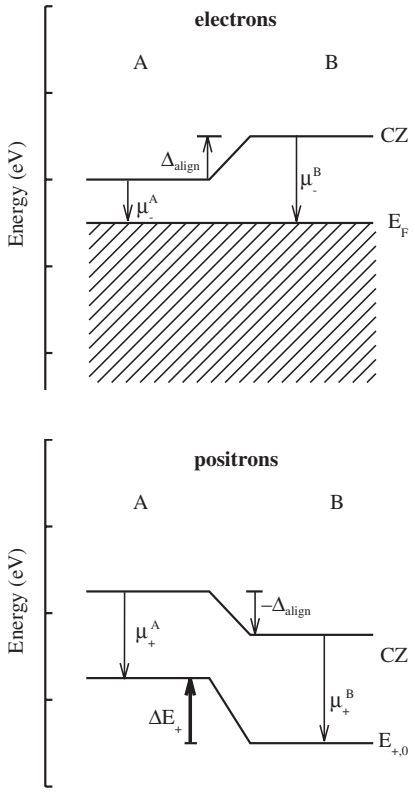

Figure 37. Schematic diagram showing alignment of the Fermi levels for the case of two metals in contact. Note that the alignment shift of the crystal zeros is $\Delta = \mu_-^A - \mu_-^A$ for electrons and $-\Delta$ for positrons.

which is also clear from Figure 37. When the positron affinity is defined as

$$A_+^{\text{METAL}} = \mu_+ + \mu_- = -(\varphi_+ + \varphi_-) \tag{52}$$

it follows from Eq. (51) that the difference in positron ground levels between the two metals is simply the difference between the positron affinities,

$$\Delta E_+^{AB} = A_+^A - A_+^B \tag{53}$$

Values for the positron affinity are commonly expressed in eV and are negative for most materials. The positron affinity is an entity that is characteristic of a material and it has been calculated for almost all metals [157], a number of semiconductors [159], a few insulators [160], and rare gases [94]. A necessary condition of the positron quantum confinement in a cluster (A) embedded in a host (B) is that $\Delta E_+^{AB} < 0$. Then the cluster represents a three-dimensional potential well for positrons. If $\Delta E_+^{AB} > 0$, the cluster acts as a potential barrier. Finally, the possibility should be considered that positrons trap at the interface.

The question now arises whether the concept of positron affinity as defined in Eq. (52) can be applied to an insulator–insulator interface. The alignment of the Fermi levels is expressed in the term $(\mu_-^A - \mu_-^B) = \Delta_{\text{align}}^{\text{METAL}}$ on the right-hand side of Eq. (51). This is true for metals where the position of the electronic chemical potentials coincides with the position of the Fermi levels. This is not true, however,

for insulators. In insulators the electronic chemical potential is defined as the distance between the top of the valence band and the crystal zero as depicted in Figure 38. E_V is the top of the valence band, E_C is the bottom of the conduction band, and E_F is the Fermi level positioned in the middle of the bandgap E_g. Figure 38 shows the electronic energy levels for MgO and Kr in contact for the case that the Fermi levels are aligned. It follows from the figure that $\Delta^{\mathrm{INS}}_{\mathrm{align}} = (\mu^A_- + \frac{1}{2}E^A_g - \mu^B_- - \frac{1}{2}E^B_g)$. The energies and energy levels displayed in the figure are to scale. The numerical values of the electronic and positronic entities for MgO and Kr are listed in Table 11 and are mainly obtained from [140, 142]. Figure 39 shows the corresponding positronic potential diagram for MgO and Kr in contact when the Fermi levels equalize. Considering Figures 38 and 39, it is clear that the difference between the positron ground potentials of the two materials is not described by Eq. (51) but by the following formula:

$$\Delta E^{\mathrm{INS}}_{AB,+} = E^A_+ - E^B_+ = \mu^A_+ - \mu^B_+ + \mu^A_- - \mu^B_- + \frac{1}{2}E^A_g - \frac{1}{2}E^B_g \quad (54)$$

Therefore, the positron affinity for insulators can be defined alternatively as

$$A^{\mathrm{INS}}_+ = \mu_+ + \mu_- + \frac{1}{2}E_g \quad (55)$$

so that Eq. (53) is still valid. Using Eq. (54) and the values gives in Table 11, we find a difference in positron ground potentials $\Delta E^{\mathrm{INS}}_{AB,+}$ of −6.7 eV. So $\Delta E_{AB,+} < 0$ and the Kr nanoclusters should act as potential wells, in contradiction with our experimental observations that do not show evidence of positron trapping in Kr.

One possible explanation is that the Fermi levels are not equalized. MgO and Kr are both insulators with large bandgaps of 7.8 and 12 eV, respectively. When there are no electrons available to align the Fermi levels, thermal equilibrium cannot be established and the vacuum levels will be aligned instead [161]. In addition, it is well known that the energy levels of rare-gas solids physisorbed on various metal surfaces are aligned to the vacuum level [162–164]. Therefore, we have also considered alignment of the vacuum levels. This is achieved analogous to the alignment procedure shown in Figures 38 and 39. Alignment of the vacuum levels is established by a potential shift $\Delta^{\mathrm{VAC}}_{\mathrm{align}} = \Delta_{\mathrm{MgO}} - \Delta_{\mathrm{Kr}}$ between the crystal zeros of the two materials. For positrons the shift is $-\Delta^{\mathrm{VAC}}_{\mathrm{align}}$, which automatically leads to the alignment of the vacuum levels for positrons, as expected. The numerical values are again listed in Table 11. The surface dipole and the positron work function of MgO, Δ_{MgO} and ϕ^{MgO}_+, respectively, were calculated with Eq. (50) using the experimental value for the electron work function of MgO, 3.8 eV [165]. The final result is that the difference between the positron ground states of the two materials is simply the difference between the positron work functions,

$$\Delta E^{\mathrm{VAC}}_{AB,+} = -(\phi^A_+ - \phi^B_+) \quad (56)$$

so that $-\phi_+$ takes the role of the positron affinity when the vacuum levels are aligned [compare with Eq. (53)]. With the values given in Table 11, this yields −0.5 eV for $\Delta E^{\mathrm{VAC}}_{AB,+}$, indicating that the nanocluster still acts as a (shallow) potential well. However, the differences in calculated energies

Table 11. Electronic and positronic data for MgO and Kr.

	MgO	Kr	Ref./Eq.
a_0 (Å)	4.212	5.72	[140, 142]

[a] Defined with respect to the crystal zero in Figure 38.

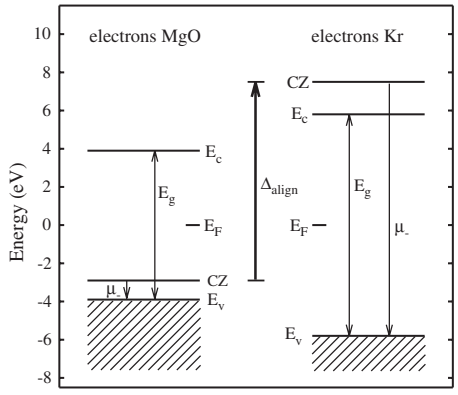

Figure 38. Electronic energy levels for MgO in contact with solid Kr, based on the data listed in Table 11. The alignment of the Fermi levels is achieved by an energy shift $\Delta^{\mathrm{INS}}_{\mathrm{align}} = (\mu^A_- + \frac{1}{2}E^A_g - \mu^B_- - \frac{1}{2}E^A_g)$ between the crystal zeros of the two materials.

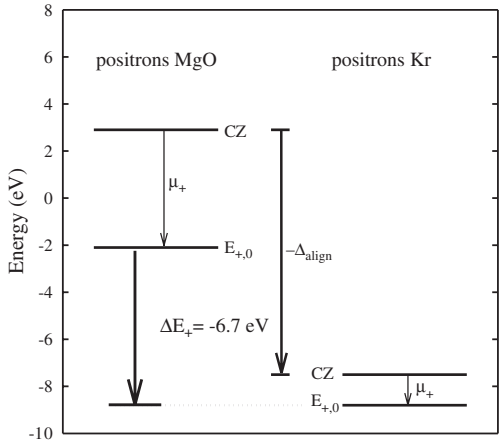

Figure 39. Positronic energy levels for MgO in contact with solid Kr, based on the data listed in Table 11. $\Delta^{\mathrm{INS}}_{\mathrm{align}}$ is defined in Figure 38.

between various theoretical models are approximately 1 eV. Furthermore, we have combined experimental and theoretical results, and the electronic and positronic data for Kr given in Table 11 are only valid for a lattice parameter of 5.72 Å while in reality, there is a distribution. Therefore, we estimate the systematic error in $\Delta E_{AB,+}$ to be at least 1.5 eV, so that it is not clear whether positrons will trap in Kr nanoclusters when the vacuum levels are aligned. The various possibilities for alignment of the electronic energy levels and the corresponding differences in positronic ground potentials are summarized in Table 12.

One more aspect to be considered is that Kr is commonly used as a moderator because positrons thermalize ineffectively in solid rare gases [166]. This means that positrons hardly lose energy when moving in "bulk" solid Kr. So even if the Kr nanoclusters would act as a potential well, a positron entering a nanocluster might not lose enough energy to be thermalized and to remain trapped inside the cluster until annihilation. In the literature, trapping in spherical Kr bubbles in metal (Ni, Cu) is reported [143, 144] and these authors conclude that the trapping occurs at the interface rather than in the nanocluster itself. We cannot fully exclude that positrons are also trapped at the MgO//Kr interface, but it is not likely. First, the TEM results suggest that the cubically shaped Kr clusters fit very well in the MgO lattice, reducing the probability of interface defects that can act as trapping sites. Second, if the positrons would trap at the interface, one would still expect an anisotropic contribution from Kr to the 2D-ACAR spectrum due to overlap of the positron wave functions with the solid Kr. Unfortunately, the anisotropy in the electronic/positronic structure for bulk Kr is not known theoretically nor experimentally, so that we cannot interpret our experimental results in more detail.

Summarizing, the experimental 2D-ACAR spectrum does not show any anisotropic contribution from Kr, showing that positrons do not trap in Kr nanoclusters. Three effects can be responsible for this. It is likely that the Fermi levels will not equalize due to the excellent insulating properties of both materials. Therefore, it is possible that the nanoclusters do not act as a positronic potential well (Table 12). Positrons do not thermalize in solid Kr, so probably the positrons would leave the cluster even if it would act as a potential well. Trapping at the interface is not likely as the cubically shaped Kr clusters fit very well in the MgO lattice. Moreover, if the positrons would trap at the interface, an anisotropic contribution from Kr to the 2D-ACAR spectrum would be expected due to overlap of the positron wave function with the solid Kr.

Table 12. Positronic potential difference between Kr cluster and MgO in contact assuming alignment of the Fermi levels in metals [Eq. (51)], in insulators [Eq. (54)], or assuming alignment of the vacuum levels [Eq. (56)].

Level alignment	$\Delta E_+ = E_+^{\mathrm{Kr}} - E_+^{\mathrm{MgO}}$	Result (eV)
Fermi (metals)	$\Delta E_+^{\mathrm{METAL}} = (\mu_+^{\mathrm{Kr}} + \mu_-^{\mathrm{Kr}}) - (\mu_+^{\mathrm{MgO}} + \mu_-^{\mathrm{MgO}})$	N.A.[a]
Fermi (insulators)	$\Delta E_+^{\mathrm{INS}} = (\mu_+^{\mathrm{Kr}} + \mu_-^{\mathrm{Kr}} + \frac{1}{2}E_g^{\mathrm{Kr}}) - (\mu_+^{\mathrm{MgO}} + \mu_-^{\mathrm{MgO}} + \frac{1}{2}E_g^{\mathrm{MgO}})$	-6.7 ± 1.5
Vacuum	$\Delta E_+^{\mathrm{VAC}} = (-\phi_+^{\mathrm{Kr}}) - (-\phi_+^{\mathrm{MgO}})$	-0.5 ± 1.5

[a] Does not apply to the MgO//Kr insulator–insulator interface.
Note: The data of Table 11 have been used to calculate the numerical values.

5.4. Discussion

Solid Kr nanoclusters have been successfully created in MgO by means of 280 keV Kr ion implantation and subsequent thermal annealing at 1100 K. The nanoclusters have been observed by X-TEM in high-resolution mode. The fcc Kr nanoclusters are rectangularly shaped with sizes of 2 to 4 nm. The lattice parameter of the solid Kr in the clusters varies from 5.3 Å for small clusters to 5.8 Å for large clusters, with the lattice parameter increasing with increasing nanocluster size. Using the Ronchi EOS, this corresponds to local pressures of 0.6–2.5 GPa. Both optical absorption spectroscopy and Doppler broadening positron beam analysis show that small defects are present in the MgO after the ion implantation and that defect aggregation occurs during annealing. Experimentally, no evidence was found for positron confinement in Kr nanoclusters. The nonequalization of Fermi levels, the poor thermalization of positrons in solid Kr, and the absence of trapping sites at the Kr//MgO interface might be the reason that positrons are not trapped in Kr clusters.

6. NANOVOIDS IN He IMPLANTED AND THERMALLY ANNEALED MgO

6.1. Introduction

Interest in the behavior of helium in MgO has two diverse origins. The first is analogous to the case discussed in the previous section, namely that MgO acts as a host material for the generation of nonlinear and other optical properties by introducing nanometer-sized metallic or semiconductor clusters. Control over the size and shape of these nanoprecipitates might be obtained by a two-step process when metallic ions are introduced in previously generated nanometer-sized voids in MgO. It is suggested that the cavities will act as gettering centers to metallic ions as has been observed for nanocavities in silicon [167, 168]. The second application for MgO is as a candidate uranium-free host matrix for the transmutation of actinides generated in nuclear reactor fuels. Alpha decay of actinides introduces helium atoms into the MgO matrix that interact with radiation damage defects. It is therefore of interest to investigate the relevant activation energies of helium dissociation from various defects where the helium might be trapped. In this section we will discuss the shape of the cavities as examined with TEM.

6.2. Experiments

Samples obtained by cleaving of MgO(100) crystals to a thickness of 1 mm and a size of 1×1 cm^2 were implanted with a dose varying from 1×10^{19} to 1×10^{20} m^{-2} ^{3}He ions with 30 keV energy. Thermal annealing of the samples was performed in a longitudinal oven in ambient air during 30 minutes. After each annealing step, the samples were analyzed by photon absorption and positron beam analysis.

Photon absorption revealed the presence of F-centers in the as-implanted sample, which disappeared after annealing to 500 K. For the high dose implanted samples annealed at 1370 K positron beam analysis indicated the presence of voids with nanometer size at a depth somewhat shallower than of the helium implantation depth [169]. In a similar experiment it was shown using neutron depth profiling that helium is released from the cavities at a temperature of about 1300 K.

For cross-sectional TEM examination slices with a thickness of about 1 mm were obtained from the MgO single crystal with the voids using cleavage fracture along {100}. Two slices were glued together with the original surfaces exposed to implantation facing each other and separated by the glue (Gatan G-1 epoxy and hardener). The coupled slices of MgO were glued in cross-section geometry on a Cu ring (3 mm outer and 2 mm inner diameter). Then the MgO was ground and polished to a thickness of about 100 μm. Using dimpling from the Cu side the thickness of the MgO in the center of the ring is reduced to about 25 μm. Finally, the dimpled sample was thinned to electron transparency by two beams of 4 kV Ar^+ ions making an angle of 6° with the top and bottom sample surfaces using a Gatan PIPS 691. TEM observations were performed using a JEOL 4000 EX/II operating at 400 kV (point to point resolution of 0.165 nm).

An overview of the implanted top layer of the MgO is shown in the bright-field TEM image of Figure 40 (viewing direction close to [001] and in a two-beam condition with the other strong beam $g = 220$). At a distance of about 50–60 nm from the edge of the foil a localized band of rectangular features can be observed. These rectangular features are visible due to Fresnel contrast resulting in a bright outer fringe and a dark inner fringe indicating the overfocus condition during imaging. Figure 41 shows the rectangular features in underfocus condition. The Fresnel contrast makes clear that rectangularly shaped voids, due to the He implantation and the annealing treatments, are present in the MgO

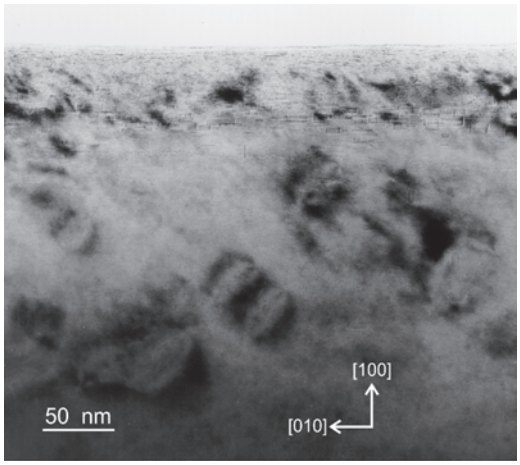

Figure 40. Bright-field TEM image (two-beam condition with other strong beam $g = 220$) showing an overview of the implanted top layer revealing the presence of sharply rectangular nanocavities as seen by Fresnel contrast in overfocused condition.

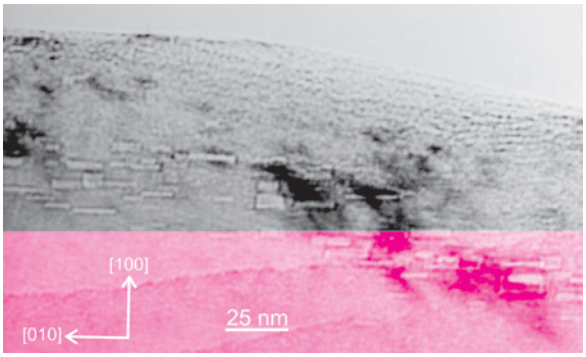

Figure 41. Bright-field TEM image (two-beam condition with viewing direction near to [001] and with other strong beam $g = 220$) showing sharply rectangular nanocavities as seen by Fresnel contrast in underfocused condition.

with observable sizes of the edges ranging between 0 and 20 nm. The crystal orientation of the MgO is well defined (with the edge of the TEM specimen still more or less parallel to the original implanted surface) and the sides of the rectangular voids correspond to cube planes of the MgO. The present results clearly indicate that already for voids in the nanometer scale range in MgO a very strong tendency for faceting is present. This is uncommon for nanoscale voids (bubbles) obtained after He implantation and annealing in metals or semiconductors and previously investigated ceramics such as α-Al_2O_3 [170–174]. Then, the nanovoids are spherical and only for increased sizes (e.g., larger than a few tens of nm) do they become faceted.

The origin of the strong tendency for faceting in the MgO system is most probably related to the high (Pauling's) ionicity of MgO. The surface energy for different facets of MgO is largely determined by the polarity of the terminating plane. Nonpolar surfaces have finite energies whereas in case of a dipole moment in the repeat unit perpendicular to the surface the energy diverges and becomes infinite [175]. Hence, for highly ionic systems spherical voids are even at a size of a nanometer unfavorable, because locally an uncompensated dipole moment perpendicular to the surface may result.

The shape of the voids is expected to be independent of its size when the Wulff construction is applied. However, for decreasing size of cavities the fraction of atoms on or near edges and also of atoms in or close at corners that contribute to the total energy of the cavity increases. Hence, the prediction of the shape by surface energy of individual facets alone will no longer apply. Minimization of the surface area with respect to the enclosed volume tends to have a controlling influence on the shape of the void. For metals and semiconductors and ceramics aforementioned this mechanism, which leads to small spherical cavities, applies, but for voids in MgO it does not. Apparently, due to the extreme anisotropy in energy of atoms in different surface states, the voids in MgO are bounded by cube planes of the MgO, independent of the size of the cavities. In the literature, surface energies for MgO (111) and (110) are quoted to be a factor 2 to 4 times larger than for the (100) surface [176].

In the region within 50–60 nm from the edge in Figure 41 hardly any cavities are found indicating the locally low He concentration after implantation. Helium in this region can have formed undetectably small clusters or can have diffused to earlier nucleated cavities at larger depth or to the surface followed by desorption. At a larger distance from the edge than where the cavities are located, other sharply contrasting features can be observed in Figure 42. These features become more apparent at a distance of about 250 nm from the edge in Figure 42, showing a strong-beam dark-field image for viewing near to [001] for $g = 420$ as indicated by the arrow. Note that the dark-field image is inverted for reasons of clarity (i.e., the gray scale from black to white is white to black instead). These features can be identified as dislocation loops, often with the same inclination to the viewing direction. Dislocation loop contrast may also originate from (partially) coherent precipitates [177]. However, in the present context of He implantation and annealing the presence of dislocation loops is not surprising whereas of precipitates it is unlikely. Dislocation loops in MgO as a result of irradiation damage followed by annealing were found to be of interstitial type with a Burgers vector of $1/2\langle 110\rangle$. The low density and large sizes of the dislocation loops compared to the cavities indicate the low concentration of implanted He and large diffusion distances at the depth of the dislocation loops.

The white dashed line in Figure 42 indicates the center of the region where the cavities are localized; although not visible in Figure 42 they could be well recognized on the original negative. For determination of the depth of the cavities and the dislocation loops below the original sample surface Figure 40 is not suitable, because during preparation of the TEM sample a part of the top layer has been removed by ion milling. On the other hand, Figure 42 is suitable for obtaining the depth of the voids and dislocation loops since the region imaged in Figure 42 is very close to unremoved glue between the surfaces of the two MgO slices. Therefore, we can be sure that the cavities are located at a depth of about 120 nm (almost all localized in between 100 and 140 nm) and the dislocation loops are localized at a depth of 150–350 nm (mostly at a depth of about 250 nm).

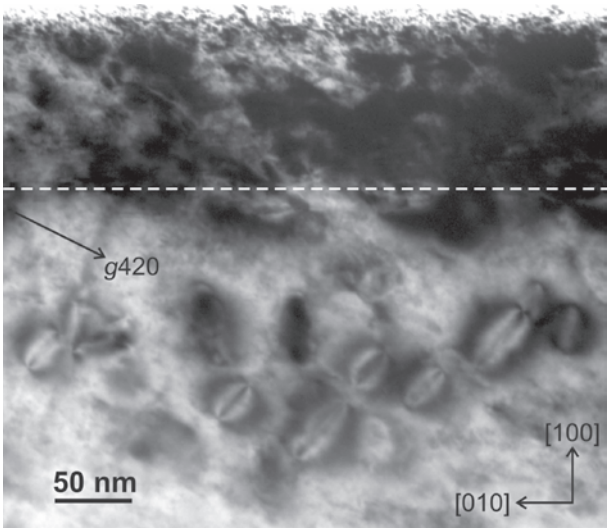

Figure 42. Strong-beam, dark-field TEM image for a viewing direction near to [001] with $g = 420$ showing dislocation loop contrast at a depth between 150 and 300 nm. The white dashed line at a depth of 120 nm indicates the center of the region where the rectangular voids are present (they are not visible in the present micrograph but clearly traceable in the original negative). For reasons of clarity the intensity scale of the image is inverted (i.e, the gray scale from black to white is white to black instead).

As mentioned earlier positron beam analysis had been performed to the sample before TEM examination. Positrons have a high affinity for trapping at vacancies and agglomerates of vacancies or voids. In general the 511 keV photon peak observed due to annihilation of the positron with an electron from the sample is Doppler broadened. The electron carries a certain momentum component to or from the detector so that broadening occurs. The momentum of the electrons encountered in the defects is generally lower than in the bulk and therefore broadening is reduced in that case. When the cavity is larger than about 0.8 nm positronium, the bound e^+–e^- pair is formed in the cavity which annihilates with even less broadening. The shape of the peak is characterized quantitatively with the aid of two parameters S and W. S accounts for the weight of the low momentum contributions and W for the high momentum contributions (see Section 2). In this section we will use the S-parameter versus positron implantation energy measurements to investigate the depth profile of the formed cavities.

The positron results are shown in Figure 43, where the S versus E curves obtained for several annealing temperatures are plotted. By fitting the results with a three-layer model

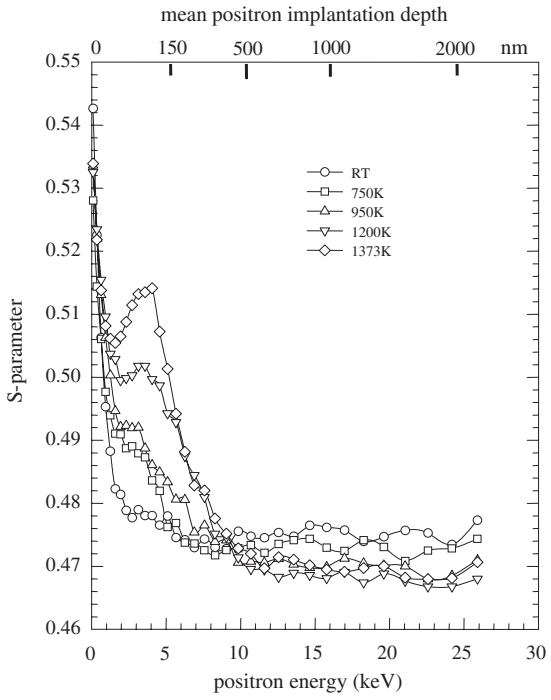

Figure 43. The S-parameter as a function of positron energy for the 1×10^{16} cm^{-2} ^3He implanted MgO(100) crystal after annealing at the indicated temperatures. The mean probe depth of the positrons is indicated in the top scale. Note the increase of the S-parameter upon annealing at the depth corresponding with the cavity layer from Figure 42.

allowing for diffusion and defect trapping of the positrons two defect layers are identified on the substrate. The first layer is the layer where according to TRIM calculations displacement damage without helium is produced by the helium implantation. During annealing the *S*-parameter increases gradually from a value of 0.478 to a saturation value of 0.505 at 1200 K. This indicates that some vacancy clustering occurred in the layer. In the second layer, where the helium was implanted and displacement damage reached its maximum, the bubbles were formed which after helium release turned into the observed cavities. The fitted *S*-parameter of 0.523 found for that layer clearly indicates the formation of positronium in line with the microscopic observation. The zone of depth where the cavities are found coincides rather well with the defect layer 2. The best fit was obtained for a zone from 100 to 140 nm. For the sample with half the helium implantation dose of the TEM sample the annealing was continued to higher temperature. It was observed that the cavities disappeared at 1500 K. At that temperature self-diffusion is a sufficiently fast process to let shrinkage of the cavities occur. We explain the formation of the cavities by the stabilization of helium during the early stages of vacancy clustering. Helium prevents the vacancy clusters from collapsing to dislocation loops; therefore three-dimensional clusters are formed. The growth of the helium filled vacancy clusters proceeds by an Ostwald ripening process: small clusters will dissociate and larger clusters or bubbles will grow by trapping the helium and vacancies from the dissociated clusters. The final stage is the release of helium from the bubbles by permeation through the top layer of the material.

It appears that a temperature window exists from 1200 to 1400 K in which helium is permeating while the cavities remain thermally stable. In earlier work [172] where MgO was neutron irradiated, cavities or voids were never observed. Apparently, it is essential to have a sufficiently high gas concentration in MgO to promote the void formation. It is well known that for a variety of ceramic materials (e.g., Al_2O_3 exposed to neutron irradiation) ordered void structures are developed. It is likely that gases, notably transmutation produced helium, are involved which may stabilize the growing voids. In contrast to metals, where helium remains bound and stabilizes the cavities or bubbles to temperatures close to melting, in ceramics helium permeates from the cavities to the vacuum at a much lower temperature and leaves cavities behind which are stable to temperatures where they dissolve by vacancy dissociation. If the implanted atom has a higher solubility than helium or hydrogen, nanoprecipitates in the case of metal atoms or gas bubbles in the case of the heavier noble gas atoms are observed. Gold precipitates have been observed in MgO [178] and gas bubbles of nanosize have been observed in UO_2 [179] and in MgO [171]. Larger gas bubbles of micrometer size are known from MgO crystals grown from the melt [180].

This section has shown that rectangular and flat nanosize cavities are formed, which have a thickness generally much smaller than the lateral dimensions. In the future it is of interest to know what morphology the cavities will have when lower helium doses are used. It has already been shown that existing cavities can be grown larger by postirradiation with hydrogen followed by thermal annealing. Of importance for the study of interfaces will be the possibilities offered to study interfaces and interfacial reactions by observing the cavities and their shape by refilling the cavities with gas or other atoms. The cavities form an interesting materials-testing laboratory in a nanoworld protected from the environment.

6.3. Calculations of the Vacancy Cluster Structures in MgO and Their Interaction with Helium

6.3.1. Methodology

It is important to study the nucleation of voids by calculating the formation energies of small vacancy clusters. Defect formation energies are compared with calculations and experimental data from literature [156, 181, 182]. Furthermore, the activation energies associated with helium migration and dissociation from vacancy-type defects are calculated. These energies are compared with the activation energy for permeation of helium through a 100 nm thick layer of (100) MgO as observed with NDP.

Calculations have been carried out using the Mott–Littleton methodology as implemented in the code CASCADE [183]. Atomistic simulations are based on a classical Born description of the lattice with pair potentials acting between atomic species. The ionic interactions have two components: a long-range Coulombic interaction and a short-range interaction, which accounts for the effect of electron cloud overlap and van der Waals energies. In this study short-range terms are approximated using parameterized pair potentials of the Buckingham form where A, ρ, and C are the potential parameters:

$$S(r_{ij}) = A_{ij}e^{-r_{ij}/\rho} - C_{ij}/r_{ij}^6 \tag{57}$$

Two distinct potential parameter sets are used in this study, the parameters of which are listed in Table 13. The potential set for the so-called full charge model was derived with the assumption that the lattice ions assume their full charge states of $+2.0e$ and $-2.0e$ for Mg and O respectively. The potential set for the partial charge model was derived for Mg and O ions with a partial charge of $+1.7e$ and $-1.7e$ [184]. This partial charge state is based on quantum mechanical calculations. The parameters of both potential sets were derived by simultaneous fitting to the relevant crystal properties (e.g., lattice parameter, elastic and dielectric constants) [184]. In addition to the pair potentials, the Dick and Overhauser shell model is used to describe polarization effects. The shell model parameters are also listed in Table 13. The method is further explained in [185]. The variations of helium–magnesium and helium–helium energies as a function of atomic separation were calculated within the electron-gas approximation [186] with subsequent fit to a Born–Mayer potential form. The important helium–oxygen potential was taken from [187], where energies were calculated within the Hartree–Fock approximation based on a distribution of oxygen ions characteristic of the UO_2 lattice.

Throughout this section, defects will be written in a modified Kröger–Vink notation (see Table 15). Activation energies for migration of vacancies and interstitials are obtained

Table 13. Potential parameters for the full and partial charge model.

			Full charge model	Partial charge model	Ref.

by calculating defect formation energies at discrete positions along the migration path and subtracting the minimum formation energy at the interstitial position from the maximum formation energy at the saddle point (see Fig. 44). The migration paths for charged magnesium and oxygen vacancies V''_{Mg}, $V_O^{\bullet\bullet}$, and charged magnesium and oxygen interstitials $Mg_i^{\bullet\bullet}$, O_i'' follow straightforwardly from the simple structure of MgO [181]. Interstitial helium atoms $He_i^{\times}$ follow the same migration path as charged oxygen and magnesium interstitials, in a ⟨100⟩ direction (see also Fig. 47).

6.3.2. Results and Discussion

First, the formation energies of Schottky and Frenkel defects, the migration activation energies of oxygen and magnesium vacancies and interstitials, as well as the migration activation energy of helium interstitials in MgO were calculated. The results are listed in Table 14. The energies reported here show good agreement with earlier INDO and pair potential calculations [181, 182] and with experimental results. In general, values reported in the literature are in between the full charge and partial charge values of Table 14. Although the absolute values calculated with the partial charge model agree better with the experimental data, the relative energies predicted by each model are essentially the same. Thus, for example, Schottky disorder is proportionally more favored over Frenkel disorder by both models.

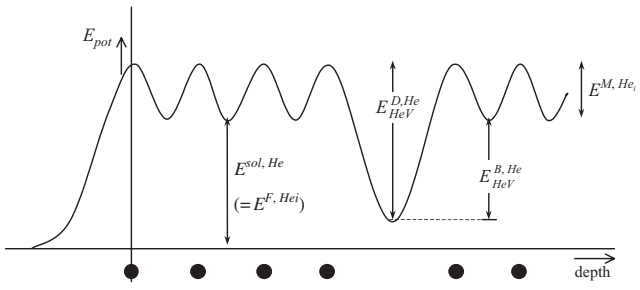

Figure 44. Potential energy diagram of helium interactions with a solid. The peaks in the potential energy diagram correspond to the location of a plane of atoms (indicated by the atoms in the bottom of the figure).

Table 14. Formation energies of Schottky and Frenkel defects, migration energies of oxygen and magnesium vacancies and interstitials, and the formation and migration energy of helium in MgO.

Defect energies (eV)		Full charge model	Partial charge model
Lattice energy	E^{latt}_{MgO}	−41.16	−29.74
Schottky pair	$E^{F,\,V_O^{\bullet\bullet}} + E^{F,\,V''_{Mg}}$	8.44	6.12
Schottky cluster	$E^{F,\,\{V_{Mg}V_O\}^{\times}}$	5.35	3.90
Frenkel–Mg	$E^{F,\,V''_{Mg}} + E^{F,\,Mg_i^{\bullet\bullet}}$	13.35	9.58
Frenkel–O	$E^{F,\,V_O^{\bullet\bullet}} + E^{F,\,O_i''}$	13.81	9.95
Migration energies	$E^{M,\,V''_{Mg}}$	2.08	1.53
	$E^{M,\,V_O^{\bullet\bullet}}$	2.12	1.56
	$E^{M,\,Mg_i^{\bullet\bullet}}$	0.64	0.46
	$E^{M,\,O_i''}$	0.58	0.47
	$E^{M,\,He_i}$	1.08	0.71
He solution energy	$E^{\text{sol,He}} = E^{F,\,He_i}$	3.19	2.80

Note: Definitions of the formation and migration energies can be found in Figure 44.

Vacancy Clusters Next, the energetically most favorable configurations of selected vacancy clusters composed of up to eight vacancies were determined. A number of possible configurations are displayed in Figure 45 and the corresponding formation energies are listed in Table 15. Again both partial and full charge models yield equivalent relative geometric preferences.

By considering Figure 45 and Table 15 it is clear that configurations which induce low polarization around the vacancy cluster are energetically favorable. An interesting extension of this hypothesis is that the energetically most favorable configuration for an eight-vacancy cluster is a cube. Here a three-dimensional configuration is preferred to any planar configuration. A vacancy cluster consisting of a monolayer "slab" induces polarization oriented perpendicular to the monolayer slab. However, when there are two adjacent monolayers of vacancies, the vertically orientated polarization induced by the two monolayers cancels to a large degree due to the alternate arrangement of magnesium and oxygen atoms in the MgO matrix. Therefore three-dimensional growth in an even number of slabs reduces the formation energy of vacancy clusters. This explains why voids in MgO are relatively easy to create.

Helium Defect Interactions Now that the configurations of the energetically most favorable vacancy clusters have been determined, an approximation for the activation energies for dissociation of the nth helium atom from a He_nV_m vacancy-type defect (i.e., $V_mHe_n \rightarrow V_mHe_{n-1} + He_i$) can be calculated. Here again V_m can be either an oxygen or magnesium monovacancy or a cluster composed of an equal number of oxygen and magnesium vacancies, totaling m vacancies. The dissociation energies $E^{D,\mathrm{He}}_{\mathrm{He}_n\mathrm{V}_m}$ have been calculated by summing the binding energy of the helium atom in the vacancy cluster, $E^{B,\mathrm{He}}_{\mathrm{He}_n\mathrm{V}_m}$, and the migration energy of interstitial helium in defect-free MgO, $E^{M,\mathrm{He}}$. The binding energy is calculated from formation energies of helium-filled vacancy clusters, $E^{F,\mathrm{He}_n\mathrm{V}_m}$, and the helium interstitial formation energy, E^{F,He_i}.

$$E^{D,\mathrm{He}}_{\mathrm{He}_n\mathrm{V}_m} = E^{B,\mathrm{He}}_{\mathrm{He}_n\mathrm{V}_m} + E^{M,\mathrm{He}} \tag{58}$$

$$E^{B,\mathrm{He}}_{\mathrm{He}_n\mathrm{V}_m} = E^{F,\mathrm{He}_{n-1}\mathrm{V}_m} + E^{F,\mathrm{He}_i} - E^{F,\mathrm{He}_n\mathrm{V}_m} \tag{59}$$

The definitions of these energies can be found in Figure 44. The calculated dissociation activation energies are listed in Table 16 and are depicted in Figure 46.

It is clear from Table 16 and Figure 46 that the dissociation energy of helium from a vacancy or vacancy cluster containing only one helium atom ($n = 1$) is more or less constant: 4.4 eV for the full charge model and 3.6 eV for the partial charge model. Helium atoms experience empty vacancy clusters as vacuum and therefore the dissociation energy does not increase with larger cavities. Only the magnesium vacancy is apparently somewhat smaller than the oxygen vacancy. Another result of importance to note is that the fifth helium atom in an oxygen vacancy ($n = 5$) is not bound at all; that is, the dissociation energy for the fifth helium atom in a $\{V_OHe_5\}^{\bullet\bullet}$ defect is less than the helium migration energy in the MgO bulk (Tab. 14, Fig. 46) for both the full charge and partial charge model. Thus the binding energy of the cluster is negative and such a cluster would not be stable.

The activation energy for helium atom dissociation from a cluster as we have calculated assumes that the migration activation energy for a helium atom, $E^{M,\mathrm{He}}$, as it moves away from the cluster, is the same as in the bulk defect-free material. However, local relaxation of the lattice surrounding the defect may increase (or decrease) this energy.

In order to learn more about the dissociation of a single helium atom from a monovacancy, the potential energy of the helium atom has been calculated along the escape trajectory from an oxygen vacancy as depicted in Figure 47. From here on, only the partial charge model is considered. The helium potential along the trajectory as a function of the distance from the center of the monovacancy is shown in Figure 48. Regarding the saddle points that can be distinguished in Figure 48, it is clear that the potential energy at the first saddle point is slightly larger than at the subsequent saddle points. It results in a dissociation energy of 3.9 eV rather than 3.5 eV [obtained with Eqs. (58) and (59)]; see Table 16. This effect is the result of the charged nature of the monovacancies: an oxygen monovacancy exhibits a charge of $+1.7\,e$ with respect to the defect-free MgO matrix. The nearest-neighbor magnesium atoms will be repelled by Coulombic interactions and the second-neighbor oxygen atoms will be attracted to the defect. The expansion and contraction of the first and second ion shells around the oxygen vacancy result in a potential barrier, which increases the activation energy of helium dissociation from a monovacancy. This effect (although without helium) has already been reported by Kotomin and Popov [182]. The increased activation energy for the monovacancy is expected to be

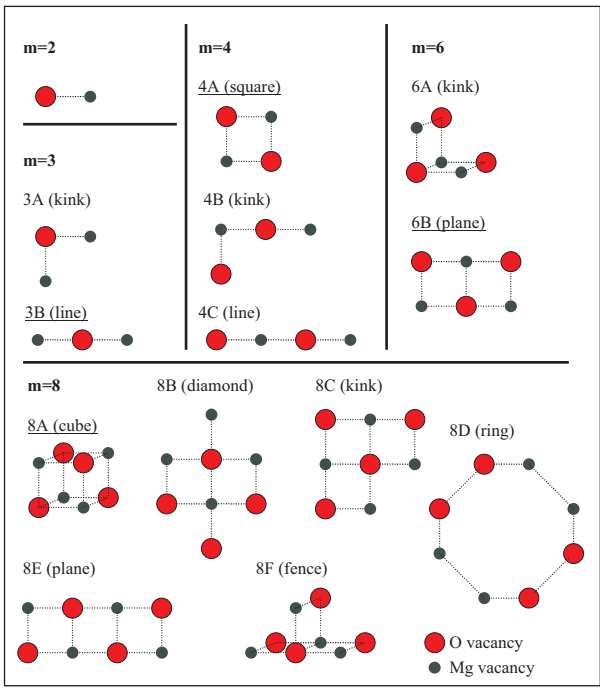

Figure 45. Possible vacancy cluster (V_m) configurations. Note that the depicted atoms represent vacancy sites. The formation energies are listed in Table 15. The energetically most favorable configurations are underlined.

Table 15. Formation energies of vacancy clusters V_m, $1 \le m \le 8$ (here m is the total number of vacancies in the cluster: either oxygen, magnesium, or both).

higher than for any of the neutral clusters since distortions to the surrounding lattice by neutral defects are much less.

Helium Permeation through MgO The calculated values of the helium dissociation energy can be compared with the results of helium permeation from cavities in MgO. A dense layer of helium bubbles at a depth of 100 nm was created by ^{3}He ion implantation in a single crystal of (100) MgO and subsequent annealing at a temperature of 1200 K [188]. By NDP it is observed that helium permeates to the surface during isochronal annealing at a temperature of 1323 ± 70 K on a time scale of 30 min. Cross-sectional transmission electron microscopy investigations have shown that the 100 nm thick layer between the cavities area and the surface is reasonably defect-free [120].

When dissolving the helium is the rate-determining step, the helium release from the layer of gas bubbles can be modeled as a quasi-stationary flow of gas. This flow is sustained by the gradient that exists from the equilibrium concentration $c_{He,\,eq}$ of dissolved gas near the cavity layer to the

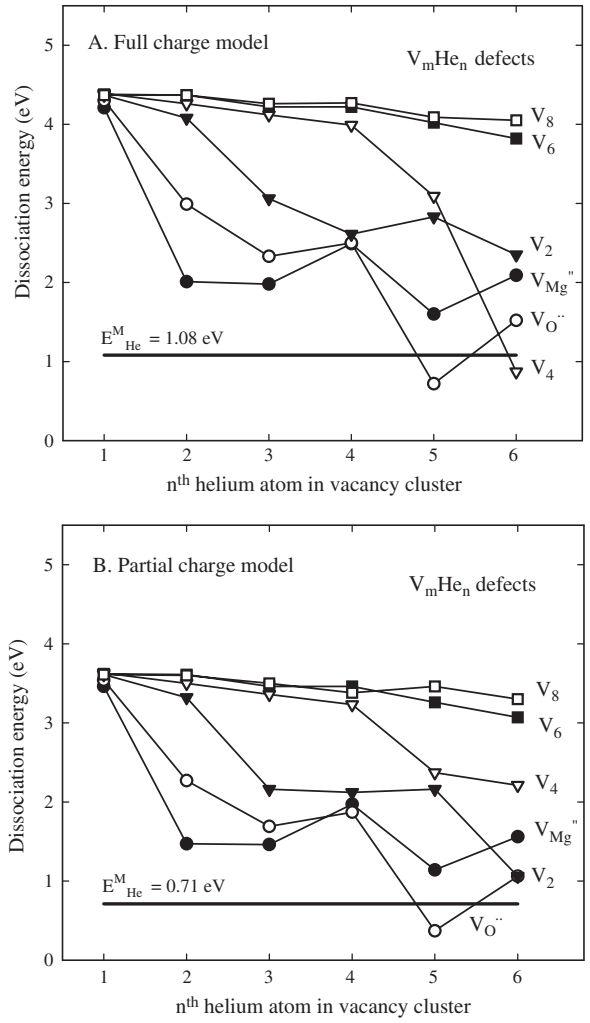

Figure 46. Activation energies for the dissociation of one helium atom from helium-filled vacancy clusters (i.e., $V_mHe_n \rightarrow V_mHe_{n-1}$ + He_i) as a function of the number of helium atoms n in the cluster prior to dissociation. Lines are drawn to guide the eye.

zero concentration near the external surface,

$$\frac{dN_{He}}{dt} = -D\frac{dc_{He}}{dx} = -D\frac{c_{He,\,eq}}{L} \tag{60}$$

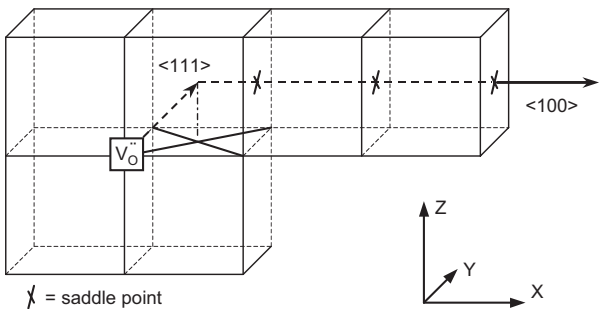

Figure 47. Assumed trajectory of a helium ion dissociating from an oxygen monovacancy.

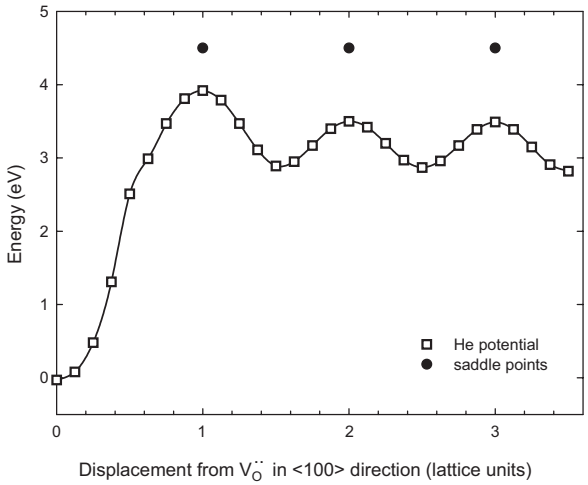

Figure 48. Potential energy graph of a helium atom dissociating from an oxygen vacancy in MgO, following the trajectory of Figure 47. Only the partial charge model is considered.

where dN_{He}/dt is the flow rate of helium atoms per unit area in m^{-2} s^{-1}, c_{He} is the concentration of helium atoms in m^{-3}, x is the depth in the sample in m, and L the depth of the cavity layer in m. D is the helium diffusivity in m^2 s^{-1} and is related to the helium migration energy E_M as [189]

$$D = \frac{1}{6}\lambda^2\frac{\omega}{2\pi}\exp(-E_M/kT) \tag{61}$$

Here λ is the jumping distance between two interstitial sites (2.1 Å), ω is a fundamental attempt frequency taken as 10^{13} s^{-1}, k is the Boltzmann constant (8.62×10^{-5} eV K^{-1}), and T is the temperature in K. Substituting 0.71 eV for E_M (Table 14) in Eq. (61), the relaxation time to establish a stationary flow $\tau_D = L^2/2D$ is of the order of 10^{-4} s, orders of magnitude smaller than the gas release time (of the order of minutes). The approach of quasi-stationary flow is therefore feasible. The equilibrium concentration of helium in MgO is [189]

$$c_{He,\,eq} = c_{MgO}\ \exp(\mu/kT - G_{sol}/kT) \tag{62}$$

with c_{MgO} the atomic concentration of MgO, 1.07×10^{29} atoms m^{-3}. μ is the chemical potential and G_{sol} the Gibbs free energy of the gas in solution. For a dense bubble layer with gas at low helium pressure and a planar configuration [189, 190]

$$\exp(\mu/kT - G_{sol}/kT) = \frac{N_{He}}{d_c}\left(\frac{2\pi\hbar^2}{mkT}\right)^{3/2}\left(\frac{kT}{\hbar\omega}\right)^3 \times \exp(-E_{sol}/kT) \tag{63}$$

with N_{He} the number of helium atoms in the bubble layer per unit area in m^{-2}, d_c the effective thickness of the bubble layer in m, m the mass of the ^{3}He atom in kg, and E_{sol} the helium solution energy as defined in Table 14 and Figure 44. Note that N_{He}/d_c represents the density of helium in the cavities. The effective layer thickness d_c equals 0.5 nm calculated as the product of the thickness of the cavity layer, 20 nm, and the void fraction of 2.5%. Substitution of

Eqs. (61)–(63) into Eq. (60) and integration with respect to time yields the following expression

$$\frac{N_{\mathrm{He}}}{N_0} = e^{-ft} \qquad \text{and}$$

$$f = \frac{\lambda^2 \omega}{12\pi L} \frac{c_{\mathrm{MgO}}}{d_c} \left(\frac{2\pi\hbar^2}{mkT}\right)^{3/2} \left(\frac{kT}{\hbar\omega}\right)^3 e^{-E_{\mathrm{perm}}/kT} \qquad (64)$$

The permeation energy, E_{perm}, is defined as $E_{\mathrm{perm}} = E_{\mathrm{sol}} + E_M$ and t is the time in s during which the permeation occurs. With a decrease in helium content of 86% ($N/N_0 = e^{-2}$) and the values given previously, the permeation energy can be calculated. This yields a permeation energy of 3.3 ± 0.3 eV, which agrees reasonably well with the dissociation energy of 3.6 eV for helium desorption from vacancy clusters calculated with the partial charge model.

As the predicted value is still somewhat higher than the experimental value, one has also to consider the mechanism of vacancy-assisted migration. The migration energy of a helium–vacancy complex is 2.3 eV calculated with the partial charge model. In order to obtain the activation energy for vacancy-assisted migration, this energy has to be added to the energy required to produce a thermal vacancy (a large concentration of vacancies is required for the process of vacancy-assisted migration). Thermal vacancies are produced at temperatures corresponding to an energy of 3.1 eV (half the Schottky defect energy as defined in Table 14) or more. Thus an activation energy of 5.4 eV for vacancy-assisted migration is obtained which makes this process much less feasible than helium permeation through the bulk.

6.4. Conclusions

The energetically most favorable configurations for vacancy clusters have been determined and three-dimensional growth of vacancy clusters is feasible, as this introduces less lattice polarization around the vacancy clusters. As a result, the energetically most favorable configuration of an eight-vacancy cluster is a cube. The partial charge model is more successful at predicting basic defect energies as the results calculated with the full charge model are in general too high when compared to experimental values reported in literature. The experimentally determined permeation energy of helium in MgO is 3.3 ± 0.3 eV as observed with NDP. This agrees reasonably well with the activation energy of 3.6 eV calculated with the partial charge model for helium dissociation from large vacancy clusters. However, the calculated activation energy for helium dissociation from a single oxygen vacancy is expected to be higher: 3.9 eV. This effect is due to lattice relaxation around the charged oxygen vacancy.

In particular, with respect to the helium defect interactions, more experimental data concerning helium desorption from MgO should be gathered in order to obtain a better understanding of the kinetics of the helium desorption process. This could be achieved with, for example, permeation experiments observed by NDP or by thermal helium desorption spectrometry (THDS). The predictions might be further improved by calculating the migration activation energies for helium from clusters explicitly. A THDS study has shown that in most cases helium release is characterized by the activation energy of $Q = 4.7 \pm 0.5$ eV with the maximum release temperature of $T_{\mathrm{max}} = 1830$ K. By applying a first order desorption model the pre-exponent factor is estimated as $\nu = 4.3 \times 10^{11}$ s^{-1}.

7. NANOCAVITIES IN SILICON

7.1. Introduction

In 1987 it was discovered by Griffioen et al. [191] that helium bubbles created by helium ion implantation in a silicon wafer could be turned into cavities by annealing to temperatures of about 800 °C. The helium and vacancies produced by implantation agglomerate in small bubbles at room temperature evolve further during annealing to larger bubbles from which at elevated temperature the helium is released. In contrast to metals, cavities in ceramics (e.g., silicon and the metal oxides considered here) are rather stable and the helium is trapped less strong. Therefore in most metals helium bubbles survive until temperatures close to melting. In silicon and most of the metal oxides (e.g., MgO, ZrO_2, UO_2) helium is released before the cavities disappear.

Subsurface layers of nanocavities are a good alternative for metal impurity gettering in silicon. Since Myers et al. [192] demonstrated in 1993 the use of the cavities for this purpose numerous studies (see, e.g., [193, 194]) have followed to unravel the details of formation and evolution of the cavities. Usually, the cavities are created by 30–40 keV helium ion implantation at depths of 200 nm but in this study the cavities are created at depths of 3–5.5 μm in order to leave more space to make certain devices in the remaining silicon top layer. Therefore, it is envisaged that the evolution of the bubbles and the release of helium is less influenced by the proximity of the surface. In other words, less of the reaction products evolving from dissociation of small helium vacancy complexes will reach the surface and therefore the bubble formation is more effective. The goal of the section is to understand the release of helium during the evolution of the defect layer from bubbles to cavities. In the first paper on release from cavities, release of 2.5 keV implanted helium ions could well be described by assuming a single cavity at shallow depth of 30 nm from the surface. Moreover, the description was restricted to cavities which were refilled with a small amount of helium (i.e., describing the low-pressure case). In this and many other studies release is monitored for bubbles at their initial pressure and for bubbles forming part of a bubble layer of thickness 10 to 50 bubble sizes [195, 196].

Thermal desorption spectrometry (TDS), NDP, non-Rutherford backscattering (NREBS), and NRA have been employed to measure the helium content and release rate during isothermal annealing at annealing temperatures of 800 and 1000 °C. TDS has also been used for isochronal annealing. X-TEM is used to monitor changes in morphology in the formed bubble layer. The helium release results can be modeled rather well when it is assumed that the helium initially is present in overpressurized bubbles. A single activation energy for helium release is revealed with a value of 1.83 (0.05) eV in agreement with the activation energy of helium permeation through silicon.

7.2. Experimental Methods

The Si(100) samples of a size of about 1 cm^2 have been implanted with the 3.5 MeV van de Graaf implanter at CERI Orleans. Two implantation energies, 1.00 and 1.55 MeV, respectively, have been used for the NDP analysis. ^{3}He was used as projectile. The amount of ^{3}He was determined by the ^{3}He$(n, p)^3$H reaction where a thermal neutron beam was used and the protons of the reaction with maximum kinetic energy of 574 keV were monitored by a Si detector. Protons originating from the helium bubble layer at a depth of 5.6 μm (1.55 MeV implantation) have 186 keV left when they leave the sample surface. Also for NRA the ^{3}He isotope is used in the ^{3}He$(d, p)^4$He reaction where the deuteron beam comes from the Orleans accelerator. In NREBS the enhanced scattering of MeV protons from ^{4}He is applied in the reaction ^{4}He$(p, p)^4$He.

It should be remarked that penetration depths and damage production of MeV ^{4}He and ^{3}He isotopes in silicon differ only marginally. Annealing for times varying up to 1.2×10^5 s were performed at two temperatures, 800 and 1000 °C. X-TEM pictures where taken at many stages of the annealing process. For one of the samples implanted at 1.6 MeV with 5×10^{16} cm^{-2} ^{4}He fluence, TDS measurements were performed on a small 1.5 mm^2 part of the sample. The sample was placed in a tungsten crucible that could be temperature programmed heated by electron bombardment. The helium release rate was monitored by a quadrupole mass spectrometer.

7.3. Annealing Results

Results of the remained fraction after several annealing steps are shown in Figure 49 for two temperatures and two fluences. Scattering of the results for NREBS is due to the limited sensitivity of the method with detection limit 3×10^{16} cm^{-2}. NDP has an intrinsic sensitivity 1000× better, but systematic errors are caused by the fact that the annealing treatments are not made for the same sample (in the 800 °C annealing series four samples were rotating) and reproducibility of the annealing oven. The NDP results showed that the bubble layer is located at a depth corresponding to the projected range of the helium. The distribution of the helium was approximated by a Gaussian at that depth. Results obtained for the FWHM of the Gaussian distribution before and after annealing are shown in Table 17. In all cases the first annealing step causes the distribution to narrow considerably. The value varies from 20 to 80% reduction; in particular for the low fluence the reduction is large. Thereafter, the width of the distribution does not change significantly. The 1000 °C annealing for the highest helium fluence yields some 20% wider distribution than the 800 °C annealing.

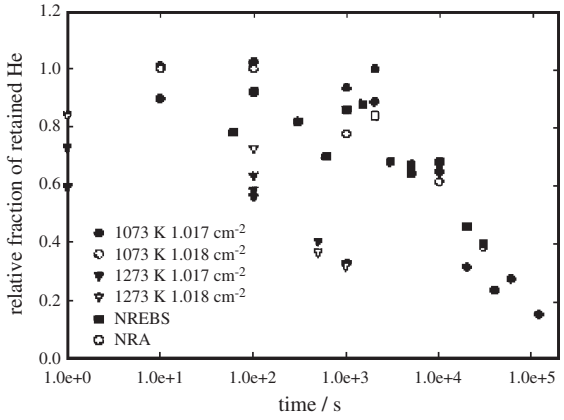

Figure 49. The retained helium fraction for silicon implanted at two fluences and 1.55 MeV helium ion energy for isothermal annealing at 1073 and 1273 K. NDP is used for helium detection. Results obtained with NREBS and NRA are also shown.

The two TEM pictures in Figure 50 show the cavity bands for 800 °C annealing of a 10^{17} cm^{-2} helium implanted sample for 10^3 and 6.1×10^4 seconds annealing time, respectively. The width of the layer with visible cavities has been determined to be 700 nm for 1000 s annealing and 500 nm for annealing up to 6.1×10^4 s. It has been found that bubbles generally increase in size by 20–50% for longer annealing periods. Note that the definition of the X-TEM width differs considerably from the previously defined FWHM determined by NDP. In X-TEM the outermost range is determined in which bubbles are visible, not taking into account the bubble density. Furthermore, the NDP measured width ignores the void fraction of the layer.

The *isothermal* helium release rate for a 5×10^{16} cm^{-2} ^{4}He implanted sample kept at 800 °C is shown in Figure 51. The advantage of TDS regarding release rate measurements is clearly demonstrated here. Due to the very high sensitivity of better than 10 ^{9}He s^{-1} and the fact that the rate rather than the content can be continuously measured the evolution of the release rate can be well monitored. It can be observed that the rate is not governed by a single relaxation time. The release process is about 10 times faster for short than for long annealing times.

Isochronal annealing with a heating rate in the temperature range from 300 to 1250 °C (600–1600 K) was not possible in one continuous run. Release rates would have turned the desorption spectrometer into saturation. Therefore, we adopted an annealing scheme where the isochronal annealing starts first with 800 K as maximum temperature and it is repeated every time to a 50 K higher temperature. The method, which is called partial annealing, keeps the release rates low and has, as will be shown later, certain advantages for desorption mechanism analysis. The results are shown in Figure 52. The plots show the desorption rates during both the heating and the cooling (thin line). With this annealing scheme the maximum release rate is found at temperatures

Table 17. FWHM of the helium distributions measured by NDP before and after annealing.

Energy (MeV)	Fluence (10^{17} cm^{-2})	Annealing temperature (°C)	As implanted (μm)	Annealed (μm)
1.55	1	800	0.37	0.31
1.55	0.5	800	0.38	0.23
1.00	0.5	800	0.27	0.11
1.55	1	1000	0.47	0.37
1.55	0.5	1000	0.37	0.25
1.00	0.5	1000	0.27	0.12

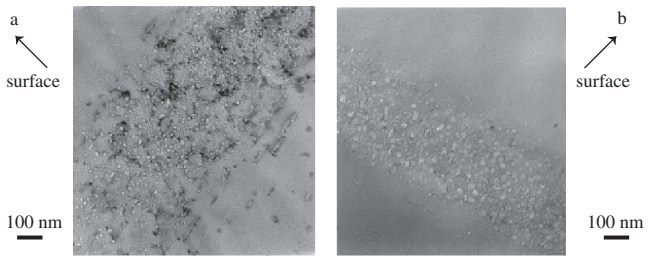

Figure 50. Micrographs (X-TEM) for helium implanted silicon (1×10^{17} cm^{-2}; 1.55 MeV) after annealing at 1073 K for 1000 (a) and 6×10^4 s (b), respectively.

higher than 1300 K (1000 °C). A small remaining fraction of helium is not released until close to the melting point of silicon. The spike is due to bursting of blisters, which develop in the final stage of the annealing process.

7.4. Bubble Evolution and Helium Release

7.4.1. First Stages of the Annealing Process

The results indicate that in the first steps of the process, in the case of isothermal annealing, during heating to the annealing temperature, a complicated defect evolution takes place. Small bubbles or platelets [197] transform into larger bubbles by loop punching and later by Ostwald ripening. It is very likely that all the gas remains contained in the bubble layer during this coarsening process. At low fluence the initial concentration of the helium in the layer is lower than for high fluence so that the layer thickness shrinks more during annealing. The bubbles will be overpressurized. Thermal growth of cavities by interstitial emission or vacancy capture is slow at 800 °C and even at 1000 °C it will take considerable time. It is thought that the cavities move by surface diffusion and eventually coalesce. Equilibrium pressures for bubbles with a size of 7 nm are of the order of 1 GPa. Thus in modeling the gas release this high pressure should be taken into account.

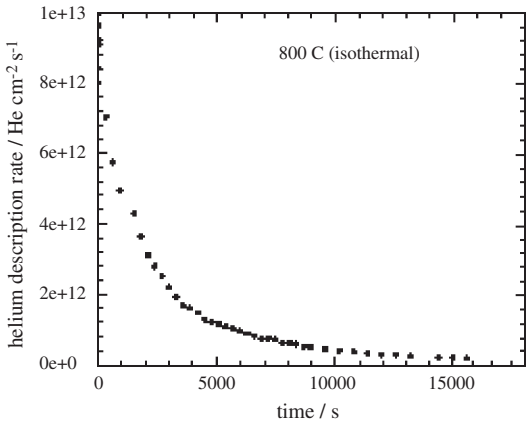

Figure 51. Release rate during isothermal annealing of 5×10^{16} cm^{-2} He implanted Si measured by TDS.

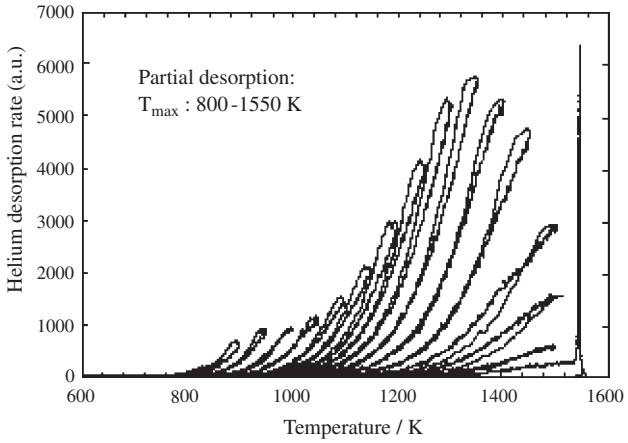

Figure 52. Partial desorption results for small samples similarly implanted as the sample in Figure 51. The heating rate was 3.6 K s^{-1}.

7.4.2. Helium Release Models for Release from Bubbles and Bubble Agglomerates

A good approximation of the helium release from a gas filled cavity is to assume that the gas release is due to a quasi-stationary flow of gas which is sustained by the gradient that exists from the concentration of dissolved gas near the cavity surface equilibrium to the zero concentration near the external surface. First, can be easily calculated that in our experiments time constants to establish equilibrium between gas in the cavity and the dissolved gas near the cavity surface are negligible compared to the observed times required to release a substantial amount of gas. Second, the relaxation time required to establish a stationary flow $\tau_D = L^2/2D$ where L is the distance from cavity to surface and D the helium diffusivity [198] is also small and of the order of seconds. Thus, the gas release rate can be obtained by solving the stationary diffusion equation for the cavity geometry of interest with the appropriate equilibrium concentration of gas c_{eq} as boundary condition near the cavity and zero concentration at the external surface. The concentration is given by equations similar to those in Section 6 for He in MgO, that is, Eqs. (62) and (63) with $\omega = 2\pi\nu$ with $\nu = 4 \times 10^{13}$ s^{-1} for He in Si [191, 192]. The gas flow is found by integrating the diffusion current $J_D = D(dc/dx)_{x=0}$ over the surface area.

For *isolated bubbles* with radius r at distance L from the surface the gas flow

$$\frac{dN}{dt} = \frac{3NP}{rL} \tag{65}$$

with P the permeability, for example, measured by [199] and applied by Griffioen et al. to describe release of low-pressure helium refilled cavities. The description has shown to work satisfactorily also for release from cavities in SPE epitaxial layers [200].

For a *bubble layer with gas at low helium pressure* a similar release rate can be derived, but because of the different geometry the flow is given by

$$\frac{dN}{dt} = \frac{NP}{d_c L} \tag{66}$$

with d_c the effective thickness of the cavity layer (i.e., void fraction times layer thickness).

It can be calculated that interbubble diffusion of helium in the bubble layer is fast compared with the release rate constant. Therefore, it is justified to consider the cavity layer as a united gas reservoir. For nonequilibrium bubbles at high helium pressure the concentration can no longer be derived based on the ideal gas law. Then, the high-pressure expression of the chemical potential μ has to be used.

In Figure 53 the concentration of dissolved gas is calculated according to the experimentally determined EOS of Mills et al. [201] for pressures up to 3 GPa. It is clearly observed that for high pressures (high gas concentrations) in the cavities the solubility strongly increases. Using the EOS of Mills et al. and assuming an initial pressure of 2 GPa (20 kbar) the retention of helium gas is calculated for the experiments shown in Figure 51. The results of the calculations shown in Figure 54a describe the experimental results for the 1073 K annealing rather well (see Fig. 51) when an activation energy for permeation of 1.8 eV and an effective thickness of 200 nm are assumed. The results for 1273 K (not shown) fit well to the experimental result. The value assumed for the effective thickness has not yet been experimentally verified. It is very difficult to derive the void fraction from the TEM pictures. Note that no attempt was made to fit the data. The results are the same when the EOS proposed by Trinkaus is used [202]. In Figure 54b the calculated isothermal release rate is plotted for the 800 °C isothermal annealing which, in line with the experimental results, shows a fast release rate at the beginning of the release process.

7.4.3. Isochronal Annealing: Activation Energy

The partial annealing experiments can give extra information on the release mechanism by considering the initial part of each desorption curve. In principle, the release is a first-order desorption process

$$\frac{dN}{dt} = -Nf \tag{67}$$

with $f = f_o \exp(-E/kT)$ the temperature dependent release frequency and N the number of retained He. Considering

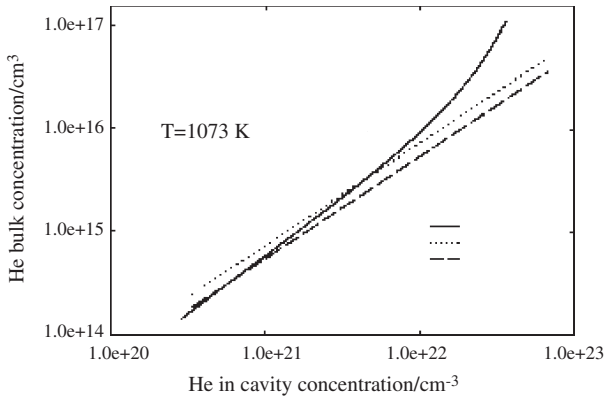

Figure 53. Helium solubility versus Helium density in cavities from the Mills et al. EOS [···] (—), ideal gas law (·····), and [191, 192], respectively.

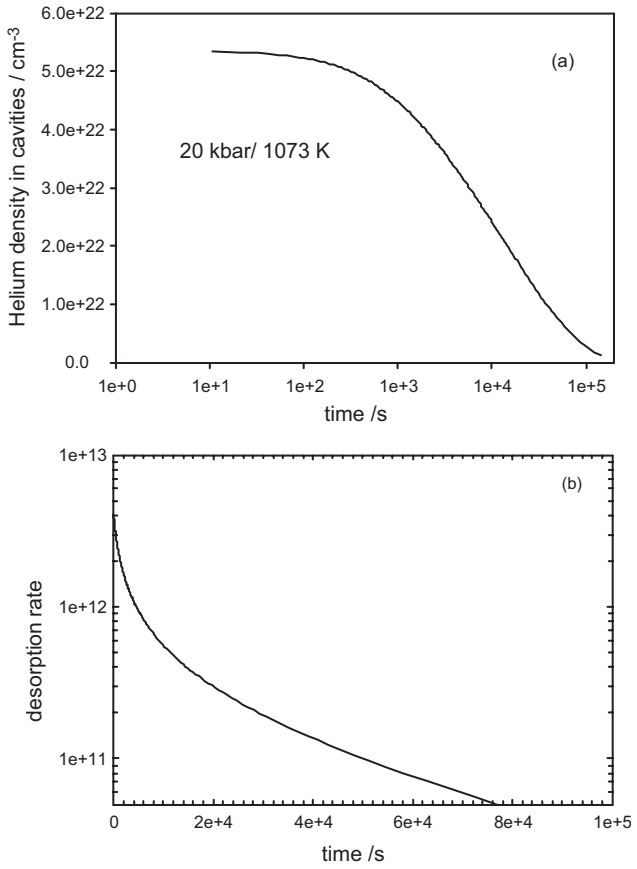

Figure 54. Calculated retained fraction (a) and release rate (b) during annealing for a 1.55 MeV helium implanted Si sample (dose 5×10^{16} cm^{-2}). The Mills et al. equation of state has been used in the theory described in the text.

only the first part of the release N can be considered to be constant and plotting of the release rate vs $1/T$ will show Arrhenius behavior. This is done in Figure 55, and it is found that the energy E derived from the slopes of the partial annealing curves is nearly constant over the whole temperature range. We found $E = 1.83$ (0.05) eV for the activation energy of the process. From the measurements also the different pre-exponential factors $N_i f_{o,i}$ of the different partial annealing treatments could be derived with i denoting the ith partial annealing. Since we know N_i we can calculate the factors $f_{o,i}$. These values have been plotted in Figure 56 vs the helium amount in the cavities. Again it is seen that the prefactor is higher when the concentration is still high. At very low retained fractions the prefactor is reduced even further. This we might ascribe to the observed enlargement of the cavities at very long annealing times. A possible mechanism might be *pressure induced thermal creep* because there is a considerable pressure exerted on the layer by the gas containing bubbles.

In another study Grisolia et al. report in more detail on the growth mechanism of bubbles and cavities in the cavity band. Variation of annealing temperature from 700 to 900 °C leads to increased coarsening. In Figure 57 it is observed that at 900 °C a majority of large cavities of size 20–50 nm survive which are concentrated in a

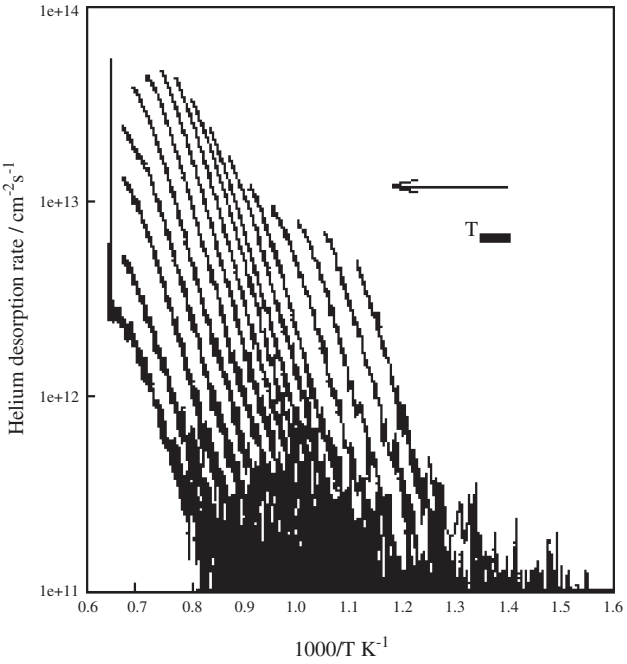

Figure 55. Partial desorption Arrhenius plot for TDS results shown in Figure 52.

narrow band below the surface. The cavity density and the size have been plotted in Figure 58. It shows a considerable decrease of density corresponding with an increase of size at temperatures beyond 800 °C. It was derived that the cavity growth was governed by an activation energy of 1.65 eV. Oliviero et al. studied the influence of the implantation temperature on the density and morphology of the bubbles and the cavities. Typical TDS results in Figure 59 for 50 keV implanted helium at low implantation temperature (473 K) show release in release peaks at temperatures around 800 and around 1200 K, respectively. The low-temperature release occurs when helium–vacancy complexes formed during the implantation break up and form larger complexes. A part of the helium is not retrapped in the newly formed larger complexes and escapes through the surface. The high-temperature release is by helium

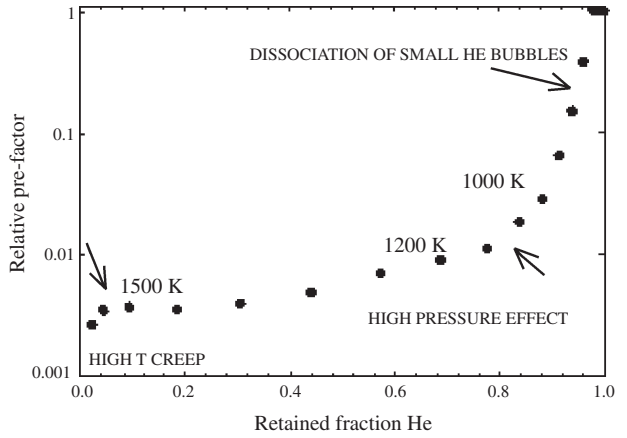

Figure 56. Relative prefactor derived from Figure 55.

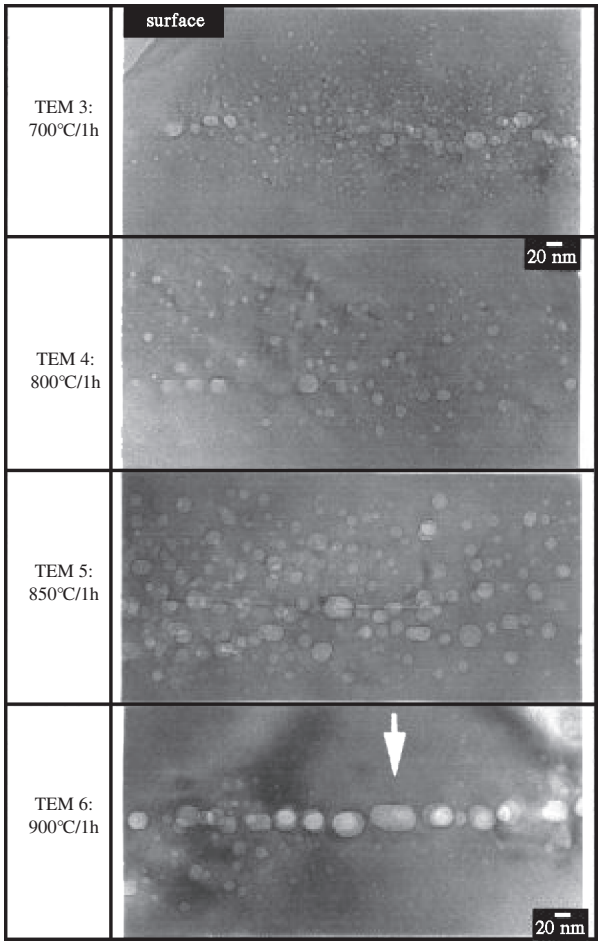

Figure 57. Micrographs showing annealing of helium implanted silicon at temperature varied from 700 to 900 °C.

permeation from bubbles when they have formed. The results are qualitatively similar to the results earlier shown for the 1.5 MeV helium implanted samples. At increasingly higher temperature (673 and 773 K) the first release peaks change their shape and the temperature of maximum helium release. This indicates that depending on the implantation temperature a certain size of helium

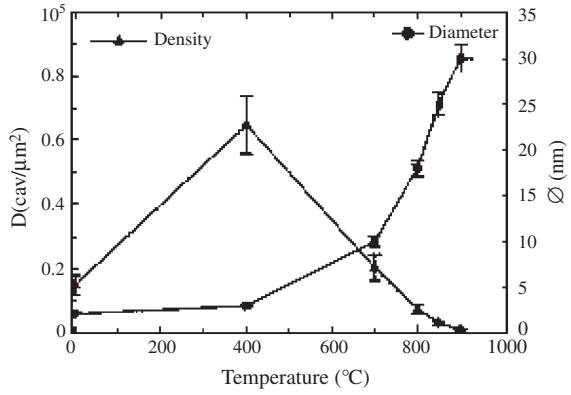

Figure 58. Cavity density and size vs temperature for helium implanted silicon.

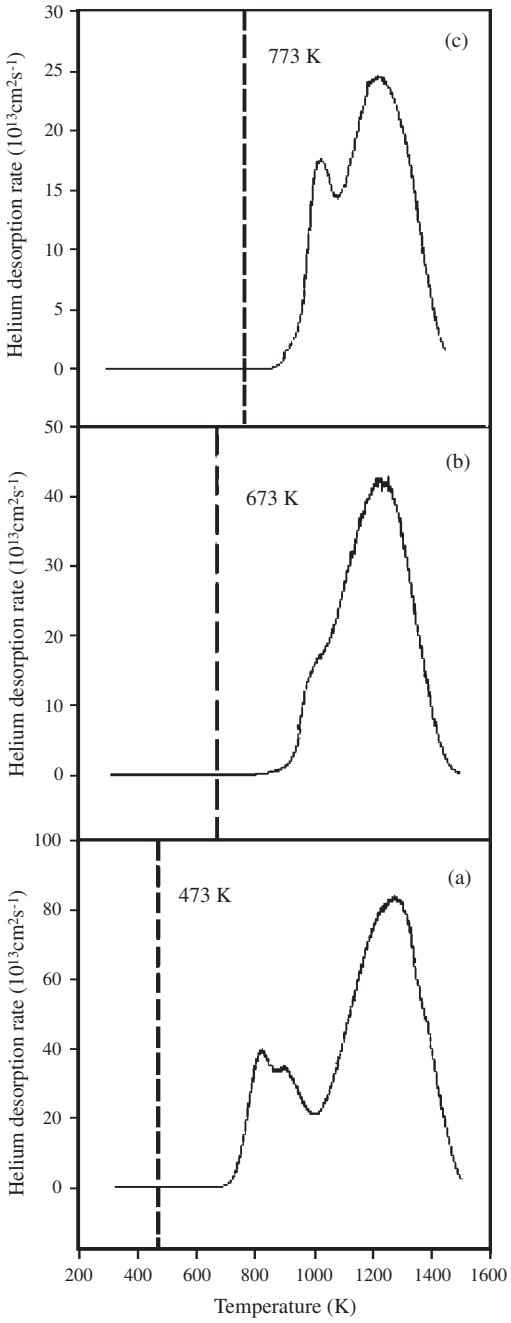

Figure 59. Helium desorption spectrum obtained after helium implantation at (a) 473, (b) 673, and (c) 773 K in silicon (5×10^{16} cm^{-2}, 50 keV). Heating rate: 5 K/s. The dashed line indicates the temperature of implantation.

vacancy complex can survive. Upon further annealing release from these complexes is observed. For implantation at 875 K (desorption spectra are not shown) the helium release is very small, because very few bubbles and cavities are formed. In Figure 60 the retained helium and the bubble/void morphology are shown for the different helium implantation temperatures. At low T small bubbles are observed and at 873 K when all helium is released larger cavities remain. At 1075 K implantation no bubbles are formed because no stable helium

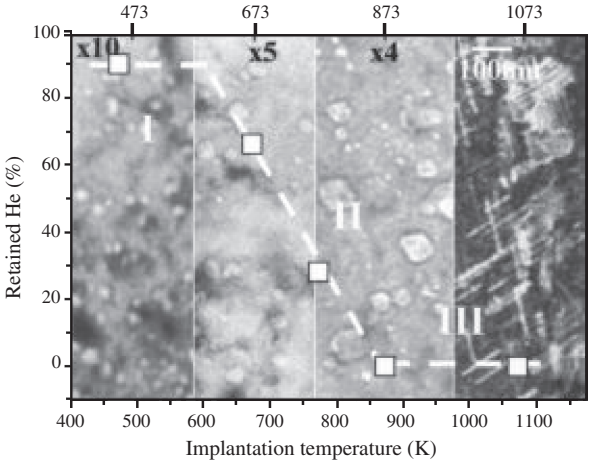

Figure 60. Helium retained in the silicon sample after helium implantation (5×10^{16} cm^{-2}, 50 keV) vs the implantation temperature. In the background, typical TEM images are presented in bright-field underfocus conditions for the 473, 673, and 873 K implantations and in weak-beam, dark-field conditions (g, $7g$) for the 1073 K implantation.

vacancy clusters can be nucleated. Instead, self-interstitial agglomerates have survived which are arranged in ⟨311⟩ defects and dislocation arrays.

In summary, the first phase of helium release from helium implanted silicon is ascribed to dissociation of small helium vacancy complexes, and in the second phase of release it is ascribed to helium permeating from a helium bubble layer to the sample surface. The fact that bubbles are overpressurized and that release does not occur from single bubbles but from a bubble layer should be taken into account. In the final stage of helium release bubble volume might increase by thermal creep thus slowing down the permeation.

8. FUTURE PROSPECTS

In the future the research on nanoprecipitates and nanocavities will develop in several interesting directions. For the nanoprecipitates better definition of the size of the implantation induced nanprecipitates or nanoclusters can be foreseen by combining ion implantation and ion lithographic mask technology. When ion implantation can be confined to well defined open areas in a mask the number of atoms implanted per opening in the mask is well defined and therefore the number of atoms constituting the nanoparticle that is formed after thermal annealing. In that manner monodisperse particles can be produced. The number of possible combinations that can be made of implanted atoms is virtually inexhaustible. Thus exotic compounds can be produced which will not form without the pressure exerted on the particle by the host matrix. Furthermore, the host matrix will impose a certain preference for interfaces and phases of the embedded particles. Also nanocavities in the metal oxides can be used as a template to create hollow particles when the internal surfaces allow wetting by implanted foreign atoms. For nanocavities in silicon a natural step in the development is to develop patterned nanostructures of cavities in ultra-large-scale integrated devices so that nanocavities for

impurity gettering are, on purpose, located in the proximity of electrically active areas of the elements of the device.

GLOSSARY

Auger process A non-radiative process in which an atom in an excited state undergoes a transition to a lower state by the emission of a bound electron (Auger electron) rather than by the emission of an X-ray. Auger electrons have a characteristic energy, unique to each element from which it was emitted. These electrons are collected and sorted according to energy to give compositional information about the specimen. Since Auger Electrons have relatively low energy they are only emitted from the bulk specimen from a depth of smaller than 3 nm.

Contrast transfer function Describes the imaging properties of the objective lens. It is independent of the object and is related to the sine function of the phase introduced by the aberration and defocus.

Doppler effect Refers to the change in the wavelength (or frequency) of energy in the form of waves, e.g., sound or light, as a result of motion of either the source or the receiver of the waves; the effect is named for the Austrian scientist Christian Doppler, who was professor at the Polytechnic in Prague and who demonstrated the effect for sound. If the source of the waves and the receiver are approaching each other, the frequency of the waves will increase and the wavelength will be shortened—sounds will become higher pitched and light will appear bluer. If the sender and receiver are moving apart, sounds will become lower pitched and light will appear redder.

Neutron An uncharged elementary particle of slightly greater mass than the proton. James Chadwick discovered it in 1932. The neutron, like other particles, also possesses certain wave properties and the field of neutron optics is concerned with such topics as the neutron diffraction and polarization of beams of neutrons. James Chadwick received the Nobel Prize in physics in 1935.

Positron annihilation A result of an encounter of the electron with its antiparticle-positron. The energy released by the annihilation forms two highly energetic gamma photons, which travel in opposite direction. These gamma rays provide a useful analysis tool, which has found many practical applications in physics and chemistry.

Positron An elementary particle having the same mass and spin as an electron but having a positive charge equal in magnitude to that of the electron's negative charge; Actually it can be regarded as the antiparticle of the electron and it is also called anti-electron and positive electron. Dirac has postulated the positron in 1930 as the "negative" energy extension of his theory of electron energy levels. Dirac received the Nobel Prize in physics in 1933.

Positronium A short-lived atomic system consisting of a positron and an electron bound together. Positronium is a temporary state in the decay of the positron. A positron in free space will quickly interact with an electron via the Coulomb force, and the positron and electron will for a short time form a bound state. This state is considered to be an atom in the sense that it is a hydrogen atom with the proton replaced by a positron.

Rutherford back-scattering technique An analytical tool that uses elastic scattering of 0.1–3 MV charged particles to analyze the surface and the outer few micrometers of solids. The depth distribution of constituents can be reconstructed with a depth resolution of 10–20 nm. The RBS technique is non-destructive since the erosion and the radiation degradation of the sample material by the particle impact is negligible. Rutherford was a British physicist who first explained that radioactivity is produced by the disintegration of atoms and discovered that alpha particles consist of helium nuclei. For these achievements, Rutherford was awarded the 1908 Nobel Prize in chemistry.

Transmission electron microscopy Because the wavelength of electrons is much smaller than that of light (of the order of pico-meters), the optimal resolution attainable for TEM images is many orders of magnitude better than that from a light microscope. Thus, TEMs can reveal the finest details of internal structure—in some cases as small as individual atoms. The point-point-resolution depends not only on the wavelength but also on the spherical aberration coefficient of the objective lens. Under special circumstances, atoms can be imaged at magnifications greater than 15 million times. Materials for TEM must be specially prepared to thicknesses, which allow electrons to transmit through the sample. Max Knoll and Ernst Ruska in Germany developed it in 1931. Ernst Ruska received the Nobel Prize in physics in 1986.

Weak phase object Image formation in a high resolution electron microscope is an interference phenomenon. The transmission of the incident wave by the object (diffraction) introduces phase shifts to the diffracted beams. For thin crystals, also called weak phase objects, the phase is assumed to be the constant. Frits Zernike at the University of Groningen, The Netherlands, discovered the phase contrast phenomenon in 1930. He received the Nobel Prize in physics in 1953.

CONTENTS

1. INTRODUCTION

Eventually, nanometer-scale devices or systems with dimensions comparable to those of viruses, molecules, or even atoms will become prevalent in all aspects of our lives. For instance, extremely useful applications such as artificial cells or cell repair robots will make it possible to replace or fix damaged cells caused by incurable diseases known today, and to extend human life expectancy. The concept of using engineered protein nanorobots to assemble and manufacture nanodevices or systems was pointed out as early as 1986 by Drexler's landmark book *Engines of Creation* [1] for nanotechnology. He argued that although proteins are not necessarily the best material in terms of mechanical strength or survivability in dry air for building physical nanosystems, it is conceivable that protein-based nanorobots can be used to autonomously build nanosystems out of molecules of much more sustainable materials such as metals and polymers. His concept is analogous to how human hands, although not very strong mechanically nor sustainable in very harsh environments, are able to forge and create much stronger and sustainable machines such as cars and airplanes. In 1992, Drexler [2] actually laid down the foundation for what scientists and engineers refer to today as "nanorobots" by theoretically showing that many different nanorobotic, manipulation, and manufacturing system designs can be realized based on existing technologies such as micromachining, protein engineering, and polymer synthesis.

However, many of Drexler's nanorobots have yet to be realized at the writing of this chapter although it is now generally accepted that one of the exciting prospects of nanotechnology is the possibility of manipulating nanoscale entities such as nanotubes and molecules in a controlled manner to produce novel devices or systems. In this chapter, we will define collectively the developmental efforts that will make this possible: "Nanorobotic and nanomanipulation" technologies, that is, techniques that will eventually allow us to move and manipulate nanoscale (10^{-9} meter) entities such as nanowires/nanotubes (e.g., see [3, 4]), nanocubes (e.g., see [5]), and molecules (e.g., see [6]) or atoms (e.g., see [7]), and assemble them into nanosystems. As an example of nanoscale robotics, it is now possible to fabricate nanoelectromechanical systems which are submicrometer machines that can be actuated through an electrical input signal to produce mechanical movement [8]. These machines can definitely be used to manipulate nanobuilding blocks in the near future.

In the future, "nanorobotics" may be extended to include the construction of robots using nanosize components with overall dimensions at the nanoscale or microscale. However, construction of "robots" at the nanoscale will be very different from constructing conventional robots due to the different dominant physical forces at the nanoscale. (For discussion of size effects on physical forces, see Fearing's survey for microscale forces [9], Sitti's survey for nanoscale forces [10], and Drexler's for a comparison of other physical

parameters [2]). Nevertheless, simple nanomechanical actuators (e.g., see [11] in 2003) and nanoscale motors (e.g., see [12] in 2000) already have been demonstrated; hence, it is conceivable that nanoscale robots can be constructed soon. As Requicha has pointed out [13], nanorobots are initially likely to be very simple and of limited capabilities. However, a large number of nanorobots can have a significant effect and can tackle complicated tasks. How are such "swarms" of robots to be controlled and programmed? This is an area of work that falls within distributed robotics and so-called artificial life [14].

It is conceivable that once nanoscale construction can be performed by programmable nanorobots, building of nanoscale devices or systems will be done much more effectively at much lower costs. Also, newer designs of these nanodevices or systems can be built and tested more rapidly. Hence, the construction of the first fully controllable or autonomous nanorobot will be a very significant milestone in global research. Examples of groups working toward this goal include Requicha [13] and Cavalcanti [15].

However, most autonomous or controllable nanoassembly and nanomanufacturing techniques are speculative at this time. Even though the potential advantages of nanoscale machinery are obvious and well recognized, practical plans for developing it from existing technology are rare. Why is it currently difficult to build nanoscale machinery? As pointed out by some experts who are trying to commercialize nanotechnology (e.g., see [16]), the main obstacle to develop nanomachines quickly is not a lack of suitable molecular components or methods for connecting them, but simply the fact that there is no existing general technique to bring molecules or nanoentities together and join them into a pattern as specified by a designer. Using existing techniques, when nanoentities are brought together, they tend to assemble in a random fashion or into what their natural affinities would produce (e.g., self-assembly). Hence, there are no "nanohands" to pick up two molecules, hold them, and join them together in a desired manner. This is like the "chicken-or-the-egg" problem; that is, in order to build nanomachines or nanorobots using "nanohands" or tools, one must first have at least a nanomachine to build a "nanohand."

Currently, there are several techniques for building general nanoscale structures, including nanoscale lithography [17], molecular imprinting [18], scanning probes used as "dip pens" [19], and self-assembly [20]. But none of these methods solve the basic problem of assembling preexisting nanostructures or molecular building blocks. They also are incapable of building atomically precise structures, so they may not be useful in solving the "chicken-or-the-egg" problem in building nanomachines.

It is arguable that biotechnology methods will possibly permit the fastest development of molecular machinery since much research effort has already been devoted to protein manipulation and engineering. For instance, self-assembly guided by DNA hybridization [21] is a possible means of solving this problem. In theory, DNA sequences attached to a molecular building block can be redesigned completely independent of the other properties of that building block material; thus novel, useful protein links can be created in this manner.

This chapter will focus on describing only technologies that are mature enough in the sense that they are generally considered by researchers worldwide whenever nanoscale manipulation is required. Excluded from this discussion are the manipulation of nanoentities by chemical means (e.g., self-assembly) or biotechnology methods (e.g., DNA-based molecular building blocks), since they more related to chemical and biological interactions rather than conventional "robotic interactions" (i.e., using controllable physical forces to manipulate matter). So this chapter will present the following topics in detail: (1) manipulation by atomic force microscope (AFM) tips, (2) manipulation by laser trapping force, and (3) manipulation by electrokinetic forces. For a discussion of each technique, the basic principles of operation are first given, followed by a comprehensive survey of past and ongoing activities in using the described method in manipulating nanoentities. Since the manipulation strategy for biological, chemical, or physical nanoentities differ, an attempt to distinguish examples of manipulation work into various categories will be discussed. However, as researchers look into and beyond these nanoscale worlds, the definition of what is biological, chemical, or physical becomes blurred, as matters of all these worlds are made of the elemental entities.

2. SCANNING FORCE MICROSCOPY ROBOTIC NANOMANIPULATION

In the late 20th century, the invention of scanning probe microscopy (SPM) [22] techniques provided a reliable way for humans to visit the nanoscale world, including even the atomic scale world. We now can "see" and also "feel," "touch," and modify nanoscale samples by using recently developed SPM based nanomanipulator systems with the help of the technology of virtual reality (VR), augmented reality, and robotics. This section will focus on the development of nanomanipulation research in the past 20 years.

2.1. Basic Principles

Scanning probe microscopy [22] is a family of microscopy techniques that generate three-dimensional (3D) topography and images of various physical properties (including surface roughness, surface potential, local resistivity, magnetic field, and so on) of samples with resolution close to atomic scale. In general, a sharp tip is rastered across the surface of samples under investigation while tip–sample interactions are monitored. Different forms of microscopy are characterized by the kind of tip–sample interactions involved, that is, scanning tunneling microscopy (STM), AFM, lateral force microscopy, electric force microscopy, near-field scanning optical microscopy, etc. [22]. The most commonly employed forms of SPM are STM and AFM and most of the commercially available SPM systems are designed to support various microscopy forms by installing suitable tips and accessories. The SPM system was originally designed for imaging purposes only, for studying surface profile of various physical properties of samples with nanometer scale resolution. Since the invention of STM and AFM systems, researchers'

attention has been increasingly attracted to modify sample surfaces and manipulate atoms, molecules, and biological entities. Solving technical problems involved in the use of STM and AFM as nanomanipulators became the major research direction in nanorobotics.

Scanning tunneling microscopy was developed by Binning et al. at IBM Research Laboratory in Zurich, Switzerland in 1982 [22]. In general, STM consists of a metallic sharp probe (usually made from tungsten, nickel, or gold) mounted on a small cantilever (with a length of about 100–200 μm), a piezoelectric scanner that provides precise motions in X-, Y-, and Z-directions, and electronics to control the motion of the piezoelectric scanner. The cantilever with a sharp probe is mounted on the 3D piezoelectric scanner and is scanned across on the sample surface in a raster manner. During the raster scan, small tunneling current between the tip and sample surface is monitored so that the distance between the tip and sample surface can be measured. The tunneling current increases exponentially as the distance between the STM tip and sample surface decreases and thus resolution less than 1 Å can be detected for the measurement. By keeping the tunneling current constant by a feedback loop during scanning, the Z-position of the tip is continually adjusted by the piezoelectric scanner. The Z-displacements of the piezoelectric scanner during raster scan are recorded and a 3D topographic map of the sample surface can be generated. The 3D surface topography obtained from STM actually reveals the structure of electron clouds of individual atoms. One of the major limitations of STM is that only conducting materials (i.e., metals and semiconductors) can be imaged using STM. Biological molecules and entities and other nonconducting materials cannot be imaged using STM.

In order to remedy the aforementioned limitations of STM, atomic force microscopy was developed by Binning et al. as a collaboration of IBM Research Lab, Zurich and Stanford University in 1986 [23]. The basic setup of AFM is similar to that of STM, but with different tips, which are typically MEMS*-fabricated with silicon (Si) or silicon nitride (Si_3N_4). During raster scanning of the sample surface, the Z-displacement of the piezoelectric scanner is adjusted by maintaining constant deflection of the cantilever and thus the atomic force exerted on the tip by a feedback loop. The cantilever deflection is detected optically by collecting reflected laser off the cantilever (which is coated by gold) using a position sensitive detector (PSD) and a differential amplifier. The PSD usually consists of two or four photodiodes to detect the minute changes in the light path of the laser which reveal the deflection and twist of the cantilever, as shown in Figure 1. Contrary to STM which can only image conducting materials, AFM can image all kinds of materials, including nonconducting materials, and can work under fluid. This allows biological entities, like cells, proteins, DNA, organelles, bacteria, viruses, etc., and any surfaces that involve a solid–liquid interface, like geologic samples, corrosive surfaces, etc., to be imaged with nanometer scale resolution. The diversity of samples that are suitable to be imaged using AFM promotes the popularity of AFM in nanotechnology. There are three operating

* MEMS stands for MicroElectromechanical System

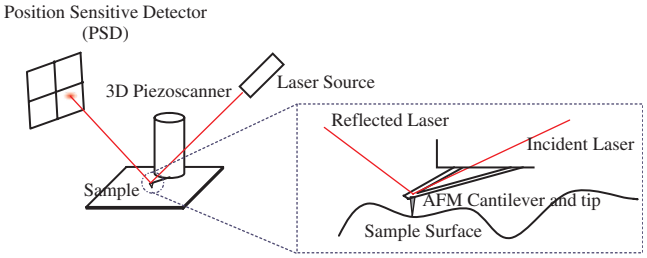

Figure 1. Schematics of an atomic force microscope. (Components are not drawn in scale.)

modes of common AFM systems, including contact mode, noncontact mode, and TappingMode™. In contact mode, the AFM tip has physical contact with the sample surface and thus contact mode can give the highest image resolution and scan rate among the three AFM operating modes. However, fragile samples, especially biological samples, may be damaged by the AFM tip under contact mode. On the other hand, the AFM tip does not have physical contact with samples under the noncontact mode and thus no damage is imposed on fragile samples. The image resolution obtained and scan rate under noncontact mode are, however, the lowest among the three modes. TappingMode™ scanning imposes minimal damage on fragile samples while maintaining high resolution of AFM images. In TappingMode™, the cantilever is oscillated at or near its resonant frequency during scanning across a sample surface and thus the cantilever taps the sample. The oscillation amplitude can range from 20 to 100 nm and the tapping force is less than 200 pN. The Z-displacement of the piezoelectric scanner is adjusted by maintaining a constant root-mean-square (rms) value of oscillation signal captured by the PSD. Since AFM can image samples of all materials and under fluids, it has become a good candidate as a nanomanipulator instead of STM recently. Both contact mode and TappingMode™ AFM can be employed to manipulate nanosized objects.

Various types of manipulation tasks are performed using AFM and STM systems. Mechanical tasks, including pushing/pulling, orienting, bending, twisting, rolling, sliding, picking-and-placing, assembling, cutting, indenting, lithography, and so on, can be achieved using STM and AFM. SPM systems can also be modified to the so-called "specific" manipulators, which only respond to particular types of molecules by coating the SPM tip with layers of catalysts, enzymes, antigens, and any chemical/biochemical molecules that only are reactive with or respond to the nano-objects of the targeted types and properties. Antigen–antibody interaction is one of the most commonly adopted mechanisms for making "specific" end-effectors and performing selective *in-situ* manipulation. Detailed discussion of the recent research results will be given in the following sections.

2.2. Early Attempts at Atomic and Molecular Manipulation

When people first employed STM or AFM to image sample surfaces at atomic scale resolution, the capability of modifying and manipulating sample surfaces of the interaction of the SPM tip (electric field and force generated by the STM and the contact force exerted on the sample surface by the AFM) was obviously observed. Many

researchers have attempted to control the surface modification or manipulation using SPM in a precise and selective fashion since the 1980s. The early attempts of surface modification experiments involved unstructured deposition or removal of atoms or clusters of atoms from sample surfaces using STM although the results were inconsistent and in an uncontrolled manner. Some of the pioneer works are listed. Becker et al., of AT&T's Bell Laboratories, created nanometer sized features on a germanium (Ge) surface by applying short and high voltage pulses using a STM tip [24]. The average size of the features is about 0.8 nm in diameter and 0.1–0.2 nm in height. Germanium atoms were adhered to the STM tip and transferred to the sample surface during each pulse while scanning. Mamin et al., from IBM's Almanden Research Center, emitted gold atoms from a STM tip to form small gold clusters on gold, glass, and platinum surfaces under vacuum by applying high voltage to the STM tip [25, 26]. On the contrary, Clery, from Hitachi Central Research Laboratory, was able to remove sulfur (S) atoms from a molybdenum disulfide (MoS_2) crystal using voltage pulses applied a STM tip so that letters and characters patterns with heights of 1.5 nm were etched out from the surface [27]. Other researchers have also made progress in the techniques of surface modification, as reported in [28–30].

As more and more attempts in surface modification in the nanometer scale have been conducted, researchers from various disciplines gained much experience in manipulating atoms and molecules and aimed to perform precise position control and manipulation of atoms and molecules that would be required for assembly of nanodevices. One of the famous examples was demonstrated by Eigler and Schweizer at IBM Almaden Laboratory in 1990 [7]. They positioned 35 Xenon (Xe) atoms to spell out the "IBM" pattern on a nickel (111) surface using a tungsten STM tip under ultrahigh vacuum and low temperature (about 4 K). Their work was the first that demonstrated the ability to manipulate atoms to form structured patterns. They also achieved similar results of manipulation of different atoms (e.g., iron) on different surfaces (e.g., copper) into various patterns (e.g., circle) with other collaborators in following years [31, 32]. Moreover, Durjardin et al. dissociated and examined individual decaboron tetradecahydride molecules ($B_{10}H_{14}$), that were adsorbed on a silicon (Si) surface, into fragments with low energy electron pulses using STM [33]. This technique can be further exploited in semiconductor manufacturing for nanometer scale site-specific doping of boron (B) in silicon (Si). Mo et al. also reported that antimony (Sb) dimers could be rotated reversibly between two stable states on a silicon (001) surface under room temperature by applying low energy voltage pulses to a STM tip [34].

In summary, the aforementioned examples of manipulation of atoms and molecules were conducted manually. Each manipulation step in these early attempts of surface alteration in the nanometer scale was not easily achieved and repeated iteratively until the desired goals were achieved. The experimental conditions for manipulation of atoms and molecules were usually demanding so that the manipulation tasks were performed by STM with application of high energy voltage pulses under ultrahigh vacuum and low temperature. Some of the experiments were also conducted on a trial-and-error basis. This made early atomic manipulation a low yield, time-consuming, tedious, and highly restricted task, with a lack of precise positional control. The experimental results were also difficult to reproduce. The development of technology of nanomanipulation has then marched to the direction of employing AFM as a nanomanipulator so that the sample type for manipulation can be extended to nonconducting and fragile biological entities.

2.3. Recent Developments in SPM

Inspired by the preliminary results of atomic manipulation obtained in late 1980s and early 1990s, more and more research groups from various disciplines (including physics, chemistry, biotechnology, computer science, robotics, etc.) in the world have joined the exploration of the nanoworld since the mid 1990s. The manipulated objects were not limited to conducting materials and the manipulation environments were not limited to ambient. The application of nanomanipulation has been extended to nonconducting materials and even objects under fluids, like polymers, living cells, DNA, proteins, etc. This led to the trend of using AFM as the major nanomanipulation tool in recent years. In order to assist operators to have better and finer control on the AFM tip (the end-effector), various types of sensor information are fed back and displayed to operators during manipulation and operators can issue motion command to the AFM tip and receive sensor feedback (especially force information) by using haptic devices. The technology of VR has also been introduced into nanomanipulation systems so that operators can have a better understanding of the environment for nanomanipulation. In additions, some of the developed AFM based nanomanipulation systems can also be teleoperated via the Internet. Some of the representative nanomanipulation technologies developed by research groups around the world are listed. One of the pioneering nanomanipulator systems was a home-built AFM developed under the telenanorobotics project of the University of Tokyo [35]. The system was also equipped with a home-built 1 DOF haptic device for normal force feedback from the AFM tip and a VR display as visual feedback. The NanoManipulator™system, integrated by the collaboration of the Departments of Computer Science and Physics of the University of North Carolina at Chapel Hill, consists of an AFM, a haptic device, and a 3D visualization system. Operators can control the real-time 2D motion of an AFM tip and receive surface topography information as force feedback via the haptic device while having synthetic 3D visual feedback of the operating environment [36]. This integrated system has been commercialized in the market. In order to have a better picture of the environment during nanomanipulation, an AFM can be built inside the vacuum chamber of a scanning electron microscope (SEM). Examples include the systems developed at Fukuda and Vachkov's laboratory at Nagoya University [37], Washington University at St. Louis [38], and the Division of Microrobotics and Control Engineering at the University of Oldenburg [39]. Some research groups also modify the end-effector (i.e., the AFM tip) of AFM based nanomanipulators by, for example, integrating micropiezoresistive force sensors [39], using capacitative ultrasonic actuators [40] on AFM cantilevers, and attaching carbon nanotubes to an AFM tip

as nanoscissors [41]. An interferometric system was also installed to a SPM system for high precision position measurement for real-time tip position control [42]. In addition, the nanomanipulator system developed at the Robotics and Automation Laboratory of Michigan State University allowed operators to control 3D motion of the AFM tip and receive 3D force feedback via the Internet in real time [43]. The nanomanipulation system developed by Friedt et al. can also be remotely controlled [44].

2.4. Survey on SPM Nanomanipulation Research

In general, nanomanipulation tasks are divided into two categories, namely 2D and 3D nanomanipulation, respectively. For 2D nanomanipulation, the SPM tip only moves along the substrate surface so that the manipulated entities only translate/slide along and rotate on the operating surface and never move off the surface. On the other hand, the position of the SPM tip can be controlled to move freely in 3D space for 3D nanomanipulation so that the 3D position and even orientation of the manipulated entities can be controlled.

2.4.1. 2D Nanomanipulation

Kim and Lieber demonstrated to the rearrangement of thin oxide structures on the underlying surface by increasing the applied load during scanning with AFM [45]. The sled-type motion of C_{60} islands has been studied by Luthi et al. using AFM [46]. By using AFM, Schaefer et al. deliberatively moved gold (Au) clusters on a smooth surface [47]. Junno et al. demonstrated the formation of arbitrary nanostructures by controlled pushing of individual GaAs particles (with diameter of about 30 nm) under ambient conditions [48]. Requicha et al. of the University of Southern California also demonstrated the construction of arbitrary patterns of gold nanoparticles using AFM under ambient conditions [49] and in liquid environments [50]. The same group also reported translational and rotational manipulation of gold nanorods on a SiO_2 surface [51, 52]. Hertel et al. demonstrated that they could straighten, bend, translate, reorient, and cut carbon nanotubes on glass substrate using contact AFM [53]. They fabricated a complex pattern (e.g., the Greek letter Θ) from a carbon nanotube bundle of 2.5 μm length. They also measured binding energy between carbon nanotubes and substrate surfaces. Postma et al. measured electronic transport on carbon nanotube junctions, buckles, and crossings that were fabricated in a controlled manner from straight and undeformed carbon nanotubes by manipulation using AFM [54]. Falvo et al. demonstrated bending of straight nanotubes into various configurations and measured resistance of multiwalled carbon nanotubes on highly oriented pyrolytic graphite with changing orientation using their AFM based nanomanipulator system with VR capability [55, 56]. Tombler et al. experimentally investigated the reversible metal–semiconducting transition property of carbon nanotubes by pressing on suspended nanotubes using an AFM tip [57]. In these experiments, the samples were first imaged in noncontact mode to minimize the lateral force acting on the samples and then manipulation was carried out with the normal force feedback switched off. The aforementioned manipulation experiments fell in the 2D manipulation category. One problem of this method is that the normal force cannot be controlled during manipulation, as the force feedback in the Z-direction was switched off. This might result in either breaking cantilevers due to large normal force or insufficient force to keep the tip in contact with the surface [36]. Another problem of this manipulation scheme was that it could only manipulate two-dimensional nanostructures on a smooth and flat substrate surface. The surface tilt must also be carefully removed before manipulation. The reported manipulation techniques also could not be extended for the development of nanoassembly techniques, like picking-and-placing nanoparts, mating of the nanoparts, and so on. One solution for the aforementioned problems is to use techniques developed for 3D nanomanipulation so that the 3D position and forces of the tip can be controlled.

2.4.2. 3D Nanomanipulation

There are also ongoing research projects focusing on 3D nanomanipulation. A promising method for 3D nanomanipulation is to build the AFM inside the vacuum capsule of a SEM. Piezoelectric vacuum manipulators constructed inside the SEM have the ability to manipulate objects along the X-, Y-, and Z-directions using the AFM tip as the end-effectors. Several experiments of manipulation of carbon nanotubes were performed using this kind of setup [37, 38, 58]. The obvious advantage of this method is that multiple end-effectors can be built inside the SEM to achieve more degrees of freedom. The manipulation can be performed between the end-effectors without the need for a substrate. The operation can also be monitored in real time. However, the measurement of the deflection of the cantilever is based on images from the SEM, whose resolution is not enough. Thus the manipulation accuracy of this method is also not comparable to that of the AFM. Since the samples are placed in vacuum and exposed to electron beam with high energy, this manipulator cannot be used to manipulate biological samples. The expense of a SEM, ultrahigh vacuum conditions, and space limitations inside the SEM vacuum capsule also impede the wide application of this method.

Different manipulation techniques have also been attempted for realization of 3D nanomanipulation. Hansen et al. proposed in [59] such that the nanoparticles were imaged in TappingMode™and pushed over a surface using contact mode, while the normal force feedback was switched on. This method can be considered as the beginning of the 3D nanomanipulation in the sense that the cantilever tip follows the topography of the surface using the internal feedback control. However, this method takes the risk of hazardous action of the feedback mechanism when switching on and off the vibration of the cantilever, changing the gains of the feedback loop, and changing other parameters such as set point and tip velocity, while the tip is touching the sample surface. Recently, some researchers have combined AFM with VR interface and haptic devices to facilitate nanomanipulation. By introducing a virtual environment of the samples, nanomanipulation using the AFM becomes much easier [36, 55]. Besides, 3D synthetic visual feedback to users, a 1 DOF haptic device had also been constructed in [60] for haptic sensing. In the manipulation mode, during approach and contact of the surface or the

object, or manipulating the object, the operator controls the X–Y–Z motion of the cantilever while feeling the normal tip–sample interaction force. However, because only the normal force is "feelable" during manipulation, this method may also take the risk of breaking the cantilever and damaging the tip when large lateral forces occur. In [36], the AFM tip was also virtually connected to a Phantom™ stylus. In imaging mode, the topography data coming from the AFM are sent to the Phantom™ controller, which reconstructs a "feelable" surface for the user. Then the user can feel the topography of the sample. In manipulation mode, the stylus can be used to move the tip over the surface while keeping the inside normal force feedback on. However, in this approach, the operator does not directly feel forces, which are proportional to the actual forces acting on the cantilever. These two methods can also be considered as the 3D nanomanipulation since the cantilever tip can be controlled either by the internal force feedback control loop or by the operator through the haptic devices to follow the topography of the surface. In addition, Li et al. introduced the concept of an AFM frame to avoid the problem caused by the "bow" effect of the piezoscanner of the AFM system in 3D manipulation [43]. Topography represented in AFM frame is always convoluted with a convex bow. A flat surface in the Cartesian frame will become a concave bow in an AFM frame as shown in Figure 2. The curvature of the bow cannot be negligible in large scan size as the uncorrected bow can be 60 nm for 90 μm $\times$ 90 μm scan size. In order to remedy the bow effect in AFM based 3D nanomanipulation, a 3D trajectory planning algorithm was proposed by Li et al. in [43]. Before 3D trajectory planning for nanolithography, the surface of the nanofixture substrate is first scanned. The 3D topography of the surface is thus represented by a matrix that records the Z-coordinate of sampled points on the sample surface. This matrix thus depicts the relation between the conventional Cartesian frame and the AFM frame with respect to the surface for manipulation. Any 3D trajectory of the AFM tip with respect to the Cartesian frame can then easily be transformed to a representation with respect to the AFM frame by a simple look-up table technique. Three-dimensional nanolithography experiments on tilt surfaces have been conducted to show the effectiveness of the approach. Figure 3 shows two scribed "CUHK" patterns on a tilt surface using an AFM with automatic surface following capability turned off (i.e., the normal force feedback was turn off). The upper pattern was scribed without 3D trajectory planning. It can be seen that the scribed depth of the four letters are different due to the surface tilt. Moreover, the left letter "C," which is scribed on the higher side, was scribed deeper than the right letter "K," which is on the lower side. On the other hand, the lower pattern was scribed with 3D trajectory planning. The depths of the scribed letters are similar in the pattern.

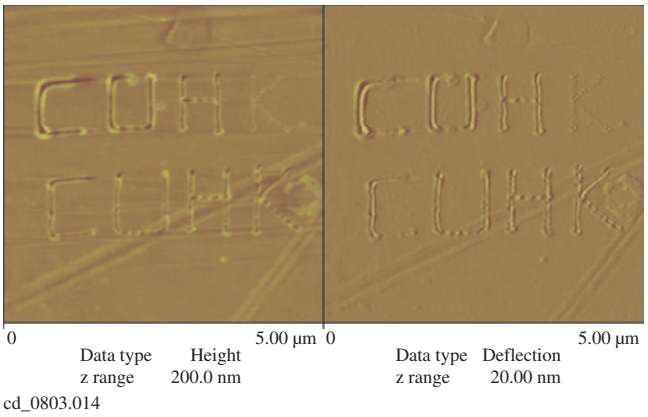

Figure 3. Nanolithography on a tilt surface. Upper: Without 3D trajectory planning, Lower: With 3D trajectory planning. Left: Height signal, Right: Deflection signal.

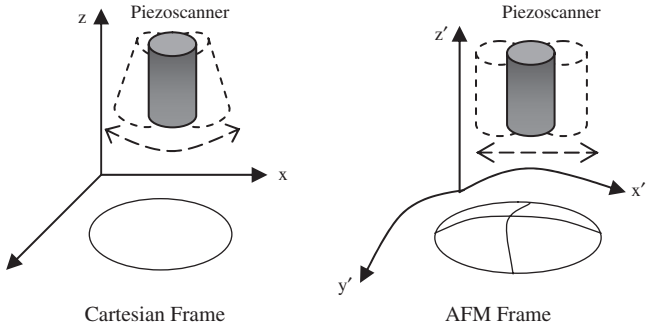

Figure 2. Cartesian frame vs AFM frame. A flat surface with respect to the Cartesian frame is a concave surface with respect to the AFM frame.

2.5. Biological Nanomanipulation

Recently, the development of the technology of nanomanipulation has attracted much attention from the areas of genomics, proteomics, cell biology, and medicine for an exciting future in the investigation of the structures and functioning mechanisms of living things and their interactions at the molecular level [61, 62]. Gutholdm et al. manipulated and studied the DNA molecules and viruses using a nanomanipulator system [63]. Biologists employed an AFM tip as a microdissection tool to reveal minute structures such as organelles and even chromosomes of cells and bacteria. Hoh et al. revealed the hexagonal array of hepatic gap junction hemichannels by applying force on an AFM tip to the top membrane of the gap junction for dissection [64]. Hansma et al. employed an AFM tip as a dissection tool to reveal DNA of plasmid [65]. Stark et al. demonstrated the dissection of human chromosomes in ambient condition and in buffer by AFM [66, 67]. They reported that the dissection results were improved with z-modulation because the lateral force during cutting was reduced with z-modulation of the AFM tip. Precise cutting with a loading force larger than 17 μN with a full width at maximum depth of 90 nm can be achieved with z-modulation. This method could also be employed for chromosomal material extraction because the chromosomal material adhered to the AFM tip after dissection. On the other hand, researchers also "functionalized" the AFM tip to form selective grippers, which only function for specific entities/molecules. This concept was first introduced by Drexler and Foster in 1990 [68]. Specially designed protein molecules and antibodies can be adhered to AFM tip to serve as a gripper for holding or manipulating

molecules in a selective manner. Similarly, site specific reactions can be activated by mounting suitable catalyzes and agents on an AFM tip. Florin et al. measured the binding affinity between receptor avidin molecules and biotin ligand molecules by binding receptor avidin to an AFM tip [69]. Fruitful results are also obtained in antibody recognition and localization [70–72]. The basic idea is to attach suitable antigen molecules on the AFM tip and measure the binding force detected by the deflection of the AFM cantilever during imaging. By analyzing the obtained binding force profile, the type and the location of the antibodies on the sample surface can then identified.

2.6. Summary

In conclusion, the development of SPM based nanomanipulation is still in a preliminary stage. Nanometer to micrometer sized entities, for instance gold nanoparticles, carbon nanotubes, protein molecules, DNA, bacteria and viruses, etc., can be pushed/pulled, slided, rotated, reoriented, picked-and-placed, and dissected using SPM under ambient condition or in liquids manually with the assistance of various kinds of input and visualization devices for sensor feedback. During nanomanipulation, operators can receive real-time force feedback and issue motion commands to the AFM tip via a haptic device and have VR based synthetic visual feedback. Some of the nanomanipulation systems can also be operated remotely via the Internet. However, our current achievement of nanomanipulation still cannot allow us to have mass production of functional nanodevices and nanorobots due to the lack of:

1. a method of precise control (both in 3D position and force) of the SPM tip, in terms of sensor design, control algorithms, and actuation;
2. designs of specific end-effectors for particular tasks;
3. complete and reliable models for different manipulation tasks, such as the nanotribological phenomenon of the interface in pushing objects [73];
4. algorithms and techniques for automated nanoassembly.

3. LASER BASED NANOMANIPULATION

Laser based manipulation of objects refers to techniques of holding or trapping of entities by optical instead of mechanical means. The entities can then be moved or manipulated by controlling the motion of the focus of the laser source using a lens and mirror system. The optical tweezers technique is most commonly employed for laser based nanomanipulation. Optical tweezers provide noncontact manipulation for nanometer to micrometer sized neutral objects in any condition, including ambient and liquid environments. The applied force on the manipulated objects can be as small as pico-Newton range. This makes optical tweezers important for biological and chemical studies of fragile samples. Ashkin, at Bell Laboratory, first demonstrated how to optically accelerate transparent latex spheres, with diameter of 1 μm, suspended in water with a mildly focused 1 W argon laser [74]. The motion of the latex spheres was observed to be guided by the motion of the beam. In 1986, Ashkin et al. developed 3D cooling of dielectric particles using a single laser source [75], which formed a strong foundation for the development of optical tweezers. The technique of optical trapping plays a significant role in the fundamental research of various areas so that S. Chu was awarded the 1997 Nobel Prize in Physics for his contributions in atom cooling and trapping using lasers.

3.1. Basic Principles

Optical tweezers are defined as 3D traps to trap or manipulate micrometer and nanometer sized neutral charged objects by using a focused laser. The source of the trapping ability of optical tweezers comes from the radiation pressure of light. The laser light employed in the optical tweezers carries momentum $p = \frac{h\nu}{\lambda}$, where h is Planck's constant, ν is the frequency of the laser, and λ is the wavelength of the laser. When the laser light hits an object, the laser is either reflected from or refracted (transmitted) through the object. The momentum carried by the transmitted laser light is different from the incident laser light. The change of momentum conveyed by the laser constitutes the radiation pressure. By the law of conservation of momentum, there must be an equal but opposite momentum change in the object. Forces are generated due to the change of momentum. The object can then be trapped when all external forces (for example, gravity and electric force) exerted on the object are balanced by the forces resulting from the change of momentum. Two forces come from the radiation pressure, namely the scattering force F_{scatt} and gradient force F_{grad}, respectively.

Depending on the size of the trapping objects, optical trapping is categorized into two regimes, namely the Rayleigh regime when the wavelength of the light is comparable to object size d or $d \approx \lambda$ and the Mie regime when the wavelength of the light is very small compared to object size, $d \gg \lambda$ [75]. In the analysis of the scattering and gradient forces in optical trapping, the dipole model is employed for objects in the Rayleigh regime which considers the wave properties of light. Dipoles are induced in the objects from the laser. The scattering force F_{scatt} comes from reflected or adsorbed light by the objects and is proportional to the light intensity and in the direction toward the laser propagation. The laser also polarizes the objects and the gradient force F_{grad} is exerted on the objects by the electromagnetic field gradient. The gradient force F_{grad} is proportional to the gradient intensity and points in the intensity gradient direction. The resultant force exerted on the objects then pushes the objects toward the laser focus. On the other hand, the ray-optics model can be employed in analyzing scattering and gradient forces of optical trapping in the Mie regime [75].

Figure 4 depicts the geometrical view of the trapping forces generated when laser light hits a dielectric sphere. The trapping force arises from the refraction of laser light, which generates change of momentum from photons of the laser light. The resultant exerted force, F, on the object brings the object toward the focus, f, of the incident laser light, as shown in Figure 4. In other words, if the center of the object is lower than the laser light focus, the object is pushed upward as shown in Figure 4(a), or vice versa as shown in Figure 4(b). Ashkin derived the mathematical expressions of the involved scattering and gradient forces

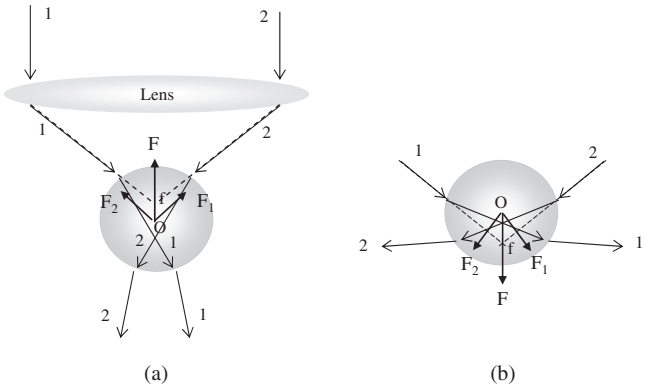

Figure 4. Trapping forces in optical trapping.

for optical trapping in the Mie regime, which depend on the power of incident laser, angles of incidence and refraction, refractive index of the suspending medium, fraction of reflected light intensity from the surface, and fraction of transmitted light intensity in the object [76]. The resultant exerted force, F, on the object is then given as $F = F_{\text{scatt}} + F_{\text{grad}} = Qn_mP/c$, where Q is the dimensionless quality factor, n_m is the refractive index of the suspending medium, c is the speed of light, and P is the incident power of the laser [76]. The quality factor Q depends on the relative refractive index of the object and the suspending medium.

Typical optical tweezers are usually installed on standard optical microscopes and the laser light can be focused by microscope objective. The objects for manipulation are placed on the microscope stage. Typical laser sources are Nd:YAG laser and argon laser with power range from 25 to 500 mW for manipulating biological entities. Typical wavelength of the laser lies around the infrared spectrum (i.e., 700 and 1060 nm). Manipulation of objects, such as moving objects, can be achieved by manipulating the position of the focus of the laser beam using complicated lens and mirror systems.

The primary application of optical tweezers is for holding and manipulating biological entities [77]. With the help of laser scalpel for microdissection, covered structures, like cell organelles, can also be manipulated optically. Ashkin and Dziedzic were the first that demonstrated trapping of living biological entities, including *Escherichia coli* bacteria and viruses in 1987 [78]. In this pioneer work, they showed that laser trapping was harmless to living biological entities with laser wavelength at 1060 nm up to several hours. Reproduction of *Escherichia coli* bacteria and yeast cells within optical traps was also reported. The optical trap generated was strong enough to translate the trapped *Escherichia coli* bacteria with speed up to 500 m s^{-1} [79]. Later research also showed that optical trapping did not damage pigmented red blood cells, green plant cells, algae, and protozoa. Manipulation of organelles and particles with plant cells and protozoa was achieved without damaging the cell membranes and only deformation of the cell shape was observed during manipulation. Aufderheide et al. also achieved similar results by directed positioning of micronuclei and other organelles to any location inside Paramecium tetraurelia bacteria without damaging the bacteria [80].

Optical tweezers were also applied in human reproduction and assisted fertilization research. Colon et al. [81] and Tadir et al. [82] both demonstrated 3D manipulation of living human sperm cells. Microsurgery was conducted for drilling channels in the zona pellucida of oocytes using optical tweezers and a laser scalpel in order to facilitate sperm penetration [83]. Conia and Voelkel also succeeded in manipulation of human gametes with optical trapping [84]. Schütze et al. succeeded in direct insertion of sperms into channels to simulate fertilization [85, 86]. Tadir et al. demonstrated how to modify preimplanted embryo and gametes with optical manipulation [87]. Optical tweezers were also found to be useful in dissection in the micro- or even nanoscale level. Blanchet et al. developed a new zona drilling technique for manipulation of internal structures of mouse embryo [88]. Weber et al. have several achievements in manipulation of cellular organelles and genomes [89]. In particular, they extracted DNA from chloroplasts from a plant cell using a laser microbeam [90] and a dissected part of a human chromosome out for cloning [91]. Liang et al. also performed intracellular surgery on chromosomes in PTK-2 cells using a laser scalpel, and optical tweezers were employed to hold the dissected distal chromosome fragments together throughout anaphase [92]. The same group also dissected and manipulated chromosomes in living newt lung epithelial cells [93]. In their experiments, they demonstrated that the dissected chromosome fragments could be easily pulled or rotated by optical tweezers when positioned at the periphery of the mitotic spindle.

Optical tweezers were applied in characterization of the structure and behaviors of various biological organelles, molecules, and mechanisms. For example, Bayoudh et al. characterized the chloroplast arrangement, shape, and consistency in cells of living leaf tissue [94]. Two optical tweezers were applied to provide two-point contacts to a single chloroplast in suspension. A microstirrer, which was constructed by the third optical tweezers holding a birefringent particle, induced tumbling motion to the suspended chloroplast and its various properties were investigated. Sakata-Sogawa et al. directly stretched looped DNA molecules using two optical tweezers and measured their molecular length [95]. The DNA looping is mainly due to the interaction among DNA binding proteins distributed along the molecular structure of the DNA molecules. The stretched tension force of the DNA molecules was about 30 pN and the measured rise per residue was computed as 3.31 ± 0.05 Å. By using two optical tweezers, Bronkhorst et al. brought two red blood cells together and then pulled them apart for the investigation of the interaction during aggregation (bringing together) and disaggregation (pulling apart) [96]. Viegal et al., in 1998, measured the stiffness of rabbit skeletal actomyosin cross-bridges using two independent optical tweezers [97]. The two ends of the actin filament were first attached to two latex beads, which were individually trapped by two optical tweezers. A third bead, which was coated with myosin, was then placed and fixed near the actin filament in order to induce a working stroke of 5.5 nm to the system. The stiffness of the cross-bridge system was then computed based on the displacements of the latex beads, which were measured by interferometry. In addition, Bennink et al. characterized the interaction mechanism of

DNA with RecA protein and YOYO-1 dye molecules using single optical tweezers [98]. Both the optical tweezers and a micropipette first captured polystyrene beads individually. Then, a DNA molecule was attached to the beads in stranded configuration by introduction of DNA buffer solution to the setup. The micropipette then moved the bead to introduce deflection of the laser beam. The displacement of the laser trapped bead could be measured, which in turn determined the force exerted to the system by moving the bead by micropipette. Elasticity and other structural parameters of in the DNA-RecA protein interaction system could be computed.

Another type of application of optical tweezers in biological applications is separation and sorting of interested biological entities out of a mixture of similar entities. Early attempts included that by Buican et al. who developed an automated technique to identify and pick up the interested cell [99] using optical trapping. Separation of bacteria in unidentified water and soil samples was demonstrated by Mitchell et al. [100] and Huber et al. [101] by using optical tweezers.

3.2. Manipulation of Chemical Entities

The primary research in manipulation of chemical entities focuses on cooling or trapping of atoms using a focused laser, i.e., confining a dense cloud of atoms in a small volume [102–104]. Furukawa and Yamaguchi reported that gold particles (with diameters in the range of 0.5–3.0 μm) suspended in water could be trapped using single optical tweezers [105]. Svoboda and Block also reported similar results [106]. Their work gave the evidence that metallic particles could also be trapped optically. Friese et al. demonstrated that micrometer-sized calcium carbonate ($CaCO_3$) particles could be either aligned along the polarization plane of the incident laser or rotated with constant speed [107]. A rotation frequency of 357 Hz could be obtained with a 1 μm thick particle and a laser beam with a power of 300 mW. Recently, Paterson et al. demonstrated controlled rotation of microscopic silica spheres, glass rods, and chromosomes that were trapped by optical tweezers with a spiral interference pattern from two laser sources [108]. The rotation speed could be higher than 5 Hz. The interferometric pattern was generated by interfering an annular shaped laser beam with a reference beam. The rotation of objects was due to the difference in optical path length of the two laser beams. The same group then constructed 3D stacked structures, which were made of microspheres with diameters of 53 μm, by the introduction of an interferometric pattern between two annular laser beams [109]. The constructed structures can be translated in 3D with a speed of 200 $\mu m\,s^{-1}$ using 200 mW laser beams and can be rotated continuously by introducing frequency difference between the two laser beams. The structures of the constructed microspheres stacks could be controlled, including asymmetric structures, by the geometry of the interference patterns of the two laser beams. Moreover, Diddams et al. developed an all-optical atomic clock by optically trapping a single $^{199}Hg^+$ ion [110]. The laser source employed in this clock was a mode-locked femtosecond (10^{-15} s) laser with output pulses at 1 GHz rate and was phase-coherently locked to the frequency of the laser light. The ultimate fractional frequency uncertainly was expected to be approaching 10^{-18}, which was much smaller than that (10^{-15}) of the world's most accurate caesium (Cs) based clock. Optical trapping of ions can be applied in realization of quantum computing systems. Duan et al. proposed an implementation scheme for quantum computation based on the Abelian and non-Abelian geometric operations by manipulating a set of trapped ions using laser [111]. In 2001, Kielpinski et al. demonstrated an implementation of memory of one qubit (the basic unit memory for quantum computing) [112]. The information of one qubit was encoded by manipulation of a pair of trapped $^9Be^+$ ions.

3.3. Summary

In conclusion, the development of micro- and nanoscale manipulation technology using laser trapping is still in the preliminary stage although extensive results in the biological areas have already been obtained. Applications of optical trapping in biological areas have been developing rapidly since the 1990s and are expected to grow in the coming decades. However, few works focus on the assembly of microdevices and nanodevices using optical tweezers. The lack of precise position control algorithms for manipulating optically trapped objects and the small workspace of optical tweezers hinder the development of an automated assembly plan using optical trapping.

4. ELECTROKINETIC BASED NANOMANIPULATION

Electrokinetic based manipulation has been considered as one of the most versatile methods in microscale and nanoscale manipulation. Research in using electrokinetic forces to manipulate microscale and nanoscale entities has been conducted actively in the past decade due to the advancement of micro/nanofabrication technology to fabricate micro/nanoscale electrodes for the generation of ultraintense electric field ($>10^6$ V/m) by small input electrical excitation. Electrokinetic forces (EK forces) generally refer to the Columbic forces imparted on particles when external electric field is applied. Precise classification of EK forces is defined according to the mechanisms by which the forces are generated. For instance, *dielectrophoretic* force is defined as the force that is generated when a neutral particle is immersed in a nonuniform ac electric field region while *electrophoretic* force is defined as the force that is generated when a charged particle is immersed in a directional dc electric field region. Nevertheless, the EK phenomena (e.g., dielectrophoresis, electrophoresis, and electro-osmosis) have been widely employed to induce mechanical motion on microscale and nanoscale entities in the areas of biotechnology (e.g., cell trapping and manipulation) and, more recently, in nanoelectronics applications (e.g., carbon nanotube and inorganic nanowire manipulation). In this section, the basic principles of these three phenomena will be discussed, followed by the examples showing how researchers worldwide employ the EK phenomena to manipulate nanoscale entities for nanoelectronics and biotechnology applications.

4.1. Basic Principles

4.1.1. Dielectrophoresis

Assume a system consisting of a neutral colloidal particle (with complex permittivity ε_1) inside a fluid medium (with complex permittivity ε_2); applying a directional electric field will cause the polarization of both the colloidal particle and the fluid medium. Consider the simplest case where the fluid medium is a vacuum space. Applying a directional electric field will only cause the colloidal particle to polarize. The polarized particle will tend to align itself with the directional electric field which results in a dipole moment ($\vec{P}$), and Coulombic forces will then be induced on the polarized particle by the electric field ($\vec{E}$). If an oscillating and nonuniform electric field is applied instead (i.e., ac heterogeneous electric field), then a gradient of electric field exists which results in an imbalance of Coulombic forces acting on both sides of the particle. Hence the resultant force acting on the particle will drive it into motion (see Fig. 5). The resultant force acting on the particle is termed dielectrophoretic force ($\vec{F}_{\text{DEP}}$). This force can be expressed mathematically as [113]

$$\vec{F}_{\text{DEP}} = (\vec{P} \cdot \nabla)\vec{E} \tag{1}$$

where ∇ is the gradient operator. For a particular case where the colloidal particle is isotropically, linearly, and homogeneously polarizable, the dipole moment induced can be expressed as

$$\vec{P} = \alpha V \vec{E} \tag{2}$$

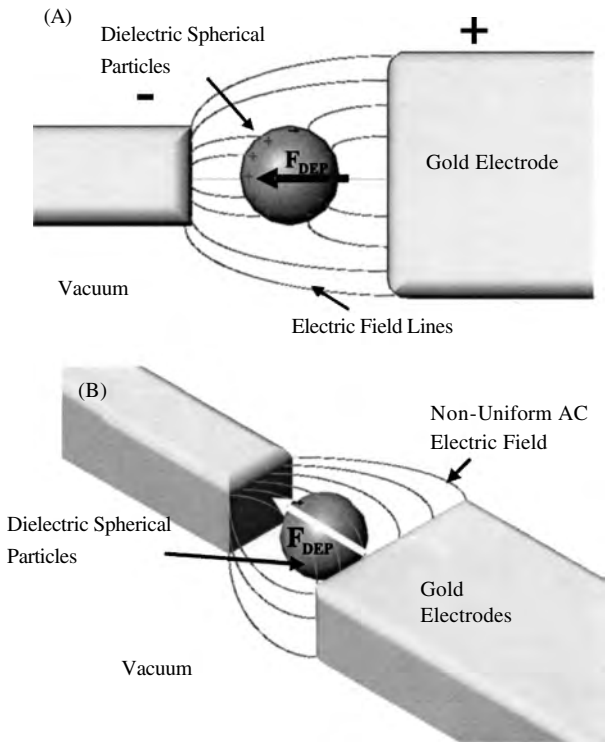

Figure 5. Principle of dielectrophoresis. (A) A spherical dielectric particle is polarized under the influence of external electric field at time Δt. (B) Under nonuniform ac electric field, dielectrophoretic force induced on the neutral spherical particle causes the mechanical motion.

where α is the polarizability and V is the volume of the particle. Combining Eq. (1) and (2), the final expression of dielectrophoretic force can be expressed as

$$\vec{F}_{\text{DEP}} = \frac{1}{2}\alpha V \nabla |\vec{E}|^2 \tag{3}$$

For general cases, if the fluid medium is not a vacuum space, then the dielectric constants for both the particle and the fluid medium have to be taken into consideration. For a spherical colloidal particle (with radius r), Eq. (3) can be further expressed in terms of the complex permittivities of the particle and the medium,

$$\vec{F}_{\text{DEP}} = 2\pi r^3 \varepsilon_2 \,\text{Re}[K(\omega)] \nabla |\vec{E}|^2 \tag{4}$$

where $\text{Re}[K(\omega)]$ is the real part of $K(\omega)$, which is defined by $(\varepsilon_1 - \varepsilon_2)/(\varepsilon_1 + 2\varepsilon_2)$. $K(\omega)$ is referred to as the Clausius–Mossotti factor, which is an important quantity to determine the direction of the dielectrophoretic force acting on a particle. The Clausius–Mossotti factor is a frequency dependent term due to the frequency dependency of the complex permittivities of materials.

From Eq. (4), there are two important points about dielectrophoresis. First, the process of dielectrophoresis depends on the gradient of the electric field strength instead of the direction of the field. Second, if the fluid medium is more polarizable than that of the colloidal particle (i.e., $\varepsilon_2 > \varepsilon_1$), then the dielectrophoretic force induced will be negative. In other words, the colloidal particle will be repelled from the region of high electric field to the region of low electric field (i.e., negative dielectrophoresis). Similarly, positive dielectrophoresis results when the colloidal particle is more polarizable than that of the fluid medium (i.e., $\varepsilon_1 > \varepsilon_2$).

4.1.2. Electrophoresis

Unlike dielectrophoresis, which can induce motion on neutral dielectric particles under a nonuniform ac electric field, electrophoresis is only effective on charged particles. Under a directional electric field generated by metal electrodes, charged particles will move toward the electrodes which are oppositely charged (see Fig. 6). In order to give insight on how electrophoresis applies on charged particles, a simple example is considered here. Assume a spherical particle of radius r, charge q, and mass m, which is in a fluid of viscosity η in a one-dimensional space system under a homogenous dc electric field E. The external electric field E will exert a Coulombic force ($F_{\text{comb}} = qE$) on the particle and drive the particle into motion. However, at the same time, a viscous drag force (or Stokes' force, $F_{\text{drag}} = -6\pi r \eta \dot{x}$) will develop to counteract the motion of the particle. Therefore the net resultant force acting on the particle is given by Newton's second law,

$$m\ddot{x} = qE - 6\pi r \eta \dot{x} \tag{5}$$

Solving Eq. (5), the equation of motion of the particle is expressed in the following forms, assuming the particle is initially at rest:

$$x = \frac{mqE}{36\pi^2 r^2 \eta^2}\left(e^{\frac{-6\pi r\eta}{m}t} + \frac{6\pi r \eta}{m}t - 1\right) \tag{6}$$

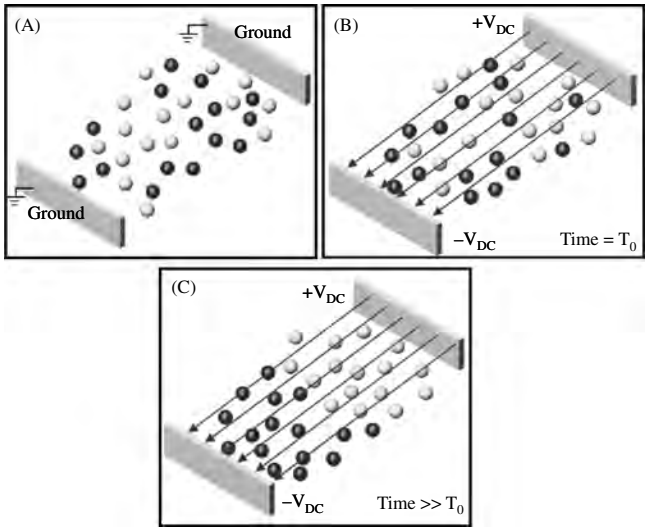

Figure 6. Principle of electrophoresis. Charged particle (orange: positively charged; blue: negatively charged) will migrate toward its opposite polarity under the influence of external electric field. (A) Mixture of charged particles with no external electric field. (B) Application of external electric field imparts forces on the charged particles; the particles move toward either the cathode or anode, depending on the net charge the particle possesses. (C) Separation of particles with different net charges will eventually be achieved.

$$\dot{x} = \frac{qE}{6\pi r\eta}(1 - e^{\frac{-6\pi r\eta}{m}t}) \tag{7}$$

From Eq. (7), the velocity of the particle will eventually come to a constant value after a finite amount of time elapse (i.e., $\dot{x} = \frac{qE}{6\pi r\eta}$), which means that the forces acting on the body are balanced, and results in constant velocity motion (i.e., Newton's first law). This is only the case when the particle is immersed in an environment where the electric field and viscosity of the medium are homogenous. As implied in Eq. (7), the velocity of the particles depends on the net charge of the particles, and therefore, electrophoresis does provide a powerful tool for separating particles with different net charges.

4.1.3. Electro-osmosis

In the simplest context, electro-osmosis is the movement of charged ions (which are formed near the surface of the solid–liquid interface) by an external electric field, which in turn moves the solvent surrounding the ions by viscous friction (or other physical forces like hydrogen bonding of water molecules or van der Waals forces, etc.), and resulting in macroscopic fluid movement (see Fig. 7). The most important factor that contributes to electro-osmosis is the formation of an electrical double layer (EDL) (i.e., a layer of charged ions) in the interface between the solid–liquid boundaries. An EDL is a layer consisting of either majority in cation or anion depending on the polarity of the charged surface. There are two possible mechanisms for the formation of an EDL [114]. The first proposed mechanism is due to surface dissociation (i.e., protons leave the surface and hence become negatively charged). For example, when silica is in contact with an aqueous solution, its surface hydrolyzes

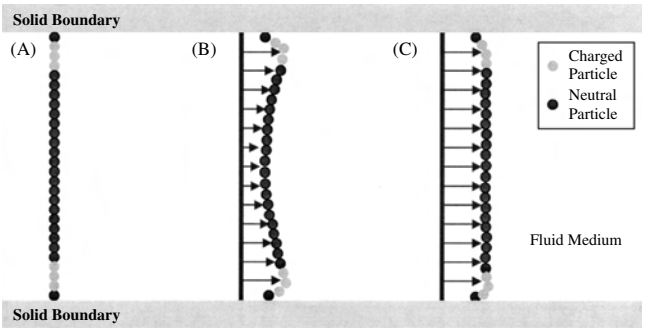

Figure 7. Original electro-osmosis mechanism proposed by Quincke and Holmholtz. The system consists of solid boundary and liquid molecules (green: charged molecules; orange: uncharged molecules). (A) Without the application of external electric field. (B) Application of external electric field causes the charged molecules (green) to move, and the viscous drag forces are then acting upon on the uncharged particles. (B) Electric field is applied for a period of time and the flow of the liquid becomes steady (i.e., constant velocity profile along the envelope).

to form silanol surface group which may be either positively charged ($SiOH_2^+$), neutral (SiOH), or negatively charged (SiO^-) [115]. The second mechanism is the bounding of the ions that already exist in the liquid. The length of the EDL is given by the reciprocal of the Debye function. Interested readers can refer to Tikhomolova [116] for more information on the Debye function.

To have a fundamental understanding between the fluid motion and the applied electric field, assume a scenario of liquid motion inside a capillary tube with sufficient large cross sectional area so that the EDLs of the solution are not overlapping. The velocity of the electro-osmotic flow (v_{EOF}) is then directly proportional to the strength of the electric field strength (E) and it was termed quantitatively by Smoluchowski in 1903 as [116]

$$v_{EOF} = \frac{\varepsilon\xi}{\eta}E \tag{8}$$

where ξ is the zeta potential (i.e., the potential between the charge surface and the electrolyte solution), ε is the dielectric constant of the fluid medium, and η is the viscosity of the solution.

4.2. Electrokinetic Manipulation of Carbon Nanotube, Metallic, and Inorganic Nanowires

With ever-increasing demand in the microelectronics industry, scientists and engineers have pushed the manufacturing limit of the minimum feature on a chip to submicrometer range in the late 20th century. Currently, the minimum feature of a typical Intel® Pentium® 4 CPU has already reached 0.13 μm [117]. However, the continual scaling down of the microelectronic devices will become physically and economically impractical in the foreseeable future. Therefore, scientists have to look into new materials and processing technologies to create *nanoelectronics* for the future.

In 1991, Iijima discovered the carbon nanotube [4], which has opened up a new research area for nanoelectronic applications. Carbon nanotube based nanoelectronic devices have already been fabricated successfully in the past few years. For example, Tans et al. [118] and Frank et al. [119] have demonstrated the single carbon nanotube transistor and quantum resistors, respectively. On another ocassion, Duan et al. exploited the usage of indium phosphide nanowires for nanoscale electronic and optoelectronics components [120]. Although many promising results have been demonstrated in using carbon nanotubes and nanowires for nanoelectronic applications, techniques to batch manipulate (or parallel assemble) those nanoentities have to be developed in order to make nanoelectronics feasible and practical. Currently, manipulation of carbon nanotube and nanowires by electrokinetic forces is one of the most active research areas for parallel assembly techniques.

Using existing micro/nanolithography technology, metal electrodes with dimensions in the range of a nanometer are currently achievable [121]. With smaller electrode pairs, ultrahigh electric field strength ($>10^6$ V/m) can be produced with low applied voltages. For example, consider a pair of microelectrodes with a gap distance of 10 μm; an electric field strength of 10^6 V/m can be produced easily by an excitation voltage of 10 V across the microelectrodes. This intense electric field strength is useful for micro/nanomanipulation.

Several groups have demonstrated successful manipulation of carbon nanotube, metallic, and inorganic nanowires using electrokinetic forces in the past few years. Yamamoto et al. have demonstrated the use of electrophoretic force to align carbon nanotubes with the dc electric field [122]. Later, the same group exploited the use of dielectrophoretic forces to separate the carbon nanotubes and the impurities which serve as a novel purification process [123]. Recently, Nagahara et al. have successfully demonstrated the use of dielectrophoretic force to manipulate individual carbon nanotubes to form electrical contacts between two metal nanoelectrodes, which is a very promising demonstration for parallel assembly of carbon nanotubes [121]. Wong and Li have recently demonstrated the formation of bulk carbon nanotubes between microelectrodes (see Fig. 8) using dielectrophoretic forces for practical sensing applications [124]. Other than carbon nanotubes, metallic and inorganic nanowires have also been manipulated successfully by Smith et al. [125] and Duan et al. [120], respectively. In particular, Dual et al. have demonstrated the parallel assembly of inorganic nanowires via an array of parallel electrode pairs, indicating an important step toward batch fabrication of nanoelectronic elements [120].

4.3. Electrokinetic Manipulation of Biological Entities and Nanoparticles

An early attempt at manipulating biological entities such as DNA molecules was shown successfully by Washiuzu and Kurosawa [126] in 1990. Many exciting results in manipulating biological entities and nanoparticles using electrokinetic approaches have been published since then.

In order to effectively investigate the effect of dielectrophoretic force on biological entities and nanoparticles,

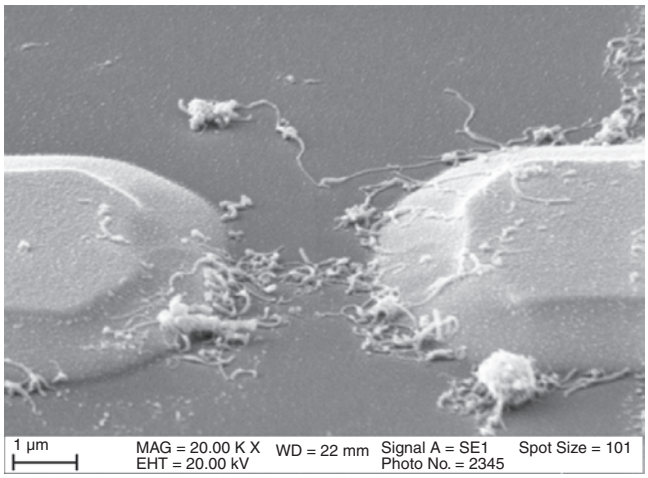

Figure 8. Scanning electron microscopic image showing the bridging of Au/Cr microelectrodes by bundled carbon nanotube by dielectrophoretic force.

Huang and Pethig developed a simple and practical methodology in designing electrode geometries in producing well-defined nonuniform electrode fields in the early 1990s [127], which was shown to be useful in collecting yeast cells to or away from the electrodes. Practical application in using dielectrophoretic force to separate leukaemic cells from human blood was demonstrated by Becker et al. in the mid 1990s [128]. In late 1990s, Hughes and Morgan successfully demonstrated the trapping of single viruses, capsids, and latex spheres, with diameters in the range of 93–250 nm inside a potential trap [129]. By utilizing both positive and negative dielectrophoretic forces, precise movement of protoplasts with 30–50 μm diameters can be controlled by a three-dimensional grid system developed by Suehiro and Pethig [130]. As implied by Eq. (4), the direction and magnitude of the dielectrophoretic force are dependent on the dielectric properties of the particles and medium, and also the electric field gradient in the medium. Using this property, a system of particles with different dielectric properties can be separated into subpopulations by dielectrophoresis and this has been successfully demonstrated by Green and Morgan in separating a carboxylate modified latex bean of 93 nm diameter [131]. Besides trapping the particles in a certain predefined space, dielectrophoresis has been found useful to mix a system of particles in chaotic mixing applications for microfluidic systems as well [132]. Apart from the dielectrophoretic approach in manipulating the biological entities, the electrophoretic and electro-osmotic approach has been proven to work in manipulating those particles as well. For instance, a conductive nanoparticle (Pd) of about 17 nm diameter can be trapped electrostatically by nanoelectrodes as shown by Bezryadin et al. [133].

5. CONCLUSION

As described in this chapter, the three most widely accepted techniques for robotic manipulation of nanoentities are: (1) manipulation by atomic force microscope tips, (2) manipulation by laser trapping force, and (3) manipulation by electrokinetic forces. However, besides chemical and

biotechnology methods for nanomanipulation, which are not described in this chapter, there are a few other techniques which have been demonstrated for nanomanipulation. For example, in terms of single molecule manipulation, magnetic particles can be attached to the molecules and then magnetic force can be used to move the molecules [134]. Hydrodynamic forces (i.e., shear force) can also be used to move or stretch molecules [131, 135, 136], and ultrasmall glass needles have also been demonstrated to manipulate molecules [137]. Nevertheless, none of the existing nanorobotic and manipulation techniques is able to solve the most pressing problem if true nanorobots are to be created some day: the ability to bring two or more molecules and join them together in a desired manner to create the first controllable "nanotool"—a tool that can then be used to make more complex nanosystems such as intelligent nanorobots that are able to autonomously manufacture to more nanosystems.

GLOSSARY

Atomic force microscopy (AFM) A form of scanning probe microscopy. The tip–sample interaction monitored during raster scan is interatomic forces between the tip and sample surface. During scanning, the cantilever deflection or interatomic force between tip and sample is kept constant in contact mode and the rms value of cantilever deflection is kept constant in TappingMode™.

Dielectrophoresis The phenomenon of inducing motion on neutral dielectric particles under nonuniform ac electric field.

Dielectrophoretic force The force generated when a neutral particle is immersed in nonuniform ac electric field region.

Electrokinetic force The Columbic force imparted on particles when external electric field is applied.

Electro-osmosis The phenomenon of moving of charged ions, formed near the solid–liquid interface, by an external electric field. The solvent that surrounds the ions is also moved by viscous friction or other physical forces, like hydrogen bonding of water molecules or van der Waals forces, resulting in macroscopic fluid movement.

Electrophoresis The phenomenon of inducing motion on charged particles under directional dc electric field.

Electrophoretic force The force generated when a charged particle is immersed in a directional dc electric field region.

Haptic device A device that allows position and orientation input from and forces/torques output to operators at the same time.

Mie regime Optical trapping occurs when the wavelength of the laser is greatly smaller than the object size.

Nanoassembly Study of how to fit together a group of nanometer sized components to form a functional machine or device.

Nanolithography The process of imprinting patterns of submicrometer size on a sample surface.

Nanomanipulation Study on how to manipulate nanometer sized entities.

Nanorobotics Study of dynamics, control, planning, sensing, and actuation of robots in nanometer scale.

Optical trapping The phenomenon of fixing or holding micrometer or submicrometer sized neutrally charged entities using focused laser. The trapping ability comes from the radiation pressure of light, which is generated by the change of momentum in the transmitted and incident laser light and is balanced by all external forces, like gravity and electric forces.

Optical tweezers A laser based device for manipulating micrometer or submicrometer sized neutral entities based on the phenomenon of laser trapping.

Optical tweezing See optical trapping.

Piezoelectric scanner A core component of scanning probe microscopes. An $X/Y/Z$ scanner that is actuated by three pairs of piezoelectric materials. Piezoelectric material extends or contracts when external ac electric field is applied.

Position sensitive detector (PSD) A core component of scanning probe microscopes. It consists of two or four photodiodes to detect the minute changes in the light path of a laser which reveal the deflection and twist of the cantilever in AFM and STM.

Rayleigh regime Optical trapping occurs when the wavelength of the laser is comparable to the object size.

Scanning probe microscopy (SPM) A family of microscopy techniques that generate 3D topography and images of various physical properties, for example height, surface roughness, local resistivity, etc., of sample surfaces with nanometer or subnanometer scale. A sharp tip is rastered across the sample surface while tip–sample interactions are monitored.

Scanning tunneling microscopy (STM) A form of scanning probe microscopy. The tip–sample interaction monitored during raster scan is tunneling current between the tip and sample surface. Since the tunneling current has an exponential relationship with tip–sample separation, the height information is derived directly from the measured tunneling current in the generation of 3D topography.

Virtual reality (VR) The technique of computer simulations that use 3D graphics and special input devices to allow users to interact with the simulation.

Nanorecognition

P. Tarakeshwar, Kwang S. Kim

Pohang University of Science and Technology, Pohang, Koreá

CONTENTS

1. INTRODUCTION

The motivation to comprehend the underlying principles of nanorecognition stems from our need to understand, predict, and design the properties of nanoscale materials and devices with respect to their chemical composition, physical characteristics, and electronic structures [1–35]. Nanorecognition in many ways is synonymous to the more well-known "molecular recognition" [36–95], but quantum effects are predominant [96–135]. For example, the recognition of (single) electrons and photons by molecules or clusters of atoms, which are of interest in the design and working of nanodevices, can only be described by using a model which explicitly takes into account the quantum characteristics of electrons and photons.

The phenomena of recognition is widespread in most chemical and biological systems and in fact is the key to the understanding of biological machinery. It is the basis of the specificity observed in enzyme–substrate [136–148], hormone–receptor [149–153], antigen–antibody [154–159], and drug–receptor interactions [160–168], in biological systems. It also leads to protein folding, oligomerization, aggregation, and the formation of nucleic acid helices [169–188]. In fact, much of the inspiration for the developments in contemporary supramolecular and host–guest chemistry emerged from efforts to understand and mimic the exquisite and intricate design observed in biological systems.

Given its widespread relevance in diverse fields of chemistry, biology, and more recently materials science, there have been intense efforts to obtain a detailed understanding of the underlying basis of molecular recognition. The "lock-and-key" theory of Fischer [189, 190] could be considered to be one of the earliest efforts to understand molecular recognition. Though the theory was originally developed to understand enzyme–substrate reactions, it was the basis of most of the initial attempts to explain molecular recognition. In this theory, the receptor–substrate complex results from a recognition of a substrate (key) by a molecular receptor (lock). However, with the advent of supramolecular chemistry and the concurrent efforts to develop molecule or atom specific hosts, it became evident that such a simplistic theory, which was purely based on steric considerations, was inadequate in explaining the affinity and specificity of hosts [191–193].

This understanding of the recognition phenomena becomes more acute in nanosystems wherein several competing interactions contribute to the recognition phenomena and hence contribute to the resulting structure and properties. Like in Figure 1, the formation of the organic nanotube is a result of the cooperative and competing interactions between two water molecules (hydrogen bonding) and between two aromatic molecules (π–π interactions) [16]. In general, the discussion of recognition phenomena is greatly facilitated, if we examine it in terms of contributions of individual molecular or atomic interactions. Though both intramolecular and intermolecular interactions influence recognition phenomena, the contribution of the latter is more significant. While a large number of interactions prevail in chemical and biological systems, the interactions which are relevant in the context of nanorecognition can be broadly classified into five different types. These include (i) hydrogen bonding, (ii) ionic interactions, (iii) intermolecular interactions involving π systems, (iv) metallic interactions, and (v) interactions involving quantum species. While it is difficult to segregate each of these interactions into water-tight compartments, we rationalize this classification in subsequent sections. It is, however, important to note that

recognition is a manifestation of several competing kinds of intermolecular interaction. This competition can either enhance or deplete the effect of each individual kind of interaction.

While it is often taken for granted, it should be pointed out that recognition per se does not imply binding/interaction [191]. It rather pertains to the structural, energetic, and thermodynamic events which precede the binding/interaction. Since the terms *binding* and *interaction* have been extensively used in literature, it is important at this juncture to distinguish the two terms. While *binding* can be said to result from the effects of several competing interactions, which could be of varying magnitudes, interaction is more specific and is either attractive or repulsive. Rather than attempting to discuss all the myriad aspects of nanorecognition, we focus our attention on the underlying physical principles governing the recognition phenomena.

Therefore, in the course of this chapter, we initially present a brief background on the development of the concept of recognition and we subsequently highlight the different aspects governing the recognition phenomena; (i) structural, (ii) energetic, and (iii) thermodynamic. The characteristics of different types of intermolecular interactions, which significantly influence recognition phenomena, are then discussed. Last, we elaborate on the competition between different kinds of intermolecular interactions and also discuss the concept of cooperativity.

Most experiments on nanosystems and for that matter on many host–guest complexes have been conducted in solid-state and solution. However, quantitative experimental investigations of most weak intermolecular interactions in complex systems are fraught with difficulties because of problems in isolating intermolecular complexes in well-defined orientations at room temperature [194–196]. In this connection, clusters, which are nothing but weakly bound aggregates of atoms, ions, or molecules, bridge the gap between atom and bulklike behavior, and hence results obtained from investigations of both atomic and molecular clusters are pertinent in understanding nearly all the principles of nanorecognition [197–233]. More compelling justifications are the numerous observations that data obtained on isolated clusters explain the bulk phase properties of nanomaterials [203] and also aid the design of new materials. In this connection, the recent design of novel nanomaterials and nanoelectromechanical devices based on results obtained from theoretical calculations of clusters merits mention [16–18, 233].

2. BACKGROUND

Contemporary interest in molecular recognition started after the pioneering discovery of the cation complexation abilities of crown ethers by Pedersen [234, 235]. Subsequent efforts by Dietrich et al. [236, 237], Gokel and Cram [238, 239], and others [7, 240, 241] revolutionized the field. Most of the early work on molecular recognition was predominantly devoted to the recognition of charged species like cations [240, 242–251]. This led to the discovery and development of a large number of host molecules (Fig. 2) capable of binding cations. The features of these hosts like podands [242], crown ethers [243–247], cryptands [248], spherands [249], and calixarenes [250] have been extensively discussed in the past. A number of hosts present in biological systems were also found to be excellent hosts for these charged species. Prominent among them are the siderophores [251], and molecules like valinomycin [252], enniatin [252], nonactin [252], etc. In most of these hosts, the cation binding is mediated through the heteroatoms (oxygen, nitrogen, sulfur) present in these hosts. While a number of practical utilities of these cation binding hosts exists [253, 254], an area of intense investigation has been the utility of these hosts in

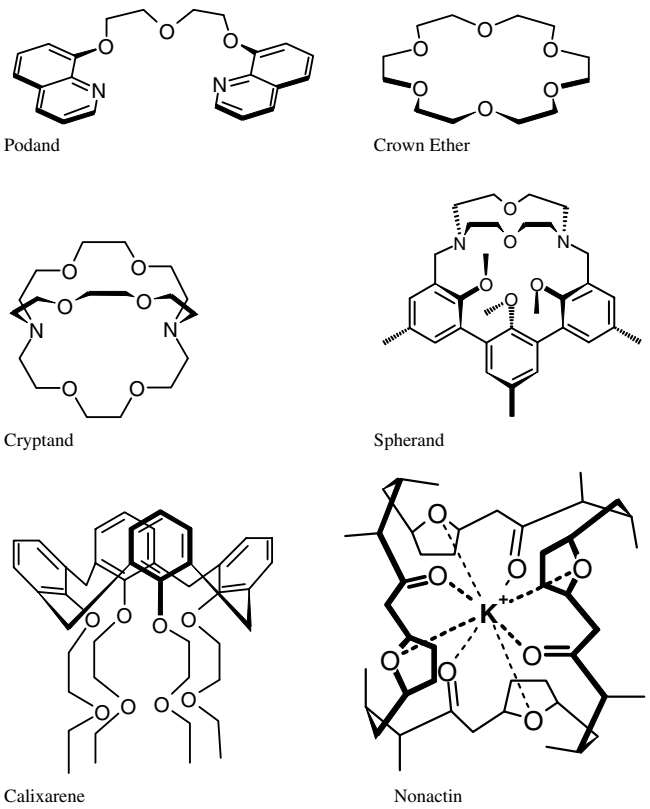

Figure 2. Some examples of cation binding hosts.

separating long-lived radioactive species from nuclear wastes [255]. This brings forth the twin issues of affinity and selectivity of these hosts toward a particular cation [56, 191, 196, 253, 254]. Most of the present work on these cation binding hosts is focused on developing environmentally benign and reusable systems, wherein the binding is reversible [253]. That is, the binding affinities can be influenced by the surrounding environment. In this context, a number of novel hosts wherein the binding of the cations to the hosts is mediated through olefinic or aromatic π systems present in the hosts have been developed. As an example, the [*n*]-beltenes which exhibit excellent affinity for the alkali metal cations are displayed in Figure 3. Apart from displaying excellent size selectivity (an issue which will be discussed in more detail in the next section), these hosts exhibit excellent affinity for a wide variety of cations and serve as useful models for understanding biological molecular recognition [256].

In the course of the development of hosts capable of binding cations, it was found that some of these hosts were also capable of binding neutral molecules and anions [241]. At the same time, a number of other host molecules like calixarenes [257], cyclophanes [258, 259], cyclodextrins [260, 261], cucurbiturils [75, 262], cryptophanes [196], and carcerands [263] were isolated, synthesized, and investigated for their neutral molecule or anion binding propensities. Interest in the binding of anions also stems from the fact that a number of biological processes involve molecular recognition of anionic species. In this context, the recent isolation of the X-ray structure of a chloride channel merits mention because it reveals the molecular basis of anion selectivity [264]. In the context of this chapter, it is interesting to elaborate briefly on the salient architectural differences between the Cl^- and K^+ channels [265–267].

The Cl^- channel has a roughly hourglass-shaped pore with a narrow constriction (its selectivity filter) near the membrane center (Fig. 4). On the other hand, the K^+ channel has

a widening, or cavity, at the membrane center (Fig. 4). The cavity in K^+ channels, working in concert with helix dipoles, helps to overcome the dielectric barrier or energy barrier experienced by an ion owing to the low-dielectric membrane environment. The Cl^- channel, however, uses only helix dipoles. Though the origin of the interaction between the ion and the protein in both the K^+ and Cl^- channels is predominantly electrostatic, the difference in the geometry of the ion channels is due to the very different characteristics of the K^+ and Cl^- ions. We elaborate on this aspect in more detail in a subsequent section on ionic interactions.

Ion-pair recognition, the simultaneous complexation of cationic and anionic guest species by receptors, is a new and emergent field in contemporary nanorecognition. Thus receptors can be designed to exhibit novel cooperative and allosteric behavior, whereby the binding of one ion can have a profound influence on the coordination of the subsequent oppositely charged ion. These systems can serve as potential hosts for the selective extraction and transportation of environmentally important ion-pair species and also be used for zwitterionic recognition [268, 269]. In this context, it is interesting to highlight the recent design of amphiionophores (Fig. 5), which can bind both cations and anions [71, 72].

While most of the previous discussion was focused on the recognition prevalent in single molecule hosts and guests, an area of equal importance is the macroscopic expression of molecular recognition (self-assembly of supramolecular and nanostructures) [191]. Essentially this implies that the focus is on the processes which follow the initial recognition event. These processes include (i) the formation of intricate shapes (templates), (ii) the recognition of these shapes or templates, and (iii) the template-directed self-synthesis of large polymolecular or nanoassemblies [66]. Therefore, molecular self-assembly can be defined as the spontaneous organization of molecules under thermodynamic equilibrium conditions into structurally well-defined and rather stable arrangements through a number of noncovalent interactions [191]. These molecules undergo self-association forming hierarchical structures. The key engineering principle for molecular self-assembly is to artfully design the molecular building blocks that are able spontaneously to undergo stepwise interactions and assemblies through the formation of numerous noncovalent weak chemical interactions (hydrogen bonding, ionic interactions, etc.). Although each of these interactions is rather weak, the collective interactions can result in very stable structures and materials. The key elements in molecular self-assembly are chemical complementarity and structural compatibility. This area has witnessed a lot of new developments in the recent past because of potential applications in the areas of liquid crystals, nanostructures of technological relevance, and the self-assembly, self-replicating characteristics of nano- and biostructures, nanoelectrical devices, and nanomechanical machinery [90–95].

Before we progress further, it is useful to highlight the distinction between the words supramolecule and supermolecule, because they are extensively used in the context of nanorecognition. Lehn has pointed out that the word "supramolecule" is used to describe large multiprotein architectures and organized molecular assemblies that result from the spontaneous association of a large undefined number of components into a specific phase having more or less well-defined microscopic organization and macroscopic characteristics depending on its nature (thin films, layers, membranes, vesicles, micelles, mesomorphic phases, solid state structures, etc.) [191]. The word "supermolecule" is used to denote singular or polymolecular association, which are well-defined, discrete oligomolecular species that result from the intermolecular association of a few components (receptor and its substrates bound together by molecular recognition) [191]. Therefore in the broad sense, supramolecular chemistry can encompass all types of molecular entitities ranging from well-defined supermolecules to extended, more or less organized, polymolecular associations.

3. PHYSICAL BASIS OF NANORECOGNITION

The principles governing nanorecognition are the same noncovalent interactions which occur in very weak complexes [232, 270], enzymatic and chemical transition states [136–148], and large molecular assemblies [92, 95]. The formation of nanostructures requires suitable specificities, optimal geometries, and reinforcing effects. Generally, nanorecognition is driven by enthalpic noncovalent forces (electrostatic, induction, dispersion) and by entropic effects [56]. A key role is played by the shape of the molecules or the molecular aggregates. While a few effects are highly specific and directional, others are less selective but are important factors in the stabilization of the eventual nanostructure. In self-assembly, a number of simultaneous interactions may occur, which would either enhance or deplete the binding at a particular site. Additionally cooperative and competitive effects play a vital role in determining the stabilitiy of the eventual nanostructure. It is important to stress that nanorecognition is a complex interplay of several structural, energetic, and thermodynamic components, each of which has a vital role in the stabilization of the observed structure.

3.1. Structural Considerations

The prevalence of the "lock and key" model around the time of the discovery of crown-ethers led to the notion that a close steric approach of the individual centers leads to optimal binding. This implied that structural/geometric considerations were enough to explain the enhanced ion selectivity of the crown-ethers. This together with the fact that the energetic effort needed by an open chain ligand to possess similar binding affinities as the corresponding macrocyclic ligand indicated that the preordained structural arrangement of the host might be an important factor governing the nature of binding [56]. However, it was soon realized that the presence of an enclosed cavity does *not* necessarily lead to increased stability even in cases where the solvent has no role to play in the interaction [56, 191]. The reason for this seemingly counterintuitive observation, which is based on the contribution of dispersive forces, is elaborated in subsequent sections. However, it is important to note that purely structural considerations though useful in explaining the binding affinities of some hosts is not very helpful in explaining most recognition phenomena. One has to take recourse to the role of both energetic and thermodynamic considerations.

3.2. Energetic Considerations

Recognition phenomena, as is observed in chemical and biochemical systems, is a juxtaposition of competing energetic elements which are either attractive or repulsive [56, 271]. Before we progress further, it is pertinent to note that a large number of terms have been employed to discuss various kinds of intermolecular forces [272],

prevalent in molecular recognition. In terms of relative importance, these intermolecular forces can be broadly described as (i) Coulombic forces, which describe the interaction between permanent charges, (ii) charge transfer forces, which describe the stabilization arising from a transfer of electrons from a highest occupied molecular orbital of one system to the lowest unoccupied molecular orbital of the other, (iii) dispersive or London attractions, which describe the attraction occurring due to the instantaneous distortions of the electron clouds of two interacting molecules. Though repulsive forces have contributions from several terms, the contribution from exchange–repulsion is the most dominant. Though not exactly equivalent, the electrostatic term describes the energies resulting from Coulombic forces, the induction term describes the energies resulting from polarization, charge redistribution, and charge transfer forces, the dispersion term describes the energies resulting from dispersive and London forces.

It is important to reiterate that the origin and magnitude of these individual attractive and repulsive elements is very different, and as will be shown in subsequent sections, are vital in governing the observed geometries and energies. Expectedly, the natures of the interacting species have important roles to play therein. Our knowledge of the nature and magnitudes of these individual interaction energies or intermolecular forces comes from two main sources: (i) quantum theory and (ii) experimental methods.

From quantum theory, we can compute, with varying levels of accuracy, what the potential energy is of a given configuration as a function of orientation, separation, etc. Quantum calculations enable us to determine the optimal geometry of the resulting species. There are a number of ways of performing quantum calculations, each with its own strength and weakness. Generally the more accurate, but computationally more intensive methods are those including electron correlation. Electron correlation energy is the energy recovered by fully allowing the electrons to avoid each other in a molecular ensemble. These correlation effects include both "dynamical" and "static" correlation effects. The inclusion of electron correlation is a prerequisite for evaluating the interaction energies because the magnitudes of both the induction and dispersion terms are critically dependent on it.

At the Hartree–Fock quantum level of theory, the interelectron repulsions are improperly treated in an averaged way [273]. As a consequence, it is of limited use in investigating the properties of most nanosystems. The methods like the second order Møller–Plesset level of theory, configuration interaction, and coupled cluster, which explicitly take into account the effect of electron correlation, are widely employed in investigating these nanosystems [232, 274, 275]. The only limiting factor, however, is the available computational resources.

Experimental methods also enable us to obtain the magnitude of individual interaction energy components. For example, dilute gas properties such as second virial coefficients, viscosities, etc. can be measured. Since most of these properties depend on the nature of the prevalent intermolecular interactions, the requisite information can be obtained by using standard equations along with a knowledge of the conditions under which the experiments were conducted. In this connection, the recent experimental determination of the magnitude of dispersion energies in a number of host–guest systems merits mention [194]. We can also obtain vital information from spectroscopy, molecular beam experiments, and more recently high resolution electron and atomic force microscopy [276–279]. The least elegant (but arguably most effective) method is to postulate a reasonable form of a forcefield, adjust the parameters for a simple system until a good fit with existing experiments is obtained, and then transfer this forcefield to other systems for use at other conditions [281].

It is useful to have an understanding of the origin of each of these intermolecular forces (electrostatic, induction, dispersion, exchange–repulsion) and a good starting point is standard perturbation theory [271, 282, 283]. The wave functions $|\psi^A\rangle$ and $|\psi^B\rangle$ of the isolated molecules A and B lead to a rigorous definition of the first, second, and higher order interaction energies in terms of the interaction Hamiltonian,

$$V^{AB} = \sum_{i\in A}\sum_{j\in B} q_i q_j / r_{ij} \tag{1}$$

In the equation, r_{ij} is the intermolecular distance. The electrostatic interaction between the two unperturbed molecules, which is equivalent to the first order term, is described by

$$\Delta E^{(1)}_{elec} = \langle \psi^A \psi^B | V^{AB} | \psi^A \psi^B \rangle \tag{2}$$

The second order terms, representing the induction and dispersion interactions, are obtained as an infinite sum over the excited states $|n^A\rangle$ and $|m^B\rangle$ of A and B:

$$\Delta E^{(2)}_{ind} = \sum_{n\neq 0} \left|\langle \psi^A \psi^B | V^{AB} | n^A \psi^B \rangle\right|^2 / (E^A_0 - E^A_n) + \sum_{m\neq 0} \left|\langle \psi^A \psi^B | V^{AB} | \psi^A m^B \rangle\right|^2 / (E^B_0 - E^B_m) \tag{3}$$

$$\Delta E^{(2)}_{disp} = \sum_{n,\,m\neq 0} \left|\langle \psi^A \psi^B | V^{AB} | n^A m^B \rangle\right|^2 / (E^A_0 - E^A_n + E^B_0 - E^B_m) \tag{4}$$

In these equations, E^A_i is the energy of the ith excited state of molecule A. In contrast to the equation for the dispersion energy, the two terms constituting the induction energy can be factored out because the integrations over $|\psi^A\rangle$ and $|\psi^B\rangle$ can be performed separately. Substituting the multipole expansion for V^{AB}, the induction energy is

$$\Delta E^{(2)}_{ind} = -1/2 \sum_{\alpha,\beta} \alpha^A_{\alpha,\beta} F^B_\alpha F^B_\beta - 1/2 \sum_{\alpha,\beta} \alpha^B_{\alpha,\beta} F^A_\alpha F^A_\beta - \text{higher order terms} \tag{5}$$

In this equation, the indices α and β denote the axes of the Cartesian coordinate frame. F^A_α is the electric field of molecule A at the multipole expansion center of the other molecule. The dipole polarizability $\alpha_{\alpha,\beta}$ describes the response to a fixed external field and is defined as

$$\alpha_{\alpha,\beta} = \sum_{n\neq 0} (\langle \psi | \mu_\alpha | n \rangle \langle n | \mu_\beta | \psi \rangle + \langle \psi | \mu_\beta | n \rangle \langle n | \mu_\alpha | \psi \rangle) / (E_n - E_0) \tag{6}$$

where μ_α are the components of the electric dipole operator. While both the electrostatic ($\Delta E^{(1)}_{\text{elec}}$) and induction ($\Delta E^{(2)}_{\text{ind}}$) energies are obtained in the fixed potential of each constituent molecule, the dispersion energy ($\Delta E^{(2)}_{\text{disp}}$) is closely associated to the coupled fluctuations of the charge distributions of both the constituent molecules A and B. In contrast to these attractive energies, the exchange energy which is repulsive for closed shell complexes emerges from the fermionic nature of electrons. Since Fermi–Dirac statistics requires antisymmetrization of the product functions $|n^A\rangle|m^B\rangle$, the first order exchange energy is usually defined as

$$\Delta^{(1)}_{\text{exch}} = \frac{\langle \psi^A\psi^B|SV^{AB}|\psi^A\psi^B\rangle}{\langle \psi^A\psi^B|S|\psi^A\psi^B\rangle} \tag{7}$$

or

$$\Delta^{(1)}_{\text{exch}} = \frac{\langle S\psi^A\psi^B|H^0 + V^{AB}|S\psi^A\psi^B\rangle}{\langle S\psi^A\psi^B|S\psi^A\psi^B\rangle} - E^A - E^B \tag{8}$$
