where H^0 is the unperturbed Hamiltonian and E^A and E^B are the ground state energies of A and B. When both $|n^A\rangle$ and $|m^B\rangle$ are exact eigenfunctions, these equations are equivalent. There is no unique term for higher order terms of the exchange energy. This is because the antisymmetrizer S mixes different orders of perturbation theory as S and V^{AB} do not commute. Moreover, the projected functions $S|n^A\rangle|m^B\rangle$ generally form a linearly dependent set. The available evidence indicates that second order exchange effects (correction of the induction and dispersion energies due to exchange) are small for most intermolecular complexes. This implies that the addition of long range energies to the exchange interactions does not lead to serious errors. In multimolecular assemblies, the total interaction energy can be written as a sum of the pairwise interaction energies (pairwise additivity). While the first order electrostatic energy is exactly additive, the dispersion energy is nearly additive (the three-body Axilrod–Teller term is generally small in the third order). In contrast, the induction energy is not pairwise additive because of interference of electrostatic fields from different sources. Furthermore, the higher order contributions in complexes containing polar molecules cannot be neglected because the induced fields can significantly alter the molecular wave functions. This in turn affects the additivity of exchange interactions because its magnitude is related to the extent of intermolecular integral overlap.

3.3. Thermodynamic Considerations

While the origin of these intermolecular forces can be understood using quantum theory, one needs to use formulas derived from statistical thermodynamics to compute them as functions of temperature. This is because most calculations based on quantum theory invoke the approximation that the atomic nuclei are stationary, with the electrons swarming about them. This is a good approximation because nuclei are much heavier than electrons. However, the resulting energies are for a hypothetical, nonvibrating molecule. Though these oscillators can be considered to be at rest in a classical mechanics model, the real quantum-mechanical oscillators are always in motion. The small residual motion at absolute zero temperature is the zero-point vibrational energy.

One can obtain the macroscopic thermodynamic properties like enthalpies, entropies, and heat capacities using the molecular partition function. The molecular energy levels ϵ_i are used to compute the molecular partition function, usually denoted by the symbol Q, as shown in the following equation:

$$Q(T) = \sum_i \exp(-\epsilon_i/kT) \tag{9}$$

The sum extends over all energy levels. However, for very high temperatures at which the molecule or molecular complex becomes unstable, the extent of the sum may be ambiguous. One should therefore note that most theoretical estimates of thermodynamic properties (i) depend strongly upon the high-energy cutoff procedure adopted and (ii) deviate implicitly from the ideal-gas model. One typically chooses the lowest energy level to be the zero of energy, so that no levels lie at negative energies. From Eq. (9), it follows that the largest contributions to Q are from the lowest energy levels. Conversely, levels that lie far above kT (207 cm^{-1} at room temperature) have only a minor effect on Q and its derivative thermodynamic quantities:

$$S = Nk\left[\frac{\partial}{\partial T}(T\ \ln Q) - \ln N + 1\right] \tag{10}$$

$$C_v = NkT\frac{\partial^2}{\partial T^2}(T\ \ln Q) \tag{11}$$

$$C_p = C_v + R \tag{12}$$

$$H(T) - H(0) = \int_0^T C_p\, dT = NkT^2\frac{\partial(\ln Q)}{\partial T}_{N,V} + NkT \tag{13}$$

Given the molecular partition function, the usual molar thermodynamic functions can be calculated based upon the following general equations. Equation (10) is for the entropy, (11) for the heat capacity at constant volume, (12) for the heat capacity at constant pressure, and (13) for the enthalpy difference relative to absolute zero temperature. N is Avogadro's number, k is the Boltzmann constant, and the ideal-gas constant $R = Nk$. The last two terms inside the brackets in Eq. (10) arise from the indistinguishability of identical molecules, which requires a factor of $(1/N!)$ in the partition function for the ensemble.

The effect of temperature on intermolecular forces can be explained using the concept of thermal energies (kinetic theory). Thus, the intrinsic stability of an intermolecular complex at a given temperature is due to the balance between their thermal and potential energies. It is of interest to note that routine physical phenomena like melting, boiling, and the presence of critical points reflect the magnitude of the intermolecular interaction. For example, the critical temperatures of neon dimer (44 K), methane dimer (191 K), and water dimer (647 K) mirror their binding strengths [280]. Similar trends can also be noted for the molar heat of vaporization.

Though energetic considerations enable the formation of the intermolecular or supramolecular complex, thermodynamic factors play a crucial role in determining the stability of the complex. As was mentioned earlier, the individual monomers involved in the recognition process undergo substantial conformational changes upon binding. These conformational changes result from the monomers trying to maximize the intermolecular interaction and minimize the induced intramolecular conformational strain. In cases where solvent is involved, desolvation effects also have an important role. All the aforementioned effects influence the nature of the intermolecular interaction through the entropy term. Experimentally, the major thermodynamic quantities like the free energy (ΔG) and enthalpy (ΔH) are obtained either by calorimetric titration or from the temperature variation of the complex stability constant (K). The complex stability constants (K) at different temperatures are obtained by using any experimental technique like potentiometry, conductometry, spectrophotometry, nuclear magnetic resonance (NMR) spectrometry, solvent extraction, etc. Based on a plot of the logarithm of the stability constant (K) and the inverse temperature ($1/T$), the enthalpy and entropy changes are obtained as the slope and intercept, respectively.

$$\ln K = \frac{\Delta H}{NkT} + \frac{\Delta S}{Nk} \tag{14}$$

Based on experimental information obtained from a large number of intermolecular complexes, it emerges that entropic effects are much more dominant in complexes predominated by electrostatic interactions. We discuss the theoretical basis of this observation in subsequent sections.

4. VARIOUS TYPES OF INTERMOLECULAR INTERACTIONS

4.1. Hydrogen Bonding

4.1.1. Definition, Importance, and Classification

Hydrogen bonding, which is one of the most widely prevalent and extensively investigated intermolecular interactions, is typically characterized by an equilibrium configuration involving a hydrogen atom donor **D** and an acceptor **A** [284–287]. Conventionally, the hydrogen bond (H-bond) is represented as (**D**–**H**$\cdots$**A**), wherein both donor **D** and acceptor **A** are electronegative atoms. One can broadly classify the experimentally observed H-bonds into three classes (weak, medium, and strong) based on the strength of their interaction. This strength, based on experimental and theoretical methods, ranges between 0 and 30 kcal/mol ($\sim$30 kcal/mol in case of the $F^- \cdots H$–F interaction). In general, weak H-bonds involve polar X–H groups like C–H or P–H, or less polar acceptors like covalently bonded fluorine atoms or π systems [232, 288, 289]. The vast majority of H-bonds discussed in literature are of medium or intermediate strength ($\sim$5 kcal/mol). Thus, the H-bonds observed in water clusters, carboxylic acid dimers, H-bonds involving uncharged species in proteins, and nucleic acids are well-known examples [290–293]. Strong H-bonds in general involve a charged species like an oxyanion as a proton acceptor and are mostly observed in enzyme active sites [294]. Though the high interaction energies involved therein have elicited a lot of debate on the exact nature of H-bonds, the properties of systems exhibiting these H-bonds have attracted a lot of interest in the context of molecular nanowires, switches, etc. Since the interaction in these strong H-bonds is predominantly mediated through electrostatic interactions, we discuss their characteristics in the section on ionic interactions.

The major reasons for the importance of H-bonding in nanorecognition are that (i) the interaction is of intermediate strength and therefore reversible, (ii) the interaction is directional and therefore one-, two-, three-dimensional structures can readily be assembled by hydrogen bonding, and (iii) the assembly is often fast and specific. As the interaction is weaker than a covalent bond, the bonding can be reversed and hence error correction can be carried out. The omnipresence of H-bonds in most biological molecules, viz. proteins and nucleic acids, is due to the aforementioned characteristics. However, the stellar role of H-bonding can be observed in the properties of water and ice.

4.1.2. Origin and Characteristic Features

Though the first proposal of H-bonding was put forward by Moore and Winmill [295], the concept gained widespread attention and recognition after the work of Latimer and Rodebush [296]. However, Pauling was the first to explain the concept of H-bonds using the example of water [297]. Thus, in comparison to similar small molecules, water might be expected to be a gas under everyday conditions—which would make the world a very different place. But water remains a liquid because H-bonds impart to the molecules extra cohesion, preventing them from flying apart into steam. In the early 1930s, Pauling proposed that these H-bonds were the result of an uneven distribution of electrical charge in the water molecule (H_2O). This was attributed to the greater electronegativity of oxygen, as a result of which the electrons cling more closely to the oxygen atom than to the hydrogen atoms. This leads to the oxygen atom being more negatively charged than the hydrogen atoms. As a result of electrostatic interactions, the hydrogen atoms of adjacent water molecules tend to stick to the oxygen atom of the neighbor. Pauling subsequently tried to explain some of the anomalies of the electrostatic theory by proposing that a small degree of electron sharing between the two water molecules contributes to the H-bond [298]. It should be noted that sharing of electrons between atoms generally results in strong, so-called "covalent bonds," like those that hold the two hydrogen atoms to an oxygen atom in individual water molecules. In the intervening years, since the first explanations of the H-bond were given by Pauling, a large body of information gleaned from both experimental and theoretical studies has led to a detailed understanding of the nature of the H-bond [284–287]. Most of these studies have incidentally been carried out on the simplest intermolecular complex containing a H-bond (water dimer) or larger clusters of the water molecules [299–323].

Incidentally, it has also been shown in the course of these investigations that most of the properties of water in the

condensed phase can be obtained from the properties of these individual water clusters. In Figure 6, the magnitudes of the different interaction energy components at different intermolecular separations of the water dimer are shown. It can be seen that the contribution of electrostatic energy is the largest attractive contributor (60%) to the interaction energy. Expectedly, the other attractive contributions (dispersion and induction) are of the same order of magnitude as the total interaction energy [321]. This implies that the magnitude of the repulsive contribution is nearly as high as the total electrostatic energy. In fact, it has been noted that the global minimum of the water dimer and similar H-bonded structures corresponds to a structure with the largest attractive contributions and a large exchange–repulsion term [324]. The local minima and the transition states, in turn, show smaller attractive terms and lower repulsion with respect to their values for the global minimum. Thus the decrease of exchange–repulsion is as important as the increase of the attractive terms.

Most of the characteristic properties of the H-bond, which are observed experimentally, can be explained to a large extent by this physical model. These characteristic properties, which provide the means to identify the presence of H-bonds, include changes in the bond lengths, dipole moments, vibrational frequencies, etc.

The **D**–H bond length is often increased upon the formation of a H-bond. These increases are particularly significant in crystal structures exhibiting H-bonds. The fundamental frequency associated with the **D**–H bond stretch is often lowered upon formation of a complex. This redshifting is one of the most sensitive probes of H-bonding in experimental systems. The origin of this effect can be attributed to the fact that the fundamental frequency of the **D**–H vibration in an isolated monomer is proportional to the energy difference between the ground ($\upsilon = 0$) and the first excited ($\upsilon = 1$) states. However, in the complex, the frequency would be different because the intermolecular van der Waals vibrations

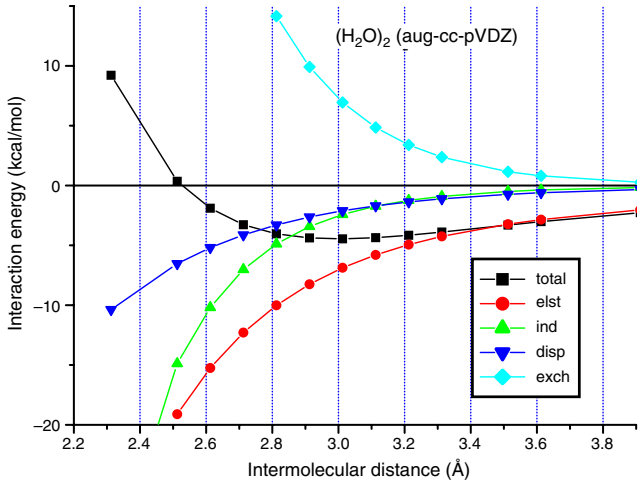

Figure 6. Magnitude of the interaction energy components of the water dimer at different intermolecular separations. The calculations have been carried out using the aug-cc-pVDZ basis set (elst: electrostatic energy, ind: induction energy, disp: dispersion energy, exch: exchange energy).

also have to be taken into account to evaluate the energies of both the ground and first excited states. The first excited state potential is always deeper in a H-bonded system because of an increase in the magnitude of the electrostatic and induction energies. Recent calculations, however, indicate the importance of dispersion energies in the magnification of the excited state potential of the H-bonded complex [325]. The H···**A** distances in H-bonded systems are very short, compared to other intermolecular bonds. This is a consequence of the strength of the H-bonds and incidentally also helped develop the concept of the H-bond. Thus, the hydrogen bonds are much shorter than the van der Waals radii of hydrogen and atom **A**. These van der Waals radii were deduced by Pauling, using the distances between the atoms in molecular crystals as a guideline [298].

It has been shown by many authors that nearly all known variants of the H-bond with widely different magnitudes can be explained using this model. Thus, the C–H···O interactions are very similar to conventional O–H···O H-bonds in most respects, but are generally weaker [87, 326]. A hydrocarbon like methane exhibits a very weak interaction with a proton acceptor such as water, with the interaction energy being only a fraction of a kilocalorie per mol. However, what distinguishes the O–H···O and C–H···O interaction is the intermolecular separation. In the former, the intermolecular O···O distance is of the order of 2.9 Å, but in the latter, the intermolecular C···O distance is of the order of 3.5 Å. Interestingly, it was also shown that electronegative substitutents on the donor carbon, like fluorine, add about 1 kcal/mol to the interaction energy and draw the two subunits together by 0.10–0.15 Å. Furthermore, the strength of the interaction is found to be much less sensitive to the nature of the proton acceptor than to the donor. Nearly all kinds of H-bonds exhibit very similar characteristics as regards their structural features. Thus, both the O–H···O and C–H···O H-bonds are disposed to a linear arrangement of the three atoms. However, the latter can be easily bent.

In the context of the redshift of the **D**–H vibrational frequency shifts upon H-bonding, mention should be made of some systems like the C–H···O interactions which exhibit a characteristic blueshift [327–329]. This blueshifting of the C–H stretch led to the characterization of the C–H···O H-bond as an "anti H-bond" [329]. However, recent studies on several systems exhibiting such a blueshifting of the **D**–H frequency shifts indicate that this blueshift is a consequence of the differing magnitudes of the individual interaction energy terms [326]. The change in **D**–H bond length is the net result of one set of forces tending toward elongation and another that pulls toward a shorter bond. While the attractive forces (electrostatic, induction, and dispersion energies) tend to push the hydrogen away from the donor atom, exchange–repulsion pulls it away from the acceptor. In the case of the O–H···O interaction, the attractive forces are slightly stronger than the exchange–repulsion, but in the case of the C–H···O H-bond, the exchange–repulsion is nearly similar in magnitude to the attractive forces or very narrowly overcomes them. The blueshift in the C–H···O is therefore a consequence of this bond contraction [326].

In the following section, we highlight some of the interesting features of H-bonds using the example of water clusters. The smallest water cluster, the water dimer, possesses a

linear structure. However, as the size of the water cluster increases, one notes interesting changes in their structures. Thus, the water trimer, tetramer, and the pentamer form cyclic structures. The hexamer heralds the onset of three-dimensional structures, a trend which extends to the larger water clusters (Fig. 7) [226, 315].

As can be seen from Figure 7, an increase in the size of the water cluster leads to an increase in the number of H-bonds. However, this increase in the number of H-bonds need not necessarily translate itself into enhanced stability. The orientation and the nature of the H-bonds also play an important role in governing the stability of the H-bonded structure. A case in point is the water pentamer. Thus, the pyramidal structure *R444*, which has six H-bonds, is nearly 3.1 kcal/mol higher in energy than the cyclic *R5* structure (Fig. 8). Furthermore, the *R33* structure, which has the same number of H-bonds as the *R444* structure, is nearly 3.3 kcal/mol higher in energy. The enhanced stability of the *R5* structure can be attributed to the role of nonadditive effects. The importance of this nonadditive effects in the energies and hence the geometries of the water clusters emerges from the earlier investigations of one of the authors

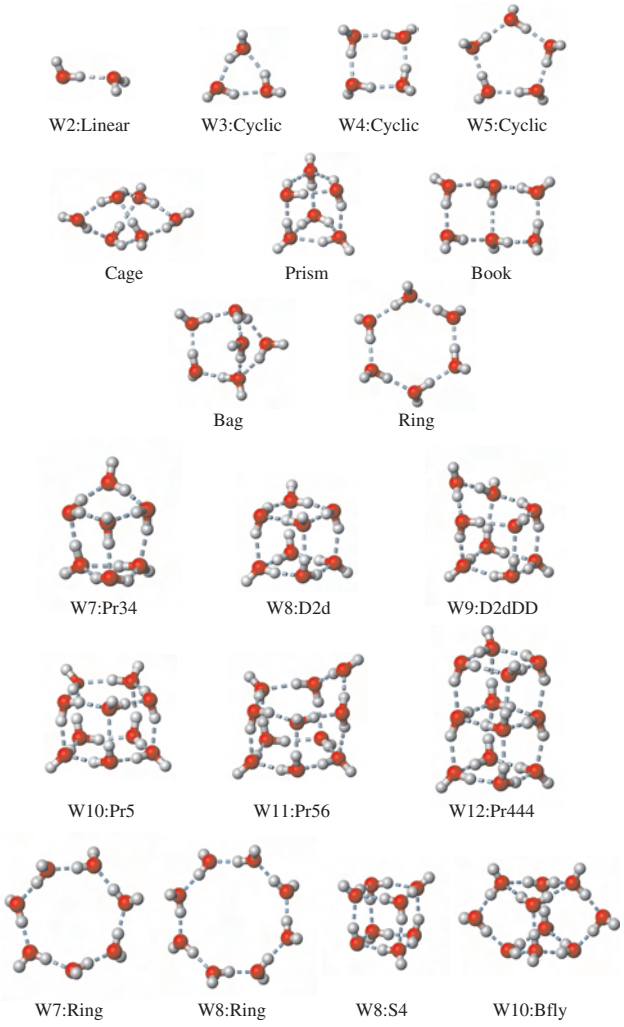

Figure 7. Structure of the water clusters from dimer to dodecamer. Note that the hexamer heralds the onset of 3D structures.

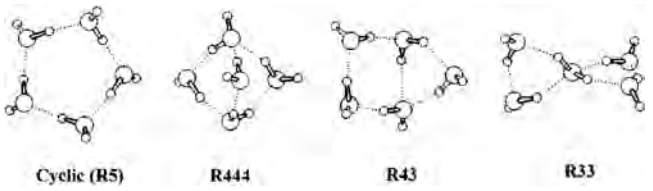

Figure 8. Various structures of the water pentamer. Presence of more H-bonds does not result in higher stability. The stability is governed by the competition between H-bond and strain energy.

[228], which led to the successful prediction of the lowest energy conformers of the water hexamer, heptamer, and octamer.

An important consequence of the presence of multiple H-bonds is cooperativity [303, 318, 330]. While its role in nanomaterial design is elaborated subsequently, we highlight some of the effects of cooperativity here. One of the most important consequences of cooperative interactions is the enhancement of the H-bond strength. Thus, in case of the water clusters, the average energy of all cluster H-bonds increases significantly (Fig. 9) with cluster size (trimer 3%, tetramer 36%, pentamer 44%, and hexamer 49%). The cooperative enhancement of the interaction energies also leads to significant geometry changes, with a progressive decrease in the intermolecular H-bonding distance. One can see this in more detail in Figure 10, wherein we have plotted the average intermolecular distance R_{O-O} as a function of the cluster size. Note that beyond a certain cluster size, there is no further decrease in R_{O-O}. On a similar note, the proton NMR shifts of these water clusters are shifted downfield as function of cluster size. In Figure 9, one can also note the consequences of cooperative effects on both the enthalpies and free energies. An interesting observation in the context of cooperative effects in water clusters is that most of the properties are nearly saturated at the water hexamer. This observation can be explained by the fact that all structures beyond the water hexamer are three-dimensional, and the OH frequency shifts are saturated at the hexamer [226, 315].

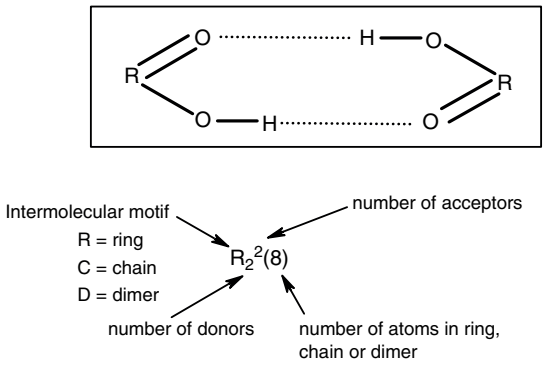

Figure 11. Components of a H-bonding graph set.

While most of the discussion on H-bonding was focused on the origin and their influence on various properties, it is useful to discuss their role in molecular assemblies. In this connection, the H-bond classification approach of Etter et al. is particularly valuable because it relies on the intermolecular specificity of H-bonds and deliberately ignores competing factors like preorganized cavities, ionic interactions, and steric interactions [331]. Based on graph theoretical concepts, they describe complex networks involving many different types of H-bonds into simpler motifs. Interestingly, the myriad patterns of H-bonds evolve from just four simple motifs. A notation describing these motifs is assigned to each different type and provides a complete and accurate description of the patterns of H-bonds in a molecular assembly at any desired level of complexity [331].

The process of assigning a graph set begins from an identification of different types of H-bonds contained in a given network. A *motif* is defined as a pattern formed by connecting molecules by just one type of H-bond. The *motif* is further characterized by one of four *designators*. These designators are C (chain), R (ring), and D (dimer) for motifs generated from intermolecular H-bonds. The S (self) designator denotes an intramolecular H-bond. The number of donors and acceptors are assigned as subscripts and superscripts, respectively. The motif size (denoted as the *degree*) is determined by the number of atoms in a ring or the repeat unit of a chain and is given in parantheses following the designator of the pattern. The procedure for assigning the graph set of an eight-membered ring formed by carboxylic acids is shown in Figure 11. In Figure 12, various motifs along with their graph sets are shown.

Based on the analysis of the graph sets of a large number of crystal structures, it soon became evident that H-bonds in organic molecules containing functional groups follow three general rules. They are: (i) all good proton donors and acceptors are used in H-bonding; (ii) intramolecular H-bonds that form a six-membered ring are preferred over intermolecular H-bonds; and (iii) the best proton donors and acceptors remaining after formation of intramolecular H-bonds form intermolecular H-bonds to one another. A number of additional rules pertaining to special classes of functional groups are also known [57]. The discussion in the preceding paragraphs clearly reveals that these rules are

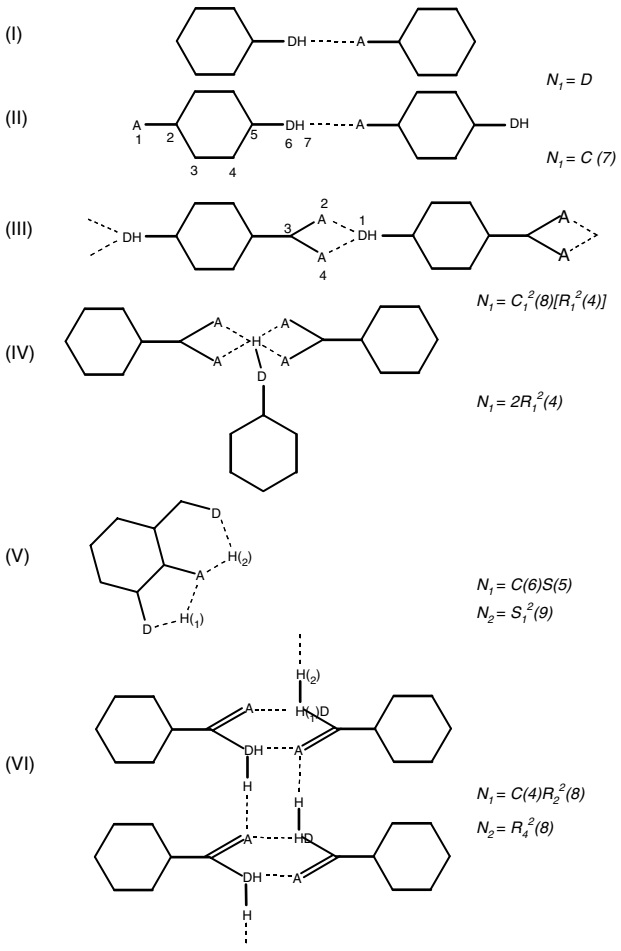

Figure 12. Examples of different motifs of H-bonds with their graph sets. The hexagons are meant to represent any organic ligand. This specific form is given so that the degrees of the patterns can be assigned in this figure. If the organic ligands were other kinds of groups, then the degrees of some of the patterns would change. Reprinted with permission from [331], M. C. Etter et al., *Acta Cryst. B* 46, 256 (1990). © 1990, International Union of Crystallography.

based purely on energetic considerations. A number of other factors which might influence H-bonding are steric effects, competing ionic forces, and the presence of multiple sites for H-bonding. The latter two are discussed in more detail in subsequent sections.

4.1.3. Manifestation

Given these characteristics of the H-bond, it is of interest to examine how these interactions have been employed in nanomaterial design. While several recent reviews exist on this subject, we highlight a few strategies employed to enhance the efficiency and selectivity of H-bonded interactions.

As was mentioned earlier, of all the three attractive interactions, electrostatic interactions play a major role in the stability of the H-bond. Therefore, a strategy, already discussed, would be to create a system wherein the positive charge upon the donor proton is increased and/or the negative charge upon the acceptor atom is increased. Additionally, the strong dependence of the H-bond on electron distribution implies that substitutent effects provide an effective means of modulating the strength of the interaction.

Indeed, this was the strategy pioneered by Wilcox and co-workers [332] and more recently studied in more detail in a complex system by Rotello and co-workers (Fig. 13) [333, 334]. Thus, the authors observed that the recognition of guests (Fig. 13a) and the dimerization of hosts (Fig. 13b) were found to be governed by the nature of the substituents. Thus the dimerization constants (K_{dim}) measured in $CDCl_3$ range from 95 M^{-1} for the host with a phenyl substituent to 41 M^{-1} for the *p*-nitrophenyl-substituted host. Interesting was the observation that the electron donating groups on the host enhanced dimerization and electron withdrawing substituents diminished recognition over a rather narrow (0.5 kcal/mol) range. On the other hand, the affinity of the guest was enhanced with electron withdrawing groups and decreased with electron donating substituents. This relationship between substituent and guest affinity in this above host–guest system can be understood if one examines the binding surface of the host. An increase in the electron density at the central nitrogen of the **DAD** surface of the host enhances H-bonding at this site and was experimentally confirmed by the observance of the maximum shifts for the N(3) proton of the guest (increases from 12.2 ppm for **b** to 19.8 ppm for **h**). This increase in the electron density, however, lessens the positive charge on the donor amide protons and hence diminishes the interactions at these two positions. In the course of these studies, it can also be seen how molecular recognition or H-bonding processes provide a means of investigating electronic communication in complex systems, which incidentally is a prerequisite for molecular wires and other devices.

The cumulative free energy of a H-bonded complex is the difference between energy required by the host or the guest to reorganize themselves to achieve a complementary binding site with each other and the enthalpically favorable interaction energy upon host–guest complexation. Thus, when the donor and the acceptor are preorganized, there is a dramatic reduction in the overall free energy of complexation because the energy required for the hosts or guest to conformationally reorganize themselves is minimized.

Though there have been a number of reports of the development of conformationally preorganized hosts [335–349], the work of Meijer and co-workers merits mention because they have spectacularly used the cues from DNA base pairing to develop controlled molecular architectures [336–345]. Basically the work involves the development of host–guest systems that form arrays of donor and acceptor atoms which can undergo spontaneous homo- and heterodimerization through the formation of quadruple H-bonds. Incidentally, quadruple H-bond arrays have been predicted to be much stronger than triple H-bond arrays [346]. These investigations also include efforts to minimize any possible repulsive interactions between the donor–donor (**D**$\cdots$**D**) and acceptor–acceptor (**A**$\cdots$**A**) sites.

Of all possible motifs which resulted from homo- and heterodimerization, the **DDAA** arrangement was found to form more effective H-bonding complexes than the **DADA** arrangement. This is because of the fact that the latter has only six repulsive secondary interactions in contrast to the two repulsive and six attractive secondary interactions of the former (Fig. 14). In the ureidopyrimidone systems, the pyridimin-4(1H)-one tautomerizes to the pyrimidin-4-ol form leading to the formation of dimers via preorganized **DDAA** or **DADA** arrays (Fig. 15), respectively. In both cases, the preorganization through the formation of an intramolecular H-bond results in the formation of self-assembled systems by linear arrays of four H-bonds. The K_{dim} in these preorganized systems are much larger than those predicted for non-preorganized arrays [343]. The juxtaposition of both preorganization and minimization of repulsive secondary interactions leads to the **DADA** array having a K_{dim} of 10^7 M^{-1}, which is nearly 100 times larger than the observed K_{dim} of 10^5 M^{-1} in the **DADA** array [343]. Meijer et al. also noted that the H-bonding propensities of

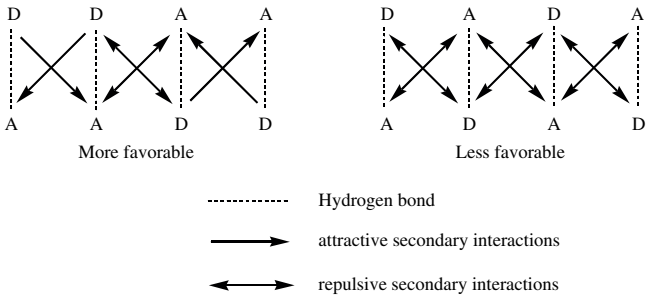

Figure 14. Attractive and repulsive secondary interactions in quadruple hydrogen bonded systems. Reprinted with permission from [334], G. Cooke et al., *Chem. Soc. Rev.* 31, 275 (2002). © 2002, Royal Society of Chemistry.

these ureidopyrimidone systems could be further tweaked by changing the electronic characteristics of the functionality in the sixth position of these heterocycles. Thus, electron donating groups result in the formation of complementary **DDAA** arrays characteristic of the pyridimin-4(1H)-one form. On the other hand, electron withdrawing substituents lead to the formation of **DADA** arrays, which is characteristic of the pyrimidin-4-ol form. In extensions of this work, helical self-assembled polymers were made by harnessing the quadruple H-bonding propensities of the ureidotriazines [343].

In the context of preorganization directed H-bonding, mention should be made of a recent work wherein the preorganized structure of calix[4]hydroquinone was used to design both one-dimensional and two-dimensional H-bond arrays [16, 18]. Interestingly this design strategy also led to the revealation that the electrochemical and photochemical properties of the parent calix[4]quinone molecule could be harnessed to design novel redox modulated H-bonds.

The strategy of redox modulation of the H-bonding process has, however, been employed in a number of previous instances [61, 350–354]. Redox processes are widely prevalent in biological systems with a number of crucial enzymatic reactions being mediated through changes in the redox states of enzyme cofactors (quinones, flavins, nicotinamides, etc.) [350, 353]. In an effort to understand the mechanism of the flavin enzymes, Breinlinger and co-workers examined the interaction of flavin with a 2,6-diaminopyridine derivative under different redox conditions (Fig. 16) [355]. What they noted was that a reduction of flavin to the corresponding flavin radical anion led to a nearly 500-fold increase in the binding constant. The role of the central N–H···N H-bond in affecting the binding constants was discounted by carrying out the binding studies in a range of H-bonding solvents, thereby confirming that the enhanced binding resulted entirely from changes in the H-bonds involving the carbonyl oxygens [355]. The use of redox modulation of H-bonds in aiding the development of addressable surfaces with device applications was also demonstrated in a recent study [354].

There have been a number of recent reports on the use of photochemical means to influence the H-bonding formation [355–357]. However, most of these changes were brought by harnessing the excited-state characteristics of π systems. Therefore, we would discuss these systems in subsequent sections devoted to intermolecular interactions involving π systems.

In the course of this section, we have examined the origin, characteristics, and different manifestations of H-bonding in various systems. In the next section, we elaborate on how the characteristics of H-bonding can be modulated by interaction with anions and cations.

4.2. Ionic Interactions

The recognition of charged ionic species has been a field of intense interest because of their utility in both biology and chemistry [36, 46, 48, 49, 52, 59, 240, 241]. In fact, the recognition of spherical substrates, positively charged metal cations (alkali, alkaline-earth lanthanides) or the negatively charged anions, is one of the simplest recognition processes. From a historical point of view, much of the early work in supramolecular chemistry emerged from efforts to mimic ion recognition in biological systems [240, 241]. In contrast to the large amount of work that has been carried out on cation binding systems and related systems [36, 46, 48, 49, 52, 59], there has been relatively little information on anion binding systems [45, 52]. However, a number of interesting developments have been made in the recognition and sensing of anionic substrates in the last couple of years [45].

4.2.1. Origin and Characteristic Features

Most of the interactions involving these ionic species are predominated by electrostatic interactions. Hence early explanations of the nature of these ionic interactions, which were based on electrostatic models, were very successful in explaining the binding of a large number of charged species to several hosts. However, it was soon realized that in addition to the charge carried by the ionic species, fundamental differences exist between the binding of cations and anions. These differences primarily emerge from the fact that anions have a lower charge to radius ratio than isoelectronic cations (Table 1) [359]. Thus, electrostatic interactions for anions are much less effective than they would be for the smaller cation.

The salient differences between complexes involving cations and anions are excellently illustrated in the small aqueous clusters of alkali metal cations and halide anions (Fig. 17) [360–376]. It should be noted that most of the available experimental investigations of these hydrated ions have benefitted from the pioneering mass spectrometry techniques developed by Okumura and co-workers [377]. A number of theoretical investigations of these hydrated clusters have been carried out to both supplement and understand the experimental investigations [363–369]. They indicate that the cationic clusters are better described than the corresponding anionic clusters. The interaction between water molecules and cations is dominated by ion–dipole interactions at long range. Consequently the hydrogens of the water molecule are oriented away from the ion. At short ranges, electron transfer tends to influence both the geometries and energetics of these systems, which indicates the importance of the size of the cation. Furthermore, the involvement of the oxygen lone pairs in the interaction with

Cation	r [Å]	Anion	r [Å]
Na^+	1.16	F^-	1.19
K^+	1.52	Cl^-	1.67
Rb^+	1.66	Br^-	1.82
Cs^+	1.81	I^-	2.06

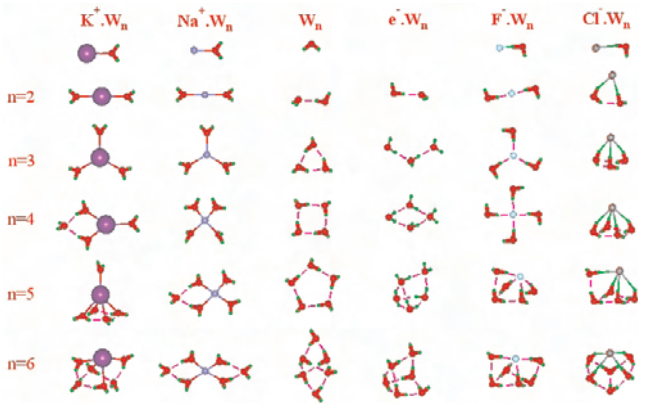

Figure 17. Structures of the complexes of water clusters with anions and cations. For more details, see [225–227, 365–369, 528, 530, 531].

the cation hinders the formation of interwater H-bonding. As a result, most of the cationic water clusters are symmetrically hydrated species. Things are, however, more complicated in the interaction of anions with these water clusters, because the electron clouds of the anion are very diffuse. The larger ionic radii of the halide anions together with the fact that the hydrogens of the water molecule are involved in the binding to the anion leads to an interesting feature of the anionic water clusters [i.e., whether the anions are solvated within a shell of water molecules (internal state) as expected in the condensed phase or the water molecules form a network which then binds the anion in an energetically favorable "surface-solvated" ionic state]. This in a way reflects the competition between the solvation of the anion versus the hydrogen bonding among the water molecules, an issue which will be discussed in more detail subsequently.

In Figure 18, the calculated interaction energies for the binding of a single water molecule with the alkali cations (Na^+, K^+) and the halide anions (F^-, Cl^-) reveal some interesting features. Irrespective of the kind of theory employed, the F^-–H_2O and Na^+–H_2O complexes possess nearly similar interaction energies. But with an increase in the size

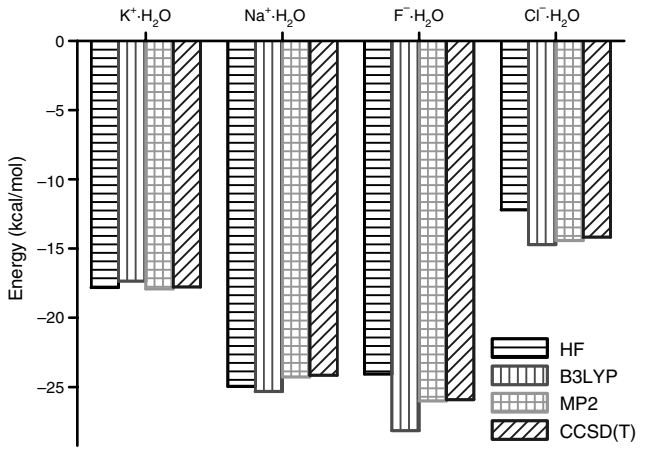

Figure 18. Interaction energies of a single water molecule with different cations and anions. The calculations were carried out using the 6-311++G** basis set.

of the cation and anion, the interaction energy of the K^+–H_2O complex is much larger than that of the Cl^-–H_2O complex. While the reason for the underlying difference is not clear, this observation has important ramifications in the design of novel nanosystems. Interestingly, the nature of the cation (metallic or organic) or anion also influences the binding characteristics. To illustrate this, a plot of the magnitude of all the interaction energy components of five cationic-H_2O complexes is shown in Figure 19. Expectedly, electrostatic interactions are the dominant contributors to the total interaction energy. The magnitudes of the induction and dispersion energies are much smaller with the latter being negligible in the case of the alkali metal cation complexes. Interesting, however, are the magnitudes of the repulsive exchange energies. Even though both the K^+ and NH_4^+ cations have nearly equivalent ionic radii, the magnitude of repulsive energy of the latter is much larger than that of the former. Apart from having an important bearing on the design of novel receptors for these cations, these observations on the intermolecular energetics of these cations explain the large variations in the affinities and selectivities of different receptors [77, 79, 378, 379].

Similar trends observed in the interaction energies of the ion complexes of crown ethers (Fig. 20) dispel the notion that the data obtained on the water monomer complexes would have little relevance to the binding of these cations to more complex systems like macrocycles [221]. It was believed until very recently that the structural rigidity of the macrocycle was one of the most important factors for their high selectivity toward particular cations [56, 86, 196]. However, it soon became evident that the ion–dipole orientation and hence induction energies govern both the magnitude and the equilibrium geometry of the complex [380]. For example, the 12-crown-4 (12c4) ligand, which has S_4 symmetry in the unbound state, has C_4 symmetry in the bound M^+(12c4) state [221]. This indicates that, upon metal complexation, two of the crown oxygens undergo a reorientation so that all four crown oxygens point toward the metal ion, which sits above the plane of the crown by a height that depends on the metal ion radius. Based on the discussion in

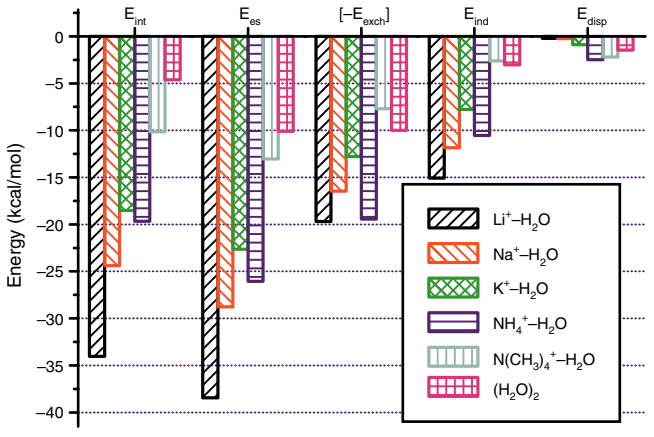

Figure 19. Decomposition of the interaction energies of the cation–water monomer complexes. Note the distinct differences in the binding of metallic and organic cations to water. The calculations were carried out using the 6-311++G** basis set.

previous sections, this geometrical transformation is a result of the complex trying to maximize the Coulombic and induction energies.

Most of the early receptors, which were designed to bind anions, were positively charged [45, 52, 257–263, 381]. Thus, the binding in most of these systems was mediated through the Coulomb-type electrostatic interactions of the positively charged receptor and the negatively charged anion [45, 381]. However, the efficacy of these positively charged receptors was poor because of problems associated with solvation (i.e., competition for binding between the anionic guests and counterions, etc.) [45, 381]. This led to the development of neutral anion binding receptors [45, 196, 381]. The binding of anions by these neutral receptors is mediated through H-bonding, ion–dipole interactions, or coordination to Lewis acidic centers present in the organometallic ligands. The electrostatic component of the individual interactions in these neutral receptors is relatively smaller than that observed in case of the positively charged receptors. As a consequence, the magnitude of the interaction is strongly dependent on the directionality of the interaction and the electron density of the anion. Apart from these data, there is relatively scarce information on the energetic origin of interaction of large molecular systems containing anions [45]. However, the available data seem to indicate that these interactions are similar to those involving cations albeit with a few exceptions [45].

4.2.2. Manifestation

The early design of cation and anion binding hosts with three-dimensional spheroidal cavities was based on the premise that they would exhibit much stronger binding with the spherically shaped ions than the flat shaped macrocycles [191–193]. Apart from helping magnify several intervening interactions, there is relatively smaller sacrifice in entropy [56, 86, 196]. A more compelling reason for the development of such hosts was the presence of concave-shaped binding sites in biological systems, like the grooves in nucleic acids,

antibody surfaces, neural synapses, etc. [196]. However, it was soon realized that the processes of exchange, regulation, cooperativity, and allostery require an inherent flexibility and adaptivity to change [196]. Thus, the inability of most rigidly organized receptors to respond to these processes far outweighs their benefits of achieving high recognition.

A large number of reviews in the recent past have detailed several aspects of these ionic interactions in various contexts [45, 52, 257–263, 381–390]. Rather than discussing all these aspects, we examine using a few examples how different types of noncovalent interactions involving ions have been useful in the quest for functional nanomaterials. Nearly all the known systems binding ions can be classified as those based on electrostatic interactions, H-bonding, hydrophobicity, and metal ion coordination.

While there is a lot of literature detailing the design of ionophores and receptors based on electrostatic recognition of ions [45, 52, 57, 59, 91, 240, 241], the more interesting aspect of these ionic interactions is their role in stabilizing transition states in enzyme–substrate reactions [254, 391–400]. Thus, there have been several reports of the activation of enzymes in organic solvents by crown ethers [254, 391–400]. The mechanism of this industrially important activation, though unclear, seems to be based on two possibilities [400]. The first is that the crown ether facilitates the transport of tightly bound water molecules from the enzyme active site into the bulk organic solvent and the second is that the crown ether complexes with the surface ammonium groups of lysine [254]. The available experimental evidence seems to validate the latter mechanism [254]. The macrocyclic interactions lead to a reduced formation of inter- and intramolecular salt bridges and consequently lower the kinetic conformational barriers. This enables the enzymes to refold into thermodynamically stable, catalytically (more) active conformations. Ionic interactions also play a direct role in the catalytic enhancement observed in enzymes. In this context, one encounters the concept of a short strong H-bond (**D**-H$\cdots$**A**$^-$), an H-bond which is characterized by high interaction energies (>15 kcal/mol) and very short H-bond distances [401–413]. In Figure 21, we highlight the role of these short strong H-bonds in explaining the origin of the spectacular catalytic enhancement observed in case of the enzyme Ketosteroid isomerase [146, 412, 413].

The work of Ward and co-workers, wherein the salts formed from organodisulfonate and guanidnium ions have been used to design an extremely large number of complex molecular architectures, is the one of the most elegant examples of the use of H-bonding based on ionic interactions in the custom design of nanomaterials [55, 414–417]. Using a variety of substitutents and strategies, a bewildering array of crystal architectures was designed (Fig. 22). Interestingly, these molecular frameworks formed as a result of these weak noncovalent interactions are structurally similar to the zeolites, wherein the metal-oxygen bonding yields a more robust and strong framework [418, 419]. The work of Seddon and Aäkeroy on the development of novel crystal architectures using various organic cations and anions also merits mention in this context [420].

The synthesis of helicates (Fig. 23) is a nice example of metal ion mediated recognition because the ligands (analogs of quatepyridine) are spontaneously assembled in the presence of Cu^+ ion [421, 422]. The double-stranded helicates are formed as a result of the ligand strands wrapping around the metal ions in a double helical pattern [421, 422]. Of particular importance is the fact that the structures are a manifestation of the tetrahedral-like coordination imposed by each Cu(biypyridine)$_2^+$ unit [421, 422]. Other metal ions like Ag^+ have also been employed in synthesis of some of the variants of these helicates [423]. The self-assembly of these helicates brings forth the issue of positive cooperativity, wherein the complexation with the metal makes the second complexation easier, and so on. Furthermore, self-recognition is also an important characteristic for the generation of these architectures because in a mixture of ligands, a helicate is preferentially consituted by identical ligands [424]. While these double-stranded dihelicates were based on metal cations, the circular helicates result from assembling Fe^+ coordinated ligands around a chloride ion [424].

Most of the ionic interactions involving the use of hydrophobic effects to trigger the recognition phenomena

involve π systems [425], which is the focus of discussion in the next section. For example, the inclusion of naphthalenesulfonates by β-cyclodextrin is a result of the displacement of the water molecules from the internal cavity of cyclodextrin by the naphthalene residues. The anionic sulfonate is in contact with the solvent and thereby controls the orientation of the naphthalene residues in the cavity [425].

4.3. Interactions Involving π Systems

Among the large number of noncovalent intermolecular interactions discussed in this chapter, interactions involving π systems are one of the principal noncovalent forces governing molecular recognition [4, 7, 43, 53, 54, 56, 61, 69, 87, 88, 353, 426–437]. They influence the structures of proteins, DNA, host–guest complexes, solid materials containing π systems, crystal structures and self-assembled supramolecular architectures [4, 43, 53, 54, 56, 61, 69, 87, 88, 353, 426–437]. These interactions also control the intercalation of certain drugs into DNA [51, 167]. The conductive properties of molecular wires formed by self-assembly of stacks of aromatic macrocycles are also of recent interest [10, 121]. A distinct advantage of the use of the interactions involving π systems in the fabrication of nanodevices is the fact that the subtle changes in the electronic characteristics of the π system can lead to dramatic effects on the structure and properties of the nanosystem. Furthermore, these changes in the electronic characteristics can be controlled either by the electrochemical or photochemical means.

However, an understanding of the nature of their origin has only started being unravelled recently. One of the reasons for this is that the strength of most of these interactions is relatively small and is dominated by dispersion interactions. As was mentioned in previous sections, it is difficult both theoretically and experimentally to quantify the contribution of dispersion interactions to the total interaction energy.

A few studies which have quantified the strength of these interactions involving π systems indicate that the strength is dependent both on the nature of the π system and the kind of countermolecule interacting with it [232, 438–453]. In general, the strength of interactions involving cations and π systems is greater than the other interactions involving π systems (π–π, π–H, π–Lewis acid). Given the ubiquity of these interactions involving π systems in a number of areas in nanoscience and nanotechnology, a detailed description of these interactions involving π systems is presented in the following sections.

4.3.1. Classification

One can classify the interactions involving these π systems based on the nature of the countermolecule with which they are interacting. Thus, when the countermolecule is a metal cation, electrostatic and induction energies dominate the interaction energy. Dispersion interactions dominate when the countermolecule is either a rare gas atom or a nonpolar molecule (gas dimers, hydrocarbons). A combination of electrostatic and dispersion interactions governs the interaction energy, when the countermolecule is polar (water or methanol clusters, Lewis acids). Unlike other kinds of interaction discussed earlier, the magnitude of repulsive interactions plays a critical role in governing the observed geometry.

As would be shown in subsequent sections, the nature of the π system (olefinic, aromatic, heteroaromatic) also influences the characteristics of these interactions. Even in aromatic systems, the presence of electron donating substituents leads to complexes with enhanced interaction energies, when compared to benzene. This enhancement is due to an increase in both dispersion and electrostatic interactions. On the other hand, the geometries of complexes formed with aromatic rings having electron withdrawing substituents is extremely dependent on the characteristics of the interaction energy. Thus, when the interaction energy is dominated by dispersive interactions, a π type of complex is formed. When electrostatic energies predominate the interaction energy, a σ type of complex involving the electron withdrawing substituent is formed. When the countermolecule is a water or methanol cluster, the size of the cluster also influences the nature of the interaction with the π system, resulting in a crucial influence on the nature of the resulting structure (σ or π).

Since most of the interactions involving π systems are mediated through the negatively charged π electron cloud, the early studies were of the opinion that purely electrostatic considerations could explain the observed trends of the interaction energies. However, it was soon realized that a purely electrostatic model could not explain the binding of rare gases or neutral molecules like methane or benzene to these π systems. Furthermore it could also not explain the exceptionally high binding energies observed in the case of the ethene systems. For example, the most recent experimental estimates of the enthalpies of binding (ΔH_0) of Na^+ to ethene and benzene are 10.7 ± 1.0 and -21.5 ± 1.0 kcal/mol, respectively [454]. Even though geometrical considerations are taken into account, the general impression would be that the enthalpy of binding of Na^+ to benzene to be three times that of ethene since benzene has three times the number of π electrons. A more interesting problem arises when one compares the interaction energy of the benzene–Na^+ and the pyrrole–Na^+ complexes. Though both of them have an equal number of π electrons, the cation–π interaction in the latter is stronger than in the former. It therefore becomes apparent that one has to take into account the differential electron density distributions of these π systems to explain the trends in interactions. In terms of energetic jargon, it implies that the magnitudes of the individual interaction energy components have to be taken into account. In the following account, we show some of the characteristics of the interactions of these π systems with various countermolecules.

4.3.2. Origin and Characteristic Features

We begin our discussion of the energetic origin of these π complexes with the cation–π interaction [432, 450]. The early explanations of origin of the cation–π interaction were predominantly based on electrostatic considerations [432]. Thus a strong cation–π interaction was associated with a more negative electrostatic potential at the center of the π system [432]. However, after a study of the interaction of the Na^+ cation with different aromatic π systems, it was realized that the variations in the electrostatic potential of the π system only mirrored the trends in the cation–π interaction energies [432]. One has to take into account other factors like the polarizability of the π system and the nature of the cation to obtain accurate estimates of the interaction energies [432]. In this connection, it is interesting to note that a detailed theoretical investigation of the interaction of the tetramethyl ammonium cation with benzene highlighted the importance of dispersion energies in the cation–π interaction [438, 439].

In order to understand these cation–π interactions, it is useful to examine the results obtained from a recent and extensive study of the interaction of different cations, which include both metallic (Li^+, Na^+, K^+, Ag^+) and organic {ammonium (NH_4^+), guanidinium ($C(NH_2)_3^+$), tetra methyl ammonium ($N(CH_3)_4^+$)} cations, with different classes of π systems, viz. alkenes (ethene), arenes (benzene), and heteroarenes (pyrrole) [450]. It can be seen from Figure 24 that the electrostatic and induction energies are the major contributors to cation–π interactions involving alkali metal cations. In particular it can be noted that the magnitude of the induction energies is nearly double that of the electrostatic energies. This predominance of the induction energies can be attributed to the interaction between the highest occupied molecular orbital (HOMO) of the π system and the empty *s* orbital of the metal cation. This MO interaction is in turn governed by energies of the orbitals involved and the size of the cation, because a smaller sized cation can

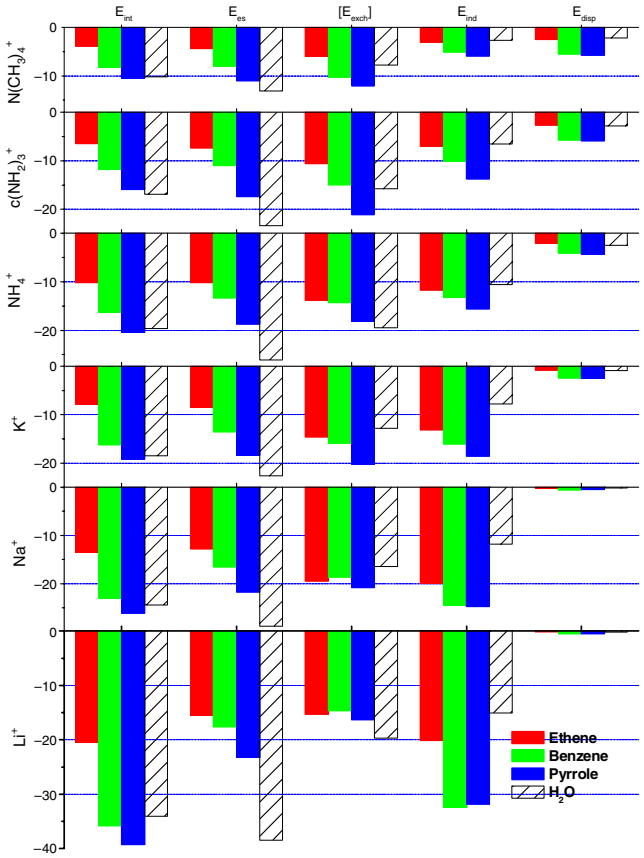

Figure 24. Decomposition of the interaction energies of cation–π and cation–water complexes. Note the distinct differences between the interaction of metallic and organic cations with various π systems. The calculations were carried out using the 6-31 + G* basis set. have a closer approach to the π system due to a decrease of exchange–repulsion at a given separation. The smaller intermolecular separation leads to a larger electrostatic stabilization and also facilitates an enhanced overlap of the constituting MOs, which in turn leads to enhanced induction energies. It should be noted that several authors attribute this kind of MO interaction to be of the charge-transfer type. The contribution of the dispersion energies is quite significant in case of the K^+ complexes, which is in contrast to the neglibile magnitudes observed in the Na^+ and Li^+ complexes [450].

The pyrrole complexes exhibit the largest electrostatic energies because the π electron density of pyrrole is much higher than that of either benzene or ethene [450]. This is because the nitrogen lone pair is a part of the delocalized π system of pyrrole [455]. The presence of the nitrogen atom in pyrrole, however, influences both the equilibrium geometries and the interaction energies exhibited by these pyrrole complexes. While the magnitudes of the induction energies are nearly similar in the Na^+ and Li^+ complexes of both benzene and pyrrole, it is much higher in case of the pyrrole–K^+ complex as compared with the benzene–K^+ complex. The innate tendency of both the small-sized Li^+ and Na^+ cations is to maximize the electrostatic stabilization by a closer approach to the π system. However, the presence of the electronegative nitrogen atom prevents a closer approach of the cation to the π system, as can be noted from the magnitude of the exchange energies (Fig. 24). The resulting larger intermolecular separation in the pyrrole complexes, as compared to the corresponding benzene complexes, limits the extent of orbital overlap. Consequently the magnitudes of the induction energies are nearly similar in the Li^+ and Na^+ complexes of benzene and pyrrole. On the other hand, the larger size of the K^+ cation precludes a close approach to either benzene or pyrrole because of increased exchange–repulsion. Consequently, both the benzene and pyrrole complexes exhibit nearly similar intermolecular separations. However, the enhanced π electron density of pyrrole results in increases in the magnitudes of both the induction and electrostatic energies.

The magnitudes of the electrostatic and induction energies in the case of the organic cation complexes of these π systems are much smaller than those observed in case of the π–alkali metal cation complexes (Fig. 24). While the repulsive exchange energies are relatively smaller, the dispersion energies exhibit large increases. Thus, a comparison of the pyrrole complexes of Li^+ and $N(CH_3)_4^+$ cations reveals that the dispersion energies of the latter are nearly 12 times larger than that of the former. However, the total interaction energy of the pyrrole–Li^+ complex is only 4 times larger than that of the pyrrole–$N(CH_3)_4^+$ complex. Electron correlation plays a very important role in the latter interaction because the π–σ^* interaction (where π is the HOMO of the π system and σ^* is the LUMO of the organic cation), which is of the inductive type, is magnified [438, 439, 450]. One of the reasons for the magnification of this induction energies upon inclusion of electron correlation is the fact that there is a depletion of electron density from the centers of the bonds and a concurrent increase in the shells around the atomic nuclei [456]. As a result, a much closer approach of the cation to the π system is facilitated. This results in an increased MO interaction and as a result a larger induction energy. The increase in the electron density around the shells of the atomic nuclei and the closer approach of the cation to the π system result in the increased dispersion energy. As in case of the interaction of these π systems with the alkali metal cations, the electrostatic energies are largest in the case of the pyrrole containing complexes. However, unlike what is observed in the case of the alkali metal cations, the induction energies are much larger in the case of the pyrrole containing complexes. Given the nearly similar intermolecular separations and the equal number of delocalized π electrons in both benzene and pyrrole, the dispersion energies are nearly similar in their organic cation complexes.

Given our discussion of the cation–water interactions in an earlier section, it is of interest to compare their characteristics with the cation–π interactions. It can be seen from Figure 24 that the total interaction energies of the cation–water complexes are comparable in magnitude to the corresponding cation–pyrrole complexes. However, what distinguishes the interactions of these cations with water and the π systems is the magnitude of the electrostatic energies, with them being dominant contributors to the total interaction energy in case of the former. The marked difference

between the water and π complexes of these cations can be attributed to the difference in the nature of the donor. In water, the donor lone pair of the oxygen atom is more localized than the diffuse π cloud of the π system. As a result, the polarizability of the former is much smaller than the latter. Hence the electrostatic contributions are larger and the induction energy contributions are smaller in case of the water complexes. The repulsive energies are higher in the case of the water complexes because the cation encounters another atom in contrast to a bond in ethene or the center of the aromatic ring (no atoms or bonds). In the context of the design of receptors, it is useful to examine the implications of these findings in understanding chemical and biological processes. By definition, a greater electrostatic contribution to the interaction energy of the complex implies that the magnitudes of the interaction energies are susceptible to the dielectric of the solvent. The fact that the electrostatic contributions are much lower in the case of the cation–π complexes than in the corresponding cation–H_2O complexes might explain the wide prevalence of the former in chemical and biological systems.

The interaction of these π systems with transition metal cations like Ag^+ requires special attention owing to the large interaction energies and the presence of *d* electrons (Table 2). The small size of the Ag^+ ion (1.26 Å) implies that the Ag^+ cation can approach much closer to the π system. However, the larger nuclear charge of the Ag leads to a much larger repulsive energy. The higher dispersion energy results from both a smaller intermolecular separation and the participation of the *d* electrons in the binding. The higher interaction energies also imply that the role of the π system in the binding is minimal. However, the equilibrium geometries can be expected to vary owing to the widely differing magnitudes of the various interaction energy components.

Since most instances of cation–π interactions in chemical and biological systems exhibit significant deviations from the kind of idealized behavior discussed, it is of interest to examine on how the magnitudes of the various interaction energy components are modulated when the cation is brought closer to the π system from larger distances. In order to do so, we have compared the interaction energy components of the benzene–NH_4^+, benzene–K^+, and ethene–K^+ complexes for various intermolecular separations in Figure 25. While the former two complexes were chosen because of the differences in cations, the latter was chosen because it allows us to examine the role of the π system. At large intermolecular separations, electrostatic energies dominate the interaction

energies of these complexes. Consequently the interaction energies for the benzene–K^+ complex are much larger than those observed in the ethene–K^+ complex but similar to those observed in the benzene–NH_4^+ complex. At short intermolecular separations, induction energies become dominant in the metal cation complexes with both the ethene–K^+ and benzene–K^+ complexes exhibiting nearly similar induction energies. The predominance of the induction energies over that of the electrostatic energies can be observed long before the onset of the equilibrium geometry in the metal cation complexes. Unlike what is observed in the metal cation complexes, much larger increases in the dispersion energies are observed in the benzene–NH_4^+ complex when the intermolecular separation is decreased. The repulsive exchange energies are much smaller in the benzene–NH_4^+ complex than in the corresponding benzene–K^+ complex and interestingly are similar in magnitude to those observed in the ethene–K^+ complex. Thus, the nearly similar interaction energies of the benzene–NH_4^+ and benzene–K^+ complexes result from a balance of dispersion and induction energies because the electrostatic and exchange energies are nearly similar and hence cancel out. The predominance of the dispersion energies in the case of the benzene–ammonium complexes implies that suitable receptors specific for the NH_4^+ cation could be designed by maximizing the dispersion energies [378, 379].

An interesting variant of the cation–π interactions is the recently discovered anion–π interactions [457–461]. Most of the studies have devoted their attention to the interaction of an electron deficient π system like hexafluorobenzene with an anion [457–459]. Though there have been no studies on the origin of the interaction, the available evidence seems to suggest that inductive energies dominate the interaction. Though there are reports of electron rich π systems like benzene interacting with oxygen or water cluster anions, the π system does not seem to play any role, with the interaction being primarily mediated through the benzene hydrogens [462].

In the order of decreasing magnitude, the interaction energies of the π–Lewis acid complexes follow the cation–π interactions. Apart from a few experimental reports detailing the interaction of Lewis acids with π systems in the context of donor–acceptor complexes and electrophilic aromatic substitution reactions, little was known about either the magnitudes or the exact nature of their interaction [463, 464]. However, in the course of our extensive investigations, it was found that the halides of aluminum, boron, and hydrogen form fairly strong noncovalent complexes with both benzene and ethene [441, 465, 466]. The magnitude of the interaction depends on the nature of the Lewis acid, with the benzene complexes of aluminum halides exhibiting interaction energies (8–15 kcal/mol) which are significantly larger than the corresponding complexes of the boron halides (3–6 kcal/mol) [441, 465, 466]. As far as our knowledge goes, the interaction energies exhibited by the aluminum halide complexes of benzene are the highest for a neutral (uncharged species) binding to it. A major difference in the binding of benzene or ethene with boron and aluminum halides is that in the complexes of the latter, electrostatic interactions have a dominant contribution to the interaction energy, while in the complexes of the former, dispersive interactions have a dominant role (Fig. 26). These findings seem to indicate that the aluminum halide complexes conform to the general behavior of donor–acceptor complexes [463]. One of the most interesting consequences of the interaction of Lewis acids with benzene is that in the lowest energy structure, the carbon atom of benzene which lies directly below the Lewis acid exhibits a dramatic increase in the negative charge when compared to the remaining five carbon atoms. A simultaneous increase in the positive charge on the hydrogen atom attached to this carbon is also noted. This increase in the negative charge (or nucleophilicity) of the carbon atom, which is independent of the nature of the Lewis acid interacting with benzene, could ease an electrophilic attack on this particular benzene carbon as a result of a significant lowering in the activation energy. Furthermore the increase in the positive charge on the hydrogen attached to this carbon would facilitate its departure after an attack by an electrophile. Similar effects have been noted in the interaction of some of the transition metal cations with benzene and C_{60} [435, 463]. The implication of this observation is enormous, because to date, the role of Lewis acids in electrophilic aromatic substitution reactions was perceived to be limited to the generation of the electrophile [464].

Complexes of the first-row hydrides (CH_4, NH_3, H_2O, HF) with π systems (π–H interaction) are of particular interest because they exhibit interactions [447] which are the prototypes of a typical hydrogen bond. In Figure 27, we

highlight the trends of various interaction energy components, their sums, spectral shifts, and selected geometrical parameters of various first-row hydride complexes of ethene and benzene complexes. It can be noted from Figure 27a that the increase in the repulsive exchange energies is more pronounced in the ethene complexes than in the benzene complexes. The reason for the anomalous behavior of the exchange energies in case of the ethene and benzene complexes lies in both the size of the donor (hydride) and the way it approaches the π system. As we progress from CH_4 to HF, the decrease in the electron density of the H-atoms involved in the π–H interaction leads to a closer approach to the π system because of a decrease of exchange repulsion at a given separation. The widely differing electron density profiles of benzene and ethene implies that the hydride aims at the midpoint of the ring (where there are no nuclei or bonds) in benzene. Consequently the decrease of the intermolecular $R_{Y-\pi_{CM}}$ distance with the decrease of the donor size would be smaller for the benzene than for the ethene complexes (Fig. 27j). The smaller variation of $R_{Y-\pi_{CM}}$ in the benzene complexes also explains the near constancy of the dispersion energies (Fig. 27b). On the other hand, the somewhat smaller decrease of $R_{Y-\pi_{CM}}$ in the ethene complexes, as we progress from NH_3 to HF, explains the slight increase in the dispersion energies (Fig. 27b). A comparison of the electrostatic and induction components of the ethene and benzene complexes plotted in Figure 27f and g reveals that in the case of complexes involving CH_4 and NH_3, their magnitudes are comparatively smaller for the ethene complexes. However, with the progressive decrease in the hydride size, the magnitude of these components in the ethene complexes is larger than the magnitudes observed in the corresponding benzene complexes. It is instructive to note that this behavior of the attractive induction energies was also observed in case of the cation–π interactions [450].

Since the donor is a diffuse π electron cloud in the case of a π H-bond, and the lone pair of an electronegative atom in the case of a conventional H-bond, it is useful to examine their salient similarities and differences. In Figure 28, the magnitudes of the interaction energy components of the water dimer and the ethene–water dimer at different intermolecular separations are plotted. It can be seen that in the lowest energy structure of these complexes, the replacement of a single water molecule by ethene results in a decrease of the electrostatic contribution of the total attractive energy by about 20% [447]. Expectedly, the contributions of induction and dispersion energies to the total attractive interaction of the water dimer are much lower than in case of the ethene–water dimer. In both systems, the magnitude of the repulsive exchange energies has a far more important role in the characterization of the equilibrium geometry than the magnitude of the attractive energies like electrostatic, inductive, and dispersive energies.

The role of dispersion and repulsive energies in governing the geometries of these π complexes is well illustrated in a study of the argon complexes of fluorine-substituted benzenes [448]. These complexes are interesting because irrespective of the widely different electron densities of the π systems, they all exhibit similar binding energies [448]. Furthermore, in all the cases, the rare gas is located on top of the π system. A detailed theoretical investigation revealed

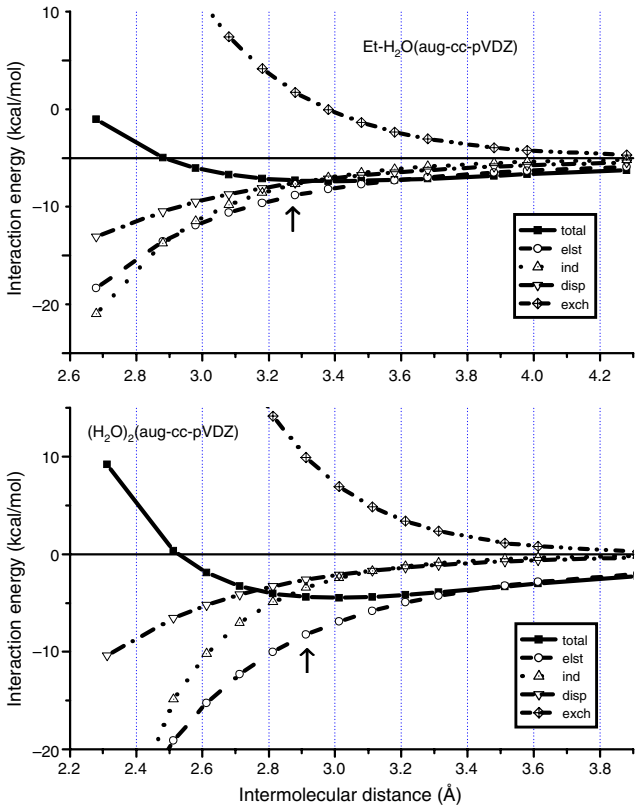

Figure 28. Variation in the magnitude of various interaction energy components as a result of changes in the intermolecular distance of the ethene–H_2O and $(H_2O)_2$ complexes.

that the lower π electron density of the *p*-difluorobenzene facilitates a much closer approach of the argon atom to the center of the π system because of lower exchange–repulsion. The dispersion energies are, however, maximized because of the decrease in intermolecular separation [448]. The role of dispersion energies can also be noted in the benzene complexes of paramagnetic atoms like nitrogen [449]. We discuss the characteristics of these paramagnetic complexes in a subsequent section.

The π–π interactions are one of the most intriguing noncovalent interactions, in the sense that the negatively charged and diffuse electron clouds of the π systems exhibit an attractive interaction [43, 87, 437, 451–453, 467]. The interaction is predominated by dispersion interactions, when the π systems possess similar electron density. However, when one of the systems is electron rich (benzene) and the other electron deficient (hexafluorobenzene), the resulting complexes are bound by induction interactions with the negative charge being transferred from benzene to hexafluorobenzene [468, 469]. The acetylene dimer is one of the simplest systems exhibiting a π–π interaction [470–473]. Though a parallel displaced conformer which involves a stacking of the two acetylene π systems exhibits a π–π interaction, the most stable conformer is a T-shaped structure, which involves the interaction of the acetylinic hydrogen with the π system of the other [473]. In the case of the ethene dimer, the most stable structure is stacked D_{2d} structure (Fig. 29), which involves the formation of a

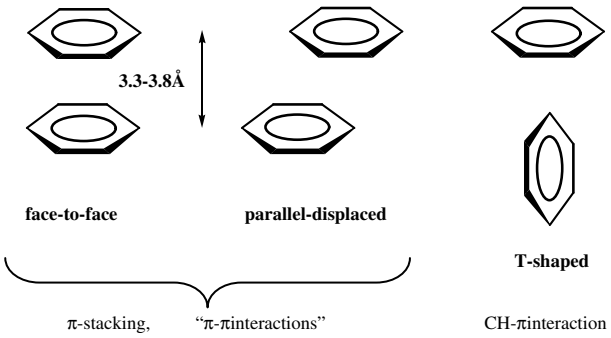

Figure 29. Different orientations of π–π interactions.

quadruple hydrogen bond [474, 475]. The interaction of two benzene rings (benzene dimer) has been widely investigated both experimentally and theoretically [437, 451–453, 467]. The experimental estimates of the interaction energy seem to be around ~2 kcal/mol, which indicates that the attraction is appreciable and significantly influences the interaction of phenyl rings in solution or other environments, in addition to other factors such as solvophobic effects [56, 196]. The interaction is predominantly based on dispersion interactions and as in case of the acetylene dimer, the benzene dimer can manifest itself in any one of the structural forms: stacked, T-shaped, or parallel-displaced (Fig. 29) [437, 467]. The available evidence seems to indicate that the parallel displaced conformation is most stable [451–453]. However, it should be noted that the isolated benzene dimer is highly fluxional and can coexist in any of the three structural forms.

A principal advantage of π–π interactions in the context of nanorecognition is the fact that the interconversion between the different conformers or the orientations of the two interacting π systems (Fig. 30) can be exquisitely controlled [230, 437, 467]. While the use of this control in the design of functional nanodevices is described in subsequent sections, it is of interest to pictorially examine the nature

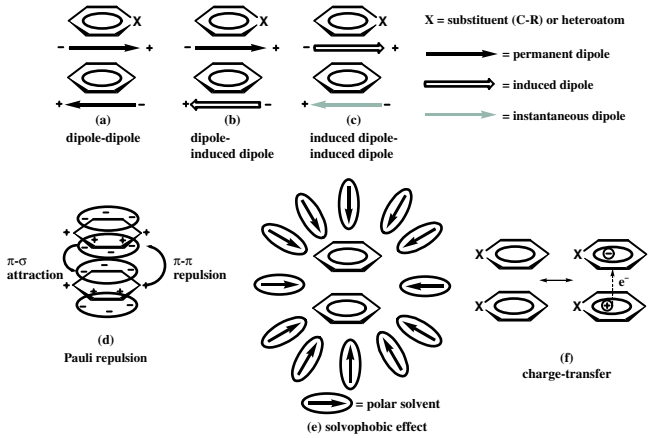

Figure 30. Schematic illustration of the electrostatic interactions between two arene moieties. For simplicity the two arene moieties are drawn in perfect face-to-face alignment. of these π–π interactions in terms of the individual components (Fig. 30) [467].

(a) Dipole–dipole (electrostatic) interactions: the interactions between the different permanent and static molecular charge distributions.
(b) Dipole–induced-dipole interactions between the static molecular charge distribution of group **A** with a proximity-induced change in charge distribution of group **B**.
(c) Induced-dipole–induced–dipole (London) dispersion interaction: the instantaneous dipole moment from a fluctuating electron cloud polarizes a neighboring molecule and induces the charges, resulting in an instantaneous dipole.

These van der Waals interactions (a)–(c) are inherently attractive and their potentials fall off rapidly with distance by $1/r^6$.

(d) Pauli repulsion: at very short distances the filled electron clouds of the interacting molecules begin to overlap and the (Pauli) repulsion between the electron shells becomes dominating.
(e) Solvophobic effects: in polar solvents, solvophobic effects leading to desolvation can stabilize an aggregation of lipophilic molecular surfaces.
(f) Charge transfer: charge transfer or electron donor–acceptor effects refer to a stabilization due to mixing of a ground state $\mathbf{A}\cdots\mathbf{B}$ with an excited charge-separated state $\mathbf{A}^+\cdots\mathbf{B}^-$. Such Coulomb attractions based on charge transfer are generally viewed as negligible and are different from static-electron donor–acceptor complexes.

The only remaining interactions which need to be discussed in the context of interactions involving π systems are the interactions involving two π systems or the interaction of a π system with neutral molecules like dihalogens [232, 463]. The complexes of these π systems with dioxygen and dihalogens have been of interest in the context of understanding gas–surface reactions and as models of charge-transfer systems [463]. In most cases, the interaction in these π complexes is dominated by dispersion energies [453, 476]. However, in case of the benzene–I_2 complex, induction energies also play a role in the binding [477].

4.3.3. Manifestation

The literature on the use of intermolecular interactions involving π systems in the design of ionophores, nanomaterials, and nanosystems is almost impossible to summarize, but an effort will be made to demonstrate their omnipresence on the basis of a few examples [7, 43, 53, 54, 56, 61, 69, 87, 88, 353].

A large number of ionophores like cyclophanes, calixarenes, etc. are based on the interaction of the ions with the π systems present in these ionophores [196, 250]. The cation–π interactions have been invoked to explain the mechanism of ion channels and more recently in understanding substrate and/or transition state recognition of several enzymes like phospholipase C, thrombin, DNA glycosylases, etc. [53]. Recently, there also has been a report of the use of cation–π interactions in stabilizing α-helices of proteins in water

[187]. An area which has benefited the most from detailed investigations of cation–π interactions is the design and development of chemsensors [50, 54]. Thus, a large number of systems capable of selectively binding microscopic traces of toxic or biologically important ions have been developed [50, 54]. Figure 31 shows the tripodal class of receptors, where suitable changes in the nature of the ligand (L) leads to highly specific binding of biologically important ions like ammonium cation, acetylcholine, etc. [77, 79, 378, 379]. Though the mechanism of ion binding is different, this tripodal class of receptors has also been found to be useful in binding biologically important anions like chloride, fluoride, etc. [383]. In the context of nanomaterials, the recent use of cation–π interactions in the synthesis of silver grid-type metalloarchitectures, C_{60}–Ag^+ interactions, and ultrathin silver nanowires also merits mention [384, 435].

The earliest expression of π–H interactions was in the "molecule-within-molecule" complexes of Cram and Collet, carcerands and cryptophanes [478]. An interesting and recent example of the use of the π–H interactions is in the encapsulation of hydrocarbon guests within the cavernous environs of the resorcinarene-based nanoscale containers (Fig. 32) [479]. An area wherein π–H interactions are expected to have a tremendous impact is the interface between biological molecules and novel nanomaterials like carbon nanotubes, fullerenes, etc. [478–480]. An understanding of this interface is central to the design and development of sensors and miniature devices for a wide variety of biological applications [481]. The interaction of water with carbon- and silicon-based surfaces is also attracting a lot of interest because of its implications in the development of carbon- and silicon-based device technologies.

π–π interactions are widely prevalent in nature. However, their use as a building tool in supramolecular chemistry

accelerated after the appearance of the paper by Hunter and Sanders on the nature of π–π interactions [437]. Though the goal of this paper was to understand the experimental aggregation of porphyrin complexes, the authors defined a set of rules on the use of these π–π interactions, which have been very useful in the design of new molecular entities [15, 481–484]. This exploitation of the

π–π interaction is exemplified in the template directed synthesis of (2)catenane (Fig. 33), which forms continuous π-donor/π-acceptor stacks in the crystal [15]. The photochemical or electrochemical control of the orientations of these π stacks could eventually lead to the fabrication of materials capable of information storage [15]. Another example of the exploitation of these π–π interactions is in the fabrication of a electrochemically controllable nanomechanical molecular system (Fig. 34) [233]. One of the advantages in the harnessing of these π–π interactions, which has already been mentioned, is the fact that the magnitude and orientation can be electrochemically or photochemically controlled. More details of the electrochemical or photochemical control of intermolecular interactions is given in a subsequent section detailing the interaction of quantum species. Another manifestation of the π–π interaction is the stacking of supramolecular porphyrin complexes, which have been conceived as receptors for peptides and nucleotides [485, 486].

In the previous section, we have examined in detail the intermolecular interactions involving π systems. Two issues which have frequently cropped up are self-assembly, self-synthesis, and the electrochemical or photochemical control of the orientations of these π systems. We discuss these issues in the subsequent sections, but before we do so, we discuss the nature of metallic interactions.

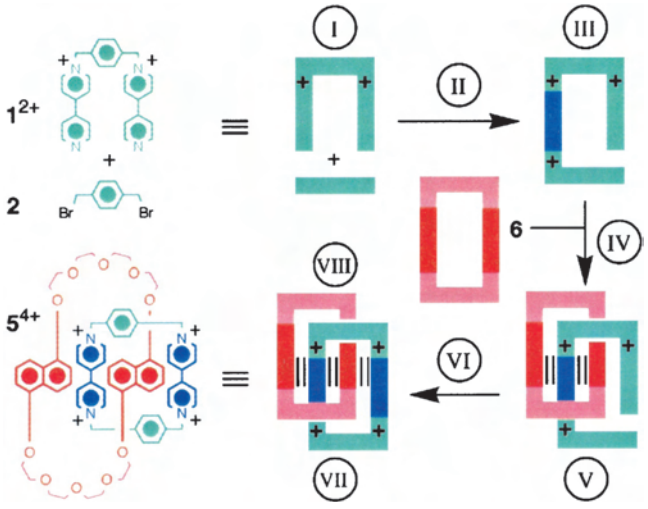

Figure 33. The delicate interplay between covalent, noncovalent, and mechanical bonds in the template-directed synthesis of the (2)catenane 5^{4+}. (I) Dication 1^{2+} does not recognize template 6 until the reaction with dibromide 2 ensues. (II) One covalent bond is formed. (III) A recognition site is switched on in the trication. (IV) Threading is driven by noncovalent bond formation. (V) Molecular recognition is switched on partially in the 1:1 complex. (VI) Another covalent bond is formed. (VII) Yet more molecular recognition is switched on, and a mechanical bond is also formed. (VIII) The weak noncovalent bonding interactions that template the formation of 5^{4+} live on inside the molecule afterward. Reprinted with permission from [15], J. F. Stoddart et al., *Proc. Natl. 4.4. Metallic Interactions

The interaction between metal atoms is generally not discussed in most reviews dealing with conventional molecular recognition. However, in the context of nanorecognition, they are of interest because most metal systems exhibit very unusual properties when their lateral dimensions are decreased to the nano- or subnanoscale [197, 487]. Apart from influencing the structural and energetic characteristics, the interactions between metal atoms also influence the electronic characteristics [8, 9, 197–200, 203–205, 488, 489]. For example, a lead (Pb) subnanowire (lateral dimensions are smaller than a nanometer) becomes a better conductor than a gold (Au) subnanowire by three orders of magnitude. This is in sharp contrast to what is observed at the macroscopic scale, wherein gold is a better conductor than lead by an order of magnitude. Apart from changes in the conductivity, the tensile/cohesive strength of metallic subnanowires is found to be much larger than that observed in bulk. This is because deformations in bulk metallic systems occur through dislocation motions, while structural rearrangements are the norm in materials at the subnanoscale. Recent advances in experimental techniques, especially scanning tunneling microscopy and high-resolution diffraction methods, have led to the unravelling of a number of unusual metallic interactions in the last couple of years [276, 279].

On a different note, conventional wisdom indicates that two interacting open-shell species would exhibit covalent interactions because more bonding orbitals would be filled than antibonding orbitals [487]. While ionic interactions are expected between closed-shell species carrying opposite charges, two closed-shell species can also be expected to interact through a combination of electrostatic, induction, and dispersion interactions. However, it would seem preposterous to expect two closed-shell species carrying similar charges to exhibit an attractive interaction. Indeed, most closed-shell systems carrying similar charges would exhibit a repulsive interaction. However, there is growing evidence that in case of metallic or organometallic species, an entire

family of attractive cation–cation interactions exists between d^8–d^{10}–s^2 systems [490–504]. Though these interactions are much weaker than most covalent or ionic bonds, they are of comparable magnitude to the typical hydrogen bonds [487, 490]. While there is a lot of debate on the origin of this interaction with some reports negating their existence in the case of the lighter elements and some attributing them to packing effects in the solid states, these interactions involving neutral and charged metallic species merit discussion.

4.4.1. Types of Bonding

The interactions in systems containing uncharged metallic species may be classified as either continuous transitions or metallic. In the former interaction, there is a continuous shift from one type of bonding to another type as function of a chemical or physical variable. An interesting feature of this kind of transition is depicted in a covalent/ionic/metallic/van der Waals tetrahedron (Fig. 35) [505], which is based on the Ketelaar–van Arkel triangular diagram.

Though there is no such thing as metallic bonding, metals could be regarded as systems with close-lying HOMOs and LUMOs [506]. Most of the typical properties of metals, conductivity, optical reflectivity, Friedel oscillations, are consequences of these small HOMO–LUMO gaps. When the metallic species are charged, as in case of interactions involving d^{10} gold cations, the interaction seems to be entirely due to dispersion interactions [487]. Additionally it has been noted that these interactions are enhanced by relativistic effects and hence are more pronounced in systems containing heavy metals with large relativisitic effects. Since the goal of most theoretical investigations of large metallic or nonmetallic systems (especially defects in semiconductors, liquid metals, small atomic clusters, phase transitions of solid state systems) is on the physical properties exhibited by the bulk, to our knowledge, there has been no detailed theoretical investigation of the nature of individual metal–metal interactions. Mention should, however, be made of an early report on the experimental observation of a large enhancement of van der Waals forces between small silver particles [507]. The enormous enhancement in the interaction was attributed to a dramatic increase in the dispersion energies.

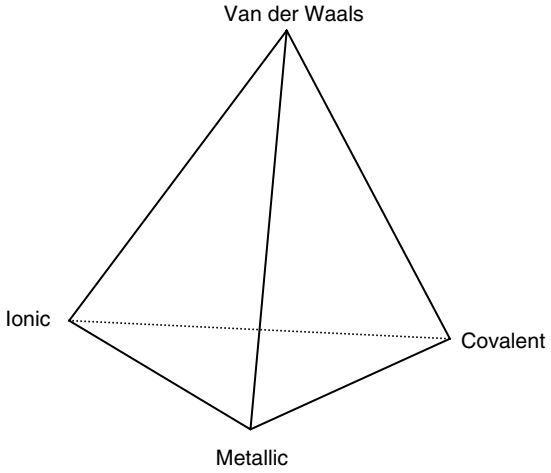

Figure 35. Covalent, ionic, metallic, and van der Waals bond transitions of metal–metal interactions: Laing's tetrahedron model based on the Ketelaar–van Arkel triangular diagram. Reprinted with permission from [505], M. Laing, *Educ. Chem.* 160 (1993). © 1993, Royal Society of Chemistry.

4.4.2. Manifestation

Against this background, we highlight a few metal–metal interactions which have been used to control supramolecular structures and their dimensionality. The foremost among them is aurophilicity, which is the tendency of two closed-shell gold(I) atoms to aggregate at distances shorter than the sum of the van der Waals radii with an interaction energy comparable to that of H-bonds [490]. It was soon realized from both experimental and theoretical studies that these gold–gold interactions are more a consequence of the interaction between the metal centers than being imposed by the ligand architecture [487, 503]. Theoretical efforts in the recent past seem to indicate that analogous phenomena (argentophilicity or cuprophilicity) also occur in interactions of other closed-shell atoms of the same period or even the same group [503]. The experimental studies, however, seem to indicate that most of these Ag(I)–Ag(I) or Cu(I)–Cu(I) interactions are supported by the ligand architecture [508]. This seems to indicate that these interactions are weaker than the corresponding Au(I)–Au(I) interactions.

Among the purely metallic interactions, the recent experimental realization of the icosahedral W@Au_{12} cluster is an interesting example of how theoretical predictions aid the design of novel and viable nanomaterials [204]. The stability of these highly symmetric metallic clusters, containing 12 gold atoms and an encapsulated central impurity atom of the 5*d* elements like tungsten, was theoretically postulated by Pyykkö and Runeberg [205]. Apart from the structural similarity to the analogous C_{60} (Fig. 36), an interesting facet of this metal cluster is that it is stabilized by aurophilic interactions and relativistic effects [204, 205]. The orbital interactions between the W 5*d* and the Au_{12} ligand orbitals lead to the icosahedral bonding h_g HOMO and antibonding h_g^* LUMO, which are separated by a large HOMO–LUMO gap of around 3 eV [204]. These small metallic clusters,

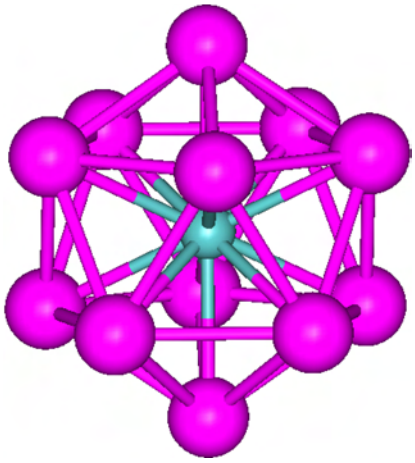

Figure 36. A purely metallic W@Au_{12} cluster, which possesses an I_h symmetry similar to an encapsulated C_{60} fullerene.

especially those of gold, apart from having applications as amplification tags in gene analysis and antigen detection [508–511], have also been implicated for their catalytic roles [512, 513].

This discussion on the role of the encapsulated atom in the stability of the small gold nanocluster leads to an interesting comparison on the role of dopants in the fabrication of nanowires. Given the current interest in the fabrication of nanowires composed of single gold, silver, or copper atoms, there is a need to obtain linear structures. The problem, however, is that these linear structures of gold nanowires are energetically less stable than the corresponding zigzag or bent structures [514, 515]. The alloying of these gold nanowires with carbon or alkali metal atoms seems to circumvent the problem by imbuing more stability on the linear structures [516]. The fact that this linearity can also be obtained by enclosing the single stranded atomic wire in an organic cage can be noted from recent studies [17, 517, 518].

4.5. Interactions Involving Quantum Species

Up to this juncture, most of our discussion on intermolecular interactions involved either molecules, atoms, or stable closed shell cations or anions. In this section, we discuss some unusual types of interactions, which involve quantum species like single electrons, photons, and paramagnetic atoms [15,19, 50, 117, 118, 334, 350, 519–544]. In previous sections, we had mentioned the control of various molecular recognition phenomena by external stimuli: photochemical control involving photons, chemical control involving changes in ion and pH concentration, and electrical control involving electrons. Apart from altering the electronic characteristics, changes in the conformations and orientations of atoms, molecules, or clusters can also be brought about by subtle control of the external stimuli (like in photochemical control, changes in the wavelength of the incident radiation can lead to selective excitation). Though the idea of exerting direct control on molecular recognition phenomena has a biomimetic origin, it has recently been realized that the implications extend to the design of novel nanomaterials. An effective control of molecular recognition phenomena in the nanodomain paves the way to several desirable goals like responsive and intelligent materials, smart sensors, molecular devices, etc. [15, 19, 50, 353].

In a related context, electrical charging has emerged as a central issue in connection with quantal nanostructures like fabricated semiconductor nanodevices like quantum dots [120], gas-phase microsystems like fullerenes [212], large organic molecules [10], molecular clusters, metal, and metal halide clusters [218–220]. Unlike macroscopic systems wherein the number of positive or negative charges that can be added is arbitrary, the number is size controlled at the nanodomain because of quantum instabilities arising from restriction of excess charge in very small spaces. Similar is the case with the interaction of photons with matter at the macroscopic and the nanodomain.

The simplest case of control is through changes in the oxidation states. For example in Figure 37, the β-cyclodextrins do not interact with the redox active guest (viologen) in the most stable +2 oxidation state [61]. However, the reduction of the viologen dramatically enhances the affinity of the violgen toward the host, β-cyclodextrin [61]. This theme of redox control finds application in the design and development of smart sensors, which can be electrochemically controlled [545].

Electron binding to atoms and molecules has played important roles in physical, chemical, and biological phenomena [521–533]. It has long been known that the presence of an excess electronic charge on biologcal important molecules like DNA and RNA can initiate events which eventually lead to radiation damage, cancer, etc. [521, 522, 546, 547]. In metallurgy, a large number of metals are produced by the electrochemical reduction of the corresponding oxides or sulfides. In both cases, electron binding is known to occur typically by occupation of an empty, or a partially empty, low-energy atomic or molecular orbital, the presence of which is manifested by a positive electron affinity of the system. But in contrast to atoms, a molecular system with a negative electron affinity can still bind an electron by holding the electron in its dipolar electric field. The possibility of such dipole-bound electrons was first proposed by Fermi and Teller in 1947 [548], and many examples have been discovered and studied in molecules and clusters since [115, 197, 526–531, 533]. When the dipole moment of a molecule exceeds 2.5 D, the molecule can bind an electron even when its intrinsic electron affinity is negative [529]. Thus, the acetonitrile anion provides a prototypical case of a ground-state dipole-bound anion molecule [115, 534, 535]. The dipole field that binds the electron can also be supplied by a cluster system even when the individual monomeric unit does not possess a large enough dipole moment. Thus, the water dimer with a dipole moment greater than 2.5 D binds an excess electron, even though the water monomer with a dipole moment of 1.85 D does not [529]. Apart from their potential role in a large number of photochemical and

biological processes [526–531], the issue of the hydrated electron is particularly interesting because with a gradual increase in the size of the water cluster, there is a dramatic change in the nature of the binding of the excess electron [532–535]. While the excess electron in the smaller water clusters is bound to the surface, it is solvated in the larger water clusters, a phenomena which extends itself to bulk water [118]. Given this background, numerous theoretical and experimental attempts have been made to unravel the precise size of the cluster at which there is a transition from a surface bound to a solvated electron [115]. An offshoot of these investigations is that changes in the size and dipole moments can lead to the design and development of effective single electron devices. An example of such a device is the molecular nano-tweezers-like structure obtained for the water hexamer anion (Fig. 38) [117]. Though this structure is not the lowest energy structure of the water hexamer anion, it provides insight into the conformational changes preceding and following the binding of the excess electron.

The formation and stability of the recently discovered multiply charged metal cluster anions is another related and interesting aspect of the binding of excess electrons [218, 549, 550]. In the case of the multiply charged anions, the electrons are bound by a repulsive Coulomb barrier (analogous to that of α-particles in heavy nuclei) [549, 550] and therefore exhibit electronic shell effects arising from magic major shells and subshells associated with ellipsoidal shapes [549, 550]. Given their potential in the isolation and synthesis of size-selected nanoclusters, a lot of effort is currently underway to examine the variation in properties as a result of changes in their sizes and charge states [197, 204, 218, 219].

This discussion about excess electrons brings to fore the related issue of charge transfer to solvent (CTTS) states of hydrated halide anions [531, 542, 551, 552]. The CTTS phenomenon was initially thought to be only of academic interest, but recently it finds importance as a device to trap electrons in polar solvents [552]. The issue of importance herein is that both the energy of the incident radiation and the size of the cluster solvating the halide are crucial to the excitation of the hydrated halide from the ground to the first excited state [552]. While the CTTS states are derived from intermolecular interactions, the corresponding intramolecular charge-transfer transitions in polar solvents find application in the design of fluoroscent molecular reporters [539]. The interaction of electrons or holes with certain kinds of conjugated polymers leads to the formation of singlet and triplet excited states. The excited singlets, which emit light, are indistinguishable from the excited states of photoluminiscence. Conjugated polymers exhibiting this kind of behavior form the basis of electroluminescence and are the impetus for the development of light-emitting devices for display and other purposes [125].

The conformational changes brought about by the interaction of photons with matter, which is the central theme of several biological processes like photosynthesis, vision, etc. [543], are also the basis for the design of molecular switches [12, 541, 542]. Before we end this section, mention should be made of the endohedral $N@C_{60}$ complex (Fig. 39) [106–110, 449]. This endohedral complex, experimentally discovered in 1996, is particularly interesting because electron paramagnetic resonance indicates that the central nitrogen atom is in its highly reactive quartet state [106–110, 449]. However, a large body of both theoretical and experimental evidence seems to indicate that the central nitrogen atom is chemically inert [106–110, 449]. Recent calculations indicate that the complex is entirely stabilized by dispersion interactions, because there is no evidence of any orbital interactions [449]. Against this background, this endohedral $N@C_{60}$ complex is being touted as a viable unit for carrying out quantum computations [553]. Additionally, the ability of C_{60} to enclose highly reactive species has paved the way for a number of interesting applications [110, 449]. It can therefore be noted from this discussion that the absence

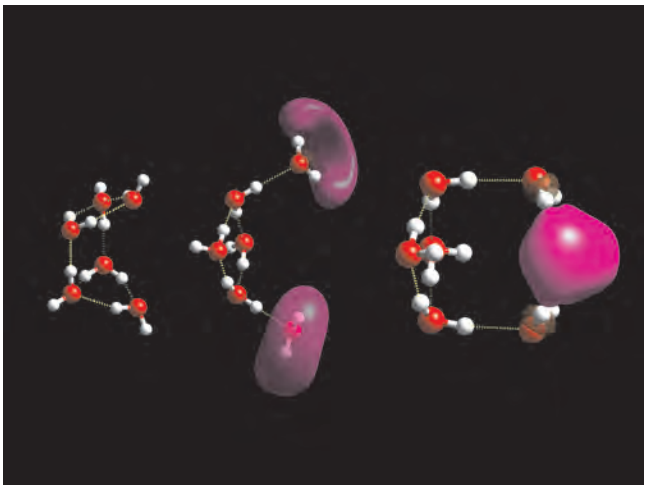

Figure 38. Electron density distributions of HOMO for the initial electron-containing structure (right) and LUMO for a structure of an intermediate electron-released neutral state (middle), and the structure of the final neutral state, upon detaching the excess electron from the initial electron-containing structure in an instant (left). It can be considered to be a prototype of a single-electron device (electron nano-tweezers). Reprinted with permission from [61], K. S. Kim et al., *J. Am. Chem. Soc.* 119, 9329 (1997). © 1997, American Chemical Society.

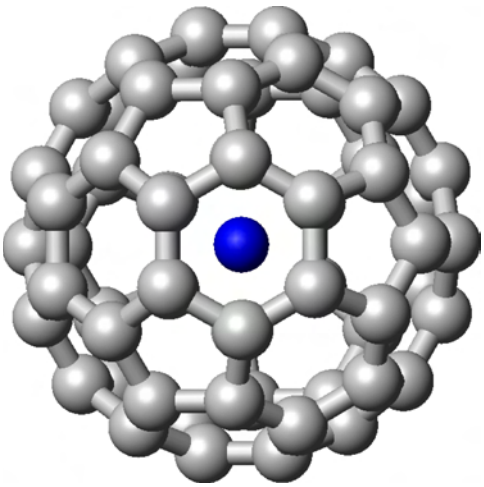

Figure 39. $^4N@C_{60}$. An example of an encapsulated fullerene wherein the highly reactive and paramagnetic nitrogen does not exhibit any orbital interaction with the C_{60} cage. The binding is through dispersion interactions.

of any interaction between two species could also provide useful applications.

5. NANORECOGNITION AND THE QUEST FOR NANOMATERIAL DESIGN

Most of the previous discussion was centered on the principles and various kinds of intermolecular interactions prevailing in nanosystems. Though we examined each interaction in isolation, the properties and structures of most nanosystems are a consequence of the cooperativity and competition of several intermolecular interactions. The importance of controlling the molecular structure and supramolecular order is amply illustrated in the phenyl based polymers–compounds containing phenyl rings linked by a σ-bond [3, 554]. They form an increasingly important class of organic materials because the presence of the phenyl ring aids the construction of a wide range of structures having a large range of active functionality. More importantly, the delocalized π-systems on adjacent rings can overlap to form extended conjugated systems. These π-conjugated organic materials are of considerable importance in materials science in recent years because their optical (e.g., fluorescence) and electrical (e.g., semiconducting) properties make them suitable for use as active components in a variety of electronic devices, including light-emitting diodes, optically pumped lasers, and field-effect transistors [1, 2, 8]. The dimensionality of these polyphenylenes can be exerted in one, two, or even three dimensions. Thus, linear conjugated polymers exhibit conjugation essentially in only one dimension and may be thought of as molecular wires. Disc-like polycyclic aromatic hydrocarbons, which may be regarded as models for graphite, may exhibit two-dimensional conjugation. Three-dimensional conjugation can be obtained from a network containing conjugated segments derived from phenylene-based dendrimers. Since charge transport is a process that is not confined to a single molecule, the stacking of the molecular species to allow 2D and 3D electronic interactions is of crucial importance in giving the high degree of order necessary to obtain an optimal overlap of the π systems, so as to obtain defect-free charge transfer. For example, if we consider 1D polymer chains, then to get good charge transfer between chains, we need to optimize their ability to undergo lamella-type packing. Similarly, with conjugated discs stacking through π interactions to form columns, we can easily envisage efficient 1D charge transport along the axis of the stacking, but to get truly 2D or 3D charge transport, we would need to obtain efficient electronic interactions between the columns.

Against this background on the importance of controlling molecular order and molecular structure, we highlight on how cooperativity and competing effects can be harnessed in nanomaterial design. Finally, we discuss how control of nanorecognition by external stimuli leads to nanodevices and molecular machines.

5.1. Cooperative Effects

One of the definitions of molecular recogntion, proposed by Rebek, is that it arises from intermolecular forces acting on complementary surfaces [38, 66, 479]. As was seen in previous sections, a vast majority of intermolecular interactions are weak and therefore reversible. However, molecules possessing multiple complementary binding sites provide a means to magnify the effect of very weak individual interactions. This effect is more commonly known as cooperativity and is responsible for the physical characteristics of a vast majority of chemical and biological systems. The basis for cooperativity can entirely be explained by the additivity of the corresponding individual free energies and formation constants. Interestingly, entropic arguments need not be invoked to explain this phenomenon. In general, the existence of multiple binding sites in natural or synthetic receptors leads to greater efficiency and selectivity in complexation. Conformational changes during the course of complexation can also lead to the functionally important allosteric systems [56, 57, 66, 191].

One of the widely known manifestations of cooperative effects which is of relevance to this chapter is self-assembly [66, 91–95]. The most interesting aspect of self-assembly is that in a number of cases, the high affinity and selectivity arise from a complementarity of size and shape than from interactions involving charges [57, 66, 191]. The derivatives of glycourils, notably cucurbituril, are one of the most well-known examples of self-assembly [75, 262]. In fact, the large number of fascinating molecular architectures (Fig. 40) formed from cucurbiturils epitomize the salient features of self-assembly [75, 83] and also lead to the concept of self-assembling capsules.

We can define self-assembling capsules as receptors with enclosed cavities that are formed by the reversible noncovalent interaction of two or more, not necessarily identical, subunits. The aggregate so formed should have a well-defined structure in solution and be capable of binding behavior that none of its individual components display alone. This definition naturally places an emphasis on three-dimensional assemblies. It specifically excludes indefinite arrays and aggregates that are not designed to act as receptors such as micelles, liquid crystals, monolayers, metal–ligand structures, and assemblies that exist only in the solid state. As such, self-assembling capsules represent a subset of self-assembling systems. Reversibly formed capsules, held together by intermolecular forces, provide one means of accomplishing recognition under equilibrium conditions (Fig. 32). This approach also gives rise to larger molecular containers that can encapsulate increasingly larger guests and incorporate the properties required for, say, catalysis [84].

5.2. Competing Effects

A number of studies on H-bonding in organic molecular assemblies have revealed that certain classes of functional groups always form H-bonds when complementary donors or acceptors are available, while other classes of functional groups only occasionally participate in H-bonding. The discussion on the concept of best donor and acceptor forming a H-bond provides a cogent tool for controlling the composition and structure of molecular assemblies. Thus, novel molecular assemblies can be designed using complementary sets of strong and weak H-bonds [57, 331, 555]. It is interesting to note that this competition between H-bonds in solid state mirrors those found in solution (or in the gas phase) [62, 87, 555].

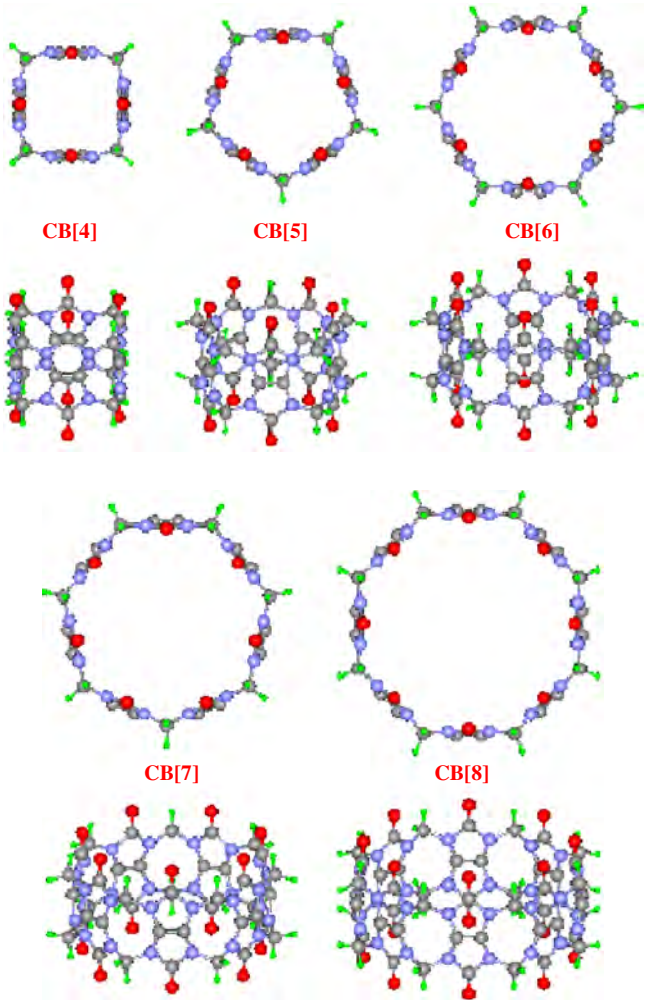

Figure 40. Self-assembly. Examples of a wide variety of molecular architectures obtained from different sizes of cucurbiturils. Adapted in part with permission from [61], J. Kim et al., *J. Am. Chem. Soc.* 122, 540 (2000). © 2000, American Chemical Society.

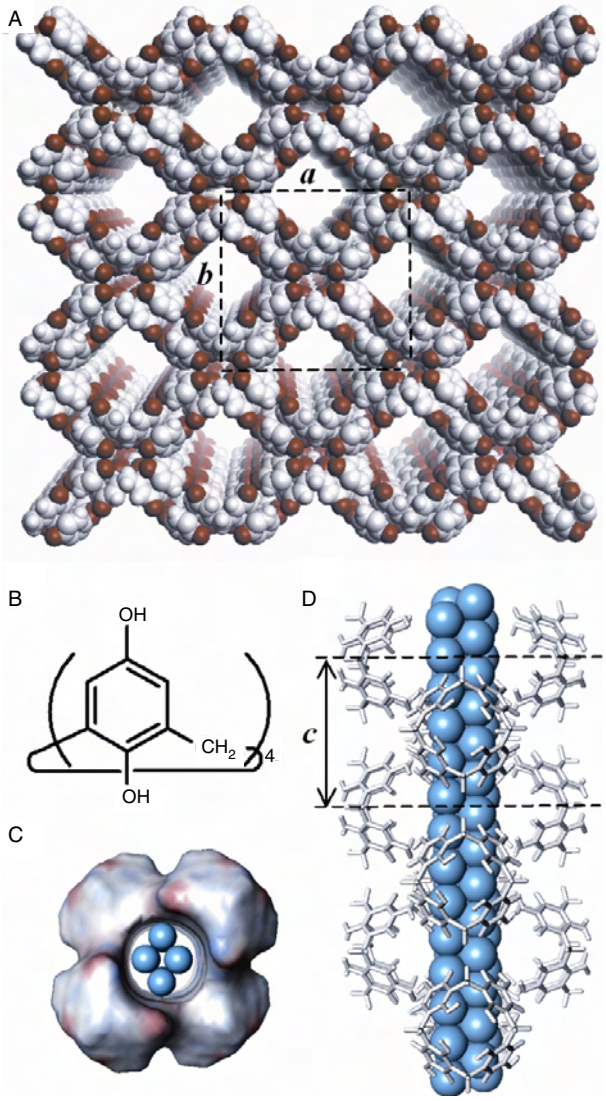

Figure 41. Fabrication of ultrathin silver nanowires from self-assembled CHQ nanotubes. (A) A schematic view of CHQ nanotube arrays based on the X-ray analysis of the crystal reveals that the pores of 0.8 × 0.8 nm^2 (with van der Waals volume excluded) are separated by 1.7 nm from the neighboring ones. O atoms are shown in red. (B) CHQ monomer. (C and D) Top and side views, respectively, of a silver nanowire inside a CHQ nanotubetemplate. The solvent-accessible surface model in (C) and the stick model in (D) show schematic views of the CHQ nanotubes. The red color of the surface represents the negative electrostatic potential on oxygen atoms. The space-filled models (blue) represent the silver nanowires. Reprinted with permission from [17], B. H. Hong et al., *Science* 294, 348 (2001). © 2001, American Assocation for Advancement of Science.

While there is a marked preference for the formation of strong H-bonds, it is of interest to note that weak H-bonds behave as steering interactions. Thus, Desiraju demonstrated that H-bonds, other than those taking part in strong H-bonds, play a crucial role in determining crystal packing [431, 555].

A stellar example of the use of competing effects in the the design of nanoarchitectures can be noted from a recent study, wherein the 1D short H-bonds and the displaced π–π stacking interactions in the calix[4]hydroquinone (CHQ) nanotube bundles compete in the assembling process (Fig. 1) [16, 18]. Incidentally, these CHQ nanotubes were used as templates in the fabrication of ultrathin silver nanowires (Fig. 41) [17, 31].

5.3. Nanodevices and Molecular Machines

As is the case with most issues discussed in this chapter, the concept of a nanodevice, or for that matter, a molecular machine, has its inspiration in nature [11–13, 15, 556]. One of the most spectacular examples of a nanodevice incorporating different aspects of nanorecognition and control is the case of the muscle linear and ATP-ase rotary motors [557].

A variety of molecular and supramolecular systems have been designed in the recent past, in which conformational changes, movements, occur as a response to external chemical, electrical, or photochemical stimuli [11, 12, 15, 233, 558, 559]. One of the advantages of the use of nanorecognition in this process is that it offers a (bottom-up) approach, which

is unlike the (top-down) approach favored by physicists and engineers. The limitations of the latter approach can already be noted in several systems.

6. CONCLUSIONS

In this review, we have discussed the principles underlying nanorecognition and various manifestations of intermolecular interactions in nanosystems. Some of the salient conclusions which can be drawn are outlined below.

(i) Nanorecognition, in addition to conventional molecular recognition, also incorporates the interaction of quantum species like electrons, photons, etc.
(ii) Given the small size of the systems involved, energetic considerations seem to be the more dominant indicator of stability in nanorecognition.
(iii) Quantum effects have to be taken into account to obtain realistic descriptions of most intermolecular interactions in nanorecognition.
(iv) Though vast strides have been made in obtaining quantitative estimates of the interaction energies of most nanosystems, the necessity of taking into account the quantum effects implies that the investigations can be carried out for very small and simple systems.

As can be seen, an understanding of nanorecognition would (i) aid the development of novel nanosystems with potential applications in pharmaceuticals, optics, optoelectronics, information storage, sensors, biotechnology, nanomedicine, nanofluidics, nanoelectronics, (ii) provide information on the methods needed to harness these nanosystems as machines and devices, and (iii) provide an increased understanding of the science behind these nanoscale processes.

GLOSSARY

Competing interactions When several kinds of intermolecular interaction prevail in a system, the magnitudes of some of them are enhanced and the others depleted. In larger systems, the interactions which are depleted are generally not considered. However, in nano dimensions, these very weak interactions have subtle effects which cannot be neglected.

Cooperativity The magnification of the effects (structural, energetic, and thermodynamic), when several intermolecular interactions prevail simultanaously in a system. In general, cooperativity is enhanced when an initial interaction makes the system more conducive for the next attractive recognition process.

Dispersion energy The attractive energy arising from the interaction of the fluctuating charge distributions of the interacting systems as induced-dipole–induced-dipole interactions. These fluctuations result from the correlation of the motion of the electrons in the system and thereby favor lower energy configurations over higher energy ones.

Electron correlation Electron correlation represents the effects which are manifested due to the instantaneous interaction between electrons.

Electron density The probability of finding any electron of a molecule or an intermolecular complex at a given point in space. The electron density is obtained by integrating the square of the modulus of an electronic wave function.

Electronic wave function The wave function Ψ is a function of the electron and nuclear positions and is based on the description of an electron as a wave.

Electrostatic energy The energy arising from the interaction of the static charge distributions of the interacting systems. They can either be attractive or repulsive.

Exchange–repulsion The repulsion due to the Pauli exclusion principle, which arises from the overlap of the occupied molecular orbitals of the interacting systems.

Hartree–Fock The Schrödinger equation is solved by assuming that the motions of particles constituting the system are independent of each other and a given particle interacts with the averaged charged distribution of other particles in the system. The multielectron wave function is described by an approximation of the unsymmetrized product of one-electron functions (orbitals).

Hydrogen bond An attractive interaction mediated through a hydrogen atom. A typical example is an interaction of the type **D**–H$\cdots$**A**, wherein **D** is a proton donor and **A** is a proton acceptor. Other examples include an interaction of the type **A**–H$\cdots$**A**.

Hydrophobicity The phenomenon of clustering of nonpolar molecules or groups in the presence of water. The driving force for this clustering is not due to the strong attraction between the nonpolar groups, but because of the high affinity of water molecules to form hydrogen bonds between themselves.

Induction energy The attractive energy arising from the interaction of the static charge distribution with the induced charge distribution of the other.

Interaction energy The sum of all the attractive and repulsive energies between two interacting systems. The more negative the interaction energy, the stronger the interaction.

Molecular recognition The processes leading to the binding and selection of substrate(s) by a receptor and culminating in some function. These processes are a result of a well-defined pattern of intermolecular interactions.

Nanorecognition Nanorecognition is synonymous with molecular recognition in most cases. However, the small size of the systems involved implies that quantum effects govern the nature of intermolecular interactions. In particular, the interactions involving electrons and photons are also included in nanorecognition.

Preorganized Molecules, in particular host molecules, which do not undergo significant conformational reorganization upon binding to a guest are said to be preorganized.

Quantum effects They represent those effects which need to take into account the dual nature (particle and wave) of the systems involved to obtain a reasonable description of their physical characteristics. Though these effects can be neglected when the systems are large, they become very important when the system under consideration is extremely small.

Relativistic effects These effects owe their existence to the very fast motion of electrons closest to the nuclei of heavy atoms.

Self-assembly The spontaneous organization of molecules under thermodynamic equilibrium conditions into structurally well-defined and rather stable arrangements through a number of noncovalent interactions.

Self-synthesis What distinguishes self-assembly from self-synthesis is that in the former, the identity of the molecules or molecular template is maintained but in the latter, an entirely new chemical system, bearing no resemblance to the original molecular template, is formed.

Supermolecule Supermolecule denotes singular or polymolecular associations which are well-defined, discrete oligomolecular species that result from the intermolecular association of a few components.

Supramolecule Supramolecules result from the spontaneous association of a large undefined number of components into a specific phase having more or less well-defined microscopic organization and macroscopic characteristics depending on its nature.

Van der Waals forces One of the older classifications of weak intermolecular forces, which represent the weak attractive and repulsive forces prevailing in an ensemble of molecules. The chemical identities of the constituent molecules are not altered as a result of van der Waals interaction. In physical terms, they represent the forces arising from not only dipole–dipole, dipole–induced-dipole or dispersion interactions but also exchange–repulsion.

Nanoscale Characterization of Biomaterials

E. Jallot

Université Blaise Pascal, 63177 Aubière Cedex, France

CONTENTS

1. INTRODUCTION

Biomaterials are defined as nonliving materials able to replace a part of the human body.

Life expectancy is now over 80 years. This increase in survivability, however, means that many people outlive the quality of their connective tissues, and the capacity of the human body to regenerate bony components that are lost or damaged is limited. Some 30 years ago, a revolution in medical care began with the successful replacement of tissues. Consequently, we have to find or to develop implants that might replace bony tissues. Two types of implants can be used: natural or synthetic [1].

The natural implants concern xenogenous, allogenous, and autogenous bone grafts. Xenogenous bone grafts are implants which come from another species. Allogenous bone grafts are implants which come from the same species. However, many problems were generally associated with them such as *in vivo* resorption, virus transfer, considerable care, high costs, and regular provocation of an immunological-defensive reaction, which limits their efficiency. Autogenous bone grafts are implants which come from the same body. These grafts are the most suitable because there is an excellent biocompatibility and no risk of virus transfer. However, removal of the bone grafts creates additional surgical trauma and its supply may not be available in sufficient quantity. To overcome all these problems, we have to find and to develop synthetic materials which might be used as bone substitutes or as prostheses [2].

The second possibility in the revolution to replace tissues was the development, or in many cases modification, of manmade materials to interface with living, host tissues. These synthetic implants are called biomaterials. The significant advantages of synthetic implants over natural implants are availability, reproducibility, and reliability. Good manufacturing practice, international standards, government regulations, and quality assurance testing minimize the risk of failure of implants. However, implants developed actually have serious disadvantages: problems of interfacial stability with host tissues, low mechanical properties, and production of wear particles. These problems limits biointegration of implants and their lifetimes. Efforts to improve properties of implants have to be made.

Actually, a lot of synthetic bone substitutes and prosthesis are available to repair bony tissues that are lost or damaged. The most widely used are polymers, metallic alloys (Ti_6Al_4V, Co–Cr, inox, ...), and bioceramics [alumina (Al_2O_3), zirconia (ZrO_2), calcium phosphates, bioactive glasses, biovitroceramics] [3, 4]. The ultimate goal of these materials is to reach full integration of the nonliving implant with living bone. With advances in ceramic technology, the application of calcium phosphate materials, bioactive glasses, and biovitroceramics as bone substitutes or as coatings on prostheses has received considerable attention, because they are highly biocompatible (well accepted in a biological environment) and they have bioactive properties [5–7]. These materials are capable, through physicochemical reactions, to establish a direct contact with bone [8]. However, many critical and complex reactions take place at the implant/bone tissue interface [9]. Structural and chemical evaluation of this interface is primordial to determine the success of an implant. Elemental composition and surface properties play a very important role in these reactions [10]. Knowledge of the elemental distribution at the biomaterial/bone tissue interface is important to understand the physicochemical mechanisms involved during the material integration and bone bonding [11, 12].

2. ANALYSIS OF BIOMATERIAL INTERFACES

Structural and chemical evaluation of biomaterial/bone interfaces requires analysis at the nanometer level. Transmission electron microscopy (TEM), energy dispersive X-ray spectroscopy (EDXS), and electron energy loss spectroscopy (EELS) are methods which permit this analysis at the required resolution. TEM and associated techniques are powerful tools which can provide chemical and physical information: interlayer thickness, chemical species, local bonding, and the nature of crystalline or amorphous products [13, 14]. On the other hand, complementary techniques like particle induced X-ray emission (PIXE), secondary ion mass spectrometry (SIMS), and atomic force microscopy (AFM) are useful to better evaluate biomaterial/bone tissue interfaces.

2.1. TEM

Development of transmission electron microscopy permits one to obtain morphological and chemical information at the nanometer scale from the sample examined. Different types of interactions can occur between incident electrons and the sample. The majority of incident electrons are transmitted, elastically diffused, and inelastically diffused. Electrons are not diffused when incident electrons are transmitted without any interaction with the specimen. This phenomenon increases when the specimen thickness decreases. Electrons diffused elastically are electrons which are diffused by the electromagnetic field created by nucleus of atoms. During this interaction, they lose a very small amount of energy of the order of some eV. This diffusion is called elastic diffusion because there is no energy transferred. Electrons diffused inelastically lose energy during collisions with electrons from atoms of the sample. This energy loss is characteristic of the atoms with which this interaction occurs. Several other signals can be generated after electron beam–sample interactions: secondary electron emission, backscattering of incident electrons, cathodoluminescence, Auger electron emission, and X-ray emission. Secondary electrons are electrons ejected from the conduction band because of their low bonding energy. Their kinetic energy is of the order of 50 eV. These electrons give topographic information about the surface. Backscattered electrons are electrons which pass near nucleus of atoms and are backscattered by the electromagnetic field of the nucleus. Cathodoluminescence represents photons which have a wavelength between 0.4 and 0.8 μm (visible). These photons are emitted by materials like semiconductors, organic molecules during the irradiation by the electron beam. Moreover, the interaction between the high energy electrons from the beam and atoms from the sample lead to atom ionization. Electrons from the inner shells of atoms are ejected from their orbits, leaving the inner shells incompletely filled. This gap is filled by an electron from the outer shells. This transition can lead to an X-ray photon emission, with an energy equal to the energy difference between the two shells or to the emission of an electron from outer shells: Auger electron.

Morphological, structural information can be obtained by contrasted images of transmitted electrons [15]. Chemical information can be obtained from the electron beam–sample interaction [15, 16]. Two of the signals generated are the X-ray signal (which is used in EDXS) and the electron energy loss signal issued from electrons diffused inelastically (which is used in EELS). These two spectrometries are used to obtain elemental and eventually chemical information. EDXS is now well developed and allows the elemental analysis of all elements with $Z > 5$. This technique permits quantitative elemental analysis, concentration profiles, and elemental cartographies with a resolution of the order of 10 nm [17]. The minimal detectable concentration is of the order of 500 ppm. EDXS allows the elemental analysis of the biomaterial–tissue interface together with the study of its ultrastructure in the transmission electron microscope [18, 19].

2.2. EDXS

X-ray energy is characteristic of the element in which the electronic transition occurred and permits one to determine the elements present in the sample [20]. Atoms are composed with many shells and many transitions can take place [21]. The K line corresponds to an X-ray generated after the ionization of the K shell, the L line corresponds to an X-ray generated after the ionization of the L shell, and so on [22]. For example, a transition from L_{III} to K is designated $K_{\alpha 1}$ and from M_V to L_{III} is designated $L_{\alpha 1}$. Transitions do not occur with the same probability. The most intense in each series are the $\alpha 1$. Considering the same line ($K_{\alpha 1}$ for example) the X-ray energy increases with the atomic number. In an atom, the K lines have a lower energy than L lines and the L lines have a lower energy than the M lines.

On the other hand, the incident electron beam can be inelastically scattered by the electromagnetic field of the nucleus of atoms in the sample. The energy loss by the electron leads to an X-ray emission of corresponding energy which is called continuum or background [23]. This background does not permit one to determine the elements present in the sample. However, its intensity is proportional to the mass of the analyzed volume and can be used for quantitative calculations [24].

2.2.1. Instruments

A transmission electron microscope generates the electron beam and gives the ultrastructural information about the sample. The electron beam size is very important to obtain an optimal spatial resolution. Actually, the scanning transmission electron microscope (STEM) permits one to obtain a resolution under 1 nm. The X-rays generated in the specimen by the electron beam are collected by a semiconductor detector, amplified, and displayed with a multichannel analyzer associated with a computer. The spectrum is displayed and stored.

The type of detector usually used is a lithium drifted silicon semiconductor detector [in short Si(Li) detector] cooled to liquid nitrogen temperature. The resolution of a detector is defined as the full width half-maximal height of the Mn K_α peak which is at an energy of 5.9 keV [25]. Actually, resolution is of the order of 140 eV. This type of detector

is protected from contamination from the microscope by a beryllium entrance window of 8 μm thickness. However, this window absorbs low energy X-rays which limits the detection to elements heavier than Na ($Z > 11$). Recent development of these detectors with an ultrathin window or window less permits the analysis of all elements down to boron.

The spectrum is composed with characteristic X-ray peaks for various elements and backgrounds (Fig. 1). We can observe the presence of carbon (C K_α), oxygen (O K_α), copper (Cu L_α, Cu K_α, Cu K_β), sodium (Na K_α), silicon (Si K_α), phosphorus (P K_α), and calcium (Ca K_α, Ca K_β). Spectral lines like $\alpha 1$ and $\alpha 2$ (respectively $\beta 1$ and $\beta 2$) are so close to each other that they cannot be resolved by the spectrometer, and the convoluted line is simply denoted α (respectively β).

2.2.2. Quantitative Analysis

Calculations of elemental concentrations are made in the computer. The quantitative analysis of a specimen links the characteristic X-ray intensity to the number of atoms which emit this characteristic X-ray. Two methods can be used to calculate concentrations: the Hall method [26–28] and the Cliff and Lorimer method [29]. In the first method, Hall proposed an alternative approach in which the mass of the matrix is measured from the intensity of the background. The concentration of an element is proportional to the peak intensity/background intensity ratio. By using standards, this method permits one to quantify elemental concentrations without the detection of all elements. Concentrations are determined separately from each other. This method can be used with all types of detectors, even those with a beryllium entrance window. However, this method has a serious disadvantage. The background of the specimen is superposed to the background of the grid support. This contribution varies with the distance between the analyzed zone and the nearest bar of the grid. In order to minimize errors induced by this phenomenon, measurements must be done as far as possible from the bars of the grid. The second method does not use the background intensity. This method is based on the fact that the sum of all elemental concentrations (weight %) in the specimen is equal to unity. Then, the elemental concentration of each element can be calculated. However, this method needs the correct detection of all elements present in the sample and especially light elements which are highly present in biological specimens. Detectors with a beryllium window entrance cannot be used.

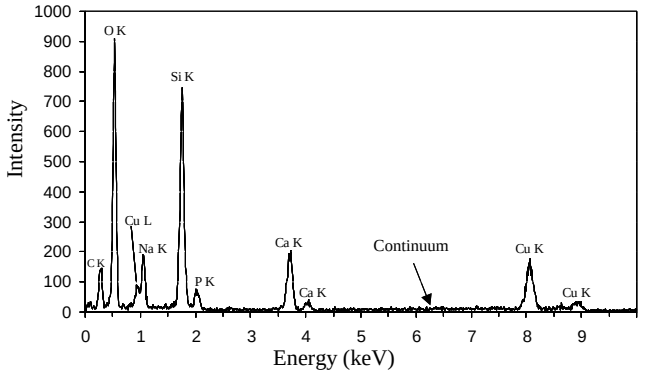

Figure 1. Spectrum showing characteristic peaks for various elements and the continuum (background).

2.2.3. Sample Preparation

For STEM and EDXS analysis at the nanometer scale the sample preparation is crucial. Several problems must be solved [30, 31].

- Ultrathin sections under 500 nm of the biomaterial–tissue interface must be prepared to perform the analysis at the resolution required. This is a very difficult step because the interface between hard materials and soft tissues must be in the sections.
- The specimen support should not contain elements of interest present in the studied sample.
- The preparation method must not change the chemical identity of the specimen. If the elements of interest in the sample are not firmly bonded, they can be solubilized during preparation [32].

Actually two preparation methods can be distinguished.

Conventional Preparation Method Biological ultrathin sections are prepared by a process including different steps [33]:

- fixation in aldehyde
- postfixation in osmium (osmium tetroxide, OsO_4)
- dehydration in increasing concentrations of alcohol
- embedding in resin
- sectioning with an ultramicrotome
- section staining with uranyl acetate and lead citrate
- carbon (C) or gold sputtering (Au)

This method allows a very good identification of the ultrastructure at the biomaterial–tissue interface [34, 35]. However, this preparation has disadvantages. Only firmly bonded elements can be analyzed. During fixation, the diffusible ions (Na, K, Cl, Mg, Ca) present in tissues and materials are lost from the sample [36]. During preparation, use of osmium, uranyl acetate, and lead citrate adds Os, U, and Pb to the sample. X-rays of these elements may interfere with X-rays of elements of interest in the sample. The gold sputtered may interfere too. Finally, chloride can be added to the sample by the resin. Table 1 summarizes different

Table 1. Common extraneous peaks causing artifacts during analysis.

Extraneous peak	Source	Interferes with these elements
Al K_α	specimen holder	Br L_α
Si K_α	contamination from microscope	Sr L_α
Cu K_α	grid	Zn K_α, Os L_α
Cu L_α	grid	Na
Pd L_α	coating	Cl K_α
Pd L_β	coating	K K_α
Os L_α	postfixation	Zn K_α
Os M_α	postfixation	P K_α
Au M_α	coating	P K_α, S K_α
Pb M_α	section staining	S K_α, Cl K_α
U M_α	section staining	K K_α

types of interference which can be generated by the sample preparation. For example, copper found in the spectrum in Figure 1 comes from the grid and copper is not present in the specimen.

Cryopreparation Methods Various methods for cryopreparation are available. The first step consists of a rapid freezing of the specimen by liquid ethane cooled by liquid nitrogen (−196 °C) or a metal cooled by liquid nitrogen [37, 38]. The high speed reduces considerably the formation of ice crystals. Then, cryosections are made with an ultracryomicrotome at a temperature of the order of −140 °C. Then, two types of analysis are possible:

- The sections are transferred to the microscope in the frozen-hydrated state and they can be studied in this state [39–43].
- The sections can be freeze-dried in the microscope chamber or they can be freeze dried and transferred to the microscope at room temperature for the analysis [38].

Other techniques including freeze-drying, freeze substitution then infiltration by resin, and finally sectioning can be used [44, 45].

These methods permit one to retain all elements of interest at their *in vivo* or *in vitro* position [46, 47]. They allow one to study ion distribution and ion diffusion in biomaterials during their interaction with tissues or in cells in contact with biomaterials [48]. Analysis is performed in a state near the *in vivo* or *in vitro* state.

2.3. EELS

EDXS is very useful for elemental analysis, but this technique is limited with its spatial resolution of analysis and its sensitivity. Electron energy loss spectroscopy appears to be a good complementary technique [49]. Its spatial resolution is of the order of the nanometer and the minimal detectable concentration is of the order of 400–500 ppm. During ionization of atoms present in the sample, electrons loss a certain amount of energy which is specific to the atom that is ionized. Detection of energy loss by the electrons that have passed through the sample permits one to determine the elemental composition and even fine structures. Sensitivity of this method for light elements is better than that of EDXS. Unfortunately, the sample must be very thin (less than 100 nm). The use of EELS is very limited for the study of biomaterials due to the difficulty in preparing sufficiently thin sections.

2.4. Selected-Area Electron Diffraction and High Resolution Transmission Electron Microscopy

High resolution transmission electron microscopy (HRTEM) and the electron diffraction mode, including selected-area electron diffraction (SAED) and microdiffraction, permit one to determine the crystalline character of a part of the studied specimens [50]. Electron beams of some nanometers in diameter are used to determine the crystalline structure. Materials are assessed as "amorphous" when electron diffraction patterns show broad and diffuse ring patterns and when there is no visible speckle in the rings. Crystalline materials give spotty diffraction patterns or spotty ring patterns. Finally, pattern analysis and calculations allow one to determine distances between atomic plans and the crystalline structure at the nanometer scale.

2.5. PIXE

Protons are charged particles which can generate characteristic X-rays in the same way that electrons do. The particle induced X-ray emission method used a 3 MeV energy proton beam to ionize atoms. This technique is used for trace element analysis because the peak to background ratio is much better than in EDXS [51]. The limit of detection of PIXE is several ppm. A further very important advantage is that PIXE can be used as a microbeam technique, which allows elemental mapping with a good spatial resolution. However, a proton beam cannot be as finely focused as an electron beam. Recent instrumental developments permit one to obtain proton beams in the order of 200–400 nm. This method is interesting to study trace elements locally at the biomaterials interface.

2.6. SIMS

Secondary ion mass spectrometry is used to analyze the surface composition and eventually a depth profile can be obtained because several layers are sputtered away. An ion beam is used to generate secondary ions from the surface specimen. The sensitivity of this method is of the order of 1 ppm and its resolution is near 100 nm.

2.7. AFM

During the last decade, developments in atomic force microscopy permit one to characterize the local properties of covered surfaces, namely the degree of coverage, the thickness of the layer, and the shape [52]. Interactions between a tip (cantilever) and specimen surface permit one to obtain images of surface structures at the nanometer scale. AFM has become a common experimental method in the investigation of biomaterials during the past 10 years [53], even if it is a delicate technique for measurements of soft materials as well as for evaluation and interpretation. This method allows one to determine adsorption of proteins on materials, surface rugosities induced by protein adsorption. Concerning bioactive materials, AFM is used to study changes of surface morphology and roughness during the bioactivity process. The structure of the apatite layer and the size of apatite crystals can be studied during interactions between bioactive materials and biological fluids [54, 55].

3. PHYSICOCHEMICAL REACTIONS AT BIOMATERIAL INTERFACES

3.1. Biomaterials Used to Replace Bony Tissues

Actually, various types of biomaterials are used in orthopaedic and maxillofacial surgery. These materials can generate different reactions at the implant/bone interface

and can be separated into three categories: biotolerant materials, bioinert materials, and bioactive materials [56–59].

3.1.1. Biotolerant Materials

Biotolerant materials are materials which are incorporated in bony tissues but with interposition of a layer of fibrous tissues between the materials and bone. For example, polymethyl methacrylate and cobalt–chrome (Co–Cr) alloy. The distance between the materials and bone is in the order of 1–20 μm [60]. The presence of the fibrous layer can lead to micromovements of the implant, corrosion, and the release of wear debris, which limits long-term stability.

3.1.2. Bioinert Materials

Bioinert materials are materials which are in contact with bone without leading to low tissue reactions and formation of a fibrous layer, for example: alumina (Al_2O_3), zirconia (ZrO_2), and titanium alloys [60]. However, there is no intimate or chemical contact between bone and implants. These materials are poorly degraded by the surrounding tissues and well accepted by the biological environment. Unfortunately, sometimes wear debris is released, which limits the efficiency of the implant and its long-term stability.

3.1.3. Bioactive Materials

Bioactive materials are defined by Hench [61] as materials capable of creating a chemical bond with surrounding tissues without interposition of a fibrous layer. This phenomenon leads to an intimate link between bone and materials. Two kinds of bioactive materials can be defined: resorbable materials and surface reactive materials.

After implantation in bony tissues, the material is progressively resorbed by bone cells (macrophages, osteoclasts), degraded by a chemical dissolution, and finally replaced by bone [62]. Material resorption and bone formation occur simultaneously in order to have a stability of the bone/material interface [63]. The fixation of these implants is called "biological fixation" with a porous ingrowth. These materials exhibit osteoconductive properties, defined as the characteristic of bone growth in porosities and bonding along the surface. Having the same chemical composition as natural bone, the calcium phosphate ceramics [64] (Table 2) and calcium carbonates ($CaCO_3$, coral) [65] are resorbable.

The dissolution process is highly dependent on the porosity, the crystalline structure, and the degree of crystallinity [66]. Calcium phosphate ceramics with macroporosities (300–400 μm) are more resorbable than calcium phosphate ceramics with microporosities (<10 μm) [67, 68]. A high crystallinity degree reduces the resorbability of calcium phosphates [69]. On the other hand, it is interesting to note that some polymers are resorbable. However, mechanisms of their degradation/resorption and biological effects of their degradation products are not well known.

Table 2. Some of the available calcium phosphates.

Calcium phosphates (synthetic)	Chemical formulae	Ca/P
Brushite, dicalcium phosphate dihydrate	$CaHPO_4 \cdot H_2O$	1
Monetite, dicalcium phosphate anhydrous	$CaHPO_4$	1
Octacalcium phosphate	$Ca_8H_2(PO_4)_6 \cdot 5H_2O$	1.33
Tricalcium phosphate	$Ca_3(PO_4)_2$	1.5
Calcium hydroxyapatite	$Ca_{10}(PO_4)_6(OH)_2$	1.67
Calcium fluorapatite	$Ca_{10}(PO_4)_6F_2$	1.67
Tetracalcium phosphate	$Ca_4P_2O_9$	2

During the last decade, considerable attention has been directed toward use of bioactive fixation of implants. The most bioactive materials are bioactive glasses, biovitroceramics, hydroxyapatites [$Ca_{10}(PO_4)_6(OH)_2$], and composite materials (hydroxyapatite–tricalcium phosphate, ...). At the interface between these materials and bone tissues a direct chemical bond is formed through a biological active apatite (Ca, P) layer [70–72]. This chemical reaction is the bioactivity property. An important advantage of bioactive fixation is that a bioactive bond to bone has a strength equal or greater than bone after 3 months. A bioactive bond to collagen fibrils of soft connective tissues is stronger than the cohesive bond of collagen fibrils. This high strength of both hard and soft tissues bonding to bioactive implants comes from the *in vivo* growth of an apatite layer of nanometer scale which binds to collagen fibrils [8].

3.2. Bioactivity Process

The bioactivity process differs with the type of material, its composition, and its structure. We can distinguish four types of bioactivity process.

3.2.1. Bioactivity Process of Bioactive Glasses

In 1970, Hench [10, 73] discovers bioactive glasses. They are amorphous materials with low mechanical properties which reduces their applications to prosthetic coatings [74, 75] and to fill bony defects [76–79]. The particular composition which initiates bioactivity is based on four oxides: (45%) SiO_2, (24.5%) CaO, (24.5%) Na_2O, and (6%) P_2O_5. The bioactivity properties of these materials depend on the percentage of these three oxides: SiO_2, CaO, Na_2O. An increase of SiO_2 considerably reduces the bioactivity and a high increase leads to a bioinert material [61]. An increase of CaO or Na_2O leads to a nonglass material. In fact, a very limited range of bioactive glass compositions, containing SiO_2–CaO–Na_2O–P_2O_5, that have less than 55% SiO_2 exhibit a high bioactivity and bond to both bone and soft connective tissues [80, 81]. Bioactive glasses can be obtained by melting the components at 1350 °C or by the sol–gel method at a lower temperature [82]. The synthesis of bioactive glasses by the sol–gel process was proposed in the last decade [83, 84]. The solutions to obtain bioactive gel-glasses were prepared from stoichiometric amounts of tetraethoxysilane, triethyl phosphate, and $Ca(NO_3)_2 \cdot 4H_2O$. Hydrolysis and condensation at low temperature create a highly interconnected three-dimensional gel network composed of $(SiO_4)^{4-}$ tetrahedral via bridging oxygen bonds or by Si–O–Ca or Si–O–P nonbridging bonds [85–88].

The bioactivity process has been studied *in vitro* during interactions between bioactive glasses and biological fluids (Table 3) or *in vivo* during interactions with bony tissues

Table 3. Ion concentrations (mmol dm^{-3}) of biological solutions used to study physicochemical reactions of bioactive materials.

	Na^+	K^+	Mg^{2+}	Ca^{2+}	Cl^-	HCO_3^-	HPO_4^{2-}	SO_4^{2-}
Simulated body fluid	142	5	1.5	2.5	147.8	4.2	1	0.5
Human plasma	142	5	1.5	2.5	103	27	1	0.5

[12, 89–92]. This process is decomposed in a complex series of physicochemical reactions including dissolution, diffusion, ionic exchange, and precipitation (Figure 2) [93–96]:

- Rapid exchange of alkali ions (Na^+) with H^+ or H_3O^+ from surrounding fluids through an exchange layer of the order of 200 nm [14].
- Loss of soluble Si to the solution resulting from breaking of Si–O–Si bonds. Soluble silicon migrates toward the surface and there is formation of Si–OH and Si–$(OH)_4$ groups at the surface. The exchange process consists of a flow of H_3O^+ ions and an equivalent flow of sodium ions into the solution from the glass represented as

$$SiO^-Na^+ + H_3O^+ \rightarrow SiOH + H_2O + Na^+$$

  Then, there is condensation and repolymerization of a hydrated Si rich layer on the surface depleted in alkali and Ca, P elements. This layer is a vitreous gel [54].
- Migration of Ca and P from the glass to the surface of the Si layer. Several authors described this phenomenon as a diffusion process through the Si rich layer.
- Growth of the vitreous gel by alkali exchange.
- Precipitation of an apatite (Ca–P) rich layer on top of the Si layer.
- Growth of the Ca–P rich layer. At the beginning the apatite crystals size is of the order of 200 nm and increases to some micrometers by consuming Ca^{2+}, PO_4^{3-}, CO_3^-, and HPO_4^{2-} from surrounding fluids. This layer incorporates collagen fibrils from surrounding tissues.

The formation of this apatite layer represents the bioactivity properties and permits a chemical link between the materials and the newly formed bone. The apatite crystals of the Ca–P layer and the apatite crystals of bone are intermingled each other which leads to a strong bonding [97]. Concerning bioactive gel-glasses, the 1–10 nm scale solid network of the gel is completely interpenetrated by pore liquid. The pore liquid consists of a highly structured hydrated layer with hydrated connective tissues. Biological molecules can exchange with these hydrated layers inside the pores and maintain their structure together with their biological properties [98, 99]. The nanometer sized pores of the gel-glass are proposed to act as initiation sites for apatite nucleation [100].

STEM is able to show unambiguously the presence or absence of thin amorphous or crystalline films at interfaces. Figure 3 shows bioactive glass particles cultured with bone cells (osteoblasts) for two days. Interactions between bioactive glass particles and the culture medium lead to the material dissolution, the formation of the Si layer, and finally the precipitation of an apatite layer. On the image, this layer appears as an electron dense layer. At this short time period, the apatite layer is of the order of 200 nm in thickness and its size will increases with time. In the case of a crystallized apatite layer, a needle-shaped structure will appear. The EDXS spectrum on this layer demonstrates the presence of Ca and P elements [75]. The apatite layer acts as a template for bone cell adhesion and differentiation [91]. Figure 4 shows a bioactive glass coating/bone interface at 3 months. We clearly notice the presence of the bioactive

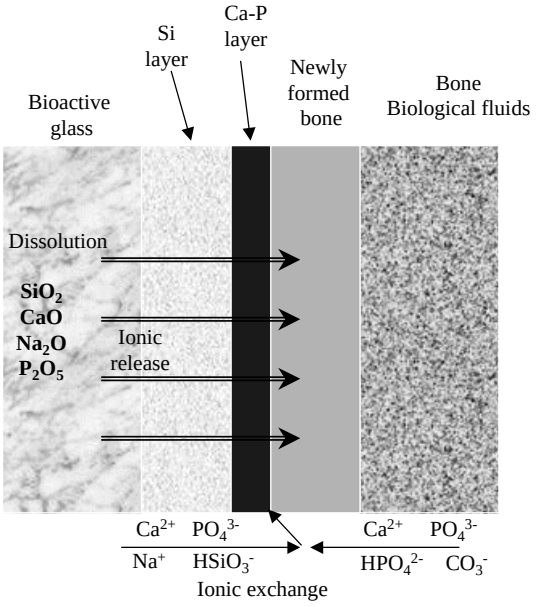

Figure 2. Schematic view of the bioactive glass/bone interface during the bioactivity process.

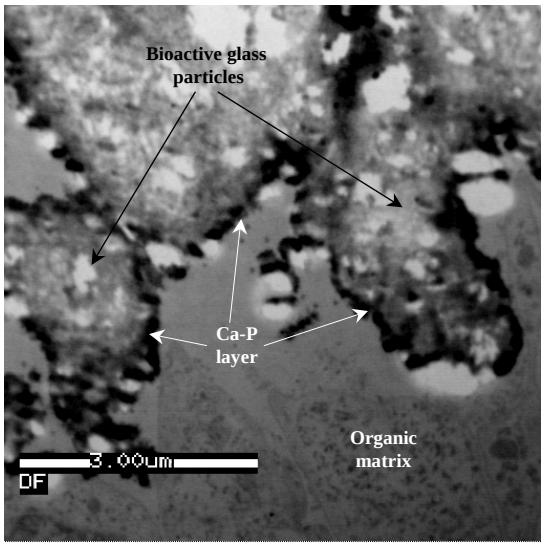

Figure 3. STEM micrograph of bioactive glass particles immersed in a biological solution with bone cells (osteoblasts) during two days. The particles are in dissolution and an electron dense layer appears (apatite layer). These particles are engulfed in an organic matrix.

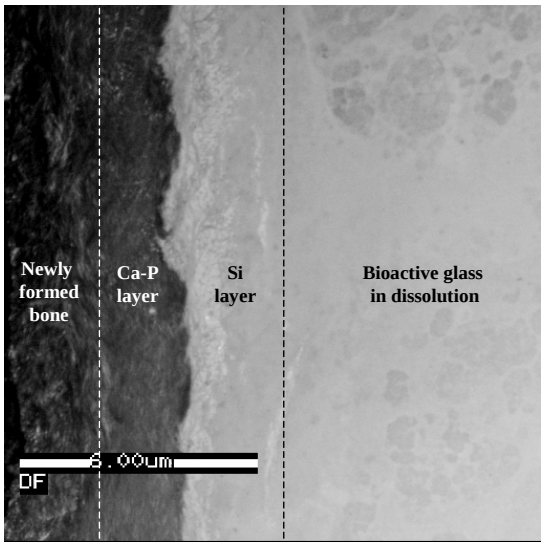

Figure 4. STEM micrograph of a bioactive glass coating/bone interface after 3 months of implantation. The bioactive glass coating is in dissolution and firmly fixed to newly formed bone through an apatite layer on top of a pure Si layer.

glass coating in dissolution, the Si layer, the apatite layer, and the newly formed bone. Intimate contact is observed between the glass and bone. Elemental profiles performed with EDXS permit one to determine the exact composition of the different zones and their evolution with time.

One of the main problems associated with the use of bioactive glasses as prosthetic coatings is high solubility, which might reduce the long-term stability of the glass. Extensive dissolution of the glass networks occurs within days. Optimization of bioactive glass properties concerns the compromise between bioactivity and solubility which is related to individual components [101–104]. For example, addition of Al_2O_3 can be used to control the solubility of the glass. However, this addition may inhibit the bone bonding [105]. Greenspan and Hench demonstrate that a concentration of Al_2O_3 higher than 2% inhibits bioactivity [106].

3.2.2. Bioactivity Process of Biovitroceramics

An *in vitro* ceramic is obtained by a temperature treatment of a glass in which nucleation factors are added in order to induce a partial or total crystallization of this glass. This treatment increases mechanical properties of the glass. A biovitroceramics has a structure and a particular chemical composition which are crucial for the bioactivity properties. Three types of biovitroceramics are elaborated [107, 108]:

- biovitroceramics composed of a vitreous matrix [(16.6%) MgO, (24.2%) CaO, (59.2%) SiO_2] in which apatite crystals ($Ca_{10}(PO_4)_6(O,F_2)$) are incorporated
- biovitroceramics (A–W) composed of a vitreous matrix in which apatite crystals and β-wollastonite crystals ($CaSiO_3$) are incorporated
- biovitroceramics composed of a vitreous matrix in which apatite crystals, β-wollastonite crystals, and whitelockite crystals ($3CaOP_2O_5$) are incorporated

All these biovitroceramics contain apatite crystals which are important in the bioactivity process. Studies of the bioactivity were made *in vitro* during interactions between biovitroceramics and biological fluids, and *in vivo* during interactions between biovitroceramics and bone [108, 109]. The bioactivity is based on (Fig. 5):

- dissolution of the vitreous matrix, wollastonite crystals, and whitelockite crystals (if they are incorporated)
- ionic release of $HSiO_3^-$, Ca^{2+}, Mg^{2+} at the surface
- precipitation of an apatite layer by consuming Ca^{2+}, PO_4^{3-}, CO_3^-, and HPO_4^{2-} from biological fluids

The formation of this apatite layer at the surface of biovitroceramics occurs without the formation of a Si rich layer [110, 111]. This layer of some micrometers in thickness permits a chemical bond between the materials and the newly formed bone.

3.2.3. Bioactivity Process of Hydroxyapatites

Synthetic hydroxyapatites are calcium phosphate ceramics elaborated under pressure and under temperature treatment of $Ca(NO_3)_2$, H_3PO_4, NH_4OH, and H_2O [112]. This ceramic is used in different forms: powders, bulk, or as coatings. For example, Figure 6 shows a STEM micrograph of nanostructures of hydroxyapatite powders. For bulk materials, various porosities are available [113]. We can distinguish microporosities (<10 μm) which permit diffusion of ions and fluids from macroporosities (100–600 μm) which permit cellular colonization. The bioactivity process was studied *in vitro* and *in vivo* [114–116]. It occurs under an acidic attack with H^+ at the material surface (Figure 7) [117]. This leads to the dissolution of hydroxyapatite crystals and a high release of Ca^{2+} and PO_4^{3-} [118, 119]. Concentration of calcium and phosphorus increase in the surrounding fluids and this supersaturation induces reprecipitation of apatite crystals at the ceramic

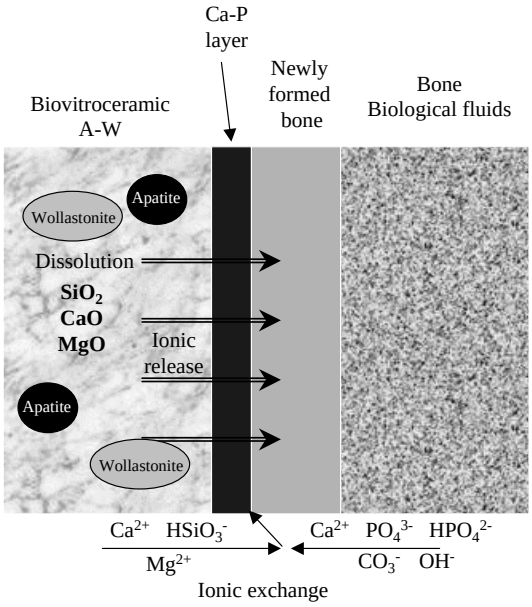

Figure 5. Schematic view of the biovitroceramic/bone interface during the bioactivity process.

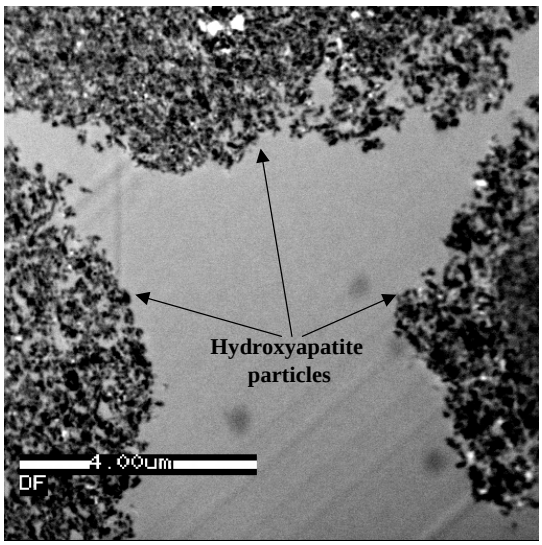

Figure 6. TEM micrograph showing nanostructures of hydroxyapatite particles.

surface [120]. These apatite crystals may incorporate Ca^{2+}, Mg^{2+}, CO_3^-, PO_4^{3-}, and organic molecules present in the surrounding fluids [121, 122]. This dissolution–reprecipitation process leads to the formation of a carbonated apatite layer at the material surface and permits a chemical bond with newly formed bone [114]. This layer is on the order of 200–800 nm [123–126]. Solubility of hydroxyapatites varies with different factors: porosity, grain size, crystallinity, sintering temperature [127–130]. An increase of the sintering temperature leads to an increase of the hydroxyapatite crystal size and finally reduces its solubility. For example, hydroxyapatite treated at 600 °C has crystals of 180 nm in size and crystals of 350 nm in size with a treatment at 1180 °C [129]. On the other hand, the solubility increases with the porosity and pore size.

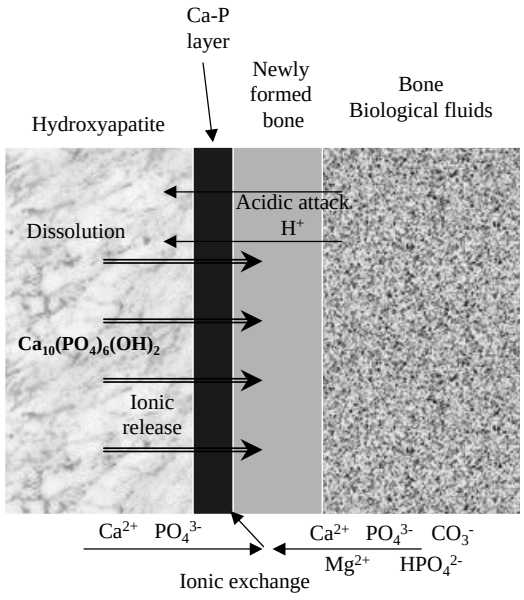

Figure 7. Schematic view of the hydroxyapatite/bone interface during the bioactivity process.

3.2.4. Bioactive Titanium

Recently, it has been found that even pure titania hydrogel prepared by the sol–gel method induces apatite formation [72, 131, 132]. When titanium is treated by immersion in alkaline solution (NaOH), a hydrated titanium oxide gel layer containing alkali ions is formed on its surface. This gel layer is dehydrated and densified to form an amorphous alkali titanate ($TiO_2 + Na^+$) layer by heat treatment below 600 °C. When the pretreated titanium is exposed to biological fluids, the alkali ions are released from the amorphous alkali titanate layer and hydronium ions enter into the surface layer, resulting in the formation of a titanium oxide hydrogel layer. The released Na^+ ions increase the degree of supersaturation of the soaking solution with respect to apatite by increasing pH, and titanium oxide hydrogel induces apatite nucleation on the titanium surface [133].

3.2.5. Apatite Precipitation Process

Determination of crystal size, nucleation, and growth of apatite during interactions with surrounding fluids is important to better understand the dissolution–precipitation process during bioactivity [134]. The combination of HRTEM, SAED, and nanoprobe electron diffraction allows one to determine morphology and structure of apatite crystals size [135]. The crystal size varies from a few nanometers to a micrometer [136]. The increase of the apatite crystal size occurs as a result of lower supersaturation in the crystallization system because of the absence of convection in space and the strong reduction in the rate of nucleation [137].

In some cases, the apatite precipitates are amorphous. During apatite precipitation, some ions like Mg^{2+} and CO_3^- are able to enter the forming apatite nuclei and thus inhibit their evolution to tiny apatite crystals [138]. These phenomena can promote a greater dissolution of the newly formed apatite precipitates [139–141].

4. CONCLUSION

Structural and chemical evaluation of bioactive biomaterial/bone tissue interfaces requires analysis at the nanometer scale. Transmission electron microscopy and associated techniques enable the chemical and physical characterization of bioactive material/bone tissue interfaces, providing information on interlayer thickness, chemical species, local bonding, and the nanostructural features which give rise to the interfacial properties, thereby enabling a full understanding not only of biomaterials after processing but also after interactions with bone tissues [142].

Bioactive materials are capable of bonding directly to bone through an apatite layer. This intimate link results from simultaneous physicochemical and biological processes. The bioactive materials in contact with bone tissues undergo dissolution with leaching and precipitation of apatite crystals occurs together with adsorption of organic compounds [143, 144]. Apatite crystals grow by epitaxial growth [145]. Simultaneously, bone cells mineralize an extracellular matrix on the materials composed with apatite crystals. Apatite crystals issued from the materials and apatite crystals issued from mineralization are intermingled which lead to a strong bonding between implants and bone.

This process of bioactivity occurs more rapidly in bioactive glasses and in biovitroceramics than in hydroxyapatite. Actually, these bioactive materials are developed and used in orthopaedic and maxillofacial surgery.

GLOSSARY

Bioactivity Property of a materials to form a direct chemical bond with bone tissues.

CONTENTS

1. WHAT IS SPINTRONICS?

Two of the most successful technologies in existence today have created the Si integrated circuit (IC) industry and the data storage industry. Both continue to advance at a rapid pace. In the case of ICs, the number of transistors on a chip doubles about every 18 months according to Moore's law. For magnetic hard disk drive technology, a typical desk-top computer drive today has a 40 Gbyte/disk capacity, whereas in 1995 this capacity was ~1 Gbyte/disk. Since 1991, the overall bit density on a magnetic head has increased at an annual rate of 60–100% and is currently ~10.7 Gbits/in^2 [1]. The integrated circuits operate by controlling the flow of carriers through the semiconductor by applied electric fields. The key parameter therefore is the charge on the electrons or holes. For the case of magnetic data storage, the key parameter is the spin of the electron, as spin can be thought of as the fundamental origin of magnetic moment. The characteristics of ICs include high speed signal processing and excellent reliability, but the memory elements are volatile. The stored information is lost when the power is switched off, as data is stored as charge in capacitors (i.e., Dynamic Random Access Memories (DRAMs)). A key advantage of magnetic memory technologies is that they are nonvolatile since they employ ferromagnetic materials which by nature have remanence.

The emerging field of semiconductor spin transfer electronics (spintronics) seeks to exploit the spin of charge carriers in semiconductors. It is widely expected that new functionalities for electronics and photonics can be derived if the injection, transfer, and detection of carrier spin can be controlled above room temperature. Among this new class of devices are spin transistors operating at very low powers for mobile applications that rely on batteries, optical emitters with encoded information through their polarized light output, fast nonvolatile semiconductor memory, and integrated magnetic/electronic/photonic devices ("electromagnetism-on-a-chip"). Since the magnetic properties of ferromagnetic semiconductors are a function of carrier concentration in the material in many cases, it will be possible to have electrically or optically controlled magnetism through field-gating of transistor structures or optical excitation to alter the carrier density. This novel control of magnetism has already been achieved electronically and optically in an InMnAs metal–insulator semiconductor structure at low temperatures [2, 3] and electronically in Mn:Ge [4]. A number of recent reviews have covered the topics of spin injection, coherence length, and magnetic properties of materials systems such as (Ga,Mn)As [5–7], (In,Mn)As [5–7], and (Co,Ti)O_2 [8] and the general areas of spin injection from metals into semiconductors and applications of the spintronic phenomena [9–12]. The current interest in magnetic semiconductors can be traced to difficulties in

ISBN: 1-58883-063-2/$35.00

injecting spins from a ferromagnetic metal into a semiconductor [13, 14], an idea that can be traced to fruitful research in epitaxial preparation of ferromagnetic transitional metals on semiconductor substrates [15]. A theory first proposed by Schmidt et al. [16] points out that due to the dissimilar materials properties of a metal and semiconductor, an efficient spin injection in the diffusive transport regime is difficult unless the magnetic material is nearly 100% spin polarized, that is, half-metallic [17]. Although there have been recent reports of successful and efficient spin injection from a metal to a semiconductor even at room temperature by ballistic transport (i.e., Schottky barriers and tunneling) [18], the realization of functional spintronic devices requires materials with ferromagnetic ordering at operational temperatures compatible with existing semiconductor materials.

2. MATERIALS SELECTION

There are two major criteria for selecting the most promising materials for semiconductor spintronics. First, the ferromagnetism should be retained to practical temperatures (i.e., >300 K). Second, it would be a major advantage if there were already an existing technology base for the material in other applications. Most of the work in the past has focused on (Ga,Mn)As and (In,Mn)As. There are indeed major markets for their host materials in infrared (IR) light-emitting diodes and lasers and high speed digital electronics (GaAs) and magnetic sensors (InAs). Most of the past attention on ferromagnetic semiconductors focused on the (Ga,Mn)As [19–42] and (In,Mn)As [43–50] systems. In samples carefully grown single-phase by molecular beam epitaxy (MBE), the highest Curie temperatures reported are ~110 K for (Ga,Mn)As and ~35 K for (In,Mn)As. For ternary alloys such as $(In_{0.5}Ga_{0.5})_{0.93}Mn_{0.07}As$, the Curie temperature is also low, ~110 K [51]. A tremendous amount of research on these materials systems has led to some surprising results, such as the very long spin lifetimes and coherence times in GaAs [4] and the ability to achieve spin transfer through a heterointerface [52–69], either of semiconductor/semiconductor or metal semiconductor. One of the most effective methods for investigating spin-polarized transport is by monitoring the polarized electroluminescence output from a quantum-well light-emitting diode into which the spin current is injected. Quantum selection rules relating the initial carrier spin polarization and the subsequent polarized optical output can provide a quantitative measure of the injection efficiency [67, 69, 70].

There are a number of essential requirements for achieving practical spintronic devices in addition to the efficient electrical injection of spin-polarized carriers. These include the ability to transport the carriers with high transmission efficiency within the host semiconductor or conducting oxide, to detect or collect the spin-polarized carriers, and to control the transport through external means such as biasing of a gate contact on a transistor structure. The observation of spin current-induced switching in magnetic heterostructures is an important step in realizing practical devices [71]. Similarly, Nitta et al. [72] demonstrated that a spin–orbit interaction in a semiconductor quantum well could be controlled by applying a gate voltage. These key aspects of spin injection, spin-dependent transport, manipulation, and detection form the basis of current research and future technology. The use of read sensors based on metallic spin valves in disk drives for magnetic recording is already a $US100 B per year industry. It should also be pointed out that spintronic effects are inherently tied to nanotechnology, because of the short (~1 nm) characteristic length of some of the magnetic interactions. Combined with the expected low power capability of spintronic devices, this should lead to extremely high packing densities for memory elements. A recent review of electronic spin injection, spin transport, and spin detection technologies has recently been given by Buhrman [7], as part of a very detailed and comprehensive study of the status and trends of research into spin electronics in Japan, Europe, and the United States. The technical issues covered fabrication and characterization of magnetic nanostructures, magnetism and spin control in these structures, magneto-optical properties of semiconductors and magneto-electronics and devices. The nontechnical issues covered included industry and academic cooperation and long-term research challenges. The panel findings are posted on a web site [7].

In this chapter we focus on a particular and emerging aspect of spintronics, namely recent developments in achieving practical magnetic ordering temperatures in technologically useful semiconductors [73–79]. While the progress in synthesizing and controlling the magnetic properties of III-arsenide semiconductors has been astounding, the reported Curie temperatures are too low to have significant practical impact. A key development that focused attention on wide bandgap semiconductors as being the most promising for achieving high Curie temperatures was the work of Dietl et al. [80]. They employed the original Zener model of ferromagnetism [81] to predict T_C values exceeding room temperature for materials such as GaN and ZnO containing 5% of Mn and a high hole concentration (3.5×10^{20} cm^{-3}).

Other materials for which room temperature ferromagnetism has been reported include (Cd,Mn)GeP_2 [74], (Zn,Mn)GeP_2 [75], $ZnSnAs_2$ [76], (Zn,Co)O [77], and (Co,Ti)O_2 [8, 78] as well as Eu chalcogenides and others that have been studied in the past [79]. Some of these chalcopyrites and wide bandgap oxides have interesting optical properties, but they lack a technology and experience base as large as that of most semiconductors.

The key breakthrough that focused attention on wide bandgap semiconductors as being the most promising for achieving practical ordering temperatures was the theoretical work of Dietl et al. [80]. They predicted that cubic GaN doped with ~5 at.% of Mn and containing a high concentration of holes (3.5×10^{20} cm^{-3}) should exhibit a Curie temperature exceeding room temperature. In the period following the appearance of this work, there has been tremendous progress both on the realization of high-quality (Ga,Mn)N epitaxial layers and on the theory of ferromagnetism in these so-called dilute magnetic semiconductors (DMS). The term DMS refers to the fact that some fraction of the atoms in a nonmagnetic semiconductor like GaN is replaced by magnetic ions. A key, unanswered question is whether the resulting material is indeed an alloy of (Ga,Mn)N or

whether it remains as GaN with clusters, precipitates, or second phases that are responsible for the observed magnetic properties [82].

3. MECHANISMS OF FERROMAGNETISM

Figure 1 shows some of the operative mechanisms for magnetic ordering in DMS materials. Two basic approaches to understanding the magnetic properties of dilute magnetic semiconductors have emerged. The first class of approaches is based on mean field theory which originates in the original model of Zener [81]. The theories that fall into this general model implicitly assume that the dilute magnetic semiconductor is a more or less random alloy, for example, (Ga,Mn)N, in which Mn substitutes for one of the lattice constituents. The second class of approaches suggests that the magnetic atoms form small (a few atoms) clusters that produce the observed ferromagnetism [82]. A difficulty in experimentally verifying the mechanism responsible for the observed magnetic properties is that depending on the growth conditions employed for growing the DMS material, it is likely that one could readily produce samples that span the entire spectrum of possibilities from single-phase random alloys to nanoclusters of the magnetic atoms to precipitates and second phase formation. Therefore, it is necessary to decide on a case-by-case basis which mechanism is applicable. This can only be achieved by a careful correlation of the measured magnetic properties with materials analysis methods that are capable of detecting other phases or precipitates. If, for example, the magnetic behavior of the DMS is characteristic of that of a known ferromagnetic second phase [such as MnGa or Mn_4N in (Ga,Mn)N], then clearly the mean field models are not applicable. To date, most experimental reports concerning room temperature ferromagnetism in DMS employ X-ray diffraction, selected-area diffraction patterns, transmission electron microscopy, photoemission, or X-ray absorption [including extended X-ray absorption fine structure (EXAFS), as discussed later] to determine whether the magnetic atoms are substituting for one of the lattice constituents to form an alloy. Given the level of dilution of the magnetic atoms, it is often very difficult to categorically determine the origin of the ferromagnetism. Indirect means such as superconducting quantum interference device (SQUID) magnetometer measurements to exclude any ferromagnetic intermetallic compounds as the source of magnetic signals, and even the presence of what is called the anomalous or extraordinary Hall effect, that has been widely used to verify a single-phase system, may be by itself insufficient to characterize a DMS material. It could also certainly be the case that magnetically active clusters or second phases could be present in a pseudo-random alloy and therefore that several different mechanisms could contribute to the observed magnetic behavior. There is a major opportunity for the application of new, element- and lattice position-specific analysis techniques, such as the various scanning tunneling microscopies and Z-contrast scanning transmission electron microscopy among others for revealing a deeper microscopic understanding of this origin of ferromagnetism in the new DMS materials.

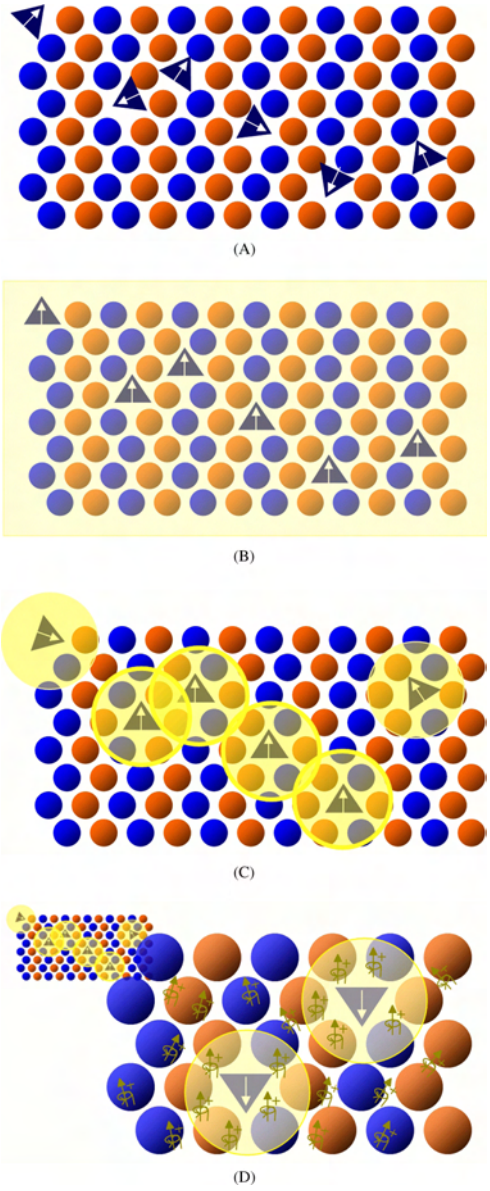

Figure 1. Semiconductor matrix with high concentrations of magnetic impurities (i.e., Mn), randomly distributed (defects), can be insulators (A) for group II–VI materials where divalent Mn ions occupy group II sites. At high concentrations, Mn ions are antiferromagnetically coupled, but at dilute limits, atomic distances between magnetic ions are large, and antiferromagnetic coupling is weak. For the cases where there is high concentrations of carriers (B) [i.e., (Ga,Mn)As where Mn ions behave as acceptors and provide magnetic moment as they occupy trivalent Ga sites], the carriers are thought to mediate ferromagnetic coupling between magnetic ions. Between near insulating and metallic cases, at low carrier regimes, hole carrier concentrations are localized near the magnetic impurity. Below certain temperatures, a percolation network (C) is formed in which clusters of holes are delocalized and hop from site to site, which energetically favors maintaining the carriers' spin orientation during the process, an effective mechanism for aligning Mn moments within the cluster network. Alternatively, at percolation limits, a localized hole near the magnetic impurity is polarized, and the energy of the system is lowered when the polarization of the localized holes are parallel (D).

The mean field approach basically assumes that the ferromagnetism occurs through interactions between the local moments of the Mn atoms, which are mediated by free holes in the material. The spin–spin coupling is also assumed to be a long-range interaction, allowing use of a mean field approximation [80, 83, 84]. In its basic form, this model employs a virtual-crystal approximation to calculate the effective spin density due to the Mn ion distribution. The direct Mn–Mn interactions are antiferromagnetic so that the Curie temperature, T_C, for a given material with a specific Mn concentration and hole density (derived from Mn acceptors and/or intentional shallow level acceptor doping), is determined by a competition between the ferromagnetic and antiferromagnetic interactions. In the presence of carriers, T_C is given by the expression [80, 85]

$$T_C = \lfloor N_O X\text{eff} \cdot S(S+1)\beta^2 A_F P_S(T_C)/12k_B \rfloor - T_{AF}$$

where $N_O X$eff is the effective spin concentration, S is the localized spin state, β is the p–d exchange integral, A_F is the Fermi liquid parameter, P_S is the total density of states, k_B is Boltzmann's constant, and T_{AF} describes the contribution of antiferromagnetic interactions. Numerous refinements of this approach have appeared recently, taking into account the effects of positional disorder [86, 87], indirect exchange interactions [88], spatial inhomogeneities, and free-carrier spin polarization [89, 90]. Figure 2 shows a compilation of the predicted T_C values, together with the classification of the materials (e.g., group IV semiconductors, etc.). In the subsequent period after appearance of the Dietl et al. [80] paper, remarkable progress has been made on the realization of materials with T_C values at or above room temperature.

The mean field model and its variants produces reliable estimates of T_C for materials such as (Ga,Mn)As and (In,Mn)As and predicts that (Ga,Mn)N will have a value above room temperature [80]. Examples of the predicted ferromagnetic transition temperatures for both (Ga,Mn)As and (Ga,Mn)N are shown in Figure 3 for four different variants of the mean field approach [91]. These are the standard mean field theory (T_C^{MF}), a version that accounts for the role of Coulomb interactions with holes in the valence band (exchange-enhanced, T_C^{X}), another version that accounts for correlations in Mn ion orientations (collective, T_C^{coll}), or an estimate based on where excited spin waves cancel out the total spin of the ground state (T_C^{est}) [91]. Note that the dependence of any of the calculated T_C values on hole density in the material is much steeper for (Ga,Mn)As than for (Ga,Mn)N. The range of predicted values for GaAs has a much higher distribution than for GaN. These data emphasize the point that the mean field theories produce fairly reliable predictions for (Ga,Mn)As but at this stage are not very accurate for (Ga,Mn)N.

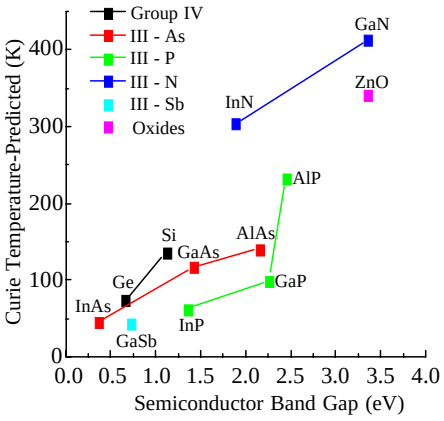

Figure 2. Predicted Curie temperatures as a function of bandgap (after [80]).

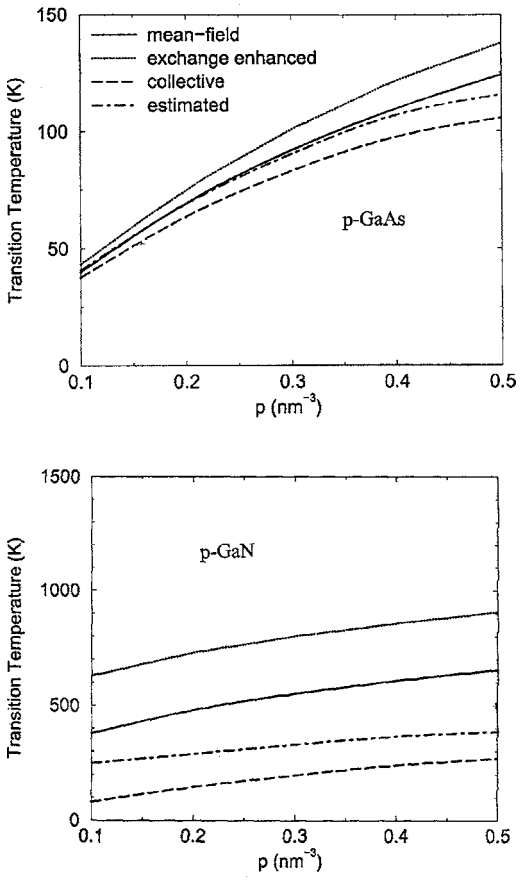

Figure 3. Predicted ferromagnetic transition temperatures in (Ga,Mn)As (left) or (Ga,Mn)N containing 5 at.% Mn, as a function of hole density. The four different curves in each graph represent results obtained from different variants of mean field theory (after [91]).

A second point largely overlooked in the theoretical work to date is that fact that the assumed hole densities may not be realistic. While GaAs can be readily doped with shallow acceptors such as C to produce hole densities of around 10^{21} cm^{-3} [92] and the Mn acceptors also contribute holes, the p-doping levels in GaN are limited to much lower values under normal conditions. For example, the ionization level (E_a) of the most common acceptor dopant in GaN, namely Mg, is relatively deep in the gap ($E_V + 0.17$ eV). Since the number of holes (P) is determined by the fraction of acceptors that are actually ionized at a given temperature T through a Boltzmann factor

$$P \propto \exp(-E_a/kT)$$

then for Mg at room temperature only a few percent of acceptors are ionized. While the Mg acceptor concentration in GaN can exceed 10^{19} cm^{-3}, a typical hole concentration at 25 °C is $P \sim 3 \times 10^{17}$ cm^{-3}. Initial reports of the energy level of Mn in GaN show it is very deep in the gap, $E_v + 1.4$ eV [93] and thus would be an ineffective dopant under most conditions. Some strategies for enhancing the hole concentration do exist, such as co-doping both acceptors and donors to reduce self-compensation effects [94] or the use of selectively doped AlGaN/GaN superlattices in which there is transfer of free holes from Mg acceptors in the AlGaN barriers to the GaN quantum wells [95]. These methods appear capable under optimum conditions of increasing the hole density in GaN to $>10^{18}$ cm^{-3} at 25 °C.

A further issue that needs additional exploration in the theories is the role of electrons, rather than holes, in stabilizing the ferromagnetism in DMS materials. All of the reports of ferromagnetism in (Ga,Mn)N, for example, occur for material that is actually *n*-type. Since the material has to be grown at relatively low temperatures to avoid Mn precipitation and therefore only MBE can be used, there is always the possibility of unintentional *n*-type doping from nitrogen vacancies, residual lattice defects, or impurities such as oxygen. Therefore stoichiometry effects, crystal defects, or unintentional impurities may control the final conductivity, rather than Mn or the intentionally introduced acceptor dopants. Once again, this is much less of an issue in materials such as GaAs, whose low temperature growth is relatively well understood and controlled.

While most of the theoretical work for DMS materials has focused on the use of Mn as the magnetic dopant, there has been some progress on identifying other transition metal atoms that may be effective. Figure 4 shows the predicted stability of ferromagnetic states in GaN doped with different 3*d* transition metal atoms [96]. The results are based on a local spin-density approximation which assumed that Ga atoms were randomly substituted with the magnetic atoms and did not take into account any additional carrier doping effects. In this study it was found that (Ga,V)N and (Ga,Cr)N showed stable ferromagnetism for all transition metal concentrations whereas Fe, Co, or Ni doping produced spin-glass ground states [96]. For the case of Mn, the ferromagnetic state was the lowest energy state for concentrations up to ~20% , whereas the spin-glass state became the most stable at higher Mn concentrations.

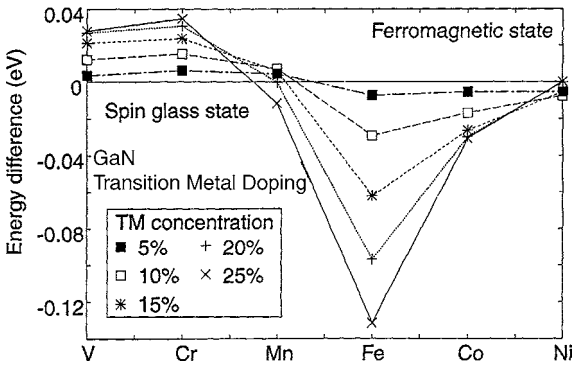

Figure 4. Predicted stability of the ferromagnetic states of different transition metal (TM) atoms in GaN as a function of transition metal concentration. The vertical axis represents the energy difference between the ferromagnetic and spin-glass states for each metal atom (after [96]).

4. EXPERIMENTAL RESULTS

4.1. (Ga,Mn)P

Ferromagnetism above room temperature in (Ga,Mn)P has been reported for two different methods of Mn incorporation, namely ion implantation [97] and doping during MBE growth [97, 98]. The implantation process is an efficient one for rapidly screening whether particular combinations of magnetic dopants and host semiconductors are promising in terms of ferromagnetic properties. We have used implantation to introduce ions such as Mn, Fe, and Ni into a variety of substrates, including GaN, SiC, and GaP

The temperature-dependent magnetization of a strongly *p*-type ($p \sim 10^{20}$), carbon-doped GaP sample implanted with ~6 at.% of Mn and then annealed at 700 °C is shown in Figure 5. The diamagnetic contribution was subtracted from the background. A Curie temperature (T_C) of ~270 K is indicated by the dashed vertical line, while the inset shows a ferromagnetic Curie temperature of 236 K.

Examples of hysteresis loops from MBE grown samples are shown in Figure 6. The hysteresis could be detected to 330 K. No secondary phases (such as MnGa or MnP) or clusters were determined by transmission electron microscopy, X-ray diffraction, or selected-area diffraction pattern analysis.

While mean-field theories predict relatively low Curie temperatures (<110 K) for (Ga,Mn)P [97, 98], recent experiments show ferromagnetism above 300 K [97, 98]. In other respects, the magnetic behavior of the (Ga,Mn)P was consistent with mean-field predictions. For example, the magnetization versus temperature plots showed a more classical concave shape than observed with many DMS materials.

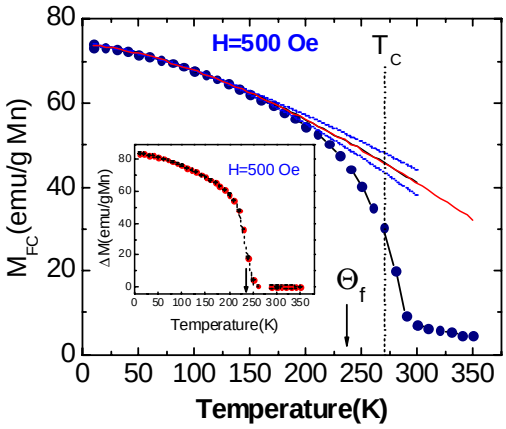

Figure 5. Field-cooled magnetization of (Ga,Mn)P as a function of temperature. The solid line shows a Bloch law dependence, while the dashed lines are 95% confidence bands. The vertical dashed line at $T_C = 270$ K is the field-independent inflection point and the vertical arrows in the main panel and inset mask to ferromagnetic Curie temperature Θ_f. The inset shows the temperature dependence of difference in magnetization between field-cooled and zero-field-cooled conditions.

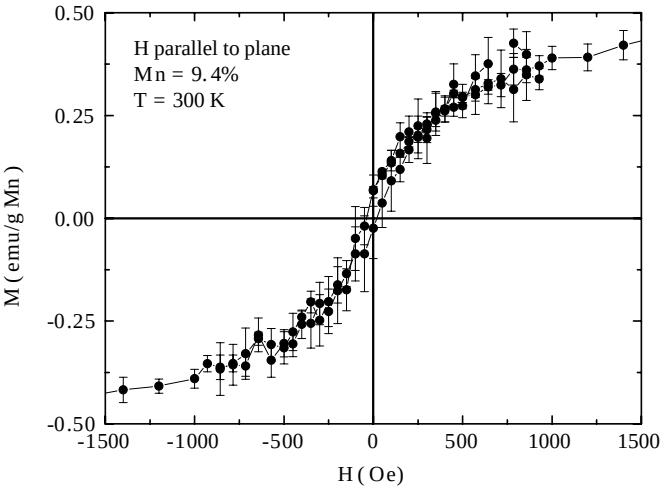

Figure 6. Magnetization versus field for MBE grown (Ga,Mn)P with 9.4 at.% Mn.

In addition, the Curie temperature was strongly influenced by the carrier density and type in the material, with highly *p*-type samples showing much higher values than *n*-type or undoped samples. Finally, the Curie temperature increased with Mn concentration up to ~6 at.% and decreased at higher concentrations [98]. No secondary phases or clusters could be detected by transmission electron microscopy, X-ray diffraction, or selected-area diffraction patterns. Similar results were achieved in samples in which the Mn was incorporated during MBE growth or directly implanted with Mn.

GaP is a particularly attractive host material for spintronic applications because it is almost lattice-matched to Si. One can therefore envision integration of (Ga,Mn)P spintronic magnetic sensors or data storage elements to form fast nonvolatile magnetic random access memories. Although it has an indirect bandgap, it can be made to luminescence through addition of isoelectric dopants such as nitrogen or else one could employ the direct bandgap ternary InGaP, which is lattice-matched to GaAs. The quaternary InGaAlP materials system is used for visible light-emitting diodes, laser diodes, heterojunction bipolar transistors, and high electron mobility transistors. An immediate application of the DMS counterparts to the component binary and ternary materials in this system would be to add spin functionality to all of these devices. A further advantage to the wide bandgap phosphides is that they exhibit room temperature ferromagnetism even for relatively high growth temperatures during MBE.

Obviously, the Mn can also be incorporated during MBE growth of the (Ga,Mn)P. The *p*-type doping level can be separately controlled by incorporating carbon from a CBr_4 source while P is obtained from thermal cracking of PH_3. A phase diagram for the epi growth of this materials system has been developed and this can be used to tailor the magnetic properties of the (Ga,Mn)P. For samples grown at 600 °C with 9.4 at.% Mn, hysteresis is still detectable at 300 K, with a coercive field of ~39 Oe.

4.2. (Ga,Mn)N

The initial work on this material involved either microcrystals synthesized by nitridization of pure metallic Ga in supercritical ammonia or bulk crystals grown in reactions of Ga/Mn alloys on GaN/Mn mixtures with ammonia at ~1200 °C [99]. These samples exhibit paramagnetic properties over a broad range of Mn concentrations, as did some of its early MBE-grown films. By contrast, Figure 7 shows room temperature ferromagnetism from more recent *n*-type (Ga,Mn)N samples.

The first reports of the magnetic properties of (Ga,Mn)N involved bulk microcrystallites grown at high temperatures (~1200 °C), but while percent levels of Mn were incorporated, the samples exhibited paramagnetic behavior [99]. By sharp contrast, in epitaxial GaN layers grown on sapphire substrates and then subjected to solid state diffusion of Mn at temperatures from 250 to 800 °C for various periods, clear signatures of room temperature ferromagnetism were observed [100, 101]. Figure 8 shows anomalous Hall effect data (left) at 323 K and the temperature dependence of sheet resistance at zero applied field for two different Mn-diffused samples and an undoped GaN control sample (right) [101]. The Curie temperature was found to be in the range 220–370 K, depending on the diffusion conditions. The use of ion implantation to introduce the Mn produced lower magnetic ordering temperatures [102].

In (Ga,Mn)N films grown by MBE at temperatures between 580 and 720 °C with Mn contents of 6–9 at.%, magnetization (M) versus magnetic field (H) curves showed clear hysteresis at 300 K, with coercivities of 52–85 Oe and residual magnetizations of 0.08–0.77 emu/g at this

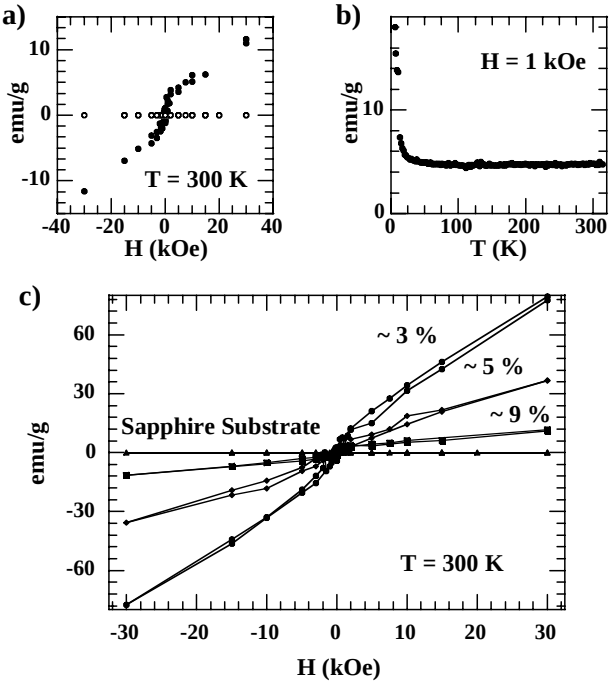

Figure 7. (a) B–H from MBE grown (Ga,Mn)N with 9.4 at.% Mn (closed circles) and from sapphire substrate (upper circles), (b) M–T of (Ga,Mn)N, (c) B–H from (Ga,Mn)N as a function of Mn concentration.

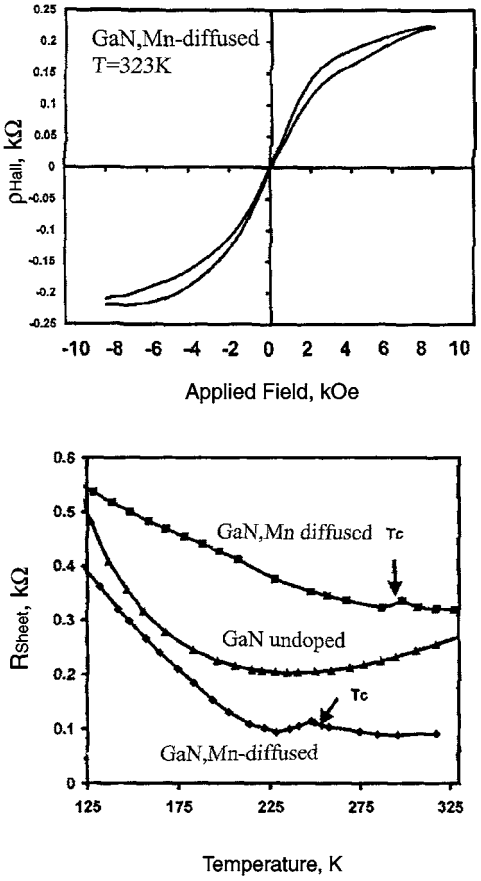

Figure 8. Temperature dependence of sheet resistance at zero magnetic field for Mn-diffused GaN and as-grown GaN (bottom) and room temperature anomalous Hall effect hysteresis curves for Mn-diffused GaN (top) (after [101]).

temperature [103]. Figure 9 shows the temperature dependence of the magnetization for a sample with 9 at.% Mn, yielding an estimated T_C of 940 K using a mean field approximation. Note that while the electrical properties of the samples were not measured, they were almost certainly *n*-type.

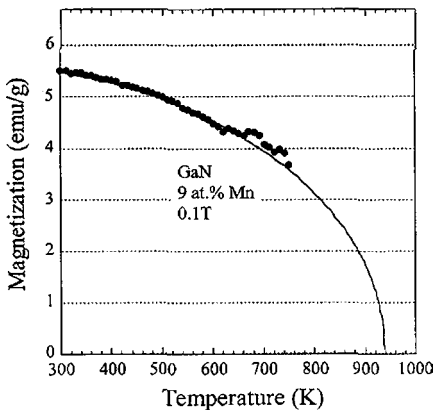

Figure 9. Magnetization versus temperature for (Ga,Mn)N sample grown by MBE with ~9 at.% Mn. The extrapolation of the curve is based on a mean field approximation (after [103]).

As we discussed above, it is difficult to obtain high Curie temperatures in *n*-type DMS materials according to the mean-field theories and this is something that needs to be addressed in future refinements of these theories. Room temperature ferromagnetism in *n*-type (Ga,Mn)N grown by MBE has also been reported by Thaler et al. [104]. In that case, strenuous efforts were made to exclude any possible contribution from the sample holder in the SQUID magnetometer or other spurious effects. It is also worthwhile to point out that for the studies of (Ga,Mn)N showing ferromagnetic ordering by magnetization measurements, a number of materials characterization techniques did not show the presence of any second ferromagnetic phases within detectable limits. In addition, the values of the measured coercivities are relatively small. If indeed there were undetectable amounts of nanosized clusters, due to geometrical effects, the expected fields at which these clusters would switch magnetically would be expected to be much larger than what has been observed. EXAFS measurements performed on (Ga,Mn)N samples grown by MBE on sapphire at temperatures of 400–650 °C with Mn concentrations of $\sim 7 \times 10^{20}$ cm^{-3} (i.e., slightly over 2 at.%) are shown in Figure 10 [105]. The similarity of the experimental data with simulated curves for a sample containing this concentration of Mn substituted for Ga on substitutional lattice positions indicates that Mn is in fact soluble at these densities. In the samples grown at 650 °C, $\leq$1 at.% of the total amount of Mn was found to be present as Mn clusters. However, at lower growth temperatures (400 °C), the amount of Mn that could be present as clusters increased up to ~36 at.% of the total Mn incorporated. The ionic state of the substitutional Mn was found to be primarily Mn(2), so that these impurities act as acceptors when substituting for the Ga with valence three. However, when the electrical properties of these samples were measured, they were found to be resistive [105]. This result emphasizes how much more needs to

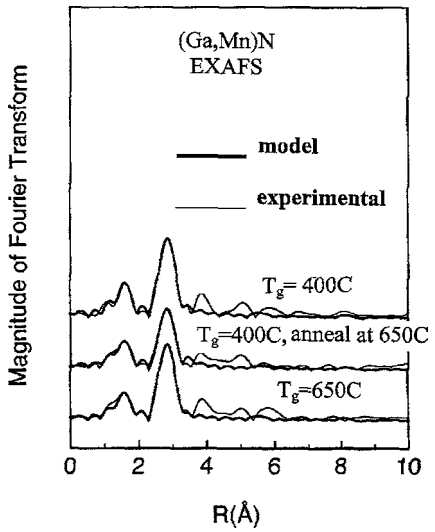

Figure 10. Fourier transforms of the Mn *K*-edge EXAFS data from Mn-doped (GaMn)N. The fine lines are the experimental data in these curves, while the course lines are the calculated curves assuming 2 at.% of Mn in the GaN (after [105]).

be understood concerning the effects of compensation and unintentional doping of (Ga,Mn)N, since the EXAFS data indicated the samples should have shown very high *p*-type conductivity due to incorporation of Mn acceptors.

Other reports have also recently appeared on the magnetic properties of GaN doped with other transition metal impurities. For initially *p*-type samples directly implanted with either Fe or Ni, ferromagnetism was observed at temperatures of ~200 [106] and 50 K [107], respectively. (Ga,Fe)N films grown by MBE showed Curie temperatures of ≤100 K, with EXAFS data showing that the majority of the Fe was substitutional on Ga sites [108]. (Ga,Cr)N layers grown in a similar fashion at 700 °C on sapphire substrates showed single-phase behavior, clear hysteresis and saturation of magnetization at 300 K, and a Curie temperature exceeding 400 K [109].

Epi growth of (Ga,Mn)N has produced a range of growth conditions producing single-phase material and the resulting magnetic properties [100–107]. In general, no second phases are found for Mn levels below ~10% for growth temperatures of ~750 °C. The (Ga,Mn)N retains *n*-type conductivity under these conditions.

In accordance with most of the theoretical predictions, magnetotransport data showed the anomalous Hall effect, negative magnetoresistance, and magnetic resistance at temperatures that were dependent on the Mn concentration. For example, in films with very low (<1%) or very high (~9%) Mn concentrations, the Curie temperatures were between 10 and 25 K. An example is shown in Figure 7 for an *n*-type (Ga,Mn)N sample with Mn ~7%. The sheet resistance shows negative magnetoresistance below 150 K, with the anomalous Hall coefficient disappearing below 25 K. When the Mn concentration was decreased to 3 at.%, the (Ga,Mn)N showed the highest degree of ordering per Mn atom [104]. Figure 7a shows hysteresis present at 300 K, while the magnetization as a function of temperature is shown in Figure 7b. Data from samples with different Mn concentrations are shown in Figure 7c and indicate ferromagnetic coupling, leading to a lower moment per Mn. Data from field-cooled and zero-field—cooled conditions were further suggestive of room temperature magnetization [104]. The significance of these results is that there are many advantages from a device viewpoint to having *n*-type ferromagnetic semiconductors.

The local structure and effective chemical valency of Mn in MBE-grown (Ga,Mn)N samples has been investigated by EXAFS [105]. It was concluded that most of the Mn was incorporated substitutionally on the Ga sublattice with effective valency close to +2 for samples with ~2 at.% Mn [105]. There was also evidence that a fraction (from 1% to 36%, depending on growth condition) of the total Mn concentration could be present as small Mn clusters [105].

4.3. Chalcopyrite Materials

The chalcopyrite semiconductors are of interest for a number of applications. For example, $ZnGeP_2$ exhibits unusual nonlinear optical properties and can be used in optical oscillators and frequency converters. $ZnSnAs_2$ shows promise for far-IR generation and frequency converters. The wide bandgap chalcopyrites $ZnGeN_2$ and $ZnSiN_2$ have lattice parameters close to GaN and SiC, respectively, and the achievement of ferromagnetism in these materials would make it possible for direct integration of magnetic sensors and switches with blue/green/ultraviolet (UV) lasers and light-emitting diodes, UV solar-blind detectors, and microwave power electronic devices fabricated in the GaN and SiC. The bandgap of $ZnGe_xSi_{1-x}N_2$ varies linearly with composition from 3.2 ($x = 1$) to 4.46 eV ($x = 0$).

Numerous reports of room temperature ferromagnetism in Mn-doped chalcopyrites have appeared. A compilation of these results and those from transition metal doped GaN and GaP are shown in Table 1. The $ZnSnAs_2$ is somewhat of an anomaly due to its small bandgap, but little theory is available at this point on the chalcopyrites and their expected magnetic properties as a function of bandgap, doping, or Mn concentration. In the only case in which electrical properties were reported, the $ZnGeSiN_2$:Mn was *n*-type [110]. There is also no information available on the energy level of Mn in the bandgap.

Table 1. Compilation of semiconductors exhibiting room temperature ferromagnetism.

Material	Bandgap (eV)	Synthesis	T_C(K)	Ref.
$Cd_{1-x}Mn_xGeP_2$	1.72	Solid-phase reaction of evap. Mn	>300	[74]
(Ga,Mn)N	3.4	Mn incorporated by diff^n	228–370	[100, 101]
(Ga,Mn)N	3.4	Mn incorporated during MBE; n-type	>300	104
(Ga,Mn)N	3.4	Mn incorporated during MBE	940	[103]
(Ga,Cr)N	3.4	Cr incorporated during MBE	>400	[109]
(Ga,Mn)P:C	2.2	Mn incorporated by implant or MBE; p ~10^{20} cm^{-3}	>330	[97, 98]
$(Zn_{1-x}Mn_x)GeP_2$	1.83–2.8	Sealed ampule growth; insulating; 5.6% Mn	312	[74]
$(ZnMn)GeP_2$	<2.8	Mn incorporated by diff.	350K	[75]
$ZnSnAs_2$	0.65	Bridgman bulk growth	329K	[76]
$ZnSiGeN_2$	3.52	Mn-implanted epi	~300	[106]

Note: Extrapolated from measurements up to ~750 K.

5. POTENTIAL DEVICE APPLICATIONS

Previous articles have discussed some spintronic device concepts such as spin junction diodes and solar cells [9], optical isolators, and electrically controlled ferromagnets [10]. The realization of light-emitting diodes with a degree of polarized output has been used to measure spin injection efficiency in heterostructures [111–113]. Such structures can reveal much about spin transport through heterointerfaces after realistic device processing schemes involving etching, annealing, and metallization. The spin transfer in such situations has proven surprisingly robust [114]. It is obviously desirable that spintronic devices are operable at or above room temperature. As an initial demonstration that (Ga,Mn)N layers can be used as the *n*-type injection layer in GaN/InGaN blue light-emitting diodes (LEDs), Figure 11 shows the LED during operation (top) and the spectral output (left). It is necessary to next establish the extent of any degree of polarization of the light emission, which might be difficult to observe in GaN/InGaN LEDs, since it has been shown that the free exciton components in the electroluminescence spectrum contribute mostly to the observed circular polarization of the emitted light [115]. While the expected advantages of spin-based devices include nonvolatility, higher integration densities, lower power operation, and higher switching speeds, there are many factors still to consider in whether any of these can be realized. These factors include whether the signal sizes due to spin effects are large enough at room temperature to justify the extra development work needed to make spintronic devices and whether the expected added functionality possible will materialize.

In addition to active and/or optical devices, wide bandgap DMS materials may also be used as passive devices. LeClair et al. [116] have recently shown an artificial half-metallic structure by using a polycrystalline sputtered ferromagnetic semiconductor (EuS) as a tunneling barrier. This barrier can function as an effective spin filter, since a tunneling electron encounters a differing barrier height depending on its spin below T_c of the barrier material (for EuS, T_C ~16.8 K). At low temperatures, the spin-filtering efficiencies were found to be ~90%. Room temperature DMS materials for these spin-filtering effects could be used to increase magnetoresistance changes in current magnetic tunnel junctions and metallic spin-valve structures.

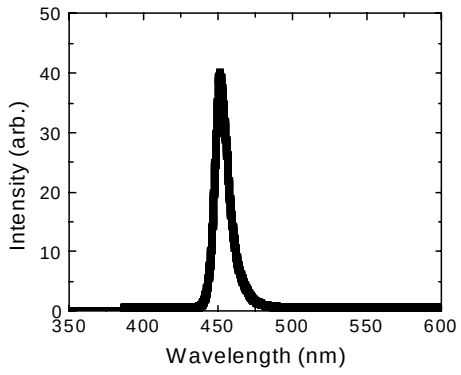

Figure 11. Spectral output from GaMnN/InGaN light-emitting diode.

6. ISSUES TO BE RESOLVED

As described earlier, there are a number of existing models for the observed ferromagnetism in semiconductors. The near-field models consider the ferromagnetism to be mediated by delocalized or weakly localized holes in the *p*-type materials. The magnetic Mn ion provides a localized spin and acts as an acceptor in most III–V semiconductors so that it can also provide holes. In these models, the T_C is proportional to the density of Mn ions and the hole density. Many aspects of the experimental data can be explained by the basic mean field model. However, ferromagnetism has been observed in samples that have very low hole concentrations, in insulating material, and more recently in *n*-type material. Models in these regimes are starting to appear [117].

An alternative approach using local density functional calculations suggests that the magnetic impurities may form small nanosize clusters that produce the observed ferromagnetism [82]. These clusters would be difficult to detect by most characterization techniques. Clearly there is a need to more fully characterize the materials showing room temperature ferromagnetism and correlate these results to establish on a case-by-case basis which is the operative mechanism and also to refine the theories based on experimental input. More work is also needed to establish the energy levels of the Mn, whether there are more effective magnetic dopant atoms, and how the magnetic properties are influenced by carrier density and type. Even basic measurements such as how the bandgap changes with Mn concentration in GaN and GaP have not been performed. The control of spin injection and manipulation of spin transport by external means such as voltage from a gate contact or magnetic fields from adjacent current lines or ferromagnetic contacts is at the heart of whether spintronics can be exploited in device structures, and these areas are still in their infancy. A concerted effort on the physics and materials science of the new dilute magnetic semiconductors is underway in many groups around the world, but fresh insights, theories, and characterization methods would greatly accelerate the process.

GLOSSARY

Dilute magnetic semiconductor A semiconductor in which some of the lattice atoms are replaced by magnetic ions, leading of ferromagnetism.

GaMnN Gallium nitride doped with a high concentration (a few percent) of Mn, to induce ferromagnetism.

Spin-fets A field effect transistor in which the spin of the electron is used to control the current flow.

Spin-led A light-emitting diode, in which at least one side of the junction is doped with Mn to produce polarized carriers, leading to polarized light emission.

Spintronics Spin transfer electronics.

Nanoscale Heat Transfer

G. Chen, D. Borca-Tasciuc, R. G. Yang

Massachusetts Institute of Technology, Cambridge, Massachusetts, USA

CONTENTS

1. INTRODUCTION

Heat transfer at nanoscale is of importance for many nanotechnology applications [1, 2]. There are typically two types of problems. One is the management of heat generated in nanoscale devices to maintain the functionality and reliability of these devices. The other is to utilize nanostructures to manipulate the heat flow and energy conversion. Examples of the thermal management of nanodevices are the heating issues in integrated circuits [3] and in semiconductor lasers [4]. Examples in the manipulation of heat flow and energy conversion include nanostructures for thermoelectric energy conversion [5, 6], thermophotovoltaic power generation [7], and data storage [8].

Heat transfer at nanoscale may differ significantly from that in macro- and microscales. With device or structure characteristic length scales becoming comparable to the mean free path and wavelength of heat carriers (electrons, photons, phonons, and molecules), classical laws are no longer valid and new approaches must be taken to predict heat transfer at nanoscale [9, 10]. Well-known examples are the failure of Fourier law to predict the thermal conductivity of composite nanostructures such as superlattices [11, 12] and the failure of the Stefan–Boltzmann law in predicting radiation heat transfer across small gaps [13, 14]. Although much has been done in this area recently, there is still an immediate need for a better understanding of thermal phenomena in nanostructures. In addition, learning to control and manipulate heat carriers in small structures may open new paths for discovery of innovative applications.

In this chapter, we review the status and progress of theoretical and experimental investigations of thermal transport phenomena in nanostructures. In Section 2, we discuss different regimes of nanoscale heat transfer and various nanoscale heat transfer phenomena. Section 3 gives a few examples that illustrate the impacts of nanoscale thermal phenomena on modern technologies. Section 4 describes several experimental techniques developed for thermal characterization of nanostructures. Section 5 summarizes modeling tools for nanoscale heat transfer, followed by a summary of this chapter.

2. FUNDAMENTALS OF HEAT TRANSPORT AT NANOSCALE

Macroscale heat transfer is often divided into three modes: conduction, convection, and radiation [15]. Heat transfer problems are solved based on the conservation laws (mass, momentum, and energy) in combination with the constitutive equations between heat flux and temperature (or temperature gradient), for example, the Fourier law of heat conduction and the Stefan–Boltzmann law for blackbody thermal radiation,

$$q = -k\nabla T \quad \text{(Fourier law)}$$
$$q = \sigma T^4 \quad \text{(Stefan–Boltzmann law)} \tag{1}$$

where k is the thermal conductivity and σ is the Stefan–Boltzmann constant (5.67×10^{-8} W/m^2 K^4). Some distinct characteristics of heat transfer at macroscale are:

1. The Fourier law is a diffusion equation while thermal radiation between two objects separated by a nonabsorbing (or weakly absorbing) medium is ballistic.
2. Thermal conductivity is a material property which may depend on the detailed microstructure of the material but is independent of the size of the material.
3. The maximum thermal radiation heat transfer between any objects is limited by the blackbody radiation.
4. In convection, the fluid in contact with the solid assumes the same velocity and temperature as the solid at the point of contact, the so-called no-slip condition.

For heat transfer in nanostructures, some of these characteristics for macroscale heat transfer disappear. For example, heat conduction can be ballistic and similar to thermal

Volume 7: Pages (429–459)

radiation; thermal conductivity is no longer a material property; thermal radiation can be larger than the blackbody radiation; and the slip of molecules at fluid–solid interface must be considered. To understand why and when these happen, one needs to examine carefully the microscopic pictures of the heat carriers including molecules, electrons, photons, phonons (quantized lattice vibrations), or their hybrid states such as plasmons and phonon–polaritons [16, 17]. Table 1 shows some elementary properties of electrons, phonons, photons, and molecules. We will start with a discussion of the characteristic lengths of some of these energy carriers. From such a discussion, different transport regimes can be distinguished [4, 9, 10].

2.1. Characteristic Lengths and Heat Transfer Regimes

From quantum mechanics, the energy carriers have both wave and particle characteristics. At macroscale, wave phenomena such as interference and tunneling usually do not appear and we often treat the energy carriers as particles. At nanoscale, however, wave effects become important and even dominant in some cases. A key question is when one should start to consider the wave characteristics. There are a few important characteristic length and time scales that determine the answer to this question, including the mean free path, the phase coherence length, the wavelength, and the thermal (de Broglie) wavelength, which we will explain.

The mean free path is the average distance that energy carriers travel between successive collisions, such as the phonon–phonon collision in a dielectric material and the electron–phonon collision in a conductor or semiconductor. The corresponding average time between successive collisions is the relaxation time. Direct calculation of the mean free path is generally difficult, particularly for electron and phonon transports in solid. The kinetic theories and experimental conductivity data are often used to estimate the mean free path. For example, the thermal conductivities of gases, metals, and semiconductors or dielectrics can be expressed as [16–19]

$$k = \frac{1}{3} C v^2 \tau = \frac{1}{3} C v \Lambda \qquad \text{(gases)} \tag{2}$$

$$k = \frac{\pi^2 n \kappa_B^2 T}{m v_F} \Lambda \qquad \text{(electrons in metals)} \tag{3}$$

$$k = \frac{1}{3}\int_0^{\omega_{\max}} C_\omega v_\omega^2 \tau_\omega \, d\omega = \frac{\Lambda}{3}\int_0^{\omega_{\max}} C_\omega v_\omega \, d\omega \qquad \text{(phonons)} \tag{4}$$

where C is the volumetric specific heat (i.e., the specific heat per unit volume), τ is the relaxation time, v is the velocity of carriers, m is the electron mass, n is the electron number density, and v_F is the electron velocity at the Fermi surface. The integration in Eq. (4) is over all the phonon frequency and correspondingly, C_ω, v_ω, and τ_ω are the volumetric specific heat, the velocity, and the relaxation time at each frequency, respectively. This distinction is necessary because phonons are highly dispersive. If Eq. (2) is used to estimate the phonon mean free path, using the measured specific heat and the speed of sound, the mean free path can be an order of magnitude lower than that based on Eq. (4) [20–22]. In Figure 1, we show the mean free path in representative media. Also shown in this figure is an example of the phonon mean free path in silicon estimated based on Eq. (2), using the reported data on specific heat and the speed of sound, which is an order of magnitude shorter than that estimated from considering the phonon dispersion.

The phase of a wave can be destroyed during collision, which is typically the case in inelastic scattering processes, such as the electron–phonon collision and phonon–phonon collision. An inelastic scattering process is the one that involves the energy exchange between carriers. If the phase destroying scattering process occurs frequently inside the medium, the wave characteristic of carriers can be ignored and the transport falls into the diffusion regime. The measure for the phase destroying scattering events is called the phase coherence length and, for electron transport, the Thouless length [23]. Not all the scattering processes, however, destroy the phase. Elastic scattering processes such as scattering of photons by particulates and the scattering of electrons by impurities do not destroy phase. Thus, the phase coherence length is usually longer than the mean free path but is not much longer, particularly at room temperatures for electrons and phonons. Therefore we can treat them as having the same order of magnitude.

Thus, one necessary condition for the inclusion of the wave effects is that the mean free path should be comparable to or larger than the structure characteristic length, such as the thickness of a film or the diameter of a wire. This condition, however, is not sufficient for actually observing the wave effects because of three additional factors, (1) the interface scattering processes, (2) the wavelength of the carriers, and (3) the spectrum of the carriers, as will be explained.

When the wave meets an interface, it will be scattered. The most familiar example is the reflection and refraction of optical waves [24]. Electron waves and phonon waves

Table 1. Basic characteristics of energy carriers.

	Electrons	Phonons	Photons	Molecules
Propagation media	in vacuum or media	in media	in vacuum or media	in vacuum or media
Statistics	Fermi–Dirac	Bose–Einstein	Bose–Einstein	Boltzman
Frequency	0–infinite	0–Debyte cutoff	0–infinite	0–infinite
Wavelength at 300 K (nm)	~10	~1	$\sim 10^5$	~0.1
Velocity at 300 K (m/s)	$\sim 10^6$	$\sim 10^3$	$\sim 10^8$	$\sim 10^2$

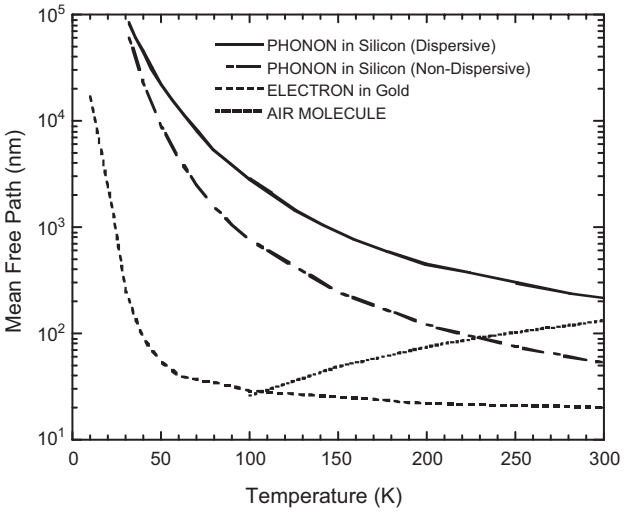

Figure 1. Mean free path for representative energy carriers.

have similar processes. For a flat interface, the phases and directions of the refracted and reflected waves are fixed relative to the incident waves. These processes thus do not destroy the phases. Periodic interface corrugations, such as surface gratings, are another example for which the incident and outgoing waves have clear fixed phase relations. Rough interfaces, however, are more complicated. If the detailed interface roughness structures are known and if the interface interaction is elastic, the directions of the reflected and refracted waves can in principle be determined from, for example, solving the Maxwell equations for photons and the Schrödinger equation for electrons and phonons. In reality, this is rarely possible and rough interface scattering is often assumed to diffuse (i.e., the reflected and transmitted waves are isotropically distributed into all directions). Often, the accompanying assumption is that the relationship between the phases of the reflected, transmitted, and incident wave is lost (i.e., the scattering is phase randomizing). Such an assumption cannot be justified easily but appears to be true in many transport processes, particularly for phonons and photons. Clearly, in addition to elastic scattering, inelastic scattering can be also strong at the interfaces and such scattering processes are phase breaking. Thus, the interface scattering can be approximated as phase breaking if the interface is rough and as phase preserving if it is smooth. Whether an interface is rough or smooth depends on the average roughness, δ, compared to the wavelength λ. For example, an approximate expression for the fraction of specular scattered phonons at an interface is [19]

$$p = \exp\left(-\frac{16\pi^3\delta^2}{\lambda^2}\right) \tag{5}$$

From this expression, we can approximately take

$$\frac{\delta}{\lambda}\begin{cases} \gg 0.1 & \text{(Rough)} \\ \ll 0.1 & \text{(Smooth)} \end{cases} \tag{6}$$

Based on the previous discussion, if the interface scattering is diffuse, the wave aspects of energy carriers can be neglected. If the interface scattering processes preserve the phase relations, coherent waves may be established over the transport domain. Even under such situations, however, wave effects may still be unobservable. There are two additional factors that one should consider. One is the wavelength of the energy carriers and the other is the thermal spread in their wavelengths.

Heat transfer usually involves a wide spectrum of energy carriers, as summarized in Table 1. However, not all the energy carriers spanning such a wide range of wavelength contribute equally to the thermal transport. The actual probability of excitation for a specific quantum mechanical state depends on the energy of the state and the temperature of the object as governed by the Fermi–Dirac distribution for electrons and the Bose–Einstein distribution for phonons and photons. The blackbody radiation is a well-known example, with the emissive power peaks at

$$\lambda T = 2898\ \mu\text{m}\cdot\text{K} \tag{7}$$

which is known as the Wien displacement law [25].

We can estimate the order of magnitude of the average wavelength of the energy carriers, λ_t, by assuming the average energy of one quantum state is $\kappa_B T/2$, where $\kappa_B (= 1.38 \times 10^{-23}$ J/K) is the Boltzmann constant and calculating the corresponding wavelength from the de Broglie relation, $\lambda = h/p$, for material waves or from the Planck relation $E = h\nu$ for phonons and photons, where $h (= 6.6 \times 10^{-34}$ J·s) is the Planck constant, p is the momentum, and ν is the frequency. This leads to

$$\lambda_t = \frac{h}{\sqrt{3m\kappa_B T}} \qquad \text{(for electrons or molecules)} \tag{8}$$

$$\lambda_t = \frac{2h\nu}{\kappa_B T} \qquad \text{(for photons and phonons)} \tag{9}$$

where v is the speed of carriers. Equations (8) and (9) are also close to the thermal de Broglie wavelength but, for accuracy, we will just call it the thermal wavelength. Figure 2 plots the wavelength as a function of temperature for these

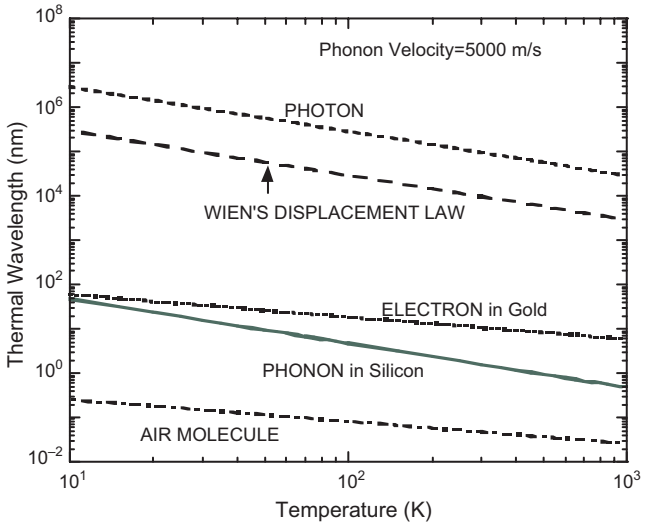

Figure 2. Thermal wavelength for representative energy carriers.

carriers with representative mass and velocity values. We also plotted the Wien displacement law. At room temperature, the wavelength orders of magnitudes are 1 Å for molecules, 10 Å for phonons, 100 Å for electrons, and 100 μm for photons.

In addition to the thermal wavelength, we should also consider the spread in energy and wavelength of the carriers. The superposition of waves forms wave packets that travel at the group velocity. In optics, the width of the wave packets is called the coherence length and is of the order of [24]

$$l_c \approx \frac{c}{\Delta\nu} \tag{10}$$

where c is the speed of light and $\Delta\nu$ is bandwidth of the radiation. This terminology will not be used here to avoid the confusion with the phase coherence length we discussed earlier. For thermal transport, the spread in thermal energy is also of the order of $\kappa_B T$. Thus, the wave packet width of the thermally excited energy carriers is of the same order of magnitude as the thermal wavelength, although a different definition can give some different results, particularly for thermal radiation [21, 26]. In the following, we will use the thermal wavelength as a measure of the wave packet size.

Because of the spread in the wavelengths of the energy carriers, the wave effects maybe smeared out and unobservable. The best example is the Young interference experiments of light passing through two slits. When the slit separation is small, interference is observable. In the opposite limit, the effect is unobservable. In this case, interference for each spectrum in the wave packet still occurs but is smeared out due to the superposition of the interference patterns of different wavelengths. In Figure 3, we show the optical transmittance of a film as a function of the nondimensional thickness (defined as the thickness parameter) obtained based on three different approaches: (1) integration of the electromagnetic wave solution over the incident spectrum, (2) optical coherence theory, and (3) ray tracing (geometrical optics) that neglects the wave effects [27]. One can see that the wave solution eventually approaches the ray-tracing approach as the film becomes much thicker than the wavelength. Thus, in the thick film limit, although consideration of the phase of the waves can lead to the correct end result, such a consideration may be unnecessary.

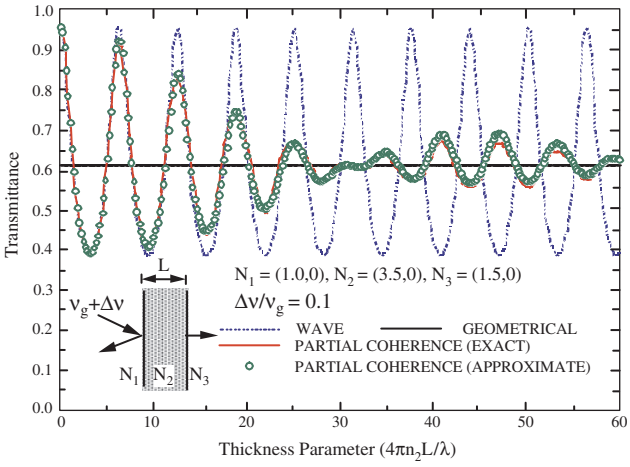

Figure 3. Transmittance of a film as a function of nondimensional thickness for a polychromatic incident wave with spectral width $\Delta\nu$ and central frequency at ν_g, calculated from three different methods, the ray tracing method (or geometrical optics) that neglects the phases of the waves, the wave method, and the partial coherence theory formulation, both including the phases of the waves. These results show that as the film becomes thicker, the wave results approach the ray tracing results. Reprinted with permission from [27], G. Chen and C. L. Tien, *Trans. ASME, J. Heat Transf.* 114, 636 (1992). © 1992, American Society of Mechanical Engineers.

Based on this discussion, we see that if the structure size is much smaller than the thermal wavelength, and if the interface scattering processes do not break the phases, the wave effects are distinct and one is likely to observe such effects as interference and diffraction. However, if the interface scattering preserves the phase but the structure is much larger than the thermal wavelength, wave effects can be obscured and not distinct. Under such conditions, as an approximation, some transport problems can be treated without considering the phase information of the energy carriers. We should emphasize, however, that this approximation is not always true. As an example of the failure of the previous approximation, we consider the acoustic wave transmission through a periodic thin film structure (i.e., a superlattice). The transmissivity was calculated with two methods, the acoustic wave transfer matrix method that includes the phases of the waves and the ray-tracing method that does not include the phase information [28]. The transmissivity is averaged thermally excited phonons incident from all allowable angles. Figure 4a and b shows the thermal conductance through a periodic superlattice, which is proportional to transmissivity. As the thickness of each layer increases, the thermal conductance approaches a constant as shown in Figure 4a. This occurs around 10 Å—the order of magnitude of the phonon thermal wavelength at room temperature. This constant thermal conductance, however, is different from that obtained with ray tracing, as shown in Figure 4b. As the number of layers in such a periodic structure increases, the figure shows a thermal conductance or transmissivity that asymptotically approaches zero as more layers are added. Clearly, in this case, ray tracing is not a good approximation to the wave approach.

Both Figure 3 and Figure 4 consider the wave propagation through thin film systems, but they lead to quite different conclusions (i.e., in the former case, the ray tracing approximation is valid while not for the latter case). We use wave packet propagation as shown in Figure 5 to explain the difference. A wave packet can experience multiple reflections in a film. In a single layer thick film (Fig. 5a), for example, the multiple reflection of a small wave packet does not overlap with itself. In a periodic structure, however, the same wave packets split at different interfaces have a chance of overlapping each other, as sketched in Figure 5b. Because of the overlapping of the same wave packets, there is always the wave interference effect, despite the fact that these effects are not reflected as periodic variations of the transmittance due to thermal averaging effects.

With the previous discussion, we can now divide the nanoscale heat transfer into several regimes as shown in Figure 6. The first demarcation line is the mean free path

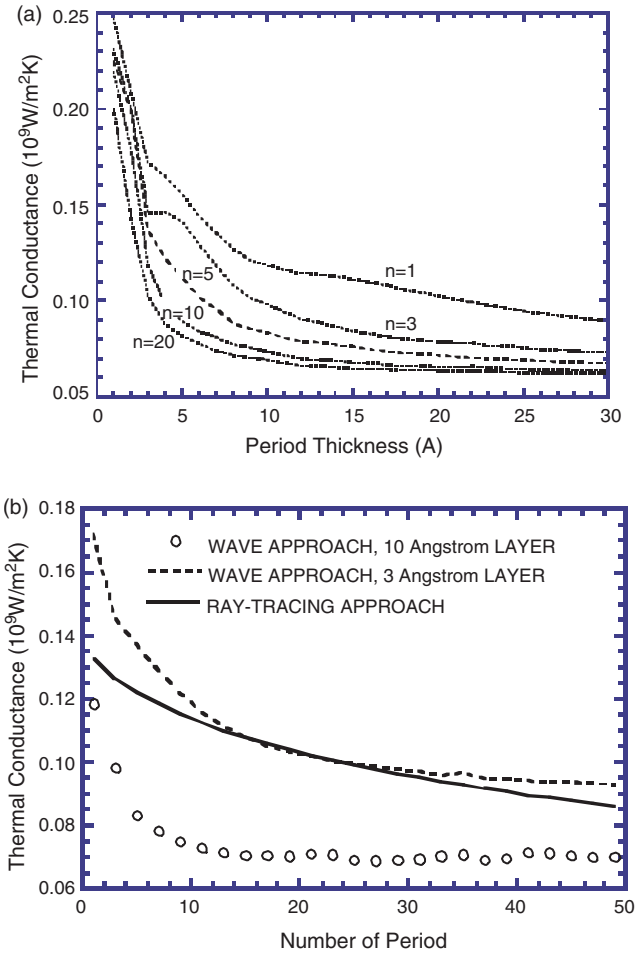

Figure 4. Thermal conductance based on calculation of acoustic waves through a periodic superlattice showing that the wave approach does not necessary lead to the same results as the ray tracing approach. Panel (a) shows that thermal conductance does not change when the layer thickness is larger than 20 Å, of the order of thermal wavelength. However, (b) shows that while the wave treatment leads to a nonzero conductance with increasing number of periods, ray tracing treatment leads to thermal conductance asymptotically approaching zero. Both calculations neglected internal scattering and assumed perfect interfaces. Reprinted with permission from [28], G. Chen, *Trans. ASME, J. Heat Transf.* 121, 945 (1999). © 1999, American Society of Mechanical Engineers.

(or phase coherence length) versus the characteristic structure size. Here, we emphasize that the mean free path and phase coherence length are values in bulk materials. Boundary effects will be discussed latter. If the structure is much larger than the mean free path, transport is a diffusion process (or drift-diffusion as for convection and electron transport under a driven current). When the structure is comparable to or smaller than the mean free path, size effects begin to appear and eventually become dominant. The actual numbers that demarcate different regimes are not to be considered accurate. For example, in rarefied gas dynamics, the continuum regime is assumed when $d/\Lambda > 100$ [29], while we used 10 in Figure 6. We further distinguish the size effects into the classical size effect regime and the quantum size effect regime, depending on whether the phase

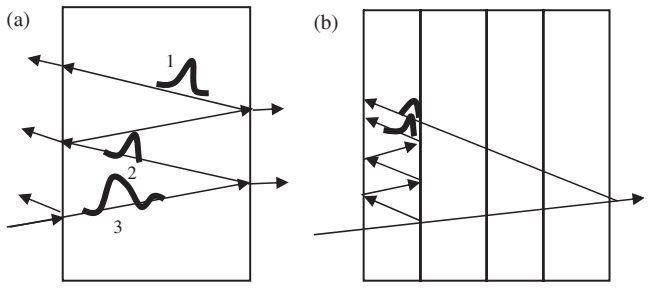

Figure 5. Traveling and interference of the same incident wave packet inside a film and a superlattice. (a) Inside a thick film, the same packet experiences multiple reflections and splitting at each reflection. When the film is thick, there is little chance that these split wave packets can overlap. The end results are that no interference beats can be observed and thus ray tracing can be used without considering the phase of the waves. (b) In a period structure, however, the same wave packets are split many times at different interfaces and it is possible a wave packet experiencing multiple reflections in one layer can overlap with that reflected into the same location from other layers. Because of this process, the ray tracing method will never lead to the same results as the wave optics even when each layer is very thick.

of the energy carriers needs to be considered. In addition to the classical and quantum size regimes, we sometimes also call these regimes particle and wave regimes or incoherent and coherent transport regimes, because it is not always necessary to treat the waves as quantized waves, such as the case for electromagnetic waves. In the classical size effects regime, one can ignore the phase of the energy carriers and trace their trajectories. Whether the transport is in the classical or quantum size effects regime depends on whether the interface scattering processes can maintain the phases of the waves. We used the terminology of interface phase-breaking scattering strength to distinguish the classical and quantum size effects regime rather than just the interface roughness, to emphasize that only complete phase breaking can justify neglecting phases associated with the carriers. In the quantum size regime, the phase information is important and must be considered. When the structure characteristic length is much smaller than the mean free path, scattering inside the medium can be neglected and the transport is ballistic. Theoretical modeling of transport in the ballistic transport

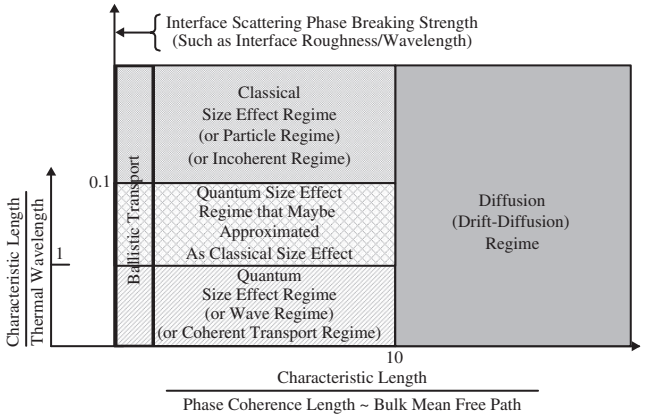

Figure 6. Different nanoscale heat transfer regimes.

regime is relatively easy. In between the ballistic and diffusive regime, both scattering at the boundary and scattering inside the medium must be considered. It is generally difficult to treat transport in this intermediate regime.

The characteristic length needs more explanation. First, the characteristic length does not have to be the structure length. As an example, in the fast heat conduction processes, a steep temperature gradient may be established over a short distance. The distance over which the temperature distribution changes significantly can be comparable to or shorter than the mean free path and in this case, size effects need to be considered. Second, a structure can have several characteristic lengths. Consider phonon heat conduction in a thin film as an example. There are two characteristic lengths. One is the film thickness and the other is the film length (or width). If the film length is much longer than the mean free path, the transport along the film plane can be described by a diffusion equation such as the Fourier law. If, at the same time, the film thickness is smaller than the mean free path, however, the thermal conductivity of the film will no longer be the same as that of the bulk constituent material of the film because lateral interfaces scatter phonons. If the lateral interface is diffuse, the transport falls into the classical size effect regime. If the lateral interface is specular, the transport falls into the quantum size regime. Thus, one can have quantized incoherent transport, quantization due to lateral interface while diffusion transport along the film plane. Electron transport in such a quantized incoherent transport regime has been studied for thermoelectric applications and it is generally agreed that the lateral quantization effect can enhance the electron energy conversion capability [30, 31]. For phonon heat conduction, however, the quantum treatment usually leads to a result that is similar to the treatment based on classical size effect treatment for a single layer thin film with specular surfaces [32] (i.e, both treatments lead to a thermal conductivity equal to that of the bulk, because the shorter thermal wavelength smears out the phonon quantization effects).

2.2. Nanoscale Heat Transfer Phenomena

With the discussion on various characteristic lengths and heat transfer regimes, we will now move on to discuss several size effects associated with three different modes of heat transfer. Because all energy carriers have both wave and particle characteristics, we will discuss first some general phenomena associated with transport in the coherent and incoherent regimes. Whether a particular heat transfer mode in a particular structure can display some of the phenomena depends on whether conditions we discussed in the previous section are satisfied.

All waves experience reflection and refraction at an interface, with the electromagnetic wave as the best-known example. For optical waves, a particularly interesting phenomenon is the total internal reflection when the refractive index of the incident medium is larger than that of the second medium and when the angle of incident is larger than the critical angle; that is [24],

$$\theta_1 \geq \theta_c = sin^{-1}\left(\frac{n_2}{n_1}\right) \tag{11}$$

where n_1 and n_2 are the refractive indices of the two media. In this case, there is an evanescent field in the second medium that does not carry a net energy into the second medium. The evanescent field decays exponentially, $e^{-x/\Delta}$, in the second medium, with a characteristic decay length

$$\Delta = \frac{\lambda_o}{2\pi n_2\sqrt{(n_1 \sin \theta_1/n_2)^2 - 1}} \tag{12}$$

Although the example is given for an electromagnetic wave, the total reflection and the evanescent wave phenomena also exist for electrons and phonons. In addition to the evanescent wave, there can also exist surface waves that decay exponentially at both sides of the interface and propagate along the interface, such as surface plasmons which are mixtures of electron and photon waves and surface phonon–polaritons which are mixed states of photons and phonons, and surface acoustic waves [33–35]. Some of the impacts of surface waves on heat transfer processes have only recently begun to be explored [36, 37].

When there are two interfaces or the interfaces have closed topology themselves, such as the two interfaces of a thin film or the surface of a sphere/wire, the waves can experience multiple reflections inside the structure. If the phase of each reflection is preserved, the superposition of the waves creates interference/diffraction effects. The new wave functions inside the structure can also be interpreted as new energy states from quantum mechanical point of view, which can also be obtained from solving the Schrödinger equation.

If the interfaces are periodic (i.e., the structures are periodic), there can be regions (for specific wavelength and periodicity combination) in which the waves are completely cancelled and no wave exists, either in specific directions or in all the directions. An example is for electromagnetic waves traveling inside a periodic thin film structure, as shown in Figure 7. In the stop band region, the reflectivity

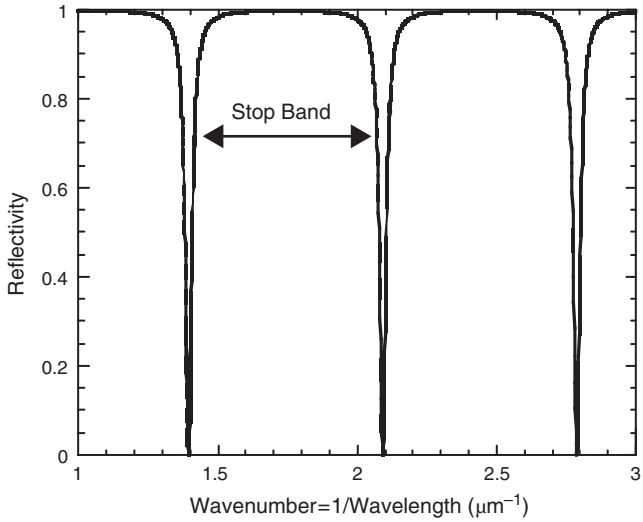

Figure 7. Calculated reflectivity of a Bragg reflector as a function of the incident photon wavelength. The refractive indices of each layer are 3 and 3.5 and the corresponding thicknesses are 417 and 352 Å for each layer, respectively.

is 100% and no waves at this frequency exist inside the film. The corresponding quantum phenomenon is the formation of electronic bandgaps that distinguish metals from semiconductors and insulators, due to the reflection of electrons in the periodic atomic potentials. Although the examples of stop bands for optical waves and that of electronic bandgap in crystalline solids have long been known, the extension of electron waves in periodic structures, such as superlattices, to form new electronic band structures [38, 39] and the extension of electromagnetic waves traveling in a three-dimensional (3D) periodic structure, to mimic what electron and phonon waves naturally do in a crystalline solids [40, 41], are relatively recent endeavors and are the precursors of the current strong drive in nanotechnology.

Wave effects offer rich possibilities because the end results depend sensitively on the phase of the waves. By changing the structures slightly, one can significantly change the phase of the waves and thus potentially engineer the transport processes. However, as discussed in the previous section, the phases are not always preserved. Phase breaking scattering events inside the solid and at the interfaces can destroy the phases and thus the wave effects. In the incoherent transport regime, the interfaces can still impact the transport because of interface scattering. These interface scattering processes generally reduce the energy flux, which can be either a problem, as for the thermal management of electronic and photonic devices [3, 4], or a blessing for other applications that demand good thermal insulation, as for thermoelectric energy conversion [6, 11].

With these general pictures, we now move on to discuss some specific heat transfer phenomena observed in nanostructures.

2.2.1. Heat Conduction

In solids, heat is conducted by electrons and phonons. In pure metals electrons dominate the conduction, while in semiconductors and insulators the dominant contribution comes from phonons. We will examine several heat conduction phenomena that are important at nanoscale, including heat conduction at a single interface, heat conduction inside thin films and nanowires, heat conduction outside nanostructures, and nonequilibrium heat conduction processes between different heat carriers.

Thermal Boundary Resistance Both electrons and phonons can be scattered at an interface. We will focus on phonons first, for which much work has been done [42]. For heat conduction perpendicular to an interface, phonon reflection implies that the energy carried by heat carriers will be reduced compared to the case when there is no interface, or equivalently, a resistance for heat flow exists at the interface. This phenomenon, called Kapitza resistance or thermal boundary resistance, has been known since the pioneering work of Kapitza [43] for liquid helium–solid interface and Little [44] for solid–solid interface, and extensive experimental and theoretical studies have been carried out in the past. At extreme low temperatures when the phonon thermal wavelength is long (Fig. 2), the interfaces are close to specular and models based on acoustic reflection and refraction for thermal boundary resistance lead to reasonably good agreement with experiment. At room temperature, however, the phonon wavelength is short and diffuse scattering can be dominant. There is no proven easy way to model the phonon reflectivity and transmissivity for such diffuse scattering processes. Two models have provided limit values for the reflectivity and transmissivity. One is the radiation model that assumes that phonons from the side with a lower maximum frequency have a unit transmissivity across the interface. By reciprocity or the principle of detailed balance, not all phonons from the side with a higher maximum phonon frequency can go over the interface. Otherwise, one side of the interface will be cooled and the other side heated, even at equilibrium. This radiation limit will provide the maximum transmissivity and thus the minimum thermal boundary resistance value. The other model, called the diffuse mismatch model, assumes that phonons are well mixed during interface scattering and there is no way to distinguish the reflected phonons from the transmitted ones on the same side (i.e., $r_{12} = t_{21}$, where r_{12} represents the phonon reflectivity for incident phonons from medium 1 into medium 2 and t_{21} is the phonon transmissivity from medium 2 into medium 1). Under this assumption, the phonon transmissivity can be expressed as [45]

$$\tau_{12} = \frac{v_2 U_2}{v_1 U_1 + v_2 U_2} \qquad \text{and} \qquad \tau_{21} = 1 - \tau_{12} \tag{13}$$

where U_1 and U_2 are the phonon energy density on media 1 and 2, respectively. This expression assumes a constant group velocity and is an extension of the low-temperature expression in [46]. If the phonon transmissivity is known, the thermal boundary resistance can be calculated from [46]

$$R = \frac{T_1 - T_2}{q} = \frac{2[1 - \langle \int_0^1 \tau_{12}(\mu_1)\, d\mu_1 + \int_0^1 \tau_{21}(\mu_2) d\mu_2 \rangle / 2]}{\int_0^1 [\int \tau_{12}(\mu_1) v_1 C_1(\omega)\, d\omega] \mu_1\, d\mu_1} \tag{14}$$

where $\mu (= \cos\theta)$ is the directional cosine and θ is the incident angle. This expression differs from the commonly used expression for thermal boundary resistance [44],

$$R_e = \frac{T_{e1} - T_{e2}}{q} = \frac{2}{\int_0^1 [\int \tau_{12}(\mu_1) v_1 C_1(\omega)\, d\omega] \mu_1\, d\mu_1} \tag{15}$$

because of the definition of temperature at the two sides of the interface [47, 48]. At the interface, phonons are in highly nonequilibrium states. The phonons coming toward the interface are at one set of temperatures (T_{e1} and T_{e2}), called the emitted phonon temperature (Fig. 8). These phonons, however, do not represent the local energy density because the reflected and transmitted phonons have different spectral distributions. If these phonons are assumed to approach equilibrium adiabatically, the final temperature T_1 and T_2 represents the local energy density. This latter temperature, defined as equivalent equilibrium temperature, is consistent with those local equilibrium temperature used in the Fourier law. At very low temperatures, as used in many experiments on thermal boundary resistance, one can place the sensors so that only T_{e1} and T_{e2} are measured [42]. At high temperatures, many experimental methods are based on extracting T_1 and T_2. For these cases, Eq. (14) should be used.

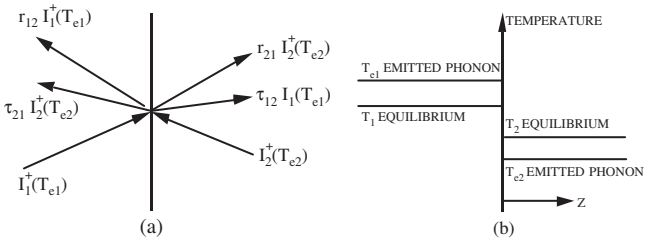

Figure 8. Illustration of phonon transport at an interface, (a) incident, reflected, and transmitted phonons, and (b) the temperature on each side of the interface. Reprinted with permission from [48], G. Chen, *Phys. Rev. B* 57, 14958 (1998). © 1998, American Physical Society.

From Eq. (14), the order of magnitude of the thermal boundary resistance is

$$R \approx \frac{2-(\tau_{12}+\tau_{21})}{C_1 v_1 \tau_{12}} \sim 10^{-9}\frac{1}{\tau_{12}} m^2K/W \qquad (16)$$

where we have used the fact that for many materials at moderate to high temperatures, $C \sim 10^6$ J/m^3 and $v \sim 10^3$ m/s. The velocity seems to be low compared to the speed of sound in many solids but is actually reasonable after considering the dispersion of the phonon spectrum. Thus, for perfect interfaces, the thermal boundary resistance is of the order of 10^{-8}–10^{-9} m^{2}K/W. This order of magnitude is consistent with molecular dynamics simulations [49] and experimental results on superlattices [50, 51].

Although this discussion is for phonons, electrons can also be reflected at an interface due to the potential mismatch at the interface. Interfacial electron transport has been studied extensively in the literature for current flow and these results can be used to predict the interface thermal boundary resistance, for example, based on the extension of the Wiedmann–Franz law from bulk to an interface [52]. If the interface is made of a metal and a dielectric, an additional energy conversion process between electrons and phonons on the metal side must be included, because eventually heat is transferred across the interface by phonons [53].

Heat Conduction in Thin Films, Superlattices, Nanowires, and Nanotubes A thin film has two interfaces. If the mean free path is longer than the film thickness, energy carriers (electrons and phonons) will be scattered more frequently at the interfaces and may experience multiple scattering. If the scattering at the interface is diffuse, as we assume for scattering due to random roughness, the thermal conductivity along the film plane will be reduced because diffuse scattering means some phonons that originally travel along the film plane direction are redirected backward. Solutions for the electrical conductivity in this classical size effect regime for a single layer of thin film, called the Fuchs–Sondheimer model, were obtained a long time ago [54–56] and are applicable to phonon heat conduction as well [3]. If the interface scattering is specular, the classical size effect model of Fuchs and Sondheimer leads to a thermal conductivity of a thin film identical to that of bulk material, because the thin film acts simply as a waveguide for the heat flow. When the film thickness is thinner than the thermal wavelength, quantum effects may be important. However, lattice dynamics calculations show that quantum effect on the energy density and group velocity leads only to a small reduction in thermal conductivity for specular interfaces [57], although there are also suggestions that the scattering mechanisms will be significantly changed, which leads to a lower thermal conductivity [58, 59]. Quite extensive studies experimentally have been carried out on the thermal conductivity of thin films. Single crystalline silicon thin films provide a model experimental system for studying the size effects, due to both the long phonon mean free path and its importance in industrial applications. In Figure 9, we show the thermal conductivity of single crystalline silicon thin films measured by several groups [60–62]. Size effects are particularly strong at low temperatures because of the increasing phonon mean free path with decreasing temperature. Polycrystalline thin films show an even larger thermal conductivity reduction, because grain boundaries greatly scatter phonons [63–70]. In the cross-plane direction, there are some measurements on the thermal conductivity of metallic and semiconducting thin films [71–73] and amorphous thin films [74–78]. Some reduction of the thermal conductivity of metallic and semiconducting thin films has been observed but the mechanisms are not well explained. For amorphous thin films, the measured thermal conductivity reduction is often explained by the inclusion of the thermal boundary resistance between the film and the substrate [74].

Superlattices are periodic thin film structures as shown in Figure 10a. Thermal properties of such structures have been studied over the last 15 years due to their importance for photonic and thermoelectric devices. Experimentally, it has been observed that superlattices have much lower thermal conductivities compared to the bulk values calculated based on the Fourier law, using the properties of their parent materials [50, 79–85]. An example of the thermal conductivity of superlattices is given in Figure 10b [83]. There are several potential explanations [11, 51]. One is the phonon spectrum change [86–91]. Figure 11a–f shows an example of the phonon spectrum of a Si/Ge-like superlattice

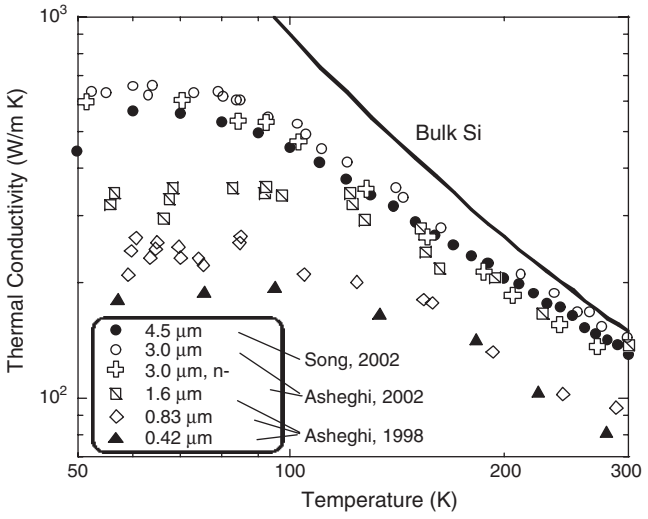

Figure 9. Thermal conductivity of single crystalline silicon thin films, showing a significant reduction as the film becomes thinner and the temperature becomes lower.

calculated from lattice dynamics [32]. Compared to the phonon spectra of the bulk materials, there are several changes: (1) phonons are folded due to the new periodicity in the growth direction, (2) the acoustic phonons in the silicon layer with a frequency higher than that in the Ge layer become flat or confined due to the mismatch in the spectrum, and (3) mini bandgaps form. The impacts of these changes on the phonon density of states and group velocity are shown in Figure 10e and f. Although the change in the density of states is relatively small, there is a relatively large change in the group velocity in the cross-plane direction. This group velocity has been proposed as an explanation for the thermal conductivity reduction [89, 92]. Comparison with experimental data, however, shows that the group velocity reduction alone cannot explain the magnitude of the thermal conductivity reduction perpendicular to the film plane nor can it explain the thermal conductivity reduction along the film plane at all [32]. The reason is that the lattice dynamics model assumes phase coherence of the phonons over the whole superlattice structure and does not include the possibility of diffuse interface scattering. Models considering classical size effects lead to reasonably good agreement with experimental data [21, 48, 93]. These theoretical and experimental studies show that it is difficult to take advantage of the wave effects of phonons in phonon transport processes, primarily due to the short phonon thermal wavelength.

Thermal conductivity of nanowires is also attracting great interests [94–106]. Naturally, the interest is in for transport along the wire axis direction. Referring to the transport regime picture in Figure 6, there are several possibilities. If the surface of the wire is specular and there is no scattering inside the wire, the transport is ballistic and phonon energy states are quantized. The Landauer formalism leads to the universal phonon thermal conductance as [101, 102]

$$K = \frac{\pi^2 \kappa_B^2 T}{3h} \tag{17}$$

This universal thermal conductance has been demonstrated [101], but at temperatures <0.8 K. At slightly higher temperatures (>3 K), the diffuse interface scattering effects begin to appear [100]. If the classical size effects picture holds (i.e., if the surface is random enough to break the phonon coherence, which is likely the case at room and high temperatures, from the large amount of data on thin films and superlattices), nanowires should have even lower thermal conductivity compared to thin films due to increased surface scattering. Experimental data on single nanowires at near room temperature are just becoming available on some nanowires and indicate a significantly lower thermal conductivity, suggesting the importance of diffuse interface scattering [104]. Clearly, transport along very long wire is diffusive. A key issue is whether the lateral quantization occurs. Boltzmann equation based modeling has seen two different approaches, one based on the bulk dispersion and imposing the surfaces as boundary conditions [105, 106]. The other first assumes that boundaries create quantized phonon states, followed by the treatment of diffuse interface scattering [98]. Which of these approaches is more appropriate depends on the strength of the interfaces breaking the phase coherence. There is no consistent answer to this question at this stage. Molecular dynamics simulations may provide a way to directly compute the thermal conductivity of nanowires [105]

Carbon nanotubes are another interesting material system that differs from the nanowires. A freestanding single wall carbon nanotube has all the atoms on the surface and the phonon modes can only propagate along the axial direction [107]. This latter attribute also means that unlike a solid nanowire in which the phonon modes inside the wire can hit the boundary (assuming boundary scattering is strongly phase breaking), phonons on the carbon nanotube sheet have no boundaries to interact with. In addition, the strong modification of the phonon dispersion can also change the scattering mechanisms. It is thus suggested that carbon nanotubes can have a thermal conductivity even higher than that of diamond [108]. Measurements and simulation data so far vary widely. Molecular dynamics simulations carried out by various group also have widely varying thermal conductivity values [109–113]. Similar is the case of experimental studies. Measurements on an isolated multiwall carbon nanotubes lead to high thermal conductivity values [99] but measurements on tangled and aligned carbon nanotubes have values orders of magnitude smaller [114–116]. At this stage, the reasons for such large discrepancies are unclear. It is quite possible that although a freestanding nanotube has high thermal conductivities, a nanotube embedded in a host sees increasing interface scattering which reduces its thermal conductivity values. Continued study on this issue is important for the potential applications of carbon nanotubes.

Rarefied Phonon Heat Conduction External to Nanostructures Although the thermal conduction reduction in thin films and nanowires is a well-known phenomenon, the size effects outside for heat conduction external to nanostructures have not received much attention. Heat generated inside nanoscale regions or nanostructures eventually will be conducted to the surrounding. When the heat generation region or the size of the nanostructure is smaller than the mean free path of heat carriers in the surrounding medium, the temperature rise of the nanostructure can be much higher than that predicted by the Fourier law [117]. To see why this occurs, we consider the heat conduction surrounding a heat generating spherical region embedded inside a semi-infinite medium. The Fourier law leads to the relation between heat transfer rate, Q, and the temperature rise at the surface of the sphere, T_s,

$$Q(\text{Fourier}) = 4k\pi r(T_s - T_\infty) = \frac{4\pi}{3} rCv\Lambda(T_s - T_\infty) \quad (18)$$

where T_∞ is the temperature of the medium away from the sphere and r is the radius of the sphere, and we have used the kinetic expression, Eq. (2), for the thermal conductivity. When the diameter of the nanosphere is much smaller than the mean free path of the heat carrier in the surrounding, however, we can neglect the scattering and treat the heat transfer between the region and the surrounding as a radiation process. This approach leads to the solution for the heat transfer,

$$Q(\text{radiation}) = \pi r^2 Cv(T_{s,e} - T_\infty) \approx 2\pi r^2 Cv(T_s - T_\infty) \quad (19)$$

where we have used $T_{s,e}$ to represent the temperatures of the phonons coming out of the nanoparticle, or the emitted phonon temperatures according to Figure 8. If there is no reflection at the interface, the surface temperature as used in the Fourier law is related to the emitted phonon temperature through, $T_s = 0.5 \cdot (T_{s,e} + T_\infty)$, which leads to the second equality of Eq. (19). Comparing Eq. (19) with Eq. (18), we can see that

$$\frac{Q(\text{Fourier})}{Q(\text{Radiation})} = \frac{2\Lambda}{3r} \quad (20)$$

Thus, in the limit where the mean free path is much larger than the sphere radius, the Fourier law overpredicts the heat transfer rate. This is because the Fourier law is only applicable when there is not a large temperature gradient within one mean free path. For the previous example, the application of the Fourier law to a region much smaller than the mean free path (surrounding the sphere where temperature varies significantly) inherently implies that there is strong scattering in this region, which is only true when the mean free path is much smaller than the region, while in reality, the mean free path corresponding to the bulk thermal conductivity is much larger.

Several theoretical studies have investigated the rarefied heat conduction cases, including transient heat conduction for planar geometries [118, 119], steady state in a spherical geometry [117], and in more complicated device structures [120, 121]. Experimentally, the rarefied heat conduction effect is proposed to explain the fabrication of nanostructures by scanning tunneling microscopy [122]. A recent experiment by Sverdrup et al. [123] provides evidence of the effect. More experimental studies are needed to demonstrate this phonon rarefaction effect beyond doubt.

Nonequilibrium between Carriers In dealing with nanoscale heat transfer, it is important to identify where and how heat is generated and how heat is exchanged between different groups of heat carriers. For example, in the fast laser heating of metals, electrons usually first absorb the photon energy and relax the energy to phonons [124–126]. Depending on the electron–phonon heat exchange rate and the rate of heat input, the electrons can be heated to a much higher temperature than the phonons. Similarly, electrons under a high electric field can be heated to a temperature much higher than that of the lattice [23]. Such "hot electron" effects have been extensively studied for electronic devices. Because electrons and phonons travel at a different rate, with the electrons much faster, hot electrons can significant change the heat source distribution. For example, most heat in a MOSFET (metal-oxide-semiconductor field-effect transistor, the most important device for very-large-scale integrated circuits such as microprocessors and semiconductor memories) is generated in the drain side where hot electrons dump their energy [127]. The release of heat from electrons to phonons can also significantly affect the lattice temperature rise. For example, electrons interact more readily with optical phonons, particularly polar optical phonons as in GaAs [128, 129]. The optical phonons, however, do not carry heat as efficiently as acoustic phonons. Consequently, depending on the energy exchange rate between optical phonons and acoustic phonons, hot optical phonons can be generated. Due to the large dispersion of acoustic phonons, it is also possible that acoustic phonons are significantly out of equilibrium with each other. There are also possibilities to create cold electrons relative to the lattice temperature, which can be utilized for thermoelectric refrigeration [130]. Studies on the impacts of nonequilibrium between energy carriers and within the same type of carriers on heat transfer processes are relatively scarce.

2.2.2. Thermal Radiation

Photons can have a long mean free path as evidenced by the solar radiation traveling to the earth and can also have a very short mean free path as the rapid decay of electromagnetic waves inside a metal. The studies of radiation heat transfer thus have traditionally spanned the ballistic to the diffusive regime [25]. Because of its short thermal wavelength, most research on thermal radiation falls into the classical size effect regime (i.e., ignoring the phase of electromagnetic waves). Compared to phonons and electrons, however, the thermal wavelength of the photons is actually very long, as clearly shown in Figure 2, and it is much easier to observe wave effects for thermal radiation than in heat conduction. Thus, the most interesting aspect of radiation heat transfer in nanostructures comes from the wave aspects of thermal radiation.

Interference effects on radiative properties of thin films have been studied [131–137]. Because of the interference effects, radiation properties, such as emissivity of thin films, can be thickness dependent. Such thickness dependence may be important for emissivity control and for the temperature control of surfaces. In nonplanar geometries, diffraction effects can also significantly change the radiative properties [138]. While these effects are relatively well known, more exciting recent advancements occur in the photonic-crystal structures that are an extension of the periodic thin film structures as Bragg reflectors into 2D or 3D structures [139–142]. Similar to the electron band structure formation in periodic atomic potential, photon energy states in such periodic structures form bands and for appropriate geometries, absolute bandgap can form such that no radiation can exist in any direction. This opens the potential of emissivity control both spectrally and directionally.

Radiation tunneling is another interesting phenomenon that has been studied for its heat transfer implications [13, 14, 143–146]. From Eq. (12), we can see that an evanescent wave extends over a distance of the order of a wavelength under the total reflection condition. This evanescent wave can become propagating if a third medium is brought close to the interface between the first and second media. When this happens, total reflection no longer happens and electromagnetic waves originally confined within the first medium can deliver energy into the third medium. This phenomenon is called tunneling. Tunneling can lead to, for example, increased heat transfer between the two parallel plates, even above the radiation heat transfer between two blackbodies [14, 144].

A very interesting recent development is the exploration of surface waves such as surface plasmons and surface phonon–polaritons [36, 37, 147–150]. Surface waves exist only at specific frequencies. The surface modes decay exponentially away from the surface and are normally not useful. However, just as in the case of tunneling, the surface mode can tunnel into a third medium if it is brought into close proximity to the first interface. An example is shown in Figure 12, which shows the increased radiation heat transfer at the surface phonon–polariton frequency of boron nitride [151]. These surface modes can also be coupled by grating structures into propagating waves in free space [148]. Because the surface waves have a relatively long mean free path and because the surface modes exist only in a narrow wavelength range, the thermal emission from such surface modes can be coherent and nearly monochromatic.

These discussions focus on the photon transport. Another effect of nanostructures is to change the optical constants. For example, the energy spectrum change of electrons and phonons due to quantum size effects will create subsequent change on the optical constants. Another example is the anomalous skin effect that occurs when the electromagnetic field varies strongly over the mean free path of electrons, similar to the nonlocal phonon heat conduction effects [19, 152]. The impacts of these changes on radiative heat transfer have not been explored, except the anomalous skin effects.

2.2.3. Convection

Convection is a process concerned with heat exchange between a solid surface and a fluid. The energy transfer in convection is due to both molecular diffusion and bulk motion of the fluid in the presence of a temperature difference. As in conductive and radiative heat transfer, convection may also experience size effects. For example, the mean free path of gas molecules becomes comparable with

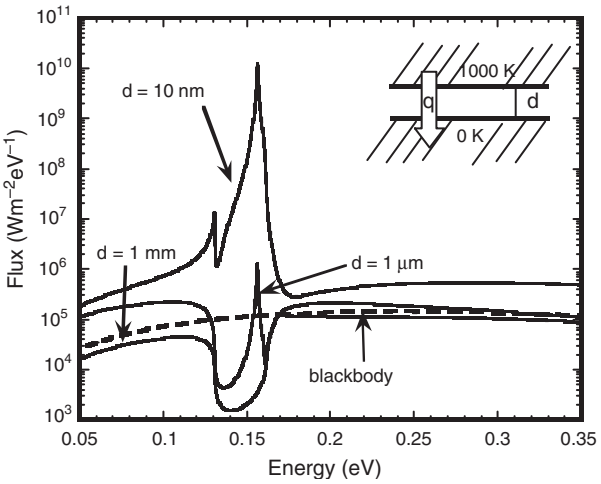

Figure 12. Spectral radiative energy transport between two half-planes of cubic boron nitride separated by a layer of vacuum of thickness d. Adapted with permission from [151], A. Narayamaswany and G. Chen, "Surface Modes for Near Field Thermophotovoltaics," unpublished.

the characteristic length of a nanostructure even at atmospheric pressures, as shown in Figure 1. This situation is similar to heat transfer in gases of low pressures and can be described by the rarefied gas theory [153]. Characteristic to this regime is the thermal creep or thermal transpiration where gas molecules creep from the cold side to the hot side along a channel with a diameter comparable to the mean free path [153]. In the case of small particles subjected to a temperature gradient this phenomenon may induce particle levitation due to thermophoresis [154]. On the other hand, liquid molecules are closely packed and have short-range interactions. Typically the continuum theory can be used to describe liquids layers as thin as 5–10 molecular diameters [155], although close to a solid surface other phenomena such as wetting, adsorption, electrokinetics, and dielectrophoresis may have to be considered [156, 157].

One way to control thermal properties of liquids is the addition of small particles to the liquid. Studies of effective thermal conductivity of solid suspensions date back to Maxwell's work on effective media theory [158]. However, recently it has been observed that the addition of nanometer size particles dramatically changes transport properties and enhances heat transfer performance of the liquids [159]. The mechanisms for enhanced heat transfer in nanofluids are not well understood [160]. Further theoretical and experimental studies are required to understand them.

3. APPLICATIONS

Energy generation and transport is a fundamental process essential to many engineering applications. Nanoscale heat transfer phenomena discussed previously have impacts on a wide range of contemporary technologies from microelectronics to bioengineering. The unusual heat transfer physics in nanostructures also opens new ways to tailor materials' properties, which in turn may lead us to innovative applications. We illustrate here with a few examples in information technologies, energy technologies, material processing, and biotechnology.

3.1. Information Technologies

Nanoscale heat transfer phenomena discussed previously have important implications for microelectronics, optoelectronics, and data storage technologies. The thermal management of microelectronics has already become a challenging issue. Nanoscale heat transfer effects may further complicate the problem [3]. Figure 1 shows that the phonon mean free path in silicon at room temperature is ~250 nm, longer than the channel length of a MOSFET device. In addition, heat is mostly generated in the drain side over a lateral dimension ~10 nm. The rarefied phonon heat conduction effect discussed before means that the Fourier law underpredicts the device temperature rise. In addition, the nonequilibrum between optical and acoustic phonons can further increase the local temperature rise. As the gate length continues to decrease, it is also predicted that the operating voltage cannot correspondingly be reduced for maintaining a low leakage current [161]. Cryogenic operation of electronic devices is being seriously considered by the microelectronics industry to improve performance. The phonon rarefaction effect will be more significant at lower operation temperatures (i.e., the deviations from the predictions of the Fourier law will become larger), because of the increasing phonon mean free path in bulk materials with decreasing temperature. How this effect will impact the scaling of microelectronic devices has not been carefully examined.

Another key component of current technological applications is semiconductor diode lasers which are usually made of multilayer thin films. Two major types of semiconductor diode lasers, edge–emitting lasers and vertical-cavity surface emitting lasers (VCSELs), are currently commercialized and used in a wide range of applications including laser printers and high density optical disks, playing a central role in today's optical communications. The excessive temperature rise in VCSELs, partly due to the high electrical resistance created by the heterointerfaces and partly due to the low thermal conductivity of the multilayer structures, had been the road block for their commercialization until a few years ago [4]. Studies on the thermal conductivity of superlattices were partly motivated by this issue. Although this problem has partly been solved for some low power applications, heating is still the most important factor limiting the power output and is more severe for near infrared lasers due to the large nonradiative recombination that is eventually converted into heat [162–165]. Edge emitting devices have less of a heating problem than VCSELs but facet damage is often associated with heating [166]. The high power outputs required to achieve reliable optical performance coupled with the low thermal conductivity of multilayer thin film structure often result in a short device life [4, 167]. The reduced thermal conductivity calls for careful design of the devices to minimize the number of interfaces and to allow efficient heat removal from the gain region.

While heating in integrated circuit and in semiconductor lasers is undesirable and needs to be "managed," it is actually used extensively as a means for writing data onto storage medium such as CDs and magnetic hard drives. For

magnetic hard drives, one of the major factors that determine data storage density is the separation between the slider and the magnetic disk known as the flying height. In present-day hard drives the flying height is around 50 nm while the disk rotates at $\sim$10, 000 rotations per minute. The airflow between the slider and the disk is crucial in maintaining the height of the disk and is very different from the prediction of continuum fluid mechanics at this small spacing [168]. Another factor to be taken into account is the thermal creep [168], and this effect has also been proposed for novel levitation-based recording systems [169]. Equally important to the storage density is the size of the magnetic domain. It is difficult to increase the storage capacity of current magnetic disks beyond a density of 40 Gb/in^2 [170] because of the superparamagnetic effect that affects magnetic domain stability. New magnetic materials with larger magnetic anisotropy are being developed [171] and heating has been proposed as a means to assist the writing processes [8, 172, 173]. Meanwhile, alternative technologies are being developed. Some rely again on heating, such as thermomechanical data storage, where data bits are written on polymer substrates by heated atomic force microscope (AFM) tips. A storage density as high as 400 Gb/in^2 has been demonstrated [8]. The writing process as well as the data reading requires highly localized spatial and temporal heat deposition. Many rewritable CDs are based on the phase change caused by laser heating [174–176]. For such applications, it is desirable to limit the heating within a small domain. Nanoscale heat transfer effects including reduced thermal conductivity of thin films and nonlocal heat conduction surrounding nanoscale heating spots can be utilized to confine heat for writing smaller spots.

These examples emphasize the small length scales involved in nanodevices and nanomaterials. A short time scale is also becoming increasingly important. Similar questions can be raised for transport at short time scales as for the small length scales. Lasers can deliver a pulse as short as a few femtoseconds (1 fs $= 10^{-15}$ s). Energy transduction mechanisms at such short time scales can differ significantly from that at macroscale [126]. Microelectronic devices are pushing to the tens of gigahertz clock frequency with a much shorter transient time. The device temperature rise in such short time scales can be very different from predictions of the Fourier law.

3.2. Energy Conversion

Energy conversion is a field that may greatly benefit from nanoscale energy transport phenomena. An example is thermoelectric cooling and power generation based on the Peltier effect and the Seebeck effect, respectively [177]. The efficiency of a thermoelectric device is determined by the thermoelectric figure-of-merit of the material $ZT = \sigma S^2 T/k$, where S is the Seebeck coefficient, σ is electrical conductivity, k is the thermal conductivity, and T is the absolute temperature. Currently, the best commercially available thermoelectric materials based on Bi_2Te_3 and its alloys has a ZT of $\sim$1. Thermoelectric devices based on this material cannot compete in performance with other well-established technologies for energy conversion. Several approaches have been explored to increase the thermoelectric figure-of-merit [5, 178]. Among those, low-dimensional thermoelectric materials structures such as quantum wells, superlattices, and nanowires have been extensively investigated [179-183]. Quantum size effects on electrons in nanostructures can be utilized to improve the electron energy conversion capability [30], while the reduced thermal conductivity of nanostructures due to increased scattering of heat carriers from interfaces can be exploited in reducing the denominator of ZT. In the past two years, different low-dimensional thermoelectric materials that show improved cooling capacity as compared to bulk materials have been reported [185, 186]. This suggests that phonon engineering is a primary tool in developing better thermoelectric materials.

The wave effects on radiation heat transfer can be utilized for thermophotovoltaic energy conversion in different ways. Photonic crystals can have the spectral emissivity tuned to match the bandgap of semiconductor photovoltaic cells [187]. Tunneling effects are being explored to increase the energy density delivered from the heat source to the photovoltaic cells [13, 188]. Surface waves, such as surface plasmons and surface phonons, can be utilized for nearly monochromatic thermal radiation, which increases the efficiency of thermophotovoltaic energy conversion [36, 151, 189] as well as the energy density if small gaps are employed to take advantage of the high energy density of surface waves.

3.3. Nanomaterial Synthesis and Nanofabrication

Nanomaterial synthesis and nanostructure fabrication are two areas where thermal transport is often important but has received less attention. Size-dependent melting point depression of nanoscrystals may be used to develop techniques for fabrication of cheap electronics [190]. A different example is related to multilayer structure masks currently used in extreme ultraviolet lithography and X-ray lithography [191]. The heat generation in these structures and its impact on the structural fabrication accuracy has yet to be investigated. Ultrafast laser nanomachining [192] and nanoimprint lithography [193], both based on short time interaction of a laser pulse with sample surface, also call for better understanding of flow and heat transfer at nanoscale and short time scale. The synthesis of nanoscale materials is a wide-open field and many nanomaterial and nanostructure synthesis methods being developed raise intriguing nanoscale heat transfer questions. For example, nanowires and carbon nanotubes have been made with different methods such as chemical or physical vapor deposition, filling of templates through liquid phase, vapor deposition, and electrodeposition [194–198]. Understanding the transport processes during nanomaterial formation will allow better control of the final material quality. Scanning probe based fabrication methods also often involve nanoscale heat transfer issues that are not well understood. For example by focusing a laser beam onto an AFM or scanning tunneling microscope tip, structures with dimensions down to 10 nm can be fabricated [199, 200]. In a different experiment an infrared laser is focused on an AFM tip

in contact with a PMMA substrate to produce pits of several hundreds Å in size [201]. Understanding the interaction between electromagnetic radiation and nanostructures and its coupling, the heat conduction, is obviously very relevant for improving these fabrication methods.

3.4. Biotechnology

Nanoscale heat transfer is also making in-roads in biotechnology. Inductively heating gold nanoparticles attached to DNA strands has been found to be a promising method to control DNA hybridization [202]. The heat transfer mechanism between the nanoparticle and DNA strand has yet to be elucidated.

4. EXPERIMENTAL TOOLS

There are two key experimental directions in studying nanoscale heat transfer phenomena. One is the thermophysical property measurements of nanostructures such as thin films and nanowires. The other is the temperature measurements, particularly temperature mapping surrounding nanoscale devices. In this section, we briefly describe some of the techniques used for thermophysical properties characterization and temperature measurement of nanometer size samples. Additional details can be found in reviews on similar topics available in the literature [11, 64, 203–205].

4.1. Thermophysical Properties Characterization

Measuring thermophysical properties is always a challenging task, even at macroscale. The thermophysical property characterization of nanostructures and microstructures is even more challenging. The measurements of the thermal conductivity, for example, normally require the determination of heat flux and temperature drop between two points of the sample, which becomes much more difficult in nanostructures than in macrostructures. Taking thin films as an example, the measurement of thermal conductivity perpendicular to the film plane (cross-plane direction) requires the determination of the temperature drop over the film thickness that ranges from nanometers to micrometers. Because thin films are often deposited on substrates, it is difficult even to create a reasonable temperature drop across the film without creating a large temperature rise in the substrate, not to mention determining the temperature drop across the film. The thermal conductivity measurement parallel to the film plane (in-plane direction) may look easier because temperature sensors can be placed along different locations in the film surface. However, the substrate makes difficult the determination of actual heat flow in the film. To overcome these difficulties, different strategies have been developed for measuring thin film thermal properties in different directions. In the cross-plane direction, the general strategies are (1) creating a large heat flux across the film while minimizing the heat flux in the substrate and (2) measuring the surface temperature rather the temperature drop. These can be realized by, for example, using microfabricated heaters directly deposited on the film. By using a small heater width, the heat flux is large when going through the film but the heat spreading inside the substrate significantly reduces the temperature drop in the substrate. Another example is to use transient or modulated heating that can limit the heat affected region close to the film. In the in-plane direction, one often used strategy is to remove the substrate such that the heat flux through the film can be uniquely determined.

In the following, we will first discuss thin film thermophysical property measurements and divide our discussion based on different heating and temperature sensing methods: the electrical heating and sensing based on microheaters and sensors, the optical heating and sensing methods, and the combined electrical/optical methods. After these discussions, we will review several methods used for nanowire property measurements.

4.1.1. Electrical Heating and Sensing Based on Microheaters and Microsensors

Microheaters and sensors can be fabricated onto the samples using microlithography techniques developed in the semiconductor industry. In some methods, the heaters are also used directly as the temperature sensor while in other techniques, separate heaters and temperature sensors are used. The advantages of the electrical heating and sensing methods, compared to optical heating and sensing, are that the amount of heat input into the sample can be precisely controlled and the temperature rise can be accurately determined. By using microheaters and microsensors, high heat flux can be created and temperature rise can be pinpointed at micrometer scales, depending on the sensor dimension. We will further divide our discussion for measurements in the cross-plane and in-plane directions.

Cross-Plane Thermal Conductivity Measurement of Thin Films One major method for measuring the cross-plane thermal conductivity of thin films is the 3ω method, initially developed for measuring the thermal conductivity of bulk materials and later extended to thin films [74, 206]. Thermal conductivity of thin films down to 20 nm in thickness has been measured using this technique [74, 206, 207]. The method has also been adapted for simultaneous measurement of the in-plane and cross-plane thermal conductivity of anisotropic thin films [83] and freestanding membranes [208]. In the 3ω method a thin metallic wire is deposited onto the sample surface to act as both a heater and a temperature sensor. An ac current with angular modulation frequency (ω) passing through the wire causes Joule heating and ac temperature oscillations of the wire with a frequency of 2ω. Due to the temperature dependence of the electrical conductivity, the resistance also has a 2ω component proportional to the ac temperature rise. The voltage drop along the wire thus contains a third harmonic (3ω) component that depends on the ac temperature rise of the heater. Since the heater measures only the temperature rise on the front surface (T_f), the temperature rise at the interface between the film and the substrate (T_s) must be determined. This can be done by two approaches. One method, often referred to as the slope method, is to calculate the temperature rise at the film–substrate interface based on the thermal conductivity of the substrate. The latter can be determined

from the frequency dependence of the measured front surface temperature [206] because the temperature drop across the film itself is frequency independent when the film is thin. Figure 13a shows an example of measured temperature rise at the front surface and inferred substrate temperature.

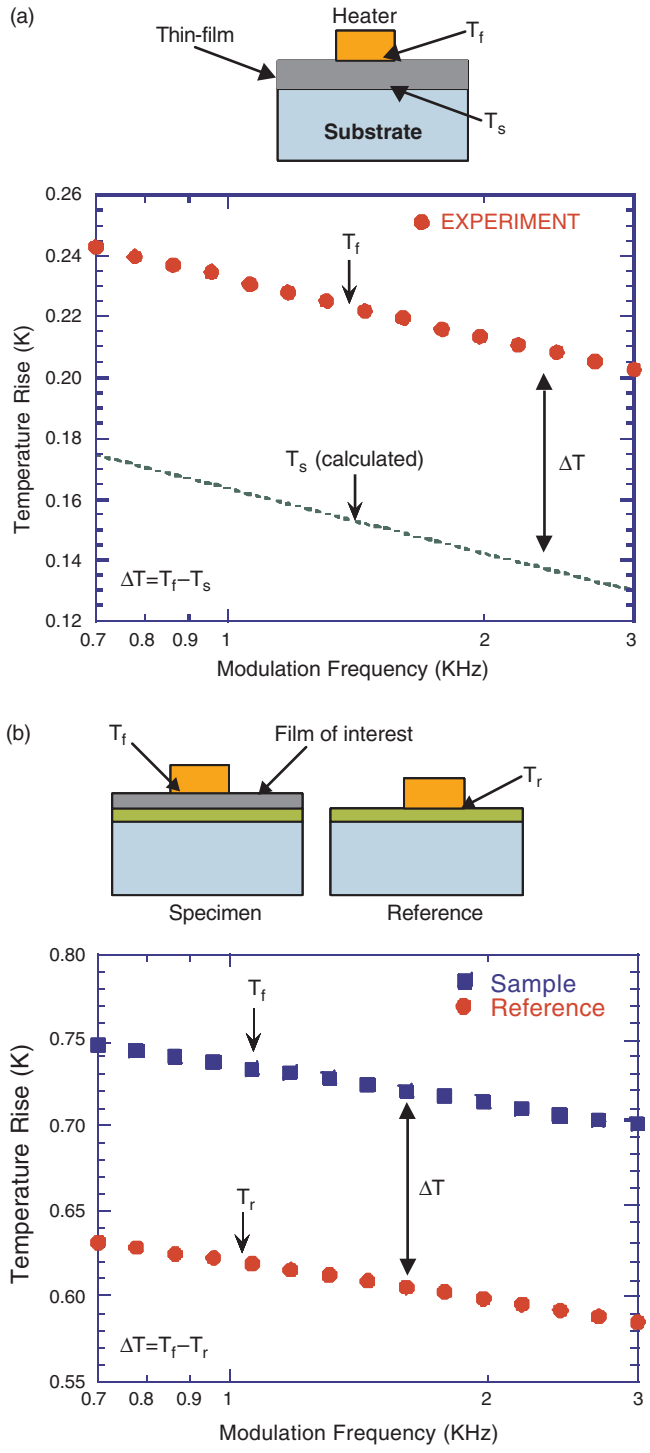

Figure 13. (a) Experimental temperature rise (T_f) and calculated substrate temperature (T_s) in the slope method. (b) Experimental temperature rise for the specimen (T_f) and reference sample (T_r) in the differential method.

Detailed modeling, however, shows that the determination of the substrate thermal conductivity based on the front side temperature measurement is prone to error when the film is relatively thick. A different way to estimate the temperature drop across the thin film is to measure it experimentally by a differential technique [209], which measures the difference of the front surface temperature rise between the actual sample and a reference sample that does not have the film. An example of the temperature rise measured by the heater onto the specimen (T_f) and reference sample (T_r) is shown in Figure 13b. Usually, the heater width is chosen to be much wider than the film thickness such that heat conduction across the film can be treated as one-dimensional (i.e., in the cross-plane direction only). Although simplified one-dimensional steady-state models are often used in extracting the cross-plane thermal conductivity of the thin film, it is important to carry out more detailed modeling when the contrast in properties between the film and the substrate becomes small. By choosing heaters of different width, for example, through the use of two heaters, one with a width much larger than the film thickness such that it is most sensitive to the cross-plane thermal conductivity, and the other with a width comparable to the thickness such that lateral spreading effect is important, both in-plane and cross-plane thermal conductivity of the thin films can be determined [83, 209].

The modulation technique as used in the 3ω method has several advantages. One is that the ac temperature field can be controlled by the modulation frequency. With reasonably high modulation frequency, the ac temperature field is confined to the region close to the heater such that the substrate can be treated as semi-infinite. This avoids the influence of the boundary condition at the substrate side. Another advantage of the modulation technique is that the ac signal is less sensitive to the radiation heat loss compared to dc measurement methods. The ac modulation also leads to the possibility of determining the substrate properties in addition to the film properties.

In addition to the 3ω method, a multisensor steady-state method was developed to measure the thermal conductivity of SiO_2 thin films deposited on silicon [210, 211]. This method relies on the temperature measurements by adjacent sensors to back up the temperature underneath the heater. Because the measurement is done at the steady state, the boundary condition at the back side of the substrate is important for determining the temperature underneath the heater.

In-Plane Thermal Conductivity Measurements Several in-plane thermal conductivity measurements have been developed by making freestanding thin film structures [65, 212, 213]. One of the configurations is to fabricate heater and temperature sensors on a large membrane as schematically shown in Figure 14a. Heat generated from the heater spread from the membrane to the frame. The other configuration shown in Figure 14b is to further shape the membrane into a narrow line and to pass current directly through the line, if the membrane is conducting or semiconducting. In this case, heat spread out along the line axis direction and the average temperature of the line is measured and correlated to the thermal conductivity.

Depending on the thermal conductivity of the film to be measured, there are several considerations one should pay

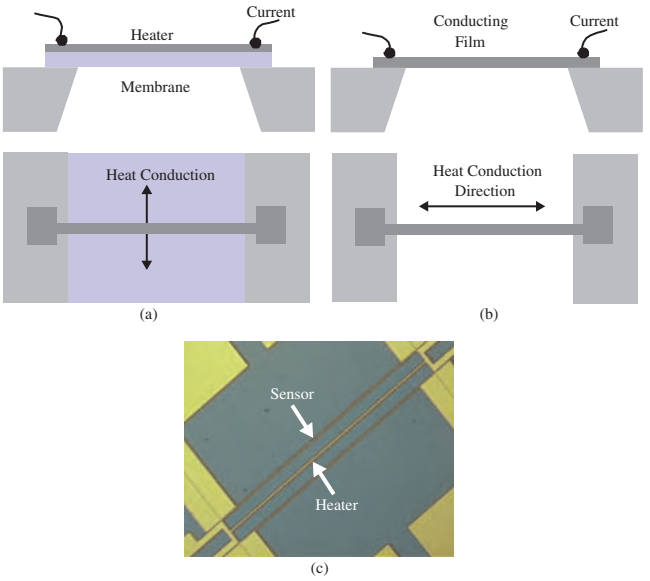

Figure 14. In-plane thermal conductivity measurement based on (a) membrane and (b) bridge structures. A fabricated membrane with the heater and the temperature sensor is shown in (c).

attention to. If the membrane method is applied to measure the thermal conductivity of a low thermal conductivity film, the structure should be designed such that heat conduction is one-dimensional, otherwise two-dimensional simulation must be carried out to back up the thermal conductivity of the film. For low thermal conductivity films, heat leakage through the heater itself may be a significant component of the total heat transfer, and thermal radiation and convection loss can further increase the uncertainties in determining the thermal conductivity. Sometimes, two different membranes are used to determine the thermal conductivity, by assuming that the effective heat transfer coefficients for both geometries are the same [212, 214]. This assumption is dangerous if the experiment is done in air because natural heat transfer coefficient scales with the heated area. Ac- or transient-based heating and measurements can reduce the effects of heat loss through the metal heater and by thermal radiation [215]. If the measured membrane has a relatively high thermal conductivity, the spreading thermal resistance in the substrate supporting the membrane can be important. Multiple temperature sensors sometimes are fabricated along the membrane to eliminate this uncertainty but the additional loss along these temperature sensors should be considered [216]. A better location is to place the temperature sensor on the substrate at the place where the membrane meets the substrate, as shown in Figure 14c.

The bridge method constrains the heat flow to one dimension [65, 212, 217]. In this sense, it avoids the potential complication of the two-dimensional heat conduction effects in the membrane. However, the thermal conductivity depends on temperature profile along the bridge, which further depends on the radiation and convection heat losses and on the thermal resistance at the two ends of the bridge. In addition, the method is only applicable if a current can pass through the film (or another conducting film with known properties is deposited onto the film).

In addition to removing the substrate, we also mention the 3ω method to measure the in-plane thermal conductivity by exploring the heat spreading effect with small heaters [83, 209, 218]. When a high thermal conductivity film, such as silicon, is separated from the substrate by a low thermal conductivity layer, such as SiO_2 [22], surface temperature can also be sensitive to the in-plane thermal conductivity [76].

4.1.2. Photothermal Methods

Microheater and microsensor based methods require microfabrication facilities. In comparison, optical based methods are more flexible and are noncontact techniques. However, since it is difficult to determine accurately the amount of heat absorbed by the sample, the optical heating based methods usually do not lead directly to thermal conductivity. Instead, these methods measure the thermal diffusivity or thermal effusivity of the sample under investigation by monitoring the sample response to time dependent heat input at the boundaries. Pulse or modulated heating is often used. By using short pulses or high frequency modulated heating, the heat affected region can be confined to close to the film such that excessive temperature rise in the substrate can be avoided.

A variety of methods have been developed based on modulated laser beam heating of the sample. The modulation heating is favored because it allows phase-locked detection of the temperature-induced signals. In these experiments, a modulated laser beam (pump) is focused onto the sample surface, producing a local rise in temperature. The detection of temperature increase can be done by various means. For example, in the photothermal reflectance method, the sample reflectivity is monitored by another laser beam (the probe) focused on same location with the pump beam [219]. The photothermal displacement technique monitors the physical displacement of another laser beam due to thermal expansion of the sample [220]. In the photoacoustic methods the surface temperature is detected by measuring the acoustic signals coupled to the piezoelectric detectors either through the air on the front surface or through the substrate to the back surface [221]. In the photothermal radiometry method, the blackbody radiation from the sample surface is detected [222]. Another way to detect temperature increase is to measure the deflection of a laser beam parallel to the sample surface, caused by the gradient of the refractive index of the gas layer adjacent to the heated spot (Mirage method) [223]. The photothermal reflectance method can also be employed to visualize the thermal wave on the surface of the sample, by moving one beam with respect to the other [224, 225]. Typically the pump beam is scanned and the probe beam remains fixed in order to avoid surface roughness effects on the reflected beam. This technique may reveal defects or grain boundaries [225].

The modulation frequency in the techniques described is typically limited to a few megahertz and often below 100 kHz. Under such modulation frequency, the ac temperature field penetrates into the substrate. Interpretation of the photothermal signals thus involves the substrate thermophycial properties. Although the latter may also be determined from the measured signal, the inclusion of the substrate thermophysical properties as unknowns also can

cause more uncertainty in the film thermophysical property determination. A method to avoid the effects of the substrate is the transient photothermal technique [226], often called pump-and-probe technique, where the transient heating pulse ranges from nanosecond to femtosecond. The main advantage of using pulse lasers is that, for a particular pulse regime, the penetration depth of the thermal wave may be small compared with film thickness. Therefore heat diffusion at nanometer length scale can be measured directly. When picosecond or femtosecond pulse lasers are used, it is not possible to detect such fast changes in temperature with typical measurement instrumentation. In this case, the temporal response is measured by delaying the probe pulse with respect to the repetitive pump pulse and measuring its reflectivity for various delay times. Other experimental setups of this technique use nanosecond lasers [227]. In this case the temperature decay is still measurable by fast radiation detectors.

Photothermal methods have been used for measuring thermophysical properties of a wide range of materials such as metallic, semiconductor, or dielectric films [219], and superlattices [80] as well as for studying grain boundaries in semiconductors [228], interface thermal contact resistance [227, 229], and thermal properties colloid metal particles [230].

4.1.3. Mixed Optical/Electrical Heating and Detection Methods

There are also several methods that employ optical heating and sensor detection, or electrical heating and optical detection. Ac calorimetry is an example where optical heating is combined with thermocouple detection, if the response time requirement is not high, as in the measurement of low thermal diffusivity samples [204]. Thermal diffusivity of the sample is determined by measuring the temperature rise at different distances from the heated spot using fine thermocouples [204] or resistive thermometers [231]. Under appropriate conditions, the thermal diffusivity along the film plane can be calculated from phase or amplitude data. Cross-plane thermal diffusivity measurement is also possible by detecting the temperature rise at the back side of the sample with a thin resistive thermometer [231]. A different way to detect the thermal response of optically heated samples is to use a fast thermoelectric effect. In photothermoelectric technique, the specimens are heated on one side by laser radiation or white light collected from a high power lamp [232, 233]. The temperature is measured on the other side by a fast responding thermocouple, which consists of the contact point between a sharp wire and the electrically conductive sample surface. The technique may be employed in thermal diffusivity measurement of freestanding films or thin films on substrates transparent to the heating beam. In addition the light spot can be scanned around the detection point to image the thermal wave on sample surface. In addition to optical heating, electrical heating is also combined with optical detection to determine the thermal diffusivity of thin films. For example, electrical heating is combined with thermal-reflectance change or thermal emission to determine the thermal diffusivity of thin film [227, 234].

4.1.4. Nanowires and Carbon Nanotubes

While the experimental methods for thermal characterization of two-dimensional structures are relatively mature, only a few attempts have been made toward thermal property characterization of one-dimensional structures. Earlier experiments on thermal transport in one-dimensional structures have been carried out by Potts and co-workers [95–97]. The motivation of the work was to observe phonon quantization in nanowires made of GaAs single crystal that is known to have a large phonon mean free path. Freestanding arrays of highly doped GaAs are resistively heated, as in the bridge method for thin film thermal conductivity measurement. Their experiment, done at cryogenic temperatures, shows that electrons and phonons are at nonequilibrium and the measured thermal conductance is due to the electron conduction. Related to the nonequilibrium interactions are the experiments of Seyler and Wybourne on the electrical conductivity of metallic nanowires on silicon substrates [94]. They observed local peaks in the electrical resistance as the dc field applied across the wires was increased. The results were explained considering the electron–phonon interaction and the quantization of the acoustic phonon in the small wires. A different testing structure, using nanowires as the suspension for a heated island, was used by Schwab and coworkers [101]. They observed quantized conductance at 1 K. At slightly higher temperatures, their experimental data can only be explained by considering some diffuse scattering at the interfaces.

A different method for thermal conductivity characterization of one-dimensional structures was developed more recently by Shi and co-workers [99, 235]. Their idea is to use freestanding microfabricated structures (islands) whose temperature can be controlled and measured individually by thin-film resistors deposited onto the surface. The nanowire is then suspended between two islands and the thermal conductivity measurements are carried out by applying Joule heating to one of the islands, while the temperatures of both islands are monitored. Key challenges of this method include the minimization of the thermal contact resistance between the specimen and the microfabricated structure, and the maximization of the thermal resistance of the suspension structure. This method has been employed to measure the thermal conductivity of multiwalled carbon nanotubes and Si nanowires with various diameters [104].

The key challenge for the property measurement of nanowires lies in sample preparation, especially aligning electrodes to nanowires or nanowires to fabricated testing structures. So far, existing reports have relied on sophisticated micro- and nanofabrication techniques. There is a need for continued development of measurement techniques and more systematic study on the thermophysical properties of nanowires.

4.2. Temperature Measurement

In addition to thermophysical property characterization, measurements of temperature distributions are also of interest in many emerging technologies. The infrared thermal imaging techniques are limited to a resolution of a few micrometers, far from the resolution needed for thermal mapping in surrounding nanostructures. Several techniques

for thermal mapping at nanoscale have been proposed and are currently under development.

4.2.1. Scanning Thermal Microscopy

Scanning probe microscopes have provided nanoscale topographical resolution and it thus appears natural to locate a temperature sensor at the apex of the probes for thermal mapping. In fact, the first attempts in thermal mapping, after the invention of scanning tunneling microscope but before the birth of the atomic force microscope, was to use a thermocouple tip to measure surface topology of nonconducting surfaces according to conductance variation [236]. Several strategies have been proposed to place temperature sensors at the apex of AFM tips [237–239]. One method is to use a thermocouple as the cantilever and the other method is to place a thermistor at the apex. Both methods have gone through many improvements in the thermal sensor fabrication [240]. The estimated spatial resolution is 30–50 nm. One key issue with contact thermal mapping is the topology effect. Surface roughness changes the thermal contact resistance between the sample and the sensing tip. Low thermal conductance cantilevers have helped to minimize the heat flow from the sample to the cantilever, which reduces the topology effects on thermal imaging [235]. Also important to the accuracy of temperature estimation are the heat transfer mechanisms between the sample and the sharp tip [235]. Thermal images from scanning thermal microscopy (SThM) have provided new information for understanding the heat generation and heat conduction mechanisms in nanostructures. However, AFM based thermal imaging still has not reached the quantitative stage. An interesting theoretical question is what the resolution of SThM means since thermal transport around the SThM can be highly ballistic and nonequilibrium.

4.2.2. Near-Field Thermal Imaging

The near-field scanning optical microscope has the capability to break the optical diffraction limit [241]. In near-field infrared microscopy [242] similar probes have been used to obtain thermal images of 2 μm wide metal strips. The aperture diameter was of 1.5 μm, approximately one order of magnitude smaller than the dominant wavelength of thermal radiation at room temperature. A method to further increase the spatial resolution of the temperature measurement is to use visible radiation to probe the local change of reflectivity with temperature [243]. However, while the spatial resolution of near-field microscopy depends primarily on the aperture size, the low transmittance through the aperture probes drastically limits measurement sensitivity. This is even worse for thermal emission measurements due to the small thermal signal. One way to overcome this problem is to use solid-immersion lenses that could improve the spatial resolution without loss in sensitivity [244]. So far, near field thermal imaging has not reached the same level as SThM in terms of the image quality and resolution.

4.2.3. Thermal Reflectance Imaging

The photothermal method relies on the change of reflectance with temperature. This effect has been used extensively in the property measurements. Because the temperature dependence of the reflectance is generally small, $(10^{-4}–10^{-6})$/K, phase-locked detection schemes are often used, which requires periodic heating [224, 246]. For photothermal reflectance based property measurements, the periodic heating is realized by an external light source [224, 245]. For the thermal imaging of electronic devices, the devices are often biased with an ac current to periodically vary the temperature fields. Although such ac biasing may not correspond to the actual device operating conditions, the thermal mapping obtained leads to qualitative information on the hot spots. Transient heating has also been used, leading to an absolute measurement of the temperature distribution [247]. The thermal reflectance method can have a resolution of the order the laser wavelength used.

4.2.4. Raman and Luminescence Based Temperature Mapping

Raman spectroscopy measures the Stokes and the anti-Stokes shift of the laser line due to the phonon scattering of light. The intensity of the Stokes and the anti-Stokes lines depends on the phonon population and thus the temperature. From the intensity ratio of the two lines, the phonon temperature can be determined. Alternatively, the linewidth can also be used for temperature determination. Raman-based temperature mapping has been used in the investigation of the facet heating of semiconductor lasers [166, 248–250]. Similarly, photoluminescence peaks also depend on temperature and have been used for temperature mapping [251]. The advantage of the Raman spectroscopy method is that the ratio of the Stokes and the anti-Stokes line intensity depends on the phonon temperature only. However, the best temperature resolution reported so far is of the order of a few degrees.

5. ANALYTICAL TOOLS

The analysis and modeling of nanoscale heat transfer phenomena are challenging and complicated by several factors. One is that the mechanisms of nanoscale heat transfer are not well understood. Figure 6 shows different possible regimes of heat transfer. The determination of which regime a specific problem at hand falls into is nontrivial. Another major problem is that heat transfer rarely occurs only at nanoscale because eventually heat is dissipated into the macroscopic environment. Many heat transfer problems are multidimensional and multiscale spanning from nanoscale to macroscale. Tools for analyzing different problems are still evolving. In this section, we will divide our discussion into four directions: (1) purely ballistic transport, (2) classical size effects, (3) quantum size effects, and (4) multiscale modeling.

5.1. Purely Ballistic Transport

If all the geometrical length scales involved in the transport processes are much smaller than the energy carrier mean free path, the internal scattering of heat carriers can be completely neglected (i.e., transport is purely ballistic). An example is the radiation heat transfer in a vacuum enclosure, which is a topic in standard heat transfer textbooks.

The short mean free paths of electrons and phonons mean that this situation only occurs in nanostructures and very often at extremely low temperatures when the mean free path is long. Modeling of heat transfer in this purely ballistic limit is relatively simple. In thermal radiation, the concept of radiation shape factors is often used for heat transfer calculations. Typical radiation heat transfer treatment is limited to the incoherent regime where the phase information can be neglected. A more general formulation is the Landauer formalism that treats transport as a transmission process [252]. The energy transfer between two points in space is

$$\begin{aligned} q_{12} &= \frac{1}{8\pi^3}\sum_p \Big[\int E(k_1)v(k_1)\tau_{12}(k_1)f_0(T_{e1}, E_{fe1})d^3k_1 \\ &\quad - \int E(k_2)v(k_2)\tau_{21}(k_2)f_0(T_{e2}, E_{fe2})d^3k_2\Big] \\ &= \frac{1}{8\pi^3}\sum_p \Big[\int E(k_1)v(k_1)\tau_{12}(k_1)[f_0(T_{e1}, E_{fe1}) \\ &\quad - f_0(T_{e2}, E_{fe2})]d^3k_1\Big] \end{aligned} \tag{21}$$

where E is the energy per carrier, v is the carrier velocity, τ_{12} is the transmissivity from point 1 to point 2, k_1 are the wavevectors at point 1, f_0 is the distribution function, and the summation is over all polarizations of the heat carriers. We have used T_{e1}, E_{fe1} to emphasize that f_o represents the carriers leaving the point 1, not necessarily the local equilibrium temperature, as we discussed in Figure 8 for the thermal boundary resistance. The second equality of the Landauer formalism for heat flux comes from the principle of the detailed balance, which says that at equilibrium, there is no net flux.

Under the Landauer formalism, the key is to calculate the carrier transmissivity from point 1 to point 2. Both the wave and particle descriptions can be included under the Landauer formalism. In Section 2.1.1, for example, we discussed several models used to evaluate the phonon transmissivity across an interface and from the Landauer formalism, one can get the expression for the thermal boundary resistance of an interface expressed by Eq. (15). Similarly, the classical thermal radiation calculation based on the radiation shape factors can be understood as the calculation of the transmissivity. Landauer formalism can also be applied to obtain the universal thermal conductance of a nanowire, by considering the quatization of the energy spectrum of nanostructures [101]. Through the calculation of the transmissivity of acoustic waves and electromagnetic waves in layered structures, the Landauer formulation has been used to study the thermal conductance of superlattices and for radiation heat transfer across small spaces and for phonon heat conduction in thin films [28].

5.2. Classical Size Effects Regime

In Figure 6, we defined the classical size regime as the region when the mean free path is long compared to the characteristic length and when the scattering at the boundaries is strongly phase-breaking and randomizing. Under this situation, the energy spectrum of the heat carriers is close to that in bulk materials, with the complication that boundaries alter the trajectory of the heat carriers. We also grouped part of the quantum size regime as approximately treatable with the approaches for classical size effect described in this section. This occurs when the thermal wavelength is shorter than the domain size, but as explained in Section 2.1, this approximation does not always work and should be used prudently. In the classical size regime, the major new physics in addition to transport in bulk materials is the boundary scattering. This is a conceptually relatively easy addition. Commonly used tools for dealing with such size effects are the Boltzmann equation and Monte Carlo simulation.

5.2.1. Boltzmann Equation Approach

The Boltzmann transport equation (BTE) applies to dilute particles such as gas molecules, electrons, phonons, and photons. In its general form, the BTE can be written as [19]

$$\frac{\partial f}{\partial t} + \mathbf{v}\cdot\nabla_{\mathbf{r}} f + \mathbf{F}\cdot\nabla_{\mathbf{p}} f = \left(\frac{\partial f}{\partial t}\right)_c \tag{22}$$

where f is the statistical distribution function of an ensemble of carriers, which depends on time t, position vector $\mathbf{r}$, and momentum vector $\mathbf{p}$. $\mathbf{F}$ is the force vector applied to the particles. The key to the Boltzmann equation is the scattering term, which is the term that restores the system to equilibrium. Quantum mechanical principles are often used to deal with scattering. The perturbation treatment in quantum mechanics leads to the Fermi golden rule of calculating the scattering probability from one quantum state to another. A general expression of the scattering integral can be formally written based on the scattering probability and the distribution function [19]. This leads to an integral-differential form of the Boltzmann equation which is difficult to solve but has often been treated in thermal radiation transport in the form of equation of radiative transfer [25, 253]. For phonon and electron transport, as well as gas transport, the relaxation time approximation is often used,

$$\left(\frac{\partial f}{\partial t}\right)_c = \frac{f_0 - f}{\tau(\mathbf{r}, \mathbf{p})} \tag{23}$$

where f_0 is the equilibrium distribution (i.e., Fermi–Dirac distribution for electrons, Bose–Einstein distribution for phonons, and Maxwell–Boltzmann distribution for gas molecules) and $\tau(\mathbf{r}, \mathbf{p})$ is the relaxation time as a function of position and momentum and is often approximated as energy-dependent rather than wavevector-dependent [254]. When multiple scattering coexists, for example, carrier–carrier scattering and carrier–impurity scattering, the Mathessien rule is often used to obtain the total relaxation time [19].

There are two different approaches to deal with the boundary scattering of nanostructures on transport processes. One is to add an extra boundary scattering term into the relaxation time through the Mathiessen rule [19]. This approach is simple and has been widely used in dealing with low temperature transport problems in bulk materials where size effects are important, but it is not accurate because while carrier–carrier scattering and carrier–impurity scattering are volumetric processes, interface scattering occurs at

the surfaces [255]. The other approach is to treat interfaces and boundaries through boundary conditions to the Boltzmann equation. In this latter approach, the relaxation time in bulk materials without any size effects is first determined. The effects of the interfaces and boundaries of nanostructures are imposed as the boundary conditions.

Classical size effects on transport processes and properties of all the energy carriers have been studied in the past. The classical size effects on electron transport were summarized in the book of Tellier and Tosser [56]. Flow and heat transfer of rarefied gas has also been studied extensively in the past [256]. Size effects on phonon transport started in the 1930s through Casimir's pioneering work [257]. The last two decades have seen a surge of investigations on phonon size effects in low-dimensional structures [11, 12].

The most studied phonon size effect is the thermal conductivity reduction in thin films. Phonon heat conduction in thin silicon thin films has been measured and modeled by Volklein and co-workers on polycrystalline thin films for thermoelectric applications [258, 259] and by Goodson and Ju for single crystalline silicon thin films [3, 22]. The modeling for the in-plane thermal conductivity of single crystalline thin films is a simple extension of the Fuchs and Sonderheim classical treatment of the electron size effects [67, 260, 261]. For polycrystalline films, the gray boundary scattering adds another relaxation time that has been grouped into the bulk relaxation time according to the Mathiessen rule. A model based on geometrical consideration rather than solving the Boltzmann equation was developed by Flik and Tien [262]. Heat conduction perpendicular to a thin film was dealt with in several papers [46, 260–265]. Majumdar [263] solved the phonon Boltzmann equation assuming that the two surfaces of the film are black phonon emitters. Chen and Tien [260] developed a model for the thermal conductivity of quantum wells based on the BTE for both the in-plane and the cross-plane directions. The in-plane thermal conductivity is based on Fuchs' solution [54] while the cross-plane direction is based on the approximate solution developed for the photon transfer equation.

Size effects in multilayer structures are more difficult to model than a single layer. The incoherent particle transport models for thermal transport in superlattices based on the Boltzmann transport equation were developed by Chen and co-workers in a series of papers for transport in both in-plane and cross-plane directions [21, 48, 93] and by Hyldgaard and Mahan for the in-plane direction [20]. The models by Chen and co-workers assume partially diffuse and partially specular interfaces, with the fraction of specular interface scattering left as a fitting parameter. Figure 15a and b shows examples of the model fitting with experimental data for both in-plane and cross-plane directions. The experimental data are from Yao [79], Yu et al. [266], and Lee et al. [50]. The good agreement seems to indicate that the phase-breaking scattering processes dominate.

The Boltzmann equation approach as has been used in thin films and superlattices can be readily extended to one-dimensional structures, such as nanowires [102, 105]. Walkauskas et al. [106] solved the Boltzmann equation for square nanowires and compared the thermal conductivity of nanowires to thin films. As expected, additional lateral surfaces cause a more pronounced reduction in the thermal

conductivity of wires compared to films. Nanowire superlattices have also been modeled recently [45].

There have been many modeling studies in the past on the thermal conductivity of porous materials due to their applications in thermal insulation [267]. These models, however, cannot be applied to nanoporous materials because they did not include size effects, as is clearly required from experimental data [268]. Several attempts to include the size effects have been made in the modeling of the thermal conductivity of nanoporous silicon [269–271] and opals [272]. Size effects on nanocomposite thermal conductivity have been considered based on the inclusion of thermal boundary resistance [273]. One major difficulty in the Boltzmann equation approach lies in the solution of the equation. The Boltzmann equation is a phase space equation with seven variables. Direct numerical solution is generally difficult. There have been a few treatments applying the Boltzmann equation to nonplanar geometries that are more relevant to actual device configurations [117, 274]. More detailed discussion will be given in Section 5.4.

5.2.2. Monte Carlo Simulation

Monte Carlo simulation solves the Boltzmann transport equation in a statistical framework. Over the last decade or so, there has been tremendous advancement in the development of Monte Carlo solution techniques for the radiative transfer equation and the Boltzmann equation for electrons and holes in semiconductors [275–280]. Only a few reports using Monte Carlo technique for phonon transport have been published in the past. Peterson [281] employed the Monte Carlo method to simulate phonon transport in a confined space while Klitsner et al. [282] performed Monte Carlo simulations to obtain temperature distribution in a crystal. More recently Mazumder and Majumdar [283] considered phonon dispersion as well as various phonon scattering mechanisms to study heat transport in complex geometries and to predict the thermal conductivities. The result showed that by fitting one parameter using experimental data of thermal conductivity at one temperature, predictions of the thermal conductivity of silicon agree well experimental data over wide temperature range. In addition, it was able to capture both the ballistic and diffusive limits. The major advantage of this method is that the simulation code can be easily adapted to complex geometries. In addition, Monte Carlo simulation can separately treat various scattering mechanisms. The major disadvantage of the Monte Carlo method is its slow speed.

5.3. Quantum Size Effect Regime with Scattering

While it is relatively straightforward to treat wave effects if no scattering exists, the physical picture becomes less clear and mathematical treatment becomes more complicated when both wave effects and scattering coexist. If there is no scattering and the detailed geometries and atomic compositions of the nanostructures, particularly the interface structures, are known, the energy states of the nanostructures can be solved from the Schrödinger equation. Examples are the electron and phonon energy states of a perfect thin film or quantum well. The existence of internal scattering, however, usually distorts the energy states from these ideal calculations. Imperfect interface structures, which are usually unknown, further add to the complexity. The quantum form of the Boltzmann equation does exist [284]; similarly, quantum Green's function methods may also be applicable for treating nanoscale heat conduction problems [285]. None of these approaches, however, have been implemented so far for realistic nanostructures. So far, all the treatments for situations when both wave and scattering are in existence are all based on various assumptions that may be valid under certain conditions. There are two approximation strategies. One approach, for example, is to assume that the quantized energy states form first, usually calculated under perfect interface conditions. These quantized states are then treated as particles based on the Boltzmann equation. We will call this quantized incoherent transport. Clearly, whether this approximation is valid or not depends on the strength of the boundary scattering in breaking or randomizing the phases.

In this section, we will discuss several approaches that include, to a certain extent, the wave mechanisms, including (1) quantized incoherent transport, (2) the molecular dynamics simulation, and (3) the fluctuation–dissipation theorem approach.

5.3.1. Quantized Incoherent Transport

The quantized incoherent transport first computes the energy spectrum of the nanostructures. The subsequent motion of these quantized energy carriers, however, is treated as incoherent. Representation treatments include electron transport in quantum wells and quantum wires for thermoelectric energy transport studies [30, 178]. Electron energy states are quantized due to lateral confinement. Transport along the film plane or wire axis, however, is diffusive, either due to interface scattering or internal scattering. Experimental measurements of the electrical conductivity of nanowires seem to validate such an approach [286, 287].

For phonon heat conduction in thin films, nanowires, and superlattices, a similar approach has also been taken [58, 59]. The phonon spectra of nanowires and thin films have been computed based on continuum acoustic wave equations or the lattice dynamics method. For heat conduction along the film plane or wire axis, the assumption of a perfect interface does not lead to much change in the thermal conductivity compared to bulk materials [57]. This is also anticipated from a pure particle-based approach because in these cases, the structures simply act as waveguides [54, 55]. Only when diffuse interface scattering is included can these approaches lead to thermal conductivity predictions that are comparable to experimental observations. However, it is not clear at this stage whether such quantized states do form or not, and if yes, as some Raman spectroscopy would suggest [288] there is no quantitative information on the fraction of the quantized states compared to the bulk states.

Phonon heat conduction in superlattices offers another test to the assumption of a quantized incoherent transport model. Different lattice dynamics models have been used to compute the phonon spectra in various superlattices and these spectra are used to calculate the phonon group

velocity [88–90]. The Boltzmann equation is used to calculate the thermal conductivity using the new group velocity and the phonon density of states, assuming that the relaxation time of the superlattices is equal to that of its parent materials. These attempts, however, have not lead to quantitative agreement with experimental results, and in fact, even the qualitative agreement is poor as the lattice dynamics would lead to the thermal conductivity decreasing with period and eventually to a flat thermal conductivity that does not change with period. Figure 16 compares the lattice dynamics result with experimental results and clearly shows that neither the absolute values nor the trends are consistent with experimental data in both in-plane and cross-plane directions [51], except in the very thin period limit where the slight recovery of experimental thermal conductivity in some superlattices seems to agree with the trends of lattice dynamics predictions. In comparison, the incoherent transport models based on the assumption that phase coherence is not important leads to results that are in agreement with experimental data, particularly in the thick period regime [48, 93], as shown in Figure 15. This does seem to suggest that the phonon heat conduction processes in thin films are dominated by incoherent transport.

Why do bulk crystal solids form phonon band structures that can be used in the Boltzmann equation calculation, while the phonon band structure-based calculation for ideal superlattices seems to fail to explain the thermal conductivity? To answer this question, we can use the wave method to calculate how many layers are required to form the superlattice spectra that assume an infinite number of layers. Transfer matrix based calculation shows that 10 periods will suffice. Thus, phonons must remain phase coherent over such periods to form new superlattice bands. If diffuse interface scattering randomizes the phase, the calculated phonon spectrum based on ideal interfaces is not valid and no superlattice mode or only partial modes form. In addition, internal scattering can also destroy the phases because 10 periods can be much longer than the phonon mean free path.

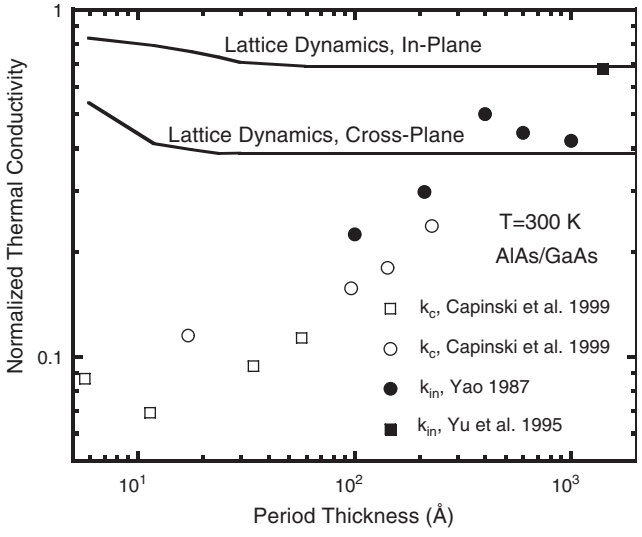

Figure 16. Comparison of lattice dynamics with experimental data. The experimental data are from Yao [79], Yu et al. [266], and Capinski et al. [80]. Adapted with permission from [51], B. Yang and G. Chen, in "Chemistry, Physics, and Materials Science for Thermoelectric Materials: Beyond Bismuth Telluride" (M. G. Kanatzidis, T. P. Hogan, and S. D. Mahanti, Eds.). One way to treat both the quantized and the bulk energy states is to introduce an imaginary wavevector into the Bloch wave functions. When the imaginary wavevector is large, the waves are highly damped and only sample few unit cells of the original crystals making up the nanostructrure and thus tend to recover to the bulk dispersion. When the imaginary wavevector is zero, the lattice waves extend over the whole structure and the new energy bands will form. The method was first used by Pendry for electron transport [289]. Simkin and Mahan introduced it to lattice dynamics for calculating superlattice thermal conductivity [290]. Their model is able to predict a minimum in the cross-plane thermal conductivity and the period dependence. However, the Simkin and Mahan model does not consider the diffusive interface scattering, which is probably one major cause of the reduced mean free path in superlattices. As a consequence, their model cannot explain the in-plane thermal conductivity reduction in superlattices, nor the absolute magnitude of thermal conductivity reduction in the cross-plane direction. Yang and Chen related the imaginary wavevector to the interface diffuse scattering [51, 291]. This approach enables the calculation of the thermal conductivity of superlattices in both in-plane and cross-plane directions, both leading to good agreement with experimental data, as shown in Figure 17.

5.3.2. Molecular Dynamics Simulation

Like lattice dynamics, classical molecular dynamics (MD) simulation also solves Newton's second law to track the motion of all atoms in a system [292–294]. The difference between lattice dynamics and molecular dynamics is that lattice dynamics uses harmonic forces while molecular dynamics inputs the true potential of atomic interaction. Bolstered by advances in computation power, MD has become a powerful tool for studying material formation processes and material properties and it is increasingly employed to study heat transfer [295–306]. Its key limitations are determination of accurate potentials and the size of systems that can be studied. Fortunately well-tested empirical potential are available for most of the material of interest. For example the Stillinger–Webber potential is often used for silicon [307]. System size is currently the greatest limitation. Recent large-scale MD simulations of fluid flows involve ~200,000 atoms and solids of 10–100 million atoms depending on necessary times of simulation [308, 309]. Unfortunately, the mean free path of heat-carrying phonons in silicon crystals is ~3000 Å [3, 48]; yet even a 1000 Å on a side cube of silicon contains ~50 million atoms and requires a long run time to accumulate phonon statistics.

Equilibrium and nonequilibrium MD simulations have been used in heat transfer studies. In the nonequilibrium approach, a temperature difference or energy flux is imposed by altering the atomic dynamics in localized boundary regions [310, 311]. In general, nonequilibrium techniques suffer from three major drawbacks: (1) the simulation

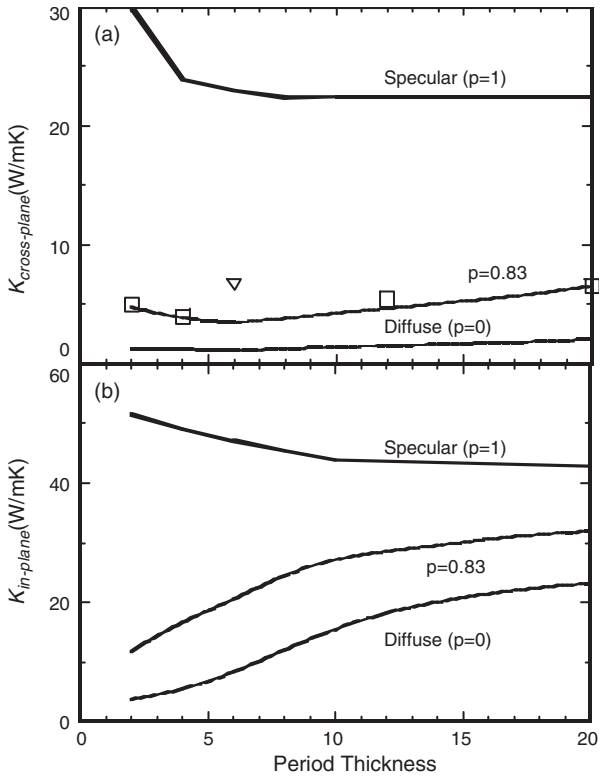

Figure 17. Thermal conductivity of GaAs/AlAs superlattices obtained from incoporating diffuse interface scattering into a lattice dynamics model; experimental data from Capinski et al. [80] are also plotted. Adapted with permission from [51], B. Yang and G. Chen, in "Chemistry, Physics, and Materials Science for Thermoelectric Materials: Beyond Bismuth Telluride" (M. G. Kanatzidis, T. P. Hogan, and S. D. Mahanti, Eds.). Kluwer Academic/Plenum, New York, 2003. © 2003, Kluwer Academic/Plenum.

domain must contain enough atoms in the boundary regions to stabilize the boundary temperatures, which increases the overall cost of the simulation; (2) the systems that can be simulated are smaller than the phonon mean free path and their small size also restricts the maximum phonon wavelength; and (3) an unphysically large temperature gradient is required to converge temperature statistics, making it difficult to determine the thermal conductivity at a particular temperature. So far, the nonequilibrium MD simulation techniques have been applied to thin films, nanowires, and carbon nanotubes [112, 301, 312].

The equilibrium approach relies on small statistical temperature fluctuations to drive instantaneous heat fluxes [313–315]. Although the time average of this heat flux vanishes, the thermal conductivity of the system to the disturbance can be calculated from the instantaneous heat flux autocorrelation function according to the Green–Kubo formula [314]. Convergence is slow, but the equilibrium approach is free of the three drawbacks associated with the nonequilibrium technique (periodic boundary conditions effectively remove the mean free path limitation [301, 303]), although care still must be taken to avoid artificial size effects of the finite simulation domain. Equilibrium methods have been used to diagnose the thermal conductivity of many materials including recent computations of high thermal conductivity materials such as silicon and diamond [301, 302]. The MD simulation of thermal conductivity of superlattices has also been explored [316–319]. Recently, Daly and co-workers used MD simulation to investigate the effects of interface mixing on the thermal conductivity in GaAs/AlAs superlattices [70]. Their simulations show that for perfect interface, the results are similar to that of lattice dynamics. For the case of superlattices with interface mixing, the simulation results are much closer to experimental data, further reinforcing the discussion we had previously on the heat conduction mechanisms in superlattices.

From the time history of individual atoms in a MD simulation, phonon spectral characteristics can be analyzed by discrete Fourier methods. Thus the relaxation time and other important properties such as phonon spectrum, group velocity, and density of states can be computed from the time history of the atomic trajectory and its velocity [320]. In principle, such information can be incorporated into the Boltzmann equation to treat heat transfer mesoscale systems that cannot be simulated directly by the MD methods. In addition, MD simulation can be the most ideal tool to study the imperfect interface and anharmonic scattering while lattice dynamics or acoustic modeling can only model the process qualitatively by assuming idealized interfaces and neglecting all anharmonic scattering in nanostructures. Some MD studies have examined thermal boundary resistance [321–324].

One theoretical drawback of the classical MD method is that it does not include the quantum statistics and quantum scattering mechanism. Such a drawback limits the MD results to high temperatures when the quantum effects are negligible. There have also been theoretical attempts to correct the difference between quantum and classical simulations. The first correction is on the temperature. Other modeling suggests that quantum effects on scattering are not large. This topic, however, needs further study.

5.3.3. Fluctuation–Dissipation Theorem Based Wave Approach

A well-established method to treat both the absorption, emission, and wave effects in thermal radiation is the fluctuaction–dissipation theorem based approach established by Rytov [325]. This approach was used to formulate the problem of radiation heat transfer between two closely spaced surfaces [14], radiative transfer in absorbing and emitting thin films [326], and recently was used for treating radiation exchange between surfaces due to surface modes [147, 151]. In this approach, the emission is related to the fluctuation of microscopic current sources, the strength of which is related to the local temperature through the fluctuation–dissipation theorem. The propagation of the electromagnetic field generated by each current source is solved based on the Maxwell equations. This approach, in theory, can be extended to acoustic waves and maybe even electron waves, but no such attempts have been reported.

5.4. Multicarrier and Multidimensional Transport

Heat transfer and energy conversion in electronic and thermoelectric devices often involve multicarriers and multiple length scales. For example, heat is typically generated in a nanometer-scale region at the drain of a MOSFET when hot electrons relax their energy to phonons and is subsequently conducted through the millimeter thick substrate to the surroundings. In this section, we will discuss the modeling of nonequilibrium electron and phonon transport and the multidimensional transport problems.

5.4.1. Coupled Electron–Phonon Transport

Traditionally, it is assumed that electrons and phonons are under local equilibrium in modeling transport phenomena in a solid. However, the equilibrium between electrons and phonons can be disrupted in many cases. For example, in the presence of a sufficiently high electric field, electrons can be energized and thrown far out of equilibrium from phonons [127]. This is termed the hot electron effect. Such a nonequilibrium condition becomes important for microelectronic devices because the electric fields become higher as the feature size shrinks. In the case of laser–material interactions, the electrons can be thrown out of equilibrium from lattice due to excitation by ultrashort laser pulses [126, 327].

For coupled electron and phonon transport in nanostructures, the electron and phonon Boltzmann equations should be solved simultaneously. This approach, however, has not been taken due to the numerical complexity involved. In the past, the electron hydrodynamic equations are often used for modeling electron transport for practical device simulation, coupled to the diffusion treatment for the phonon heat conduction [328–331]. The hydrodynamic equations assume that electrons and phonons are in local equilibrium with their own pools. In a quite similar way, Qiu and Tien studied conversion and transport phenomena during ultrafast processes such as femtosecond to nanosecond laser–material interactions based on treating electrons and phonons as separate systems [126, 332]. Their theoretical and experimental studies show that it is the nonequilibrium nature between electrons and phonons during the femtosecond laser–metal interactions, rather than the hyperbolic heat conduction effect, that dominates the observed experimental phenomena. However, in these models, the ballistic transports are not counted, neither for electrons nor for phonons. Sometimes the electron transport is solved from the full-blown Boltzmann equation or Monte–Carlo simulation to count the ballistic nature of electrons [333]. However, very little work has been done to study the effect of ballistic phonon transport on electron transport. Concurrent modeling of the nonequilibrium electron and phonon transport based Boltzmann equation is desirable.

Along the same line, the coupled electron–phonon transport is the basis for solid-state energy conversion such as thermoelectric and thermionic cooling and power generation. Taking thermoelectric cooling as an example, electrons take energy away from phonons at a metal–semiconductor interface, carrying it to the hot side, and rejecting it to phonons. Although the macroscopic thermoelectric phenomenon is well understood [334], some questions remain, such as what happens at the interface and how phonons are cooled and heated by electron systems. There are a few papers dealing with nonequilibrium electron and phonon transport in thermoelectric research [46, 335, 336] but the full picture of coupled electron–phonon transport near the interface has yet to be clarified.

5.4.2. Multilength Scale and Multidimensional Transport

Heat conduction in most devices is multidimensional and involves length scales from nanoscale to macroscale. Modeling the energy transport and conversion processes in such multiple length scale devices is very challenging. The solution of the Boltzmann equation has been limited to a few a simple geometrical configurations such as thin films and superlattices [76, 337]. In principle, the discrete ordinates method, the spherical harmonics method, and the Monte Carlo method developed for thermal radiation

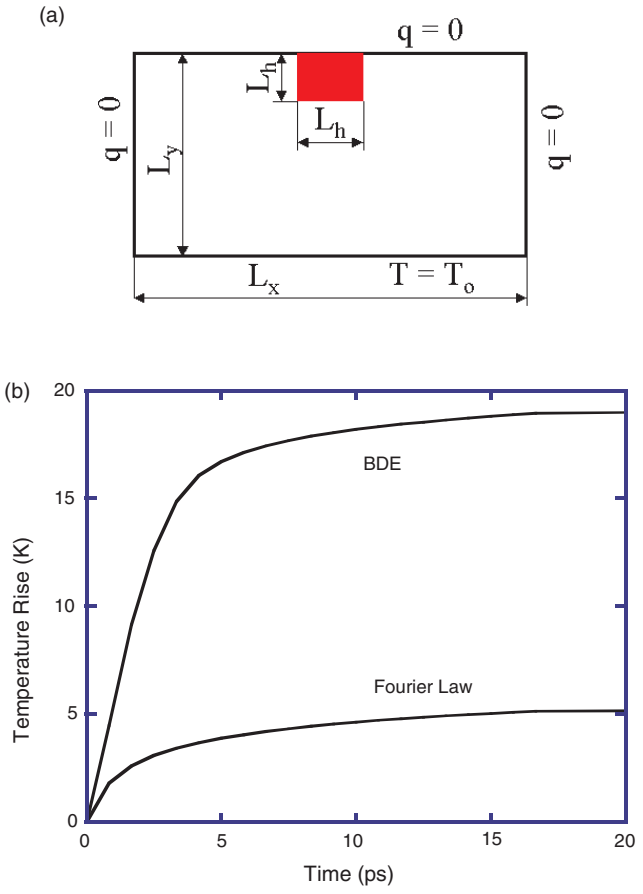

Figure 18. Comparison of the peak temperature rise of nanoscale heat source. (a) a 10 nm × 10 nm ×1μm hot strip embedded in the silicon substrate and (b) the peak temperature predicted by the Fourier law is much smaller than that predicted by the ballistic–diffusive equations. Reprinted with permission from [121], R. G. Yang, et al., in "Proceedings of the 12th International Heat Transfer Conference" (J. Taine, Ed.), Vol. 1, pp. 579–584. Elsevier, Paris, 2002. © 2002, Elsevier.

[253] can be used to solve the Boltzmann transport equation. However, fewer studies have gone beyond nonplanar and multidimensional geometries [117, 120, 121, 271, 283, 338, 339].

Direct numerical solution of the Boltzmann equation, however, is usually slow. Approximate methods that are capable of capturing the major size effects but easier to implement are thus desirable. One such method, for example, is to focus on the interface region only by introducing appropriate boundary conditions, while away from the boundaries the usual diffusion or drift-diffusion equations are used. Examples are the velocity slip boundary condition for rarefied gas flow [256] and the Deissler temperature jump boundary condition for photon radiation heat transfer [25]. Similar interface conditions, called diffusion–transmission interface conditions, have been introduced for phonon and electron transport [340].

Another approximation that provides further improvements compared to the introduction of special interface conditions is to split the carriers inside the medium into two groups—a ballistic component and a diffusive component. The ballistic component originating from boundaries and nanoscale heat sources experiences outscattering only. This group can be explicitly solved through a path integral. The transport of the scattered and excited heat carriers is treated as a diffusive component with the diffusion approximation. This approach was first used for thermal radiation [253] and was recently employed by Chen to develop the ballistic–diffusive heat conduction equations. Yang et al. [121, 338] applied the ballistic–diffusive equations to study the phonon rarefaction effect, the heat transfer surrounding a nanoscale heat source. The heat source is similar to the phonon hot spot generated in a MOSFET device. A 10 nm $\times$ 10 nm $\times$ 1μm hot strip is embedded in the silicon substrate (Fig. 18a). The power generation rate is 1×10^{19} W/m^3, typically for a period of $\sim$10 ps. Figure 18b shows the highest temperature rise in the device as a function of time. Both Fourier law and ballistic–diffusive equations predict a saturation temperature rise after 10 ps. The peak temperature predicted by the Fourier law is much smaller than that predicted by the ballistic–diffusive equation, due to the rarefied phonon heat conduction effect discussed in Section 3. The experiment by Sverdrup and co-workers [123] also demonstrates such a phonon rarefaction effect.

6. SUMMARY

In this chapter, we discussed the uniqueness of heat transfer phenomena in nanostructures. Figure 6 summarizes different heat transfer regimes that one may encounter at nanoscale. When the structure characteristic lengths are comparable to the mean free path, size effects become important. In the classical size effect regime, the phase of the energy carriers can be neglected while it must be included in the quantum size effect regime. The distinction between the classical and the quantum size effect regime depends on the phase-breaking strength of the interface scattering processes, which is not well understood now. Thermal wavelength provides another length scale to judge whether the bulk energy spectrum is a good approximation. This length scale, however, must be used carefully because although the average energy spectrum does not change much when the structure is much larger than the thermal wavelength, the group velocity in specific transport directions can have significant changes, as in the case of superlattices. Some examples of nanoscale heat transfer phenomena in the quantum regime include interference, tunneling, and even coherent thermal emission. In the classical size effect regime, diffuse interface scattering tends to reduce the heat transfer through the system.

Nanoscale heat transfer phenomena can have significant implications for a variety of contemporary technologies, some undesirable as the classical size effects on the thermal management of microelectronics and optoelectronic devices, while others can be utilized to improve the data storage density or energy conversion efficiency, as in thermoelectric cooling and power generation and in thermophotovoltaic energy conversion. Nanoscale heat transfer is also related to nanomaterial synthesis and nanofabrication and some emerging biotechnologies.

Experimental and modeling tools for nanoscale heat transfer are discussed. Various measurement techniques have been developed in the past for the thermophysical property determination of thin films and superlattices. Experimental techniques for characterizing nanowires and other nanostructures, such as nanowires and nanoparticles, still need further development. Impressive progresss has been made in thermal imaging at nanoscale based on the scanning probe microscope but the technique has stayed mainly at a qualitative level. With regard to modeling, the classical size effects region and purely ballistic transport regimes can be treated reasonably well. Key challenges exist for the regime when both wave effects and scattering coexist because scattering can change the energy spectrum of nanostructures. At room temperature, experimental studies so far suggest that phonon transport falls mostly into the classical size effect regime while electron transport can fall into the quantized incoherent transport regime. From the discussions, it is clear that much work remains to be done in both experimental and modeling arenas.

GLOSSARY

Acoustic phonons The lower branches of phonon modes in the dispersion curves.

Blackbody radiation The radiation emitted by a blackbody. A blackbody is a virtual object that absorbs all radiation incidents on it.

Dispersion relation Relates the frequency of a carrier, ω_k, to its wavevector k. The *group velocity* of the carrier can be found from the dispersion relation through $v_k = \frac{\partial \omega_k}{\partial k}$.

Elastic scattering There is no net change of energy of each involved particle before and after an elastic scattering process.

Inelastic scattering The energy of some of participating carriers changes before and after an inelastic scattering process. Refer to elastic scattering.

Mean free path The average distance a particle moves between succesive collisions.

Optical phonons The upper branches of phonon modes in the dispersion curves, refer to acoustic phonons.

Phonons Quanta of lattice waves in solids.

Phonon-polariton The hybrid mode of the coupled phonon and electromagnetic transverse wave field.

Phonon rarefaction Occurs when the heating/cooling region is much smaller than the phonon mean free path.

Stokes/Anti-Stokes shift Represents a change in energy (frequency) of photon scattered by a substance due to photon-phonon interaction. The scattered photon may have a smaller frequency (Stokes shift) or higher frequency (anti-Stokes shift) depending whether a phonon has been generated or absorbed during the scattering process.

Thermal boundary resistance or Kapitza resistance Used to describe the additional thermal resistance due to the reflection of energy carriers at an interface when the heat transports across the interface.

CONTENTS

1. INTRODUCTION

Ferromagnetic thin films and multilayers have been researched intensively in recent years for applications in various magnetic recording and nonvolatile memory devices [1]. Interest in these materials has increased dramatically since the discovery of giant magnetoresistance (GMR) in multilayers comprised of alternating ultrathin (10 to 50 Å) ferromagnetic/noble metal layers. Briefly, the GMR effect can be understood in terms of spin-dependent scattering of conduction electrons at ferromagnetic/nonmagnetic interfaces. Conduction electrons with a spin direction parallel to a material's magnetic orientation move freely, providing low resistance. Conversely, conduction electrons with spin direction opposite to the material's magnetic orientation are hampered by more frequent collisions with atoms in the material, producing higher resistance.

In computer and data processing systems the main form of data storage and retrieval is based on magnetic recording systems, either magnetic disks or tape drives [2–16]. Information is written and stored as magnetization patterns on a recording media and can be transferred back and forth using a magnetic sense head. In addition magnetic random access memories (MRAM) are used for storage and processing of very high bit densities. These devices offer advantages over semiconductor memories as they are radiation-hard and infinitely rewritable, with high storage densities, and fast access time. Finally there are magnetic sensors, transducers, and actuators which are used in automobiles, aircraft, hydraulic equipment, and defense applications (mine detection, perimeter defense) [1, 9]. In all of these structures there is the need to pattern the magnetic layers [17] which are generally thin films of materials such as NiFe, NiFeCo, which are often incorporated into multilayers comprising magnetic and nonmagnetic materials.

The fabrication of read/write heads and other magnetic storage elements requires methods for producing submicrometer features in multilayer structures involving NiFe and NiFeCo [1, 13–17]. Due to the relative involatility of the etch products of these materials in conventional plasma reactors, virtually all of the patterning is performed using ion beam etching or lift-off processes [17–20]. Both of these methods have drawbacks for producing very small features—ion beam etching has poor selectivity with respect to mask materials and can produce redeposition of the sputtered materials onto the feature sidewalls that degrades the magnetic performance of the devices [18, 19] while lift-off processes typically suffer from poor yield relative to direct etch removal methods.

In a typical reactive plasma process, exposure of NiFe and NiFeCo to chlorine or other associated feed gases produces a reaction or selvedge layer consisting of involatile etch products (i.e., $NiCl_X$, $FeCl_X$, $CoCl_X$ species) [18–22]. Since these do not leave the surface and their atomic volumes are typically larger than those of the elements they are formed from, there is actually net deposition, rather than etching. There are basically two methods to enhance desorption of the etch products. The first is to heat the sample during plasma exposure to increase etch product volatility, but typically temperatures above 300 °C are required [18]

ISBN: 1-58883-063-2/$35.00

Encyclopedia of Nanoscience and Nanotechnology
Edited by H. S. Nalwa
Volume 7: Pages (461–475)

and this exceeds the thermal "comfort zone" of most magnetic multilayer structures. The second is to employ a high ion flux in conjunction with the reactive chlorine neutral flux incident on the sample. The ion energy, however, must be kept low under these conditions to avoid mask degradation and loss of etch selectivity. The etch rates are a strong function of ion flux, ion energy, and plasma gas composition, all of which may be interpreted in terms of balancing formation of chloride etch products with concurrent ion-assisted desorption of these products. Thus, the role of ion bombardment is critical in this mechanism. Alternative plasma chemistries including bromine or iodine containing plasmas were also examined under high density plasma conditions. The interhalogens ICl and IBr have been found to dissociate readily in high density plasma sources, producing high concentrations of reactive species.

However, one concern with this process is the effect of residual chlorine or chlorinated etch residues remaining on the sidewalls of etched features. We report on the effectiveness of several different *in-situ* or *ex-situ* cleaning processes after Cl_2/Ar high density plasma etching of GMR elements. We find that inductively coupled plasma (ICP) etching does not degrade the magnetic performance of single or multilayer structures, and subsequent water rinsing or *in-situ* H_2 or SF_6 plasma cleaning is efficient in preventing corrosion.

Another method for preventing corrosion is applying noncorrosive gas chemistries such as CO/NH_3 or CO_2/NH_3. Nakatani [23] reported use of a noncorrosive CO/NH_3 plasma chemistry for NiFe, in which the etch products are expected to be carbonyls [e.g., $Fe(CO)_5$]. The resultant etch rates were $\leq$300 Å/min^{-1} for $Ni_{0.8}Fe_{0.2}$, a factor of about three higher than purely physical Ar^+ sputtering under the same conditions. The reactor employed was noncommercial and might be classified as a magnetron-type, medium ion density system. We report on a parametric investigation of CO/NH_3 etching of NiFe, NiFeCo, and related thin film materials using an ICP reactor. We find maximum etch rates for NiFe and NiFeCo in the range 350–400 Å/min^{-1}, with the rates being a strong function of $CO:NH_3$ ratio, source, and radio frequency chuck power, and pressure. We also compared use of CO_2 to replace CO, though this does not appear to offer any advantage in etch rates.

In this chapter, a comparison is given of high density plasma reactors such as electron cyclotron resonance, and ICP based on either corrosive gas chemistries (Cl_2, IBr, ICl) or noncorrosive gas chemistries (CO/NH_3, CO_2/NH_3) will be described for the etching of NiFe, NiFeCo, and other elements in magnetic multilayers. The influence of postetch cleaning procedures on magnetic properties is also examined. Finally, the selectivity for etching the magnetic materials over common mask materials (photoresist, SiO_2) was measured over a broad range of conditions.

2. MAGNETIC DEVICES

2.1. Theory of GMR

In any material, some conduction electrons will be oriented with "up" spins, and some will be oriented with "down" spins. The material can be viewed as having two independent conduction channels, one for each electron spin orientation. The measured current will be the sum of these channels:

$$j = \sum_s j_s \qquad (s = \uparrow, \downarrow) \tag{1}$$

In a nonmagnetic material, these two currents are equal. In a magnetic material, such as Fe or Co, the two currents are different: interaction of a conduction channel with its surroundings will be spin-dependent. First, the conduction electron energy bands will be different for majority spin electrons (spin parallel to the magnetization). Second, minority and majority spin electrons will have different scattering potentials when they encounter impurities and interfaces. Thus, in a bulk ferromagnetic material, the resistivity of the majority spin channel ($\rho\uparrow$) is typically different from the minority spin channel ($\rho\downarrow$) [24, 25].

In a multilayer structure where the layers are antiparallel, however, the up conduction channel will be scattered as majority spin electrons in one layer and as minority spin electrons in the next layer, and vice versa. For this reason, the net resistivities of two channels will be the same and approximately equal to the average resistivity of the two channels in the bulk:

$$\begin{aligned} \rho_\uparrow &= a + b \\ \rho_\downarrow &= a - b \\ \bar{\rho} &\cong \frac{1}{2}(\rho_\uparrow + \rho_\downarrow) = a \end{aligned} \tag{2}$$

Conductivities (σ) of the two channels (σ_1, σ_2) add in parallel and the resistivity is the reciprocal of the conductivity. So

$$\rho_{\text{tot}} = \frac{1}{\sigma_1 + \sigma_2} = \frac{\rho_1 \rho_2}{\rho_1 + \rho_2} \tag{3}$$

In the absence of an applied field, $\rho_1 = \rho_2 = \bar{\rho}$, and the total resistivity will be

$$\rho_0 = \frac{1}{2}\bar{\rho} = \frac{1}{2}a \tag{4}$$

At the saturation field, on the other hand, $\rho_1 = \rho\uparrow$ and $\rho_2 = \rho\downarrow$. The layers will be oriented in parallel:

$$\rho_{\text{sat}} = \frac{\rho_\uparrow \rho_\downarrow}{\rho_\uparrow + \rho_\downarrow} = \frac{a^2 - b^2}{2a} \tag{5}$$

Clearly,

$$\rho_{\text{sat}} < \rho_0 \tag{6}$$

In other words, an applied magnetic field (for instance, a field stored in magnetic media) "short circuits" the magnetic layers, reducing the total resistivity. This short circuit is observed as the GMR effect.

2.2. Basic Mechanism of GMR

Giant magnetoresistance is largely caused by a quantum effect called spin-dependent scattering, which results from the fact that the spin of an electron can point either up or down. Electrical resistance is caused by the scattering of electrons, but magnetic materials scatter spin-up and spin-down electrons differently (Fig. 1) [26].

Given a difference in resistivity between spin-up and spin-down electrons, the low resistance of the multilayer is generated when conduction electrons with a spin direction parallel to a material's magnetic orientation move freely. Conversely the higher resistance can be produced when conduction electrons with spin direction opposite to the material's magnetic orientation are hampered by more frequent collisions with atoms in the material.

A structure consists of two magnetic layers separated by a nonmagnetic spacer layer. If the layers are magnetized in the same direction, both will scatter electrons in the same way and the structure will have almost the same resistance as the bulk material. However, if the layers are magnetized in opposite directions, one layer will mainly scatter spin-up electrons, while the other will scatter spin-down electrons. The overall resistance will increase.

The key point is that only a weak magnetic field is needed to change the orientation of the magnetic fields in the layers. By using a strong antiferromagnet to keep the orientation in one of the layers constant, changes in resistance can be linked to the magnetic state of the other layer.

There are two significant advantages of GMR over competing devices. First, the large resistance change yields a strong signal and, second, the technology is compatible with integrated circuit technology, so that GMR devices can be included as part of a chip package to make smaller, faster, less expensive sensors and memory chips.

2.3. GMR Read Heads

In the past couple of years, production of read heads for hard-disk drives has been largely converted from thin-film inductive heads to magnetoresistance heads using thin-film 80:20 nickel/iron magnetoresistors. This conversion was needed in order to get larger signals from smaller storage bits and keep pace with improvements in hard drives.

A read head detects a transition in magnetization stored in the disk as the head passes over it. The magnetic field produced by the transition is either up (head-to-head magnetization transition) or down (tail-to-tail magnetization transition).

The GMR read head uses a feature called a spin valve, which is etched into a material whose edge is oriented along the direction of the disk surface. Spin valve material is normally composed of four thin films: a sensing layer, a conducting spacer, a pinned layer, and an exchange layer. The first three films are very thin, allowing conduction electrons to frequently move back and forth between the sensing and pinned layers via the conducting spacer (Fig. 2) [26]. The magnetic orientation of the pinned layer is fixed and held in place by the adjacent exchange layer, while the magnetic orientation of the sensing layer changes in response to the magnetic field from the disk. A change in the magnetic orientation of the sensing layer will cause a change in the resistance of the combined sensing and pinned layers.

In the GMR read head, the magnetization of the pinned spin-valve layer is directed vertical to the disk surface, and the soft layer lies parallel to the surface in the absence of a field from the disk. Up and down magnetic fields, which create smaller or larger resistance in the spin valve, are generated by stored magnetic data on a rotating disk.

2.4. Magnetic Random Access Memory

Nonvolatility, the ability to store data when electricity is off, is a much desired memory property in applications where data retention is critical. Semiconductor nonvolatile random access memory technologies, such as electrically erasable programmable read-only memory and flash memory, suffer from slow write times and wear out after data are stored more than 1 million times. Memory that uses magnetic materials can have fast write times and can store data indefinitely.

Working memory systems using these MRAM chips have been used for space and missile applications in which resistance to radiation damage is critical. Nonvolatility and

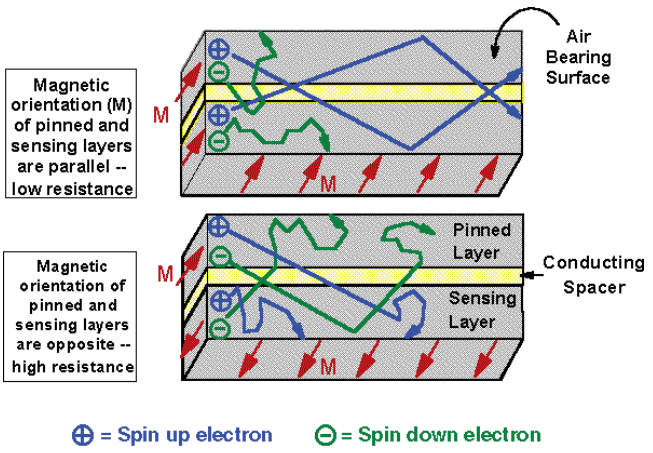

Figure 1. The giant magnetoresistance effect is due to the large difference in electrical resistance between two magnetic states of a metallic multilayer film.

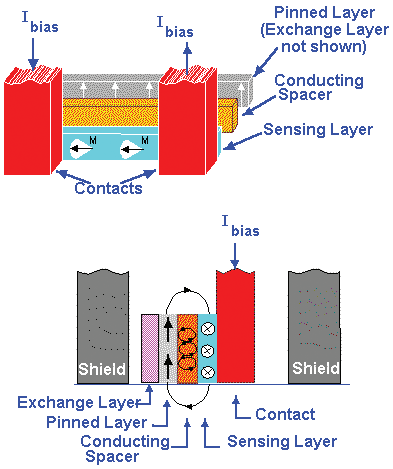

Figure 2. Schematic and operation of GMR head.

radiation hardness are important for space missions, and magnet storage is intrinsically radiation-hard. Recently, GMR materials have been used to make MRAMs with faster read access times.

With proper design of the areal geometry and the right thickness of magnetic films, submicrometer-size MRAM cells (single memory bits) have been made to operate like a spin valve, and they have been called "pseudo spin valve" devices. They promise very high density, high speed, and nonvolatile memory applications.

A newer high-magnetostrictive innovation, called a spin-dependent tunneling (SDT) device or magnetic tunnel junction, uses tunneling current through a thin dielectric between two ferromagnetic films. SDT devices work in a way similar to GMR devices. When two magnetic layers are magnetized in the same direction, the tunneling current is generally higher than when the two magnetic devices are magnetized in opposite directions.

3. PATTERNING PROCESSES

3.1. Transition from Wet Etching to Dry Etching

Etch processes may be classified by their rate, selectivity, uniformity, directionality (isotropy or anisotropy), surface quality, and reproducibility. All etching processes involve three basic events:

1. Movement of the etching species to the surface to be etched.
2. Chemical reaction to form a compound that is soluble in the surrounding medium.
3. Movement of the by-products away from the etched region, allowing fresh etchant to reach the surface.

Both (1) and (3) usually are referred to as diffusion, although convection may be present. The slowest of these processes primarily determines the etch rate, which may be diffusion or chemical-reaction limited. There are two different etching methods by using two quite different media: liquid chemicals (wet etching) and reactive gas plasmas (dry etching). Wet etching is performed by immersing the wafers in an appropriate solution or by spraying the wafer with the etchant solution [27].Wet-chemical etching is superior to dry etching in terms of effectiveness, simplicity, low cost, low damage to the wafer, high selectivity, and high throughput. However, the main limitations of wet etching include its isotropic nature which results in roughly equal removal of material in all directions, making it incapable of patterning submicrometer features, and the need for disposal of large amounts of corrosive and toxic materials. As the requirements developed for increasing circuit density and narrower linewidth in the manufacture of very large-scale integrated circuit/ultra-large-scale integrated circuit devices, it became necessary to have new etching methods to replace the wet etching. Dry etching methods became favorable etching processes for integrated circuit manufacture. Plasma-driven chemical reactions and/or energetic ion beams are used to remove materials in dry etching system. The most significant advantage of dry over wet etching is that it provides higher resolution potential by overcoming the problem of isotropy. Other benefits are the reduced chemical hazard and waste treatment problems, and the ease of process automation and tool clustering.

3.2. Ultimate Goals of a Dry Etch Process

The success of a etch process must be measured by the following nine parameters. The greatest challenge is that each parameter can usually only be optimized at the expense of at least one of the others.

3.2.1. Critical Dimension Uniformity

Uniformity across the wafer—including densely populated areas and large open spaces and within high aspect ratio features—is critical to maintain consistent device performance. Aspect ratio dependent etching, also known as "microloading," is a common nonuniform problem.

3.2.2. Selectivity

Defined as the ratio of the etch rate of one material versus that of another, the selectivity of the material being etched to the overlying masking layer (typically photoresist) is usually of the most concern, since this impacts critical dimension and profile control and the thickness of resist required (thinner photoresist is required to adequately resolve smaller feature sizes, so selectivity must increase as geometry shrinks). Also of concern is the selectivity to the underlying material upon which the etch stops. Different selectivity specifications may be given for edges and flat areas, since edges tend to etch faster.

3.2.3. Etch Rate

A high etch rate is needed to keep the throughput of the system or process module high (usually measured in Å/min). There is usually a trade-off between etch rate and other parameters, such as selectivity and damage.

3.2.4. Etch Profile Control

It is usually desirable to have an anisotropic profile, that is, one where the etched feature edges are close to vertical, to maximize packing density on the chip. But it is also desirable to have a flare out at the top of the feature to enable good step coverage in subsequent deposition steps.

3.2.5. Low Damage

Damage is an obvious concern. The high energy of the plasma can create currents on the wafer surface that cause electrical damage and energetic ions can cause mechanical damage to the films' crystalline structure.

3.2.6. Residue

Residue which coats the interior of the etch chamber is a difficult problem to avoid. In addition to requiring more frequent cleaning, residue is also a source of contamination. The most significant factors in controlling residue are temperature, bottom rf power, backside cooling, and process pressure.

3.2.7. Corrosion

Corrosion is mainly a problem in metal etch. Upon exposure to water vapor (i.e., air), chlorine will immediately attack metals. Integrated postetch treatments help eliminate this problem.

3.2.8. Particle Control

Particle control is another critical measurement of etch system performance. Today, fewer than 0.05 particles/cm^2 that are >0.35 μm in size are required.

3.2.9. Sidewall Passivation

Sidewall passivation is important both during and after the etch. Carbon from the photoresist mask typically combines with etching gases and etch by-products to form a polymerlike material on the sidewall of the feature. This is usually a requirement in creating anisotropic profiles. The biggest challenge is that after the etch, this polymer must be removed.

3.3. Basic Mechanism of the Etch Process

The optimization of etch of these parameters—uniformity, selectivity, etch rate, profile control, damage, and residue control—requires an understanding and fine-tuning of the two very different mechanisms through which etching occurs.

As shown in Figures 3 and 4, one mechanism is purely chemical. Reactive species generated in plasma react with the wafer surface and create volatile etch products that are swept away. By careful selection of the gases that are flowed into the plasma (typically chlorine and/or fluorine containing gases), it is possible to achieve very high selectivity through this process. However, since films tend to etch in all directions at once, the result is an isotropic etch. The other mechanism is purely physical. Energetic ions crossing the sheath transfer large amounts of energy and momentum to the substrate. The force of these ions can be strong enough to physically remove material. At low pressure where the mean free path is long, the ejected sputtered material can cross the reactor vessel and reach opposing walls. The main benefit of this etch mechanism is that it provides some directionality to the etch, making it possible to achieve highly anisotropic profiles. However, it is the least selective mechanism and also suffers from the disadvantages of low etch rate, damage, and trenching [28].

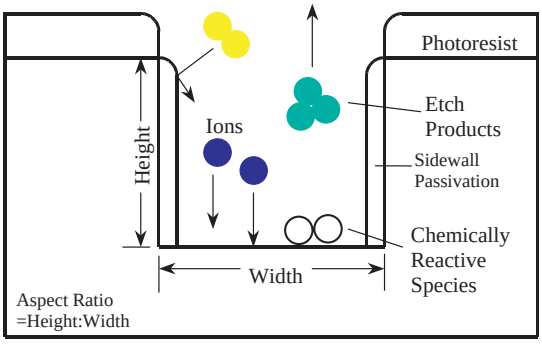

Figure 3. Schematic of plasma etching; etching occurs because of two etch mechanisms: chemical reaction and ion bombardment.

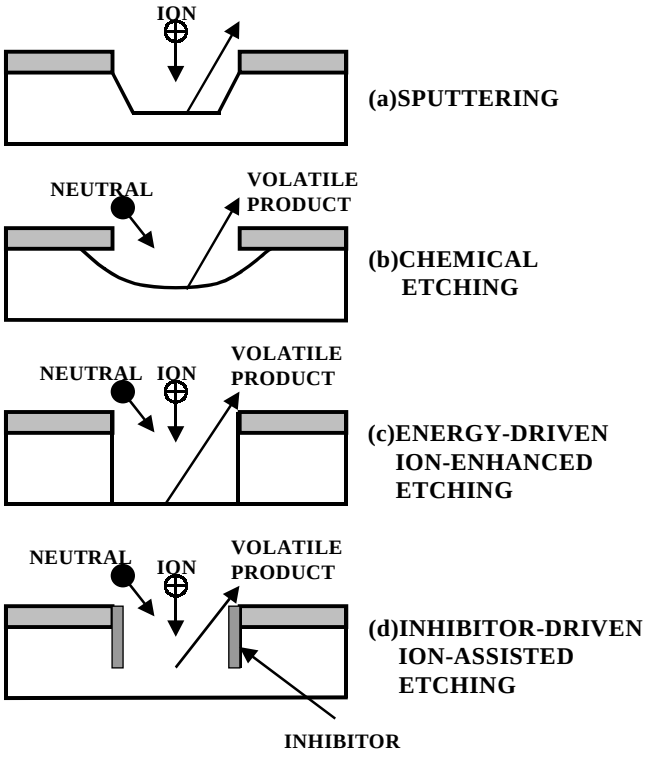

Figure 4. The four basic mechanisms of plasma etching: (a) sputtering, (b) purely chemical etching, (c) energy-driven ion-enhanced etching, and (d) inhibitor-driven ion-assisted etching.

3.3.1. Sputtering

In sputtering, impinging particles (usually positive ions accelerated across the sheath) strike the surface with high kinetic energy. Some of the energy is transferred to surface atoms which then are ejected, leading to a net removal of material. This process is distinguished from other etching mechanisms in that the interaction is mechanical. It is sensitive to the magnitude of bonding forces and structure of a surface, rather than its chemical nature, and quite different materials can sputter at similar rates. In a way this is symptomatic of using ion bombardment with energy far higher than the surface binding energy.

3.3.2. Chemical Etching

Chemical etching comes about when active species from the gas phase encounter a surface and react with it to form a volatile product. Product volatility is necessary for chemical etching since involatile products would coat the surface and protect it from further attack. In this type of mechanism the plasma reactor converts the feed into reactive chemical species, which are usually free radicals. There is usually no directionality and the etching can be specific (high selectivity) since it its governed by the relative chemical affinities between the etchant species and exposed materials. Because of this lack of directionality, chemical etching is commonly called isotropic etching.

3.3.3. Energy-Driven Ion-Enhanced Etching

There is usually little or no etching when the substrate surface is exposed to neutral chemical species alone in the absence of ion bombardment. Impinging ions damage the substrate material by virtue of their impact energy and thereby render the solid substrate more reactive toward incident neutral radicals.

3.3.4. Inhibitor-Driven Ion-Assisted Etching

Inhibitor-protected sidewall ion-enhanced etching differs from energy-driven ion-enhanced etching in that the chemical etching reaction in spontaneous, even without ion bombardment. Neutral etchant species from the plasma spontaneously gasify the substrate, and ions play a role by interaction with another component—a "protective" inhibitor film. The role of ions in the surface-inhibitor mechanism is to clear the inhibitor from horizontal surfaces that are bombarded by the flux of ions impinging in the vertical direction. The protective film is not removed from the vertical walls of masked features because these surfaces only intercept those few ions that are scattered as they cross the sheath. This protective film may originate from involatile etching products or from film-forming precursors that adsorb during the etching process.

3.4. Dry Etching Techniques

3.4.1. Plasma Etching

A wafer is exposed to a reactive gas such as chlorine which is in some cases dissociated in a plasma to create highly reactive atoms. Etching is isotropic or crystallographic, and temperature and reactant flux are used to adjust etch character. During the purely chemical etching process, three steps occur: adsorption of the necessary species on the materials surface, chemical reaction, and desorption of the products. The advantage of the technique is rapid etch rates, but the drawbacks are isotropy, a tendency for strong loading effects, and release of heat.

3.4.2. Ion Beam Etching

Ion beam etching (ion milling) uses a broad-area ion beam composed of a nonreactive gas such as Ar with high ion energy. This technique only relies on physical sputtering. The uniform ion beam bombards a wafer to cause etching. Since ion beam etching is very anisotropic and the wafer is not exposed to plasma, it is well suited for etching of certain patterns.

A major problem with ion beam etching is that the etch rate is very low because of the nature of physical sputtering, and it is also recognized that the etch rate of ion milling is very much dependent upon the incidence angle. It typically peaks at between 30° and 50° and becomes very small when angle is larger than 80°. There are a number of factors that limit the application of ion beam etching. First of all, etch products, usually nonvolatile, can redeposit on the wafers, especially onto the sidewalls of the etch mask that degrades the magnetic performance of the devices. When the film plane is normal to the ion beam, the etch rate of the sidewalls is very small since the incidence angle there is close to 90°. As a result, after the etch mask is removed, undesired fence and trenches are often left on the edges of the etched patterns.

3.4.3. Reactive Ion Etching

Reactive ion etching uses radio frequency (rf) power to maintain a plasma. Applied rf power makes electrons accelerate in the sheath region changing direction upward and downward. The accelerated electrons can lose a large fraction of their kinetic energy through dissociative collisions with molecules and atoms. Because electrons are light and have high energy, they diffuse fastest, leaving an excess of positive charge and a plasma potential that is positive relative to the electrode. Since charged particles are most abundant in the central glow of the plasma, most of the potential drop appears across the sheath. Positive ions are accelerated through the sheath and strike the samples, giving rise to a physical etch component. In addition, ion flux is coupled with ion energy. High plasma densities and ion fluxes are gained at the expense of extremely high applied voltages and damage levels.

3.5. High-Density Plasma Reactor

Increasingly, the limitation of traditional plasma etch technologies—which has resulted in the trend to high density plasma sources—is primarily one of process pressure. In the pressure regime of a few hundred millitorr where it is relatively straightforward to create a plasma, it becomes difficult to get etchant in and reaction by-products out of openings that are smaller than about 0.25 μm. The problem is more severe with higher aspect ratio.

The solution is to go to lower pressures, where the mean free path lengths of gas molecules and ions are longer, which reduces scattering collisions that can cause loss of profile control.

However, this is not as simple as it may seem since it requires a switch to a different type of plasma source—a so-called high density source—that is capable of generating enough ions to achieve acceptable etch rates at reduced pressure. High density sources are designed to more efficiently couple input power with the plasma, resulting in greater dissociation of etch species.

Although a wide variety of high density source types have been developed, they generally fall into one of three categories: electron cyclotron resonance (ECR), helicon resonance, or ICP type sources. All three are in use on production equipment. The main difference is that ECR and helicon sources employ an external magnetic field to shape and contain the plasma, while ICP sources do not [29]. (See Figure 5).

3.5.1. Electron Cyclotron Resonance Plasma

Various methods have been developed for reducing ion energies in the discharge while trying to maintain anisotropic etching. One of the methods involves the addition of magnetic fields configured to reduce electron loss from the plasma and the sample. This method of magnetically enhancing the discharge is called ECR plasma etching. In ECR discharges, free electrons in the plasma are forced to

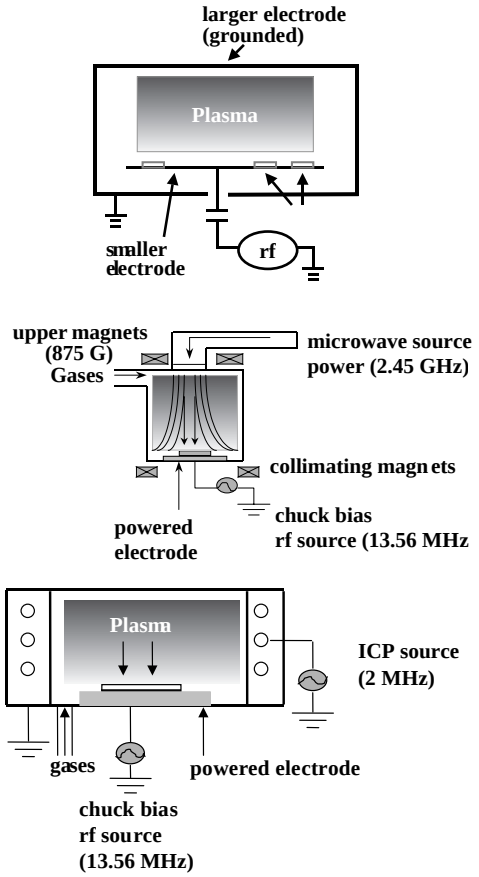

Figure 5. Schematics of typical RIE (top), ECR (center), and ICP (bottom).

orbit about magnetic field lines while absorbing microwave energy. At the cyclotron resonance condition, outer shell electrons from gas molecules in the discharge may also be liberated, leading to a very high degree of ionization in the plasma. Since the motion of the electrons is constrained by the external magnetic field, fewer are lost by collisions with the reactor walls than conventional reactive ion etching (RIE), and therefore the plasma potential relative to ground is much lower. The resultant energies of an ion reaching the sample to be etched are typically $\leq$15 eV. ECR etching should lead to much lower levels of damage than conventional RIE processes. ECR sources operate at the relatively high ion density of 10^{11}–10^{12} cm^{-3} compared with RIE tools ($\sim 10^{9}$ cm^{-3}). ECR tools can also provide independent control of the ion energy and ion flux. Ion energy is controlled by rf or direct current (dc) biasing of the substrate holder while control of the ion and neutral flux is achieved by varying the microwave power and neutral gas pressure. In addition, ECR discharges are capable of low pressure operation due to their efficient dissociation of gases from the discharge.

3.5.2. Inductively Coupled Plasma

Another high density plasma, ICP, has become popular because of disadvantages of the ECR technology. ECR suffers from difficulties in uniformity. The power supply may also limit the scaling of the ECR approach without the development of higher power magnetrons. The primary disadvantages of the ECR technology are the limits due to a commercially available, automatic-tuning microwave power supply, and the physical limits of the magnets required to create a uniform magnetized plasma. ECR tools appear difficult to scale to process wafers larger than 200 mm.

In the ICP geometry, a rf coil encircles the chamber. The important features of this coil are that it carries rf current and generates a magnetic field in the upward and downward directions. The time rate of change of the individual magnetic field generates an electric field. Acceleration of the electrons is determined by the magnitude of the electric field, confining them in a circular motion. The plasma, first formed in the shape of a ring following the path of electrons, will diffuse to the center of the chamber and then downward toward the sample. The electrons, in a circular path, will have only a small chance to be lost to the chamber walls, resulting in low dc self-bias. Ion energy, separated from the ion flux, can be controlled by applying another rf source at the chuck [30]. Unlike ECR plasma sources, there is no resonance between electron motion and the frequency of the driving fields in ICP sources. Therefore, ICP sources have advantages over ECR sources, including easier tuning, scaling up, and lower cost.

The push to continually increase bit densities in magnetic storage devices places emphasis on techniques for patterning submicrometer metallic multilayer structures. The component materials within these multilayers may include NiFe, NiFeCo (both are used for structures based on the GMR effect), NiMnSb (a Heusler alloy potentially useful in advanced spin-valve structures), or the collossal magnetoresistance (CMR) materials $LaCaMnO_3$, $LaSrMnO_3$, and $PrBaCaMnO_3$. A general problem when processing magnetoresistive materials is their relative involatility in conventional dry etching techniques such as RIE.

Practical etch rates may be achieved under high density plasma (HDP) conditions, where the high ion flux is able to promote desorption of halogenated etch products. Both ICP and ECR systems have proven capable of providing the necessary ion-to-reactive-neutral ratio ($>$0.02). We have completed an examination of the etch rates of the three basic classes of materials (i.e., NiFe, NiMnSb, and the perovskite-based CMR materials) in different plasma chemistries and also measured the long-term magnetic and structural stability of dry etched magnetic multilayer stacks. In the latter case, we used MRAM elements as our test vehicle.

The NiFe and NiMnSb layers were deposited on Si (100) substrates by direct current magnetron sputtering from composite targets. Typical layer thicknesses were 5000 Å. Liquid delivery metal organic chemical vapor deposition using 2,2,6,6-tetramethyl-3, 5-hepanedionato (TMHD) precursors [i.e., $La(TMHD)_3$, $Sr(TMHD)_2$, $Mn(TMHD)_3$, and $Ca(TMHD)_2$] was employed to deposit films of $La_{0.41}Ca_{0.59}MnO_3$ on Al_2O_3 (0001) single crystal substrates at 700 °C. The precursors were transported by N_2 carrier gas, with direct injection of O_2 and N_2O as oxidants. Films of $Pr_{0.65}Ba_{0.05}Ca_{0.3}MnO_3$ were deposited on Si (100) in a pulsed laser ablation system (248 nm KeF laser, 10 kHz, 2.5 J/cm^{-2} energy density) at a substrate temperature of 700 °C and

an O_2 partial pressure of 250 mTorr. All of the CMR films were 1500–2500 Å thick.

Finally, the MRAM structures consisted of the following layers deposited on 300 Å of SiN_x on 8500 Å of SiO_2 on Si: 80 Å NiFeCo, 15 Å CoFe, 35 Å Cu, 15 Å CoFe, 80 Å NiFeCo, 200 Å Ta, 550 Å TaN, and 800 Å CrSi. The deposition was performed by Ar ion-assisted sputtering. A 3000-Å-thick SiO_2 mask was patterned by SF_6/Ar RIE as the etch mask for subsequent high density plasma patterning of the metal layers.

The etching was performed in either a Plasma-Therm 790 ICP or a Plasma-Therm SLR 770 ECR reactor. In both systems the samples were thermally bonded to a radio frequency powered (13.56 MHz) chuck which was He-backside cooled. The respective HDP sources were powered up to 1000 W at either 2 MHz (ICP) or 2.45 GHz (ECR). The gases were injected directly into the sources through electronic mass flow controllers at a typical load of 15–20 standard cubic centimeters per minute. We investigated halogen-(Cl_2, BI_3, BBr_3, ICl, IBr, SF_6), CH_4/H_2-, and CO/NH_3-based mixtures since these cover the full range of possible etch products (i.e., metal chlorides, bromides, iodides or fluorides; metal organics or carbonyls).

Magnetic properties before and after plasma etching were determined using superconducting quantum interference device magnetometry (Quantum Design MPMS-5S00) at 4.2 K. Scanning electron microscopy (SEM) was used to examine sidewall smoothness on etched features.

Under RIE conditions (i.e., zero watts HDP source power) we invariably saw net deposition on the samples upon exposure to halogenated mixtures, or essentially no etching with CH_4/H_2 and CO/NH_3 mixtures. Examination of the halogen-plasma exposed surfaces by Auger electron spectroscopy revealed large concentrations of chlorinated residues. Since the halogenated etch products have larger lattice constants than their pure metal constituent and the products are essentially involatile under RIE conditions, one observes a buildup of these species as shown schematically in Figure 6 [31–33].

Table 1 shows a compilation of results for NiFe etching in the different chemistries investigated. The highest rates were achieved with Cl_2/Ar, where the role of the inert gas additive is to provide ion-assisted desorption of the chlorinated etch products. We found that the mass of these inert species also played a role, with Xe providing slightly faster

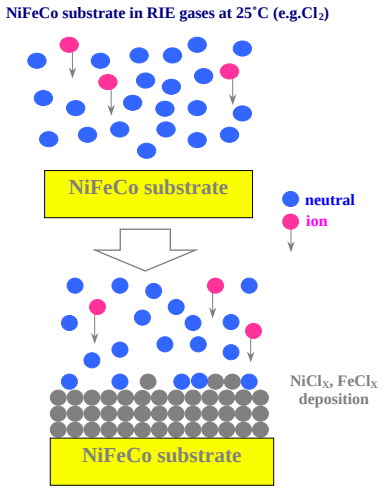

Figure 6. Schematic of involatile layer build-up during Cl_2-based RIE of NiFe at room temperature.

rates than either Ar or He addition. The rates with these Cl_2-based mixtures were approximately a factor of two faster than with pure Ar sputtering. Bromine- or iodine-based plasma chemistries produced lower rates than with chlorine and were close to Ar sputter rates. Both CH_4/H_2/Ar and SF_6/Ar led to extremely low etch rates, while the CO/NH_3 mixture had a slight degree (40%) of chemical enhancement. It has been suggested that the role of the NH_3 is to suppress dissociation of the CO so that carbonyl etch products can form, but an alternative explanation might be that atomic hydrogen scavenges surface carbon species and prevent carbonization of the NiFe surface. The fact that Cl_2-based plasma chemistries produce the fastest rates for NiFe (and plasma chemistries produce the fastest rates for NiFe and NiFeCo) is consistent with the higher vapor pressures of the chlorinated etch products relative to their brominated or iodidated counterparts.

Table 2 shows the corresponding comparisons for NiMnSb. In their cases the Cl_2-based mixtures produce excellent etch rates (1500–5000 Å/min^{-1} for both ICP and ECR tools), but the fastest rates were achieved with SF_6/Ar mixtures. By sharp contrast, NF_3/Ar showed net deposition rather than etching for source powers >100 W or at high NF_3 percentages. The surface under these conditions

Table 1. Comparison of plasma chemistries for NiFe etching.

Chemistry	Typical etch rates	Corrosive	Comments
$10Cl_2/5Ar$	600 Å min^{-1} ICP >1000 Å min^{-1} ECR	Yes	Chemical enhancement of 100% Etch rate with Xe>Ar>He
$13CO/2NH_3$	250 Å min^{-1} ICP 500 Å min^{-1} ECR	No	Chemical enhancement of ~20%–40% CO_2 less effective than CO
$5CH_4/10H_2/5Ar$	<100 Å min^{-1} ICP, ECR	No	Slower than Ar sputtering
$10SF_6/5Ar$	<100 Å min^{-1} ICP, ECR	No	Slower than Ar sputtering
$10BI_3/5Ar$	500 Å min^{-1} ICP, ECR	Yes	Less effective than Cl_2/Ar
$10BBr_3/5Ar$	200 Å min^{-1} ICP, ECR	Yes	Slower than Ar sputtering
10ICl/5AR	500 Å min^{-1} ICP, ECR	Yes	Excellent surface morphology
10IBr/5Ar	500 Å min^{-1} ICP, ECR	Yes	Excellent surface morphology

Table 2. Comparison of plasma chemistries for NiMnSb etching.

Chemistry	Typical etch rates	Corrosive	Comments
$10SF_6/5Ar$	>10,000 Å min^{-1} ICP, ECR	No	Selectivity ≥20 over Al_2O_3
$10NF_3/5Ar$	300 Å min^{-1} ICP, ECR	No	Narrow process window
$10Cl_2/5Ar$	3,000 Å min^{-1} ICP, ECR	Yes	Selectivity ≥5 over Al_2O_3
$10BCl_3/5Ar$	5,000 Å min^{-1} ICP, ECR	Yes	Selectivity ≥5 over Al_2O_3 Attacks native oxide
10ICl/5Ar	1500 Å min^{-1} ICP, ECR	Yes	Threshold ion energy 120 eV
10IBr/5Ar	1500 Å min^{-1} ICP, ECR	Yes	Threshold ion energy 230 eV

showed strong Mn enrichment and were oxidized, with an underlying Sb-deficient region. With all of the plasma chemistries, careful attention had to be paid to the removal of the native oxide prior to the commencement of etching to avoid the presence of a relatively long incubation time.

For the CMR materials, we did not observe any chemical enhancement in etch rate with any of the plasma chemistries discussed (Table 3). The etching was dominated by physical sputtering under all conditions investigated, with etch yields typically <0.1 and relatively high ion energies (>150 eV) needed to initial removal of material.

A key issue with the use of corrosive gas mixtures for etching metallic multilayers is that of postetch stability of the patterned structures. Severe corrosion and delamination of the films is observed in the absence of preventive measures. We examined use of several different postetch treatments. The first was simply rinsing the samples in deionized water immediately upon opening the chamber (which is contained within a N_2 dry box). The samples were then thoroughly dried with filtered N_2. In the other three methods, various *in-situ* plasma cleaning procedures were examined. After Cl_2/Ar etching was complete, the chamber was evacuated for 15 min, and then a 30 mTorr discharge of either H_2, O_2, or SF_6 (500 W source power, 5 W chuck power) was used to clean the residual chlorine for 10 min prior to removal of the samples from the reactor. In these cases, no H_2O rinsing was performed. It should be pointed out that all of these cleaning procedures have been employed previously for removing etch residues after Cl_2-based plasma etching of Al interconnects in Si microelectronics.

Figure 7 shows the magnetization of each of the samples over a period of approximately six months. In each case the samples were simply stored in air between the measurements and no special precautions were taken to prevent corrosion. Each of the cleaning procedures produces samples with extremely stable magnetic characteristics. This is also reflected in their appearance. Figure 8 shows SEM micrographs of patterned MRAM elements three months after Cl_2/Ar etching and postetch cleaning. There is no indication of corrosion on any of the samples and the sidewalls are smooth (to the resolution used in the photos). There is no indication of striations often observed on dry etched features. Note, however, that in the case of O_2 plasma cleaned samples there was a slight decrease in the magnetization per unit volume relative to the samples treated in water or H_2 or SF_6 plasmas. A possible reason for this is that the feature sidewalls become more oxidized than with other treatments, leading to a degradation in magnetic properties.

A comprehensive survey of etching results for magnetic materials in different plasma chemistries has produced the following conclusions:

(i) The optimum chemistry for NiFe is Cl_2/Ar, for NiMnSb is SF_6/Ar, while no chemical enhancement of etch rates for CMR oxides was observed.
(ii) Postetch rinsing in H_2O or *in-situ* plasma cleaning with H_2, O_2, or SF_6 discharges are all effective treatments for removing chlorine etch residues. Of these, only O_2 plasma exposure appears to degrade the magnetic properties of MRAM stacks. Once the residues are removed, there is no change in magnetic or visual properties over a period of ~six months (extent of our study).
(iii) The CO/NH_3 chemistry, while being noncorrosive, produces relatively slow etch rates and is only suitable for patterning of thin (<1000 Å) structures.

Table 4 shows thermochemical data for the potential metal chloride or metal carbonyl etch products for NiFe and

Table 3. Comparison of plasma chemistries for CMR etching.

Chemistry	Typical etch rates	Corrosive	Comments
$10SF_6/Ar$	500 Å min^{-1} $LaCaMnO_3$ ICP, ECR	No	No chemical enhancement
$5CH_4/10H_2/5Ar$	200 Å min^{-1} $LaCaMnO_3$ ICP, ECR	No	No chemical enhancement
$10Cl_2/5Ar$	1500 Å min^{-1} $LaCaMnO_3$ ICP, ECR 900 Å min^{-1} $LaSrMnO_3$ ICP 300 Å min^{-1} $PrBaCaMnO_3$ ICP	Yes	Physically dominated under all conditions for all three materials
$10BI_3/5Ar$	500 Å min^{-1} $LaCaMnO_3$ ICP, ECR	Yes	Etch yield <0.1 threshold ion energy <100 eV
$10BBr_3/5Ar$	500 Å min^{-1} ICP, ECR	Yes	Threshold ion energy ~150 eV

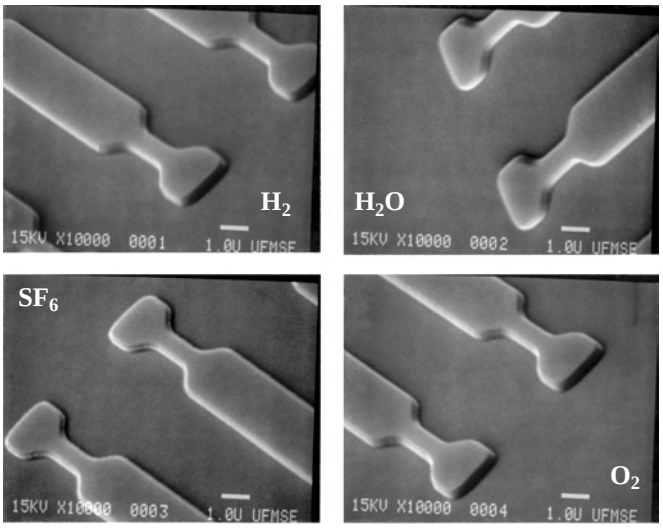

Figure 8. SEM micrographs of MRAM elements after etching in ICP Cl_2/Ar plasmas and subsequent cleaning in H_2, SF_6, or O_2 discharges, or by H_2O rinsing. The micrographs were taken three months after these processes, with the samples having been stored in room ambient.

Table 4. Thermochemical data for potential etch products.

Species	$\Delta H^0_{f.298\ K}$(kJ/mol)	$S^0_{298\ K}$(J/mol K)	$\Delta G^0_{f.298\ K}$(kJ/mol)
$FeCl_2$ (s)	−341.833	117.947	−302.342
$FeCl_3$ (s)	−399.405	142.336	−333.930
$CoCl_2$ (s)	−312.545	109.266	−269.647
$NiCl_2$ (s)	−304.930	98.157	−258.779
$Fe(CO)_5$ (s)	−766.090	337.078	−696.975
$Fe(CO)_5$ (s)	−727.849	439.286	−389.207
$Ni(CO)_4$ (s)	−631.784	319.560	−588.980
$Ni(CO)_4$ (s)	−601.576	415.507	−587.378
$Co(CO)_4$ (s)	−562.100	−337.442	−535.024

NiFeCo in Cl_2 or CO/NH_3 plasmas. From this data we can calculate the Gibbs free energies of reactions of Ni, Fe, and Co with atomic or molecular chlorine and with CO and CO_2. There are several important features of these data in Table 5. First, the reaction of the metals is more favorable with atomic chlorine than with Cl_2, which emphasizes the need for efficient dissociation of the feedstock gas in the plasma source. Second, CO is more reactive with the metals than is CO_2, as we have previously reported in a comparison of the two gases. We emphasize that in a plasma etching environment there will be a strong ion-assisted component to the etch mechanism and the thermodynamic data provide only a guide to the reaction pathways [34–37].

4. DRY ETCHING MECHANISM OF Cu AND MAGNETIC MATERIALS WITH UV ILLUMINATION

In recent years several research groups have studied dry etching of copper for the next generation of metallization in the semiconductor industry, focusing on development of new etch techniques to increase etch rate [38–47]. They used Cl_2 plasmas with or without photon sources using ultraviolet (UV) lasers, UV lamps, illumination, and infrared light. In contrast to conventional dry etching that requires relatively high temperatures (>200 °C) in order to produce practical etch rates, they all reported substantial enhancement of etch rates at low temperatures [48]. Among them Choi and Han first reported high etch rates of about 3000 Å/min at room temperature with Cl_2 discharges in an ICP system.

Magnetic materials such as NiFe and NiFeCo are widely used in sensors, MRAMs, or read/write heads for data storage industry. Due to the relative inertness of these materials there is a strong interest in the development of high density plasma etching processes for them. There are two basic plasma chemistries for the etching of NiFe and NiFeCo under ICP conditions, namely Cl_2 and CO/NH_3. However, the etch rates are still low (<500 Å/min) and are limited by desorption of the etch products such as $NiCl_x$, $FeCl_x$, and $CoCl_x$[49–65]. Cho et al. first reported the effect of UV illumination on the etch rates of the NiFe-based magnetic materials.

Table 5. Thermodynamic data for possible etch reactions.

$\leftrightarrow Ni(CO)_4(g) + 2O_2(g)$	$\Delta G^0_r = 990.2$ (kJ/mol)
$Co(s) + 2Cl(g) \leftrightarrow CoCl_2(s)$	$\Delta G^0_r = -380.3$ (kJ/mol)
$Co(s) + Cl_2(g) \leftrightarrow CoCl_2(s)$	$\Delta G^0_r = -269.6$ (kJ/mol)
$Co(s) + 4CO(g) \leftrightarrow Co(CO)_4(g)$	$\Delta G^0_r = 13.6$ (kJ/mol)
$Co(s) + 4CO_2(g) \leftrightarrow Co(CO)_4(1) + 20_2(g)$	$\Delta G^0_r = 1042.5$ (kJ/mol)

Since the etch mechanism with UV illumination has not been studied in detail, in this chapter we propose an etch mechanism of copper and magnetic materials with UV irradiation based on subprocesses occurring in the Cl_2–ICP etching system. We also carried out ICP etching of NiFe and NiFeCo in Cl_2/Ar discharges with or without UV illumination. We found that the chlorination of the copper surface is enhanced with UV irradiation and the absorption of UV photons by metal chlorides is critical to enhance the removal rate of chlorides. The proposed etch mechanism of copper showed good agreement with observed data determined by mass spectrometry, taken from the literature.

There are likely five subprocesses involved in etching of copper with UV illumination:

1. Photodissociation of Cl_2 in gas phase.
2. Surface chlorination.
3. Absorption of UV photons by reaction products.
4. Photoassisted removal of reaction products.
5. Gas-phase reactions between desorbed species.

4.1. Photodissociation of Cl_2

In addition to formation of Cl radicals by electron collision in the bulk plasma, more Cl_2 molecules are dissociated by collision between photons and molecules:

$$Cl_2 + h\nu \rightarrow 2Cl \tag{7}$$

The above reaction readily occurs because the bond strength of Cl_2 is 2.5 eV and the UV photon energies are 2–4 eV. Hence, compared to the plasmas without UV illumination, the photodissociation reaction provides a chlorine-enriched environment, and the reactive chlorine radicals easily take part in surface reactions.

4.2. Surface Chlorination

When the copper surface is exposed to UV radiation, electrons are ejected by the photoelectron effect and are captured by chlorine radicals near the surface, leading to chlorination of the copper surface:

$$Cu(s) + h\nu \rightarrow Cu^+ + e \tag{8}$$

$$xCl(g) + e \rightarrow xCl^-(g) \tag{9}$$

$$Cu(s) + xCl(g) \rightarrow CuCl_x(s) \qquad \Delta G_r^o = -226(\text{kJ/mol}) \tag{10}$$

In contrast to dry etching without UV illumination, UV photons promote the chemistry at the copper surface, resulting in fast deposition of metal chlorides on the surface with low activation energy. This chlorination reaction is induced by photons and the reaction rate is thus a strong function of photon flux or UV intensity. Since the unreacted Cu surface absorbs UV photons and is readily chlorinated by the above reaction, most sites of the copper surface will be chlorinated, leading to the formation of stoichiometric copper chloride.

Under chlorine-enriched conditions, copper chloride may further react with chlorine radicals to form $CuCl_2(s)$

$$CuCl(s) + Cl(g) \rightarrow CuCl_2(s) \qquad \Delta G_r^o = -146\ (\text{kJ/mol}) \tag{11}$$

The chlorination reactions of (10) and (11) may produce the copper chlorides having a Cl content equal to or greater than the stoichiometric ratio (i.e., $x \geq 1$). If there are no UV photons involved, the Cl concentration will be strongly dependent on reaction time. The surface chlorination also weakens Cu–Cu bond strength, resulting in lowering the etch threshold.

4.3. Absorption of UV Radiation by Reaction Products

The enhancement of etch rate with UV illumination indicates that the UV photons play an important role in the etching mechanism. The clue to this suggestion is the optical properties of the reaction products, $CuCl_x$. Tables 6 and 7 show the optical constants of some materials available in terms of reflectivity and adsorption depth. Compared to metal copper, CuCl has a much smaller reflectivity (or longer adsorption depth). This indicates that copper chloride absorbs most UV photon energies, and in turn the photons excite electrons of the reaction products so that the bond strength becomes weaker. This phenomenon may play a key role in increasing the etch rates of copper. If a metal chloride has a low absorption capacity of UV light, the effect of UV illumination will be less significant. Hence, the overall etch process of metals with UV illumination is limited by absorption of UV radiation, which is determined by optical properties of the metal chlorides.

4.4. Photoassisted Removal of Metal Chlorides at the Surface

As soon as the copper chlorides are formed, they absorb UV radiation, resulting in excitation of valence electrons in the $CuCl_x$ layer, weakening bond strengths of $CuCl_x$ and $CuCl_x$–Cu. This could lead to rupture of surface bonds and subsequent desorption. It is noteworthy that CuCl has a direct bandgap of 3.26 eV at 300 K. The UV photon energies in the range 2–4 eV can also be utilized to sublime the copper chloride [1.6 eV for $Cu_3Cl_3(g)$ and 2.2 eV for $CuCl(g)$]. Hence, the possible photoassisted removal process of the chlorinated surface can be described as

$$CuCl(s) + h\nu \rightarrow Cu(g) + Cl(g) \tag{12}$$

$$3CuCl(s) + h\nu \rightarrow Cu_3Cl_3(g) \tag{13}$$

$$CuCl(s) + h\nu \rightarrow CuCl(g) \tag{14}$$

$$Cu(s) + h\nu \rightarrow Cu(g) \tag{15}$$

[c] Estimated using $n = \Sigma x_i n_i$ and $\kappa = \Sigma x_i \kappa_i$, where x_i is atomic fraction of element i.

Photon-sputtering represented by Eq. (15) could occur on the unchlorinated or etched surface due to the lower bond energy of Cu–Cu (1.83 eV)than UV photon energies.

The photon-assisted etch reactions of (12)–(15) are greatly affected by UV intensity because they do not occur without formation of copper chloride and the formation rate is a function of photon flux, implicating a higher etch rate with higher UV intensity.

4.5. Gas-Phase Reactions between Desorbed Species

Some of the desorbed molecules tend to capture electrons, form negative ions, and react with reactive radicals such as Cl and Cu. There are many possible reactions among desorbed species, radicals, and ions in gas phase. They can be summarized as

$$CuCl(g) + e \rightarrow CuCl^{-}(g) \quad (16)$$

$$CuCl_2(g) + e \rightarrow CuCl_2^{-}(g) \quad (17)$$

$$CuCl(g) + Cl(g) \rightarrow CuCl_2(g) \quad (18)$$

$$CuCl^{-}(g) + Cl(g) \rightarrow CuCl_2(g) + e \quad (19)$$

$$CuCl(g) + Cu(g) \rightarrow Cu_2Cl(g) \quad (20)$$

$$CuCl_2^{-}(g) + Cu(g) \rightarrow Cu_2Cl_2(g) + e \quad (21)$$

$$CuCl_2^{-}(g) + Cu(g) + Cl(g) \rightarrow Cu_2Cl_3(g) + e \quad (22)$$

$$CuCl_2^{-}(g) + Cu(g) + Cl(g) \rightarrow Cu_2Cl_3(g) \quad (23)$$

$$Cu_2Cl_2(g) + Cl(g) \rightarrow Cu_2Cl_3(g) \quad (24)$$

$$Cu_2Cl_2(g) + Cu(g) \rightarrow Cu_3Cl_2(g) \quad (25)$$

$$Cu_2Cl_3(g) + Cu(g) \rightarrow Cu_3Cl_3(g) \quad (26)$$

The gas-phase reactions under plasma and UV illumination conditions indicate that the most favored forms of product gas are $CuCl_2$ [Eqs. (17)–(19)] and Cu_2Cl_3 [Eqs. (22)–(24)]. This may be confirmed with examining the relative peak intensities of the observed mass distributions of species using mass spectrometry. Although we may consider photoassisted dissociation of $CuCl(g)$ and $Cu_3Cl_3(g)$, it seems unlikely due to the high bond energy of Cu–Cl, 3.97 eV. The ionization energies of copper chlorides are also quite high: 10.7 eV for $CuCl^{+}$, 9.6 eV for $Cu_2Cl_2^{+}$, and 9.7 eV for $Cu_3Cl_3^{+}$. Hence the ionization of copper chloride gases does not occur under the UV illumination conditions.

Successful etching of NiFe and NiFeCo with Cl_2 plasmas has been reported. However, due to the relative involatility of the etch products such as $NiCl_x$, $FeCl_x$, and $CoCl_x$ the attainable etch rates are quite low ($\leq$500 Å/min). The etch rates of these materials in a high density plasma reactor are function of ion flux, ion energy, and plasma composition. To examine the effect of UV illumination on etch rate we have to know the optical properties of the magnetic materials and reaction products. However, their optical properties are not available yet. There is, however, a substantial increase in etch rate with UV illumination over etching without UV irradiation.

Table 8 summarizes the mass distributions of desorbed gaseous products observed from thermal etching and photon-induced etching of copper. These mass distributions are normalized to the Cu_3Cl_3 intensity. It is seen that for thermal desorption, the major gases are Cu_3Cl_3 at 860 K and CuCl at 920 K, but no $CuCl_2$ and Cu_2Cl_3 are observed.However, UV laser induced etching showed that the dominant gas species were Cu, Cu_2Cl, Cu_2Cl_3, and Cu_3Cl_2 with laser fluence of 0.26 J/cm^2 per pulse with 532 nm, and Cu, Cu_3Cl_2 and Cu_3Cl_3 with 0.66 J/cm^2 and 355 nm. The observation of copper signal is attributed to photon sputtering due to the strong laser energy. By contrast, Kwon et al. reported $CuCl_2$ and Cu_2Cl_3 as the dominant gases observed from ICP etching of copper with UV illumination regardless of chlorine content in copper chlorides. It is also interesting to note that the desorbed gases are Cl, CuCl, $CuCl_2$, Cu_2Cl, Cu_2Cl_2, Cu_2Cl_3, Cu_3Cl_2, and Cu_3Cl_3 in all cases of photon-assisted etching. Furthermore, no observation of $CuCl_2$ and Cu_2Cl_3 during the thermal desorption indicates that their presence in the etching with UV illumination does not originate from cracking of Cu_3Cl_3 by the ionizer of the mass spectrometer. It seems clear that $CuCl_2$ and Cu_2Cl_3 are produced in the ICP etching of copper with UV illumination. Hence, overall these previous results support the etch mechanism proposed in this chapter.

Kwon et al. also confirmed that the copper chloride layer formed with UV illumination had a higher chlorine content than stoichiometry (i.e., $x > 1.0$) regardless of reaction time, and it was composed of $CuCl(s)$ and $CuCl_2(s)$. This is contrary to the much lower chlorine content obtained without

Table 8. Mass distributions of desorbed gases from thermal etching and photon-induced etching of copper at various conditions.

	Mass distribution

UV illumination. However, this result is attributed to the fact that the copper surface is easily chlorinated under UV illumination because UV photons promote the chemistry at the surface and lower the activation energy. Choi and Han reported the activation energy of 0.12 eV, which is much lower than the energy of 1.6 eV required to sublime $CuCl(s)$ to $Cu_3Cl_3(g)$. This confirms that the dry etching with UV illumination is not a simple thermal desorption, but a non-thermal etch mechanism due to the presence of UV photons.

Figure 9 shows the effect of UV intensity on etch rate and the chlorine content in the copper chloride, adapted from the experiments by Kwon et al. They measured etch rates and Cl contents with varying UV intensity at $Cl_2/N_2 = 1.5$, 2 mTorr, 500 W ICP source power, and room temperature. The etch rates increased linearly with UV intensity up to certain point and then remained almost constant, while the Cl concentration in the copper chloride was independent of UV intensity and maintained at 1.2–1.3, implying coexistence of $CuCl(s)$ and $CuCl_2(s)$. The insensitivity of chlorine atomic ratio to the UV intensity indicates that the UV photon energies used in their experiment are enough for the surface chlorination to occur and to form $CuCl_x$ having $x > 1.0$. The photon-assisted etch of the copper chloride layer occurs very quickly since the $CuCl_x$ layer has low reflectivity but high absorption depth (see Table 2) and absorbs most UV photons as soon as the layer is formed. The increase in etch rate with UV intensity is believed to occur because the photon-assisted removal rate of copper chlorides is faster than the deposition rate of $CuCl_x$, indicating that the deposition rate of copper chloride controls the overall etch process. However, at higher UV intensity the $CuCl_x$ formation rate is also increased due to the increased photon flux, and is thus in equilibrium with the photon-assisted etch rate.

Figure 10 shows the effect of ICP source power in our reactor on etch rates of $Ni_{0.8}Fe_{0.2}$ (top) and $Ni_{0.8}Fe_{0.13}Co_{0.07}$ (bottom) with or without UV illumination in Cl_2 plasmas at 10 sccm Cl_2/5 sccm Ar, 200 W rf chuck power, 2 mTorr, and room temperature. In these experiments an unfiltered 400 W Hg arc lamp was used for UV irradiation. Details of the experiment are described elsewhere. There is net

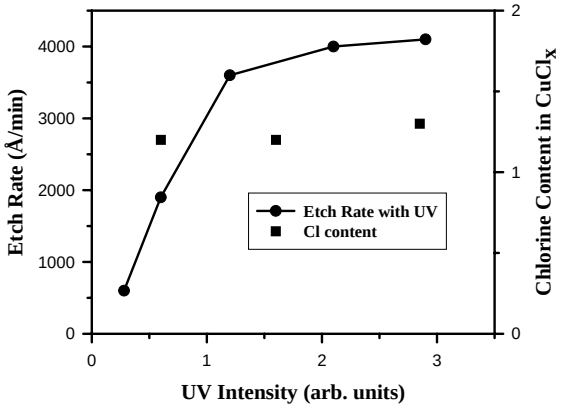

Figure 9. The effect of UV intensity on etch rate of copper and chlorine content in the copper chloride at $Cl_2/N_2 = 1.5$, 2 mTorr, 500 W ICP source power, and room temperature. Adapted from [6], D. E. Heim et al., *IEEE Trans. Magn.* 30, 316 (1994) and [8], R. E. Fontana et al., *IEEE Trans. Magn.* 32, 3440 (1996). © 1994 and 1996, IEEE.

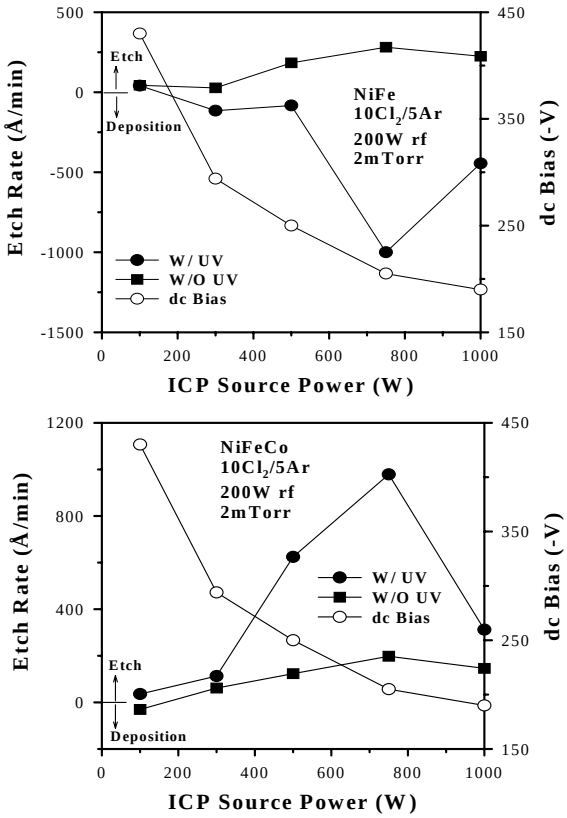

Figure 10. The effect of ICP source power on etch rates of NiFe (top) and NiFeCo (bottom) with or without UV illumination in Cl_2 plasmas at 10 sccm Cl_2/5 sccm Ar, 200 W rf chuck power, 2 mTorr, and room temperature.

deposition observed on NiFe, indicating the rate of formation of metal chlorides is greater than their removal rates. This result also implies that reaction products such as $NiCl_x$ and $FeCl_x$ are not absorbing UV photons. The increase in the formation rate of metal chlorides is attributed to the increased chlorine radicals with UV illumination and the chemistry promoted at the surface by photons. In contrast to NiFe, NiFeCo showed an overall increase in etch rate with UV illumination, especially at moderate ICP source powers (500–800 W). This may be attributed to two factors: (1) lower binding energy of NiFeCo than NiFe (for example, see the Fe–Co phase diagram; addition of Co to Fe lowered the melting point of FeCo alloy) and (2) greater absorption capacity of UV photons by $CoCl_x$ than by $NiCl_x$ and $FeCl_x$. The latter is unlikely because Ni, Fe, and Co are elements all in the same period and the same group so that the alloys and metal chlorides have similar optical properties (Tables 2 and 3), and furthermore the atomic ratio of Co (i.e., 0.07) is too small to affect the overall optical properties of etch products. However, to clearly understand the effect of UV illumination on the dry etching of magnetic materials, more systematic studies, in particular, the dependence of etch rates on optical properties of $NiCl_x$, $FeCl_x$, and $CoCl_x$, need to be conducted.

With the UV-enhanced process, very clearly defined features can be patterned into Cu, as shown in the scanning electron micrographs of Figure 11. The etching was

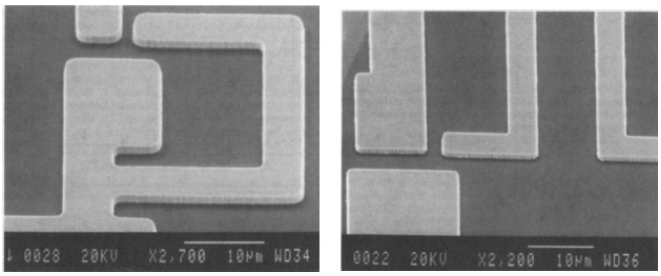

Figure 11. SEM micrographs of features etched into Cu layers on Si, using ICP Cl_2/Ar discharges.

performed at 75 °C in Cl_2/Ar in this case, whereas to achieve similar rates without UV illumination required etch temperatures ≥150 °C.

An etch mechanism with UV illumination was proposed to better understand the ICP etching of copper and magnetic materials. The photodissociation of Cl_2 provides a chlorine-enriched environment near the surface, and UV photons promote the chemistry at the copper surface, leading to fast deposition of metal chlorides on the surface with low activation energy. The proposed model predicts that surface chlorination under UV irradiation produces copper chlorides having Cl content equal to or greater than the stoichiometric ratio (i.e., $x \geq 1$). The overall etch process of metals with UV illumination is limited by absorption of UV radiation, which is determined by optical properties of the metal chlorides. The proposed etch mechanism showed gaseous etch products are CuCl, $CuCl_2$, Cu_2Cl, Cu_2Cl_2, Cu_2Cl_3, Cu_3Cl_2, and Cu_3Cl_3, verified with reported mass spectrometry data [8] and the dominant gas species are $CuCl_2$ and Cu_2Cl_3 in the etching with UV illumination. The Cl_2–ICP etching of magnetic materials with UV illumination showed no enhancement in etch rate for NiFe but a substantial enhancement for NiFeCo mainly due to lower binding energy of NiFeCo. However, to clearly understand the effect of UV illumination on the dry etching of magnetic materials, more systematic studies have to be carried out in terms of the absorption of UV photons by $NiCl_x$, $FeCl_x$, and $CoCl_x$.

5. CONCLUSIONS

Nanoscale patterning of MRAM elements and other magnetic structures is possible using high density plasma etching, combined with appropriate lithography. The choice of plasma chemistry is determined by the materials used in the structure, and both corrosive and noncorrosive chemistries are available.

GLOSSARY

High density plasma A discharge with an average ion density above approximately 10^{11} ions per cubic centimeter.

Ion-induced damage Any disruption of the properties of a material by the energetic ions that bombard its surface during dry etching.

Magnetic random access memory A form of nonvolatile magnetic memory that is promising for data storage.

Plasma chemistry The combination of gases used to create reactive etch products with the sample upon creation of a plasma.

Plasma etching Use of a reactive plasma to etch controlled amounts of a sample exposed to the plasma; also called dry etching.

CONTENTS

1. INTRODUCTION

"Nano" signifies one of the most important scientific topics of modern physics, chemistry, and the life sciences. It promises interesting technological developments in the near future, especially in the fields of information technology and modern drug discovery. From a fundamental point of view, nanoscopic probe particles provide the means to explore the structural and dynamic natures of matter on a tiny length scale and improve our understanding of physicochemical processes on a fundamental level.

In this chapter, we will describe the use of specially designed nanoscopic particles in optical tracer experiments. These studies comprise the exploration of transport phenomena in dense interacting colloidal systems, polymer melts, etc. on a micrometer length scale, elucidating for instance interparticle interactions or the mechanism of complex transport processes. A variety of different optical techniques to address these fundamentally important problems has been developed during the last one to two decades, ranging from direct microscopic observation of probe particles [1–5], automatized via modern computers, to more complex fluorescence spectroscopic [6–11] or light-scattering [12–20] techniques. Each technique requires special optical properties of the probe particles, which have to be designed accordingly. For example, nanoscopic probes suitable for fluorescence techniques have to be chemically modified with fluorescent dye molecules or semiconducting metal clusters. On the other hand, the probe particles have to be prepared in such a way that they do not influence the behavior of the surrounding sample itself. These restrictions provide a major challenge for chemical synthesis, which is rewarded by the scientific knowledge one can get from experiments with nanoscopic optical tracers.

A second use of nanoscopic optical tracers lies in modern drug discovery. Potential drugs are identified by their ability to interact with biochemical molecules, which is monitored in an in vitro assay where a preferrably fluorescent probe is used for detection. Here, nanobeads can be used to generate or enhance a signal. Fluorescence confocal single molecule detection [21–27] applied to drug discovery allows the use of highly miniaturized sample volumes and accurate detection of biochemical interactions, and the combination with nanobeads expands the range of applications.

Our contribution is organized as follows: In a first section about optical microrheology, we will start with a short overview of the theoretical background of transport processes in soft condensed matter systems. This part will mainly cover the relationship between standard dynamical-mechanical relaxation experiments using a conventional rheometer, and the information one may get from the optical nanotracer experiments. We will conclude this section with a review of the optical techniques used for optical nanotracing, also providing some illustrative experimental examples taken from the recent literature. The second section of our contribution will deal with the use of nanoparticles in pharmaceutical drug discovery and diagnostics. Here, we will mainly consider recent developments in high throughput drug discovery using fluorescence detection techniques.

2. OPTICAL MICRO- AND NANORHEOLOGY

2.1. Diffusion of Nanoscopic Probe Particles and Mechanical Spectroscopy

Only seven years ago [28], Mason and Weitz set the basis for so-called optical microrheology [28–34]. They have shown that by determination of the single particle trajectories of

ISBN: 1-58883-063-2/$35.00

tiny probe particles embedded in a complex fluid, it is possible to extract the frequency-dependent linear viscoelastic moduli, that is, the flow and elastic properties, of the sample. This new approach provides some important advantages, such as extended frequency range and the ability to probe the dynamic within a micrometer length scale. The latter is especially important for structurally heterogeneous systems, where conventional rheology only can provide a meaningless average result. The motion of a probe particle dispersed in a complex viscoelastic fluid is described by a generalized Langevin equation [35–41]:

$$m\dot{v}(t) = f_R(t) - \int_0^t \zeta(t-\tau)v(\tau)d\tau \tag{1}$$

with m the particle mass and $\dot{v}(t)$ the time derivative of the particle velocity. $f_R(t)$ is the random forces acting on the probe particle and includes both stochastic Brownian forces exerted on the probe particle by thermally incited density fluctuations within the fluid, and, in the case of higher concentrations of probe particles, direct interactions between individual particles. The integral term represents the viscous damping or friction of the fluid and incorporates a generalized time-dependent memory function $\zeta(t)$, which basically includes the viscoelastic moduli of the fluid. For a complex viscoelastic fluid, the fluctuation-dissipation theorem, which describes the relation between the stochastic density fluctuations driving the probe particle motion and the viscous damping of this motion due to energy dissipation (Note: Both effects are caused by the same stochastic Brownian force $f_R(t)$. The so-called fluctuation-dissipation theorem connects diffusive mobility and viscous friction.), is given by

$$\langle f_R(0)f_R(t)\rangle = k_BT\zeta(t) \tag{2a}$$

with $\langle f_R(0)f_R(t)\rangle$ the time-correlation function of the stochastic force and k_BT the thermal energy. For a simple viscous fluid, the memory function $\zeta(t)$ is replaced by the shear viscosity η_0, and Eq. (2a) becomes

$$\langle f_R(0)f_R(t)\rangle = k_BT\eta_0 \tag{2b}$$

Based on Eqs. (1) and (2a), it can be shown that the viscoelastic memory function $\zeta(t)$ is related to the velocity autocorrelation function $\langle v(0)v(t)\rangle$ and hence to the mean squared displacement of the probe particle $\langle \Delta r^2(t)\rangle$ [28]. After Laplace transformation, a generalized Stokes–Einstein relation (GSER) is obtained:

$$\widetilde{G}(s) = s\tilde{\eta}(s) = \frac{k_BT}{\pi as\langle \Delta\tilde{r}^2(s)\rangle} \tag{3}$$

with s the frequency in the Laplace domain, $\widetilde{G}(s)$ the viscoelastic modulus, $\tilde{\eta}(s)$ the frequency-dependent viscosity of the complex fluid, a the radius of the probe particle, and $\langle \Delta\tilde{r}^2(s)\rangle$ its mean squared displacement. For a viscous fluid, the probe particle is freely diffusing, and its mean squared displacement is simply given by

$$\langle \Delta\tilde{r}^2(s)\rangle = 6D/s^2 \tag{4}$$

In this case, the viscosity is independent of frequency s, and Eq. (3) becomes the well-known Stokes–Einstein equation relating self-diffusion coefficient and shear viscosity η_0:

$$\eta_0 = \frac{k_BT}{6\pi aD} \tag{5}$$

In conventional rheological measurements, the complex dynamic-mechanical modulus $G^*(\omega) = G'(\omega) + iG''(\omega)$, with $G'(\omega)$ the elastic or storage modulus representing the elasticity of the sample and $G''(\omega)$ the loss modulus representing the viscous flow properties of the sample, is measured typically with an oscillatory shear rheometer [42]. A thin film of the sample (thickness about 0.1–1 mm, diameter a few cm) is deformed periodically with a motor, and the resulting stress transferred by the sample to a transducer is measured (see Fig. 1).

It is important to note that the stress and, correspondingly, the viscoelastic moduli of the sample usually depend on the deformation frequency ω. To illustrate the significance of the viscoelastic moduli, let us regard the two extreme cases: For an elastic solid body, suchas a rubber ball, which, upon stress, shows neither flow nor permanent deformation, $G'(\omega) \gg 0$ and $G''(\omega) = 0$. On the other hand, for a simple viscous fluid, suchas water or very dilute solutions, $G'(\omega) = 0$ and $G''(\omega) \gg 0$, and, upon stress, all energy is dissipated into the sample. Complex fluids, suchas concentrated colloidal dispersions, polymer gels, etc., have both elastic and viscous components.

To compare $\widetilde{G}(s)$ obtained from microrheological measurement with $G^*(\omega)$ determined by conventional rheology, one could, in principle, calculate first the Laplace transform and then the Fourier transform of $\widetilde{G}(s)$. In their first experiments, Mason and Weitz preferred to fit $\widetilde{G}(s)$ by a functional form and determined $G^*(\omega)$ by analytic continuation of this fitted form. The authors have verified the validity of the sketched formalism by three different experimental examples: (1) A highly concentrated (56 vol%) colloidal suspension of silica particles of radius 210 nm in ethylene glycol studied by diffusing wave spectroscopy (DWS), a special light-scattering technique that will be discussed further beyond; in this case of a concentrated colloidal dispersion studied by DWS, probe particles and sample are identical: The viscoelastic behavior is mainly determined by direct interactions between the nanoscopic colloidal particles. (2) An emulsion of uniformly sized oil droplets of radius 530 nm, stabilized with a surfactant and suspended in water, volume fraction of the droplets 62%; here, as in

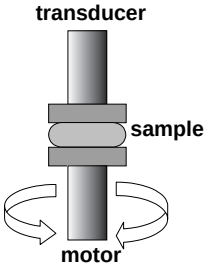

Figure 1. Sketch of a typical oscillatory shear rheometer.

case of example (1), probe particles and sample are identical. (3) An entangled polymer solution of high molecular weight polyethylene oxide dissolved in water, containing a small amount (2 vol%) of nano-sized polystyrene latex spheres of radius 210 nm as optical probe particles; in this last example of a polymer gel, the latex probe particles only serve to visualize the viscoelastic behavior of the polymer network but do not influence it. In all three cases, Mason and Weitz [28] found excellent agreement between the viscoelastic moduli determined by standard rheological measurements and by the new microrheological approach using optical tracer techniques.

Here, it is important to mention that the generalized Stokes–Einstein equation (Eq. (3)), which relates the single probe particle dynamics to the complex viscoelastic modulus, is only valid at certain length scales and within a limited frequency regime [43–47]: If the medium is inhomogeneous on the particle length scale, the tracer particle will follow the easy way, and its dynamics will predominantly sample local regions that provide the least resistance to deformation. Therefore, these soft cavities are oversampled. Only if the size of the probe particle is much larger than the characteristic length scale of the viscoelastic fluid, the single-particle dynamics reflect the overall viscoelasticity of the dispersing medium. For this reason, optical probes for microrheological measurements are usually several hundred nanometers in size. A recent experimental development provided a solution to this problem: By simultaneous determination of the correlated displacement of two probe particles [48, 49] separated by a distance that is large compared both to the particle size and the characteristic length scale of the viscoelastic medium, using for example optical video microscopy, the result becomes independent of both size and shape of the probe particles. This correlated two-particle displacement, also called two-point microrheology, directly reflects the bulk viscoelasticity of the medium and does not suffer from the length scale restrictions present in studies of single-particle dynamics in microscopically heterogeneous media.

The GSER (Eq. (3)) is not only limited to probe particles larger than the characteristic length scale of a heterogeneous viscoelastic medium, for example a polymer network, but is also restricted in respect to the frequency window $\omega_L < \omega < \omega_U$: The lower frequency ω_L is given by the longitudinal compression mode of the polymer network, and the upper frequency cutoff originates from fluid inertia effects. Due to the important perspectives for the experimentalist, the validity of the GSER has recently become a very important subject in the field of theoretical physics. For a more detailed discussion, which is far beyond the scope of this contribution, we therefore refer to the literature [35, 36, 40, 41, 44–47].

We have tried to sketch how the microscopic dynamics of an optical probe, also called microrheology, and conventional rheological techniques are connected. This formalism, developed just a few years ago, opens up a rich field for the experimentalist: Now, not only can the dynamics of optical probes be used to study simple viscous fluids where the Stokes–Einstein equation holds (Eqs. (4) and (5)), but it is also possible to investigate complex viscoelastic samples and even to determine the viscoelastic moduli in a frequency regime not accessible by conventional rheological methods.

2.2. Experimental Techniques

In this section, we will try to illustrate the importance of optical microrheology by a presentation of various recently developed experimental methods. The interested reader is also referred to a short but comprehensive review about optical microrheology techniques by Mukhopadhyay and Granick [50] that has just been published. All these techniques have in common the fact that their fundamental experimental quantity is the mean squared displacement of a nano- to micron-sized probe particle determined by optical methods. However, they differ strongly in time and length resolution, as well as in the optical properties of their probe particles. Depending on the scientific problem, the suitable technique or even a combination of various methods has to be chosen carefully.

2.2.1. Optical Video Microscopy

In optical video microscopy [1–5], the motion of a nanoscopic probe particle is directly observed with the help of an optical microscope. Images of the particle positions are recorded with a video camera and fed to a personal computer. The major advantage of this technique is that it is capable of tracking many probe particles simultaneously. For this reason, it also allows one to measure the correlated motion of two individual particles necessary for the 2-point microrheology [49] mentioned above. Another advantage is the very small sample volume necessary for microscopic studies ($<100\ \mu$L). However, serious disadvantages of optical videomicroscopy are its limited spatial resolution (>100 nm) and, more crucially, the limited time resolution of modern video hardware (ca. 0.001–0.01 seconds). Therefore, the technique is not suited to study very elastic fluids, where rapid particle motion on a very short length scale is to be expected. In general, currently only the long-time or, correspondingly, the low-frequency regime of the dynamic mechanical modulus $G^*(\omega)$ of a viscoelastic fluid can be studied by videomicroscopy. In the near future, new technical developments, for example high speed cameras and faster computers, will enhance the time scale of this technique to much shorter times (higher frequencies).

Standard optical microscopic techniques are limited to very thin samples, restricting the observable particle motion to two dimensions. Therefore, well-suited samples are biological monolayers or bilayers, such as cell membranes. Here, optical microscopy, where already one single particle can be detected, is much better suited than light scattering techniques, which, due to the low contrast of an individual particle, need to average the signal from many probes, and therefore are only suited for bulky samples. The restriction of optical microscopy to two dimensions can be overcome by confocal microscopy [51–55], which, although on a very slow time scale of seconds, allows one to change the plane of focus systematically within a sample, thereby creating a three-dimensional microsopic image.

For videomicroscopy, it is necessary to distinguish clearly the probe particles from the surrounding medium by sufficient optical contrast. This optical contrast of the

probe particles may be based on fluorescence (fluorescence microscopy), for which purpose the probes have to be labeled with fluorescent dyes or even semiconducting metal clusters. The latter are much better suited because of their higher stability in case of irradiation [56–59]. It is also possible to tune the wavelength of both excitation and fluorescence via the size of the metal clusters [60, 61]. Alternatively, dark field microscopy [62, 63] may be applied, where the probe particles are distinguished from the surrounding medium by their enhanced light scattering power. Compared to conventional optical transmission microscopy, both the fluorescence and the dark field techniques have the advantage that tracers even much smaller than the wavelength of light (400–800 nm) are clearly visible and therefore can be used as probe particles.

Next, let us consider a recent example of single particle tracking by optical microscopy: The diffusion of individual fluorescent tracer particles has been studied in thin (d = 2–3 μm) concentrated colloidal suspension layers [5]. For this purpose, a few fluorescent tracers (<1 vol%) of radius 260 nm have been added to a dispersion of nonfluorescent colloidal particles of the same size suspended in water. The preparation of suitable tracers has been quite simple: To an aqueous dispersion of the colloidal particles, consisting of the two monomers acrylamide and styrene and prepared by standard radical emulsion polymerization, a solution of the hydrophobic strongly fluorescent dye Nile Red [64–66] in the organic solvent chloroform has been added dropwise. The latex particles are swollen by the organic solution, and, after evaporation of the chloroform, the fluorescent dye, which is not soluble in water, remains within the particles. It should be stressed that the fluorescent label in this case is only incorporated and not chemically attached to the nanoscopic probe particle. A few drops of this tracer dispersion are added to a concentrated dispersion of nonfluorescent particles. Under a fluorescence microscope, only the dye-labeled tracer particles are visible as sketched in Figure 2.

Since the fluorescent tracer particles can be distinguished individually, their single particle dynamics can be studied. The shortest time scale of the measurements of about 0.1 seconds was limited by the digital frame grabber, the interface translating the signal from a video camera on top of the fluorescence microscope into a digital picture that can be analyzed by computer. The smallest length scale of the experiment as well as the length scale resolution is about 250 nm, that is, half the wavelength of visible light. The position of the center of an individual tracer particle is determined by a special computer algorithm and is stored as a function of time. From these raw data, the mean squared displacement $\langle \Delta r^2(t) \rangle$ can be calculated, which yields the self-diffusion coefficient D (see Eq. (4)).

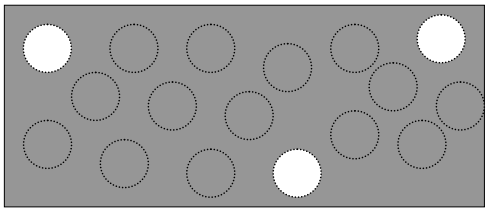

Figure 2. Sketch of the image obtained by fluorescence microscopy from a colloidal dispersion containing nonfluorescent (gray) and fluorescent (bright) colloidal nanoparticles.

In this example, all particles influence the dynamic behavior of the system, but only the tracers are observed. Their individual motion reflects interactions with other invisible colloidal nanoparticles. From the dependence of single particle motion on total particle concentration, the range of the interparticle interactions can be deduced. In case of hard spherical particles, for instance, the diffusion coefficient is expected to depend on particle volume fraction φ roughly as [67–71]:

$$D(\varphi) = D_0(1 - 2\varphi) \tag{6}$$

with D_0 the diffusion coefficient found for very dilute colloidal dispersions and given by the Stokes–Einstein equation (Eq. (5)). The acrylamide-styrene latex particles in aqueous dispersion have been found to show the hard sphere behavior described by Eq. (6), although they contained a small number of surface charges originating from the polymerization initiator potassium peroxodisulfate. This example illustrates the possibility to determine the range of interparticle interactions from the probe dynamics of individual optical nanotracers.

The tracers described above have been prepared in a very primitive way by simply incorporating fluorescent dye molecules by solution swelling. A more sophisticated way is the preparation of cross-linked colloidal nanoparticles with dye molecules chemically incorporated in their network structure [72, 73]. To avoid labels sticking out from the particle surface and thereby changing the interparticle interactions of the probe particles, a protective shell that carries no labels can be formed around the fluorescent core. These particles can be isolated and redispersed in various organic solvents while maintaining their topology.

As a second important example for the application of optical video microscopy, we next will consider in more detail the two-point microrheology mentioned above: This technique is very important to determine the macroscopic dynamic mechanical properties of samples that are heterogeneous on a microscopic length scale. As presented in the theory section, conventional microrheology is based on the generalized Stokes–Einstein relation (Eq. (3)). This approach does not agree with conventional rheological methods in case of inhomogeneous samples. To solve this problem, Crocker et al. [49] have used multiparticle video tracking to measure the displacement vectors of several tracers simultaneously. Their experimental quantity of interest is the ensemble averaged tensor product of the tracer displacements:

$$D_{\alpha\beta}(r, \tau) = \langle \Delta r_\alpha^i(t, \tau) \Delta r_\beta^j(t, \tau) \delta[r - R^{ij}(t)] \rangle_{i \neq j,\, t} \tag{7}$$

where i and j label different particles, α and β label different coordinates, and R^{ij} is the distance between particles i and j. δ symbolizes the delta function and becomes 0 if $r \neq R^{ij}(t)$. In the limit of long distances $r \gg a$, one gets:

$$\widetilde{D}_\pi(r, s) = \frac{k_B T}{2\pi r s \widetilde{G}(s)} \tag{8}$$

where $\widetilde{D}_\pi(r, s)$ is the Laplace transform of $D_\pi(r, \tau)$ and the off-diagonal tensor elements vanish. Here, it should be noted that Eq. (8) in contrast to Eq. (3) contains no dependence on probe particle size a. Therefore, the experimental quantity $D_{\alpha\beta}(r, \tau)$ is independent of the size and shape of the probe particles. Based on Eqs. (7) and (8), a distinct mean squared displacement can be defined:

$$\langle \Delta r^2(\tau) \rangle_D = \frac{2r}{a} D_\pi(r, \tau) \tag{9}$$

Crocker et al. [49] use this distinct mean squared displacement instead of the single particle displacement to calculate the dynamic mechanical modulus from the GSER (Eq. (3)). Whereas the Brownian motion of a single tracer is driven by the superposition of dynamical modes with wavelengths greater than the particle size a, the correlated motion of two tracers is driven by those modes with wavelengths greater than their separation r rather than a. Thus, the correlated motion of two tracers separated by more than the coarse-graining length scale in an inhomogeneous medium will depend only on the coarse-grained $G^*(\omega)$, even if the size of the tracers themselves is much smaller than the characteristic length scale of the sample.

As an experimental control, Crocker et al. [49] studied dispersions of submicron fluorescent beads as tracers ($a =$ 235 nm) dispersed in a glycerol/water mixture with epifluorescence. A few hundred particles were imaged simultaneously, and a series of images of total duration 10 minutes was recorded on a videotape, which later could be analyzed by computer. As expected for a homogeneous medium, they found good agreement between single particle mean squared displacement and distinct mean squared displacement. To demonstrate the effectiveness of the new approach for the exploration of inhomogeneous fluids, Crocker et al. [49] compared two-point microrheological measurements of an aqueous guar solution containing high molecular weight mesoscopic aggregates with those from a mechanical rheometer. Dynamic mechanical moduli determined from the distinct displacements agreed very well with the rheological results, whereas the moduli determined from the single particle displacements were far too small and also showed the wrong frequency dependence (since a small single tracer particle oversamples the "softer" regions of a heterogeneous fluid; see above). The heterogeneous guar system therefore nicely demonstrated the superiority of two-point microrheology in case of microscopically heterogeneous samples. As an additional application, the authors studied the dynamics of fluorescent tracers within a filament network of polymerized F-actin obtained from purified rabbit muscle.

2.2.2. Dynamic Light Scattering Using Tracers

Standard Dynamic Light Scattering Dynamic light scattering (DLS) has become a common tool for particle sizing [74–77] by studying the dynamics of the particles of interest in a very dilute dispersion. More recently, DLS also has been applied to study diffusion in highly concentrated colloidal dispersions to explore their phase behavior and the interparticle interactions [15, 16, 19, 78, 79]. The typical setup of a DLS experiment is sketched in Figure 3.

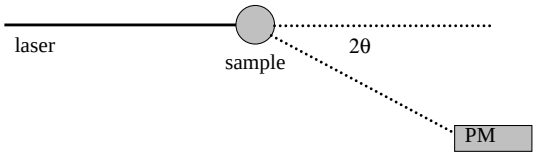

Figure 3. Setup for DLS experiments (top view).

A coherent laser beam is focused onto the sample cell, typically a cylindrical cuvette of diameter 1 cm made from Suprasil glass. The time-dependent scattered light intensity $I(t)$ is detected under an observation angle 2θ with a photomultiplier. It is important that the sample be nearly optical transparent since multiple scattering spoils the simple relation between observation scattering angle 2θ and the inverse length scale of the experiment q (see Eq. (10)). However, recently a new light-scattering technique called diffusing wave spectroscopy (DWS) [80–86] has been developed, which is explicitly based on multiple scattering events and therefore is suitable to investigate tracer particle dynamics also in highly concentrated turbid samples. This method will be reviewed in the next section.

Let us consider the standard DLS technique in some more detail: Due to the Brownian motion of the scattering particles, the intensity pattern $I(t)$ shows characteristic fluctuations with time. For data evaluation, the time intensity autocorrelation function is determined using a hardware correlator. In the case of simple Brownian motion in a viscous fluid medium, this correlation function provides a direct measure for the self-diffusion coefficient D

$$\begin{aligned} \langle I(t)I(t+\tau) \rangle_t &= g_2(q, \tau) = 1 + e^{-2Dq^2\tau}, \\ q &= \frac{4\pi n_D \sin \vartheta}{\lambda} \end{aligned} \tag{10}$$

with τ the correlation time, q the scattering vector, n_D the refractive index of the medium, and λ the wavelength of the laser light. To investigate more complex dynamics of scattering probe particles, it is possible to calculate the mean squared displacement $\langle \Delta r^2(t) \rangle$ from $g_2(q, \tau)$. Therefore, DLS experiments measure the same quantity as determined by direct observation of the probe particles with an optical microscope ($\langle \Delta r^2(t) \rangle$), at comparable length scales of 100 nm–10 μm but on much shorter time scales (as short as 100 nanoseconds).

In case of samples containing a large amount of scattering particles, the DLS measurement no longer probes single particle dynamics, but collective diffusion, which is based on multiple-particle density fluctuations. To measure single particle diffusion in such a multiple-particle system, analogous to video microscopy a special host-tracer technique has to be applied: Matrix particles are dispersed in a refractive index matching solvent to minimize their scattering intensity. A small amount of strongly scattering tracer particles is added to the dispersion. Therefore, basically the situation depicted in Figure 2 is obtained: only part of the particles present in the sample is visible to the experiment. It should be noted here that the scattering intensity strongly depends on both particle size a and the refractive index difference of the probe particles in respect to the surrounding medium Δn_D.

For particles with radius $a < 100$ nm, the scattered intensity per particle in principle is given by

$$\langle I(q,t)\rangle \sim a^3 \Delta n_D^2 \tag{11}$$

Using an adequate host-tracer system, DLS experiments are sensitive only to the tracer particles, the sample therefore optically corresponding to a very dilute dispersion where single particle mobility easily can be determined (in an invisible but highly concentrated matrix). This approach has been used previously to study self-diffusion in colloidal dispersions in the glass transition regime [18, 87–91], that is, at very high particle concentrations close to the liquid–solid transition. Both host and tracer particles have been quite large ($a \sim 100$ nm). Therefore, a comparatively small difference in refractive index of host and tracer particles ($\Delta n_D \sim 0.10$–0.15) has been sufficient.

Also, tracer light scattering experiments on much smaller colloidal particles ($a \sim 10$–20 nm) have been reported [92, 93]. To obtain a sufficient scattering contrast between host and tracer particles, a much larger value of Δn_D is needed in this case. To achieve this goal, the technique of resonance enhanced Rayleigh scattering reported by Stanton et al. [94] can be applied: This method is based on choosing the wavelength of the incident laser light close to an absorption band of the scattering particles, which leads to an extreme enhancement of the scattered intensity. As adequate tracer particles, highly cross-linked polyorganosiloxane μ-gels containing small gold clusters [95], which absorb light in the wavelength regime of the incident laser beam (514 nm), have been prepared. Liz-Marzán and Philipse [93] previously have employed a similar system, silica-coated gold clusters, in their tracer DLS measurements of concentrated colloidal suspensions.

Using light absorbing nanoscopic tracers in DLS experiments, an unusual and interesting phenomenon has been encountered: Whereas intensity time correlation functions usually are expected to show a simple exponential decay, from which the self-diffusion coefficient can be determined (see Eq. (10)), in this case strongly oscillating signals have been found [92, 96]. This phenomenon has been attributed to convective flow of the scattering probe particles resulting from the heating of the illuminated part of the sample by the laser beam. Based on a detailed data analysis (see Eqs. (12a) and 12(b)), it has been possible for the first time to quantify a convective flow pattern using dynamic light scattering with optical nanotracers [92]. The tracer particles exhibit a superposition of their ordinary diffusive Brownian motion and a ballistic part following the convective flux of the dispersion, yielding the following signal in a DLS experiment:

$$\begin{aligned} g_1(\vec{q},\tau) &= [g_2(\vec{q},\tau) - 1]^{0.5} \\ &= \{\exp(i\vec{q}\vec{v}\tau) + \exp[i\vec{q}(-\vec{v})\tau]\}\exp(-Dq^2\tau) \\ &= \ldots\ldots\ldots = 2\cos(\vec{q}\vec{v}\tau)\exp(-Dq^2\tau) \end{aligned} \tag{12a}$$

$$\vec{q}\vec{v} = \frac{4\pi n_D \sin(\vartheta)}{\lambda}\cos(\vartheta)v = \frac{2\pi n_D}{\lambda}\sin(2\vartheta)v \tag{12b}$$

In Eq. (12a), the sum of two complex exponentials corresponds to the convective motion of the scattering nanotracers, whereas the simple exponential term contains the diffusive part. As a consequence, the correlation function becomes a superposition of an oscillatory part and an exponential decay, and basically looks like a damped oscillation function. The convective flow pattern corresponding to Eq. (12a) is sketched in Figure 4.

In case of this simple convection geometry, the sum of two complex exponentials simply yields a cosine function as shown in Eq. (12a). The argument of this cosine function, and therefore the frequency of the oscillations found in the time intensity correlation function, $g_1(\vec{q},\tau)$ depends both on scattering vector q and particle flow velocity v (see Eq. (12b)).

This example illustrates how optical nanotracers can be used also to investigate complex transport phenomena suchas thermal convection. Here, we should stress once more that DLS experiments are limited to optically transparent samples with only a small amount of scattering probe particles present in the illuminated sample volume. However, many viscoelastic samples of interest are turbid and show strong multiple scattering. A solution to this problem is provided by diffusing wave spectroscopy (DWS) [31, 80–86], a revolutionary dynamic light scattering technique presented in the next section.

Diffusing Wave Spectroscopy Whereas in standard DLS experiments a single scattering event from a moving probe particle is detected, in DWS basically the scattered light itself is diffusing: Many scattering probe particles participate in a typical light path through the medium, and very small displacements of these particles, due to their diffusive Brownian motion, cause a decorrelation of the intensity of scattered light. As a consequence, DWS measurements are sensitive to probe particle displacements on length scales much smaller than the wavelength of light, that is several Å. In addition, these displacements may be probed over the extraordinary wide range of time scales from 10^{-8} to 10^5 seconds. Microrheological measurements using DWS have recently been applied to a variety of systems, ranging from turbid colloidal suspensions in which the scattering particles are intrinsic to the medium [97, 98], to weakly scattering media, such as polymer solutions and gels, rendered turbid by the addition of colloidal probe particles [30, 97, 99–103].

The DWS method is based on the same principle as standard DLS: the time-averaged intensity autocorrelation function is determined by collecting the scattered intensity $I(t)$

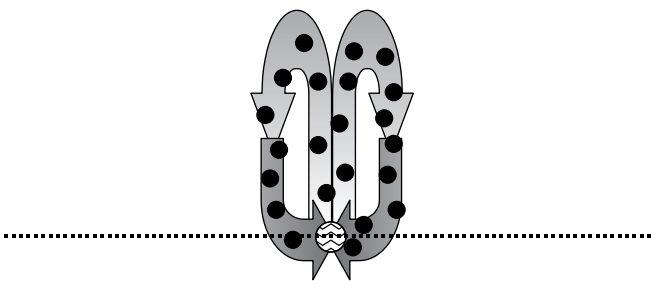

Figure 4. Convective flow pattern of a dispersion of light absorbing nanotracers (●) heated by the incident laser beam (≋) during a DLS experiment. Only flow components within the scattering plane (dotted line) contribute to the correlation function (see Eq. (12a)).

from a single speckle (= patch of scattered light, fluctuating in intensity with time) over a sufficiently long period of time and calculating $g_2(\tau)$ with a hardware correlator. Next, the time-averaged field autocorrelation function $g_1(\tau)$ is calculated. As in case of DLS, the mean squared displacement of a single probe particle $\langle \Delta r^2(t) \rangle$ can be determined from $g_1(\tau)$. The main difference between DLS and DWS is that the scattering vector q plays no role in DWS experiments, that is, the length scale is not defined by the wavelength of the laser and the scattering angle as in DLS.

The importance of DWS from the point of view of microrheological measurements, besides its general applicability to turbid samples, is based on two technical improvements of the standard DWS technique [104–106]. Recently, a new procedure has been developed to extend DWS measurements to the study of non-ergodic media, that is, complex viscoelastic fluids with dynamic heterogeneities. In such systems, the motions of the embedded scattering particles are hindered by spatially dependent elastic forces. Hence, each particle only probes a restricted portion of its total phase space, which, due to the disordered nature of the medium, varies from particle to particle. As a result, each speckle contains a distinct "frozen" portion of the scattered intensity in addition to a fluctuating part, and the temporal intensity profile of each speckle is different. For such non-ergodic materials, an explicit ensemble average must be performed in order to obtain a meaningful autocorrelation function. As Scheffold et al. have shown [106], this ensemble average can be performed by simply placing an ergodic, turbid "reference" sample cell in series after the primary non-ergodic sample of interest. As a suitable reference, a turbid suspension of strongly scattering colloidal nanoparticles has been used. The thermal fluctuations of this ergodic reference cell spatially average the non-ergodic signal from the sample cell. Principal requirements of the reference cell are that it be less turbid than the sample cell and that its characteristic decorrelation time be much longer than the longest correlation time to be measured in the non-ergodic sample of interest. The longest time scale of this two-cell DWS technique [106] is therefore limited by the fluctuation time of the reference cell, which is typically in the order of seconds for colloidal particles in a viscous Newtonian fluid. One drawback of this technique is that, as in conventional DLS, the correlation function is calculated by averaging the time-dependent scattered intensity with respect to a reference time over the duration of the experiment. To obtain sufficient statistical data accuracy, the total measurement time therefore has to be much longer than the longest correlation time of $g_2(\tau)$. If the scattering properties or the dynamical properties of the sample change during the duration of the experiment, the correlation function becomes meaningless. Thus, like standard DLS, the two-cell DWS technique is not useful for systems that are evolving on experimental time scales.

To shorten the experimental time scale significantly, another technique to detect the scattered intensities of multiple speckles simultaneously and partially replace the time average in the intensity correlation function by an ensemble average over various speckles recently has been developed: multispeckle correlation spectroscopy using a charge coupled device (CCD) camera as an area detector [107–109]. The CCD chip here basically works like an array of photomultipliers, and several hundred speckles can be monitored simultaneously. As a consequence, the total duration of the experiment can be shortened by a factor of more than 100 compared to the single-channel method using only time averaging for the correlation function. The shortest time scale accessible by the multispeckle CCD camera based approach is limited by the frame rate of typical CCD systems, which nowadays typically is in the order of 1,000 Hz.

Correlation times covered by two-cell DWS range from 10^{-8} to 10^{0} seconds. On the other hand, the time regime of the CCD multispeckle approach ranges from 10^{-3} to 10^{5} seconds. Used in concert, these two techniques can probe dynamics in complex viscoelastic samples, even if those are turbid and dynamically heterogeneous (non-ergodic), on the extraordinary wide range of timescales from 10^{-8} to 10^{5} seconds, at a length scale of probe particle displacements of several Å.

2.2.3. Forced Rayleigh Scattering

In the preceding section, we have seen that dynamic light scattering techniques, due to the time averaging necessary for calculating the intensity correlation function with sufficient statistical accuracy, afford a total measurement duration much longer than the longest correlation time. Therefore, their correlation time scale is limited to typically 10^{0} seconds. Using the multiple speckle approach with a CCD area detector [107–109], the time average can be partially replaced by an ensemble average, which shortens the measurement time significantly and provides access to a correlation time scale up to 10^{5} seconds. To measure the ultraslow dynamics of nanoscopic probe particles encountered, for example, in polymer melts, the presented correlation techniques are fairly inadequate. Here, a holographic grating technique, forced Rayleigh scattering (FRS) [110–112], provides the ultimate solution. This optical tracer technique practically holds the world record in the study of very slow diffusional processes: It covers diffusion coefficients in the range from 10^{-10} down to 10^{-20} m^2s^{-1}. Standard DLS, for comparison, typically covers diffusion coefficients in the range 10^{-5} to 10^{-14} m^2s^{-1}. By combination of standard tracer DLS with the multispeckle approach, this regime can be enhanced down to 10^{-17} m^2s^{-1}.

Why is FRS so efficient in exploring ultraslow dynamical processes? The typical experimental setup of a FRS experiment is sketched in Figure 5.

FRS is based on the following principle [110, 112]: The interference of two coherent laser beams (I, II) creates a holographic grating by selectively destroying photoreactive dye labels within the sample. These labels are chemically bound or physically incorporated into the nanoscopic probe particles whose dynamics are to be studied. The holographic grating is a periodic arrangement of bleached and nonbleached particles and therefore corresponds to a periodic spatial modulation of the optical properties of the sample, that is, refractive index and light absorption coefficient. Thermally incited diffusion of the labeled particles (Brownian motion, see above) leads to a successive destruction of the ordered holographic lattice with time by mixing probe particles containing bleached and nonbleached labels.

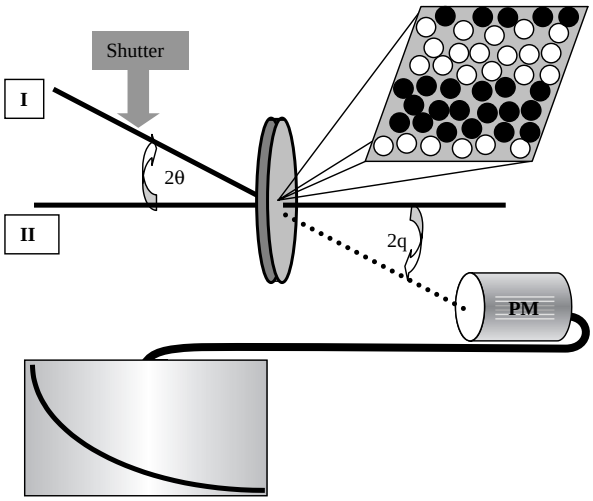

Figure 5. Experimental setup of an FRS experiment.

The actual status of the holographic lattice and thereby the progress of its destruction can be monitored by Bragg diffraction of an attenuated laser beam at the lattice. For nanoscopic optical tracers in a viscous medium, the Bragg diffracted intensity as a function of time is simply given by

$$I(q,t) = A\exp(-2Dq^2t) \tag{13}$$

The scattering vector q is defined by the lattice constant of the holographic lattice, which itself is determined by the interference angle between the two laser beams according to

$$q = \frac{2\pi}{d} = \frac{4\pi\sin(\theta)}{\lambda} \tag{14}$$

Eq. (13) looks identical to Eq. (10), which was used to extract the self-diffusion coefficient from DLS experiments. Note, however, that in DLS the measured scattered intensity shows a fluctuating pattern, and the exponentially decaying function $g_2(q,\tau)$ is a time-averaged intensity correlation function, whereas in FRS experiments the measured scattered intensity itself exhibits the exponential decay. Therefore, in case of the FRS experiment the correlation time and the duration of the experiment are of the same order. This is the reason why FRS can address much slower particle motion than DLS. Compared to video microscopy, the length scale and time scale of the FRS experiment are about the same. However, since the holographic lattice consists of very many probe particles, the signal statistics in case of FRS are much better. For these reasons, considering the limited duration of any experiment (due to stability of the sample, the experimental setup, etc.), FRS is capable of monitoring much slower probe diffusion than all other techniques presented in this article. The shortest time accessible by FRS is determined by the duration of the bleaching laser pulse creating the holographic grating and is typically the order of 10^{-2} seconds. However, besides its strong merits, like any scattering technique FRS has one major disadvantage compared to the direct observation of the particle motion in real space using video microscopy: In the case of complex dynamics of the tracers, for example a combination of diffusive and nondiffusive modes found for tiny probes in complex heterogeneous viscoelastic media, resulting FRS signals are very difficult to interpret. Here, we should mention that the interpretation of DLS measurements in case of complex transport phenomena also may become nontrivial, as has been demonstrated above by the example of convective motion [92, 96].

Let us illustrate the potential of FRS by one recent example: frozen copolymer micelles are nanoscopic model particles consisting of a solid spherical core surrounded by a corona of dangling polymer chains. Embedded in a thermoplastic melt of polymer chains, these particles as additives largely influence the dynamical mechanical properties of the system. To investigate this effect in more detail, microrheological measurements by FRS have been employed on a system consisting of polystyrene (PS)—polyisoprene (PI) micelles (PS core, PI corona) embedded in a homopolyisoprene melt [113–117]. In this system, the micelles serve both as implicit part of the sample and as optical tracers, as already seen in some of the other experimental examples sketched above. To be suitable for the FRS experiment, the micelles have selectively been labelled within their core with a photoreactive dye. The topological architecture of this complex nanoscopic optical tracer system is sketched in Figure 6.

By measuring the self-diffusion coefficients of the micelles in various matrix polymers, which differed in their molecular weight, in dependence of micelle concentration, the characteristics of the interaction potential of the micelles (effective particle size, particle softness) could be determined. Surprisingly, it has been found that the Stokes–Einstein relation (Eq. (5)) is valid even for such a complex system: Using the zero-shear viscosity of the matrix polymer and the self-diffusion coefficients of the micelles interpolated to infinitely dilute samples, a hydrodynamic particle radius has been obtained, which fitted nicely to the topological size of the micelles as determined by X-ray and neutron scattering.

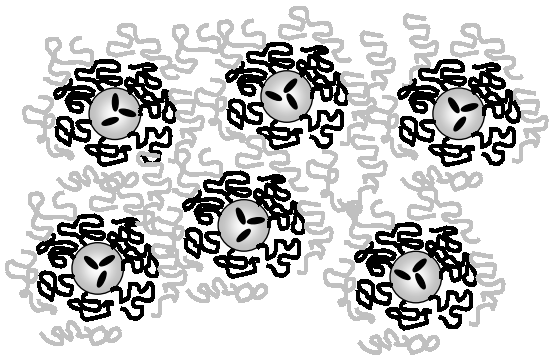

Figure 6. Copolymer micelles containing photoreactive labels (sketched as black ellipsoids within the [gray] micellar core) as tracers for microrheological studies by FRS, embedded in a homopolymer melt.

2.2.4. Optical Techniques for Microrheological Measurements in Direct Comparison

Let us close this overview on microrheological techniques using optical nanotracers by a tabellaric summary and a direct comparison (see Table 1).

The optical properties of the employed tracers strongly depend on the technique to be used, and range, as we have seen, from fluorescent or photoreactive to simply scattering light. Suitable nanoscopic tracers usually are prepared by modification of colloidal particles with organic or metallic pigments. All techniques are able to measure the quantity necessary to determine the dynamical properties of the system, and directly related to the viscoelastic moduli of the sample, the mean squared displacement $\langle \Delta r^2(t) \rangle$. The time scale of video microscopy and FRS, in case of the former, at present only limited by technically available video equipment, is insufficient to explore the dynamic mechanical spectrum $G^*(\omega)$ of a given sample in detail, especially in the regime of very short time scales (high frequencies ω). On the other hand, DWS is limited to much shorter length scales than the other methods, but is the only technique to study turbid samples.

One of the more important optical tracer techniques not discussed so far is laser deflection particle tracking (LDPT) [118], which determines the trajectory of a single diffusing colloidal probe sphere of radius several hundred nm by detecting the laser light scattered from a tightly focused beam in forward direction. If the tracer moves even slightly away from the beam's axis, the scattered light will contain an off-axis intensity asymmetry reflecting the sphere's position. One advantage of the LDPT technique is that it affords only a very small sample volume (about 5 μL). The length-scale resolution of LDPT is about 0.1 nm, at a smallest sampling time of about 10^{-4} seconds. Therefore, LDPT seems to be a powerful tool for optical microrheology. In contrast to DLS, DWS, and FRS, which only measure the mean squared displacement $\langle \Delta r^2(t) \rangle$ since they are averaging over very many probe particles at once, LDPT, like video microscopy, tracks individual particles and therefore is suited to determine the statistical distribution function of the squared particle displacements ($P[\Delta r^2(t)]$). $P[\Delta r^2(t)]$ provides more detailed information on the dynamical properties of complex samples than simply $\langle \Delta r^2(t) \rangle$, especially in the case of heterogeneous systems. Here, time and length scales of LDPT are much superior compared to current video microscopy. On the other hand, as discussed above, video microscopy is capable of tracking many particles simultaneously. This not only enables an ensemble average and thereby sharply shortens the duration of the experiment, but also allows the determination of the correlated motion of several particles as used in two-particle microrheology.

Last but not least, we would like to mention another technique based on nanotracers that are both photoreactive and fluorescent: fluorescence recovery after photobleaching (FRAP) [119–124]. This method has successfully been applied to diffusion studies in highly concentrated colloidal dispersions as well as in biological systems, and in principle works similarly to forced Rayleigh scattering (FRS). First, a periodic grating is generated by selective photobleaching of the nanoscopic tracers within the sample. Second, the time development of the amplitude of this grating is monitored not by Bragg diffraction (FRS) but by directly detecting the spatial fluorescence intensity modulation. For a more detailed description, the interested reader is referred to the literature.

In conclusion, a rich variety of optical methods employing nanoscopic tracers for microrheological measurements has been developed during the last decade. Each has its advantages and disadvantages: Some are (still) very limited in time and length scales and therefore not yet well-suited to explore the dynamic-mechanical spectrum of a viscoelastic sample. Others are restricted by the optical and structural qualities of the sample to be investigated, or require optical nanotracer particles with a special complicated architecture, which are difficult to prepare. In the near future, new technical developments and experimental strategies will further enhance our possibilities for such measurements. The necessity of optical microrheology to explore the dynamics of complex viscoelastic systems in detail at time scales not accessible by conventional dynamic-mechanical measurements exists without doubt; the careful choice of the suitable method depends on the interest of the researcher and on the sample under study.

3. OPTICAL NANOTRACERS IN DRUG DEVELOPMENT

3.1. General Remarks on Drug Development

Drug discovery is a very time consuming and expensive process—until a new product reaches the pharmacist's shelves more than 10 years have passed and over $300 million have been spent. The steadily increasing knowledge in life sciences and the rapid progress in technology and computing also influence drug discovery with new methods that promise higher efficiency. The development of a new drug is a complex process involving many different disciplines. Before the actual drug discovery, scientists focus on particular physiological processes and their associated diseases to identify biomolecular interactions suchas an enzyme

Table 1. Direct comparison of optical techniques used for microrheological measurements.

Method	Tracers	Sample	Time scale	Length scale
Video microscopy	fluorescent	transparent	10^{-3}–10^{4} s	100–10,000 nm
DLS	scattering	transparent	10^{-8}–10^{0} s	100–10,000 nm
DWS	scattering	turbid	10^{-8}–10^{0} s	0.1–10 nm
FRS	photoreactive	transparent	10^{-1}–10^{4} s	100–10,000 nm

and substrate or a receptor and ligand as therapeutic targets. With purified biomolecules, an assay test system is developed, potentially involving nanoparticles with special optical properties, allowing one to monitor the desired interaction itself as well as the influence of an active substance. This assay is used to screen a large amount of unknown artificial or natural substances, the compound library, which is an important capital of pharmaceutical companies having grown over years to a number of several hundred thousand or million compounds. After primary screening, the potentially active substances, called hits, are characterized in more complex and cellular assays and are also used in animal models. This secondary screening phase may involve several loops of chemical modifications to optimize so-called lead compounds in their physiological impact. Only five in 5,000 hits reach a stage called "Investigational New Drug" (IND), being promising enough to be registered for testing in humans where three clinical phases have to be passed. In phases I and II, the effect of the compound on a small number of healthy people and on patients is tested. Phase III involves a large number of patients for comprehensive testing on adverse effects and the best way of administering and using the drug. Only one in five compounds is finally approved: Obviously drugs being withdrawn in clinical phases constitute a substantial financial loss. In the whole process, the early steps and especially the primary screening are most easily accessible to new advances and are ideal for optimization since the testing of hundreds of thousands of compounds multiplies both effort and costs quickly [125–128].

For wet random screening, conventional techniques use large sample volumes of up to 100 μL in a carrier array of 8×12 reaction wells (96 well microtiter plate) for each test. The signal is often based on radioactive or, preferably, less hazardous fluorescent probes utilizing for example mass differences for polarization [129] or a change in total signal intensity upon reaction, and many assays involve washing steps to minimize the unspecific background. Over recent years conventional technologies have been adapted to condensed carrier formats with 384 (16×24) or even 1,536 (32×48) reaction wells of 10 μL each. However, in a small sample volume a bulk signal is often too weak [130]. Several new readout technologies have a high sensitivity, for example in assays based on energy transfer with lanthanide fluorophores, which have a long life time in the microsecond range, providing a low background in a time resolved measurement [131, 132]. Also the use of micro particles is common in drug discovery. Some well established methods use micro particles as a solid support to facilitate washing and to accumulate a signal [133]. In another sensitive assay, special beads are used that emit photons after binding to a radioactively labeled ligand [134]. Recently, nanoparticles have been used for their optical properties of scattering light, either when linked to surfaces [135] or in solution [136]. These techniques involve a special optical setup and have so far been applied to diagnostic purposes. In diagnostics, similar assay systems are used, as in drug discovery, but they are not optimized for throughput or linked into such complex logistical processes, and are therefore more flexible in sample handling and general application of new technologies.

One of the most sensitive techniques used in drug discovery is the confocal detection of single molecules. Due to a small sample volume in the focused laser beam, using piezo-dispensing the sample volume can be pushed down to 1 μL where unspecific adhesion and evaporation can still be controlled. Molecular properties of the fluorescently labeled probe are exploited using fluorescence correlation spectroscopy (FCS) [22, 137–139] or a new method called fluorescence intensity distribution analysis (FIDA) [26, 140–144]. With FIDA, the specific brightness of fluorescent molecules can be determined. Even in mixtures, populations with different specific brightness can be separated and characterized. Based on FIDA, more algorithms have been developed to use other fluorescent molecular properties suchas rotational and translational diffusion or life time. The advantage of such a highly developed technique in screening is the high information content on molecule number and characteristics, as well as on the background, so that artifacts can be identified and eliminated, improving the data quality. A typical way to set up an assay would be to determine one specific brightness of the probe bound to a target protein and another of the probe not bound, and to quantify the number of molecules in one and the other species. Thus the influence of an active compound can be measured by its ability to interfere with the probe binding to the target molecule instead. If the brightness of the fluorescent molecule is not changed upon binding and if other techniques also provide no readout, due to both biomolecules having a similar mass and being too large for polarization or FCS, nanoparticles can be applied [145–147]. After a modification suchas protein coating, this small solid support behaves like a macromolecule that accumulates fluorescently labeled molecules, creating a species with an enhanced brightness, and can thus be separated from unbound ones. The details of such an assay setup will be elucidated in the following sections.

3.2. Fluorescence Nanoparticle Assays

3.2.1. Fluorescence Intensity Distribution Analysis

For fluorescence fluctuation measurement on single molecules, a confocal microscope is used, which is equipped with lasers in the visible nanometer range and a sensitive avalanche photodiode (APD). The optics provide a pinhole and a highly focusing objective to create a confocal spot of about 1, 1, and 4 μm in x, y, and z directions. The stream of photon counts generated with such a system can be analyzed in various ways now that APDs and computational power together with underlying mathematical models are available, the most commonly known being FCS.

For FCS the fluorescence fluctuations are analyzed by calculating their autocorrelation function, which characterizes the average time the molecules are present in the confocal observation volume. Assuming that the size of the observation volume is known, it may be used together with the residence time to calculate the diffusion coefficient of the species under investigation. Still, the use of FCS in drug discovery is constrained because, upon interaction of two molecules, the mass or volume of the observed product has

to increase at least by a factor of eight to cause a twofold change in the diffusion coefficient (see Eq. (5)). Also, a change in fluorescence brightness can usually not be corrected, leading to a misinterpretation of such a reaction. FCS in combination with nanoparticles is a useful technique for diagnostics because it gives a good signal due to the large mass of the particles compared to proteins; however, for drug discovery, acquisition times are too long due to their slow diffusion. Here, FIDA provides a useful alternative.

In a typical FIDA measurement, the acquisition time is divided into time windows of equal width (usually 40 μs), and a frequency histogram (see Fig. 7) is calculated from the number of photon counts detected in each time window.

This histogram is fitted directly to give information on specific brightness and the average number of a given species within the confocal volume, involving several mathematical models and assumptions. FIDA and its related theories are described in detail elsewhere [141, 142, 144] and central points are only commented here briefly. The first point to be considered in any fluorescence intensity analysis is the spatially inhomogeneous optical excitation and detection profile, which leads to a distribution of fluorescence intensities of the fluorophore within the observation volume and therefore has to be taken into account. The excitation profile can be addressed accurately with a point spread function, but a narrowly focused laser beam is also well-described by a Gaussian–Lorentzian profile, which is multiplied with the detection profile (defined by the pinhole) to calculate the spatial brightness function. By selecting an appropriate model, adjustment parameters can be introduced that describe the spatial brightness (and volume elements with different discrete fluorescence intensities can be calculated), which can be verified by a control measurement. The main reason that fitting of the frequency histogram has not been considered a practical advance for a long time is the theory that freely floating particles located at different coordinates contribute independently to the fluorescence signal, thus requiring a direct calculation of convolutions, a mathematically clumsy and time-consuming process. A much more efficient approach is offered by the theory of generating functions, which is a convenient mathematical representation widely used in addressing problems in mathematical statistics. It has the drawback of lacking a simply understandable physical meaning, but conversely has the advantage of enabling the formulation of theories that would otherwise be too complex.

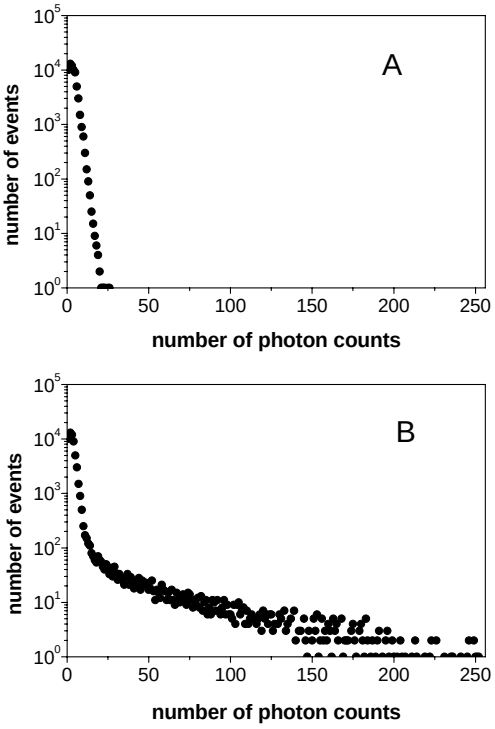

Figure 7. Photon frequency histogram of nonbound fluorescently labeled molecules (A) and of labeled molecules bound to nanoscale particles (B). The histogram shows brighter particles as events with a higher number of photon counts. A FIDA fit yields a specific molecular brightness for nonbound molecules of 7.6 ± 0.3 kHz and for the bright complexes (several labeled molecules bound to a single nanoparticle) of 1620 ± 27 kHz, indicating a loading of over 200 labeled molecules per nanoparticle.

The FIDA theory has formed the basis for the development of a series of related methods, namely two-dimensional FIDA [143] and fluorescence intensity and lifetime distribution analysis combining FIDA and fluorescence life time [142], which yield extended molecular information in addition to the molecular brightness and provide high statistical accuracy. Another intriguing but obvious approach is to divide one photon stream into different time windows to extract the specific molecular brightness and also the diffusion time, which is realized in fluorescence intensity multiple distribution analysis [144], being in a way the combination of FCS and FIDA. This new method requires longer measurement times (>2 sec) for a well-defined data set and also more extensive evaluation, therefore being mainly used for diagnostic applications also in combination with nanoparticles.

3.2.2. The Biochemistry of Nanoparticle Assays

Nanoparticles with a diameter between 50 and 200 nm used in biochemical assays must be hydrophilic and accessible to protein coating and consist usually of materials like polysaccharides or polystyrene with additional surface charges in case of the latter. To investigate nanoparticles, which have a large diffusion time and therefore would otherwise require a long measurement time, the laser beam is scanned through the sample in order to capture a sufficient number of events. There are different ways to design an assay using nanoparticles, the straightforward approach being the coupling of one binding partner to the particle and attaching a fluorescent label to the other binding partner (see Figure 8).

The sensitivity of the assay and therefore its usefulness for screening is determined by the readout sensitivity so that reagent concentrations have to be adjusted. For a FIDA fit, the average number in the confocal volume of any species should be between 0.005 and 50, which is roughly equivalent to 5 pM and 50 nM, respectively. Also, the nanoparticle should be bright enough compared to the background of free ligand so that an affinity in the low nanomolar range (10–100 fluorescent labels per nanoparticle) is required

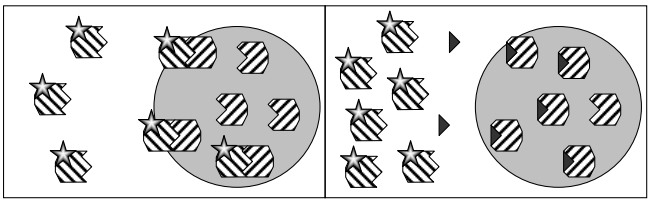

Figure 8. Nanoparticle assay where one binding partner ( ) is covalently bound to the particle, and the other binding partner ( ) is labelled with a fluorescent dye thus generating a FIDA signal when accumulating at the surface of the nanoparticle. An active compound (►) would compete for the binding sites of the target molecule located on the surface of the nanoparticle, thereby reducing the fluorescence brightness of the particle.

for the binding partners. With these constraints, a typical nanoparticle assay can be described as follows: The concentration of the nanoparticle is usually adjusted between 10 and 50 pM, avoiding any unspecific binding or light-scattering effects. Depending on the size of the coated binding partner, a number between 50 and 500 molecules can be attached to particles with a diameter of 50 nm. In an example, considering a rather large protein with a mass of 100,000 Dalton (100 kDa), it is reasonable to expect a final concentration of 500 pM of protein coated to a total of 10 pM nanoparticles (50 binding sites [ ] per nanoparticle). If the labeled binding partner ( ) has a dissociation constant (K_D) of 1 nM and is also added in this concentration, half of all coated proteins, that is 25 out of 50, are expected to be occupied with the labeled binding partners. Using in this example a specific molecular brightness of the free labeled protein of 30 kHz, the FIDA readout would give the following results (In a real experiment, results would obviously be influenced by experimental accuracy!): Species 1 corresponding to the free labeled binding partner with a specific molecular brightness of 30 kHz has a number density of 0.75 (1 nM added, roughly equivalent to an average of 1 molecule in the confocal volume; 25 labeled proteins bound per particle, 0.01 nM particles present, i.e., 0.25 nM bound, leaving 0.75 nM of free ligands). The bound species 2 would have a molecular brightness of 750 kHz (assuming 25 of 50 proteins per nanoparticle complexed with the labeled binding partner, each having a molecular brightness of 30 kHz; $25 \cdot 30$ kHz $= 750$ kHz) and a number density of 0.01 (The bright nanoparticles are measured as the second component.) To condense all parameters into one meaningful number, the degree of binding is calculated by dividing the intensity of the bound protein, which is obtained by multiplying the species number density with its specific molecular brightness, by the total intensity of both bound and free labeled binding partner. In the example, the degree of binding would be 25% $(750 \times 0.01/(750 \times 0.01 + 30 \times 0.75) = 0.25)$. For screening measurements, the analysis would be stabilized and the number of free parameters would be reduced by determining the molecular brightness of both species in control measurements and fixing it for subsequent sample measurements. The decrease of the binding degree can then quickly be determined in samples with compounds binding to the free labeled protein and thus preventing it from accumulating to the nanoparticle.

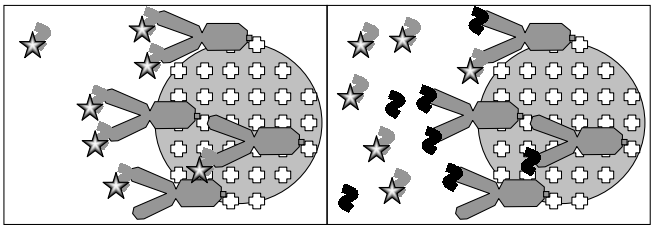

Figure 9. Competition assay where the labeled probe ( ) is complexed to the nano particle via a biotinylated (■) fix antibody ( ) linked to coated Streptavidin ( ). The analyte ( ) will compete for the binding site, which is detected as a lower specific particle brightness in FIDA measurements.

For drug discovery or diagnostics, it is always favorable to establish generic assay systems to minimize effort and risk. This can be done with nanoparticle assays by using a standard protein for coating so that the particles do not have to be modified for each individual assay. An appropriate coating protein also used for several conventional applications is streptavidin, which is found in egg white and binds biotin, an essential vitamin, with exceptionally high affinity most likely to prevent microbial growth. By attaching one or more biotin molecules to a protein, it can easily be linked to the nanoparticles. Other tools commonly used for a more advanced assay design are monoclonal antibodies: For a number of proteins that play an important physiological role, several antibodies directed to different distinct parts of the protein are available. To link an antibody, either streptavidin-coated nanoparticles and biotinylation can be used or the tight specific binding of a special antibody part to Protein A. Antibodies are ideally used to set up analytical assays, following a competition or a sandwich binding principle. In a competition assay (see Figure 9), the protein recognized by the antibody is labeled to function as a probe and is used to generate the FIDA signal. If the analyte, that is, the protein in its natural unlabeled form, is present the binding degree of the probe will decrease in a concentration-dependent manner.

In the sandwich assay (see Figure 10), another binding step is introduced, and the probe is replaced by a second monoclonal antibody, which is labeled. The analyte can now bind to the first antibody linked to the nanoparticle and is itself bound by the second labeled antibody, thus accumulating its fluorescence to the nanoparticle and generating a higher binding degree.

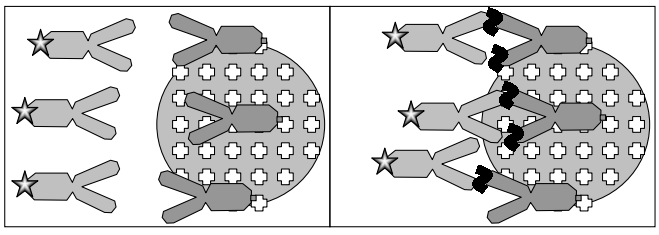

Figure 10. Sandwich assay where the nanoparticle has a high brightness if the analyte ( ) is present, so that the second antibody carrying a fluorescent label can be accumulated.

In general, a so-called positive or increasing signal, as is the case for the sandwich assay, is preferred, being less prone to artifacts. On the other hand, in this case each additional binding partner is required to have a high affinity in order to generate a high binding degree.

4. CONCLUDING REMARKS

We have tried to review the use of nanoscopic optical tracers both in microrheology and modern drug discovery. It has been shown that nanoparticles with special optical properties, suchas fluorescence, photoreactivity, or strong light-scattering power, are very useful to access detailed information in the field of soft condensed matter and biological systems. Here, the possibilities of the new method of microrheology, that is, determination of viscoelastic properties of complex fluids by tracking of small tracer particles, will develop even further in the future with technical improvements such as high-speed CCD cameras, high-speed image recording, etc. On the other hand, fluorescence techniques in combination with fluorescent nanoparticles will continue to play an important role in modern drug discovery, since they provide rapid access to significant signals from a very small number of probe particles.

GLOSSARY

Assay A controlled experiment for the quantitative estimation of a substance by measuring its effect in a living organism (in vivo) or its reactivity with an isolated biologically active substrate (in vitro). Optical nanotracers can be employed to enhance the experimental signal for such quantification using special fluorescence techniques.

Brownian motion Random motion of nanoscopic particles embedded in a fluid medium, driven by thermally incited density fluctuations of the medium. The particle trajectories are characterized by a "random walk" pattern, with the particle mean squared displacement in dependence of time t given as $\langle \Delta r^2(t) \rangle = 6\,Dt$ and D the self-diffusion coefficient.

Generalized Stokes-Einstein equation $\widetilde{G}(s) = s\tilde{\eta}(s) = k_B T/\pi\, as\langle \Delta \tilde{r}^2(s) \rangle$ relates the single particle mobility, expressed by the mean squared displacement of a tracer particle $\langle \Delta \tilde{r}^2(s) \rangle$, to the viscoelastic modulus of a complex fluid $\widetilde{G}(s)$. s is the Laplace transform variable of the time t. The generalized Stokes-Einstein equation provides the basis for optical microrheology.

Multiparticle video tracking One of the most powerful techniques used in optical microrheology, since it allows one to measure the single particle trajectories of several tracer particles simultaneously. A videocamera and a videorecorder are used to record the particle positions of the tracer particles observed under an optical microscope as a function of time. Later, the picture sequence is analyzed using digital image processing.

Optical microrheology By determining the trajectories of a diffusing tracer particle embedded in a viscoelastic fluid, using optical techniques, the viscoelastic moduli of the fluid are calculated using the generalized Stokes-Einstein equation.

Viscoelasticity Behavior of complex fluids, which shows a combination of simple liquid behavior (viscous flow) and solid behavior (elasticity) usually explored using oscillatory shear experiments (mechanical spectroscopy). The viscoelasticity is described by the viscoelastic modulus $G^* = G' + iG''$, a complex number containing an elastic contribution G' and a viscous contribution G''. As described in this chapter, microrheology provides a powerful alternative to explore the viscoelastic properties of complex fluids.

Nano-spintronics for Data Storage

Yihong Wu

National University of Singapore, Singapore and Data Storage Institute, Singapore

CONTENTS

1. INTRODUCTION

Nanotechnology is one of the hottest research fields in the science and engineering arena. Of the many potential applications of nanotechnology, one of the most promising ones is in data storage, particularly the hard disk drives. This is because the physical size of the recording bits of hard disk drives is already in the nanometer regime, and continues shrinking due to the ever-increasing demand for higher recording densities. If the pace of areal density increase is maintained at the current level for about ten years, the dimension of the recording bit will reach the sub-10 nm regime. At this level, both the writing and reading processes will become extremely challenging, if not impossible.

The rapid shrinkage of bit size poses formidable challenges to the read sensors. This is because the sensor must be made smaller or at least comparable to the bit size, and at the same time, its sensitivity must be improved continuously so as to compensate the loss in signal-to-noise ratio due to the decrease in the bit size. The former has to rely heavily on the advance of nanotechnology, and the latter on an emerging field called spintronics [1–4]. The combination of these two fields has played an important role in advancing the areal density of magnetic recording from a few gigabits/in^2 to the current level of more than 100 Gbits/in^2 [5–8]. In addition to hard disk drives, the technologies developed have also been applied to magnetic random access memories (MRAMs) [9–11]. Further advance in the two fields is the key to realizing terabits/in^2 hard disk drives and gigabit nonvolatile memories within this decade. This chapter is intended to provide an updated review of nanometer-scale spintronics for data storage applications, with emphasis on the application of metal-based spintronics in magnetic sensors and memories.

To have a clear picture of the scope of this review, Figure 1 illustrates how spintronics is positioned in the hierarchy of various different types of data storage technologies. The data storage devices can be categorized into three major groups, that is, magnetic and optical data storage, and solid-state memory. Each of them can be divided further into several subgroups, and here, we only focus on magnetic data storage and solid-state memory. Among the magnetic storage devices, the hard disk drive (HDD) is the dominant secondary mass storage device for computers, and very likely also for home electronic products in the near future. The HDD is an integration of many key technologies, including head, medium, head-disk interface (HDI), servo, channel coding/decoding, and electromechanical and electromagnetic devices. Among them, the read head is the only component that has experienced the most changes, including some revolutionary ones in terms of both the operating principle and the structural design and fabrication processes during the last decade. The ever-increasing demand for higher areal densities has driven the read head evolving from a thin-film inductive head to an anisotropic magnetoresistive (AMR) head, and recently, the giant magnetoresistive spin-valve (GMR SV) head. There are two different forms of GMR SVs, depending on whether the sense current flows in the film plane (CIP) or perpendicular to the film plane (CPP). Currently, CIP SVs are dominant, but CPP SVs are more promising for future extremely high-areal-density heads. In addition to CPP spin valves, a magnetic tunnel junction (MTJ) with low junction resistance is also one of the potential candidates for future read sensors. The MTJ is particularly useful for MRAM applications.

Encyclopedia of Nanoscience and Nanotechnology
Edited by H. S. Nalwa
Volume 7: Pages (493–544)

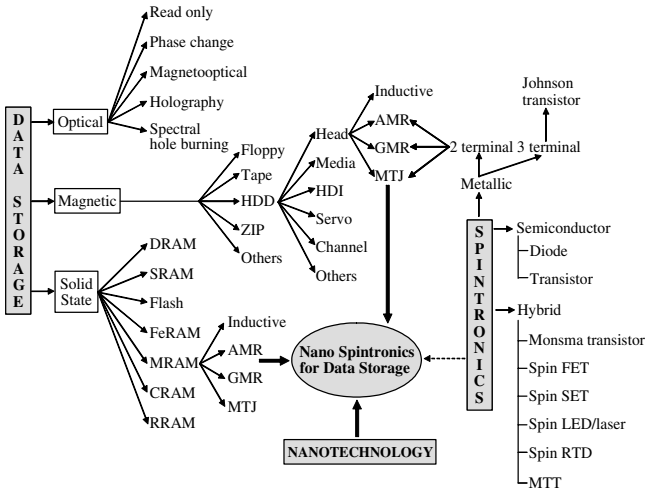

Figure 1. Spintronics and its applications in data storage and electronics. The acronyms are: DRAM—dynamic random access memory, SRAM—static random access memory, FeRAM—ferroelectric random access memory, MRAM—magnetic random access memory, CRAM—chalcogenide random access memory, RRAM—resistance random access memory, ZIP—zip drive, HDI—head–disk interface, AMR—anisotropic magnetoresistance, GMR—giant magnetoresistance, MTJ—magnetic tunnel junction, FET–field-effect transistor, SET—single-electron transistor, LED—light-emitting diode, RTD—resonant tunneling diode, MTT—magnetic tunnel transistor.

As is with the case of read sensors, the MRAM started from the ferrite core design to AMR, GMR pseudospin valve, and the current MTJ cell design. However, it is only after the introduction of MTJ that the MRAM has taken off, and is expected to be in mass production in a few years' time. The GMR and MTJ sensors are generally called magnetoelectronic or metal-based spintronic devices, which are the focuses of this review. The metal-based spintronic devices are based primarily on the spatial modulation of electron spins through using layered structures of magnetic and nonmagnetic materials. The lack of capability in charge modulation in these types of structures may eventually limit their ultimate performances in terms of both the magnetoresistance and other functionalities. To address this issue, recently, a great deal of effort has been devoted to the development of magnetic semiconductors which allow the modulation of both the spins and charges. The advance in this field may eventually lead to spintronic devices with performances superior to their metal-based counterparts. In addition to pure metal-based or semiconductor-based spintronic devices, hybrid devices making use of both technologies also have been explored actively in recent years.

The organization of the rest of this chapter is as follows. Section 2 gives a brief introduction to the basics of magnetic data storage and spintronics, and explains why both the spintronics and nanotechnology are crucial for magnetic data storage. Section 3 discusses different types of magnetoresistance effects, and their applications in read sensors. In-depth reviews of the magnetic and electronic aspects of spin valves are given in Sections 4 and 5, respectively. Section 6 deals with the MTJs, with their applications in MRAMs discussed in Section 7. Section 8 touches briefly on the semiconductor spintronics. Finally, we discuss the future trend of data storage and the role of spintronics in future data storage in Section 9.

2. BASICS OF MAGNETIC DATA STORAGE AND SPINTRONICS

2.1. Magnetic Recording and Magnetic Memory

The hard disk drive at the system level is the integration of many key technologies and components, which include the storage medium, read/write transducer, channel coding/decoding, servocontrol, head/disk interface, tribology, and electromechanical and electromagnetic systems [12–14]. In this subsection, however, we focus on the physics and materials aspects of magnetic recording, that is, topics related to the storage medium and read/write heads [15].

The thin-film medium for a hard disk drive is a stack of multiple layer thin films formed on either an NiP-coated aluminum alloy or a glass substrate [16]. Among the multiple layers of thin films, the early hard disk media only employed a single magnetic layer as the recording layer, which is usually a polycrystalline alloy of Co, Cr, and Pt with additional elements such as Ta or B to improve the magnetic properties. The latest magnetic media, however, employ more than one magnetic layer as the recording layer, such as the antiferromagnetically coupled (AFC) media to improve the thermal stability of the information bits recorded on the hard disk [17–19]. When recording the information onto the disk, a writer which can generate a sufficiently high magnetic field is used to switch the magnetization of a localized area of the media to one of two fixed directions, with one of them representing digit "1" and the other representing digit "0." Each of the localized areas can be considered as one bit. Each bit consists of a number of partially exchange-coupled magnetic grains, as shown schematically in Figure 2.

When reproducing the information from the disk, the early disk drive employs the same write head as the read head, that is, the signal is detected by measuring the voltage change across the coils induced by the flux variation when

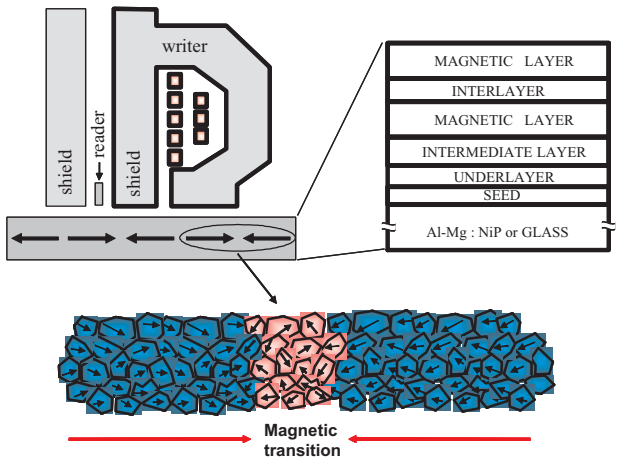

Figure 2. Schematic of a magnetic recording head and media. The head typically consists of an inductive writer and an AMR or GMR reader.

the head passes by the recorded media. Although the performance of the inductive head had been improved continuously to meet the requirement of rapidly increasing areal density, its structural design and working principle did pose certain limitations to the ultimate performance of this type of head. That is the reason why, in the beginning of the 1990s, a new type of head which is based on the anisotropy magnetoresistance of certain magnetic materials was introduced by IBM, and later also adopted by other head and drive companies. This type of head is widely called an AMR head [20]. The AMR effect stems from the spin–orbit interaction of electrons, and thus it normally appears in magnetic materials; its value, however, varies from less than 1% to a few percent, depending on the type of material. The common material that is used for an AMR head is Permalloy, of which the MR ratio is about 2–4%. It decreases almost linearly with thickness for ultrathin films (<10 nm).

Although the AMR head showed much better performance in terms of sensitivity and scalability than the thin-film inductive head, its pace of structural miniaturization and performance improvement was soon outpaced by the rapid advance in areal density. The rapid increase of areal density requires simultaneously a decrease in both the bit length and the track width. The former requires a thinner and more sensitive sensor, while the latter requires a large magnetoresistance (MR). Unfortunately, it is difficult for the AMR head to satisfy both requirements simultaneously because the MR ratio of the AMR head decreases rapidly when its thickness is reduced to less than 10 nm [21]. On the other hand, in 1988, a much larger MR effect, that is, GMR, was discovered in artificially made magnetic and nonmagnetic multiple layers [22, 23]. The MR ratio of this type of superlattice structure is more than one order of magnitude larger than that of the AMR. The GMR structure, however, could not be applied directly to the read head as it was because of the large magnetic field that is required to switch the magnetization of the magnetic layers from one direction to the other. This has prompted IBM to invent a more practical structure for a read sensor which is called a spin valve [24].

The state-of-the-art spin valve consists of a dozen thin layers, the heart of which is a trilayer structure consisting of two ferromagnetic layers separated by a nonmagnetic spacer, which is usually copper. The signal detection principle is based on the fact that the resistance of the trilayer is dependent on the relative orientation of the magnetization of the two ferromagnetic layers. The resistance is high when the magnetizations of the two layers are in opposite directions, and low when they are in the same direction. To have a linear response from the sensor, the angle between the two magnetizations is normally set at 90° at zero field, with one of them "pinned" at a direction perpendicular to the media surface through exchange coupling with an antiferromagnet, and the other free to rotate in response to the fringe field of magnetic transitions recorded on the magnetic media.

There are two different forms of spin-valve sensors, depending on whether the current flows in the plane of the stack of layers or perpendicular to them. The former is called a current-in-plane, or CIP, spin-valve sensor, and the latter a current-perpendicular-to-plane, or CPP, sensor [25]. So far, CIP is dominant, but CPP is expected to play an important role in future terabit recording systems. An alternative to the CPP spin valve is the magnetic tunnel junction, or MTJ, in which the current also flows perpendicular to the plane [26–29]. The major difference between the CPP spin valve and the MTJ is that the latter is composed of two ferromagnetic layers separated by an insulator instead of a metal. Therefore, the electrical conduction in MTJ is based on quantum-mechanical tunneling. The MTJ is attractive because its MR ratio is generally more than double that of spin valves. However, the primary drawback of MTJ is that its junction resistance is generally larger than that of the CIP or CPP sensors, which may affect its performance as a read sensor due to the increase in thermal noise and the decrease in bandwidth when the junction size is reduced to a certain value. In addition to this, the quantum-mechanical nature of electron transport also causes shot noise which increases with the intensity of the output signal. Thus, the major application of MTJ so far is in MRAM. As one of the newcomers in the memory hierarchy, the MRAM has the potential to replace some of the commercially available memories in the near future.

Except for the inductive read head, all other read sensors discussed above make use of both the charge and spin properties of electrons. AMR stems from spin–orbit interaction, while the spin valve and MTJ operate based on the spin-dependent scattering and tunneling both inside the magnetic layers and at the magnet/nonmagnet or insulator interfaces. In contrast to Si-based electronics, the GMR-based sensors are often referred to as a subcategory of an emerging field called spintronics (see Fig. 1).

2.2. Spintronics

Electrons possess both charges and spins. The motion of charges forms the current. The ability to control or modulate the charge transport has made it possible to form functional devices such as diodes and transistors. This is so far only possible in semiconductors instead of metals because the latter have too many electrons per unit volume; the variation of charge distribution, if any, is limited to a few atomic layers at the surface that can hardly cause any measurable change in the conductance of the metal. Therefore, functional electronic devices have not been realized in pure metals with dimensions larger than the mean-free path of electrons. Although they belong to the same family of metals, metallic magnetic materials have another additional degree of freedom which can be used to vary their electronic transport properties—the spin of electrons. As the spin of electrons in magnetic materials can be easily manipulated using an external magnetic field without suffering the electrostatic screening effect as the charges do when they are subjected to an electric field, it is possible to alter the conductivity of magnetic materials without changing the carrier distribution inside the material. This forms the basis of GMR-based electronics or sometimes is also called magnetoelectronics. It is a subfield of spintronics or spinelectronics [1–4].

The spintronics in its broader sense contains all types of electronics that make use of both charges and spins. In semiconductor-based electronics, we only control the

charge motion, and ignore the spins. In fact, it is difficult to control the spins in semiconductors because they do not have specific directions under normal conditions, unless the electrons are injected into from external sources with a net polarization. On the other hand, in metallic magnetic materials, it is easy to control the spins due to the strong ferromagnetic coupling among the spins, but it is difficult to control the charges. Therefore, a question naturally arises here: Can we have a kind of material in which we can control both charges and spins? The answer is "yes," and this type of material is called a magnetic semiconductor [30–32]. The magnetic semiconductor is usually made through adding magnetic impurities to host semiconductors. It is not necessary, however, that every semiconductor can be made magnetic using this approach because some of them still do not exhibit any magnetic properties even after they are doped with a substantial amount of magnetic impurities. Some of them, although being magnetic, show a very low Curie temperature [33, 34]. However, the situation changed drastically in recent years due to the intensive efforts made by researchers in this field in many research organizations. Several different types of magnetic semiconductors having a Curie temperature higher than room temperature have been found. These include, but are not limited to, GaN:Mn [35, 36], CdGeP:Mn [37], GaP:Mn [38], TiO_2:Co [39], and ZnO:Co [40]. It should be noted, however, that all of these are based on preliminary experimental results; further experiments are required to verify the results. The progress was made not only in materials themselves, but also the application of these materials in creating new functional devices such as semiconductor-based magnetic tunnel junctions [41, 42] and spin-injection devices [43, 44]. Although the current technology for a read sensor is based on metallic spintronics, semiconductor-based spintronics has the potential to provide sensors or storage elements with superior performances for next-generation data storage devices.

Although the read sensor for magnetic recording and storage cells for magnetic memory are based on spintronics, the storage of information in disk media is still based on classic physics, and it does not involve spintronics. However, as the bit size continues decreasing, one day the bit size will approach that of atoms. At this stage, a fundamental change in the information storage principle might be required. One of the possible scenarios is to store information in the reciprocal space or energy domain. In this case, the spin of electrons and nuclei instead of the magnetization of magnetic grains will be important. This is closely related to another emerging field called quantum information storage [45].

2.3. Nanotechnology and Magnetic Data Storage

Nanotechnology is indispensable for all kinds of data storage devices, be it magnetic, optical, or solid-state devices. This is because the common driving force for any type of data storage technology is the areal density, provided that the bit-cost performance also improves with the areal density. As a rule of thumb, the bit size shrinks by one order when the areal density increases by two orders. Figure 3 shows the size of a square bit as a function of the areal density. The bit size falls into the nanometer regime (1–100 nm) when the areal density reaches 70 Gbits/in^2, which was already realized about two years ago. To write information to and read information from these small bits, the write and read heads must have a size which is smaller than or at least comparable to that of the bit. In addition to the read/write head, the spacing between the disk and the head must also be kept as small as possible, and in a practical case, it is about one fifth of the bit size. Therefore, once the areal density enters the hundreds of gigabits range, the dimensions of almost all of the key components in magnetic recording have to be in the nanometer regime.

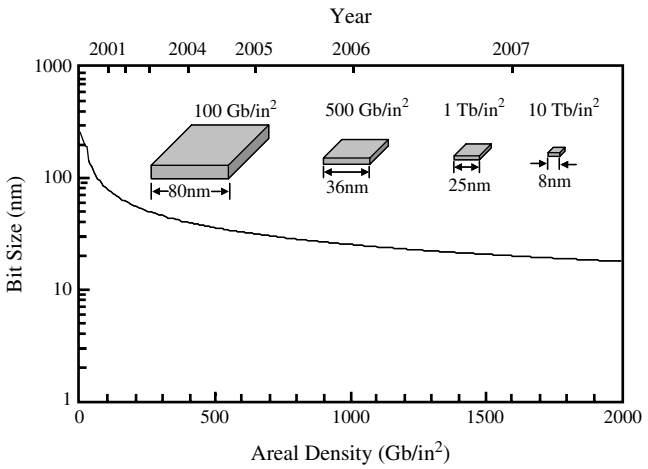

Figure 3. Bit size as a function of areal density for square bits. Also shown is the year at which the areal density will be reached by assuming a compound annual growth rate of 60%. Inset shows the size of square bits at areal densities of 100, 500, 1000, 10,000 Gbits/in^2, respectively.

The continuous shrinkage of bit size poses formidable challenges to both media and read heads. For low-areal-density recording, each single bit contains tens of thousands of small magnetic grains. At this level, one will not "feel" the difference when one or two grains are missing. However, the number of grains per bit decreases monotonically with the areal density. At 100 Gbits/in^2, the number of grains is reduced to less than 100. This results in an increase of media noise due to the particulate nature of the media. One of the possible ways to suppress the noise is to reduce the grain size of the media so that each bit will contain a greater number of grains. However, this is not so straightforward because the superparamagnetic phenomenon will appear, making the information bit thermally unstable. Although the recent advance in multiple-layered media has greatly enhanced the thermal stability of the media with small grains, it is still far from being a perfect solution. The thermal stability of the media is not only just affected by the grain size, but also very much by the grain size distribution. The latter is technically more challenging because one must use a mass-production technique which can produce not just small grains, but also monodispersed grains. This is the area where nanotechnology is expected to play an important role. One of the possible ways to realize such a kind of media is to fabricate single-domain particles or dots by using nanofabrication techniques [46–48]. Although one of the major applications of nanostructured magnetic materials and nanomagnetism is in storage media,

we will not discuss this further in this chapter because, so far, the media are still in the "passive" form, and do not involve spintronics.

Now we turn to the read sensor, which is our main focus in this chapter. We are concerned about the sensor when its size is reduced because, first, the sensor size must be reduced accordingly when the bit size decreases, and second, the output and impedance of the sensor are dependent on the sensor size. So far, the sensor fabrication has leveraged the semiconductor manufacturing processes. But this trend is going to be reversed because the size shrinkage of read sensors has outpaced the shrinkage of critical dimensions of integrated circuits [49]. In a few years' time, the dimension of the sensor will approach 50 nm, at which point there may not even be a solution for the semiconductor industry at the moment. In addition to the manufacturing issues, one also needs to find a way to improve the performance of the sensors so that the output of the sensor will not decrease significantly when its size is reduced.

The above discussion demonstrates clearly the importance of nanotechnology and spintronics in magnetic recording and memory devices. In fact, spintronics is closely related to nanotechnology because most of the phenomena related to bulk and surface magnetism have a characteristic length in the nanometer regime. In the rest of this chapter, we discuss in detail the fundamental concepts and latest development of metallic spintronics and its applications in magnetic data storage.

3. MAGNETORESISTANCE AND THE ASSOCIATED READ SENSORS

3.1. Anisotropic magnetoresistance

The resistivity of a nonmagnetic material is usually independent of the magnetic field. However, this may not be the case for magnetic materials. The phenomenon that the resistivity of a ferromagnetic material depends on the relative angle between the current and magnetization direction of the material is called the anisotropic magnetoresistance effect, or AMR, which was discovered in 1857 by Thomson [50]. A series of theoretical studies carried out a century later showed that the AMR effect stems from the spin–orbit interaction [51]. The importance of the AMR effect was recognized in the 1970s when a large AMR was found in a number of alloys based on iron, cobalt, and nickel [52]. Materials exhibiting a normal AMR effect show a maximum resistivity when the current is parallel to the magnetization direction ($\rho_{||}$) and a minimum resistivity when the current is perpendicular to the magnetization direction ($\rho_{\perp}$). A measure for the size of this effect is the AMR, ratio which is defined by

$$\mathrm{MR} = \frac{\rho_{||} - \rho_{\perp}}{\rho_{||}} \tag{1}$$

At intermediate angles between the current and magnetization direction, the resistivity of an AMR material is given by

$$\rho(\theta) = \rho_{\perp} + (\rho_{||} - \rho_{\perp}) \cos^2 \theta \tag{2}$$

where θ is the angle between the current and the magnetization direction.

3.2. AMR Sensor

The immediate application of the AMR was in magnetic recording because sensors based on the AMR effect offer higher output as compared to the thin-film inductive head [53, 54]. Although, for Ni (Fe, Co) alloys, the largest AMR effect so far was found for $Ni_{70}Co_{30}$, 26.7% at 4.2 K and 6.6% at 300 K [52], the material of choice for magnetic recording applications is permalloy because of its softness, high permeability, and low magnetorestriction. The typical AMR ratio for thin permalloy films (30–50 nm) is about 2%, although the AMR of its bulk counterpart can be as high as 4% [13, 21]. When being used as a sensor, the magnetization direction is normally set at 45° with respect to the current direction at zero field so as to maximize the sensitivity [55]. This is apparent from the fact that the first derivative of ρ is maximum when $\theta = 45°$.

Figure 4 shows a schematic drawing of an AMR sensor element. For the sake of simplicity, we assume that the external magnetic field points in the y-axis direction. Assuming that the entire element is a single-domain particle with a uniaxial anisotropy, the magnetization direction can be obtained from minimization of the energy density [13]:

$$\varepsilon = -HM_s \sin\theta + K_u \sin^2\theta + \frac{1}{2} H_d M_s \sin^2\theta \tag{3}$$

Note that here only the magnetostatic energy, anisotropy energy, and demagnetizing energy are taken into account; all other energy terms are neglected. In Eq. (3), H is the external magnetic field, M_s is the saturation magnetization, K_u is the uniaxial anisotropy energy constant, H_d is the demagnetizing field, and θ is the angle between the magnetization and easy axis direction. Minimizing the energy density gives

$$\sin\theta = \frac{H}{2K_u/M_s + H_d} = \frac{H}{H_k + H_d} \tag{4}$$

where $H_k = 2K_u/M_s$ is the anisotropy field. Substituting Eq. (4) into Eq. (2) yields

$$\rho(H) = \rho_{||} - (\rho_{||} - \rho_{\perp}) \left(\frac{H}{H_k + H_d} \right)^2 \tag{5}$$

For soft materials, $H_k \ll H_d$; therefore,

$$\rho(H) = \rho_{||} - (\rho_{||} - \rho_{\perp}) \left(\frac{H}{H_d} \right)^2 \tag{6}$$

It is apparent from the above equation that the simple AMR sensor element exhibits a nonlinear response to the external field, which cannot be used as a read sensor for magnetic recording as it is. However, it is not difficult to realize from

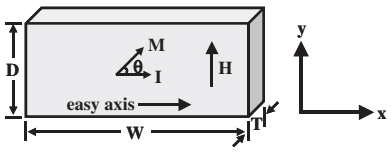

Figure 4. Schematic of a single-domain AMR sensor element. H is the external field, M is the saturation magnetization, and I is the current.

Eq. (6) that the sensor can be made linear if an additional field which is much larger than that of the external field is added to it to make the total effective external field as $H' = H + H_B$ with $H_B \gg H$. In the case of $H_d \gg H$, which is true for magnetic recording, Eq. (6) becomes

$$\rho(H) \approx \rho_{||} - (\rho_{||} - \rho_{\perp})\left(\frac{H_B}{H_d}\right)^2 - (\rho_{||} - \rho_{\perp})\frac{2HH_B}{H_d^2} \qquad (7)$$

It shows that now the sensor responds linearly to the external field. H_B is the so-called bias field or, more precisely, the traverse bias field because it is perpendicular to the easy axis direction of the sensor element. In actual sensor design, the strength of the bias field is chosen such that the magnetization direction at zero field is about 45° away from the easy axis so as to maximize the sensitivity. It is obvious from Eq. (7) that the smaller the demagnetizing field, the larger the sensitivity.

There are many different ways to form a traverse bias. Among them, the most successful was the soft adjacent layer (SAL) bias scheme, in which a soft ferromagnetic layer is laminated with the sensing layer via a thin insulating spacer, as shown schematically in Figure 5 [55–58]. As the SAL is normally chosen such that most of the current flows through the sensing layer, the magnetic field induced by the sensing current magnetizes and saturates the SAL into one direction (pointing upward in Fig. 5). The fringe field thus generated, in turn, provides a traverse bias to the sensing layer itself. The SAL scheme offers several advantages, such as adjustable bias field, relatively uniform bias field distribution, and reduced demagnetizing field. Although it also has drawbacks such as the current shunting effect, it so far has remained the most successful engineering design. In actual sensors, in addition to the traverse bias, one also needs a longitudinal bias to stabilize the domain structure so as to reduce the Baukhausen noise caused by the domain-wall motion [55, 56].

As we mentioned above, the AMR sensor, intrinsically, is not a linear sensor. In addition to the nonlinearity issue, it also suffers drawbacks such as thermal asperity [59] and side reading asymmetry [60, 61]. Perhaps the most fatal shortcoming of the AMR sensor is that it is difficult to scale it down in thickness so as to meet the requirement of shrinkage in bit length and reduction in $M_r t$ of the media [21]. These intrinsic characteristics of the AMR plus the tremendous progress made in GMR in the early 1990s have determined the short lifetime of the AMR sensor in the history of hard disk drives. It was gradually replaced by the spin-valve sensor, which was first introduced into disk drives by IBM in 1997.

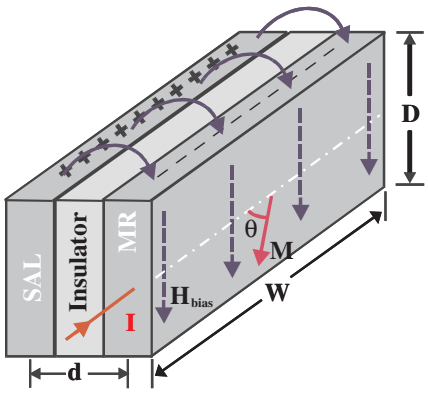

Figure 5. Schematic of an AMR sensor using an SAL bias. The sensor consists of an MR element as the active layer and a soft adjacent layer (SAL) for traverse bias. The MR element and the SAL are separated by an insulating spacer.

3.3. Giant Magnetoresistance

In the second half of the 1970s, researchers at IBM developed a technique which allows growing ultrathin films with extraordinary accuracy in thickness control. It was based on the vacuum evaporation technique, but with a several orders of magnitude lower base pressure as compared to the normal high-vacuum evaporator. At this base pressure and appropriate partial pressures of the source materials, it is possible to have a mean-free path of the evaporated materials that is larger than the distance between the source material and the substrate for most of the molecules or atoms. In other words, the evaporated molecules or atoms form beams, and impinge directly on the substrate surface to initiate the growth. Therefore, the technique is generally called molecular beam epitaxy (MBE) [62]. The word "expitaxy" was used because MBE had been mainly employed to fabricate semiconductor materials which are normally single-crystalline materials grown epitaxially on the substrates. The most attractive point of MBE is that it not only allows the growth of ultrathin single-layer film, but also makes it possible to grow layered structures of different materials. This opened an important field in materials science called artificial structures. In particular, when the layers are a few atomic layers thick, they form a so-called superlattice structure [63]. It also made it possible to create quantum-well structures in which the electrons of one type of material are confined by the potential steps formed between this material and the other types of materials at both sides. This led to tremendous advances in semiconductor devices. Being inspired by the work carried out by the semiconductor community, researchers in the surface-science community started to use the same technique to study surface magnetism and magnetic interactions across an ultrathin antiferromagnetic or nonmagnetic spacer [64]. These research activities led to the discovery of giant magnetoresistance in Fe/Cr superlattices [22]. As shown in Figure 6, the resistance of such a superlattice structure is high at zero field, decreases when a magnetic field is applied in both directions along the sample surface, and finally saturates at a field H_s of about 2 T. The MR ratio of superlattices with an [Fe(3 nm)/Cr(0.9 nm)] × 60 structure was measured to be about 45% at 4.2 K, which is much larger than the AMR effect [22]. It was proved soon afterward that the resistance of the superlattice structure depends on the relative orientation of the magnetization of the adjacent magnetic layers. At a Cr thickness of 0.9 nm, the magnetizations of adjacent Fe layers are antiferromagnetically coupled at zero field, but are realigned into the same direction when the external field is sufficiently high to overcome the exchange-coupling field.

The mechanism of GMR can be understood using the simple two-current model [65–67, 284, 285]. In this model,

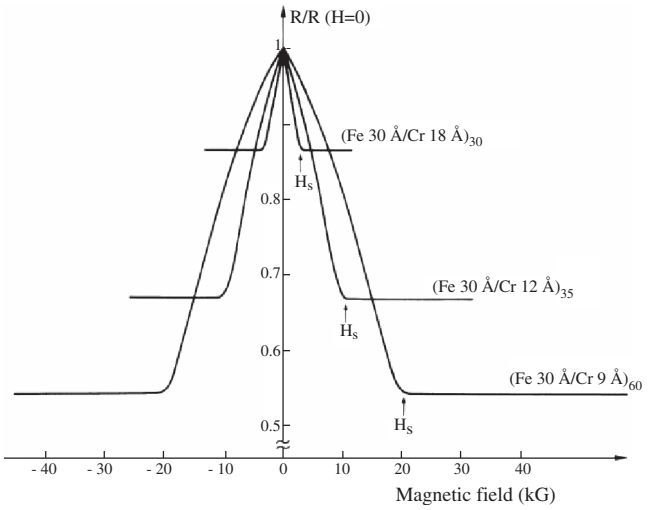

Figure 6. Magnetoresistance of Fe/Cr superlattices. Both the current and the applied field are along the same [110] axis in the film plane. Reprinted with permission from [22], M. N. Baibich et al., *Phys. Rev. Lett.* 61, 2472 (1988). © 1988, American Institute of Physics.

the electrical conduction of ferromagnetic materials is considered carried out by two independent channels of spin-up and spin-down electrons. Due to the different density of states distribution of spin-up and spin-down electrons near the Fermi level, the mean-free path for spin-up electrons is normally larger than that of spin-down electrons due to the larger scattering probability of s electrons to spin-down d-electron states (when the density of states of spin-down electrons is higher than that of the density of states of spin-up electrons). When all of the magnetic layers are ferromagnetically exchange coupled, the spin-up electrons will experience less scattering when they cross the nonmagnetic layer entering other magnetic layers within the spin-diffusion length, which is normally larger than the mean-free path. The resistivity of the spin-up electrons in this case can be considered as a constant over the film stack, and is denoted by $\rho_{\uparrow\uparrow}$. Similarly, the resistivity of the spin-down electrons can also be considered as a constant, and is denoted by $\rho_{\uparrow\downarrow}$. As in the simple two-current model, we ignore the spin-flip scattering, that is, no mixing of the two conduction channels; the total resistivity is given by $\rho_P = \rho_{\uparrow\uparrow}\rho_{\uparrow\downarrow}/(\rho_{\uparrow\uparrow} + \rho_{\uparrow\downarrow})$. However, the situation changes when the magnetic layers are antiferromagnetically coupled. This is because both the spin-up and spin-down electrons will experience frequent scattering when they cross the multiple layers. The two conduction channels will have the same resistivity, which is given by $(\rho_{\uparrow\uparrow} + \rho_{\uparrow\downarrow})/2$, leading to a total resistivity of $\rho_{AP} = (\rho_{\uparrow\uparrow} + \rho_{\uparrow\downarrow})/4$. The MR ratio is thus given by

$$\mathrm{MR} = \frac{\rho_P - \rho_{AP}}{\rho_{AP}} = -\left(\frac{\rho_{\uparrow\uparrow} - \rho_{\uparrow\downarrow}}{\rho_{\uparrow\uparrow} + \rho_{\uparrow\downarrow}}\right)^2 \tag{8}$$

The negative sign indicates that the resistivity at saturation state is lower than that at the zero-field state. A quantitative treatment of the GMR effect is possible using either the Boltzmann transport equation [68–70] or the quantum Kubo formula [71–73] using either the simple parabolic band structure or the more realistic band structures [74, 75]. These models can predict very well the dependence of GMR on the material and structural parameters of the multilayers. More details can be found in other review articles [76, 77]. For a magnetic/nonmagnetic multilayer with the film plane parallel to the xy plane, the linearized Boltzmann equation becomes [68–70]

$$\frac{\partial g^{\uparrow(\downarrow)}(z,\vec{v})}{\partial z} + \frac{g^{\uparrow(\downarrow)}(z,\vec{v})}{v_z \tau^{\uparrow(\downarrow)}} = \frac{eE}{mv_z}\frac{\partial f_o(\vec{v})}{\partial v_x} \tag{9}$$

where

$$g^{\uparrow(\downarrow)}(z,\vec{v}) = f^{\uparrow(\downarrow)}(z,\vec{v}) - f_0(\vec{v})$$

is the deviation of the electron distribution function from the equilibrium Fermi–Dirac distribution $f_0(\vec{v})$. Here, $\tau^{\uparrow(\downarrow)}$ represents the relaxation times for spin-up (spin-down) electrons, e is the elementary charge of electrons, m is the electron mass, $\vec{v}$ is the velocity, and E is the electrical field. The general solution of Eq. (9) is

$$g_{\pm}^{\uparrow(\downarrow)}(z,\vec{v}) = \frac{eE\tau^{\uparrow(\downarrow)}}{m}\frac{\partial f_0(\vec{v})}{\partial v_x}\left[1 + F_{\pm}^{\uparrow(\downarrow)}(\vec{v})\exp\left(\frac{\mp z}{\tau^{\uparrow(\downarrow)}|v_z|}\right)\right] \tag{10}$$

where $+(-)$ is for $v_z > 0$ ($v_z < 0$). $F_{\pm}^{\uparrow(\downarrow)}(\vec{v})$ can be obtained by using the boundary conditions for $g_{\pm}^{\uparrow(\downarrow)}(z,\vec{v})$ at both the interfaces and top and bottom surfaces. After $g_{\pm}^{\uparrow(\downarrow)}(z,\vec{v})$ is obtained, the total current per unit length in the y direction (assuming the field along the x direction) can be obtained by first integrating $(-e)v_x g_{\pm}^{\uparrow(\downarrow)}(z,\vec{v})$ in $\vec{v}$ space, followed by integrating with respect to z. The MR ratio can thus be obtained from the difference in conductivities between the parallel and antiparallel alignment of the magnetic layers.

3.4. Interlayer Coupling

The underlying mechanism of GMR is the long-range magnetic exchange coupling between transition metals across a nonmagnetic spacer, which was first observed in the Fe/Cr/Fe(001) system [78]. Although the GMR effect was originally observed in Fe/Cr superlattices with a fixed Cr layer thickness, subsequent studies have revealed the oscillatory behavior of interlayer coupling in this system and many others [79–81]. More importantly, these results were obtained not only from high-crystalline-quality samples grown by MBE, but also from polycrystalline samples deposited by sputtering. This has greatly accelerated the research in this field because of the wide availability of sputtering systems. As one of the typical results, Figure 7 shows the oscillatory behavior of magnetoresistance of Co/Cu superlattices observed by Parkin et al. on dc magnetron-sputtered samples [79]. Four well-defined oscillations with a period of about 1 nm are seen at both 4.2 and 300 K. This system later became the most important system for metal-based spintronic devices.

It was soon realized that the oscillation in GMR is a general phenomenon in ultrathin magnetic and nonmagnetic multiple layers, and its origin comes from the periodical switching from ferromagnetic to antiferromagnetic

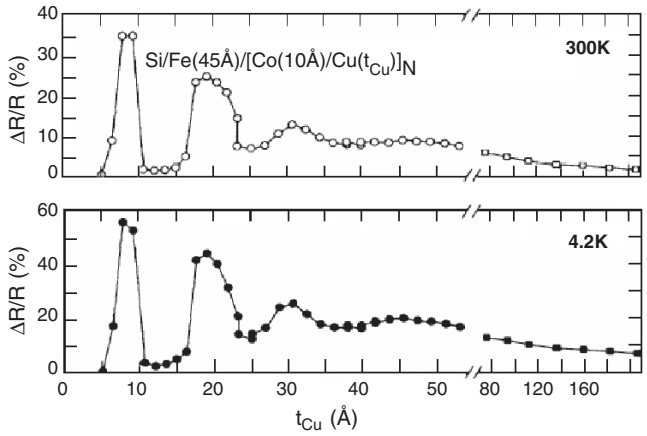

Figure 7. Dependence of saturation traverse magnetoresistance on Cu spacer layer thickness for a family of related superlattice structures of the form Si/Fe(4.5 nm)/[Co(1 nm)/Cu(t_{Cu})]$_N$. An additional Cu layer was deposited on each film structure such that the uppermost Cu layer was about 5.5 nm thick. The number of bilayers in the superlattice N is 16 for t_{Cu} below 5.5 nm (solid and empty circles) and 8 for t_{Cu} above 5.5 nm (solid and empty circles). Adapted with permission from [80], S. S. P. Parkin et al., *Phys. Rev. Lett.* 66, 2152 (1991). © 1991, American Institute of Physics.

alignment and vice versa of the adjacent ferromagnetic layers when the thickness of the nonmagnetic layer varies every few atomic layers [82]. It was found that both the GMR and the saturation magnetic field of Fe/Cr multiple layers oscillate at a period of about 1.5 nm. The latter suggests that the relative angle of the magnetization direction of the two ferromagnetic layers oscillates between 0 and 180° because it is easier to saturate the two layers when they are in parallel alignment, and difficult when they are in antiparallel alignment. This was soon confirmed by the neutron [83] and Brillouin scattering experiments [84]. Furthermore, detailed investigations have revealed the existence of two coupling periods [85–90].

Various models have been proposed to account for the oscillatory behavior of exchange coupling of the magnetic/nonmagnetic multiple layers, which include primarily the quantum-well model [91–97] and the Ruderman–Kittel–Kasuya–Yoshida (RKKY) interaction model [98–101]. Both models have been able to describe the origin of the exchange coupling, in particular, the oscillations in the sign and strength of the coupling. In what follows, we explain briefly the RKKY model by closely following the treatment by Bruno and Chappert [100, 101] and Fert and Bruno [102]. The interaction between two ferromagnetic layers across a metallic spacer has its basis in the interaction between two magnetic impurities in a host metallic material. According to the RKKY model, the effective exchange interaction between two spins $\vec{S}_i$ and $\vec{S}_j$ is given by

$$H_{ij} = J(\vec{R}_i - \vec{R}_j)\vec{S}_i \cdot \vec{S}_j \tag{11}$$

where the exchange integral is

$$J(\vec{R}_i - \vec{R}_j) = -\frac{1}{2}\left(\frac{A}{V_0}\right)^2 \frac{V_0}{(2\pi)^3}\int d^3\vec{q}\chi(\vec{q})\,\exp[i\vec{q}\cdot(\vec{R}_i - \vec{R}_j)] \tag{12}$$

Here, V_0 is the atomic volume and

$$\chi(\vec{q}) = 2\mu_B^2 \frac{V_0}{(2\pi)^3}\int d^3\vec{k}\frac{f(\varepsilon_{\vec{k}}) - f(\varepsilon_{\vec{k}+\vec{q}+\vec{G}})}{\varepsilon_{\vec{k}+\vec{q}+\vec{G}} - \varepsilon_{\vec{k}}} \tag{13}$$

is the susceptibility of the host materials. The integrations over $\vec{q}$ and $\vec{k}$ are to be performed within the first Brillouin zone, and $\vec{G}$ is a vector such that $\vec{k} + \vec{q} + \vec{G}$ belongs to the first Brillouin zone. In the case of free electrons at zero temperature, the Fermi surface is a spherical surface with a radius defined by the Fermi wavevector $\vec{k}_F$. The probability distribution function $f(\varepsilon_{\vec{k}})$ drops to zero sharply at the Fermi surface, resulting in a logarithmic singularity at $\vec{q} = 2\vec{k}_F$ for $\chi(\vec{q})$. The Fourier transforms of $\chi(\vec{q})$ give oscillations to J with a period of $\Lambda = \lambda_F/2$, and λ_F is the Fermi wavelength.

For interactions between two ferromagnetic layers (hereafter, we refer them to as FM_1 and FM_2), the interaction integral may be obtained by summing over all of the pairs of spins belonging to FM_1 and FM_2. For the sake of simplicity, we assume that both layers are one atomic layer thick. Without the loss of generality, we first look at the interaction between a single spin located at position O of FM_1 and all of the spins belonging to FM_2, which is given by

$$I_{1O,2} = \frac{d}{V_0}S^2 \sum_{j\in FM2} J(\vec{R}_O - \vec{R}_j) \tag{14}$$

The above summation can be further simplified by treating FM_2 as a thin layer with a uniform spin distribution, that is,

$$\sum_{F2} \to \frac{d}{V_0}\int_{F_2} d^2\vec{R}_{||} \tag{15}$$

Here, $\vec{R}_{||}$ is the in-plane component of $(\vec{R}_O - \vec{R}_j)$. The interaction integral is then given by

$$I_{1O,2}(z) \approx \left(\frac{A}{V_0}\right)^2 S^2 \frac{m}{16\pi\hbar^2}\frac{d^2}{z^2}\sin(2k_F z), \text{ for } z \to \infty \tag{16}$$

which is also an oscillation function with a period of $\Lambda = \lambda_F/2$. This is too short to explain the long oscillation periods observed experimentally. Subsequent studies pointed out that the contradiction comes from the invalid assumption that the thin FM_2 layer has a continuous and uniform spin distribution. By taking into account the discreteness of the spin distribution in the FM_2 plane, the interaction integral is given by

$$I_{1O,2}(z) = -\frac{1}{2}\left(\frac{A}{V_0}\right)^2 S^2 \frac{d}{(2\pi)^3}\int_{-\infty}^{+\infty} dq_z \times \exp(iq_z z)\int d^2\vec{q}_{||}\chi(\vec{q}_{||}, q_z) \sum_{\vec{R}_{||}\in FM_2} \exp(i\vec{q}_{||}\cdot\vec{R}_{||}) \tag{17}$$

The last term suggests that $\vec{q}_{||}$ cannot take any arbitrary value but the in-plane reciprocal lattice vector $\vec{G}_{||}$; otherwise, its value will be zero. This gives an effective wavevector

$[(2k_F)^2 - G_{||}^2]^{1/2}$, which is responsible for the multiperiodicity due to different $G_{||}$ in different directions. Figure 8 shows the cross section of the Fermi surface for an fcc (001) spacer. The first Brillouin zone (FBZ) and the auxiliary prismatic zone are represented by the solid and dashed contours. The wavevectors giving rise to oscillatory interlayer coupling are indicated by the horizontal bold arrows: (a) free-electron approximation, and (b) Cu Fermi surfaces. Also shown are the vectors giving rise to oscillations in the (111) direction (oblique arrows).

On the other hand, the long oscillation period can also be understood based on the argument that the spacer thickness does not vary continuously in Eq. (16); rather, it only takes discrete values $z = (N+1)a$ with N an integer number [99, 103, 104]. Because of this discrete sampling or aliasing effect, one obtains an effective period

$$\Lambda = \frac{\pi}{|k_F - n\pi/a|} \tag{18}$$

where n is an integer chosen such that $\Lambda > 2a$, with a being the atomic spacing of the spacer in the thickness direction. This gives a period which is much larger than $\lambda_F/2$ (see Fig. 9).

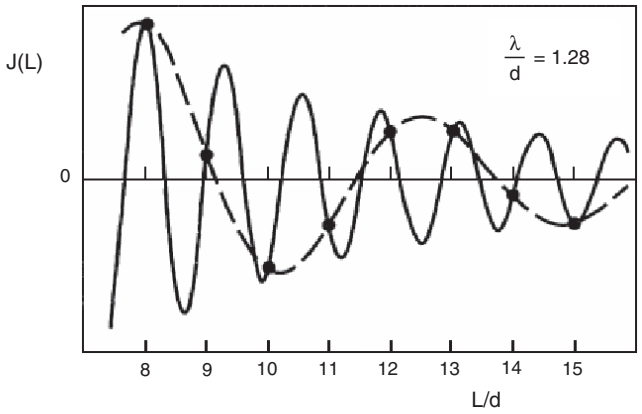

Figure 9. Full curve: exchange-coupling strength of two ferromagnetic layers across a monovalent fcc (100) metal (arbitrary units) calculated using the continuum version of the RKKY model. Broken curve: the actual coupling strength with the experimentally measured periodicity for $L = Nd$. Here, L is the thickness of the spacer, d is the atomic layer spacing in the thickness direction, and N is an integer number. Adapted with permission from [99], R. Coehoorn, *Phys. Rev. B* 44, 9331 (1991). © 1991, American Institute of Physics.

3.5. Spin Valve

The research on read sensors using the GMR effect commenced soon after the GMR effect was reported. This is because it gives a much higher MR ratio as compared to its AMR counterpart. However, the original GMR structure consisting of Fe/Cr, Co/Cu, or other types of magnetic multiple layers could not be applied to read sensors in the original form because of their large saturation fields, and also the nonlinear response near the zero-field point. The most straightforward way to reduce the saturation field is to reduce the exchange coupling between the ferromagnetic layers through increasing the thickness of the spacer. However, a completely decoupled or weakly coupled multilayer structure does not function properly as a sensor because of the possible inconsistent movement of all of the magnetic layers under an external field. One of the possible ways to overcome the drawback of the decoupled GMR stack is to use two decoupled layers with one of them much softer than the other, so that the former will respond to a small field, while the latter will only change its magnetic state when it is subjected to a large field [105, 106]. This kind of structure, in principle, can form a good sensor, provided that the hard layer is not only truly hard, but also has the same crystalline structure as that of the soft layer. Unfortunately, this kind of material is still not available at present. Therefore, most of the experiments on decoupled bilayers have been performed on NiFe/Cu/Co or Co/Cu/Co systems. In the latter case, the two Co layers may have different coercivities, and their values are dependent on the individual layers' thicknesses. Although a relatively large magnetoresistance with a small saturation field has been obtained in these kinds of structures, they were still unsuitable for data storage applications due to the instability of the hard layer. However, this type of structure has served as a good object for studying spin-dependent transport in magnetic/nonmagnetic multilayers [107, 108]. They can also be used for MRAMs [109]. The magnetic stiffness of the hard layer may be improved by using an antiferromagnetically coupled hard/Ru/soft triple-layer structure to replace the single-layer structure [110, 111].

To address the issues involving noncoupled magnetic multilayers, IBM invented a device called the spin valve in 1991 [24, 112, 113]. A typical spin valve in its simplest form

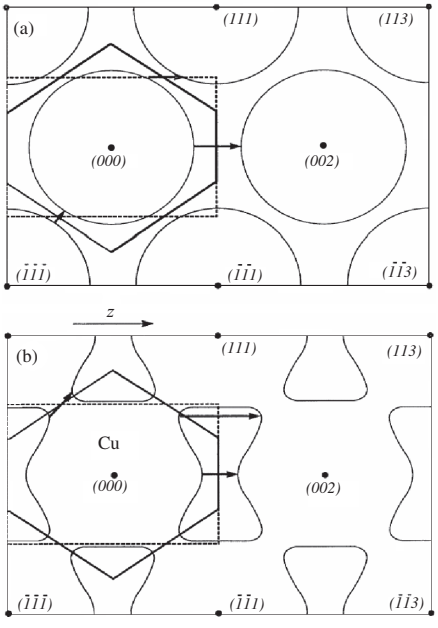

Figure 8. Cross section of the Fermi surface for an fcc (001) metal and the corresponding vectors giving rise to oscillatory interlayer coupling in both the (001) and (111) directions (indicated by the horizontal and oblique arrows, respectively). (a) Free-electron model. (b) Cu Fermi surface. Adapted with permission from [100], P. Bruno and C. Chappert, *Phys. Rev. Lett.* 67, 2592 (1991). © 1991, American Institute of Physics.

consists of two ferromagnetic layers separated by a nonmagnetic spacer and an antiferromagnetic (AFM) layer in contact with one of the ferromagnetic layers (see Fig. 10). The thickness of the spacer is chosen such that there is little exchange coupling between the two FM layers. The magnetization of one of the FM layers which is in direct contact with the AFM layer is "pinned" by the latter, and thus this FM layer is commonly called a pinned layer. On the other hand, the magnetization of the other FM layer is free to rotate to respond to an external field, and thus it is called a free layer. The typical material for the FM layer is NiFe or CoFe, while that for the spacer is generally copper. A thin layer of Co or CoFe with high Co composition is often added at the FM and Cu interface so as to increase the MR ratio due to its high polarization ratio and less interdiffusion at the interface with Cu [114, 115]. The choice of AFM is an issue of high complexity due to many practical considerations, which will be discussed shortly.

When being used as a read sensor [116], a constant current is applied to the sensor, and its voltage change caused by the fringe-field variation from the media is detected as the readout signal. In order to increase the linear density, usually two shielding layers are used to "shut off" the influence of neighboring bits (see Fig. 11). Depending on how the current is applied, there are two different types of sensors, that is, the Current-in-plane and current-perpendicular-to-plane sensors, as discussed earlier. As the name suggests, in the former case, the current flows in the plane of the sensor stack (see Fig. 11), while in the latter case, the current flows perpendicular to the plane. The small resistance of the metallic multilayers makes it quite challenging to measure the magnetoresistance of the CPP structure. Several approaches have been taken to address this issue, including the use of superconducting electrodes and reduction of the lateral size using lithography [117, 118] or selective growth in the pores of nanoporous membranes [119–121]. The results obtained showed that the CPP MR ratio is much larger than the CIP MR ratio. Alternatively, the GMR can also be measured with the current-at-an-angle (CAP) through growing the GMR structure on grooved substrates [122]. Since, so far, CIP sensors dominate in practical applications, we discuss the CIP sensors first.

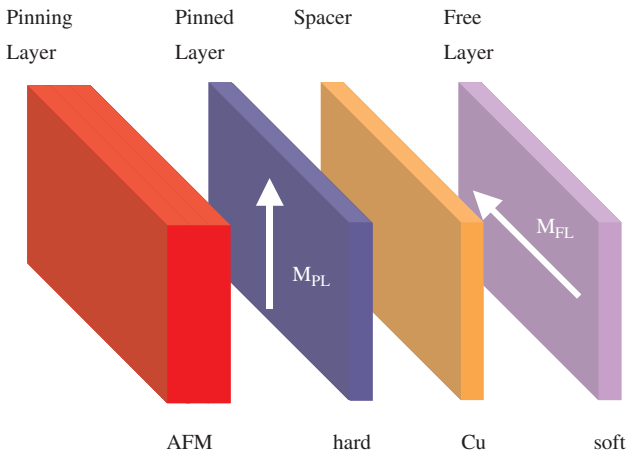

Figure 10. Schematic of a simple spin-valve structure.

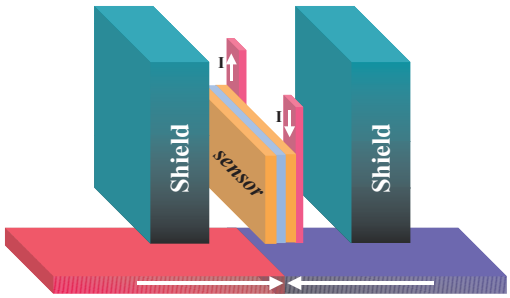

Figure 11. Spin valve used as a read sensor in CIP mode.

The M–H and MR–H curves of a typical spin valve are shown schematically in Figure 12. Due to the small thickness of the spacer, there always exists an interlayer coupling between the free and pinned layers. The nature of the interlayer coupling can either be ferromagnetic or antiferromagnetic, depending on whether the orange peel or RKKY coupling dominates. We will come back to this topic shortly. For the particular spin valve whose characteristics are shown schematically in Figure 12, the free and pinned layers are ferromagnetically coupled. Therefore, the magnetization of the spin valve is at maximum, while the resistance is at minimum at zero field. When the applied field increases in the opposite direction of the pinning field (in this case, in the positive direction), the magnetization of the free layer was first reversed, resulting in an antiparallel alignment of the free and pinned layers. This corresponds to the high-resistance state. When the applied is further increased, it will eventually reverse the magnetization of the pinned layer. This will realign the magnetization of the pinned layer with that of the free layer, recovering the low-resistance state. Decreasing of the applied field after the saturation in the positive direction will cause the magnetization of the pinned layer to be reversed first, followed by the reversal of the free layer, and finally, the two magnetic layers realign with each other again at negative fields. In general, a large exchange bias field and a small interlayer-coupling field are desirable for read-head applications.

The performance of a read sensor is normally characterized by the size of the MR effect. It can be either the MR ratio or the sheet resistance change ΔR_S. The former is given by [24, 123–125]

$$\frac{\Delta R_S}{R_S} = \left(\frac{\Delta R_S}{R_S}\right)_0 \left(\frac{1-\cos(\theta_F - \theta_P)}{2}\right) \tag{19}$$

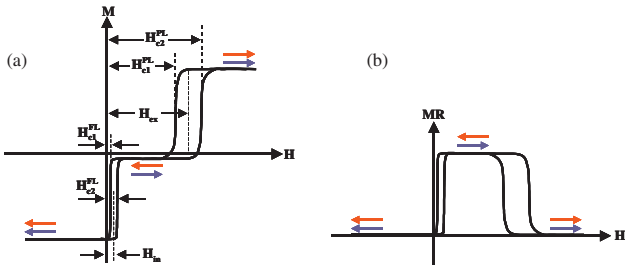

Figure 12. Schematics of M–H (a) and MR–H (b) curves of a typical spin valve (H_{ex}: exchange-bias field; H_{in}: interlayer coupling field between free and pinned layer; $(H_{c1}^{FL} - H_{c2}^{FL})$: coercivity of free layer; $(H_{c1}^{PL} - H_{c2}^{PL})$: coercivity of pinned layer).

where R_S is the sheet resistance and ΔR_S the change in sheet resistance. $(\Delta R_S/R_S)_0$ is the maximum MR ratio when the magnetizations of free and pinned layers are switched from parallel alignment to antiparallel alignment. θ_F and θ_P are the angles between the parallel direction and the magnetization direction of the free and pinned layers, respectively. It is apparent from this equation that a linear response can be obtained through setting θ_P to 90°. This is because $\sin\theta_F$ is proportional to the external field, as we discussed in Section 3.2 for AMR sensors. In addition to its linear response, the spin valve also exhibits a much higher MR ratio as compared to the AMR sensors. However, even though that is the case, there has been and there is still a strong demand for the improvement of the spin-valve sensors. Figure 13 shows the estimated track width and required sensor sensitivity at an aspect ratio of 4:1 for different areal densities by assuming that the sensor has to generate an output voltage of 1 mV. The solid and dashed curves are obtained by assuming a read track width of 80 and 60% of the track pitch, respectively. From this figure, one can see that a threefold increase of the sensor sensitivity is required for increasing the areal density from 100 Gbits/in^2 to 1 Tbits/in^2.

From Eq. (19), one can see that the MR ratio of a spin valve is affected by two factors of different origin. The prefactor of the right-hand-side term of Eq. (19), that is, $(\Delta R_S/R_S)_0$, is mainly determined by the spin-dependent electronic transport properties of the spin valve, while the rest is more or less determined by its magnetic properties. As summarized in Figure 14, the improvement in spin-valve design has proceeded from both the magnetic and electronic aspects. In a certain sense, the original spin valve proposed by IBM can be regarded as the first step in the improvement of the pseudospin valve that still remains the simplest, yet the most attractive design should the materials problem be solved in the future. In what follows, we first discuss the

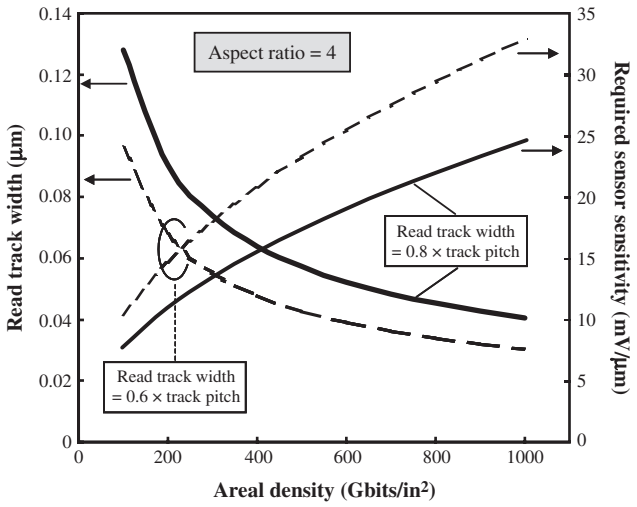

Figure 13. Estimated read track width and required sensor sensitivities at different areal densities by assuming an aspect ratio of 4:1. The solid and dashed curves are obtained by assuming the read track width to be 80 and 60% of the track pitch, respectively. The sensitivity requirement is obtained by assuming that the sensor would generate an output voltage of 1 mV.

magnetic aspect of spin valves, followed by a discussion on the electronic aspect. We will refer back to Figure 14 again when necessary.

4. MAGNETIC ASPECTS OF SPIN VALVES

Like a transistor which needs a proper bias to work properly, the spin valve also needs a proper magnetic bias so as to achieve a linear response with minimized asymmetry, if any [13, 15, 55, 123]. The main tasks of magnetic design of spin valves are: (1) to set the magnetization of the pinned layer as rigid as possible in the vertical direction (see Fig. 10), (2) to make the free layer as soft as possible, and to align its initial magnetization direction parallel to the media surface, (3) to eliminate Baukhausen noise induced by domain wall movement, and (4) to make the sensor thermally stable at elevated temperature under normal operation conditions and corrosion resistive. Of course, in practical cases, one also has to consider the ease of manufacturing and reliability of the devices. To achieve all of these goals, one needs to set a proper traverse and longitudinal bias for the spin valve using appropriate materials. The former is employed to "pin" the magnetization of the pinned layer as rigid as possible, while the latter's role is to maintain the single-domain status of the free layer, and at the same time, without sacrificing its softness.

4.1. Traverse Bias

4.1.1. Exchange Bias

Traverse bias is achieved through the use of exchange bias (EB) formed at FM/AFM interfaces [Fig. 10 and Fig. 14(d)], which was discovered about half a century ago [126]. The exchange bias at the FM/AFM interface is usually established through a magnetic annealing and cooling process, in which the sample is first heated up to above the Néel temperature of the AFM, and then is cooled down to room temperature in the presence of a magnetic field with a strength of one to a few tesla. The exchange-biased FM/AFM bilayer is characterized by a shift of the hysteresis loop in the opposite direction of the exchange-bias field direction and an increase of the coercivity of the FM layer, as shown schematically in Figure 15(a).

The exchange bias in AFM/FM bilayers is a very complex issue. Despite intensive studies, the phenomenon itself is still not fully understood [127–130]. A number of theoretical models have been proposed to account for the experimental data, which include, but are not limited to: (1) the coherent rotation model [131], (2) the Néel model [132], (3) the random interface model, (4) the AFM domain wall model [133, 134], (5) the interface spin canting model [135], (6) the random and compensated interface model, and so on [136–139]. Obviously, the coherent rotation model is the simplest one which assumes that: (1) both the FM and AFM layers are single-crystalline materials, (2) the AFM layer has a rigid spin configuration which is not affected by any strength of an external field, and its interfacial layer is fully uncompensated, and (3) the magnetization reversal of the FM layer is accomplished through coherent magnetization

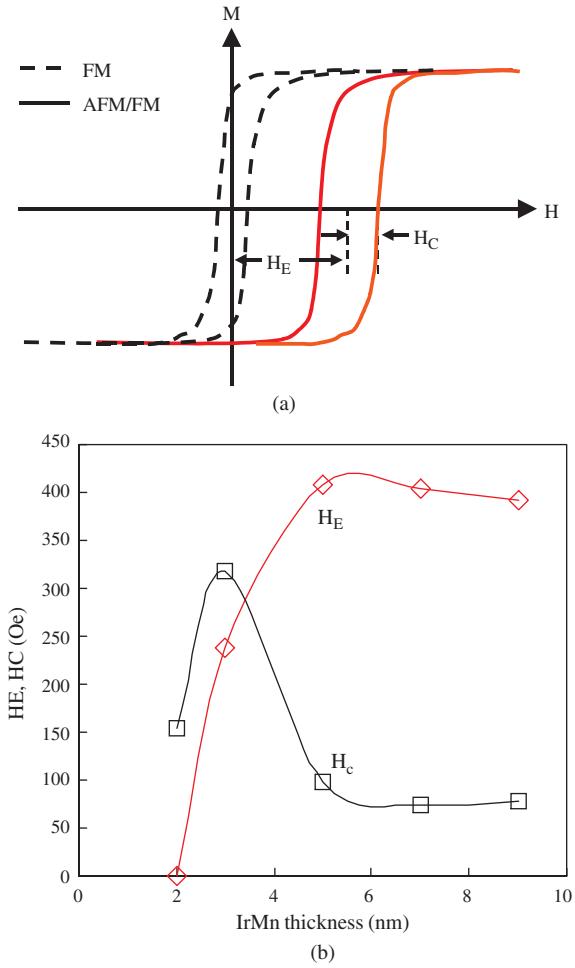

Figure 15. (a) Schematic hysteresis curves of a single FM layer (dotted line) and an FM/AFM exchange-coupled bilayer (solid line). (b) Dependence of exchange-bias field on the thickness of AFM material for an NiFe (3 nm)/IrMn bilayer system.

rotation. Under these assumptions, the exchange field is given by

$$H_{EX} = \frac{2J\vec{S}_{FM} \cdot \vec{S}_{AFM}}{a^2 M_{FM} t_{FM}} \tag{20}$$

where J is the exchange parameter, $\vec{S}_{FM}(\vec{S}_{AFM})$ is the spin of the interfacial atom of the FM (AFM) layer, $M_{FM}(t_{FM})$ is the magnetic moment (thickness) of the FM layer, and a is the cubic lattice constant. Although the above equation does agree with the experimental observation that H_{EX} decreases with t_{FM}, it yields a value for H_{EX} that is by orders of magnitude larger than that of the experimental data. The simple model fails to explain the asymmetry observed in the hysteresis either. This has prompted the proposal of various improved models. Among them, two models have been quite successful in explaining the observed value of H_{EX}. Mauri et al. proposed a model that is able to explain the observed exchange bias without the need to remove the condition of strong interfacial coupling at the FM/AFM interface [134]. This is made possible by allowing the formation of parallel domain walls, either in the AFM layer or in the FM layer,

wherever the energy is lower. By assuming that the domain wall forms at the AFM side of the interface, they obtained the following expression for the exchange field:

$$H_{EX} = \frac{2\sqrt{A_{AF}K_{AF}}}{M_{FM}t_{FM}} \tag{21}$$

where $A_{AF}(K_{AF})$ is the exchange stiffness (magnetocrystalline anisotropy energy constant) of the AFM layer.

Malozemoff argued that any realistic model should not be based on the assumption of an atomically perfect uncompensated AFM surface, and proposed a random interface model [133]. It was shown that, for a real interface with finite roughness, it becomes energetically favorable for the antiferromagnet to break up into domains with perpendicular domain walls. This model yields an exchange-coupling field of

$$H_{EX} = \frac{2z\sqrt{A_{AF}K_{AF}}}{\pi^2 M_{FM}t_{FM}} \tag{22}$$

where z is the number of order unity. Therefore, the exchange field predicted by both the AFM domain wall model and the random interface model is of the same order; this is because both are determined by the characteristic domain wall energy.

The parallel domain wall model requires the existence of a spiral spin structure in the AFM layer [140], which has been observed recently in both the conventional FM/AFM bilayers [141] and artificial FM/AFM bilayers [142]. The formation of an AFM domain wall is found to be affected by the magnetization of the FM layer. The exchange coupling between the FM and AFM layers occurs on a domain-by-domain basis [143]. Due to the dominant role of the AFM domain walls in exchange coupling, the exchange bias is generally sensitive to the defects in the AFM layer.

4.1.2. AFM Materials

Above is a far too brief introduction of the exchange-coupling mechanism at the FM/AFM interfaces. An in-depth discussion of this topic can be found in several excellent review papers [127–130]. In what follows, we turn to different material systems that have been developed for practical applications in spin valves [144, 145]. As discussed earlier, the key to the proper operation of a spin valve is to "pin" the magnetization of the reference layer in a direction that is perpendicular to the media surface, which forms a 90° angle with respect to the easy axis of the free layer at zero field. The former is achieved using the exchange bias at the AF/AFM interface. To realize a reliable and linear operation of the spin valve, the following issues have to be considered carefully when choosing the AFM materials.

1. Size of the exchange bias field: As a subtle rotation of the magnetization of the pinned layer will cause asymmetry and degradation of the output signal, the pinning field must be sufficiently high (>300 Oe) so as to make the reference layer "rigid" under a moderate external field.
2. Thermal stability: The exchange-bias field usually decreases with temperature. In what way and how fast it decreases, however, depends not only on the intrinsic properties of the materials, but also their structural properties, thickness, and techniques that are used to prepare the materials. The temperature at which the exchange-bias field vanishes is called the blocking temperature. A high blocking temperature (>250 °C) is required to ensure that the sensor functions properly not only at room temperature, but also at elevated temperatures. This is important because the temperature of the active region of the sensor may rise to 60–120 °C during normal operation.
3. Large resistivity of the AFM layer: As the AFM layer itself does not contribute to the MR effect, a high-resistivity material is desirable for suppressing the current-shunting effect. In this sense, the ideal AFM material should be an insulator. Unfortunately, most of the oxide-based AFM materials like NiO can hardly satisfy other requirements, and thus are unsuitable as AFM materials for practical device applications.
4. Small critical thickness: The exchange-bias field is found to be quite insensitive to the thickness of the AFM when it is sufficiently thick. However, it starts to drop rapidly when the thickness decreases to a certain value, which is largely determined by the properties of the AFM material. As an example, Figure 15(b) shows the results for an $Ni_{80}Fe_{20}$(3 nm)/IrMn bilayer system. The onset thickness for this process is called the critical thickness. Considering the temperature dependence of the exchange field, the thickness of the AFM must be chosen well beyond the critical thickness in practical devices. However, a large AFM thickness will result in a large total thickness of the sensor, which is undesirable for sensors for high-areal-density hard disk drives. Therefore, AFM materials with smaller critical thickness are desirable for spin-valve applications.
5. Good corrosion resistance: AFM materials with poor corrosion resistance are unsuitable for practical applications.
6. Low-temperature process: The thermal annealing process may affect the performance of spin valves if the annealing temperature is too high. Therefore, a low-temperature process is preferred.

The AFM materials investigated so far include: (1) Mn-based alloys, (2) Cr-based alloys, and (3) Fe, Co, or Ni-based oxides [144, 145]. Among them, Mn-based alloys are the most widely studied, and several of them have already been applied to practical spin-valve sensors. The Mn-based alloys can be roughly divided into two groups. One group includes FeMn, IrMn, RhMn, RuMn, and the other includes NiMn, PtMn, PdMn, and some of the ternary alloys of these elements. The crystalline structure of the first group is fcc, while that of the second group is fct (CuAu–I). FeMn/NiFe (CoFe) is the most widely studied system which exhibits an exchange bias of about 420 Oe for a 4 nm thick NiFe without thermal annealing. However, it has a low blocking temperature of about 150 °C and poor corrosion resistance, and thus is unsuitable for read sensor applications. Another system that does not require thermal annealing is IrMn/CoFe

(or NiFe). It has a better corrosion resistance and smaller critical thickness as compared to FeMn. Both are desirable for sensor applications. However, its moderate blocking temperature of 250 °C limits its applications in a real drive environment. Although, in general, a thermal annealing process (at 200–300 °C) is required to establish the AFM phase, the (Ni, Pt, Pd) Mn family gives a much higher blocking temperature (350–450 °C), better corrosion resistance, and a higher exchange-bias field (500–800 Oe), and thus is being used in real devices. The primary drawback of this group of materials is their large critical thickness, which may limit their applications in ultrahigh-density recording applications. Table 1 lists the properties of some widely studied AFM materials [144–160].

4.1.3. Synthetic AFM

As discussed earlier, the exchange-bias field is inversely proportional to the thickness of the FM layer. For practical applications, however, one needs a certain thickness for the pinned layer so as to optimize the electrical properties of the sensor. This affects the sensor in two aspects. One is the reduction in the exchange-bias field, and the other is the magnetostatic coupling with the free layer. Although one can use the sense current field to counterbalance the magnetostatic field, it may sacrifice the stability of the pinned layer. A novel structure which can solve both problems is the synthetic ferrimagnet which consists of two antiferromagnetically coupled FM layers via a thin Ru layer [see Fig. 16(a)]. The corresponding synthetic antiferromagnet in which one of the FM layers of the synthetic ferrimagnet is exchange coupled to an AFM layer can be used as the pinning and pinned layers for spin valves [161–171].

The partial cancellation of the magnetic moments from both layers gives a smaller net moment, and thus an increased exchange-bias field and a reduced magnetostatic-coupling field. In addition to these advantages, it also provides a better thermal stability, although the blocking temperature itself remains the same. Shown in Figure 16(b) is a schematic drawing of a typical spin valve using the synthetic AFM as the pinned layer [also see Fig. 14(e)]. As the exchange bias is inversely proportional to the magnetic moment thickness product of the pinned layer, compared to parallel alignment, the exchange-bias field in antiparallel alignment is enhanced by a factor of [21]

$$f_{P-AP} = \frac{M_{1s}t_1 + M_{2s}t_2}{M_{1s}t_1 - M_{2s}t_2} \tag{23}$$

where $M_{1s}(M_{2s})$ and $t_1(t_2)$ are the magnetic moment and thickness of the first (second) pinned layer, respectively. On the other hand, the demagnetizing field is proportional to the magnetic moment thickness product of the pinned layer itself. Therefore, the stability of the pinned layer is effectively increased by a factor of

$$[(M_{1s}t_1 + M_{2s}t_2)/(M_{1s}t_1 - M_{2s}t_2)]^2$$

Although it is not shown in Figure 16, the synthetic ferrimagnet can also be used as the free layer, which can effectively reduce the magnetic thickness of the free layer without sacrificing its physical thickness [172]. However, the longitudinal bias may affect the stability of the synthetic layer [173].

Table 1. Properties of widely studied AFM materials.

Materials	H_{ex} (Oe) (NiFe 4 nm[a])	Required thickness (nm)	T_B (°C)	Resistivity ($\mu\Omega \cdot$ cm)	Corrosion resistance	Annealing
FeMn	420	7[b]	150[b, c], 165[e], 175[f], 170[j]	150, 130[b]	Poor	No[b]
IrMn	200	7[d], 7.5[e], 10[l]	190/230[d], ~250[e, f], 130[l]	200, 325[d]	Good[a, k] Moderate[e]	No[k]
NiMn	>390	>25[b], 35[d], 30[e]	450[b], >425[d], 430[g], 400[f, j]	175[b], 210[d]	Moderate Good[e, k]	Required[b]
PtMn	500	30	380[p], 400[f], 310[j]	~200	Good	Required
PdPtMn	280	25[d, m]	300[m], 350[d, f]	185[d]	Good	Required

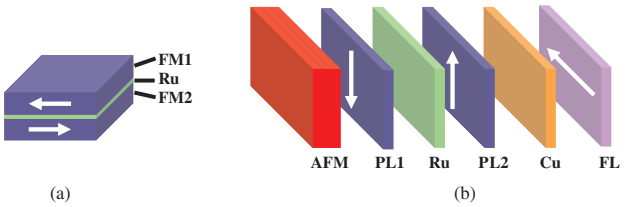

Figure 16. Schematic of a synthetic ferrimagnet (a) and spin valve using the synthetic ferrimagnet as a pinned layer (b).

4.1.4. Hard/Ru/Soft Synthetic Ferrimagnet

The use of AFM as the pinning layer has two drawbacks: (1) all of the useful AFMs reported so far for spin valves are metals which contribute negatively to the MR due to the current-shunting effect, and (2) most AFMs have a moderate or low blocking temperature, and some of them also show poor corrosion resistance. Based on this background, there have been several works in which hard/Ru/soft synthetic ferromagnets have been used as the pinning and pinned layers [see Fig. 14(f)] [110, 111, 174]. Preliminary experimental results showed that these types of spin valves have a good thermal stability [110, 111]. However, it would be quite challenging to improve other properties of the spin valves due to either the mismatch of the crystalline structure of the hard and soft layer or the insufficient hardness of the hard layer.

4.1.5. Exchange Spring

Further simplification of the synthetic ferrimagnet would be the hard/soft exchange spring structure [Fig. 14(g)]. This type of structure was proposed recently by Carey et al. using cobalt ferrite as the pinning layer [175]. A high MR ratio, 12.8%, and a high pinning field, 1500 Oe, have been obtained without compromising the softness of the free layer. In this particular case, the pinning layer is an insulator which may also help to reduce the shunting current, and thus is desirable for obtaining a high MR ratio.

4.2. Longitudinal Bias

The traverse bias is to set a proper direction for the magnetization of the pinned layer. For a spin valve to function properly, one also needs to set a proper longitudinal bias for the free layer. This is to both obtain a good linearity with less asymmetry and to suppress the Baukhausen noise. The former is achieved through setting the magnetization of the free layer at 90° with that of the pinned layer, parallel to the media surface. This, in turn, can be achieved through first inducing an easy axis in an appropriate direction during deposition of the free layer, and then using the shape anisotropy to stabilize it in the same direction. However, the shape anisotropy alone may become insufficient as the aspect ratio of the sensor decreases. The following additional magnetic fields need to be taken into account when designing the sensor: (1) the fringe field from the pinned layer, (2) the RKKY and orange-peel coupling field from the pinned layer, or so-called interlayer coupling field, (3) the current-induced field from highly conductive layers such as the spacer layer, and (4) other fields such as imaging fields from different sources [123]. Figure 17 shows schematically

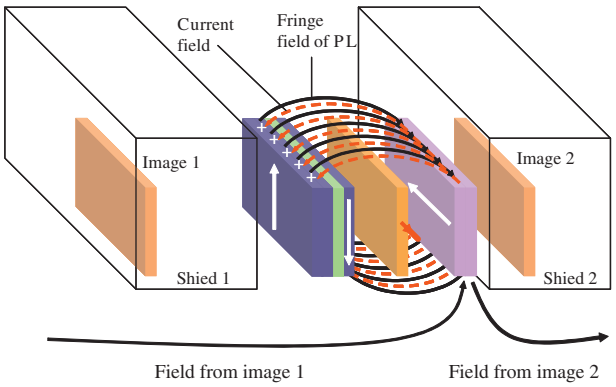

Figure 17. Different kinds of magnetic fields exerted on the free layer. For a spin valve to function properly, it is of importance to balance out all of the components so as to make the net field as close to zero as possible. Here, PL (FL) stands for pinned layer (free layer).

the flux lines of various field components exerted on the free layer. It is worth noting that the direction and magnitude of the current-induced fields are adjustable through controlling the sensing current, whereas the various field components from the pinned layer are fixed once the sensor fabrication is completed. Therefore, in practice, it is of importance to ensure that magnetic fields from sources other than the sense current be able to be compensated later by the current field under normal operation conditions. Ideally, all of the external fields other than the signal field from the media should be reduced to zero so as to obtain a high sensitivity, good linearity, and null asymmetry for the read sensor. However, this also means that the sensor is too susceptible to external disturbances. This will induce noises or baseline popping and a shift in the readout signal, in particular, the domain formation and movement-induced Baukhausen noise. The latter is an issue of high complexity because it depends on many factors, such as the material and shape of the free layer and the process to form it and the effect of other layers. Therefore, as in the case of AMR sensors, a longitudinal bias of an appropriate strength is normally used to suppress the multidomain formation in the free layer of spin-valve sensors [55, 116, 176, 177, 178, 179]. Most of the longitudinal biasing techniques for spin-valve sensors stems from the earlier work on AMR sensors, and may be divided into two groups. The first group is based on exchange bias between a ferromagnet and an antiferromagnet [see Fig. 18(a)–(d)], and the second group is based on the magnetostatic interaction or exchange coupling between a ferromagnetic soft film and a permanent or hard magnet [see Fig. 18(e)–(h)].

4.2.1. Permanent Magnet-Based Bias

Contiguous Junction So far, the most widely studied bias scheme which is also employed in real disk drives is the contiguous (or abutted) junction using a permanent magnet (typically, a CoCrPt alloy), as shown schematically in Figure 18(e) [180–182]. The key to forming a proper bias in this scheme lies not only in the selection of a proper material with an appropriate thickness, but also in the control of the junction shape between the permanent magnet

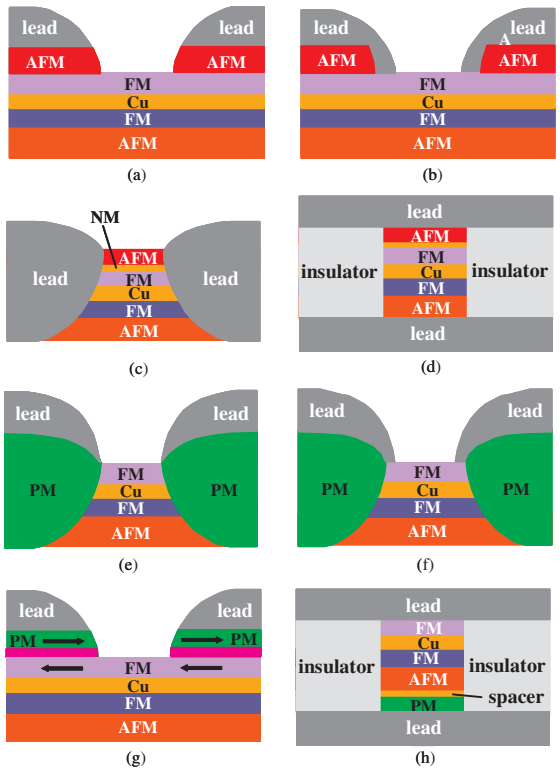

Figure 18. Schematics of different types of longitudinal bias schemes. (a) Patterned exchange. (b) Lead-overlaid patterned exchange. (c) Long-distance exchange. (d) Same as (c), but in CPP mode. (e) Contiguous junction with PM. (f) Lead-overlaid contiguous junction with PM. (g) Patterned synthetic ferrimagnet. (h) Parallel PM. The acronyms used are: PM—permanent magnet, FM—ferromagnet, AFM—antiferromagnet, NM—nonmagnetic layer. In (a)–(d), the top and bottom AFMs are two different types of materials.

and the active element of the sensor [183–188]. The overhanging of the permanent magnet on top of the free layer should be minimized; otherwise, it will cause hysteresis or kinks in the transfer curves, resulting in instability in the readback signal [189–191]. The ratio between the $M_r t$ of the permanent magnet and the $M_s t$ of the free layer or the soft layer should be optimized so as to obtain a good tradeoff between sensitivity and stability. The typical value is about 1.1–1.4 or even higher, depending on the shield-to-shield distance [123, 186, 192–194]. A small shield-to-shield distance requires a stronger permanent magnet. The microstructure of the permanent magnet also affects the performance of the sensor. The shape and cleanness of the junction are important for forming low-contact-resistance junctions, which is the key to suppressing the temperature rise of the reader [195]. To avoid oxidation and contamination at the junction interface, the permanent magnetic and contact are normally formed using a self-aligned lift-off process using a "mushroom" resist pattern formed on top of the sensor element [178, 179, 184]. The CoCrPt layer is typically grown on a Cr seed layer to have a higher coercivity, typically 1500–2500 Oe [196]. The uniform coverage of the seed layer on the junction edge is crucial to obtain a high-coercivity film along the entire junction. Poor seed-layer coverage may result in instability in the MR curve of the read sensor [197].

Lead-Overlaid Patterned Permanent Magnet The contiguous junction longitudinal bias is by far the most widely used bias scheme in real products. The drawback of this scheme, however, is that the bias field usually is not uniform across the longitudinal direction of the sensor. It is normally stronger at the two edges and weaker at the center. If the center portion is properly biased, then it is unavoidable that the edge regions will be overbiased, leading to the formation of so-called dead regions. These inactive regions will, in general, degrade the sensitivity of the senor. The influence of the dead region becomes more prominent when the read track narrows, in particular when the sensor width decreases to below 0.3 μm [198, 199]. An alternative scheme which can suppress the effect of the inactive region is the so-called lead overlaid structure in which the contact electrodes are extended over the abutted junction, and thus form a direct electrical contact with the inactive region of the sensor [Fig. 18(f)] [200]. Zhang et al. carried out a comparative study of magnetic noise in read heads with a contiguous junction and a lead overlaid design [201]. It was found that, at 0.25 μm magnetic read width and 4 mA bias current, the magnetic noise is twice as large as Johnson noise for the lead overlaid design, while it is comparable to Johnson noise for the contiguous junction design. The higher magnetic noise is attributed to a weaker longitudinal bias field with the lead overlaid design. This may affect the performance of read heads with a lead overlaid design at higher areal densities.

Patterned Synthetic Ferrimagnet Recently, the author's group proposed an alternative bias design in which patterned magnets are placed on top of the two edges of the free layer via an ultrathin Ru film such that the permanent magnets are antiferromagnetically coupled to the free layer [Fig. 18(g)] [202]. In conventional overlaid permanent magnet design or contiguous junction design with overlapping areas, the domain structure near the edges of the free layer is not so stable because the magnetic field generated by the permanent magnet inside the free layer always changes sign at the edges. In the new design, however, the antiferromagnetic coupling between the permanent magnet and the free layer forms a flux closure surrounding the permanent magnet, and thus improves the domain stability near the edges. Micromagnetic modeling has shown that, in addition to the domain stability, the sensitivity of the sensor with the new design is also higher than that of the contiguous junction design.

Permanent-Magnet-Based Design for CPP and MTJ Sensors The contiguous and lead overlaid designs are not suitable for CPP and MTJ sensors unless insulating permanent magnets are used to form the longitudinal bias or an additional insulating layer is added between the permanent magnet and the electrode at two edges. Redon et al. proposed a modified version of contiguous junction or patterned permanent design for an MTJ head through removing the portion of the pinned layer that is overlapped with the permanent magnet [203]. The results of micromagnetic modeling showed that the modified design is able to improve the performance of the MTJ head through suppressing the influence of the inactive region underneath the permanent magnet. Sin et al. proposed a design in which the longitudinal bias is formed through the magnetostatic coupling

from a permanent magnet placed at the other side of the pinned layer, as shown schematically in Figure 18(h) [204]. This design is suitable for CPP and MTJ sensors because there are no conducting materials at the two sides of the sensor element.

4.2.2. Antiferromagnet-Based Bias

Patterned Exchange As with the case of permanent magnet-based longitudinal bias design for spin valves, the exchange-biased designs also stemmed from the works on MR sensors [178, 179, 205, 206]. Among the exchange-domain stabilization designs, the most widely investigated is the patterned exchange design in which a patterned layer of antiferromagnetic material is fabricated on top of the free layer before the electrical lead is deposited [see Fig. 18(a)] [199, 207, 208, 209]. The advantage of this structure over the overlaid abutted junction structure is that the dead region is almost removed from the edge. In addition to this, the reduction in parasitic resistance associated with the junction improves the signal-to-noise ratio. However, in this case, one may need to use additional process steps to set the pinning direction of the patterned AFM layer because the exchange-bias direction of longitudinal bias for the free layer is 90° away from that of the traverse bias for the pinned layer (see Fig. 19). Another potential disadvantage of this design is the side reading due to the portions of the sensors underneath the patterned AFM layers. This might be suppressed by increasing the exchange-bias strength and the conductivity of the electrical contacts. It might also be reduced using the lead overlaid structure shown in Figure 18(b).

Long-Distance Exchange The most straightforward way to stabilize the domains of the sensing layer of MR and GMR heads is to add an AFM layer on top of the sensing layer. In fact, this has been employed in the early design of an MR head [177]. This design, however, lacks the flexibility in precise control of the bias field. It was often found that the exchange bias is too strong, which stiffens the magnetization of the sensing layer from rotation into the traverse direction, resulting in a low sensitivity. However, recently, there has been a revived interest in this design owing to the recent development of our understanding of the exchange bias and the ability to control the bias field through the insertion of an ultrathin nonmagnetic spacer at the AFM/FM interface [210–213]. Using Cu as the spacer, Nakashio et al. and Mao et al. successfully applied this design to a CIP spin-valve head and an MTJ head, respectively [Fig. 18(c) and (d)] [210, 211]. This type of design is particularly suitable for a CPP head.

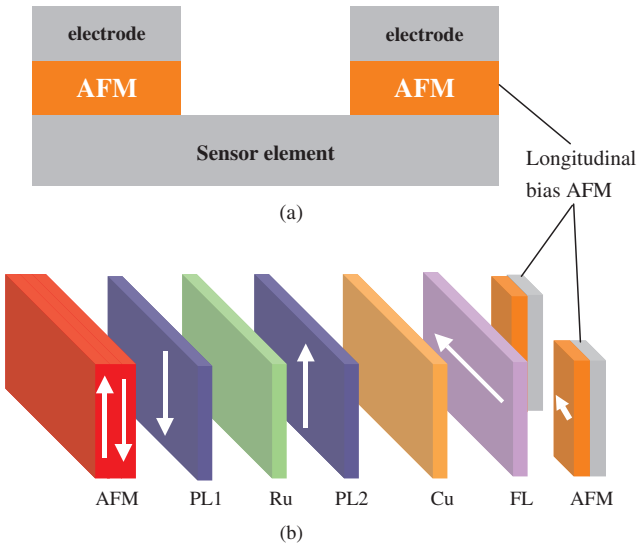

Figure 19. Cross-sectional view (a) and three-dimensional schematic structure (b) of spin valves with patterned-exchange longitudinal bias.

5. ELECTRONIC ASPECTS OF SPIN VALVES

Analogous to a transistor, the traverse and longitudinal biases discussed above are to set a proper working point for the spin valves. As is the case with transistors, once a proper working point is chosen, the performance of a spin valve is largely determined by its intrinsic properties, that is, the magnitude of the MR caused by the spin-dependent scattering at both the interfaces and the ferromagnetic layers. Although the spin valve exhibits a much higher MR as compared to the AMR sensor, the ever-increasing areal density requires continuous improvement of the performance of the spin valve. To this end, a variety of spin valves have been proposed and studied both theoretically and experimentally. These include, but are not limited to: (1) a multiple spin valve (e.g., dual spin valve), (2) a spin-filter spin valve, (3) a specular reflection spin valve, (4) a nanooxide-added spin valve, and (5) a nanooxide-added dual spin valve. In what follows, we explain briefly the motivation and underlying mechanism for each of these different types of spin valves illustrated schematically in Figure 14.

5.1. Spin Filter Spin Valve

The magnetoresistance of a CIP spin valve can be thought of as originating from the difference in the mean-free path (MFP) of the majority and minority electrons, at least phenomenologically. By making use of this phenomenon, Gurney et al. derived a novel method to measure the MFP of electrons in different materials such as Cu, AuCu, Co, NiFe, and Fe [214]. In this technique, a back layer is added to a spin valve with a thin free layer, and its effect on ΔG $(=G_P - G_{AP})$ is studied systematically at different back-layer thicknesses. Here, G_P and G_{AP} are the conductances of the spin valve in parallel and antiparallel configurations, respectively. It was found that, to a good approximation, ΔG can be written as

$$\Delta G = \Delta G_f + \Delta G_B[1 - \exp(-t_B/\lambda_+)] \qquad (24)$$

where ΔG_f is the conductance change due to the free layer, t_B is the thickness of the back layer excluding the inactive layer, if any, at the interface with the free layer, λ_+ is the MFP of majority electrons in the back layer, and ΔG_B is the conductance change due to the back layer when $t_B \gg \lambda_+$. The MFPs measured by this technique for Cu, Co, NiFe, and Fe are 19.2, 5.5, 4.6, and 1.5 nm, respectively. This result

implies that the addition of a back layer with an appropriate thickness can enhance the MR of a spin valve with an ultrathin free layer (so-called back-layer effect). The idea behind this is that the back layer helps to retain or even enhance the MFP of majority electrons, while it has little effect on the MFP of minority electrons. Kamiguchi et al. extended this concept to synthetic spin valves, and called them spin-filter spin valves [see Fig. 14(h)] [215]. The back layer is retermed a high-conductance layer (HCL). Note that the synthetic pinned layer is not shown in the schematic drawing in Figure 14(h) because we want to focus on the pure electronic effect. At a free layer thickness of 2–4 nm, the MR ratio can be enhanced by about 10% using the spin-filter design [216]. It is worth noting that, in addition to the enhancement of the MFP of majority electrons, the back layer or HCL also helps to better balance the current-induced fields at the free layer due to the redistribution of a certain portion of current to the HCL, leading to a lower asymmetry of the readout signal. For example, at a free layer thickness of 4 nm, Ueno et al. showed that the readout asymmetry can be reduced from 10% for a conventional spin valve to 3% for a spin-filter spin valve [216]. However, the improvement of the MR in a spin-filter design is only up to a certain extent because the HCL also increases the shunting current, which in turn will reduce the MR. Therefore, in most practical cases, the back layer is employed in combination with other techniques such as the nanooxide to improve the performance of advanced spin valves.

5.2. Dual Spin Valve

The most straightforward way to improve the MR ratio of a spin valve is to increase the number of free/pinned layer pairs. This has prompted the proposal and development of dual spin valves, in which the free layer is shared by two pinned layers at both sides (see Figs. 14(c) and 20) [217–223]. The MR of a typical dual spin valve can be 30–60% higher than that of a single spin valve, depending on the materials, device structure, and fabrication processes [21, 217, 218, 224]. The fabrication of a dual spin valve requires the use of AFM materials which are able to form exchange bias both at the top and bottom of the FM layer, and with a small critical thickness. Special cautions are needed in choosing the thickness of the two Cu spacers because two identical spacers may make it difficult to adjust the traverse bias field in the free layer using the sense current once the sensor fabrication is completed [223].

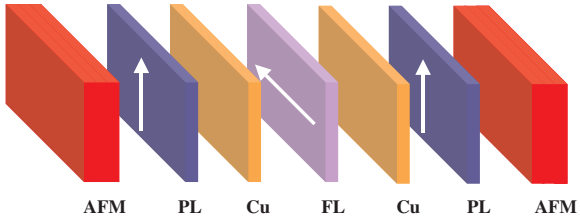

Figure 20. Schematic of a dual spin valve.

5.3. Specular Spin Valve

The dual spin valve consists of one free layer and two pinned layers. Can we increase the MR further by simply increasing the number of free and pinned layers? The answer is negative because different free layers may respond to the external field in a slightly different way, which may result in extra noises in the readout signal or degradation of the sensitivity. The only way to overcome this is to use antiferromagnetically coupled ferromagnetic/nonferromagnetic pairs. But as discussed earlier, this type of sensor is only applicable to the detection of a large magnetic field. One of the possible ways to increase the effective number of free layers without the need to add more layers physically is to increase the specular reflectivity of electrons at the outer surface of the free and pinned layer, respectively. As shown schematically in Figure 21, if the specular reflectivity at both surfaces is unity, the trilayer can be considered effectively as the repetition of the same unit in an infinite number of cycles. However, the difference between the equivalent structure and the real structure of the same type is that the former only has one free layer physically, and thus does not suffer from the drawbacks caused by the existence of a plural number of free layers.

5.3.1. Specular Spin Valve Using Insulating Antiferromagnet

The most straightforward way to implement this kind of structure is to use insulating AFM layers such as NiO and α–Fe_2O_3 to form an AFM/active layers/capping layer, AFM/active layers/AFM or AFM/active layers/NM/AFM sandwich structure (Fig. 14(j)). This has been verified experimentally to be very effective in increasing the MR ratio [219, 225–229]. The specular reflection enhancement effect was first described quantitatively by Swagten et al. in spin valves with structure NiO(50 nm)/FM1/NM1/FM2/NM2/NiO(10 nm), with FM1 = Co (2 nm), NM1 = Cu (2 nm), FM2 = Co (t), NM2 = Cu (1.2 nm) [225]. The second nonmagnetic layer, in this case, a 1.2 nm thick Cu, is used to isolate the exchange coupling between the top NiO and the second ferromagnetic layer (FM2), so that the top NiO functions only as a pure insulator. The decoupling effect of NM2 has been confirmed in the measured M–H curves, in which FM2 was found to switch at almost zero field. Using this structure, Swagten et al. obtained an MR ratio as high as 25% at 10 K and 15% at room temperature [225]. A semiclassical model has been invoked to interpret the experimental results, which suggests that the

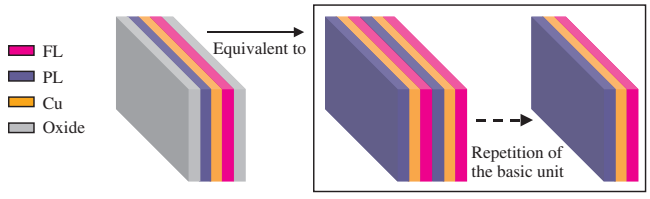

Figure 21. The number of the free layer (FL) and pinned layer (PL) can be increased effectively by increasing the specular reflectivity of both the top and bottom surfaces to unity.

enhancement of the MR is attributed to the enhancement of specular reflection at the metal/insulator interfaces. Also using the same NiO oxide, but in a dual spin valve with a structure NiO50/Co2.5/Cu1.8/Co4/Cu1.8/Co2.5/NiO 50 (thicknesses are in units of nanometers), Egelhoff et al. obtained an MR ratio of 21.5% at room temperature [219]. The large MR ratio was attributed to both the dual spin-valve structure and the enhanced specular scattering of electrons at the Co/NiO interfaces. Although NiO has a desirable electric property, its low exchange bias field and low blocking temperature make it an unfavorable choice for real read sensors. Hasegawa et al. carried out the first study on the possibility of using α–Fe_2O_3, another insulating AFM, to construct specular spin valves [226]. The MR ratio that has been obtained for a spin valve with structure glass/α–Fe_2O_3/$Ni_{80}Fe_{20}$6/Cu2.2/$Ni_{80}Fe_{20}$9/Cu4 (thicknesses are in units of nanometers) was only about 3.7%. Sugita et al. [227] and Kawawake et al. [228] grew α–$Fe_2O_3$50/Co2/Cu2/Co5/Cu0.4 (thicknesses are in units of nanometers) spin valves on a polished (110) plane of an α–Al_2O_3 single-crystalline substrate. The MR ratio obtained was as high as 18%. It was further increased to 27.8% for a dual spin valve with a structure α–Al_2O_3/α–$Fe_2O_3$50/Co2/Cu2/Co5/Cu2/Co2/α–$Fe_2O_3$50 (thicknesses are in units of nanometers). In either case, however, the unidirectional exchange-bias field is very small. The pinned layer is more or less a hard magnet instead of a soft layer pinned by an AFM. The coercivity of the bottom Co layer is more than 1200 Oe. The large MR ratio again was attributed to the enhanced specular reflection at α–Fe_2O_3/Co interfaces.

In addition to oxides, metals can also be used as the capping layer to increase the MR of spin valves. Although the mechanism of MR enhancement is not fully understood, it is believed that the potential step at both the free layer/capping layer interface and the capping layer/air interface may have helped to enhance the specular reflection of electrons. Compared to oxide capping layers, the metallic capping layer has certain limitations in thickness because too thick a capping layer will cause an increase in the shunting current, and thus leads to a decrease in the MR ratio [230, 231]. Although it has not been investigated in detail, this type of structure might be useful for CPP spin valves.

5.3.2. Specular Spin Valve Using Insulating Ferromagnet

Recently, Carey et al. [175] and Maat et al. [232] used insulating cobalt ferrite as pinning layers to improve the performance of spin valves. Spin valves with a high MR ratio (12.8%) and a large pinning field (about 1500 Oe) have been successfully fabricated. In this case, pinning is realized through an exchange-spring type of coupling between two ferromagnets [see Fig. 14(g)].

5.3.3. Nanooxide Added Spin Valve

As discussed above, the use of oxide AFM can greatly enhance the MR of spin valves. These oxides, however, are unsuitable for practical applications due to their low exchange bias field, low blocking temperature (for NiO), or large thickness required. This has led to the proposal of inserting nanooxides at the middle of the pinned layer of bottom spin valves. This, in combination with the top oxide capping layer, was found to greatly enhance the MR of spin valves. Since the pioneer work of Kamiguchi et al. [215], the nanooxide effect has been studied intensively to enhance both the magnetic and electronic properties of advanced spin valves [233–264]. The nanooxide, in general, is inserted at the middle of the pinned layer, and in the case of synthetic spin valves, it is normally inserted at the middle of the pinned layer that is nearer to the spacer. It is more effective when being used together with an insulating capping layer, leading to the so-called double specular spin valve [see Fig. 14(k)]. The nanooxide can be formed using different techniques such as natural oxidation, plasma oxidation, remote plasma oxidation or so-called atomic beam oxidation, ion beam oxidation, and ion-assisted oxidation. The plasma- and ion-based techniques were found to be able to form denser oxides than natural oxidation. Under optimum conditions, the oxides improve the MR without compromising the magnetic and thermal stability and the ESD robustness of spin valves. Read heads with sensitivity in the range of 6–10 mV/μm or higher have been demonstrated using nanooxide-added spin valves [257]. As the results obtained from different works are, to a certain extent, dependent on specific experimental conditions, the results are not always consistent with one another. Table 2 summarizes the representative works on specular spin valves reported so far in the last few years. Due to the large number of publications, the author cannot guarantee that the collection is complete. In what follows, we use our own results as examples to describe the main effect of nanooxide.

The Role of Oxide in Pinned Layers The roles of the bottom oxides are twofold. First, they reduce the surface roughness of the subsequently deposited layers, and second, they enhance the specularity of the pinned layer. The improvement of the surface roughness has been confirmed through both direct measurement of the surface roughness using AFM and measurement of the interlayer coupling field between the free and pinned layers [249]. In general, there are two major coupling fields between the free and pinned layers of different origin: (1) orange-peel coupling, and (2) RKKY coupling. The former is dominant in samples with rough interfaces, while the latter becomes more important when the interfaces become atomically flat. The orange-peel coupling decays exponentially with the thickness of the spacer, and for a sinusoidal roughness profile, it is given by [265]

$$H_{\text{int\_OP}} = \frac{\pi^2 A^2}{\sqrt{2} t_F \lambda} M_F \exp(-2\pi\sqrt{2} t_s/\lambda) \tag{25}$$

where A and λ are the amplitude and wavelength of the roughness profile, t_F and t_s are the thicknesses of the free and spacer layer, respectively, and M_F is the magnetization of the free layer. The original concept was extended to thin films with a structure of hard/spacer/soft by Kools et al. in 1999 [266]. Although Eq. (25) is modified slightly, the exponential dependence of the coupling field on the spacer thickness is still the same.

Table 2. Summary of the findings reported in nanooxide-related works.

Research group	Structure of spin valve (thicknesses are in nm)	GMR (%)	H_{in} (Oe)	H_{ex} (Oe)	Remarks	Ref.
1. NIST, Univ. Minnesota, Univ. California	NiO 50/Co 2.5/Cu 1.8/Co 4/ Cu 1.8/Co 2.5/NiO 50	21.5			First experimental indication of specular reflectivity enhancement	[219]

On the other hand, as discussed before, the strength of RKKY coupling oscillates with spacer thickness:

$$H_{\text{int\_RKKY}} \propto \frac{1}{t_F}\frac{1}{t_s^2}\sin\left(\frac{2\pi t_s}{\Lambda}+\phi\right) \tag{26}$$

where Λ is the oscillation period and ϕ is the phase factor. Except for a few reports [244, 257], the oscillation can hardly be seen in normal spin-valve samples without nanooxides. However, it can be observed easily in samples with nanooxides. The suppression of orange-peel coupling has also been achieved in Cu/Co superlattices through the introduction of a proper amount of oxygen during the growth of the entire film stack [233, 267].

To confirm both effects of nanooxide, spin valves with the structure Ta3/NiFe2/IrMn6/CoFe3/Cu(t)/CoFe1/NiFe2/CoFe1/Cu1/Ta1 [t denotes the thickness of the spacer layer; thicknesses are in nanometers, hereafter, we call them conventional SVs (CSV)] and SVs with the structure Ta3/NiFe2/IrMn6/CoFe1.5/NOL/CoFe1.5/Cu(t)/CoFe1/NiFe2/CoFe1/OX/Cu1/Ta1 [hereafter, we call them nanooxide-added SVs (NOL-SV)] were deposited on Si(100) substrates coated with a 1 μm thick thermally oxidized SiO_2 layer by using an ultrahigh vacuum sputtering system operating at a base pressure of 5×10^{-10} torr. Here, NOL denotes the natural oxidation of the CoFe layer. Oxidation was conducted in a separate chamber, by exposing the fresh CoFe surface to pure oxygen atmosphere. The exposure time was 1 min, but the pressure was controlled from 1×10^{-4} to 1.6 Pa. The specimens were magnetically annealed at 275 °C for 1 h under magnetic fields of 1 T in a commercial magnetic vacuum annealing oven under a pressure of 1.0×10^{-6} torr. The MR was measured by using a linear four-point probe method. The sheet resistance was calibrated by measuring the MR on a microstructural bridge with 400 μm length and 100 μm width.

Figure 22(a) shows the dependence of the MR ratio and interlayer coupling field on the oxygen exposure dose used to oxidize the CoFe layer. It is found that H_{int} decreases almost monotonically with the oxygen exposure dose, decreasing from 31 Oe in a CSV to 4 Oe in an NOL–SV. On the other hand, the MR ratio increases from 9 to 14% with an increasing O_2 exposure dose from 10^{-8} to 0.1 min Pa, which saturates when the exposure dose is over 0.1 min Pa. Shown in Figure 22(b) are the sheet resistance R_{sq} and its change ΔR_{sq} as a function of O_2 exposure dose. R_{sq} decreases initially, reaches a minimum at an oxygen exposure dose of about 10^{-3} min Pa, and increases when the oxygen dose increases. The initial decrease of the sheet resistance might be attributed to the enhancement of specular scattering of electrons at the interface between the metal and NOL.

Figure 23 shows the MR (a), interlayer coupling field (b), sheet resistance (c), and change of sheet resistance (d) as a function of Cu thickness. The enhancement of surface smoothness can be seen from the oscillation of the interlayer coupling field with the Cu layer thickness in NOL–SVs, as shown in Figure 23(b) (solid circle). Also shown in the figure are the experimental results for conventional spin valves (open circle) and the fitting curve according to

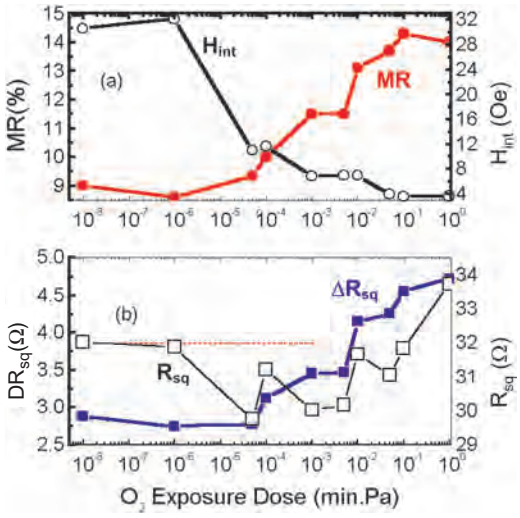

Figure 22. (a) MR ratio (solid circle) and H_{int} (open circles) as a function of O_2 exposure dose. (b) Sheet resistance (open squares) and change of sheet resistance ΔR_{sq} (solid squares) as a function of O_2 exposure dose for a series of SVs with the structure Ta3/NiFe2/IrMn6/CoFe1.5/NOL/CoFe1.5/Cu2/CoFe1/NiFe1/CoFe1.2/NOL/Cu1/Ta1 with a deferent O_2 exposure dose. The thicknesses are in nanometers.

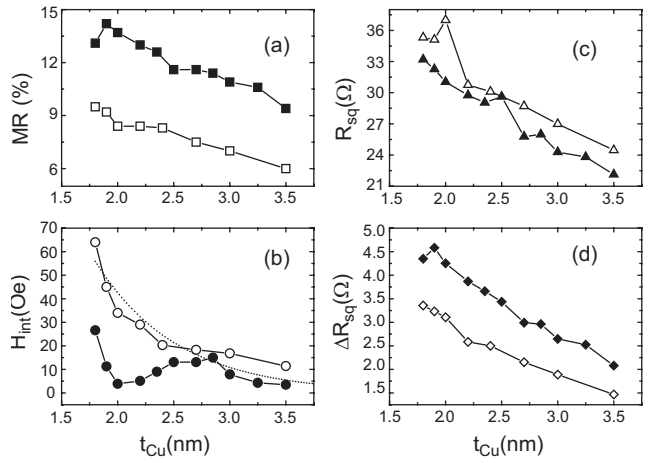

Figure 23. Spacer (Cu) thickness dependence of MR (a), H_{int} (b), sheet resistance R_{sq} (c), and sheet resistance change (d) for two batches of SVs with the structure Ta3/NiFe2/IrMn6/CoFe3/Cu(t)/CoFe1/NiFe2/CoFe1.2/Cu1/Ta1 (open symbols) and Ta3/NiFe2/IrMn 6/CoFe1.5/NOL /CoFe1.5/Cu(t) /CoFe1/NiFe2/CoFe1.2/NOL/Cu1/Ta1 (solid symbols). The dotted line in (b) was fitted by using Néel's orange-peel coupling equation. The thicknesses are in nanometers.

Eq. (25) (dotted line). Although the interlayer coupling is still ferromagnetic in the entire range of the Cu thickness that has been investigated, the clear oscillation in NOL–SVs and the monotonic decrease with Cu thickness in CSVs clearly demonstrate the effectiveness of NOL in improving the surface roughness. Figure 23(c) and (d) shows the dependences of the sheet resistance and its changes on the Cu thickness, respectively. It is interesting to note that the nanooxide-added spin valve has a smaller R_{sq}, but a larger ΔR_{sq} than the conventional spin valve in the entire thickness range for Cu, leading to a larger MR ratio in the whole range, as shown in Figure 23(a). It is also interesting to note that the maximum of MR corresponds to the minimum of the interlayer coupling field. This can be understood readily because, at this thickness range, the free and pinned layers are antiferromagnetically coupled if one subtracts the orange-peel coupling field from the total coupling field. Very recently, we have been able to achieve antiferromagnetic coupling routinely in spin valves with oxide capping layers.

Effects of Different Types of Oxides There are many different types of oxides that can be used to improve the performance of the spin valves. The selection of oxides that have been studied so far is more or less based on the availability of the elements that are used to form the oxides in individual deposition systems. In general, one has more choices for the capping layer than that for the NOLs inserted in the middle of the spin valves because the latter will affect the magnetic properties of the spin valves. For example, if it is inserted in the middle of the pinned layer, it cannot be too thick; otherwise, it will separate the pinned layer into two sublayers, and result in a substantial decrease of the exchange bias. Although it can be made thicker if it is inserted at the AFM/seed layer interface, it cannot be too thick; otherwise, it will affect the crystalline texture of the layers that are subsequently deposited on top of the oxide. This eventually will lead to a decrease of exchange bias. Bearing all of these in mind, the author's group has carried out a systematic study on: (1) how different types of oxides affect the performance of the spin valve, and (2) which position is more desirable in terms of performance and manufacturability [250].

To investigate the effect of different types of oxides, we fabricated simple top and bottom spin valves with oxides being added at different locations, as shown schematically in Figure 24. The oxides that we have investigated include $CoFeO_x$, TaO_x, AlO_x, $NiFeO_x$, and CuO_x. The effects of these oxides on the interlayer-coupling field H_{in}, exchange bias H_{ex}, and MR ratio are shown in Figure 25. The main results can be summarized as follows. First, the exchange bias of the top spin valve is much smaller than that of the bottom spin valve. This is caused by both the property of the AFM (in this case, IrMn) itself and the oxide-induced changes in the texture of the underlying layers. The latter is especially severe in the case of TaO_x and AlO_x. $CoFeO_x$ and $NiFeO_x$ are better because they were formed from the oxidation of CoFe and NiFe, which already had a well-established texture before the oxidation took place. So does Cu because it is usually used as the texture control layer for NiFe and CoFe. Second, the interlayer-coupling field of the top spin valve is, in general, smaller than that of the bottom spin valve, except for the case using AlO_x. This again suggests that the nanooxide has the surface smoothening effect, as discussed earlier. The improvement is particularly remarkable for $CoFeO_x$. Finally, we can see that the MR ratio of the top spin valve, in general, is larger than that of the bottom spin valve. Comparing these results, we can see that $CoFeO_x$ is, so far, the most desirable bottom oxide, while AlO_x seems to be a better choice for the top oxide. For other oxides to be better than $CoFeO_x$, one must find a material that has a similar crystalline structure and texture as that of the CoFe layer in spin valves.

Effect of the Position of Oxide In addition to the types of oxides, we have also carried out a systematic study on the position of oxide, that is, which position is more suitable for the bottom oxide. Figure 26 shows schematically the different positions that have been investigated. These are: (1) inside the AFM layer, (2) at the AFM/first pinned layer interface, (3) at the Ru/second pinned layer interface, (4) inside the second pinned layer, (5) at the second pinned layer/Cu interface, (6) inside the spacer, (7) at the Cu/free layer interface, and (8) at the top surface. In what follows, we describe the results for cases (4)–(6).

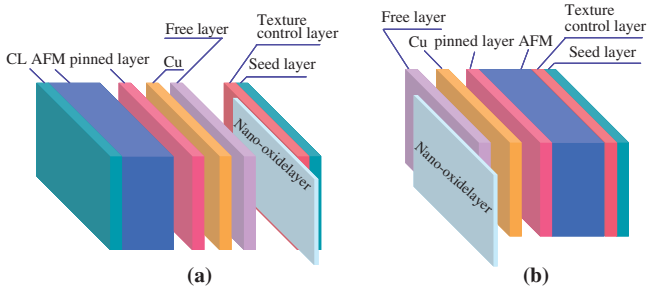

Figure 24. Schematic of a top spin valve with a nanooxide inserted at the free and texture control layer interface (a), and a bottom spin valve with a nanooxide capping layer (b).

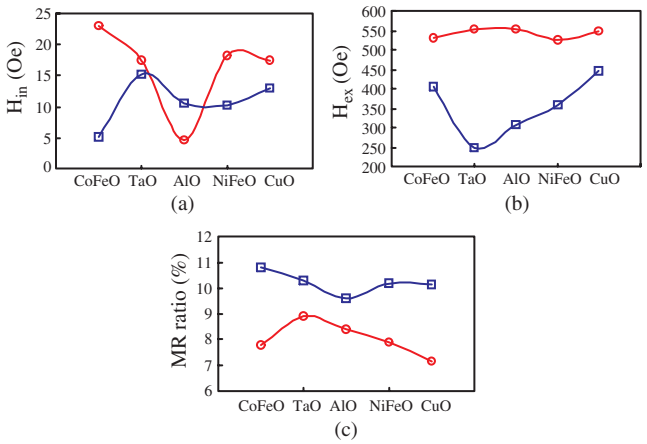

Figure 25. Effect of different nanooxides on the interlayer coupling field (a), exchange bias (b), and MR ratio (c) of bottom (open circles) and top (open squares) spin valves whose structures are shown in Figure 24.

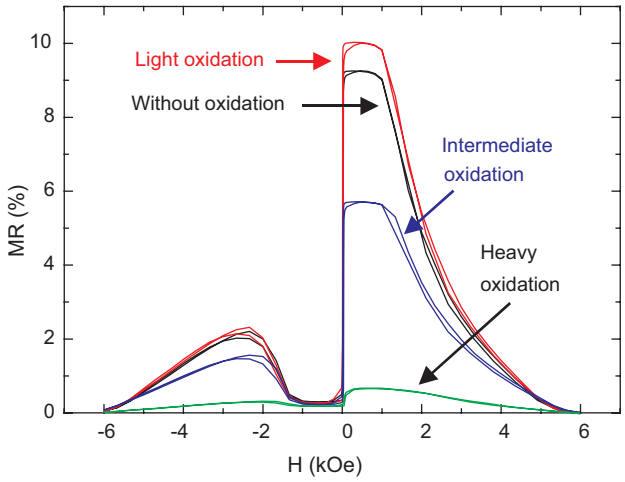

Figure 27. MR–H curves of spin valves oxidized under different oxygen doses at the surface of the second pinned layer.

Figure 27 shows the MR–H curves of case (5), in which the spin valve has a structure Ta3/NiF2/IrMn8/CoFe2.5/Ru0.8/CoFe2/NOL/Cu2.2/CoFe2/Cu1/Ta1.5 (thicknesses are in nanometers). Here, NOL stands for the nanooxide layer. The NOL was formed through natural oxidation of the second pinned layer in a separate chamber, with the thickness being controlled by the oxygen dose. After the oxidation was completed, the sample was brought back again to the growth chamber for the deposition of the rest of the layers. All of the deposition and oxidation processes were accomplished in a multiple-chamber ultrahigh-vacuum system without breaking the vacuum. As can be seen from the figure, the MR ratio initially increases under light-oxidation conditions, beginning to decrease when the oxygen exposure dose increases, and eventually vanishing out as the oxidation process continues. Figure 28 shows the detailed dependence of the MR ratio and the interlayer coupling on the oxygen dose. It is worth noting that the interlayer-coupling field decreases and the MR ratio increases in the light-oxidation regime by increasing the oxygen dose. However, the former increases sharply when the latter starts to decrease as the oxygen exposure dose is further increased. The behavior of the MR ratio is easily understood, but it is not as straightforward to explain the sharp increase of the interlayer-coupling field. As the interlayer-coupling field normally decreases by decreasing the pinned layer thickness [266], it is plausible to postulate that the sharp increase of H_{in} has something to do with the decrease of the spacer thickness because the surface roughness should not change so drastically. Figure 29 shows the X-ray diffraction spectra of spin valves under different oxidation conditions. Curves (a)–(d) correspond to cases (1)–(4) shown in Figure 28. The peak at an angle of about 41.2° is from the IrMn layer, while that at about 43.7° is from the rest of the layers. It is worth noting that the higher degree peak splits into two new peaks in case (d): one at an angle of about 42.9°, and the other at about 44°. Although the details are not well understood at present, it seems that Cu has been oxides partially to form copper oxide or a mixture of copper oxide and CoFe oxide. The sharpness of the interfaces has been investigated using low-angle X-ray reflectometry. As shown in Figure 30, the four curves corresponding to the four different cases shown in Figure 29 can hardly be differentiated from one another. This implies that the change in surface roughness is unlikely responsible for the sharp increase of the interlayer-coupling field shown in Figure 28. The results demonstrate that it is difficult to form a controllable oxide at the interface between two materials if both can be readily oxidized. Figure 31 shows schematically the possible oxidation processes. Under heavy oxidation conditions, the loosely absorbed oxygen atoms on the $CoFeO_x$

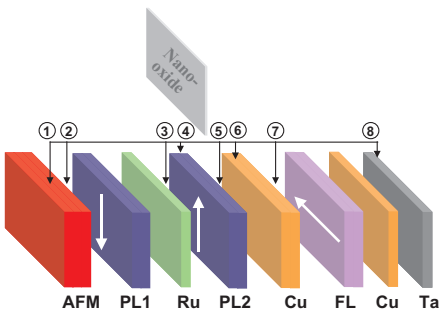

Figure 26. Schematic of the nanooxide-added spin valves with the oxide inserted at different locations. Here, PL1 and PL2 refer to the first and second pinned layers, respectively, and FL stands for the free layer.

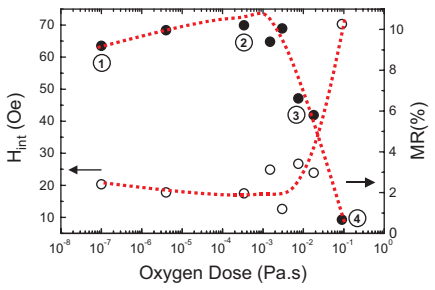

Figure 28. Dependence of the interlayer coupling field and MR ratio of spin valves on the oxygen dose that was used to oxidize the second pinned layer.

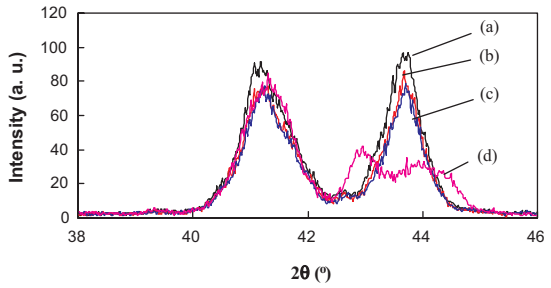

Figure 29. High-angle X-ray diffraction spectra of spin valves oxidized under different conditions. Cases (a)–(d) correspond to cases (1)–(4), respectively, in Figure 28.

surface may result in a partial oxidation of the subsequently deposited Cu layer. This may explain the sharp increase of the interlayer coupling field when the oxygen exposure dose exceeds a critical value.

From the above discussion, it is clear that adding NOL at the second pinned layer/Cu interface might not be a viable approach due to its narrow process window. The next position that has been widely studied since the first report of the nanooxide spin valve is in the middle of the pinned layer. Figure 32 shows the dependence of the interlayer-coupling field and the MR ratio on the oxygen exposure dose for which the spin valve has the structure Ta3/NiF2/IrMn8/CoFe2.5/Ru0.8/CoFe1.5/NOL/CoFe1.5/Cu2.2/CoFe2/Cu1/Ta1.5 (thicknesses are in units of nanometers). In this case, the oxide was formed in the middle of the second pinned layer. As can be seen from the figure, the interlayer-coupling field is almost constant at the beginning, decreases, and then increases again when the oxygen exposure dose increases. The MR ratio, however, increases first, then decreases, and increases again. Although it is difficult to understand the behavior of the MR, one thing that is clear is that the process window of adding oxide at this position is much wider than that of the previous case; thus, it is more desirable from the point of view of manufacturability.

The last position to be discussed here is the middle of the spacer. This position has not been discussed before, and thus it is worth investigating how it affects the performance of the spin valve. One tends to think that this will affect

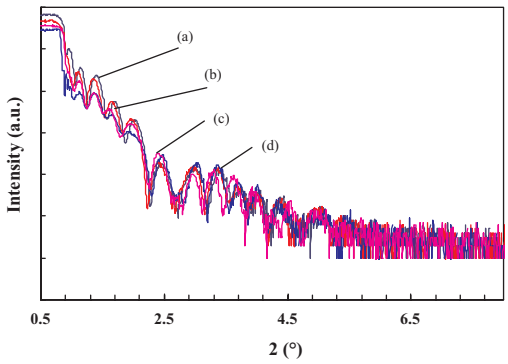

Figure 30. Low-angle X-ray diffraction spectra of spin valves oxidized under different conditions. Cases (a)–(d) correspond to cases (1)–(4), respectively, in Figure 28.

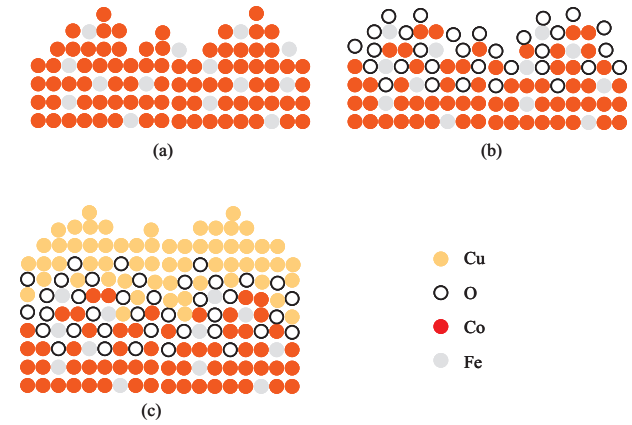

Figure 31. Schematic illustration of the oxidation process of CoFe (b), and the subsequent deposition and partial oxidation of Cu (c). (a) shows the CoFe surface before oxidation.

the performance adversely because it may reduce the mean-free path of electrons. However, as shown in Figure 33, the MR ratio indeed increases with the oxygen exposure dose that is used to oxidize the Cu layer in a spin valve with a structure Ta3/NiF2/IrMn8/CoFe2.5/Ru0.8/CoFe2/Cu1.2/NOL/Cu1.2/CoFe2/Cu1/Ta1.5 (thicknesses are in units of nanometers). This might be attributed to the enhancement of scattering probability at the free layer/Cu/pinned layer interfaces. In this case, the MR will increase provided that the scattering inside the spacer is spin conserved. Further study is required to understand the underlying mechanism.

As we mentioned above, the study of the nanooxide effect is still at an early stage. A theoretical framework has yet to be formulated to guide the selection of oxides and their positions in the spin valves. Further experimental investigations are required to study the structural properties of the nanooxide-added spin valves. Before ending this section, we show in Figure 34 the MR–H curve of a dual spin valve with a structure Ta3/NiFe2/IrMn5/CoFe1/NOL/CoFe2.3/Cu2.15/CoFe2/Cu2.15/CoFe2.3/NOL/CoFe1.0/IrMn5/Ta1. After the optimization of structure and processes, we have successfully obtained an MR ratio of 27.2%, which we believe is the highest value ever reported for all-metal spin valves. Although the exchange-bias field is too low for practical

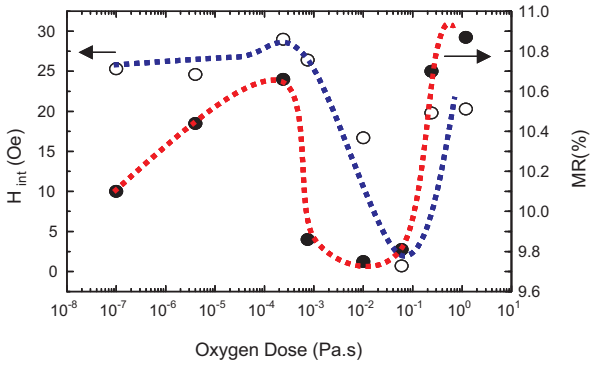

Figure 32. Dependence of the interlayer coupling field and the MR ratio of the spin valves on the oxygen dose that was used to form the oxide at the middle of the second pinned layer.

applications, this might be solved by replacing IrMn with other AFM materials such as PtPdMn and NiMn.

5.4. CPP Spin Valves

5.4.1. Why CPP?

So far, most of the discussion has been concentrated on CIP spin valves. Although many of the fundamental concepts for CIP spin valves are directly applicable to CPP spin valves, there are some differences in how their performance can be improved. In this section, we first explain why we still need CPP spin valves for data storage, followed by a discussion on possible ways for improving the performance of CPP spin valves.

The areal density of a hard disk drive is the product of the linear density and track density. The former is determined by many component and system parameters, while the latter is largely determined by the capability of lithography techniques. In what follows, we first focus on linear density, which is defined as

$$\text{linear density} = \frac{1}{\text{bit length}} = \frac{\text{channel density}}{PW_{50}} \tag{27}$$

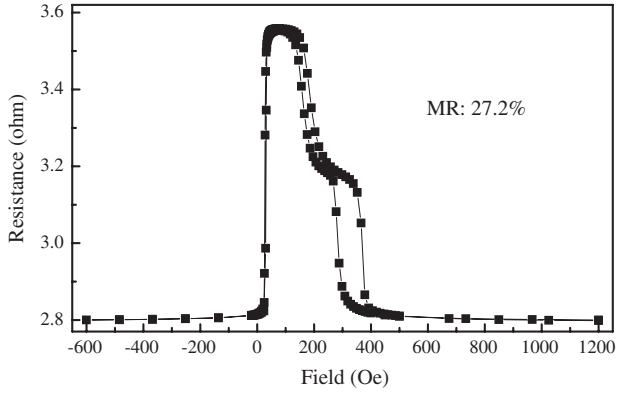

Figure 34. MR–H of a double specular dual spin valve with a structure Ta3/NiFe2/IrMn5/CoFe1/NOL/CoFe2.3/Cu2.15/CoFe2/Cu2.15/CoFe2.3/ NOL/CoFe1.0/IrMn5/Ta1. Here, the thicknesses are given in nanometers.

where PW_{50} is the full-width-at-half-maximum of the readout pulse from an isolated transition. The channel density is a parameter that reflects the efficiency of the channel coding scheme (~2.5–3). The PW_{50} can be estimated using the following equation:

$$PW_{50} = \left[2(g + t/2)^2 + 4(d_{\text{eff}} + a)^2\right]^{1/2} \tag{28}$$

where

$$d_{\text{eff}} = \sqrt{d(d+\delta)} \quad \text{and} \quad a = k\left(d_{\text{eff}}\frac{M_r t}{Hc}\right)^{1/2} \tag{29}$$

Here, d is magnetic spacing, g is the gap length between the sensor and the two shields, t is the thickness of the sensor, δ is the thickness of the media, and a is the transition width. M_r and H_c are the remnant and coercivity of the media, respectively. k is a parameter with a value ranging from 1 to 2. The above equation suggests that there are many possible ways to increase the linear density, although the reality is that none of them is an easy task. Although one can always try to push all of the parameters to their individual upper or lower limits, it would make more sense if one tries to determine which parameter is of more relative importance first. To this end, we have tried to find the rate of change of PW_{50} with respect to different parameters by assuming that we have already achieved 100 Gbits/in^2. It turned out that

$$\frac{\partial PW_{50}}{\partial d} = 2.6\frac{\partial PW_{50}}{\partial(M_r\delta/H_c)} \quad \text{and}$$
$$\frac{\partial PW_{50}}{\partial d} = 2.1\frac{\partial PW_{50}}{\partial(g+t/2)} \tag{30}$$

where the following parameters have been used for the calculation: $d = 12$ nm, $\delta = 12$ nm, $M_r\delta/H_c = 12.5$ nm, $k = 1$, and $g + t/2 = 45$ nm. It is clear that the most sensitive parameter is the magnetic spacing, followed by the read gap length, and then media parameters. If the areal density continues increasing at an annual compound rate of 60%, in fewer than five years, we will reach 1 Tbit/in^2 [268]. Now, the question is: What kind of sensor is required for this level of areal density?

To answer this question, we first look at what are the requirements on bit length and track width for terabit recording. Shown in Figure 13 are the estimated read track width and required sensor sensitivities at different areal densities by assuming an aspect ratio of 4:1. The solid and dashed curves are obtained by assuming the read track width to be 80 and 60% of the track pitch, respectively. The sensitivity requirement is obtained by assuming that the sensor will have to generate an output voltage of 1 mV. The read head for terabit recording would require a bit length as small as 12 nm, assuming that the read track width is 80% of the track pitch. This leads to a pulse width of about 36 nm, assuming that the channel density can be increased to 3. Assume that all other parameters are approaching their practical limits, such as $d = 5$ nm, $\delta = 5$ nm, and $M_r\delta/H_c = 6.25$ nm (maybe even smaller); then $g + t/2$ must be as small as 17 nm. This means that almost no read gap is allowed in sensors for terabit recording. This poses formidable challenges for CIP read sensors because one needs electrodes

between the two shields. Furthermore, the sensitivity of the sensor also has to be increased by a factor of 2–3, which means that the MR ratio must be around 30%. This might be possible for advanced spin valves at the sheet film level (as we have already achieved an MR ratio of about 27%), but it would be difficult to achieve the same figure at the sensor level.

Based on this background, the CPP spin valve is being studied as one of the possible candidates for high-density recording applications [269–279]. One of the advantages of the CPP spin valve over the existing Current-in-plane spin valve is that it allows the elimination of the insulating gap layer in the read head, which will contribute to the increase of the linear density [see Fig. 35(a)]. More importantly, the output voltage of the CPP sensor does not scale linearly with the width of the sensor as the CIP does. Assume that one has a read element with width W, height H, and thickness T, as shown schematically in Figure 35(b); the outputs of the sensor in the CIP and CPP modes are given by

$$\begin{aligned} \langle \Delta V_{\max}^{\mathrm{CIP}} \rangle &= \Delta\rho_{\mathrm{CIP}} \langle W \rangle J \\ \langle \Delta V_{\max}^{\mathrm{CPP}} \rangle &\approx \Delta\rho_{\mathrm{CPP}} \langle T \rangle J \end{aligned} \tag{31}$$

Here, $\Delta\rho_{\mathrm{CIP}}$ and $\Delta\rho_{\mathrm{CPP}}$ are the resistivity change due to the GMR effect (nominal values including the nonactive regions), $\langle W \rangle$ and $\langle T \rangle$ are the average width and thickness of the active region, and J is the current density. The above equations suggest that the CPP sensor is more suitable for ultrahigh-density recording because it is much easier to control the thickness than to control the lateral dimension. This is because the former is determined by the film thickness, while the latter is determined by lithography. Therefore, the CPP sensor is also advantageous from the manufacturability point of view. Note that the above discussion is only valid for constant current density operations. The dependence of the output signal on the sensor width will be relaxed for the CIP sensor when it is operated under a constant power.

5.4.2. Sensitivity Enhancement of CPP Sensors

Both theoretical and experimental studies on the CPP–GMR started shortly after the discovery of CIP–GMR in ferromagnetic/nonmagnetic multilayers [280–285]. It was found experimentally that the CPP–GMR is larger than the CIP–GMR in multilayer samples [280, 281, 286–288]. For spin valves, Vedyayev et al. estimated theoretically that the CPP–GMR should also be larger than the CIP–GMR [289]. By starting with the Boltzmann equation, Valet and Fert derived an analytical equation for the CPP–GMR [284]. This was later extended to the treatment of an exchange-biased spin valve with a typical structure AFM/FM/NM/FM [290, 291]. In the case where the spin diffusion length is much longer than the layer thicknesses, Bass and Pratt obtained [291]

$$A\Delta R = \frac{4(\beta\rho_F^* t_F + \gamma AR_{F/N}^*)^2}{2\rho_F^* t_F + \rho_N t_N + 2AR_{F/N}^* + AR_{AF/F}} \tag{32}$$

where t_F, t_N, and t_{AF} are the thicknesses of the ferromagnetic, nonmagnetic, and antiferromagnetic layers, and $AR_{AF/F}$ is the specific resistances at the anitiferromagnetic layer (AF)/ferromagnetic layer (F) interface. The bulk spin asymmetry coefficient (β), interface spin asymmetry coefficient (γ), ρ_F^*, and $AR_{F/N}^*$ are defined as

$$\begin{aligned} \beta &= \frac{\rho_F^{\downarrow} - \rho_F^{\uparrow}}{\rho_F^{\downarrow} + \rho_F^{\uparrow}}, & \gamma &= \frac{AR_{F/N}^{\downarrow} - AR_{F/N}^{\uparrow}}{AR_{F/N}^{\downarrow} + AR_{F/N}^{\uparrow}} \\ \rho_F^* &= \frac{(\rho_F^{\downarrow} + \rho_F^{\uparrow})}{4}, & AR_{F/N}^* &= \frac{(AR_{F/N}^{\downarrow} + AR_{F/N}^{\uparrow})}{4} \end{aligned} \tag{33}$$

where $\rho_F^{\uparrow}(\rho_F^{\downarrow})$ and $AR_{F/N}^{\uparrow}(AR_{F/N}^{\downarrow})$ are the bulk resistivity, and specific resistances at the F/N interfaces, for the majority and minority electrons, respectively. The above equation was obtained by assuming that the specific resistances between the ferromagnetic layer and antiferromagnetic layer or the contacts are independent of the direction of electron spin with respect to the local magnetization direction. On the other hand, in another extreme case where the spin diffusion length of the ferromagnetic layer is shorter than its thickness, $A\Delta R$ is given by [291]

$$A\Delta R = \frac{4(\beta\rho_F^* l_{sf}^F + \gamma AR_{F/N}^*)^2}{2\rho_F^* l_{sf}^F + 2AR_{F/N}^* + \rho_N t_N} \tag{34}$$

where l_{sf}^F is the spin diffusion length of the F layers, and all other notations are the same as those in Eq. (32).

When being used as a read sensor, the output voltage of a CPP SV sensor is given by $\Delta V = \alpha J A \Delta R$. Here, J is the current density whose maximum value is limited to $\sim 10^7$ A $\cdot$ cm^{-2} due to electron migration and power consumption considerations, and α is the head efficiency coefficient multiplied by the dynamic range coefficient of the sensor, which is about 0.2–0.5, depending on the structure of the read head. Assuming $\alpha = 0.2$ and $J = 5 \times 10^7$ A $\cdot$ cm^{-2}, an $A\Delta R$ of 10 m$\Omega \cdot \mu$m^2 is required to obtain an output voltage of 1 mV. A typical spin valve, however, can only have an $A\Delta R$ of about 1–2 m$\Omega \cdot \mu$m^2 [270, 274, 279]. Therefore, the performance of the CPP SV has to be improved before it can be applied to read heads. From Eq. (32), which applies to most of the practical cases, one can see that $A\Delta R$ can be increased by increasing the parameters in the numerator or decreasing the parameters in the denominator. We focus on the numerator first. The most straightforward way to increase $A\Delta R$ is to increase the thickness of the F layers. However, this is not a preferred approach because the free layer of a read sensor must

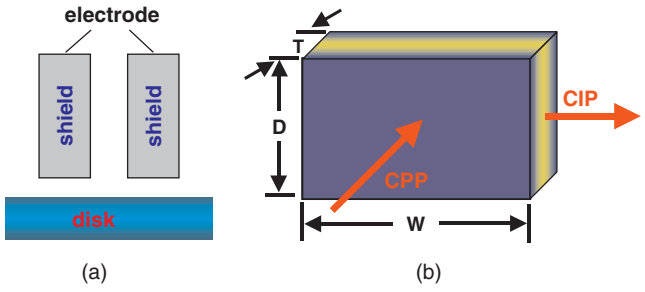

Figure 35. (a) Schematic drawing of CPP read head in which the shields can also be used as the electrodes which help to eliminate the read gap. (b) Schematic of a sensor element used in both the CPP and CIP modes.

be made as thin as possible; otherwise, it will degrade the sensitivity of the sensor. Although the values of other parameters, β, γ, and $AR^*_{F/N}$, can also be increased, their contribution to the enhancement of $A\Delta R$ is moderate because all of these parameters are determined by the properties of the constituent materials [272]. We are now left with only one parameter in the numerator, ρ^*_F, which is given by $\rho_F/(1-\beta^2)$. If one can find a way to increase the resistivity of the F layers without changing β significantly, then $A\Delta R$ will increase accordingly. It would be even more desirable should β be increased simultaneously. One of the possible approaches is to add nanooxides inside the F layers [270, 274]. The nanooxide effect is twofold. One of the effects is to increase the effective resistivity of the F layers without significantly changing the spin asymmetry coefficient. The second effect is to enhance the specular reflection of electrons so as to increase the number of F/N layers effectively. Nagasaka et al. showed that the nanooxide-added CPP spin valves exhibit an $A\Delta R$ 25 times larger than that of the conventional spin valves [274]. Focusing on the denominator, Gu et al. showed that the CPP–GMR in permalloy-based spin valves can be enhanced by increasing the spin-memory loss in ferromagnetic layers [292]. The particular structure that has been investigated by Gu et al. is Nb250/Cu10/FeMn8/Py12/Cu20/Py($t1$)/FeMn($t2$)/Py(12-$t1$)/Cu10/Nb250, where Py stands for permalloy, layer thicknesses are in nanometers, $t2 = 0.5$ or 1 nm, and $t1$ was adjustable from 1 to 11 nm. The ultrathin FeMn layer inside the free layer was used to increase the spin memory loss due to its extremely short spin diffusion length of about 1 nm. Although significant improvement in $A\Delta R$ has been obtained using this technique, the maximum value of $A\Delta R$ obtained is still below 2 $m\Omega \cdot \mu m^2$.

Among all of these techniques that have been investigated, the nanooxide gives the most significant enhancement to $A\Delta R$ without the need to introduce more layers or to increase the layer thickness physically; thus, it is desirable for practical applications. However, the oxide must be sufficiently thin; otherwise, it will affect the flow of electrons across the spin-valve stack in the CPP mode or increase the total resistance to an unacceptable level. However, if the oxide layer is too thin, it will lose its original functionality as an electron-reflection or resistivity-enhancement layer. Therefore, using oxide alone, one may not be able to obtain the same effect as what has been obtained in the CIP mode. In addition to the number of layers, $A\Delta R$ also increases with the bulk and interface spin asymmetry coefficient, as we discussed above. This might be achieved through using half metals as the electrodes, but so far, no suitable materials have been found. Based on this background, we have proposed a possible solution to overcome this difficulty [277].

It is known from the research work on semiconductor devices that electrons can be reflected not only by a single potential barrier of large height, but also by a superlattice-type of structure with moderate barrier heights at the interfaces, provided that the thickness of each layer is chosen such that it is one quarter of the de Broglie wave of electrons [293, 294]. This type of structure is often called an electron Bragg reflector [Fig. 36(a)]. It is relatively easy to realize this kind of structure in semiconductors because the de Broglie

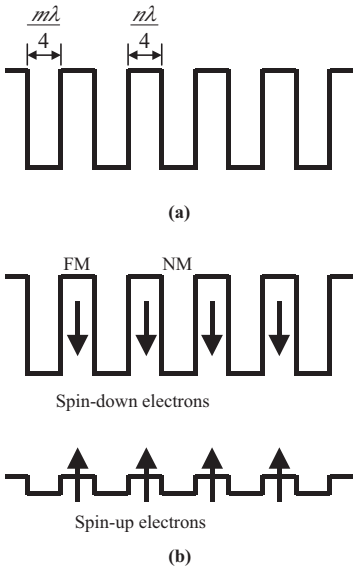

Figure 36. Schematic of a spin-independent Bragg reflector (a), and a spin-dependent Bragg reflector (b).

wavelength is relatively large. In metallic materials, however, the electron wavelength is close to the Fermi wavelength, which is just about 0.1–0.2 nm. If this is the "true" length scale, it is almost impossible to build a Bragg reflector for electrons using metallic materials. Fortunately, due to the discreteness of the atomic layers, the actual wavelength of the electron packet, or so-called envelope functions, is given by $2\pi/\Delta K$ [295]. Here, ΔK is the magnitude of the wavevector that spans the appropriate stationary points of the Fermi surface. This gives a wavelength of about 1.1 nm for Cu, for example. The Bragg reflection will occur when the conditions $d_{FM} = m\Lambda_{FM}/4$ and $d_{NM} = n\Lambda_{NM}/4$ are satisfied. Here, d_{FM} and d_{NM} are the thickness of the ferromagnetic and nonmagnetic layers, respectively, and m and n are odd integer numbers. If one chooses m and n in the range of 3–4, the thickness of each layer should be well within the controllable range of the state-of-the-art sputtering systems.

Now, a question arises here: How can the electron flow in the CPP mode if one has a perfect Bragg reflector in the spin-valve stack? The point is that the quantum-well states only form when all of the ferromagnetic layers are ferromagnetically coupled, and they only exist for the minority electrons [295]. In other words, the Bragg reflector in a magnetic/nonmagnetic multiple layer is a spin-dependent reflector [see Fig. 36(b)]. It reflects only the minority electrons, but lets the majority electrons flow almost freely. This will effectively increase the bulk and interface spin asymmetry coefficient, and thus $A\Delta R$ of spin valves. Note that the picture given here is based on the ballistic transport of electrons instead of diffusive transport; thus, Eqs. (32) and (34) might not be directly applicable to this case.

Figure 37 illustrates some of the possible structures of CPP sensors using the electron Bragg reflectors, which consist of a number of pairs of CoFe and Cu. The thickness of Cu can be chosen such that it facilitates a strong parallel coupling between the adjacent ferromagnetic layers, but at the same time, it satisfies the Bragg reflection condition.

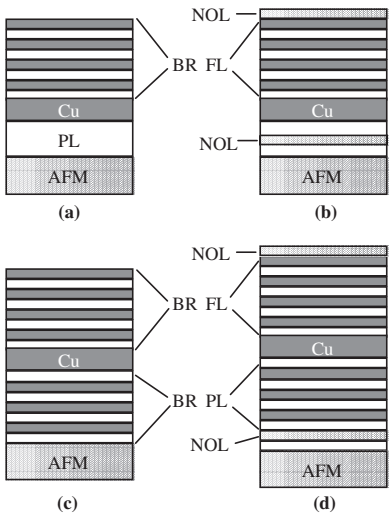

Figure 37. Schematic of some possible CPP spin valves using both nanooxide and Bragg reflectors. Here, BR stands for Bragg reflector, NOL refers to nanooxide, and FL (PL) is the free (pinned) layer.

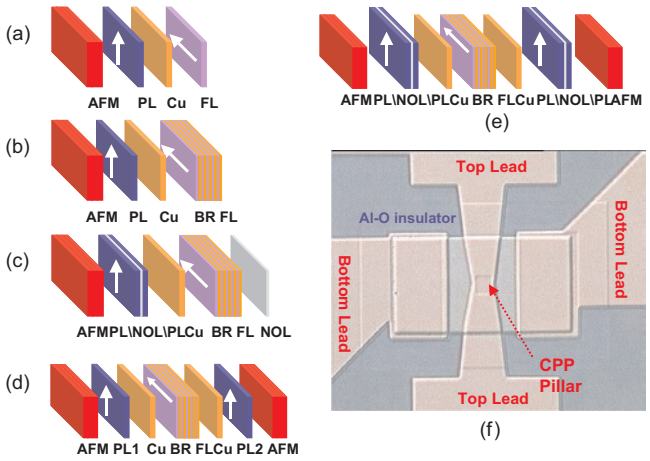

Figure 38. (a)–(e) Schematic drawings corresponding to sensor type A–E. (f) Optical micrograph of typical CPP sensors.

If the priority is to achieve ferromagnetic coupling, any difference in the thickness of the Cu layer to the value that is requested by the Bragg condition can be compensated by the thickness of the corresponding ferromagnetic layer. The m and n are not necessary to be the same; m can be small so as to reduce the total thickness of the Bragg reflectors. The Bragg reflectors can be used either in the free layer only [Fig. 37(a) and (b)] or in both the free and pinned layers [Fig. 37(c) and (d)]. To enhance the specular reflection effect, ultrathin oxides can be added at both the top of the free layer and the middle of the pinned layer [Fig. 37(b)]. The same approach can be taken for spin valves using Bragg reflectors at both the free and pinned layers [Fig. 37(d)]. Further to these steps naturally will be the one that adopts dual spin-valve structures, as is the case with Current-in-plane spin valves. The functions of the nanooxide are twofold. First, it increases the specular reflection. Second, it reduces the interface roughness so that the electron interference effect can occur.

A series of experiments have been carried out to verify the concept. The sheet films were fabricated using ultrahigh-vacuum sputtering. The detailed sputtering conditions can be found in [249, 250]. After the sheet film was fabricated, it was patterned into elements with different sizes using the e-beam lithography and ion-milling processes. The CPP spin valves that have been fabricated include: (1) simple single spin valves without nanooxides and Bragg reflectors (type A), (2) single spin valves with a Bragg reflector free layer (type B), (3) single spin valves with both a Bragg reflector free layer and a nanooxide cap layer (type C), (4) dual spin valves with a Bragg reflector free layer (type D), and (5) dual spin valves with both a Bragg reflector free layer and nanooxides at both the top and bottom pinned layers (type E). Figure 38 shows a schematic drawing of the spin-valve structures. The Bragg reflector used has a structure [CoFe(1.4 nm)/Cu(1.1 nm)] $\times$ 5. The antiferromagnet and pinned layers are IrMn (8 nm) and CoFe (3 nm), respectively. The top oxide was formed through the oxidation of NiFe, and the oxide in the middle of the pinned layer was formed through natural oxidation of CoFe. The total thickness of the CoFe pinned layer was always kept constant.

To ensure a reliable measurement of the change in the resistance–area product, we first tried to determine the dependence of the junction resistance on the junction area. Figure 39 shows the typical results for types A, B, C, and E spin valves. As can be seen from the figure, the junction resistance is inversely proportional to the junction area, indicating that current distribution is quite uniform over the entire junction. Similar results have been obtained for type D sensors. Table 3 lists the R_J and ΔR_J of the five different types of spin valves. In general, we can see that both the nanooxide and the Bragg reflector can improve the performance of the spin valve. The large junction resistance is due to the contact resistance at the sensor/electrode interface. We are currently developing a new technique to remove the junction resistance from the measured data. But

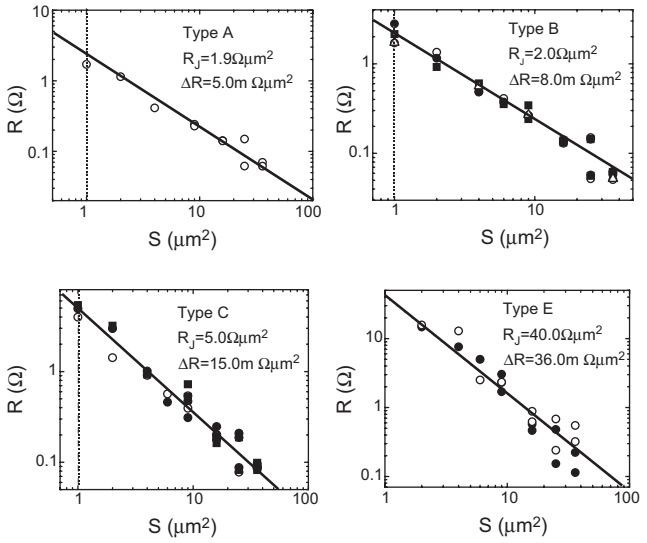

Figure 39. Dependence of the junction resistance on the junction area for different types of CPP spin valves.

Table 3. R_J and ΔR_J of different types of CPP spin valves.

	Type A	Type B	Type C	Type D	Type E
R_J ($\Omega \cdot \mu m^2$)	1.9	2.0	5.0	20	40
ΔR_J ($m\Omega \cdot \mu m^2$)	5.0	8.0	15	26	36

the junction resistance will not affect the accuracy of the measured $A\Delta R$ as much because we have already shown in Figure 39 that the current distribution problem is negligible in these samples.

The above results show that a well-designed and fabricated Bragg reflector may play the same role as a nano-oxide, but the former is more suitable for CPP spin valves because it does not increase the resistance substantially, as the oxides do. The results shown here are preliminary; we cannot exclude other effects introduced by the insertion of the laminated free layers. But we believe that this type of structure will become more useful in the future when suitable magnetic semiconductors are available because it is much easier to form Bragg reflectors using semiconductors. Although it is not in spin valves, a similar type of electron interference effect has already been observed in magnetic tunnel junctions grown epitaxially on a single-crystal substrate [296].

6. MAGNETIC TUNNEL JUNCTIONS

Another type of sensor that operates in the CPP mode is the magnetic tunnel junction (MTJ) [26–29]. The key difference between the CPP GMR sensor and the MTJ is that the electrical conduction in the former case is based on the spin-dependent scattering effect, both inside the ferromagnetic layers and at the ferromagnetic/nonmagnetic interfaces, while that in the latter is based on spin-dependent quantum mechanical tunneling across a thin potential barrier. To have a sound understanding of MTJ, we first look at the basic properties of a normal nonmagnetic tunnel junction. A typical quantum-mechanical tunnel junction is a sandwich of two conductive electrodes separated by a thin insulating barrier layer. For a tunnel junction with a sufficiently high potential barrier, the tunneling current can be calculated using the transfer Hamiltonian approach, which reads [297, 298]

$$I = A\int_{-\infty}^{\infty} |M|^2 D_1(E+E_{F1}) D_2 \times (E+E_{F2}+eV) \times [f(E+E_{F1}) - f(E+E_{F2}+eV)]dE \quad (35)$$

where

$$M = \frac{\hbar^2}{2m}\iint_S (\Psi_1 \nabla \Psi_2^* - \Psi_2^* \nabla \Psi_1)\cdot dS$$

is the matrix element of the transfer Hamiltonian, D_1 and D_2 are the density of states for the left and right electrodes, respectively, f is the Fermi distribution function, S is the cross-section area of the junction, m is the electron mass, $\hbar$ is the Planck constant, V is the bias voltage, E is the electron energy, E_{F1} (E_{F2}) is the Fermi level of the left (right) electrode, and A is a constant. Ψ_1 and Ψ_2 are the wavefunctions of the electrons at the initial and final states. In the case where the voltage applied across the junction is small, one has

$$f(E+E_{F_1}) - f(E+E_{F_2}+eV) = -\left.\frac{\partial f}{\partial E}\right|_{E=E_F} \cdot (eV) \quad (36)$$

$$G(V=0) = \frac{dI}{dV} \propto |M|^2 D_1(E_F) D_2(E_F) \quad (37)$$

where G is the conductance. For tunnel junctions with ferromagnetic electrodes, Eq. (37) is still valid, except that D_1 and D_2 are now dependent on the spin polarization of electrons. This is known to result in a different tunneling conductance between the parallel and antiparallel alignment of the magnetizations of the two electrodes, as shown schematically in Figure 40. The total conductance in the parallel configuration is thus approximately given by

$$G^{\uparrow\uparrow}(V=0) \propto D_1^{\uparrow}(E_F) D_2^{\uparrow}(E_F) + D_1^{\downarrow}(E_F) D_2^{\downarrow}(E_F) \quad (38)$$

and that in the antiparallel configuration is

$$G^{\uparrow\downarrow}(0) \propto D_1^{\uparrow}(E_F) D_2^{\downarrow}(E_F) + D_1^{\downarrow}(E_F) D_2^{\uparrow}(E_F) \quad (39)$$

Here, $D_1^{\uparrow}(D_1^{\downarrow})$ and $D_2^{\uparrow}(D_2^{\downarrow})$ are the density of states of the majority (minority) electrons of the two electrodes, respectively. In deriving the above equation, we have assumed that spin is conserved during tunneling. The junction magnetoresistance (JMR) is defined as

$$\text{JMR} = \frac{1/G^{\uparrow\downarrow}(0) - 1/G^{\uparrow\uparrow}(0)}{1/G^{\uparrow\downarrow}(0)} \quad (40)$$

which can be further reduced to

$$\text{JMR} = \frac{2P_1P_2}{1+P_1P_2} \quad (41)$$

Here,

$$P_1 = [D_1^{\uparrow}(E_F) - D_1^{\downarrow}(E_F)]/[D_1^{\uparrow}(E_F) + D_1^{\downarrow}(E_F)]$$
$$P_2 = [D_2^{\uparrow}(E_F) - D_2^{\downarrow}(E_F)]/[D_2^{\uparrow}(E_F) + D_2^{\downarrow}(E_F)] \quad (42)$$

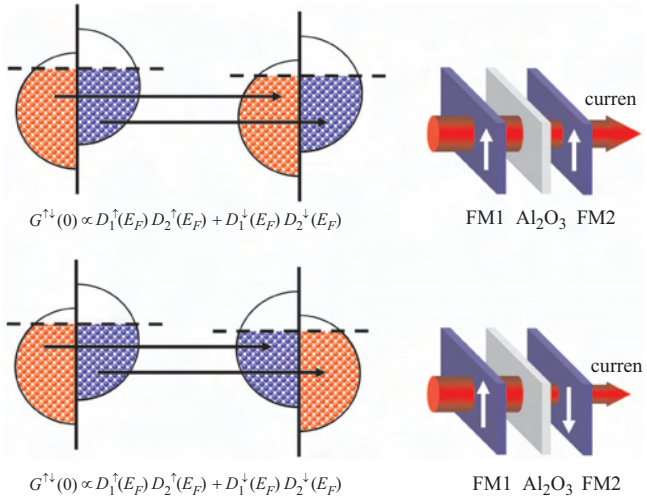

Figure 40. Schematic illustration of spin-dependent tunneling across an insulating barrier.

are the spin polarizations of electrons in the two ferromagnetic electrodes. This is the result that has been predicted by the Jullière model [26]. Assuming a typical value of 0.5 for P_1 and P_2, this simple model predicts a JMR of 40%. Note that an alternative definition for the tunnel magnetoresistance (TMR) frequently used in the literature is TMR $= 2P_1P_2/(1 - P_1P_2)$. Obviously, the TMR is always larger than the JMR, although the actual size of the magnetoresistance effect is the same. Although the Jullière model predicts a quite large MR, it was not until 1995 that MR ratios of about 20% were first reported by two groups for magnetic tunnel junctions at room temperature [28, 29]. Miyazaki and Tezuka [28] reported on an $Fe/Al_2O_3/Fe$ tunnel junction, 1×1 mm^2 in area, that exhibited a TMR ratio of 18% at room temperature. The barrier layer was formed through natural oxidation of 5.5 nm Al in air for 24 h. At about the same time, Moodera et al. fabricated magnetic tunnel junctions with CoFe and Co or NiFe as electrodes and oxygen-plasma oxidized Al as the barrier [29]. An MR ratio of 18% (in this case, JMR) has been obtained at low-bias voltage and room temperature in $CoFe/Al_2O_3/Co$ junctions with an area of 6×10^{-4} cm^2. The large MR ratio was attributed to the smoothness and small thickness of the electrodes. In both works, the magnetic tunnel effect was observed in large-area $FM/Al_2O_3/FM$ junctions fabricated by shadow masks. Gallagher et al. reported on the fabrication of microstructured magnetic tunnel junctions using a simple self-aligned lithographic process adopting an exchange-biased structure [299]. The combination of photo and electron-beam lithographies made it possible to cover a range of junction areas spanning five orders of magnitude (10^{-2}–10^3 μm^3). The MR ratio obtained ranges from 15 to 22% at room temperature and in fields of a few tens of Oersteds. The microstructured and exchange-biased magnetic tunnel junctions were further developed to have a higher MR ratio (42%) and moderate specific junction resistance ($\sim 60\ \Omega \cdot \mu$m^2), and were applied to prototypes of MRAMs [10]. After these pioneer works, a tremendous amount of effort was devoted to the development of magnetic tunnel junctions and their application in MRAMs and read heads. In what follows, we try to summarize some of the key issues that have been addressed in the literature for magnetic tunnel junctions.

6.1. Electrodes

6.1.1. Spin Polarization

The simple theoretical model suggests that ferromagnetic materials with large spin polarizations are the key to achieving a high MR. For a transition metal ferromagnet, the spin polarization is largely determined by whether the electrons participating in electrical conduction have an *s*-like characteristic or a *d*-like characteristic, or a mixture of these two. As the MR is determined by the spin-dependent density of states at the Fermi surface, its value is largely determined by the extent to which the *s* and *d* bands appear across the Fermi surface. However, the experimental determination of spin polarization for each material is quite challenging. The most straightforward way to determine the polarization is to use the spin-polarized photoemission spectroscopy technique, but it lacks the necessary energy resolution. An alternative technique that has been pioneered by Tedrow and Moservey is based on the spin-polarized tunneling across an FM-superconductor tunnel junction which gives a submillielectron volt energy resolution [300]. Recently, a new technique based on the point contact between the sample and a superconductor has been developed [301, 302]. This technique measures the polarization ratio using Andrew reflection. The point contact setup allows the measurement of samples in various forms, and it also does not require the use of a magnetic field. The values of P measured for some of the magnetic materials using both the point-contact Andrew reflection technique and tunneling techniques [301–305] are shown in Table 4 (note that spin polarization of Co and Ni should be negative in the processes where 3*d*-band electrons are dominant). Among them, NiMnSb, $La_{0.7}Sr_{0.3}MnO_3$, and CrO_2 are so-called half metals, which theoretically should have a polarization of 100%. As shown in Table 4, most soft magnetic materials have a polarization of 40–50%, corresponding to a JMR of about 30–40% (or a TMR of 38–67%). Theoretically, the sign of JMR can either be positive or negative, depending on the signs of P_1 and P_2. However, most of the experiments using NiFe, CoFe, Co, and Fe as the electrodes and Al_2O_3 as the barrier have produced positive MRs. Sharma et al. observed a negative MR in $NiFe/Al_2O_3/Ta_2O_5/NiFe$ composite barrier junctions, which was attributed to the different spin polarizations of NiFe at the two different interfaces, one with Al_2O_3 and the other with Ta_2O_5 [306]. Negative MR has also been observed by De Teresa et al. in $La_{0.7}Sr_{0.3}MnO_3$ (LSMO)/barrier/Co tunnel junctions, when $SrTiO_3$ (STO) was used as the insulating barrier [307]. This is in good agreement with the fact that the spin polarization of LSMO is positive [308], while that of the 3*d*-band density of states of Co at the Fermi level is negative. However, when Al_2O_3 was used as a barrier, the MR turned back to positive, and with a very different bias dependence. The authors concluded that the electronic structure of the barrier and the barrier–electrode interface has a strong influence on the spin polarization of electrons. Similar results have also been observed for magnetic tunnel junctions using $Ni_{40}Fe_{60}$ and Fe as the electrodes and STO as the insulating barrier [309], and in Fe_3O_4/STO/LSMO [310]

Table 4. Measured values of polarizations for different materials.

Materials	Polarization (%)	Ref.
Co	42 ± 2	[301]
	37 ± 2	[302]
Ni	46.5 ± 1	[301]
	32 ± 2	[302]
Fe	45 ± 2	[301]
$Ni_{80}Fe_{20}$	37 ± 5	[301]
$Co_{50}Fe_{50}$	$53\pm$	[301]
NiMnSb	58 ± 2.3	[301]
$La_{0.7}Sr_{0.3}MnO_3$	78 ± 4	[301]
$La_{2/3}Sr_{1/3}MnO_3$	95	[303]
CrO_2	90 ± 3.6	[301]
Fe_3O_4	-39	[304]
Sr_2FeMoO_6	60 ± 3	[305]

and CrO_2/natural barrier/Co [311] tunnel junctions. These results imply that the barrier material and/or the electronic structure of electrode/barrier interface play an important role in determining the sign of the spin polarization. This is consistent with the *ab initio* calculations of de Boer et al. on the Co(001)–HfO_2 interface [312], Oleinik et al. on the Co/Al_2O_3/Co interface [313], and Tsymbal et al. on the Fe/O surface [314], which suggest that the polarization of tunneling electrons is governed by the mechanism of electronic bonding at the metal/oxide interface.

6.1.2. Surface Roughness (Bottom Electrode)

One of the major problems that resulted in the failed attempts to produce high-MR MTJs before the early 1990s is related to the surface roughness of the first or bottom electrode on which the insulating barrier and top electrode are formed. If the surface roughness exceeds a certain critical value, the MTJ will fail either magnetically or electrically or in both ways. The former is mainly caused by the dipole or orange-peel coupling between the bottom and top FM electrodes, while the latter is caused by pinholes formed in the thin insulating barrier. Schrag et al. reported on measurements of the magnitude of Néel orange-peel coupling due to interface roughness in a series of magnetic tunneling junction devices [315]. The samples studied were Si(100) substrate/Ta/Al/NiFe/FeMn/Co(PL2)/Ru/Co(PL1)(pinned)/Al_2O_3(barrier)/NiFe(free)/Al/Ta with the thickness of the barrier, free, and pinned layers varying from sample to sample. Results from magnetometry and transport measurements are shown to be in good agreement with the theoretical model of Néel. In addition, the authors have also used transmission electron microscopy to directly probe the sample interface roughness, and obtain results consistent with the values obtained by magnetometry and transport methods. A similar type of study was also carried out by Li et al. using high-resolution transmission electron microscopy [316]. With an *in-situ* scanning tunneling microscope, Tegen et al. directly measured the roughness of the films, and found a close correspondence between the values for the coupling fields determined by the magnetooptical Kerr effect and the ones computed on the basis of the measured morphology parameters [317]. The authors confirmed an increase of the dipole coupling between the magnetic layers with decreasing barrier thickness, as predicted by the theoretical model [Eq. (25)]. In addition to topographic roughness, Tiusan et al. showed that, in samples involving polycrystalline magnetic films, beyond the orange-peel coupling, an important class of interaction is related to the dispersion fields associated with magnetic inhomogeneities, or magnetic roughness, arising from the local anisotropy fluctuations [318]. The roughness problem becomes more serious when fabricating MTJs for read-head applications due to the roughness of the lower shield layer. Sun et al. reported on the use of a gas cluster ion beam to smooth the shield layer, and successfully obtained an RA as low as 3.6–6.5 μm^2 and an MR ratio of 14–18% for MTJs grown on the smoothed shield layers [319].

6.1.3. Effect of Nonmagnetic Interfacial Layers

A spin-dependent quantum well forms in an ultrathin nonmagnetic metal sandwiched either from both sides by magnetic materials or from one side by a magnetic material and the other side by an insulator or vacuum [295, 320, 321]. In the former case, quantum-well states exist only when the magnetic layers are in parallel alignment, and in both cases, they are formed for minority electrons only. The observation of quantum-well states, however, requires atomically sharp interfaces due to the short wavelength of electrons in metals. For an ideal magnetic tunnel junction with a structure FM/NM/insulator/FM, theories predict an oscillation in the MR effect as a function of the NM layer thickness because the spin polarization of the tunneling electrons oscillates as a result of the resonant tunneling via the quantum-well states [322–324]. Moodera et al. fabricated Co/Au/Al_2O_3/$Ni_{80}Fe_{20}$ MTJs on liquid-nitrogen-cooled glass substrates with the thickness of Au varying from 0.1 to 1.2 nm [325]. It was found that the JMR decreases with the thickness of Au, which might be understood as the consequence of decrease of spin polarization [326–328]. But what was interesting was that a negative JMR was observed in the thickness range of 0.6–0.8 nm, which came along with an unusual bias dependence. The authors have shown that both results could be explained by taking into account the quantum-well states formed in the NM layer based on the Slonczewski model [329]. LeClair et al. also observed an inversion of sign of the MR in Co/Ru/Al_2O_3/Co tunnel junctions, but they attributed this to a strong density-of-states modification at the (interdiffused) Co/Ru interface [330].

Yuasa et al. fabricated MTJs on single-crystal Cu substrates of the structure Co(001)/Cu(001)/Al–O/$Ni_{80}Fe_{20}$ using molecular beam epitaxy, and they observed for the first time clear oscillation of the JMR as a function of the Cu layer thickness [296]. High-resolution transmission electron microscopy revealed that both the bottom electrode and the Cu layer were grown epitaxially on the Cu substrate, leading to atomically flat interfaces between Co and Cu and Cu and Al–O. As expected, the oscillation period at zero bias was about 1.1 nm, which is consistent with the value observed in GMR oscillation. As the spin polarization of electrons in Co and $Ni_{80}Fe_{20}$ was found to be positive in tunnel junctions with Al–O as the barrier, the negative peaks of the JMR observed in these junctions were attributed to the negative polarization of electrons formed in the Cu quantum wells.

6.2. Barrier Materials

6.2.1. Different Kinds of Barriers

The key to fabricating a high-quality MTJ is to form a pinhole-free and uniform ultrathin barrier layer of AlO_x [28, 29, 298, 331]. Although other types of insulating materials have also been investigated as the tunnel barrier, such as Ta_2O_5 [332–335], AlN_xO_y [336–339], $ZrAlO_x$ [340, 341], GaAs [342], GaO_x [343], diamond-like carbon [344], ZnS [345, 346], $SrTiO_3$ [347–350, 307, 351], MgF_2 [352], ZnSe [353], Cu_3N [354], MgO [355–359], HfO_x [360–362], TaO_x/AlO_x [306, 363], so far, AlO_x was found to be the most suitable barrier material for MTJ.

6.2.2. Formation and Characterization of AlO_x

The AlO_x layer can be formed using various methods, such as natural oxidation [28, 364–370], plasma oxidation [29, 371–377], ultraviolet (UV)-light-assisted oxidation [378–381], ion beam oxidation [382], radical oxidation [383], ozone oxidation [384], atomic layer chemical vapor deposition [385], and other equipment-specific techniques. In general, plasma or other energy beam-based techniques are faster and produce denser and more uniform oxides compared to natural oxidation, either in air or in pure oxygen. The property of the oxide formed is also dependent on the types of the process gases. Using $Kr–O_2$ plasma, Tsunoda et al. obtained a TMR of 58.8% at room temperature after annealing the junction Ta5/Cu20/Ta20/Ni–Fe5/Cu5/$Mn_{75}Ir_{25}$10/$Co_{70}Fe_{30}$2.5/Al–O/$Co_{70}Fe_{30}$2.5/Ni–Fe10/Cu20/Ta5 (thickness in nanometers) at 300 °C, while the achieved TMR ratio of the MTJ fabricated with the usual $Ar–O_2$ plasma remained 48.6% [386]. This improvement is remarkable considering the fact that the MR obtained so far using other oxidation methods is about 50% [387].

Under Oxidation of Al High-resolution transmission electron microscopy study by Bae et al. [388] revealed that natural oxidation occurred preferentially through the grain boundary of Al grains, leading to isotropically expanded AlO_x grains when Al is fully oxidized. On the other hand, in plasma oxidation, a flat AlO_x layer formed uniformly on the Al layer, leading to a sharp interface with the underlying metallic Al layer. Ando et al. conducted a systematic study of the microstructure of the barrier oxide formed using different methods [389]. It was found that it is easier to form a uniform oxide within a short time period using plasma oxidation. This is because, in addition to the full coverage of the Al surface, the energetic oxygen species are also able to penetrate into the grain boundaries. On the other hand, in the case of natural oxidation, it is difficult for oxygen to penetrate into the grain boundaries. Therefore, the as-deposited MTJs with barrier layers formed by plasma oxidation normally show a higher MR as compared to those with naturally oxidized barriers. Mitsuzuka et al. studied the interface structure of magnetic tunnel junctions with naturally oxidized AlO_x barriers using X-ray photoelectron spectroscopy (XPS) [390]. The MTJs studied had a structure Fe (50 nm)/AlO_x/CoFe (30 nm), where the barrier layer was formed through natural oxidation of Al with a thickness ranging from 0 to 5 nm. It was found that the MR showed a maximum value when Al is about 2–3 nm in thickness. The XPS analysis showed that an Al layer thicker than 1 nm covers the entire surface of the lower electrode. However, unoxidized Al remains when Al is thicker than 1 nm. For Al layers greater than 3 nm, the MR ratio is strongly affected by unoxidized Al, probably due to the decrease of spin polarization caused by the unoxidized Al layer. Zhang et al. reported on the effect of natural oxidation conditions on the performance of MTJs. It was found that natural oxidation at a lower oxygen pressure produces an MTJ with a lower RA and a smaller MR ratio as compared to those formed by a higher pressure oxygen oxidation [368]. Rutherford backscattering analysis confirmed the inadequate oxidation of Al at low oxygen pressure. Natural oxidation and UV-assisted oxidation are suitable for formation of MTJs of a low area–resistance product using ultrathin Al layers [391]. It was reported that a two-step or multiple steps of natural oxidation helps to improve the uniformity of the oxidized barrier layer [369, 392].

Pinholes The quality of the barrier layer plays a dominant role in determining the characteristics of the tunnel junction [393]. Allen et al. reported on the imaging of pinholes by electrochemical decoration of the pinholes using Cu [394]. The results obtained were found to be consistent with the breakdown voltage analysis [395]. Dimopoulos et al. reported that the "defective" sites of the barrier can also be detected using a barrier impedance scanning microscopy technique [396].

Inhomogeneity and Defects of the Barrier Layer Ando et al. studied the local current distribution of MTJ with a structure Ta5/$Ni_{80}Fe_{20}$5/IrMn15/Co5/Al1.3-oxidation using conducting atomic force microscopy [397]. Here, thickness is given in nanometers. It was found that the current distribution can be explained by assuming a Gaussian distribution for the barrier thickness with a mean value of 1.2 nm and a standard deviation of 0.1–0.15 nm. A similar study was also carried out by Luo et al. [398]. Rippard et al. used ballistic electron emission microscopy to study thin aluminum oxide tunnel junction barriers formed both by magnetron sputter deposition and thermal evaporation [399, 400]. It was found that the barriers made by oxidation of evaporated Al become fully formed at a thickness as small as 0.6–0.7 nm, while a thicker Al (0.9–1.1 nm) layer is necessary to form a continuous barrier by magnetron sputtering. Although the decrease of barrier thickness generally contributes to the reduction of RA, if the barrier is too thin, it will also cause reliability problems when the MTJs are used as read sensors or storage cell elements. Oliver et al. reported on dielectric breakdown studies on magnetic tunnel junctions having ultrathin barriers [401]. The MTJs, with a structure Ta5/PtMn25/CoFe2.2/Ru0.9/CoFe2.2/Al-oxidation/CoFe1/NiFe2.5/Ta15 (thicknesses are in nanometers), were fabricated by magnetron sputtering and patterned by deep ultraviolet photolithography to a junction area of about 0.2 μm^2. The tunnel magnetoresistance was 15–22% and RA 7–22 $\Omega \cdot \mu m^2$ for junctions having a 4.75–5.5 Å Al layer oxidized naturally. The authors observed two types of breakdown: abrupt dielectric breakdown at an effective field of 10 MV/cm determined by the thickness of the tunnel barrier, and a gradual breakdown related to defects in the tunnel barrier. After the breakdown, a metallic pinhole is created, the size of which depends on the maximum current applied to the junction. The current flowing through the pinhole creates a strong circular magnetic field that curls the local magnetization in the free layer around the pinhole. The subsequent free-layer reversal is very sensitive to the pinhole location. The electric properties after breakdown can be well described by an ohmic resistor and a tunnel magnetoresistor connected in parallel. Kikuchi et al. also reported similar types of phenomena in the breakdown processes [402]. The existence of pinholes in low-junction-resistance samples has been discussed in the context of a size-dependent breakdown voltage that decreases by increasing the junction size.

6.3. Annealing Effect and Thermal Stability

Postgrowth annealing at temperatures in the range of 220–400 °C was found to be effective in improving the performance of magnetic tunnel junctions, beyond which anneal will deteriorate the performances of MTJ [403]. The highest temperature at which the MR starts to decrease monotonically with temperature is highly dependent on the materials and device structures. This has a significant impact on the application of MTJs in MRAMs because standard back-end technology for the metallization of CMOS circuits requires annealing in the forming gas at 350–450 °C. Many attempts have been made to reveal the mechanisms for MR enhancement at intermediate temperatures and the loss of the MR at elevated temperatures. We summarize some of the results reported in the literature below.

6.3.1. Effect on the Barrier Layer

Anneal at moderate temperatures was found to improve the quality of the barrier layer through decreasing its thickness, increasing its barrier height, improving its homogeneity at interfaces with the electrodes, and reducing the defects inside the barrier. Parkin et al. reported on the thermal annealing study of an MTJ with a structure $Cr_{80}V_{20}25/Co_{75}Pt_{12}Cr_{13}15$/Al–plasma oxidation/Co15/Al20 or $Co_{88}Pt_{12}15$/Al20 [404]. Here, the layer thickness is in units of nanometers. It was found that the MTJ is thermally stable at temperatures greater than 300 °C. A comparison of cross-section transmission electron micrographs of an untreated sample and a similar one annealed at 350 °C indicates that the thickness of the amorphous tunnel barrier is slightly decreased after annealing. The resistance–area product and the MR of the devices initially increase slightly for lower temperature annealing treatments up to about 200–250 °C. For annealing at higher temperatures, both the MR and the resistance–area product decrease monotonically, although the MR decreases at a more rapid rate. MR values of ~10% were still obtained after annealing to ~350 °C. Due to the thick barriers used in these particular samples, the resistance–area product is in the range 5–6 $M\Omega \cdot \mu m^2$.

Sousa et al. reported on the thermal annealing effect of exchange-biased MTJs. Two series of samples were studied: one series with resistance–area products of 10–13 $M\Omega \cdot \mu m^2$, and the other with resistance–area products of 25–30 $k\Omega \cdot \mu m^2$ [405]. The former has a structure Ta7/Cu4/Ta7/NiFe6/CoFe3/Al_2O_3/CoFe3/MnRh18 or TbCo12/Ta3, and the latter has a structure Ta7/NiFe10/CoFe2/Al_2O_3/CoFe4/MnR17/Ta3. The barriers of samples with higher resistance–area products were formed depositing 1.8 nm Al, followed by 90 s plasma oxidation with a density of 6 mW/cm^2, and those of the lower resistance–area product samples were fabricated depositing 1.1–1.3 nm Al, and then followed, respectively, by 20 and 15 s plasma oxidation at a power density of 4 mW/cm^2. The junction tunneling magnetoresistance was found to increase from 22–26% in high-resistance samples and 22–37% in low-resistance samples, upon anneal up to 200–230 °C. Rutherford backscattering analysis suggested that anneal improved the asymmetry in both the oxygen distribution inside the barrier and the junction parameters. The MR increase in lower resistance samples was attributed to the increase of the barrier height. The increase of the barrier height and decrease of the barrier thickness were also observed by Nowak et al. [406].

Ando et al. studied the annealing effect on MTJs having the structure Ta/(Cu,Pt)/$Fe_{20}Ni_{80}$/IrMn/$Co_{75}Fe_{25}$/Al-oxide/$Co_{75}Fe_{25}$/$Fe_{20}Ni_{80}$/Ta [407]. When the Al thickness, oxidation time, and annealing temperature were 0.8 nm, 15 s (10 s), and 300 °C (250 °C), the TMR, RA, and TMR enhancement ratio against the as-grown samples were 49% (31%), 1.1 $k\Omega \cdot \mu m^2$ (230 $\Omega \cdot \mu m^2$), and 70% (100%), respectively. In order to investigate the annealing temperature dependence of the TMR ratio, the authors measured the local electrical properties for a Ta/$Fe_{20}Ni_{80}$/Pt/$Fe_{20}Ni_{80}$/IrMn/$Co_{75}Fe_{25}$/Al-oxide multilayer using the conductive atomic force microscopy technique. The current image became very homogeneous after annealing at around 300 °C for 1 h. The increase of the TMR ratio of the junction after annealing was thus attributed to both the increase of barrier height and the decrease of barrier height fluctuation. The degradation of TMR after annealing in excess of 350 °C was due to the decrease in barrier height, leading to the increase of leakage currents.

Schmalhorst et al. systematically investigated the structural, magnetic, magnetotransport, and tunneling properties of CoFe(1.5 nm)/Ru(0.9 nm)/CoFe(2.2 nm)/Al_2O_3/$Ni_{81}Fe_{19}$ (6 nm)/Ta (5 nm) junctions for different Al thicknesses and oxidation times after isochronal annealing up to 500 °C. The mean breakdown voltage of the junction increases with temperature, saturates at an annealing temperature of about 300–350 °C, and remains constant up to almost 500 °C. This implies that Al oxide is extremely stable, and its stability is improved by thermal annealing. The latter might be related to the defect reduction inside the barrier layer [408].

6.3.2. Effect on Electrodes

Dimopoulos et al. reported that, compared to Co/Ru/Co, Co/Ru/$Co_{50}Fe_{50}$ is more advantageous when being used as the pinned layer in MTJs due to its excellent thermal stability [409]. After successive annealing steps up to 400 °C, magnetic tunnel junctions with structures Cr (1.6 nm)/Fe (6 nm)/Cu (30 nm)/Co (1.8 nm)/Ru (0.8 nm)/$Co_{50}Fe_{50}$ (2.8 nm)/Al (1 nm)–plasma oxidation/CoFe (1 nm)/ Fe (6 nm)/Cu (5 nm)/Cr (3 nm) as pinned layers were found to still present a significant tunnel magnetoresistance of nearly 20%, and an almost intact magnetic rigidity of the hard magnetic system. The improvement in thermal stability was attributed to the improvement of the Ru/CoFe/AlO_x interfaces in terms of interdiffusion.

Due to the finite and negative enthalpies of formation of most transition metal oxides, the electrodes will also be partially oxidized during annealing, as revealed by X-ray photoelectron spectroscopy studies. However, the mechanism still remains unclear regarding how the partially oxidized interfacial layers are related to the enhancement or degradation of the tunnel magnetoresistance [410]. The oxidation of the electrode might be suppressed, if it has adverse influences on the MTJ, by inserting a thin layer of magnetic oxide at the barrier/electrode interface. During the annealing process, due to the much larger and negative enthalpy of

AlO_x as compared to most magnetic oxides and the larger affinity of oxygen for Al, oxygen will tend to move to the barrier layer instead of the electrode. Using this technique, Zhang et al. fabricated tunnel junctions with an interposed Fe oxide layer between the Al_2O_3 barrier (t_{Al} = 8–9 Å) and the top CoFe pinned layer, and obtained a large tunneling magnetoresistance of 39% after 40 min anneal at 380 °C [411, 412]. The annihilation of the CoFe oxide during postgrowth annealing was also observed by Dimopoulos et al. in Cr (1.8 nm)/Fe (6 nm)/Cu (30 nm)/Cr (1.8 nm)/Fe (6 nm)/Cu (30 nm)/$Co_{50}Fe_{50}$ (1 nm)/Al–plasma oxidation/Fe (6 nm)/Cu (10 nm)/Cr (5 nm) samples, leading to the improvement of aluminum oxide's stoichiometry [413]. Matsukawa et al. fabricated MTJs with structures of bottom electrode/PtMn/CoFe/Ru/ CoFe/$Fe_{1-x}Pt_x$/Al oxide/$Fe_{1-x}Pt_x$/NiFe/top electrode (x = 0.05–0.75), in areas from 2 × 2 to 30 × 30 μm^2, using conventional photolithography and the ion-milling method. After a postgrowth anneal at 400 and 420 °C, the TMRs of MTJs with $Fe_{1-x}Pt_x$ (x = 0.1–0.2) were still about 40 and 30%, respectively [414].

6.3.3. Diffusion of Mn

In addition to oxidation of electrodes, overoxidation of Al will also cause oxidation-induced diffusion of Mn from the pinning layer to the barrier layer during the postgrowth annealing. Samant et al. investigated the thermal stability of MTJs with a structure Si(100)/0.5 μm thick SiO_2/Ti5/Pd15/$Ir_{23}Mn_{77}$ or $Fe_{50}Mn_{50}$14/$Co_{80}Fe_{20}$2.4/Al1.3–plasma oxidation/$Co_{80}Fe_{20}$3/Pd1.5 (thickness is given in nanometers) using near-edge X-ray absorption fine-structure spectroscopy [415]. It was found that structures with IrMn antiferromagnetic exchange-bias layers are much more thermally stable than similar structures with FeMn exchange-bias layers. In either case, however, diffusion of Mn from the antiferromagnetic layer through thin exchange-biased ferromagnetic layers to the tunnel barrier is observed at elevated temperatures (>300 °C). Yoon et al. investigated the Mn diffusion in an NiFe/MnIr/CoFe/AlO_x multilayer after annealing at 300 °C using Auger electron spectroscopy and X-ray photoelectron spectroscopy, wherein it was found that the magnitude of Mn diffusion is correlated to the excess oxygen generated from the plasma oxidation of the AlO_x tunnel barrier [416]. The analysis showed that Mn diffusion was driven by the preferential oxidation of Mn at the oxide insulator interface due to its larger (negative) enthalpy of formation compared to iron and cobalt oxides. Saito et al. reported on the thermal stability study of dual-spin-valve-type double-tunnel junctions with structures Ni–Fe/Ir–Mn/$Co_{50}Fe_{50}$/AlO_x/$Co_{90}Fe_{10}$/AlO_x/$Co_{50}Fe_{50}$/Ir–Mn/Ni–Fe and Ni–Fe/Ir–Mn/$Co_{50}Fe_{50}$/AlO_x/$Co_{50}Fe_{50}$/Ni–Fe/$Co_{50}Fe_{50}$/AlO_x/$Co_{50}Fe_{50}$/Ir–Mn/Ni–Fe, fabricated using photolithography and ion-beam milling [417]. In order to clarify the mechanism of the loss of the MR ratio and that of $V_{1/2}$ (bias voltage at which the MR decreases to half of the zero-bias value) above 320 °C, the authors carried out an XPS study in $Ni_{81}Fe_{19}$/Ir–Mn/$Co_{50}Fe_{50}$/AlO_x multilayers annealed at various T_A. The Mn oxide peaks in addition to the Mn peaks (both $2p_{1/2}$ and $2p_{2/3}$ peaks were observed) were observed in the temperature range ≥300 °C. It was found that a small amount of Mn and Mn oxide reached the CoFe/AlO_x interface at T_A = 300 °C due to interdiffusion of Mn. The oxygen redistribution and homogenization occur between AlO_x and Mn in the range of T_A > 320–350 °C, leading to an increase of defect states in the barrier. This increase in defect states above 320–350 °C was assumed to be responsible for the decrease of both the MR ratio and $V_{1/2}$ due to the spin-independent two-step tunneling via defect states in the barrier. The Mn diffusion might be suppressed by increasing the pinned layer thickness [418].

6.4. Basic Characteristics of MTJ

A practical exchange-biased magnetic tunnel junction has a structure that is very similar to that of a spin valve, except that the Cu spacer is replaced by an ultrathin insulating layer (see inset of Fig. 41). Figure 41 shows a schematic of a typical MTJ structure. When measuring the magnetic response, a constant current is applied through one of the top and bottom electrodes, and the voltage drops across the other two terminals are measured when a magnetic field is swept within a certain range from a positive value to a negative value. However, caution must be taken when interpreting the data because the measured MR could be affected significantly by the current distribution effect [419–424].

Although the MR ratio is much higher than that of a typical spin valve, the MTJ does have a few drawbacks compared to spin valves when they are used as read sensors. These include: (1) large junction resistance, (2) bias voltage dependence of the MR, and (3) temperature dependence of MR. The junction RA of an MTJ can be as high as on the order of MΩ · μm^2. Although it can be lowered by reducing the barrier thickness and height, this will generally result in a lower MR ratio. For example, the MR ratio drops to about 13% when the RA is reduced to 5 Ω · μm^2 [425]. As an example, Figure 42 shows the magnetoresistance curve of a typical MTJ with a junction area of 80 μm × 80 μm fabricated in the author's group. For this specific device with a structure Ta20/$Ni_{81}Fe_{19}$20/$Co_{90}Fe_{10}$2/Al(1 nm)-oxidation/$Co_{90}Fe_{10}$2/$Ni_{81}Fe_{19}$7/$Fe_{50}Mn_{50}$20/Ta5 (the thicknesses of other layers are given in nanometers), the TMR ratio is 44.6% at a dc bias of 4.3 mV and the RA is about 250 kΩ · μm^2 [426]. Shown in Figure 43 is the bias voltage dependence of the MR ratio of this particular MTJ. As can be seen from the figure, the MR drops to almost half when the bias voltage is increased to about 0.4 V. Although this value does vary with the MTJ structure, it is roughly in the range of 0.3–0.5 V for most of the MTJ structures [427–435]. Although the mechanism is still not fully understood, it is believed that it is caused by both the bias-induced change in the barrier profile and the energy-dependent density of states for both the majority and minority electrons [436, 437]. It is argued that magnon excitation

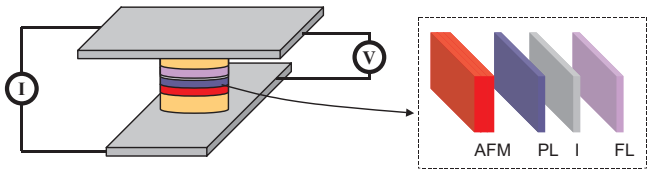

Figure 41. Typical structure of a magnetic tunnel junction device.

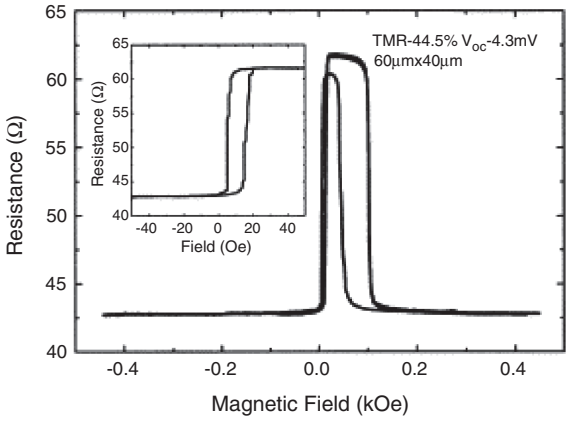

Figure 42. MR–H curve measured at room temperature for an MTJ with a structure Ta20/$Ni_{81}Fe_{19}$20/$Co_{90}Fe_{10}$2/Al(1 nm)-oxide/$Co_{90}Fe_{10}$2/$Ni_{81}Fe_{19}$7/$Fe_{50}Mn_{50}$20/Ta5. Inset shows the minor curve. Here, the thicknesses are given in nanometers. Reprinted with permission from [426], K. B. Li et al., *J. Magn. Magn. Mater.* 241, 89 (2002). © 2002, Elsevier.

in the magnetic layer might also be one of the possible reasons [438]. The energy-dependent density of states model can be roughly understood as follows. From Eq. (41), one can find that

$$\frac{\partial(\mathrm{JMR})}{\partial V} = \frac{2}{(1+P_1P_2)^2}\frac{\partial(P_1P_2)}{\partial V} \tag{43}$$

which reduces to $(\partial(\mathrm{JMR})/\partial V) = (4P/(1+P^2)^2)(\partial P/\partial V)$, when $P_1 = P_2 = P$. For electrodes with positive spin polarizations, the JMR will decrease with voltage when $(\partial P/\partial V) < 0$. Substituting Eq. (42) into $(\partial P/\partial V) < 0$, one obtains $(D^{\downarrow}(\partial D^{\uparrow}/\partial V) - D^{\uparrow}(\partial D^{\downarrow}/\partial V)) < 0$, which can be further simplified to $(\partial \ln(D^{\uparrow}/D^{\uparrow})/\partial V) < 0$. This implies that the JMR will drop if the ratio between the density of states for majority electrons and that of the minority electrons decreases with the bias voltage. As we will discuss shortly, the decrease of JMR with bias voltage is undesirable for practical applications. One of the possible approaches for reducing the bias voltage dependence is to use a double-tunnel junction [439]. Using the double junctions, it is possible to raise the voltage at which the MR drops to half of the low-bias value to 0.9 V, which is almost double that of a single-tunnel junction [440]. The voltage dependence can also be reduced using Hf-inserted AlO_x barrier layers [441].

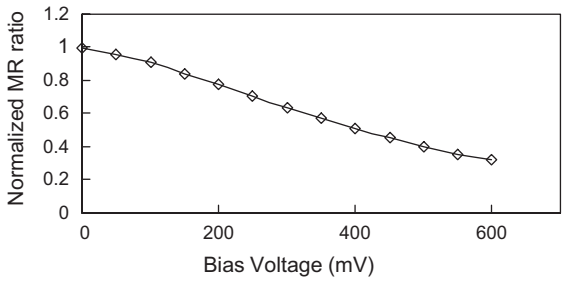

Figure 43. Bias voltage dependence of the MR ratio of an MTJ with the structure Ta20/$Ni_{81}Fe_{19}$20/$Co_{90}Fe_{10}$2/Al(1 nm)-oxide/$Co_{90}Fe_{10}$2/Ni_{81}Fe197/$Fe_{50}Mn_{50}$20/Ta5. Here, the thicknesses are given in nanometers.

In addition to voltage dependence, the MR ratio of MTJ was also found to decrease with temperature [430, 405, 442–446]. According to Shang et al. [442], Hagler et al. [444], and Wingbermühle et al. [445], the temperature-dependent total conductance of an MTJ can be written as

$$G = G_{DI}(T)[1 + P_1(T)P_2(T)\cos(\theta)] + G_{\mathrm{IN}}(T) \tag{44}$$

where $G_{DI}(T)$ indicates the direct tunneling conductance and $G_{\mathrm{IN}}(T)$ represents the spin-independent conductance via localized states, θ is the angle between the magnetizations of the two electrodes, and $P_1(T)$ and $P_2(T)$ are the temperature-dependent spin polarizations. The temperature dependences of $G_{DI}(T)$ and spin polarizations $[P_1(T)$ and $P_2(T)]$ are due to the temperature dependences of Fermi distribution and magnetizations, respectively, and are given by $G_{DI}(T) = CG_0T/\sin(CT)$ with $C = 1.39 \times 10^{-4}d/\sqrt{\phi}$, and $P_1(T) = P_{01}(1-\alpha_1T^{3/2})$, $P_2(T) = P_{02}(1-\alpha_2T^{3/2})$. Here, α_1 (α_2) is a material-dependent parameter, d is the barrier thickness in angstroms, ϕ is the barrier height in electronvolts, and G_0 is the value of $G_{DI}(T)$ at zero degrees Kelvin.

6.5. Applications of MTJ in Read Head

Magnetic tunnel junctions can be used either as read sensors in hard disk drives [447–453] or memory cells in MRAMs. Following are some advantages and drawbacks of MTJs compared to spin valves when they are used as read sensors.

6.5.1. Large Output Signal

For an MTJ sensor element with width W, height H, and thickness T, the maximum output voltage is given by

$$\Delta V_{\mathrm{MTJ}} = \frac{I\Delta RA}{W \cdot H} = J\Delta RA \tag{45}$$

where J is the current density, and ΔRA is the change in resistance–area product of the MTJ. The maximum output voltage refers to the value that is obtained when the magnetizations of the two FM layers are switched from a parallel alignment to an antiparallel alignment or vice versa. The actual output is normally a fraction of this due to the limited dynamic range of the read sensor and the head efficiency factor. In practice, however, the output is limited by the characteristic dependence of JMR on the dc bias voltage, that is [454],

$$\Delta V_{\mathrm{MTJ}}(V) = V_B \cdot \mathrm{MR}_0 \cdot (V_{\max} - V_B)/V_{\max} \tag{46}$$

where V_B is the bias voltage, MR_0 is the MR ratio at zero bias, and $V_{\max}$ is the voltage at which the MR becomes zero. In deriving the above equation, we have assumed that the MR ratio decreases linearly with the bias voltage. The maximum output signal is thus given by

$$\Delta V_{\mathrm{MTJ}}(V_B = V_{\max}/2) = \frac{1}{2}V_{\max} \cdot MR_0 \tag{47}$$

Assume that MR_0 = 5–10% at device level, and $V_{\max}$ = 800 mV; it gives an output voltage of 20–40 mV. On the other hand, the maximum output signal of a CIP spin valve

with thickness T, width W, current density J, and sheet resistance change ΔR_S is given by

$$\Delta V_{SV} = J \cdot \Delta R_S \cdot T \cdot W \tag{48}$$

Using typical values of $J = 1\times10^7$ A/cm^2, $\Delta R_S = 4\ \Omega$, $T =$ 30 nm, and $W = 1\ \mu$m, the maximum output voltage will be given by 12 mV. Of course, the actual output signal for both cases when being used as a read head is much smaller than these values due to the low head efficiency. We can see that the maximum output signal of an MTJ is much higher than that of a typical spin valve. Moreover, the output of the spin valve scales with its width. Therefore, the MTJ head becomes more advantageous than the CIP spin-valve head in terms of output signal when the track width shrinks into the submicron regime, which is already the case in the latest products.

6.5.2. Current-perpendicular-to-plane Operation

As is with the case of CPP GMR sensors, it is possible to remove the insulating gap in the MTJ heads, and thus they are more suitable for higher linear density heads.

6.5.3. Large Junction Resistance

The primary drawback of MTJ is its large junction resistance, in particular, when its size shrinks. The large junction resistance will result in both a small bandwidth and a low SNR of the read signal [455]. For high-frequency operations, the sensor resistance is required to be less than 100 Ω [425]. Figure 44 shows the dependence of the junction resistance as a function of the reader width by assuming that the sensor has a square shape and the resistance–area product is 1 $\Omega \cdot \mu$m^2. Also shown in the figure are the estimated sensor widths for applications at different recording densities. It is clear that the MTJ may not be suitable for read heads at an areal density of more than 200 Gbits/in^2. Jury and Wang reported on a possible approach to extend the bandwidth of the MTJ head using a simple buffer amplifier, which leads to an SNR improvement of 5–10 dB over a no-buffer configuration for frequencies between 100 MHz and 1 GHz, with a slight reduction of SNR at low frequencies [456].

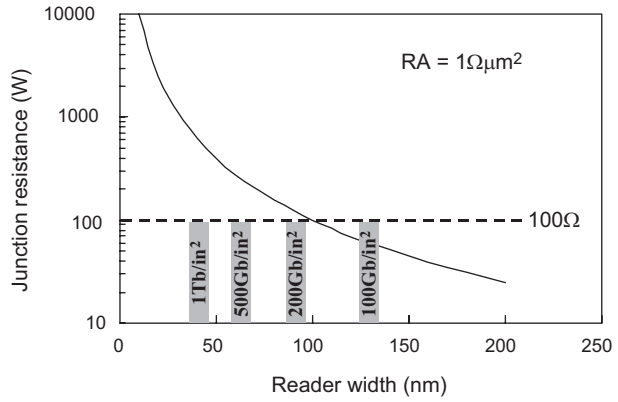

Figure 44. Junction resistance of MTJ as a function of reader width (see text for the assumptions that have been used to calculate the resistance).

6.5.4. Noises in MTJs

In addition to thermal noise, the MTJ also suffers from shot noise which increases with the sensing current [425, 455], $1/f$, and/or telegraph noise [457–461]. This makes the signal-to-noise ratio of MTJ smaller than that of the spin valve, even when the output signal is the same. The shot-noise voltage is given by $V_S = (2eVRB)^{1/2}$, while that of thermal noise is given by $V_{\text{th}} = (4k_BTRB)^{1/2}$. Here, e is the elementary charge of electrons, V is the bias voltage, R is the resistance of the sensor element, B is the bandwidth, k_B is the Boltzmann constant, and T is the temperature. Assuming $V = 400$ mV and $T = 300$ K, one can easily find that $V_S/V_{\text{th}} = 2.8$. The dominance of shot noise in the MTJ was found by Shimazawa et al. in their front flux guide-type magnetic tunnel junction heads [448]. George et al. reported that, depending on the quality of the barrier, the measured value of shot noise in an MTJ can be much lower than that predicted by theory [462]. In tunnel junctions with pinholes, the shot-noise voltage is reduced by a factor of $[R_P/(R_T + R_P)]^{1/2}$, with R_T and R_P the ideal tunnel resistance and the lumped parallel resistance due to the conductive paths of pinholes, respectively. Unfortunately, the decrease of shot noise due to pinholes does not necessarily lead to the increase of SNR because the pinholes also result in a decrease of JMR. Although it is not specific to MTJ, all types of MR heads also exhibit magnetization noise which may exceed the thermal noise when the sensor volume becomes very small [463].

Using the latest MTJ heads, Mao et al. [464] demonstrated an area density of 120 Gbits/in^2. Further optimization in materials, structures, and fabrication processes may improve the MTJ technology further, and render them suitable for higher areal density applications.

7. MAGNETIC RANDOM ACCESS MEMORY

7.1. Introduction

Although spin valves and MTJs have been invented for hard disk drive applications, they have also found important applications in memory devices. Computer memories featuring the following features are always highly demanded: (1) nonvolatility, (2) high density, (3) short cycle time, (4) low-power consumption, (5) low cost, (6) high reliability, (7) infinite lifetime, and (8) radiation hard (for special-purpose applications). A variety of memories have been commercialized. These include DRAM, SRAM, ROM, Flash EEPROM, and FeRAM. However, none of them is able to satisfy all of the requirements. Furthermore, most of these memories (e.g., DRAM) store information using charges; it is difficult to perform down-size scaling once it reaches a certain dimension due to the degradation of SNR. MRAM has been studied intensively as one of the promising candidates to replace some of the existing memories [9–11, 465–473]. In the case of disk drive applications, the spin valves and MTJs are employed as sensors to sense the magnetic fields from the information bits recorded on the hard disks. But when being used as cell elements in memories, the sensors themselves are used to store the information. The basic

structure of the memory cell is still the same as that of the sensor, but in the former case, one makes use of the saturation region of SVs and MTJs rather than the linear region used in read sensors.

7.2. Different Kinds of MRAM Designs

The concept of magnetic random memory itself is not new, but the early magnetic memory did not become popular due to both the drawbacks of its own design and the rapid advances made in semiconductor memories. However, the concept of using two crossed wires to write cells selectively is still applicable to current MRAMs. The key difference between the early magnetic memory and today's MRAM is that the former used an inductive signal to detect the storage state, while the latter utilizes AMR [9], GMR [474–479], or the spin-dependent tunneling phenomenon [10, 11, 299] to detect the signals. This has made it possible to remove the coils from the memory arrays, and at the same time, to increase the readout sensitivity, leading to the miniaturization of the cell elements. The first AMR-based MRAM was developed by Honeywell in the mid-1980s. However, its application was mainly limited to certain niche markets due to its high cost and relatively poor performance attributable to the low MR ratio. With recent advances in GMR and MTJ technologies, renewed interest has arisen in MRAMs since the mid-1990s. Due to the large read/write current and a relatively low SNR of large cell arrays of GMR-based MRAMs, most of the recent works on MRAMs are based on the MTJ design.

Figure 45 shows a schematic of an MRAM design using MTJs and the corresponding cell structure using one MTJ and one transistor per cell. The memory cells are formed at the cross junctions of the bit and word lines. Each memory cell consists of an MTJ for storing the information and a transistor for reading the cell selectively. The transistor can also be replaced by either a diode [480, 467] or can even be removed from the cell, as will be discussed shortly. A typical MTJ cell consists of a pinning layer to pin the reference layer, a storage layer to store the information, and a thin insulator to separate the two magnetic layers. The signal readout is based on the spin-dependent tunneling resistance of the MTJ by supplying a small sensing current to a specific cell. As the sensing current is only used to detect the relative orientation of the magnetization of the two magnetic layers instead of being used to switch the magnetization, it can be kept at a relatively low level. This is in contrast to the readout process of MRAMs using pseudospin valves, wherein larger currents are needed to switch the magnetization of the free layer from one direction to the opposite so as to detect the state of the stored bit (the so-called dynamic readout process).

7.3. Write Operation of MRAM

The write operation can be understood by looking at how a single-domain particle switches under two orthogonal fields, as shown schematically in Figure 46. Assuming that the magnetization switching occurs via coherent rotation, or based

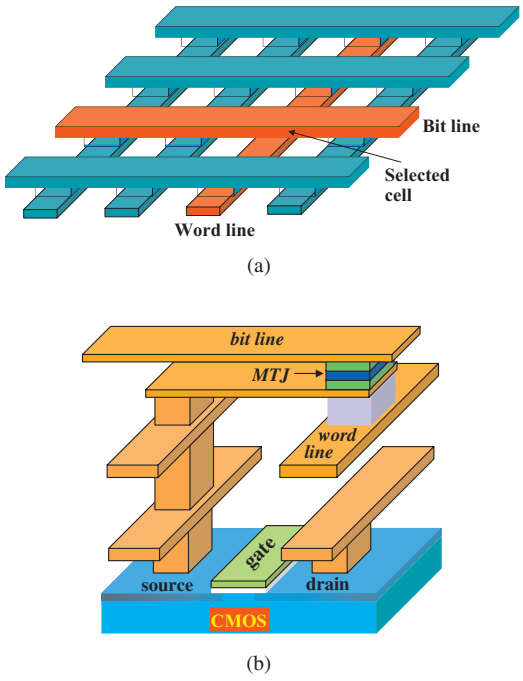

Figure 45. Schematic of the MRAM architecture using MTJ (a) and memory cell design using a transistor and an MTJ (b).

on the so-called Stoner–Wohlfarth (SW) model, the switching field can be obtained through the minimization of the energy density:

$$\varepsilon = -HM_s \cos(\phi - \theta) + K_u \sin^2 \theta$$

where H is the external magnetic field, M_s is saturation magnetization, K_u is the anisotropy energy constant, and θ and ϕ are the angle between the easy axis and M_s and H, respectively. Note that here only the Zeeman energy and the anisotropy energy are taken into account. Minimizing the energy density gives

$$h_\perp = -\cos^3 \theta, \quad h_{||} = \sin^3 \theta, \quad \text{or} \quad h_{||}^{2/3} - h_\perp^{2/3} = 1 \tag{49}$$

Here,

$$h_{||} = H_{||} M_s / 2K_u = \frac{H_{||}}{2K_u / M_s}$$
$$h_\perp = H_\perp M_s / 2K_u = \frac{H_\perp}{2K_u / M_s} \tag{50}$$

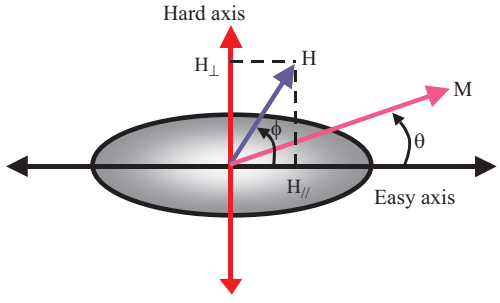

Figure 46. Schematic of the SW model for a single-domain particle.

are the reduced parallel and perpendicular components of the external field. Equation (44) gives an asteroid curve, as shown in Figure 47. To achieve magnetization reversal, the magnetic field vector must be such that its endpoint ends outside the asteroid (point *B*, for example). For some of the points inside the asteroid, although one of the field components is larger than that of point *B*, their magnetizations still cannot be switched. This simple mechanism makes it possible to write the individual cells selectively [481, 482].

In practice, however, the magnetization reversal process of the memory element is much more complicated than what is predicated by the simple single-domain model [469]. The magnetization switching process of rectangular elements is usually unrepeatable due to the formation of edge domains at the flat ends of the element. Elements with tapered ends have been introduced to suppress the formation of the edge domains [483]. Although the switching process becomes relatively repeatable, the tapered ends result in an increase in the switching field. An excellent review of the micromagnetics of MRAM was given by Zhu and Zheng [484]. Using Lorentz transmission electron microscopy, Kirk et al. [485, 486] and Yi et al. [487] found that the switching field of small magnetic elements can either increase or decrease, depending on whether the ends are gently curved or exhibit sharp corners. In element arrays, the magnetostatic interactions among the elements were also found to affect the switching process of individual elements [488, 489]. A unique design that makes the switching process repeatable, and yet is more suitable for ultrahigh-density memory is the vertical magnetoresistive random access memory (VMRAM) [471, 476, 484]. The VMRAM cell consists of a ring-shaped CPP spin valve with two FM layers separated by a nonmagnetic layer. The formation of a stable flux-closure configuration of the magnetization makes the switching process more robust and predictable.

The formation of edge domains is also sensitive to process-related defects in the magnetic element. This was found to result in fluctuations of the switching field among different cells [10]. As one of the examples, Figure 48 shows

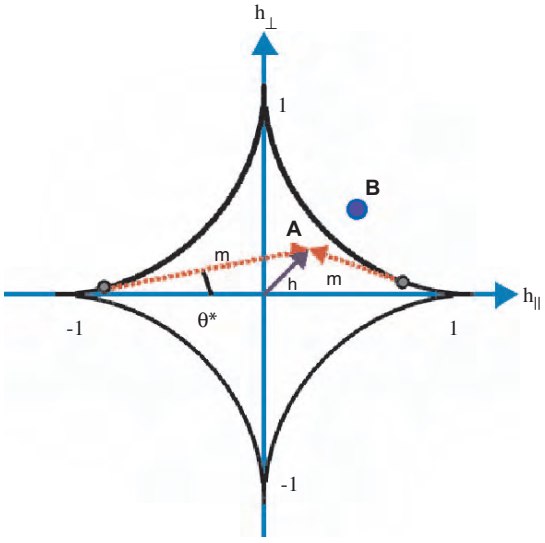

Figure 47. Asteroid curve for a single-domain particle.

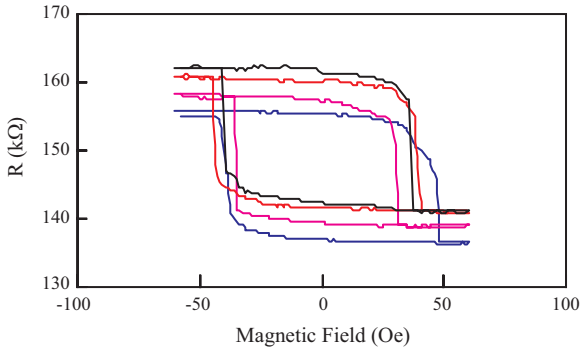

Figure 48. M–H curves of four identical cells with the structure Cr/Cu/Cr/Ta /NiFe /IrMn /CoFe/Ru/CoFe /AlO_x /CoFe /NiFe/CoFe/AlO_x/CoFe/Ru/CoFe/IrMn/Ta.

the *M–H* curve for a double-tunnel-junction MRAM with four cells of the same size fabricated in the author's group. Although they were fabricated using identical processes and were placed one next to another on the same wafer, the switching fields differ from one another. In addition to the fluctuation of switching fields among different cells, the shift of the switching curve along the field axis also requires a large tolerance for the switching current [490]. The latter stems from various magnetic couplings between the free and pinned layer, and thus must be minimized by process optimization. In the case of mass production, how to achieve a narrow distribution for the switching field for millions or billions of cells is a great challenge.

In addition to switching field fluctuation reduction, efforts have also been made to reduce the absolute value of the switching field, which is proportional to the write current. Currently, the write current is about a few milliamperes; it will increase to more than 10 mA when the element size shrinks to less than 100 nm [491]. Tehrani et al. reported that the effective write current can be reduced by covering the word line (Cu wire) with a high-susceptibility soft magnetic layer from all sides but the side that is facing the MTJ cell [492]. Under optimum conditions, it is possible to reduce the write current by a factor of 2–4 [491]. Further reduction of the write current can be achieved by reducing the distance between the word line and the MTJ cells. When the demagnetizing field is taken into account, the switching field of an MRAM cell using MTJ is proportional to the thickness of the free layer and inversely proportional to the size of the cell. Therefore, it is important to keep the thickness/width ratio constant during down-size scaling of the cell. Finally, the write current can also be reduced by reducing the shape anisotropy and increasing the anisotropy of the material itself by using, for example, synthetic ferrimagnets as the free layer [493].

7.4. Read Operation of MRAM

As we mentioned in the beginning of this section, one of the key features of the MRAM is that the information is stored in the relative orientation of the magnetization of two separate magnetic layers rather than in the charged/discharged state of capacitors. Therefore, it is more suitable for scaling down to small structures, at least, in terms of output signal.

As discussed in the MTJ section, the maximum output signal of an MTJ is given by

$$\Delta V_{\mathrm{MTJ}}(V = V_{\max}/2) = \frac{1}{2} V_{\max} \cdot \mathrm{MR}_0 \qquad (51)$$

In principle, it is independent of the cell size, although it may decrease by reducing the size in actual devices. As the MTJs in MRAMs detect the resistance difference between parallel and antiparallel states, the peak-to-peak output voltage is in the range of 120–160 mV, which is much larger than the output voltage of a read sensor. The use of double-tunnel junctions may further boost this value [494]. One of the key concerns in the readout process of MRAMs at the product level is the fluctuation of MR values among the large number of cells. Fortunately, the rapid progress in process development has now made it possible to suppress the fluctuation of MR at an acceptable level. For example, Tehrani et al. reported that the mean value and standard deviation of MR in their particular samples were successfully suppressed to 5 and 1%, respectively, over a 200 mm wafer [492].

7.5. Diode-Free/Multilayer/Multilevel Designs

The existing 1 MTJ/1 T cell design not only makes the MRAM costly, but also makes it difficult to reduce the dimensions of the entire MRAM cell. A switch-free design is much more desirable for fully making use of the advantages of MRAMs [495, 496]. Figure 42 shows an example of such a MRAM design using MTJs. As there is no switching diode or transistor associated with each MTJ, all of the cells are electrically mutually connected, forming a large resistor network. This will reduce the amplitude of the readout signal due to the current-shunting effect, as shown schematically in Figure 49. The author's group has proposed a simple peripheral circuitry to reduce the shunting current [496]. As shown schematically in Figure 50, the simple circuit is basically a voltage follower. It sets an equal electrical potential for adjacent bit lines so as to prevent current shunting to other paths when a selected bit is being read. Although it is only shown here for a 2×2 cell, it can be easily scaled up to large-scale cell arrays without the need to increase the complexity of the peripheral circuit. The effectiveness of this

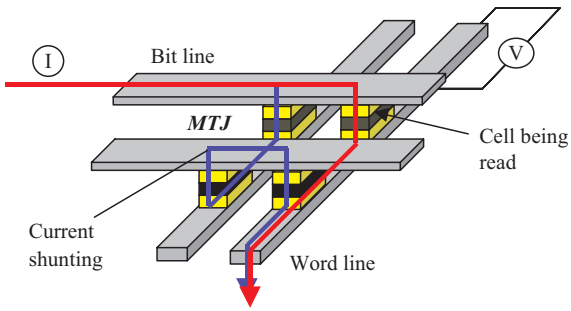

Figure 49. Schematic diagram of a switch-free 2×2 MRAM cell array. When a sensing current is supplied to a selected cell to read out the data, a part of the current is shunted to other cells, resulting in a decrease in the readout signal.

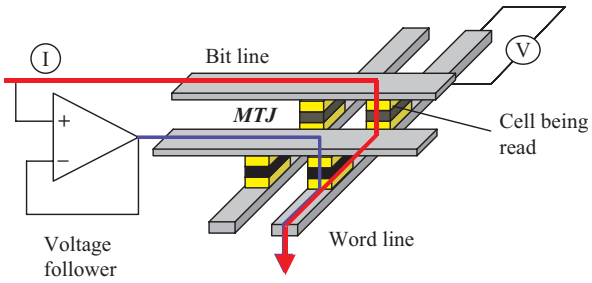

Figure 50. Schematic diagram of a switch-free 2×2 MRAM cell array. A simple peripheral circuitry is used to reduce the shunting current.

method has been verified experimentally [496]. The diode-free design is particularly useful for building multiple-layer MRAMs. In addition to multiple-layer design, multilevel or multistate design also remains as one of the options for realizing gigabit MRAMs in the future [497–500].

7.6. Electrical Field Driven Memory

The MRAM in its present form is intrinsically a current-driven device, at least during writing. The most desirable memory should be the one such that only reading involves current, while writing is based on an electrical field effect. This kind of memory is difficult to be implemented using metallic magnetic materials because their magnetic properties cannot be altered by a static electric field, at least at the moment and under normal conditions. The necessity of generating a magnetic field from a current to switch the magnetization in current MRAMs increases the complexity of the design and manufacture of such devices. Although magnetization switching based on "spin transfer" has been studied extensively, which has the potential to simplify the MRAM design, the current that is needed to switch the magnetization is still comparable to the write current of existing MRAMs [501–508]. Very recently, Zhuang et al. [509] demonstrated the first prototype of an electrical-field-driven RAM using the colossal magnetoresistance effect (CMR). As it is based on the huge change of resistance at two different states, it is also dubbed a resistance random-access memory or RRAM. For a $0.8\ \mu\mathrm{m} \times 0.8\ \mu\mathrm{m}$ cell, the write current was 0.2 mA, which is much smaller than the write current of MRAMs. The RRAM is particularly suitable for multilevel memories due to its large resistance change between two different states (by a factor of 10–1000). Another field which can be explored for creating electrical-field-driven memory devices is magnetic semiconductors. Ohno et al. recently demonstrated electrical-controlled ferromagnetism in (In, Mn)As-based magnetic semiconductors, but so far, it has not been implemented in any form of functional devices [510].

8. SEMICONDUCTOR SPINTRONICS

In this chapter, we have focused on metal-based spintronics and its application in data storage. Another important emerging field is the spintronics that uses nonmagnetic semiconductors, magnetic semiconductors, and metal/semiconductor hybrid structures. A number of device

concepts have been proposed, and some of them have been verified experimentally. These include, but are not limited to: (1) the spin field-effect transistor [511], (2) the spin-valve transistor [512], (3) the magnetic semiconductor tunnel junction [513, 514], (4) magnetic semiconductor diodes [515], (5) the hybrid Hall effect device [516], magnetic tunnel transistors [517], and spin-dependent light-emitting devices [518–520]. The greatest advantage of spintronics using semiconductors is that it can be integrated into the existing microelectronics. Furthermore, it also offers the possibility of controlling the magnetic properties using an electric field, which may lead to novel nanodevices, which is not possible using metal-based magnetic materials. Research activities in semiconductor spintronics have expanded almost exponentially in recent years. An in-depth coverage of this topic is out of the scope of this chapter because we focus on data storage, which at the moment is still dominated by metal-based spintronics. Semiconductor-based spintronic devices may find applications in data storage, but they need to overcome many technical hurdles before they can be used in hard disk drives. This is because most of the semiconductors can only be grown on high-quality crystalline substrates instead of the AlTiC substrates used currently for sliders. Most of the semiconductor epilayers are also too fragile to sustain the various lapping/polishing processes employed in current magnetic head fabrication processes. Therefore, semiconductor-based spintronic devices are more suitable for future memory and logic devices. The latest reviews of semiconductor-based spintronics can be found in [4, 31], and the April 2002 issue of *Semiconductor Science and Technology*.

9. FUTURE TREND OF DATA STORAGE AND THE ROLE OF SPINTRONICS

Most of the existing data storage devices can be categorized into three major groups: electronic, magnetic, and optical devices. The electronic storage devices store the information using charges. Therefore, the absolute number of electrons that are used to store one bit of information matters because it will determine the SNR of the readout signal. To this end, various types of capacitance enhancement techniques have been developed, such as bottle-shaped deep trenches, hemispherical grains, and three-dimensional structures over the bit line. In addition to the innovation in designs, efforts are also being made to develop suitable high-K capacitor dielectrics. In the field of flash EEPROMs, multibit and multilevel technologies are also being introduced to increase the storage capacity.

Optical storage, on the other hand, has the most diversity among all kinds of data storage devices. This is because, as shown schematically in Figure 51, light as an electromagnetic wave carries more information than its static counterpart of electrical and magnetic fields. Depending on which parameter in the electrical field expression that is used to read or store the information, various types of optical data storage technologies have been developed, and some of them have been commercialized. These include: (1) read-only memory (ROM), (2) phase-change (PC) disk, (3) magnetooptical (MO) disk, (4) multiple-layer storage, (5) holographic

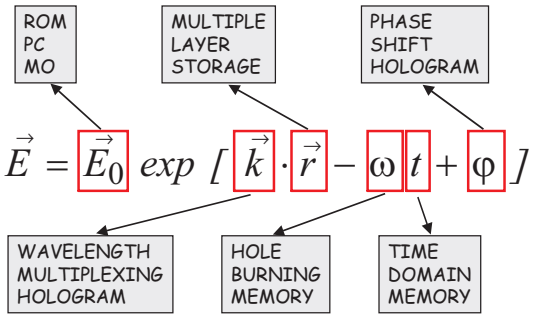

Figure 51. A wide range of optical data storage technologies that has been developed using the different properties of light waves.

data storage, (6) hole-burning memory, and (7) time-domain memory. The wave nature of light makes it possible to realize the storage of information in real space [(1)–(4)], reciprocal space [(5), (6)], and the time domain. If we focus only on real space recording, the areal density of optical storage is limited physically by the fact that a certain number of photons are required to reproduce the information with an acceptable SNR. When the bit becomes very small, the number of photons that come back from a tiny bit is limited by the intensity of the light, which is in turn determined by the damage threshold of the storage medium. Of course, in practice, the areal density of real space optical recording is largely determined by how small one can focus the laser spot into and, at far field, it is determined by the diffraction-limited performance of the optical system. Although near-field optics can reduce the spot size to a certain extent, it is still insufficient to compete with the state-of-the-art magnetic recording devices.

The magnetic storage devices which have been the focus of this chapter store the information using the spin of electrons. Although the output of CIP sensors scales with the size of the information bit, the output of CPP sensors including MTJ is relatively insensitive to the size of the sensor. However, even for the latter, the SNR scales inversely with the bit size. Therefore, the areal density of magnetic recording will be limited either by the SNR or by the thermal stability of the bit, whichever gives the lower density. Although large ballistic magnetoresistance has been obtained in magnetic nanocontacts [521, 522], one still has to find a way to convert it into a useful sensor for read heads, in particular, the linearity and low-field requirements.

If the bit size of all of these different types of storage devices keeps shrinking, it will eventually approach the size of atoms. When we reach that stage, we will probably have to seriously look at the information storage in reciprocal space. As mentioned above, the concept of reciprocal space recording has already been explored in optical data storage. A similar concept should also be explored in charge- and spin-based memories. This will lead to the general concept of quantum information storage. Nanometer-scale spintronics is expected to play a bridging role to bring the classic data storage into the quantum information storage era (see Fig. 52).

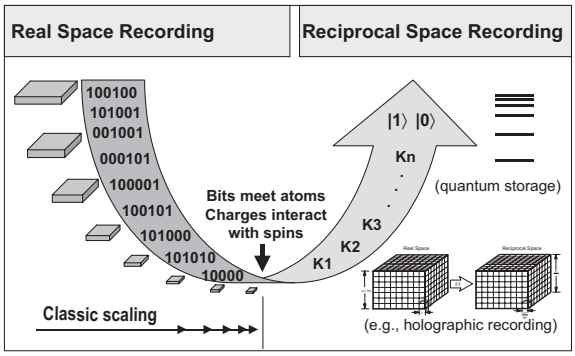

Figure 52. Future trend of data storage.

GLOSSARY

Anisotropic magnetoresistance (AMR) A phenomenon that describes the variation of the resistance of a single piece of magnetic material when it is subjected to an external field.

Current-in-plane GMR Magnetoresistance for the case that when the current is parallel to the film plan.

Current-perpendicular-to-plane GMR Magnetoresistance for the case that when the current is perpendicular to the film plan.

Giant magnetoresistance (GMR) A phenomenon that describes the variation of the resistance of a laminar structure of magnetic and nonmagnetic materials when it is subjected to an external field.

Magnetic data storage A data storage device or system that stores information by the relative orientation of the magnetization of localized regions of a storage medium.

Magnetic nanostructures Magnetic materials/structures with a size comparable to those of domain wall or Fermi wavelength of electrons in one or more spatial directions.

Magnetic random access memory (MRAM) A nonvolatile memory whose storage cell is a magnetic tunnel junction.

Magnetic semiconductor A semiconductor with ferromagnetism.

Magnetic tunnel junction (MTJ) A triple layer of magnet/insulator/magnet whose resistance is dependent on the relative orientation of the magnetizations of the two magnetic electrodes when electrons tunnel through the barrier.

Nanomagnetism Magnetism at nanometer scale.

Nanotechnology A frontier in the multidisciplinary field of physics, chemistry, biology, and engineering which allows one to design and fabricate materials, devices, and systems at atomic and molecular level.

Non-volatile memory A memory that maintains the information stored when the power is off within a certain time period.

Read sensor A device that is used to read the information from the storage medium by detecting the magnetic fluxes changes from the magnetic transitions.

Real space recording Information storage devices or systems which store information in real space.

Reciprocal space recording Information storage devices or systems which store information in K or energy space.

Spintronics Electronics that makes use of both the charge and spin degrees of freedom of electrons.

Spin-valve A triple layer consists of a hard magnetic layer, a non-magnetic spacer, and a soft magnetic layer whose resistance is dependent on the angle between the magnetization directions of the two magnetic layers. When being used at low fields, the magnetization of the hard layer is considered "fixed" while that of the soft layer is free to respond to the change of the external field.

ACKNOWLEDGMENTS

The author is grateful to the members of the Nano Spinelectronics Group at the Data Storage Institute, especially Dr. Kebin Li, Dr. Jinjun Qiu, Dr. Yuankai Zheng, Dr. Zaibing Guo, Dr. Guchang Han, and Ms. Luo Ping for their assistance with some of the experimental data. He is also grateful to Dr. Li Wang and Mr. Yatao Shen for their assistance with some of the literature survey work. He would also like to acknowledge the support of Prof. Chong Tow Chong, Dr. Thomas Liew, and Dr. Chang Quan Teck.

Nanostorage

Jooho Kim

Samsung Electronics, Suwon, Korea

CONTENTS

1. INTRODUCTION

For terabyte memory that will be necessary after five–ten years in the information industry, nanostorage may be the most promising solution, together with three-dimensional memory using a hologram method. In general, nanotechnology means a technology able to make a structure below the 100 nm scale with good efficiency. It is defined that nanostorage also means information storage of nanometer scale, which has below 100 nm data bits. In order to retrieve the below 100 nm data bits, we should use near-field optics or surface plasmon phenomena with a current optical system. First, as a typical method, a superresolution near-field structure will be described. Next, we will give an account of an electrical nanostorage method. Other technologies such as scanning near-field optical microscopy (SNOM), solid immersion lens (SIL), magnetic amplifying magneto-optical system (MAMMOS), and heat-assisted magnetic recording (HAMR) for nanostorage also will be explained briefly. Although each technology has a potential, it is thought that a terabyte memory may be achieved much faster through the fusion of these technologies.

2. NANOSTORAGE BY SUPERRESOLUTION NEAR FIELD

A near field represents the electromagnetic field near the surface of a fine probe, a hole, or scattering center such as silver (Ag), gold (Au), aluminum (Al), and so on. Near the surface, there exist very short wavelength components, compared with that of incident light. These short-wavelength components are able to retrieve the signals below the resolution limit. Through conventional far-field optics, we can write and retrieve the signal just within the resolution limit, $\lambda/(4 \cdot \mathrm{NA})$, where λ is the laser wavelength and NA is the numerical aperture of the optical system. From current study of a system of 405 nm (λ) and 0.85 (NA), we can write and retrieve around 150 nm mark length signals by a phase-change media storage system, that is the so-called Blu-Ray disk [1]. This resolution limit theory is also applied to a magneto-optical storage system. Basically, we cannot retrieve signals of below 100 nm from a current optical system. Therefore, methods using an SIL and an SNOM have been studied for retrieving magneto-optical (MO) signals by near-field coupling thus far. By the SNOM near-field technology, it has been reported that signals below 100 nm can be retrieved [2–8]. Recently, the superresolution technique combined with the near field also has been introduced [9, 10]. This system has been studied with phase change recording materials such as GeSbTe, AgInSbTe, and surface plasmon near-field signals have been analyzed by the reflectivity difference caused by the phase change. Within a superresolution near-field (SRNF) structure, a specially designed mask layer is partially changed to a transparent (Sb) or light-scattering center ($\mathrm{Ag} + \mathrm{O}_x$) by laser heat distribution. This partially changed area of the mask layer generates an aperture-type (Sb) near field or a scattering center (surface plasmon)-type (AgO_x) near field. In this section, we introduce a variety of recording systems in the superresolution technique combined with the near field. First, we will discuss whether magneto-optical signals also keep their Kerr

Encyclopedia of Nanoscience and Nanotechnology
Edited by H. S. Nalwa
Volume 7: Pages (545–552)

polarization feature in the surface plasmon near field, and can be applied to the superresolution near-field structure. As another topic, the reactive diffusion recording mechanism and its superresolution technique using a near field is described in order to improve the resolution limit. The superresolution near-field structure medium has the almost same principle and results in both a magneto-optical and a phase change medium. Results using typical magneto-optical media will be described in the next section.

2.1. Magneto-Optical/Phase Change Nanostorage

In MO disks, magnetic superresolution (MSR) and MAMMOS techniques have been proposed with special readout and recording magnetic layers consisting of GdFeCo and TbFeCo [11, 12]. And it has been reported recently that a transparent aperture (Sb)-type superresolution near-field structure MO disk can also enhance the signal intensity of the below resolution limit [13]. Moreover the light-scatter-center-type (AgO_x) superresolution near-field MO disk overcomes the theoretical resolution limit, and can retrieve signals up to a 100 nm mark length. A carrier-to-noise ratio (CNR) at a mark length of 150 nm, which is below the resolution limit, is more than 20 dB compared to 0 dB in conventional disks. This means that the Ag particles or their clusters generated in AgO_x film can enhance MO signals by approximately 100 times those of the conventional MO disks, and a nonmagnetic light-scattering center can conserve the polarized MO signals. This optical mask layer for near-field retrieval is nonmagnetic, but has optically nonlinear characteristics. The basic structure of a typical AgO_x superresolution disk is composed of six layers: dielectric ($ZnS–SiO_2$, 60 nm)/mask (AgO_x, 15 nm)/dielectric ($ZnS–SiO_2$, 25 nm)/recording (TbFeCo, 25 nm)/dielectric ($ZnS–SiO_2$, 25 nm)/reflective (Ag, 50 nm) layers. All films are deposited by RF magnetron sputtering with the composite targets, except for the AgO_x film. The AgO_x film is produced by RF-reactive magnetron sputtering using a pure Ag target and a gas mixture of oxygen (O_2) and argon (Ar).

To obtain the superresolution near-field effect in MO disks, we determine the characteristics of the superresolution near-field MO disk with an AgO_x mask film at different readout powers [13]. Signal enhancement is obtained up to a 100 nm mark length at a high readout power of 3.0 mW. In contrast, the same disks do not show any signal enhancement at a low readout power of 1.0 mW. This suggests that the AgO_x layer changes partially to heat-generated Ag by strong laser heat, as reported by Tominaga et al. [14]. Although a MAMMOS technique can amplify crescent-shaped domains of 80 nm breadth, MO signals from circular magnetic domains with a size of 300 nm cannot be enhanced by applying MAMMOS [15]. However, it has been reported that the circular domains can be detected by near-field coupling up to less than 100 nm using an optically nonlinear AgO_x mask layer. The circular shape can be confirmed using a magnetic-force microscope (MFM) [13]. In MAMMOS, the length of the crescent-shaped magnetic domains in the radial direction is usually about five times more than that of the breadth. It is thus difficult to increase the radial recording density. On the other hand, the marks recorded with the superresolution near-field technique are circular, and the area density is much larger than that in MAMMOS. To examine the wavelength effect, authors measured the signal intensities of one sample disk using two different disk drives with a wavelength of 680 nm (NA 0.55) or 405 nm (NA 0.65). In the case of a 680 nm wavelength, they could read out up to a 170 nm mark length. On the other hand, in the case of a 405 nm wavelength, the resolution was up to a below 100 nm mark length. On the basis of this result, a shorter wavelength also retrieves much smaller marks in near-field optics. It has also been reported that the conservation ability of a polarized MO signal in an AgO_x light scattering type is much higher than that of Sb transparent aperture-type superresolution near-field MO disks from carrier to noise ratio (CNR) comparison.

To reveal signal enhancement by the light-scattering center in superresolution near-field disks, the electric-field intensity has been estimated using Sb and AgO_x as the mask layer by computer simulation with a finite-differential time-domain (FDTD) method, as shown in Figure 1 [13]. The light-scattering center and transparent aperture were assumed as an Ag particle and as an Sb amorphous transparent aperture. The aperture and scattering center were fixed at 200 nm in this simulation. It has been reported that the z component of the electric field of the light-scattering center (AgO_x) is about 20 times stronger than that of the transparent aperture (Sb) underneath the mask layers. This result agrees with the experimental results, although polarization components of the MO layer are not considered in this simulation. As is well known, a surface plasmon only appears under some conditions at the interface between a metal and a dielectric material. In order to generate the surface plasmon effectively, we have to use a total reflection method, or gratings, or a rough surface in general [16]. Shalaev describes that the aggregated Ag particles or their clusters with a size range of $\sim$100 nm may also generate plasmons, resulting in huge local-field enhancements of optical nonlinear factors in some special sizes and its fractal dimensions [17]. The strong electric-field enhancement, in some cases, can be up to 10^{10}, which is four orders magnitude larger than the average for the unique film. The enhancement effect was actually observed as surface-enhanced Raman images by NSOM. On the other hand, by the refractive-index evaluation of AgO_x in recent work, the index is shifted from its initial AgO_x (mostly Ag_2O) with $2.5+1.5j$ to a more Ag-rich state with $0.7+3.7j$ as the readout power is increased, generating a light-scattering center. The Ag-rich local phase may be compatible with the localized states of Ag mentioned by Shalaev [17]. It should be noted that the electric field returned or transmitted from superresolution near-field structure disks is partly polarized. This effect plays an important role for signal preservation in superresolution near-field MO signals, although details are not clear at the moment. It has been confirmed that the 100 nm MO signal can be retrieved by the superresolution near-field effect with a light-scattering center (AgO_x), and it has been found that the nonmagnetic layer can conserve the Kerr polarization. The results indicate the possibility to enhance the resolution of MO circular signals further, up to less than a 100 nm mark length.

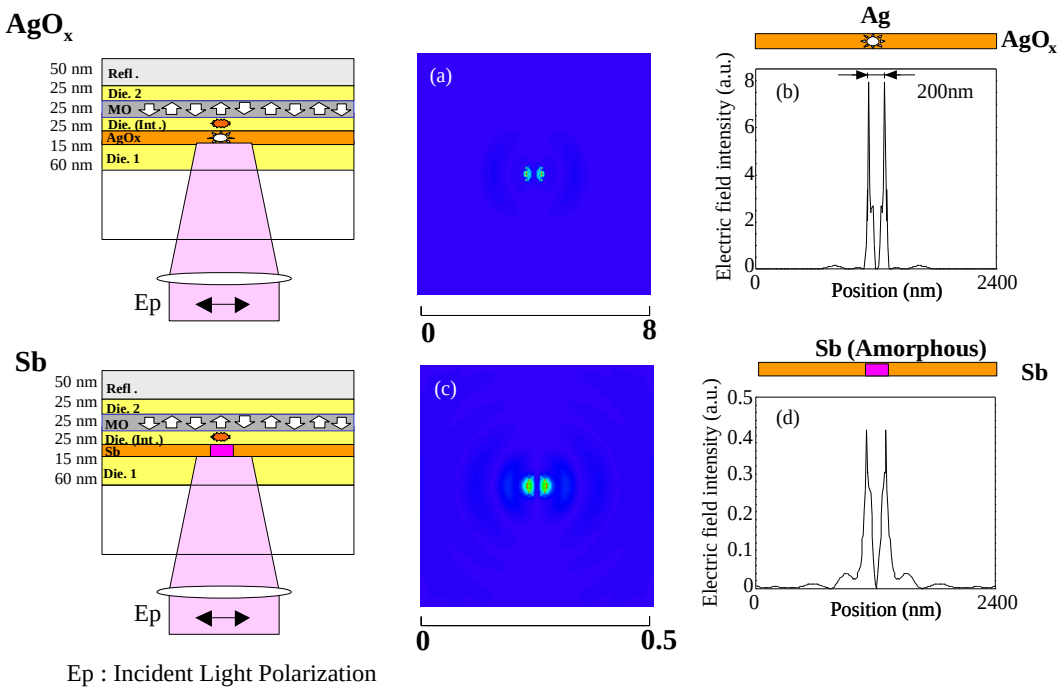

Figure 1. Electric fields of z components beneath mask layers calculated by FDTD. (a) Near-field distribution scattered in the X–Y plane of superresolution near-field structure using AgO_x film and (b) field intensity. 2.2. Thermal Reactive Diffusion Nanostorage

The recording mechanism of MO data storage is magnetization reversal by an external magnetic field and laser heat (thermomagnetic recording), which results in magnetic Kerr and Faraday rotation of incident light [18]. In contrast, phase change (PC) recording uses the transformation from the amorphous to crystalline phase by external laser heat, which results in a reflectivity change [19]. To achieve terabyte capacity data storage, a superresolution near-field structure has been proposed, and succeeded in retrieving signals less than 100 nm mark length using an AgO_x (light-scattering center type) or Sb (transparent aperture type) mask layer [20, 21]. As a recent result, it has been proposed to carry out reactive recording by applying a rare-earth transition metal (RE–TM) for making the nanostorage, and the reaction process and mechanism have been reported. [22]. To elucidate the mechanism, authors examined the optical constants, magnetic, and thermo-optical properties. In this section, a reactive recording with RE–TM and application to optical data storage will be described for 50 nm nanostorage.

The structure has been designed by considering the crystallization of RE–TM and the reaction between RE–TM and dielectric layers. To reveal the reaction process and mechanism, the thermo-optical property of the RE–TM samples having a three-layer structure sandwiched between ZnS–SiO_2 dielectric layers has been examined. The transmittance of the as-deposited and 783 K heated samples greatly changed from 400 to 1300 arbitrary units; the difference was about 900. This behavior is similar to a completely oxidized RE–TM single-layer sample. In the case of the phase change recording material (PC, GeSbTe) sample, the difference was just 150. Comparing the as-deposited sample to the 873 K heated sample, optical constants of RE–TM film at a 633 nm wavelength, n, k (refractive index: n, extinction coefficient: k) were changed from 3.3, 4.0 (as-deposited) to 2.2, 0.3 (873 K heated), respectively. This means that the sample becomes almost transparent. It is thought that the above change is related to the crystallization and reaction of RE–TM. It has been reported that RE–TM is first crystallized to α-TM and α-RE, and then followed by crystallization of the intermetallic compound of RE–TM in amorphous RE–TM film [23]. It is supposed that the reaction includes both the sulfuration and oxidation of RE–TM (mainly sulfuration). It has been reported that sulfur in ZnS–SiO_2 is easily released, and diffuses into a PC (GeSbTe) recording layer by external heat, then significantly changes the optical constants [24, 25]. Oxidation of amorphous RE–TM has also been mentioned by several researchers; the preferential oxidation is of a Tb atom (strong affinity for oxygen) and an oxidation reaction with SiO_2 dielectric layers of RE–TM [26–28]. It is thought that the crystallization of amorphous RE–TM film occurs predominantly during the range of the first step (573–763 K) as a result of a slow increase of transmittance. In the region of the second step (763–783 K), the thermal-activated reaction of the film seems to occur predominantly as a result of the rapid increase of transmittance. An attempt was also made to obtain the activation energy for the transition from Kissinger's formula ($\ln(A/T_t^2) = E_a/k_B T_t + C$), where A is the heating rate, T_t is the transition temperature at heating rate A, and k_B is the Boltzmann constant [29]. The activation energy for the transition of the sample was

about 2.31 eV, which is similar to the 2.51 eV of the GeSbTe phase change material [30]. There is no large increase of transmittance in an RE–TM film sandwiched with Si_3N_4 dielectric layers with increasing temperature. This means that free sulfur and nonbridging oxygen (NBO) within RF-sputtered ZnS–SiO_2 dielectric layers plays an important role in the reactive recording of an RE–TM film [31]. Examining the photograph taken by a transmission electron microscope (TEM), it has been found that the RE–TM thin film is crystallized and reacted; the RE–TM layer is diffused into ZnS–SiO_2 dielectric layers, and volume expansion occurred in the 783 K heated sample. Authors have also investigated the magnetic properties of the samples to confirm the reacted state of the RE–TM film. The magnetic properties (coercivity: *Hc*, magnetization: *Bs*) of the heated-sample (873 K) sandwiched with ZnS–SiO_2 dielectric layers were the same as those of completely oxidized RE–TM film. The heated sample (873 K) sandwiched with Si_3N_4 dielectric layers, however, kept the magnetic properties (lower *Hc* and larger *Bs* than those of the as-deposited sample). From this result, it has also been confirmed that the oxidation reaction of the RE–TM recording layer occurs with increasing temperature. All of these reactions make it possible to store nanoscale data bits of around 50 nm.

Figure 2 represents the basic apparatus for optical storage and characteristics of the sample. The RE–TM recording layers have been applied to a superresolution near-field structure disk, and compared with a PC superresolution near-field structure disk with an AgO_x mask layer. The CNR (24 dB) of the sample disk by RE–TM (MO) reactive recording was twice as high as the result (12 dB) of the PC superresolution near-field structure disk for 100 nm mark length signals. Examining the spectrophotometer results, it was found that the samples of three-layer structure have a similar large reflectivity change (20%) in the blue laser region (405 nm), compared with 23% in the red laser region (635 nm) between as-deposited and 873 K heated samples. It is thus thought that we can apply the sample disks to the blue laser drive system as well as the red drive system, and we can expect to have better CNRs in the blue laser drive system. Current results using a blue laser (405 nm) system reveal the 50 nm signal retrieval, which has 15 dB CNR.

3. NANOSTORAGE BY REACTIVE ELECTRICAL CIRCUIT

The concept that nanometer level devices perform the basic functions of digital electronics may be realized by means of a variety of techniques, such as experiments based on monomolecular devices [32], molecular junctions [33, 34], electrodeposition of nanoparticles [35], and nanolithography [36]. In this section, we will introduce the attainment of complete electrical nanodevices based on the Hall effect through a thermal-activated reaction between rare-earth transition metal and dielectric material, using a nanosecond laser pulse or nanoresolution electron beam reactive electrical circuit (REC) method [37]. A physically mixed phase structure by cosputtering with RE–TM and dielectric material, which shows a metallic conductivity (above $10^3\ \Omega^{-1} \cdot cm^{-1}$) in less than 10% ZnS–$SiO_2$ composition, was used in order to generate the whole homogeneous reaction. The thermal-activated reaction and the interdiffusion related to a sulfuration and an oxidation of RE–TM [22] result in an outstanding change of electronic transport properties. The resistivity of the mixed structure samples is steeply altered by a magnitude of about 10^3 according to the increase of the reaction temperature, which may be strongly related to the previous thermal-activated reaction (Fig. 3). This result suggests that an electrical insulator and a conductor can be fabricated by controlling the reaction temperature. The 773 K heated sample decreases the resistivity with

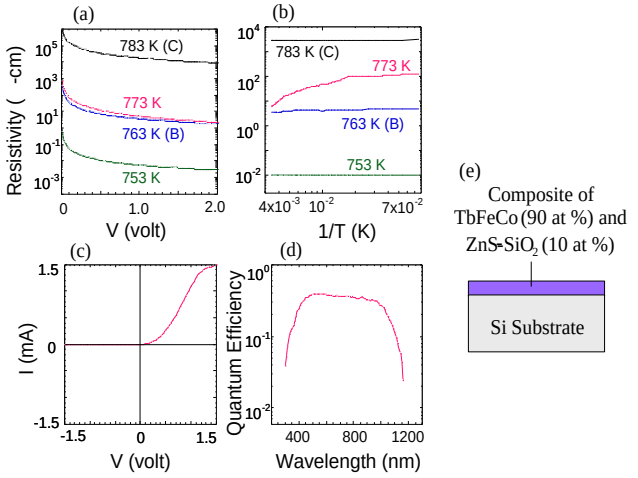

Figure 3. Electronic transport properties. Substrates in (a), (b) plots are quartz, and those in (c), (d) are Si wafer. (a) Effect of heating temperature on resistivity. (b) Temperature dependence of resistivity $R(T)$: the voltage was measured at a fixed current of around 0.1 μA. (c) I–V curve of the 773 K sample on an Si substrate (p-type). (d) Wavelength dependence of quantum efficiency: the cell size is 7×7 mm^2, and incident photons are 4.53×10^{13}/cm^2. (e) Structure and materials of the reactive semiconductor sample. Reprinted with permission from [37], J. H. Kim et al., *Appl. Phys. Lett.* 80, 2764 (2002). © 2002, American Institute of Physics.

increasing temperature like a typical semiconductor, while the other samples do not show such a behavior. A notable distinction among the samples is the degree of the oxidation, sulfuration, and diffusion of Fe, Co. In order to confirm the semiconductor properties more precisely, samples were prepared on an Si substrate, and the *p–n* junction characteristics were measured. The *I–V* (current–voltage) curve of the reacted sample at 773 K on Si substrate (*p*-type) shows a clear characteristic of the *p–n* junction diode, where V_F (forward voltage) is around 0.3 V. The quantum efficiency of the sample on Si substrate (*p–n* junction) as a photodiode is about 0.4 in the range of 450–1000 nm wavelength. This means that semiconductor devices such as a photodiode and a solar cell [38, 39] can be fabricated by the above simple thermal-activated reactions (Fig. 3).

The transparent thermal-activated reaction areas with a circular and line shape were confirmed by an optical microscope (transmittance mode) photograph. In the case of the circular shape, about a 50 nm size reacted dot was obtained, using an optical system with a laser wavelength (λ) of 405 nm and a lens numerical aperture of 0.65. The semiconductor or insulator sections are obtained by controlling the laser beam power intensity. The result represents the possibility of 50 nm dot or line fabrication. Moreover, if an electron beam is applied to the fabrication, it is expected that the 5–10 nm dots or lines [36] will be obtained by the above reaction.

A nanoelectronic device can be fabricated using the above reactions and the Hall effect. The Hall field $(\mathbf{E_H})_y$ [40] is the electric field $(\mathbf{j} \times \mathbf{B})_y$, developed across two faces of a (semi-) conductor when a current $\mathbf{j_x}$ flows across a magnetic field $\mathbf{B_z}$. By combining the incident current and external perpendicular magnetic field in the sample memory cell, an electronic signal will be put in storage within the semiconductor or condenser (insulator) area [37]. Authors, thus, have suggested that a 2.5×10^9–2.5×10^{11} (2.5–250 G) bit/in^2 capacity of flash memory or DRAM can be fabricated by means of the nanosecond laser pulse or electron-beam-induced reaction by some beam intensity profile control. A variety of devices, like a DRAM, flash memory, Hall element, *p–n* diode, and metal–oxide–semiconductor (MOS) transistor, may be fabricated with the combination of the insulator, semiconductor, and metal areas by controlling the electron beam or laser power intensity whose temperature can be calculated by computer simulation and actual experiments [41]. The results in this technology indicate the potential of a thermal-activated reaction to fabricate a variety of electronic devices for nanostorage.

4. NANOSTORAGE BY SCANNING NEAR-FIELD OPTICAL MICROSCOPE

Betzig and coworkers have tried to record and retrieve nanometer scale magneto-optical signals by an SNOM [42–45]. They obtained a 60 nm magneto-optical domain, which is equivalent to a 100 Gbit/in^2 areal density. An argon ion laser was used for reading and writing. A neutral density filter was placed in the read beam so that read powers were below the threshold for modifying the written bits. An acousto-optic modulator (AOM) switched the write beam on and off for selectively writing patterns into the film. Retardation plates were used to control the polarization state of the light at the aperture since the MO reading is strongly polarization dependent. The Faraday effect causes the input light to be rotated as it traverses the samples, with the direction of rotation dependent on the magnetization of the sample in any particular region (Fig. 4).

The sample was ten multilayers of alternating 4 Å Co and 10 Å Pt sputter coated onto a glass substrate. This material was sufficiently ferromagnetic to result in a permanent magnetization that will allow for observation of the Faraday effect. In this case, application of an external field is not necessary, and the polarity of the permanent magnetization can be modified locally to write bits into the sample. The SNOM was also used to write MO bits using the probe. By increasing the input power, the temperature of the sample immediately beneath of the tip was raised to the Curie temperature, which might be roughly 300 °C. This allows the magnetization of this heated region to switch its polarity to the opposite of its surrounding areas. For an input power up to 4.5 mW, no domain is formed. The authors suggest that either the power is too low for the sample to be heated near the Curie temperature or the heated region is too small to form a stable magnetic domain. They have succeeded in a domain formation of 60 nm size at higher powers such as 6.0–8.0 mW.

Authors have suggested that the bit density may increase to up to 100 Gbit/in^2 by using cleaner films (reducing bit errors) and using applied magnetic fields to increase the contrast, which is equivalent to 60 nm magnetic domain mark storage. Although the contrast mechanism responsible for the near-field writing process is not completely clear, the authors were convinced that it is an MO effect [42], that is, that it involves a rise to the Curie temperature and a flipping of the magnetic domain: whether through a thermal or an optical effect. Although write speeds in these experiments are limited to ~10 kHz, the authors suggest that ~10 MHz/channel may be possible. Obvious improvements to this technique might involve better film surface cleanliness and decreased fly height (to below 10 nm), in keeping with current directions in magnetic storage research. As a technique used with SNOM, but with potentially significant benefit to SNOM data storage, Betzig et al. also introduced the fiber laser probe [46]. With this probe, output power equivalent to about 10^{14} photons/s was achieved through tuning of the boundary conditions at a tapered near-field aperture that served as the back reflector of the fiber laser cavity. This represents an improvement of

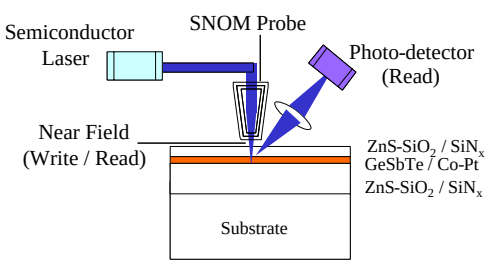

Figure 4. Schematic diagram of SNOM system and structure.

about three–four orders of magnitude over the photon output of conventional probes. Of particular importance in the present application are the higher read speeds that should result.

5. NANOSTORAGE BY SOLID IMMERSION LENS

The SIL has been introduced as a near-field instrument of optical microscopes, as shown in Figure 5. Terris and coworkers have utilized an SIL configuration for implementing near-field high-density MO data storage [47, 48]. The resolution limit of classical optics is inversely proportional to the numerical aperture (NA) of the optical system. Thus, increasing the NA decreases the distance between distinguishable features. Although the SIL approach appears to have a fundamental density limit, it has a benefit in significantly faster read and write rates that are much closer to those of the current MO technique. And although this SIL technique presents a near-field alternative to the SNOM methods for improving the density of MO data storage, significant obstacles remain. Perhaps most troubling is the necessity to provide a practical method of rapid flying lens above the MO medium at a height that keeps the lens in the near field of the medium, that is, ~50 nm. The authors suggested that if this could be accomplished, use of higher index SILs and shorter wavelength sources might result in 100 nm signal data retrieving [47, 48].

Kishima et al. [49] have developed a near-field optical storage using a superhemispherical SIL [47] in an attempt to improve the recording density. Therefore, in combination with a blue–violet light source of 405 nm wavelength, an areal density of over 50 Gbit/in^2 (80 nm bit signal) is expected. In the realization of near-field data storage, precise control of the air gap between the optical head and the recording medium is important, as described above. Authors have achieved active control of the air gap by developing a capacitance air-gap servo method detection of electrostatic capacitance by forming an electrode on the bottom of the SIL, and controlling the optical head position by mounting it on a two-axis actuator [50]. Furthermore, adopting a 1 mm diameter miniature SIL resulted in a lightweight lens unit and an improved servo bandwidth. The developed optical head had satisfactory optical characteristics, and enabled reading and writing with 80 nm bit signals. A phase change material, that does not required an external magnetic field, was used as a recording medium. Generally, the phase change medium consists of GeSbTe recording material sandwiched between dielectric ZnS–SiO_2 materials. In their work, near-field recording using the phase change medium with a land and groove structure was verified, and 80 nm mark storage was also confirmed with a TEM observation, a result which is equivalent to 50 Gbit/in^2 data storage.

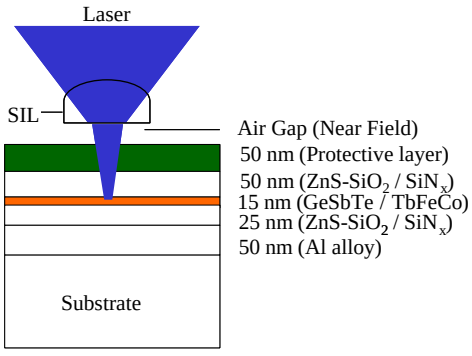

Figure 5. Structure and materials for SIL nanostorage.

6. NANOSTORAGE BY MAGNETIC AMPLIFYING MAGNETO-OPTICAL SYSTEM

Magneto-optical storage possesses a very great advantage of high-density recording compared to nonmagnetic optical storage because MO recording is almost the same as a perpendicular magnetic recording. However, the high-density recording below a 100 nm data bit is recorded by very tiny domains, so the readout MO signal decreases, and correct data reproduction becomes impossible. In order to amplify the small MO signal, MAMMOS technology has been proposed [51, 52]. The readout layer (GdFeCo) and recording layer (TbFeCo) were prepared by a magnetron sputtering process on a polycarbonate substrate of 1.2 mm thickness. Both magnetic layers were separated with nonmagnetic intermediate layers (SiN_x). The Curie temperature (T_c) and compensation temperature (T_{comp}) of the GdFeCo are about 350 °C and room temperature, respectively. Also, the corresponding values for the TbFeCo layers are about 270 °C and room temperature. The external field (H_e) in the expanding direction makes the size of the copied domain in the readout layer (GdFeCo) increase up to the same size as the laser spot. In this process, the readout signal is amplified to the signal saturation level, and is retrieved as shown in Figure 6 [51].

Authors have tried to detect much smaller MO domains than a 100 nm size. Pulse-width signals of a recording field from 20 to 100 ns were applied to a MAMMOS medium. These values can be estimated as a recording domain length of 20–100 nm since the disk linear velocity was 0.8 m/s. The signal waveform of the MAMMOS disk with a lower readout power and 200 Oe readout field shows a clear MO signal in the 20 nm domain, and the signal intensity is almost saturated. From this result, it was confirmed that a 20 nm length magnetic domain can be reproduced clearly, although the data transfer rate is a little late [53].

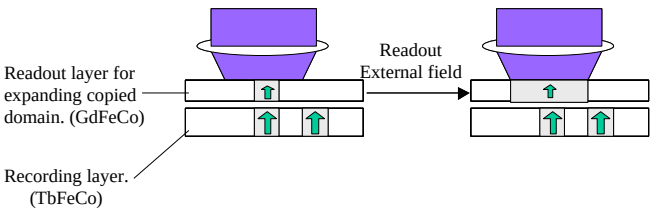

Figure 6. Domain expansion of MAMMOS disk.

Table 1. Basic characteristics of a variety of nanostorage methods.

	SRNF	REC	SNOM	SIL	MAMMOS	HAMR
Minimum bit length	50 nm	50 nm	60 nm	80 nm	40 nm × 80 nm	50 nm
Areal density	250 Gbits/in^2	250 Gbits/in^2	100 Gbits/in^2	50 Gbits/in^2	200 Gbits/in^2	250 Gbits/in^2
Hardware (application)	Next DVD	DRAM flash memory	Next DVD, MO	Next DVD, MO	Next MO	HDD
Principle	Near field	Hall effect	Near field	Near field	Amplifying domains	Heat-assisted magnetic recording
Materials	MO/PC	RE–TM	MO/PC	MO/PC	MO	Magnetic
Issue point	Signal intensity	Mass production	Head–media spacing	Head–media spacing	Data-transfer rate	Head/magnetic material

7. NANOSTORAGE BY HEAT-ASSISTED MAGNETIC RECORDING

To assure the thermal stability of the magnetic data, the medium must satisfy $K_uV/k_BT > 70$, where K_u is a uniaxial anisotropy constant, V is the isolated grain volume, k_B is Boltzmann's constant, and T is the ambient temperature [54]. This is commonly termed the superparamagnetic limit. A higher density (smaller bit cells) requires a larger media anisotropy, which in turn requires a large coercivity. The coercivity of the high-density medium approaches the maximum field that can be generated by conventional recording heads. It has been suggested that the superparamagnetic limit can be overcome by heating the media optically to momentarily reduce the coercivity of the media during recording. Very small aperture lens (VSAL) and SIL technologies have been suggested for generating extremely small spots [55–57]. The aperture in the shape of a rigid waveguide is deposited onto the end facet of a semiconductor laser. The waveguide is operated above cutoff, but FDTD calculations indicate that the rigid constriction amplifies the field in the center of the waveguide. A bow-tie antenna, in some sense the complement of the rigid waveguide, has also been proposed as a means for concentrating the field at the center of the antenna gap [58, 59]. This HAMR technology combined with above technologies has already demonstrated a magnetic spot size below 100 nm in hard disk storage technology [60]. Recently, using a giant magnetoresistive (GMR) head, a tunneling magnetoresistive (TMR) head, and perpendicular recording, it was reported that 250 Gbits/in^2–1 Tbit/in^2 would be able to be achieved [55, 61].

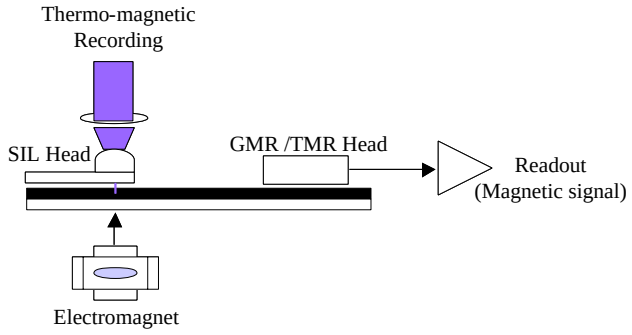

Figure 7. Recording and readout system of HAMR.

8. CONCLUSIONS

The basic characteristics of a variety of nanostorage methods are summarized in Table 1. Each technology has its originality and potential for terabyte memory or nanostorage, and is expected to be developed in three–five years. Although these technologies also have problems of commercialization due to the difficulties of a nanometer-scale mechanical control or a signal process of near-field light, a terabyte nanostorage actually should be introduced into the storage industry in five–seven years. At that time, all storage technologies may be fused into one, including the hard disk medium, which may be called a fusion memory or a synthesis memory using plural technologies.

GLOSSARY

Faraday and Kerr effects When polarized light transits through a magnetized material (Faraday effect) or reflects on the surface (Kerr effect), the polarized direction is altered by the effect of the magnetization.

Giant magnetoresistive (GMR) head Head perceiving the variation of electric resistance according to the magnetization direction of media. This head is designed to utilize a giant magnetoresistive phenomenon.

Hall effect An electric field is generated when a current flows across a magnetic field on a (semi-) conductor's two faces. The generated electric field is called the Hall field, and this phenomenon is called the Hall effect.

Optical mask layer Thin-film layer that became different optical constants by a laser intensity or a thermal reaction.

Superparamagnetic limit Magnetic-material size limit that changes from a ferromagnetic to a superparamagnetic material. Below the limit, ferromagnetic material loses its remanent magnetization in the state of no applied field (impossible to store magnetic data).

Surface plasmon near field (Localized) surface plasmon occurs by the vibration of free electrons on the tip of a metal probe as being irradiated by a laser or light. In this case, if the tip diameter is several tens of a nanometer, a spot size of several tens of a nanometer can be formed with much stronger light intensity on the near the tip, although incident light has a wavelength of several hundreds of a nanometer.

Tunneling magnetoresistive (TMR) head Head perceiving the variation of electric resistance according to the

magnetization direction of media. This head is designed to utilize a tunneling magnetoresistive phenomenon.

Nanostructured Carbide-Derived Carbon

A. Nikitin, Y. Gogotsi

Drexel University, Philadelphia, Pennsylvania, USA

CONTENTS

1. INTRODUCTION

Carbon is a fundamental building block of material in living organisms. Carbon is present in all organic substances and a whole class of materials—polymers—is based on carbon compounds. Pure elemental carbon has been one of the most important inorganic materials for a long time. Carbon is the only element that has a major monthly scientific journal named after it which publishes papers on carbon materials only (*Carbon*, published by Elsevier Science). One of the reasons for this is that carbon exists in four different allotropes—graphite, diamond, fullerene, and carbine—which have numerous applications. Moreover, diamond and fullerenes have journals dedicated to them (*Diamond and Related Materials* and *Fullerene Science and Technology*). The recently discovered carbon nanotubes are the most important building blocks in nanotechnology and are considered to be the strongest fibers known. It is amazing that carbon materials can cover the whole range of properties that scientists and engineers need. For example, diamond is the hardest material known (microhardness of above 100 GPa) and is used to make cutting tools, while graphite is one of the softest materials (microhardness is about 1 GPa) and is used as a solid lubricant. While diamond is a wide-band-gap semiconductor, graphite is a good electrical conductor. Carbon nanotubes can have the conductivity of copper (metallic single-wall nanotubes) or silicon (semiconducting single wall nanotubes). In addition to the known carbon allotropes, amorphous or disordered carbons form a whole new class of materials for which all properties, such as electrical conductivity, hardness, wear resistance, gas permeability, optical transparency, and many others, can be finely tuned by controlling the sp^2/sp^3 carbon ratio, porosity/density, size and ordering of nanocrystals, and inclusions of various allotropic forms of carbon and other elements.

There are many ways to produce carbon materials. Very high temperatures are typically required for the synthesis of ordered graphite because of the very low mobility of carbon atoms in its covalently bonded layers. Diamond is produced either at high pressures or by using plasma and other high-energy activation techniques. Fullerenes and nanotubes are manufactured in plasma as well. Chemical vapor deposition (CVD) is currently a common method for synthesis of thin and thick films of diamond, disordered graphitic carbon, and nanotubes. Many porous and disordered carbons, including carbon fibers and activated carbons, are made by thermal decomposition of organic compounds. The age of nanotechnology requires new methods that enable engineers to control the growth of carbon materials at the atomic level, provide better structural control, and have the capability to produce novel carbon structures such as nanotubes, onions, nanocrystalline diamond or nanoporous carbon with a narrow pore size distribution for gas storage, batteries, supercapacitors, and other applications.

It has previously been shown that selective etching of carbides is an attractive technique for the synthesis of various carbon structures [1]. Carbon produced by extraction of metals from carbides is called carbide derived carbon (CDC). Leaching in supercritical water, high-temperature treatment in halogens, vacuum decomposition, and other methods can be used to remove metals from carbides to produce carbon coatings or bulk and powdered carbon. Linear reaction kinetics has been demonstrated for the chlorination of SiC [2] which allowed transformation to any depth up to the complete conversion of the particle or component to carbon. CDC demonstrated a variety of carbon phases depending on experimental conditions. Amorphous and nanocrystalline graphitic carbon [3], nanotubes [4], carbon onions, nanocrystalline diamond [5], and ordered graphite have been reported. Thus, this method allows the synthesis of almost every carbon allotrope. Since the carbide lattice is used as a template and metal is extracted layer by layer, atomic-level control can be achieved in the synthesis

process. The structure of the carbon can be templated by the carbide structure, with the opportunity for further structural modification by controlling the temperature, environment, and other process variables. An important advantage of the CDC process over CVD or physical vapor deposition (PVD) for coating synthesis is that the transformation is conformal and does not lead to change in the carbide sample size and shape. This may be of particular importance in nanotechnology, when nanometer range accuracy must be achieved.

Significant progress in CDC synthesis has been achieved over the past decade, but no review of the carbon synthesis by extraction of metals from carbides has been published. This chapter presents a summary of the work done in this exciting area that shows various approaches to CDC synthesis (leaching by supercritical water, halogens, salts, and decomposition in vacuum), analyzes similarities and differences between different techniques, and describes the variety of structures produced, their applications, and the potential of this method for producing new carbon structures with useful properties.

2. SELECTIVE ETCHING OF CARBIDES BY HALOGENS

2.1. Chlorination of Carbides for Production of Chlorides

A manufacturing process based on the reaction of silicon carbide with chlorine gas was reported in 1918 for the first time [6]. Hutchins patented a method for the production of silicon tetrachloride using the reaction

$$SiC + 2Cl_2 = SiCl_4 + C \quad (1)$$

The reaction was conducted by passing dry chlorine over silicon carbide heated to a temperature of 1000 °C or above. For this purpose a resistance furnace, illustrated in Figure 1, was developed consisting of a vertical cylindrical shell with a carbon heating rod inside it. The main product of the reaction, silicon tetrachloride vapor, passed through the outlet pipe into a condenser. Residual carbon, considered to be "in the form of graphite," was disposed. An improvement of this method was patented in 1956 [7]. In order to remove carbon without cooling off the reactor, air was periodically blown through it to remove carbon in the form of gaseous oxides CO and CO_2. This method has been used for the commercial production of $SiCl_4$.

Treatment of other metal carbides in the chlorine gas was used for the purpose of producing corresponding metal chlorides. Therefore, the kinetics of chlorination for titanium and niobium carbides [8] and zirconium carbide [9] was studied. The reactions

$$MeC + x/2Cl_2 = MeCl_x + C \quad (2)$$

where $x = 4$ when Me = Ti, Zr and $x = 5$ when Me = Nb, were conducted in a quartz tube flow reactor in a temperature range of 600–800 °C in the case of TiC and NbC and 450–950 °C in the case of ZrC. Samples were produced by hot-pressing the carbide powders. Reaction rates

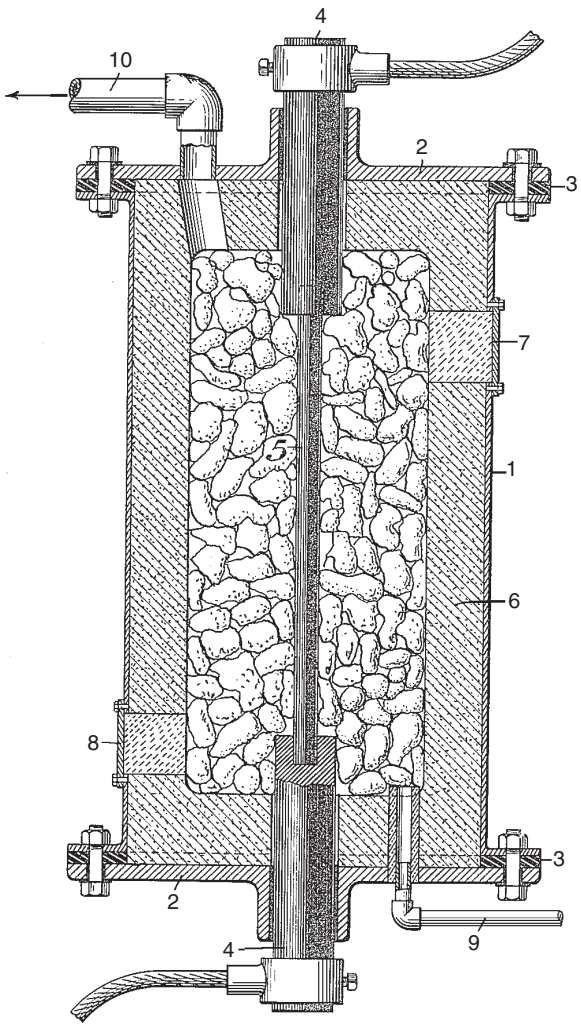

Figure 1. Vertical furnace for the silicon tetrachloride production [6]. (1) Steel shell; (2) head; (3) insulating gasket; (4) carbon terminal; (5) carbon resistor rod; (6) shell lining; (7) opening; (8) opening; (9) inlet pipe; (10) outlet pipe.

were monitored by measuring the weight loss and the amount of formed chlorides. Carbon formed on the surface of the samples in the course of the reaction was considered to be porous graphite or a carbonaceous "cinder." This layer did not affect the reaction rate at 400 °C but at higher temperatures the diffusion resistance was considerable. In the case of niobium carbide, the chlorination rate at 600 °C was higher than at 800 °C. This phenomenon was initially attributed to increased adhesion of the carbon layer to the carbide surface, but our recent work shows that it should primarily be attributed to changes in the CDC structure. For some carbides, the mechanism of the interaction with chlorine and the composition of reaction products may change with temperature. Therefore, it is important to understand the thermodynamics of the reactions of carbides with halogens.

2.2. Thermodynamic Simulations

Thermodynamic simulations were performed to predict the equilibrium composition of the chlorination products for a number of carbides [10, 11]. Calculations were done using

Gibbs energy minimization software in the temperature range from 300 to 1300 °C. The initial systems included carbide and chlorine gas with optional addition of hydrogen and oxygen at various pressures and carbide/gas molar ratios.

The calculations were done for a closed system with constant total pressure: the solid phase was treated as a mechanical mixture of compounds with unit activities and the gas phase as a mixture of ideal gases. It was found that carbon formation is expected as a result of halogenation of SiC, TiC, ZrC, V_2C, NbC, Nb_2C, TaC, Ta_2C, Cr_3C_2, Mo_2C, MoC, W_2C, WC, BaC_2, CaC_2, SrC_2, Al_4C_3, B_4C, and Fe_3C (see Fig. 2). In the SiC–Cl_2(g) system, reaction (1) is most favorable. At higher temperatures (above 900 °C) probability of $SiCl_3$(g) formation increases. In the SiC–Cl_2(g)–H_2(g) system the predicted amount of carbon is somewhat lower than that in the SiC–Cl_2(g) system and it decreases with increasing H_2:Cl_2 ratio. The maximum equilibrium amount of carbon is obtained around 800 °C (see Fig. 2a). At increased pressure, the temperature at which the carbon content in the reaction products is maximized increases. A small addition of oxygen leads to the formation of silica but does not affect the relative amounts of other species in the system. The calculations are generally in good agreement with experimental results. We have conducted thermodynamic simulations for interactions of a variety of carbides with chlorine and other halogens as well as halogen-containing gases such as HCl and HF. It may be concluded that a very large number of carbides can be used for CDC synthesis.

2.3. Effect of Halogenation Techniques on Properties of CDC

CDC did not attract the attention of researchers before 1959, when Mohun introduced "a fourth class of amorphous carbons" along with the three known ones (hard carbons, soft carbons, and carbon black) [3]. The term "mineral carbons" was proposed for carbons formed by chlorination of inorganic carbides, whose corresponding chlorides are volatile, followed by elimination of the residual chlorine, to distinguish them from carbons of organic origin. Unlike the latter, whose composition also includes substantial quantities of hydrogen and other elements, CDC was claimed to be real elemental amorphous carbon. Chlorination of silicon, aluminum, boron, titanium, and zirconium carbides as well as zirconium carbonitride was conducted in the temperature range from 150 °C for ZrC · ZrN to 1650 °C for SiC. Reactor tubes were made of quartz or mullite and provided with an external electric heater. Due to the strong exothermic effect of the reaction and the substantial size of the samples (20–250 g) the temperature of the sample was rather difficult to control. After the chlorination process was finished, the carbon samples were cooled in an atmosphere of chlorine or dry nitrogen. Then the samples cooled in the chlorine atmosphere were treated to remove chlorine.

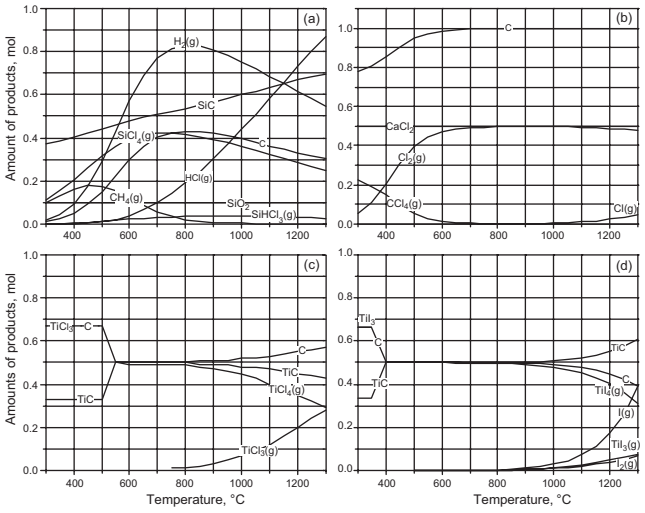

Figure 2. Examples of calculated equilibrium composition for the carbide/halogen systems at ambient pressure. Initial compositions: (a) Cl_2 (0.9 mol)–H_2 (1 mol)–O_2 (0.1 mol)–SiC (1 mol); (b) Cl_2 (1 mol)–CaC_2 (0.5 mol); (c) Cl_2 (1 mol)–TiC (1 mol); (d) I_2 (1 mol)–TiC (1 mol).

Mohun extended his study and eventually patented the new materials and the process of their production [12, 13]. Methods employed for the dechlorination of the CDC samples were described in detail and included heating in the static air, heating in a gas stream (air, nitrogen, water vapor, and carbon dioxide), vacuum dechlorination, and wet dechlorination with the use of various washing solutions. Chlorine content in the samples was monitored by measuring weight loss during dechlorination and the pH of the aqueous suspension. It was found that passing nitrogen or another gas over the sample heated to 150 °C at atmospheric pressure provided rapid and complete dechlorination. Of considerable importance are the chlorides which remain trapped in the carbon when the reaction is complete. It was shown that they are readily removed by any cyclic fluctuation in temperature or pressure carried out at the same time as dechlorination. Some physical and chemical properties of the CDC reported in these patents are summarized in Table 1. Another interesting property of this CDC was the absence of measurable paramagnetic electron spin absorption. This distinguishes CDC from organic chars in which the free radicals are trapped during the carbonization of organic matter.

The chlorination setup used in this study is a common setup for heat treatment of solid samples in the flowing gases. A version of the apparatus is presented in Figure 3.

2.4. Nanoporous Structure and Adsorption Properties

The porous structure and molecular sieve properties of CDC were first investigated by Boehm and Warnecke in 1975 [14]. Carbon samples were prepared by treatment of tantalum and silicon carbides in flowing chlorine at 500 and 900 °C respectively. Completeness of the reaction was confirmed by the disappearance of the X-ray diffraction (XRD) reflexes of the original carbides. The samples from TaC were then heat-treated at various temperatures.

The adsorption isotherms of CDC were measured for N_2 at −196 °C, for CO_2 at −79 and 0 °C, and for a variety of organic adsorptives at 25 °C. All the isotherms were of type I in the Brunauer classification, which indicates a nanoporous structure in the CDC samples under study. There is a maximum in the N_2 uptake for CDC from TaC after

Table 1. Properties of CDC from SiC [12, 13].

	Temperature of chlorination (°C)	1050	1200	1650	1050	825

heat treatment at 1450 °C. The low capacity of the carbon prepared at 500 °C was explained by the presence of tantalum pentachloride, which blocked a considerable part of the pore volume. However, our experience shows that the very small pore size can limit applicability of the sorption techniques for analysis of CDC produced from transition metals carbides at ~500 °C. The maximum pore volume accessible to N_2 in CDC after heat treatment at 1450 °C was 0.644 cm^3/g and this is in excellent agreement with the theoretically calculated value of 0.645 cm^3/g. Evaluation of the CO_2 isotherms of the CDCs heat-treated in the range 500–1100 °C gave a maximum pore volume of 0.273 cm^3/g.

Adsorption of organic vapors (benzene, tetrachloromethane, toluene, and α-pinene) demonstrated strong molecular sieve effects for CDC from TaC heat-treated above 1500 °C. It was possible to separate low molecular weight gases using CDC from SiC treated in hydrogen at 800 °C, proving it to be suitable for gas chromatography. For example, O_2, N_2, CO, and CO_2 could be separated with a 1 m column at 30 °C; CH_4, C_2H_2, C_2H_4, and C_2H_6 were separable at 100 °C.

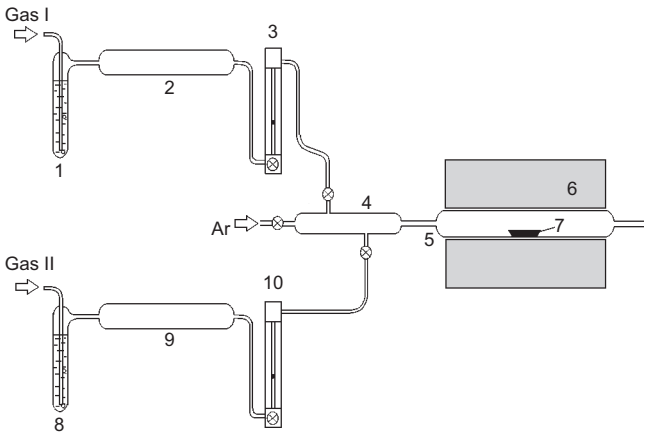

Figure 3. Schematic of a laboratory chlorination setup. (1, 8) Sulfuric acid; (2, 9) desiccant; (3, 10) flowmeter; (4) mixing column; (5) fused silica reaction tube (3–8 cm in diameter); (6) resistance furnace; (7) sample.

The porous structure and adsorption properties of CDC from silicon carbide and carbides of the transition metals of IV–VI groups were systematically studied by Fedorov et al. in the early 1980s [15–18]. Three forms of silicon carbide (green and black α-SiC and β-SiC, no temperature indicated) [15]; titanium carbide in the temperature range 500–1100 °C [16]; carbides of zirconium, hafnium, vanadium, niobium, tantalum, chromium, and molybdenum at 700 °C; and tungsten monocarbide, WC, at 1100 °C [17] were treated in flowing chlorine in a quartz tube reactor. Vapors of bromine and iodine were used in addition to chlorine for etching zirconium carbide [18]. Completeness of the reaction was determined by the measuring weight loss during the process and by the amount of carbide in the sample.

The porous structure of the obtained CDCs was studied by a combination of pycnometric, mercury-porosimetric, and sorption methods. Theoretical values of the apparent density δ were calculated (assuming that no shrinkage of the samples occurred during the chlorination process, which was confirmed by electron microscopy) using the formula

$$\delta = dA \tag{3}$$

where d is the carbide density and A is the mass fraction of carbon in the carbide. Theoretical total pore volume V_Σ was calculated on the basis of the given pycnometric density of carbon ($d_C = 2.00$ g/cm^3) by the formula

$$V_\Sigma = \frac{1}{\delta} - \frac{1}{d_C} \tag{4}$$

It was found that the theoretical δ and V_Σ values are generally in satisfactory agreement with the experimental data, provided the porosity of the initial carbide granules is accounted for.

According to the IUPAC definition, porosity in solids is classified by pore size [19]:

(i) pores with widths exceeding about 50 nm are called *macropores*;
(ii) pores of widths between 2 and 50 nm are called *mesopores*;
(iii) pores with widths not exceeding about 2 nm are called *micropores*.

We use the designation *nanopores* for the pores of ≤2 nm because this term reflects their actual size more properly.

Sorption analysis was carried out with the use of benzene vapor as an adsorptive. The isotherms were of type I in the Brunauer classification, characterizing these carbons as nanoporous adsorbents. The sole exception was CDC from molybdenum carbide, which had developed mesopore volume. This was explained as a result of the atomic ratio between metal and carbon which is twice that of other transition metal carbides. The isotherms were evaluated using Dubinin's theory of the volume filling of nanopores. The characteristic energy of adsorption, which is the principal parameter used to describe nanoporous structure, of the CDCs in question was comparable to that of the best activated carbons.

The temperature dependence of the porous structure of CDC from TiC is of particular interest [16]. It was shown that the sample produced at 500 °C had a higher apparent density, which was explained by presence of titanium tetrachloride's occupation of a significant part of the pore volume. Virtually equal values of total pore volume were observed for the samples produced at 700, 900, and 1100 °C while the pore size distributions were different; the mesopore volume increased with increasing chlorination temperature as a result of three-dimensional ordering of turbostratic carbon structures. The mesopore volume measured by benzene adsorption and mercury porosimetry (pores of equivalent radius 3–200 nm) is presented in Figure 4. This is evidence that CDC produced at 1100 °C had a part of mesopores of equivalent radius less than 3 nm.

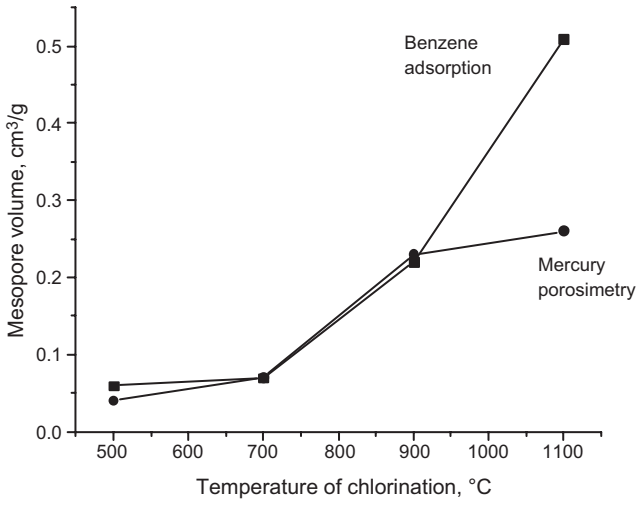

Figure 4. Mesopore volume of CDC from TiC [16].

The temperature dependence of the porous structure of CDC produced from TiC in the presence of 3d-transition-metal catalysts was obtained in [20]. Titanium carbide samples were chlorinated for 1 hour over the wide temperature range of 400–1200 °C. Pure TiC samples as well as TiC with the addition of a mixture of cobalt and nickel dichloride and ferric chloride were treated. The specific surface area, S_{BET}, was calculated using BET theory from the data of nitrogen sorption at −196 °C; the nanopore volume W_{na} was determined by measuring dynamic benzene adsorption at room temperature (see Table 2).

The chlorination of aluminum carbide and the properties of carbon materials produced thereby were reported in [21, 22]. The nitrogen sorption isotherm of a low temperature carbon (300 °C) was of a type I in the Brunauer classification, indicating this sample has a nanoporous structure. The isotherms of materials produced at 500–900 °C were of type IV, which indicates the presence of mesopores [19]. Total pore volume (V_Σ), average pore size according to BJH theory, specific surface area according to BET theory, and nanopore volume using *t* plots were calculated. The results are summarized in Table 3.

The porous structure of CDC from ZrC depends on the nature of the reacting halogens as was shown in [18]. Equal values of total pore volume consisting purely of nanopores were found by measuring benzene adsorption in the samples prepared by treatment in chlorine, bromine, and iodine at 800 °C. At the same time their sorption capacities for halogens differed significantly. The highest capacities for bromine and iodine adsorption were observed to correspond to CDC samples prepared by bromination and iodination respectively. It was considered as evidence that the porous structure of CDC was "imprinted" by the size of the halogen and the evolving zirconium tetrahalogenide molecules.

Fedorov summarized his experimental results [15–17] with the addition of previously unpublished data in 1995 [23] (see Table 4). CDC samples from boron and uranium carbides and single crystals of titanium, zirconium, and niobium carbides were produced by chlorination at 700 °C. It is notable that CDC from single crystals absolutely did not have macroporosity, distinguishing it from carbons produced from sintered and powder samples of carbides having initial porosity of 6 to 16% vol. This means that the original macropore volume of sintered carbides did not change during the chlorination process and can be controlled by controlling the

porosity of the carbides. The total volume and characteristic dimensions of meso- and nanopores can be predicted and achieved by the selection of proper binary or ternary carbide and variation of the chlorination process parameters. This statement is illustrated with the example of CDC produced from a number of TiC–HfC solid solutions of variable composition. The linear dependence of the total pore volume and characteristic energy of benzene adsorption on composition is shown in Figure 5.

A systematic study of the significance of the initial carbide porosity on the porosity of the corresponding CDC was reported [24, 25]. Four dense pyrolitic carbides produced by CVD from $MeCl_4$(g)–CH_4(g)–H_2(g) (Me = Si, Ti, Hf, and Zr) were treated in chlorine gas at 600–1100 °C [24]. As in the case of CDC from single-crystal carbides, the CDC materials from pyrolitic carbides were completely nanoporous, and the experimental values of apparent density and total pore volume were in good agreement with theoretical ones. The data on the porous structure of these materials are also presented in Table 4. The porous structure of the carbon materials prepared by chlorination of silicon carbide with various initial porosities was investigated in the work [25] and is presented in Table 5. The authors concluded that the uniformity of the pore size and shape makes CDC a good model system for the investigation of the sorption process in nanopores. Eventually, these CDCs were used for a study of the association of water molecules in nanopores [26, 27].

The average pore sizes for some materials described in [23] were calculated in the review by Gordeev [28] and data on specific surface area are given in Table 6.

The calculation of the porosity of CDC in the general case for the reaction

$$Me_kC_l + kp/2nCl_2 = k/nMe_nCl_p + lC \qquad (5)$$

was carried out in the theoretical work [29]. It was found that the total pore volume per unit volume is equal to

$$V_V = d(1-\varepsilon_0)\left(\frac{1}{d}\frac{\varepsilon_0}{1-\varepsilon_0} + \frac{\alpha}{d} - \frac{\alpha}{d_C}\frac{lM_C}{M}\right) \qquad (6)$$

where V_V is the total pore volume per unit volume (cm^3/cm^3), ε_0 is the total pore volume of the initial carbide, α is the fractional conversion of reaction (6), and M_C and M are the molecular masses of the carbon and carbide.

A novel method for the production of nanoporous carbon articles of any shape having sufficient mechanical strength was developed by Gordeev et al. [30–32] and Fedorov et al. [33]. In this method, an intermediate blank of metal carbide having a porosity in the range of 30% to 50% by volume is formed in the desired shape. The blank is then impregnated with carbon as a binder by exposing it to a gaseous

hydrocarbon mixture at a temperature exceeding the decomposition temperature of hydrocarbons (700–1000 °C) until the mass of the blank increases by 10%–25% due to the formation of pyrocarbon. The blank is then thermochemically (900–1100 °C) treated in gaseous chlorine. A nanoporous structure is formed during removal of volatile chlorides of the carbide-forming elements according to reaction (5). In a variation of the method, the silicon carbide blank may be impregnated with liquid silicon, with which the hydrocarbon mixture interacts to form a secondary silicon carbide. Removal of the free and bonded silicon in the form of silicon tetrachloride occurs during the following thermochemical treatment. The porous structure of the prepared carbon articles was studied by the hydrostatic weighing method to determine total pore volume and apparent density, and by measurement of benzene adsorption in saturation conditions to determine the nanopore volume. The specific surface area was determined by evaluating nitrogen adsorption isotherms at −196 °C according to the BET and Langmuir theories. The obtained data are presented in Table 7. Typical pore size distribution in a composite material prepared using TiC is illustrated in Figure 6 [32].

It was shown that macroporosity developed in the course of the formation of the carbide–pyrocarbon composite remained unchanged after thermochemical treatment in the chlorine environment [33]. Thus, adsorbents with a controlled diporous structure were produced. The influence of pyrocarbon content on the porous structure and physical properties, including resistivity, heat conductivity, and compression strength, was systematically studied [34] for

the CDC–pyrocarbon composites prepared from SiC. The dynamics of adsorption of benzene vapor by the CDC–pyrocarbon composites prepared from Mo_2C was investigated in [35]. Based on the results, a capillary-condensation mechanism was proposed for this process. A study of the capillary impregnation dynamics showed that the amount of liquid benzene passed through a unit cross-section of the material is proportional to the square root of time [36].

2.5. Analysis of CDC by X-Ray Methods, Electron Microscopy, and Raman Spectroscopy

In Mohun's work [3, 12, 13], graphitization degree (i.e., average size of graphite crystallites) of the CDC was determined by means of XRD. Significant graphitization was only observed in samples obtained at higher temperatures. The diameter of crystallites in the sample produced from SiC at 1650 °C was about 4 nm. The graphitization degree also depended on the duration of the chlorination process: samples produced at 1050 °C (24 hr) and 825 °C (630 hr) demonstrated the same graphitization degree. CDC samples produced at lower temperatures were completely amorphous and showed absolutely no diffraction pattern.

The structure of CDC was also investigated in the early work [37] by XRD. CDC for that study was produced in the course of neutron activation analysis of silicon carbide [38]. β-SiC was treated in flowing chlorine in a quartz tube reactor at 1200–1250 °C. Some samples were slowly cooled after the chlorination and stored for several months prior to XRD measurement. Debye–Scherrer films of them showed only the diffuse rings typical for amorphous substances. Another sample of CDC prepared for XRD was fresh (2 days old) and was rapidly cooled after chlorination in a stream of cold nitrogen. Debye–Scherrer films showed, in addition to the diffuse rings, a number of spotty lines of which most were identified as β-SiC. The samples were easy to break under the touch of fingertips, while the quenched samples were hard and brittle. It is notable that the size and shape of the bodies did not change during the reaction.

L_a and L_c values for heat-treated CDC from TaC were calculated from the corresponding XRD patterns in [14].

Table 7. Properties of CDC–pyrocarbon composites.

Apparent density (g/cm^3)	0.7–0.87
Total pore volume (% vol.)	55–80

Compressive strength (kg/cm^2)	92–102
Carbon content (% mass)	99.1–99.6

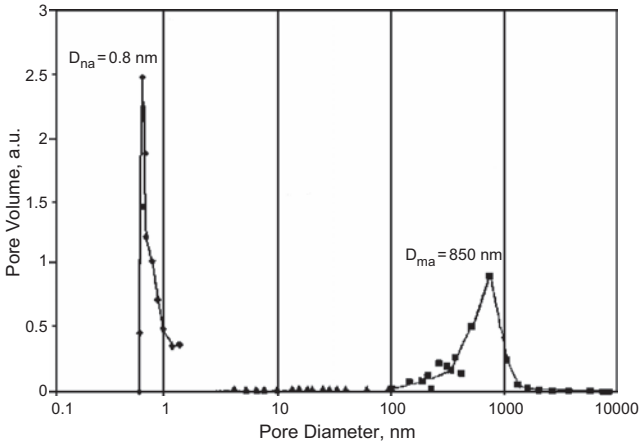

Figure 6. Pore size distribution in the nanoporous article prepared on the basis of TiC derived carbon [32, 137]. ■—mercury porosimetry data; ▲—gas sorption data, BJH method; ♦—gas sorption data, Horvath–Kawazoe method.

The L_a dimensions were larger than for conventional activated carbons treated to the same temperatures. In contrast, the L_c dimensions were very low, as presented in Figure 7. Distinct graphite reflexes became apparent after heat treatment of the CDC from SiC at 2000 °C.

According to the authors' opinion [14], as-prepared CDC from SiC and TaC consists of rather extended layers with very little parallel stacking and the layers must be warped and bent. Upon heat treatment, the first effect is a pronounced increase in the diameter of the coherently scattering segments of the layers. Consequentially, the pore volume accessible to the adsorptives increases. The open structure begins to collapse at 1500 °C as the stacks of carbon layers grow in height and the distance between these stacks shrinks. The pore volume tends toward zero at 1900 °C, and at 2800 °C the layers align to form the graphite structure.

In 1997 Boehm claimed the first observation of carbon nanotubes from electron micrographs taken in 1972 of a

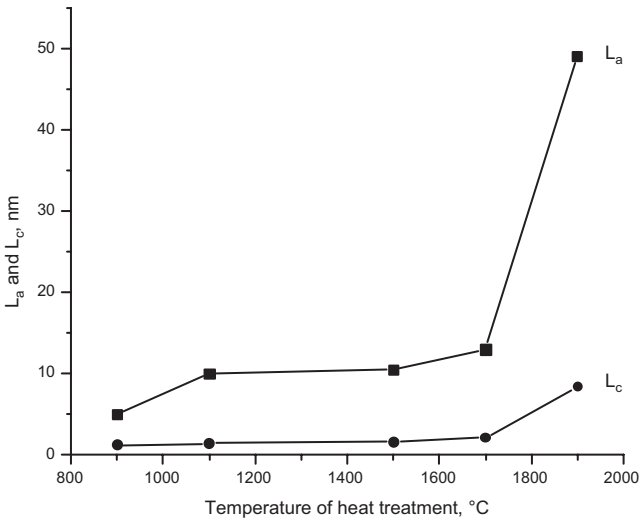

Figure 7. Dimensions of graphite crystallites in the heat-treated CDC produced from TaC at 500 °C [14].

sample of CDC prepared by chlorination of silicon carbide at 800–850 °C [39]. The image of the nanotubes was published in 1978 in the paper by Millward and Jefferson [40]. However, such features could be observed only in a few particles and were considered atypical for this carbon material. Boehm assumed that the carbon nanotubes were not produced during the chlorination reaction, but might be present in the silicon carbide precursor. However, our experience with SiC-derived carbon shows that the formation of multiwall nanotubes (MWNTs) is fairly common and possibly catalyzed by impurities [1].

Further investigations of CDC structure were reported in a number of papers by Gordeev et al. [41–46]. A small-angle X-ray scattering (SAXS) study of the structure of CDC prepared from 6*H* SiC single crystals, polycrystalline α-SiC [41], and polycrystalline SiC, TiC, and Mo_2C [42] produced by treatment in chlorine gas at 700–1000 °C was conducted. The measurements were carried out both in reflection and transmission. The obtained angular dependences of the scattering intensity obtained were treated as a result of scattering from nanoparticles of different size. By decomposing the experimental curves into components corresponding to particles with different gyration radii R_g, scattering distribution functions with respect to gyration radius were found. It was shown that particles with $R_g \approx 1.0$–1.2 nm were the largest fraction in CDC from α-SiC and a 6*H* SiC single crystal [41]. A considerable fraction of 3–6 nm particles was also found in CDC from the 6*H* SiC single crystal. A possible cause of the larger particles' formation in the case of single crystals is their lower chlorination rate and consequently longer treatment time. According to [42], particles with $R_g \approx 0.5$ nm made up the largest fraction in porous carbon, irrespective of the type of the starting carbide. However, samples prepared from different carbides differed in the degree of nanoparticle uniformity. The most uniform in size were nanoparticles in the samples prepared from SiC, in which, on average, R_g was less than 0.6 nm. Nanoparticles in the porous carbon produced from Mo_2C were about twice as large.

The SAXS studies of nanoporous carbon samples obtained from polycrystalline α-SiC, TiC, and Mo_2C and a 6*H* SiC single crystal suggested that the nature of the CDC structure was fractal [43]. Two systems of nanoclusters observed in the CDC structure differed in the type of stacking of their structural elements: small-scale mass fractals of a dimension $1 < D_2 < 3$ and a size $L_2 = 5$–9 nm, which depended on the type of the initial carbide, and large-scale nanoclusters having a size $L_1 > 55$ nm. In most samples, large-scale nanoclusters can be regarded as objects with a fractal surface and a dimension $2 < D_1 < 13$, which also depends on the type of the initial carbide. Large-scale nanoclusters in CDC obtained from Mo_2C proved to be mass fractals with a dimension $D_1 > 2$. The peculiarities of the structural formation of nanoporous carbon obtained from various carbides were also discussed.

The XRD and SAXS data on the CDC structure from [41–43] were revised and summarized with confirmation from high resolution transmission electron microscopy (HRTEM) images in the report [47]. It is notable that, in addition to amorphous and partially graphitized carbon,

some diamond nanocrystallites were detected in the CDC from SiC.

XRD, SAXS, and X-ray photoelectron spectroscopy were used to study the structure of CDC powders produced by chlorination of polycrystalline α-SiC powders with various degrees of dispersion (8–10, 180–200, and 800–1000 μm) [44]. SAXS data were used to derive the distribution function for scattering inhomogeneities with respect to gyration radii, $m(R_g)$. It was shown that the mean size and the fraction of large particles both increase with increasing grain size in the starting powder. As shown by the diffraction patterns, the degree of graphitization of the nanocluster structure increases simultaneously, which is attributed to the longer times required to carbonize coarser grains. An analysis of photoelectron spectra for 1*s* electrons of carbon atoms showed that, for most of the C–C bonds (>65%), the hybridization of valence bonds is intermediate between those for graphite and diamond (sp^x, where $2 < x < 3$), which is indicative of the bending of graphene-like layers in nanoclusters.

A study of the temperature dependences of the electrical resistivity, Hall coefficient, and thermoelectromotive force in the temperature range 1.5–300 K for the materials characterized by SAXS in [43] showed that the structural units responsible for the character of charge transport in these materials were carbon nanoclusters of 1–3 nm in size [45]. The conduction in all the samples studied was found to be of hole type with a high concentration ($n_h \sim 10^{20}$ cm^{-3}) of current carriers.

A new mechanism of nanopore formation in carbon materials produced by the interaction of carbides with chlorine was proposed in [46]. In essence, this method is the following. A series of nonlinear chemical reactions proceed during a chemical interaction between chlorine and carbide. If the external parameters, component fluxes, and diffusion rates satisfy certain relations, a self-organization process can occur, which results in the creation of a periodic nanoporous structure in the carbon material formed. A mathematical model was proposed, the main characteristics of the process were calculated, and the restrictions on the parameters at which the formation of the porous structure becomes possible were found.

The chlorination process of titanium carbide and the obtained CDC were extensively investigated with the use of HRTEM and XRD [20, 48]. HRTEM images of carbon fragments from TiC treated in chlorine at 900 °C revealed that the major part of the carbon structure consisted of three-dimensionally disordered graphitic planes [48]. However, "onionlike" structures were often seen at particle edges. These structures were represented by concentric spherical graphitic shells, interpenetrated and overlapping each other. The outer diameter of the shells was in the range 15–35 nm. The distance between graphitic planes in the shells was 0.34 nm, larger than the interplanar distance in graphite. The carbon sample from TiC had a very high specific surface area (1400 m^2/g) and pore volume and a statistically narrow pore size distribution. As a comparison, HRTEM images of CDC produced at 1000 °C from SiC did not indicate onion-like shells. However, our work showed the formation of carbon onions in CDC produced from SiC [5]. The mechanism of their formation via diamond nanoparticles is described in [49]. HRTEM images of carbon onions and other forms of carbon found in CDC are presented in Figure 8.

It was found that the presence of transition-metal chlorides in the reaction mixture significantly influenced not only the porous structure of CDC from TiC but its degree of graphitization as well [20]. The degree of graphitization was calculated from the XRD pattern according to the empirical formula

$$q = \frac{I_{002}/I_{100}}{14.3} \cdot 100\% \qquad (7)$$

where I_{002} and I_{100} are the relative intensities of graphite (002) and (100) reflections in the diffraction pattern; 14.3 is the I_{002}/I_{100} ratio in high density pyrolitic carbon without an amorphous constituent. As presented in Table 2, the substantial difference between the two series of samples was observed at chlorination temperatures above 700 °C. On the basis of these data, confirmed by HRTEM images, the authors drew the conclusion that the chlorination of TiC generally yields an amorphous carbon below 1000 °C, while at higher temperatures clusters of graphitized carbon appear in the amorphous carbon matrix. The addition of small amounts of the catalytically active metal chlorides of the iron subgroup leads to the formation of better organized carbon structures such as turbostratic and graphitic lamellae at temperatures as low as 800–900 °C.

The structure of CDC produced from aluminum carbide at 300–900 °C was examined in [21, 22]. Degree of graphitization (q) was calculated from XRD patterns according to the method used in [20] and is presented in Table 3. XRD data were confirmed by HRTEM. The CDC sample prepared at 300 °C consisted mainly of amorphous carbon, while increased amounts of ordered structures were observed in materials produced at 500 °C. The CDC from Al_4C_3 produced at 700 °C consisted, to a large part (~80%), of barrel-like multiwall nanoparticles and nanotubes. The sample chlorinated at 900 °C was primarily turbostratic carbon forming randomly oriented bandlike graphitic lamellae and large sheets. The observed nanobarrels were considered to be intermediates between empty onionlike particles and multiwall nanotubes and were patented as a "nanotubular carbon material" [50].

Raman spectra of CDC prepared from polycrystalline α-SiC and TiC were reported in [51]. The spectra were shown to be of a multicomponent nature, which distinguishes this group of materials from graphites and disordered carbon structures. A series of low-frequency modes were detected and anisotropy and dispersion effects were revealed. The results obtained argue in favor of a cluster structure of nanoporous carbon and size quantization of the electronic and vibrational spectra in carbon nanoclusters. The main structural elements of the nanoclusters in the porous framework were small fragments of bent or broken graphene sheets. The presence of fragments of strained cubic or hexagonal diamond was observed in a number of cases.

Formation of carbon films and carbon-rich surface layers was repeatedly observed during the investigation of high-temperature corrosion of SiC-based ceramics in mixed oxygen–chlorine environments [52–58] and the etching of

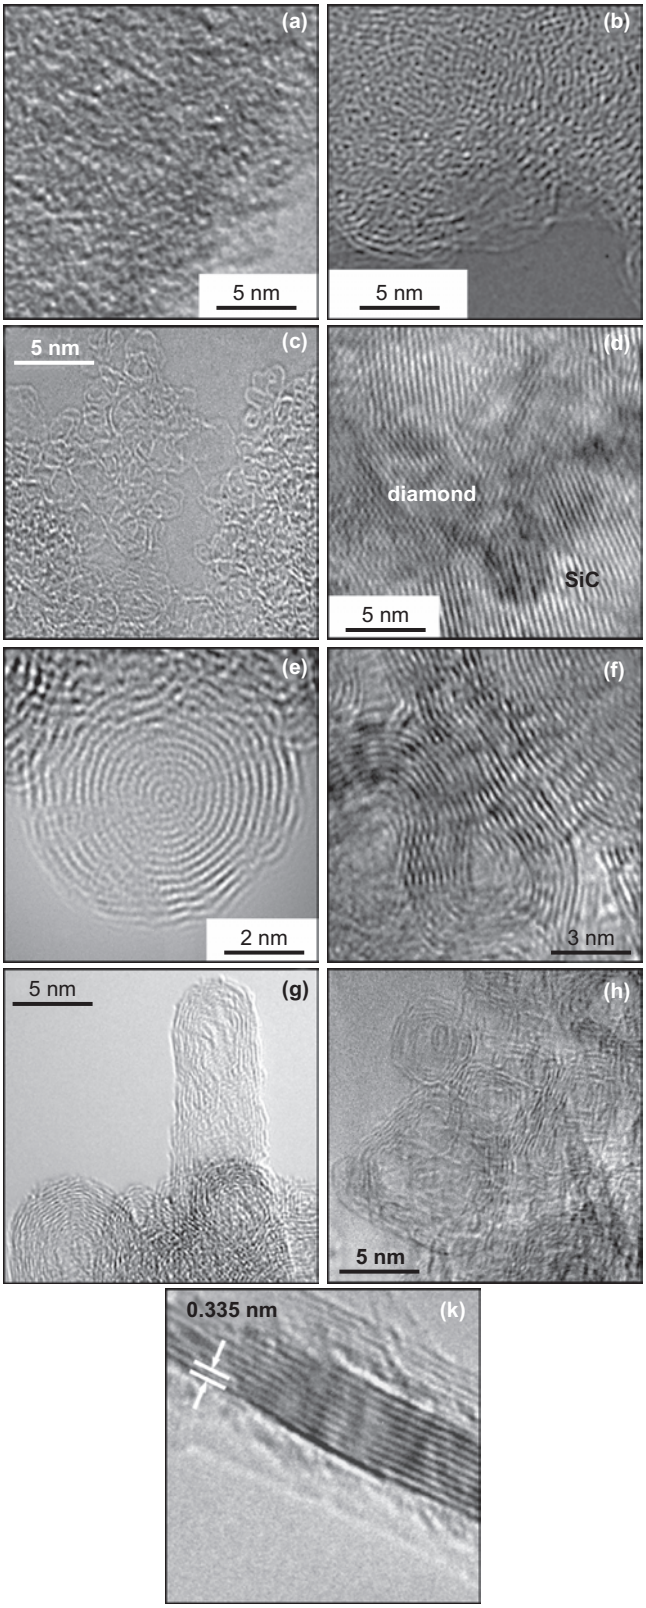

Figure 8. HRTEM images of various forms of carbon found in CDC samples. (a) Amorpous carbon; (b) disordered graphite; (c) fullerene-like carbon; (d) nanodiamond; (e) onion; (f) ribbons; (g) MWNT; (h) barrel-like particles; (k) planar ordered graphite.

SiC surfaces with chlorine and fluorine-containing gases for device fabrication [59–62]. The properties and structure of the formed carbon were not the object of cited studies; moreover, its formation was frequently considered to be undesirable.

Carbon coatings on silicon carbide powders and monolithic specimens produced by treatment in diluted chlorine and chlorine–hydrogen mixtures were examined by Gogotsi and McNallan in a series of works [1, 2, 5, 10, 63–65]. β-SiC powder was treated in Cl_2(2–3.5%)–H_2(0–2%)–balance Ar gas mixtures in the temperature range 500–1000 °C at ambient pressure [10, 63, 64]. Experiments were continued for 5–72 hours depending on the reactivity. The progress of the reactions conducted at 800 °C was monitored by thermogravimetric analysis. The mass decreased approximately linearly with time until it approached a minimum value which was dependent on the ratio of chlorine to hydrogen. Gas mixtures that were low in hydrogen produced the highest reaction rates. Uniform amorphous carbon or nanocrystalline graphite films, as shown by XRD, Raman spectroscopy, and TEM, were produced by treatment in Cl_2–Ar media. In the Raman spectra, D- and G-bands of disordered graphite were observed. From the relative intensities of these bands the size (L_a) of the graphite crystallites was evaluated to be 2–4 nm as presented in Table 8. As the treatment temperature increases, the size of these crystallites and the thickness of the film formed after a fixed period of exposure both increase. BET specific surface areas of carbon layers were calculated using the results of N_2 adsorption measurements and taking into account the presence of unreacted silicon carbide (Table 8). High values of surface area supply evidence that nanoporous carbon coatings were produced.

The addition of hydrogen into the reaction mixture not only reduced the reaction rate but influenced the composition and properties of the products. The sharp diamond band at ca. 1330 cm^{-1} was observed in the Raman spectra of the powder treated in 2.6% Cl_2–1.3% H_2–Ar at 950 °C, and diamond regions were clearly visible under an optical microscope. Other bands which may correspond to crystallized and amorphous diamond were present in the Raman spectra as well. Thus, hydrogen plays a significant role in the formation of diamond by stabilizing the dangling bonds of the cubic diamond formed from the structure of β-SiC upon the extraction of silicon.

Carbon coatings prepared by chlorination of other carbide materials including TiC [11, 66] and TaC [11] were so far reported to consist of disordered graphitic or amorphous carbon without the presence of sp^3 hybridized species.

Chlorination of SiC fibers was also studied [67, 68]. Fibers from polymer precursors are nanoscale mixtures of SiC,

Table 8. Specific surface area and size of crystallites of CDC powders.

Media	T (°C)	t (hrs)	S_{BET} (m^2/g)	L_a (nm)
3.5% Cl_2–Ar	600	27	400	2.0–2.5
	600	48	1163	2.4–2.6
	1000	20	1010	2.0–4.5
2% Cl_2–2% H_2–Ar	1000	72	10	1.0–4.5

carbon, and SiC_xO_y. Their chlorination can be conducted at 400 °C and above, well below the temperatures necessary to produce CDC on SiC crystals or micropowders.

Treatment of monolithic sintered and CVD samples of α- and β-SiC under the conditions described previously [10] resulted in the formation of gray, translucent (in thin sections) films in the cases of low Cl_2:H_2 ratios in the reaction mixture [1, 2, 5, 65]. These nonporous films probably acted as a diffusion barrier and prevented further reaction. Lattice fringing, electron diffraction patterns, and electron energy-loss spectroscopy confirmed the formation of nanocrystalline diamond-structured carbon. The analysis of Raman spectra supported the presence of sp^3 bonding, which is also confirmed by the very high hardness (up to 50 GPa) and Young's modulus (up to 600 GPa) of these coatings.

CDC coatings produced by treatment in chlorine or chlorine–hydrogen mixtures at Cl_2:H_2 ratios equal to or larger than 2:1 consisted of a loosely attached, powdery top carbon layer with a dense, highly disordered, adherent amorphous or nanocrystalline layer below it. The adherent layers were shown to be composed of a mixture of graphitic and diamond-structured carbon [5] or highly disordered sp^2-carbon [2]. The thickness of the carbon layer increased linearly during the process. Because the kinetics is linear, the controlling factor of the reaction is not the diffusion of reactant species through the growing carbon layer. Therefore, the layer is nanoporous.

A theoretical study of graphite and diamond growth on the (1000) Si surface of 6*H* SiC was carried out using molecular dynamics simulation [1, 69]. It was shown that very high lattice strains do not allow the continuous growth of diamond on SiC, and fragmentation occurs that leads to nanocrystalline material. Small diamond clusters on SiC are predicted to show good adhesion to the substrate and maintain sp^3 coordination of carbon atoms in the cluster. A TEM study [5] proved that SiC was converted to sp^3 carbon, and formation of crystalline diamond-structured carbon occurred from disordered Si-depleted SiC within nanometers of the SiC/C interface. Growth of larger crystals of diamond-structured carbon was probably the result of the coalescence of continuous nanocrystalline regions. The presence of hydrogen helps to maintain the sp^3 hybridization of carbon by stabilizing the dangling bonds.

A detailed HRTEM study of diamond crystals produced by treatment of SiC in the gas mixtures (1–3.5%)Cl_2–(0–2%)H_2–Ar at 1000 °C showed that growth of diamond under these conditions occurred epitaxially on the SiC surface [49] (see Fig. 8d). It has been shown that the presence of hydrogen in the environment is not required for diamond synthesis. However, hydrogen can stabilize the nanocrystals and lead to the formation of thick diamond films. If no hydrogen is added, diamond nanocrystals transform to graphitic carbon, forming carbon onions and other curved graphitic structures. Diamond formation is also favored by the low synthesis temperature providing moderate carbon mobility. This result is in accordance with X-ray photoelectron spectra of CDC from SiC, TiC, and ZrC produced at various temperatures [70], in which it was shown that the degree of sp^3 hybridization increases as the process temperature is reduced from 1100 to 350 °C.

3. SELECTIVE ETCHING OF CARBIDES BY MELTS AND SUPERCRITICAL WATER

3.1. Reaction of Calcium Carbide with Inorganic Salts

Saltlike carbides react at elevated temperatures with a number of reagents resulting in carbon formation along with other reaction products [71]. Infrequent reports on this carbide-thermal process and the resulting carbon material were all devoted to calcium carbide reactions with the metal salts [72–78]. Generally, the process can be considered as a high-temperature exchange reaction of calcium carbide and metal salt, producing a calcium salt and a new unstable saltlike carbide that decomposes to give free metal and carbon [77].

This method was first applied for the production of macrocrystalline graphite with the use of magnesium chloride [72]. The process included the following exchange and decomposition reactions:

$$CaC_2 + MgCl_2 = MgC_2 + CaCl_2 \quad (8)$$

$$2MgC_2 = Mg_2C_3 + C \quad (9)$$

$$Mg_2C_3 = 2Mg + 3C \quad (10)$$

The reaction mixture was heated to 600–1275 °C for 1–5 hours. The best yield and quality of graphite were achieved in the range 950–1200 °C. After the removal of the unreacted carbides, salts, and amorphous carbon the yield was as much as 85%. XRD showed that both graphitic and turbostratic carbon were present in the product. It is important to note that since $CaCl_2$ has a high melting point (772 °C) and low vapor pressure, pure CDC cannot be produced by chlorination of CaC_2 (Fig. 2b).

The porous structure and adsorption properties of the CDC material prepared by the carbide-thermal process were first studied by Fedorov et al. [73]. The reaction of calcium carbide with sodium chloride according to the overall equation

$$CaC_2 + 2NaCl = 2C + 2Na + CaCl_2 \quad (11)$$

was conducted in the temperature range 400–900 °C and resulted in a sorption-active carbon material. The parameters of the porous structure were determined by measuring benzene sorption isotherms. As one may see from Table 9,

Table 9. Parameters of the porous structure of CDC from CaC_2 + NaCl.

Temperature (°C)	V_{na} (cm^3/g)	V_{me} (cm^3/g)	S_{me} (m^2/g)
400	0.13	0.50	332
500	0.22	0.24	102
600	0.11	0.40	198
700	0.00	0.63	253
900	0.04	0.12	55

Note: V_{na} and V_{me} are volumes of nano- and mesopores, respectively; S_{me} is the specific surface area of mesopores.

carbonaceous materials from CaC_2 have extensive and variable mesopore volume but a lower specific surface area compared to CDC produced by chlorination of carbides.

Measurements of the free carbon yield at various CaC_2:NaCl ratios in the initial mixture showed that two reaction pathways are possible at 900 °C [76]. The chloride-catalyzed decomposition of CaC_2 takes place at low CaC_2:NaCl ratios (1:0.03–1.2 eq.). Reaction (11) proceeds at higher CaC_2:NaCl ratios.

The technique for producing CDC adsorbents from CaC_2 includes the following steps: mixing of the initial components with the particle size of 100–300 μm in the ratio 1:(1–3), compaction at 5–40 MPa, thermal treatment at 600–1000 °C followed, if necessary, by a water-acid treatment, drying, and crushing. The properties of the CDC adsorbents prepared by reaction of CaC_2 with a variety of chlorides are summarized in Table 10. These sorbents can be used as soil detoxifiers, gas drying agents, chemical adsorbents, and catalysts [78].

3.2. Hydrothermal Leaching of Carbides

3.2.1. Thermodynamic Analysis

The thermodynamic stability of a number of metal carbides under hydrothermal conditions was analyzed in [79]. The possible corrosion routes and products were predicted using Gibbs energy minimization sofware. Thermodynamic calculations were conducted for the temperature range from 300 to 1000 °C and pressures of 2 and 200 MPa for the M_xC–nH_2O(g) system, where $n = 2$ and 10 and $x =$ Si, Ti, Ta, Nb, W, and B. The following idealization was supposed from these calculations: hydrothermal fluid is treated as a steam, the solid phase is a mechanical mixture of compounds with unit activities, and the gas phase is a mixture of ideal gases. Furthermore, kinetic factors and effects such as pH were not taken into consideration.

The analysis indicated that carbon, MeO_x, CH_4, CO_2, CO, and H_2 are the main products of hydrothermal corrosion in the temperature range of the study. The principal reactions in the M_xC–nH_2O(g) system can be written as follows:

$$x/2\mathrm{MeC} + x\mathrm{H_2O} = \mathrm{Me}_{x/2}\mathrm{O}_x + x/2\mathrm{CH_4} \quad (12)$$

$$\mathrm{MeC} + (x+1)\mathrm{H_2O} = \mathrm{MeO}_x + \mathrm{CO} + (x+1)\mathrm{H_2} \quad (13)$$

$$\mathrm{MeC} + (x+2)\mathrm{H_2O} = \mathrm{MeO}_x + \mathrm{CO_2} + (x+2)\mathrm{H_2} \quad (14)$$

Table 10. Parameters of the porous structure of CDC from CaC_2.

Chloride	V_{na} (cm^3/g)	V_{me} (cm^3/g)	S_{me} (m^2/g)	W_0 (cm^3/g)	E_0 (kJ/mol)
LiCl	0.08	0.35	95		
KCl	0.26	0.71	270	0.25	19.7
$MgCl_2$	0.11	0.41	115		
$AlCl_3$	0.02	0.46	127		
$SnCl_2$	0.27	0.42	94		
$PbCl_2$	0.39	0.49	111		
$ZnCl_2$	0.21	0.58	382	0.20	18.6
$MnCl_2$	0.14	0.41	101	0.15	14.8
$CoCl_2$	0.16	0.38	95	0.17	18.6
$NiCl_2$	0.14	0.24	87	0.13	19.2

$$\mathrm{MeC} + x\mathrm{H_2O} = \mathrm{MeO}_x + \mathrm{C} + x\mathrm{H_2} \quad (15)$$

$$\mathrm{MeO}_x + n\mathrm{H_2O} = \mathrm{MeO}_x \cdot n\mathrm{H_2O} \quad (16)$$

These calculations show that the formation of carbon on the surface of SiC depends crucially on the H_2O:SiC ratio. Three regimes can be identified:

1. At low H_2O:SiC ratios, both carbon and silica are deposited on the surface.
2. At intermediate H_2O:SiC ratios, carbon and silica are formed. Silica is dissolved in water according to eq. (16). Thus, reaction (15) tends to move further to the right.
3. At higher H_2O:SiC ratios (ca. 10) neither carbon nor silica precipitates, dissolving in the excess of water.

It is shown that the yield of methane, which is unstable at high temperatures, decreases with temperature and thus the yield of elemental carbon produced due to the instability of CH_4 increases. Higher pressures lead to a slight increase in methane stability and, accordingly, to a lower yield of carbon.

TaC, TiC, and NbC show behavior which is very similar to that of SiC. In particular, TaC seems to be more stable at low amounts of water. Carbon formation is calculated for TaC at temperatures above 700 °C and only at relatively low pressures. It is important to remember that most metal oxides, unlike silica, cannot be easily dissolved in supercritical water. Thus, a mixture of carbon and metal oxide is produced. The calculated behavior of WC is somewhat different as compared with previously discussed carbides. The carbide W_2C and a number of stable oxides may form. Free carbon is predicted to form only at the lower temperatures. Boron carbide is the only carbide from the group studied that is not predicted to convert to free carbon under hydrothermal conditions. These calculations provide some general guidelines and, as will be shown, are generally in good agreement with experimental results.

The formation of carbon-rich layers on the surface of carbides was repeatedly detected in the course of investigations on the controlled oxidation of HfC [80–85], ZrC [84–89], and TiC [83, 85] at low oxygen pressures (0.02–16 kPa). These layers contained up to 25 at% carbon in addition to metal oxides and oxicarbides. This carbon was mainly amorphous as characterized by Raman spectroscopy. In some cases, the formation of carbon of the hexagonal diamond structure was observed [86].

3.2.2. Experimental Results

The hydrothermal formation of carbon from carbides was first reported in 1994 by Gogotsi and Yoshimura [64, 90–93]. This phenomenon was observed during corrosion studies performed on amorphous SiC (Tyranno) fibers at 300–800 °C and about 100 MPa. Tyranno fiber is a type of silicon carbide fiber which contains titanium and oxygen and is made by pyrolysis of an organometallic polymer precursor. It consists of SiC nanocrystals which are connected by Si–O–C and Ti–O (Ti–C–O) interlayers; the structure can be considered as an amorphous SiO_xC_y matrix with nanometer-size β-SiC inclusions.

The outer surface of the fibers treated at temperatures of up to 450 °C remained smooth and almost featureless. Auger electron spectroscopy depth analysis of the surface layer showed that a carbon layer containing traces of silicon was formed [91]. The thickness of this layer varied from 10–20 nm to 1–2 μm. Raman spectra of the fibers showed the graphite (G) and disorder-induced (D) bands, thus confirming the formation of amorphous or nanocrystalline carbon [90]. The crystallites were of very small size and sp^2 C–C bonds dominated.

The formation of amorphous carbon on the surface of Tyranno fibers after hydrothermal treatment at 300–400 °C and 100 MPa was also reported in [64, 67, 94, 95]; on the surface of CVD-SiC fibers after treatment at 400–700 °C and 200 MPa [96]; and on the surface of α- and β-SiC platelets, whiskers, and powder at 600–800 °C [64, 79, 94, 95, 97]. Some amount of disordered diamond, as well as graphite and amorphous carbon, was found on the surface of α- and β-SiC powder and single crystals after treatment at 300–800 °C and 100–500 MPa [98–102]. The hydrothermal method was also found to be suitable for the preparation of CDC from other carbides including WC, TaC, NbC, and TiC at 500–750 °C and 100–170 MPa [79].

3.3. Carbides as a Source of Carbon in High Pressure–High Temperature Synthesis of Diamond

Diamond has been synthesized from graphite at high pressure and high temperature (HPHT) using some transition metals as a solvent catalyst. This process is accompanied by the formation of stoichometric and nonstoichometric metal carbides. The role of metal carbides in the diamond formation process was disputed [103, 104]. According to the suggested mechanism, a stoichometric iron or chromium carbide with higher carbon content decomposes into the carbide with a lower carbon content to precipitate diamond.

A HPHT process of diamond formation from carbides in the presence of metal oxides or halogenides was patented in 1988 [105, 106]. Diamond powders can be prepared from carbides of silicon, calcium, aluminum and other elements at pressures >1 GPa in the temperature range 400–1200 °C according to the general reaction equation

$$a\mathrm{MeC}_x + \mathrm{Me'X}_{y/a} = a\mathrm{MeX}_y + \mathrm{Me'C}_z + (ax - z)\mathrm{C}_{\mathrm{diam}}$$

where X = O, F, Cl, Br; $0 \le z < ax$. For example, diamond was produced after treatment of a stoichometric mixture of Al_4C_3 and MoO_2Cl_2 at 1.5 GPa and 400 °C.

The first detailed description of the HPHT synthesis of diamond from silicon carbide in the presence of metal solvent-catalyst was published by Hong et al. [107, 108]. The SiC–Co systems with a weight ratio of 1:8 were treated at pressures of 4.5 or 5.5 GPa and temperatures of 1400–1550 °C. At a pressure of 5.5 GPa and temperatures of 1430–1550 °C, the SiC decomposed and diamond and graphite appeared. Using the Ni–Mn–Co alloy as a solvent catalyst was proved to be more effective in the synthesis of diamond from SiC [109]. Diamond formed rapidly in the SiC–$Ni_{70}Mn_{25}Co_5$ system at a pressure of 5.4–6.0 GPa and temperature of 1350–1570 °C. The carbide was completely decomposed during 6 minutes of HPHT treatment. After oxidizing the graphite in a hot mixture of H_2SO_4 and HNO_3, the yield of diamond powder was 56%. It was shown that the mechanism of diamond formation in the SiC–metal system is different from that in the graphite–metal one. First, SiC decomposes into carbon and silicon, and then carbon, by the action of the metal catalyst, is separated into diamond and graphite while silicon may dissolve in the metal. HPHT synthesis of diamond from boron carbide was conducted in the work [110]. A significant amount of diamond grains was obtained at pressures ≥5.8 GPa and temperatures ≥1460 °C.

The formation of diamond films and particles was observed in the course of iron carbide decomposition under HPHT conditions. Diamond films were heteroepitaxially grown on the surface of the cubic boron nitride particles at 5.2 GPa and 1370 °C [111]. Homoepitaxial growth of the diamond films was performed by treating the mixture of Fe_3C and diamond seeds at 5.6 GPa and 1430–1470 °C [112]. Decomposition of high-purity Fe_3C powder at 5.3 GPa and 1360 °C resulted in diamond particles. These experiments have also confirmed the possibility of intermediate carbide formation in the HPHT process of diamond formation in the graphite–metal systems.

4. THERMAL DECOMPOSITION OF CARBIDES

It is known that silicon carbide, as well as many other carbides, decomposes or melts incongruently at high temperatures [71]. This thermal decomposition in vacuum or an inert environment is characterized by the formation of carbon and the melting and evaporation of metal, because the melting point of graphite exceeds that of most metals.

Carbon formed after the heat treatment of SiC in vacuum at temperatures up to 2000 °C approximately was first mentioned in 1960 in the discussion attached to [37]. Just as in the case of carbon material prepared from silicon carbide by selective removal of silicon by chlorine gas, a pseudomorph of the original carbide sample was observed. In other words, the size and shape of the original particles did not change during the reaction. The same phenomenon was observed in 1963 during of the thermodynamic study of SiC dissociation [113].

A few attempts to investigate the structure of carbon obtained by the decomposition of silicon carbide were reported in the following decades. An XRD study was conducted by Badami [114, 115] in which single crystals of α-SiC ($6H$) were heated to temperatures of about 2050–2150 °C for 1 hour at a pressure of 10^{-5} Torr [114]. The sample produced by heating to 2050 °C had undergone only partial decomposition as demonstrated by its diffraction pattern. On the basis of an examination of various parts of the sample produced at 2150 °C, the following structure was proposed. The pseudomorph contained two distinct structures: a matrix of turbostratic carbon with a strong preferred orientation of the carbon layers parallel and perpendicular to the layers of silicon carbide, and within this matrix there were crystalline regions of graphite having a common c axis and axial symmetry about it. X-ray data on the pseudomorph from single crystals of $6H$ silicon carbide decomposed at

2280 °C in vacuum for 1 hour showed that an outer layer of turbostratic graphite formed, and deeper inside the sample were single crystals of graphite whose orientation was also determined by the structure of SiC [115]. Further into the interior, turbostratic graphite was found again, and, finally, completely disordered carbon. A possible mechanism for the decomposition was the collapsing of two layers of carbide lattice to give one layer with a hexagonal arrangement of carbon atoms. Molecular dynamics modeling shows that graphite layers can be accommodated on the surface of SiC [1]. Electron diffraction studies detected the formation of graphite on the surface of a SiC crystal at temperatures as low as 1200 °C.

Selected area electron diffraction was used to investigate the decomposition of single-crystal β-SiC whiskers [116]. A cluster of the whiskers, averaging about 300 nm in diameter, was heated to about 2400 °C at 10^{-6} Torr for 2–3 min. The whiskers were found to be in various stages of decomposition. Graphite crystallites about 10 nm or less in diameter were observed at the outer surface of the partially decomposed whiskers. Based on the selected area diffraction patterns, it was concluded that the crystallites grew with their basal planes tangent to the whisker surface. No evidence was found to indicate that the formed carbon was structurally related to the parent silicon carbide.

Thermal decomposition in vacuum (10^{-10} Torr) of Si- and C-faces of 6*H* SiC(0001) crystals was studied by low energy electron diffraction and Auger electron spectroscopy [117]. The formation of a graphite monolayer started at 800 °C. On the Si-face this monolayer was monocrystalline with the unit mesh rotated 30° with respect to the SiC unit cell. On the C-face this layer was polycrystalline with the unit mesh randomly oriented. The authors proposed that the collapse of the carbon of three successive SiC layers is the most probable mechanism for the initial stages of the graphitization of SiC basal planes. These results agree well with ellipsometric data on the surface decomposition of 6*H* SiC(0001) crystals [118]. It was also shown that rate of the carbon layer growth on the carbon face is about five time higher than that on the silicon face. Our modeling work showed that a graphite layer can form on the (0001) surface of 6*H* SiC, and good adhesion is expected for the first two monolayers [1].

Iijima studied the decomposition of silicon carbide under electron beam irradiation in 1982 [119]. Small flakes of 6*H* SiC were irradiated with the electron beam at a pressure of 10^{-6} Torr. The decomposition was controlled to some extent by halting the irradiation after a short exposure to the beam. Electron diffraction patterns showed a gradual disappearance of the SiC reflections with simultaneous graphitization of the sample. The preferred orientation of graphite was similar to the X-ray diffraction observations of Badami [114]. However, the decomposition process was not completely topotaxial, which is confirmed by electron micrographs. Many ordered graphite bands and no regions of amorphous or turbostratic carbon were recognized in these micrographs. Images of the interface between SiC and graphite clearly showed the topotaxial mechanism of the reaction.

A consideration of transport processes leading to the formation of the carbon pseudomorph during the thermal decomposition of SiC was attempted by Motzfeldt and Steinmo [120]. The vapor pressure over the SiC(s)–C(s) was studied by means of the Knudsen effusion method for three different orifice sizes. It was found that surface diffusion is of great importance in the process. The overall process was pictured in the following way: the outermost layer of the SiC crystal loses silicon by evaporation from the surface, and a layer of microporous carbon is left. A gradient in silicon is established through this layer and silicon from the interior moves through it by surface diffusion and then evaporates from the surface. One can find indirect evidence on silicon surface migration during the silicon carbide decomposition in the report from 1970 [121].

The only published source on the thermal decomposition of carbides other than SiC is [122]. Decomposition of aluminum carbide was carried out by heat treatment at 2400 °C and atmospheric pressure for 2 hours in argon. Formed graphite crystals had a low *c*-spacing (0.33545 nm), chemical purity, large size, and general absence of cleavage and twinning.

4.1. Synthesis of Carbon Nanotubes

A new interest in the field of the thermal decomposition of silicon carbide arose in 1997 when Kusunoki et al. discovered growth of self-organized carbon nanotube (CNT) films during the process [4]. The β-SiC (3*C*) particles were heated to about 1700 °C at 2×10^{-5} Pa for a few minutes in a TEM equipped with a YAG laser heating holder. Overlapped carbon nanotubes with caps of 2–5 nm oriented along the [111] direction on the (111) surface plane of β-SiC single crystal were found (Fig. 9) By heating the specimen to 1900 °C, the shape of CNTs became sharp and they began to grow in various directions. Although the authors did not claim SWNT formation, the image in Figure 9 suggests that single-wall nanotubes were present.

The possibility of the transforming of SiC to nanotubes on larger SiC particles by means of heating the particles in

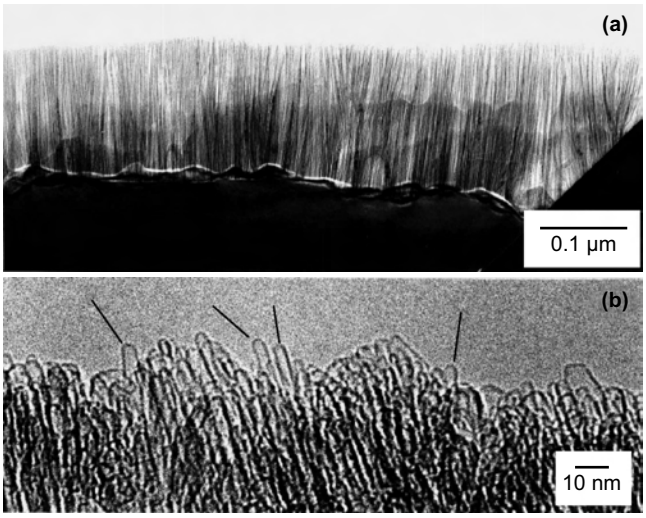

Figure 9. (a) TEM image of the surface of a decomposed α-SiC wafer. (b) Top of the nanotube layer in (a). Arrows show tube caps typical of a SWNT. Reprinted with permission from [124], M. Kusunoki et al., *Jpn. J. Appl. Phys.* 37, L605 (1998). © 1998, Publication Board, Japanese Journal of Applied Physics.

a vacuum resistance furnace was investigated in [123]. SiC powder was heated to 1600–1700 °C for 10 to 15 minutes on a tungsten boat. Dense layers of MNWTs without nanoparticles were observed on the surface of 40% of the SiC powder. The typical nanotubes size was 20–50 nm in diameter and up to 1 μm in length. As in the previous work [4] most of the nanotubes tended to grow almost perpendicular to the original surface of the particle.

A large-area nanotube film was prepared on the surface of an α-SiC wafer by heating at 1700 °C and 10^{-4} Torr for 30 min [124]. The nanotubes were 2–5 nm in diameter and 0.15 μm in length, similar to those shown in Figure 9. The aligned nanotube film was formed uniformly all over the surface of a wafer $3 \times 5 \times 0.34$ mm in size. The (0002) lattice distance of the graphite making up the CNTs was found to be 0.344 nm from the electron diffraction pattern.

Kusunoki et al. proceeded with the investigation of surface decomposition of the α-SiC (0001) single-crystal wafers in the temperature range 1300–2000 °C at 10^{-4} Torr for 30 min [125]. When a wafer was heated at 1300 °C, small caps of 2–5 nm in size consisting of a couple of layered graphite sheets were formed all over the SiC crystal. When the wafer was heated at 1500 °C, the length of CNTs increased to 50 nm after 0.5 h and to 180 nm after 6 h of heat treatment. When the wafer was heated at 1500 °C for 0.5 h in a better vacuum (10^{-6} Torr), the length of the CNTs was only 25 nm. This fact indicated that the oxidation process is essential for CNT formation. Finally, when the SiC wafer was heated at 2000 °C for 0.5 h, a graphite layer of 10 μm in thickness was formed. On most of the layer, graphite sheets were oriented parallel to the $(0001)_{SiC}$ plane and, under this condition, CNTs were not observed. HRTEM micrographs oriented along a CNT axis plan-view direction showed that these CNTs are multiwall and contained two to five walls.

An electron energy-loss spectroscopy line-scan profile showed the segregation of oxygen at the interface between the CNT film and SiC plane. This result indicated that residual oxygen in the vacuum chamber plays an important role in the formation of CNTs. Temperature dependence of the CNT size allowed the authors to propose a model of their formation mechanism, which consisted of three stages. First, at temperatures over 1000 °C, several graphite sheets are formed parallel to the $(0001)_{SiC}$ plane by oxidation of SiC. Second, at around 1300 °C carbon nanocaps are formed by the generation of bubbles of a SiO gas, and the graphite sheets start to stand up. Finally, CNTs grow toward the interior of the SiC crystal (Fig. 10).

The initial growth process of CNT from SiC was also investigated by time-resolved HRTEM [126]. A sample of 3*C* SiC single crystal was resistively heated to 1360 °C at a pressure of less than 4×10^{-5} Pa. Dynamic observation was conducted at a time resolution of 1/60th of second. Two types of CNT were observed with diameters of 0.8 and 1.5 nm. It was shown that amorphous carbon was first formed and then crystallized to graphene sheets parallel to the (111) plane. Carbon nanotubes were formed by the lift of a part of the graphene sheet along the [111] direction due to the generation of pentagons and heptagons.

A remarkable difference between the carbon structures on Si(0001) and C(000$\bar{1}$) faces of an α-SiC single crystal was

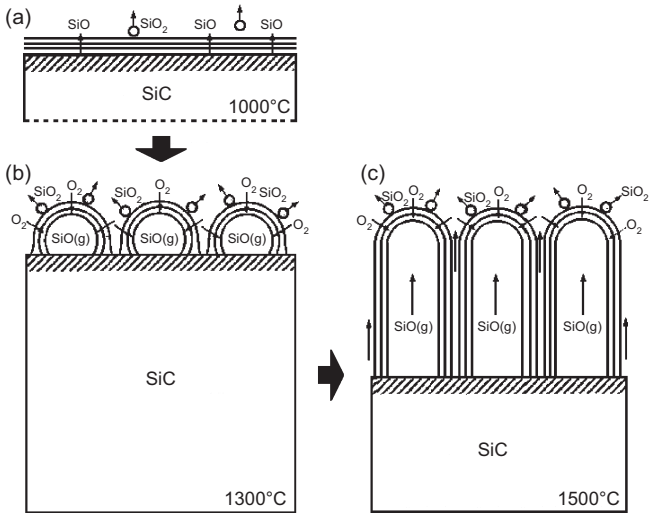

Figure 10. Schematic diagram for the formation mechanism of the CNT film on a SiC crystal by the surface decomposition. Reprinted with permission from [125], M. Kusunoki et al., *Philos. Mag. Lett.* 79, 153 (1999). © 1999, Taylor & Francis.

observed after its decomposition in the temperature range 1200–1700 °C for 30 minutes [127, 128]. Cross-sectional HRTEM of the C-face showed cap formation and CNT growth according to the proposed model, while HRTEM of the Si-face showed that flat graphite sheets were formed parallel to the surface. The difference between C- and Si-faces was confirmed during the process of creating freestanding CNT films by sublimating decomposition of 3*C* SiC(111) films, which were epitaxially grown on Si(111) substrate and afterwards removed [129]. SiC films could be converted to CNT only after removal of the Si- layer.

However, in a later study by Derycke et al., CNTs were found on a Si(0001) face of partially decomposed 6*H* SiC wafers using scanning tunneling microscopy (STM) and atomic force microscopy (AFM) [130]. Heat treatment of the samples at 1650 °C was performed in ultrahigh vacuum ($<10^{-9}$ Torr) by passing a current through them. STM and AFM images clearly showed highly ordered single-walled nanotube (SWNT) networks on and below the surface with their axes parallel to it (Fig. 11). The nanotubes had a very narrow size distribution in the 1.2 to 1.6 nm range.

Nanotubes prepared by surface decomposition of SiC were found to be exclusively of the zigzag type [131]. CNTs were grown on the C(000$\bar{1}$) faces of a 6*H* SiC single crystal wafer by heating it to 1500 °C at a very low heating rate under vacuum (10^{-2} Pa). HRTEM images indicated that the zigzag CNT structure evolved from Si–C hexagonal networks in the SiC crystal by the collapse of carbon layers that remained after the silicon removal. This work is the first report on the selective preparation of carbon nanotubes of the same structure. Previous synthesis methods, such as arc discharge, laser evaporation, and chemical vapor deposition, usually result in zigzag, armchair, and chiral types of CNTs coexisting in the products.

Reduced silicon carbide decomposition temperatures are needed to form carbon nanotubes in the presence of metal catalysts [132]. The metal-coated substrates of polycrystalline

SiC were heated to 1000–1200 °C at 10^{-2} Torr in a vacuum electric furnace. Carbon tubular nanostructures (tubes and fibers) grew in the case of Pt, Ni, Co, Rh, and PtPd at 1200 °C. Scanning electron microscopy observation revealed that the synthesized structures ranged from 100 nm to 10 μm in length. According to TEM images, the synthesized CNTs are MWNTs ranging from 2 to 10 nm in diameter. Most of the tubular structures included a metal particle of corresponding diameter at the tip. The growth mechanism is thought to be similar to that of a CVD process.

Thus, both SWNTs and MWNTs can be formed by the CDC technique with and without catalysts.

5. APPLICATIONS

It has already been mentioned that CDC has a variety of applications including molecular sieves, sorbents for gas chromatography, soil detoxification, dehumidification, and catalysis. This section describes some other potential applications of CDC in more detail.

5.1. Supercapacitors

Carbide-derived carbon is an attractive material for electrodes of electrochemical double-layer capacitors, commonly called "supercapacitors" [133]. Among the advantages of CDC, the high specific surface area and controlled pore size distribution are the most important. Strength and mechanical stability are also necessary for good electrode performance.

Two approaches to the design of the CDC electrode bodies have been proposed. The first one was developed for production of nanoporous carbon articles of any prescribed form and sufficient mechanical strength [30–32] and was employed for the preparation of supercapacitor electrodes [134–136]. The parameters of porous structure and specific capacitance of prepared electrodes measured in aqueous solutions using potassium hydroxide and sulfuric acid as electrolytes are presented in Table 7.

The second approach is more conventional: CDC powder is mixed with an appropriate binder and then formed and treated to achieve mechanical strength [137]. Particular attention in this work was paid to selective control of the resultant pore size in the electrodes to tailor them to fit the ionic size of the positive and negative electrolyte ions employed in the capacitor. Even though the method of manufacturing nanoporous carbon by chlorination of selected carbide or carbide mixtures under appropriate conditions gives good control of the size distribution of nanopores in the resulting carbon particles (see Table 11), some additional refinement of the process control was considered to be desirable. This was achieved by exposing the CDC samples to an oxidizing medium such as water vapor, carbon dioxide, or concentrated nitric or sulfuric acid. The effects of this treatment were controllable widening of the nanopores and removal of physically and chemically adsorbed chlorine. Examples of electrochemical properties before and after modification are given in Table 12.

5.2. Hydrogen Storage

The low atomic weight and density of carbon facilitate great interest in hydrogen uptake and storage in carbon nanomaterials [138]. It is known that hydrogen uptake depends on the porous structure of the adsorbent. The relationship between hydrogen uptake and BET specific surface area for various carbonaceous materials, including activated carbons and nanofibers, is presented in Figure 12 [139]. The experiments on dissociative adsorption of hydrogen on the compact CDC adsorbent prepared according to Gordeev et al. [30–32] were mentioned in [28]. It was shown that the material under study was able to adsorb hydrogen at 300–600 °C and that the adsorbed hydrogen was strongly bonded and could be desorbed at elevated temperatures in the range of 400–1200 °C.

The process of hydrogen sorption by CDC was investigated at temperatures of 300–700 K and pressures of 200–580 atm using the method of thermodesorption spectrometry [140, 141]. Thermodesorption spectra registered in the temperature range of up to 1500 °C consist of several chemisorption-induced phases in several independent states on the surface of the nanoporous carbon. The desorption peaks at 500–550 and 800–850 °C were attributed to the hydrogen adsorbed on dangling carbon bonds and

Table 11. Examples of influence of the carbide precursor on capacitance.

Initial carbide	Nanopore volume (cm^3/g)	S_{BET} (m^2/g)	Specific capacitance (F/g)
Al_4C_3	0.60	1353	251
B_4C	0.78	1782	217

Table 12. Properties of nonmodified and modified CDC materials.

Initial carbide	Type of material	S_{BET} (m^2/g)		Specific capacitance (F/g)	
		powder	electrode	dc = −1.4 V	dc = +1.4 V
SiC	nonmodified	1086	931	5.8	79.9
	modified (H_2O)	2140	1567	92.8	88.1
TiC	nonmodified	1485	1054	80.5	113.4
	modified (H_2O)	2232	1639	111.2	142.5

graphite-like carbon surfaces, respectively. Each of the states is characterized by the activation energy and pre-exponential factors of the desorption rate constants. The apparent activation energy and heat of sorption were estimated. It was also shown that doping the CDC samples with 0.5 wt% of palladium increased hydrogen uptake by about 2.5 times.

The nondissociative hydrogen uptake for two types of CDC materials was explored in [142]. Multiwalled nanobarrels (MWNBs) prepared by thermochemical treatment of aluminum carbide in chlorine gas [48] and amorphous nanoporous carbon (ANPC) from silicon carbide were used. The specific surface area (BET) of the ANPC was 1000 m^2/g while the MWNB had a density of 0.75 g/cm^3 and S_{BET} = 600 m^2/g. The isotherms of hydrogen adsorption were measured at temperatures of −196, −78, and 27 °C in the pressure range of up to 10 MPa. At the highest hydrogen pressure the maximum differential uptake was determined to 2.9 wt% (27 °C) and 4.1 wt% (−196 °C) for the MWNB and 2.6 wt% (27 °C) and 3.3 wt% (−196 °C) for the ANPC. The total uptake was calculated to be 3.2 wt% (27 °C) and 6.2 wt% (−196 °C) for the MWNB and 2.8 wt% (27 °C) and 4.2 wt% (−196 °C) for the ANPC. Values of hydrogen uptake for the MWNB and ANPC are comparable with other carbonaceous materials (Fig. 12). The larger hydrogen uptake and smaller S_{BET} of MWNB evidently indicated the presence of a significant amount of nanopores in the sample which were inaccessible for nitrogen molecules.

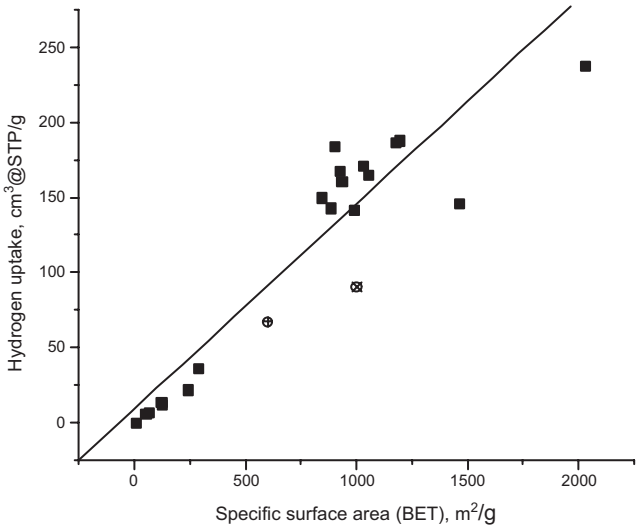

Figure 12. Hydrogen adsorption at −196 °C and 0.1 MPa versus BET surface area for various carbonaceous materials [139]. ⊕—MWNB, ⊗—ANPC [142].

5.3. Lithium-Ion Batteries

Lithium can be inserted reversibly within most carbonaceous materials, and a high amount of reversible insertion is the main requirement for their application as anodes in lithium-ion batteries [143]. A study of lithium diffusion in CDC materials and the phase composition of the produced lithiated samples was recently reported [144, 145]. Bulk carbon specimens prepared according to the technique of Gordeev et al. [32] from carbides of silicon, titanium, and molybdenum were lithiated in the temperature range of 30–200 °C. The concentration profiles of lithium in the carbon specimens were measured using the nuclear reaction $^7Li(p,a)^4He$. The obtained diffusion coefficients were in the range of 10^{-9}–10^{-7} cm^2/s and dependent on the pore size and the diffusion time. Based on these results, a process mechanism is mainly Li diffusion along pore walls and accumulation in pores followed by the formation of metal clusters [144].

The phase composition of the lithiated CDCs was examined by XRD. Intercalation phases LiC_6, LiC_{12}, and LiC_{24} were observed. In some cases, the formation of the undesirable phases of carbonate Li_2CO_3 and carbide Li_2C_2 was detected. Lithiated samples free of carbonate and carbide phases were prepared when the lithium evaporation pulse duration was less than the interval between the impulses.

5.4. Pt-Catalyst on CDC Support

Platinum supported on carbon (Pt/C) is widely used as a catalyst for hydrogenation and oxidation reactions. The porous structure of the carbon support is of primary importance in the catalyst performance. CDC provides the advantages of a narrow pore size distribution and variable pore diameters. Pt/C catalysts are usually prepared by adsorption from a solution of a platinum-containing species on the selected carbon material followed by reduction of the platinum compound to the metal state (see, for example, [146]). This method is applicable to CDC. A novel, one-stage method the for preparation of Pt/C catalysts from SiC was proposed by Ersoy et al. [147, 148]. Silicon carbide ceramics were treated in the Cl_2–H_2–Ar gas mixtures according to the technique described in [10, 63, 64]. Additionally, metallic platinum was present in the reaction zone in the form of foil or wire. In this case, Pt particles were dispersed in the produced material forming interlayers within the carbon layer. The proposed mechanism of the process consists of platinum transport to the SiC/C interface via the gas phase in the form of triplatinum trichloride, after which the Pt_3Cl_3 reacts with Si from the SiC resulting in Pt and $SiCl_4$.

5.5. Tribological Coatings

Metal carbides are widely used in a variety of machining and sliding contact applications. Despite their high corrosion and wear resistance, these materials are not lubricious. A novel process for the formation of a low-friction carbon layer on the SiC surface was recently introduced [2, 65]. Tribological characterization of the silicon carbide ceramics coated using this process was carried out in [149]. Sintered α-SiC and CVD β-SiC specimens were treated in the Cl_2–H_2–Ar mixtures of various composition at temperatures from 700 to 1000 °C and ambient pressure. Tribological tests were performed which measured the friction coefficients and wear rates by means of the standard ball-on-disk method. The produced articles had friction coefficients up to seven times lower than the untreated SiC. The friction coefficients of ~0.1 were almost independent of the type of initial material and the parameters of the ball-on-disk test including contact load and sliding speed. As evidenced by the wear track features, the primary deformation process appears to be plastic flow of the carbon layer, resulting in a smooth surface as the wear process progresses. These coatings can work in dry (nitrogen or vacuum) and humid (air or water) environments, with and without lubricants, and can be used in dynamic seals of water pumps and other tribological applications.

6. CONCLUSIONS

The synthesis of almost all known carbon structures including amorphous and nanocrystalline graphitic carbon, single-wall and multiwall nanotubes, carbon onions, nanocrystalline diamond, and ordered graphite is possible by the extraction of metals from carbides. Since the metal carbide lattice is used as a template and metal is extracted layer by layer, atomic level control can be achieved in the synthesis process and the structure of the carbon can be templated by the carbide structure, with an opportunity for further modification by controlling the temperature, pressure, composition of the environment, and other process variables.

Thermodynamic analysis shows the possibility of carbon synthesis from almost any carbide under appropriate process conditions (temperature, pressure, and etchant). While more than 50% of experimental data have been obtained on SiC, about 20 other carbides have been successfully used to produce CDC.

The linear kinetics of CDC growth in a broad temperature range allows transformation to almost any depth and the synthesis of coatings, powders, and freestanding CDC membranes. This is due to the open nanometer-size porosity in the material. The pore structure of CDC can be tuned very finely by using different carbides, etching agents, and temperature. The average pore size can be controlled with an accuracy of better than 0.1 nm and the pore size distribution produced is narrower than in activated carbons having a similar average pore size which were derived from organic precursors.

Noncatalytic and catalytic synthesis of carbon nanotubes by thermal decomposition of SiC in vacuum has been demonstrated. Catalyst-free nanotube brushes or powders can be produced using this method.

Nanocrystalline diamond can be formed by the extraction of silicon from silicon carbide. It is usually surrounded by amorphous carbon. Continued heat treatment of the nanodiamond at about 1000 °C and higher temperatures results in graphitization and the formation of carbon onions within a few micrometers of the SiC/carbon interface. This onion-containing layer can grow to a thickness of more than 100 μm with uniform structure and properties. The diamond-containing interlayer and the sawlike interface toward the metal carbide explain the excellent adhesion of CDC coatings and the onionlike surface layer is responsible for their excellent tribological properties.

It has been shown that the presence of hydrogen in the environment is not required for diamond synthesis. However, hydrogen can stabilize the diamond nanocrystals in CDC and lead to the growth of thick diamond-structured layers. If no hydrogen is added, diamond nanocrystals transform to graphite, forming carbon onions and other curved graphitic nanostructures.

Low-temperature treatment in halogens produces amorphous carbon with a narrow pore size distribution in the range of 0.5–2 nm. Additionally, mesopores or macropores can be incorporated by varying the starting material (e.g., using porous ceramics) and process parameters. CDC produced from dense ceramics or single crystals has only nanopores and can be used in molecular sieves.

Various approaches to CDC synthesis include decomposition in vacuum, leaching by supercritical water, halogens, and molten salts. CDC structures produced by these techniques have some similarities but also many differences. For example, carbon nanotubes can be produced by high-temperature vacuum decomposition, while amorphous nanoporous carbon is generated by treatment in halogens or supercritical water below 1000 °C.

An important advantage of the CDC process over CVD or PVD for the synthesis of thin carbon coatings is that the transformation is conformal and does not lead to a change of the carbide sample's size or shape. This may be of particular importance in tribological coatings or in nano/microtechnology applications when high surface quality and nanometer range accuracy must be achieved. Powders, fibers, and carbide components of any shape can be coated with carbon using the CDC process.

CDC synthesis can be environmentally friendly even when halogens are used for metal extraction. This process allows the utilization of metal halogenides generated as a by-product of carbon synthesis. Alternatively, the halogenides can be decomposed in the high-temperature zone of the furnace to produce a metal and halogen, which can be returned to the reactor creating a closed-cycle process. The use of low-cost furnaces and moderate temperatures in halogen-assisted synthesis allows the large-scale production of nanostructured CDC.

Potential applications of CDC include supercapacitors, lithium ion batteries, molecular sieves, gas storage (hydrogen, methane and other), gas separation, filtration of liquids and gases, catalyst support, and adsorbents for soil and air decontamination, gas chromatography, and other purposes. CDC films can be used as tribological coatings in dynamic seals and other applications involving sliding or rolling friction. They have a low friction coefficient of 0.02 to 0.2 and,

unlike other carbon materials, work well in both wet and dry environments. Specific structures produced by this process can find other applications in nanoelectronics and electrochemistry, or as ultralight structural or multifunctional materials.

GLOSSARY

Adsorption isotherm An adsorption isotherm for a single gaseous adsorptive on a solid is the function which relates at constant temperature the amount of substance adsorbed at equilibrium to the pressure (or concentration) of the adsorptive in the gas phase.

Amorphous carbon A carbon material without long-range crystalline order. Short-range order exists, but with deviations of the interatomic distances and/or interbonding angles with respect to the graphite lattice as well as to the diamond lattice.

Carbide-derived carbon (CDC) Carbon material produced by selective extraction of metal atoms from a carbide crystal lattice by halogens, supercritical water, oxygen at a low partial pressure, or other etchants, or in vacuum.

Carbon nanotube A nanoscale (1–100 nm) carbon structure produced by rolling graphene sheet(s) into a tube.

Graphitization A solid-state transformation of thermodynamically unstable nongraphitic carbon into graphite by means of heat treatment.

Hydrothermal synthesis Synthesis of material using supercritical water.

Lithium-ion battery An electrochemical battery based on lithium metal as anode.

Nanodiamond A diamond with particle size of 1–10 nm produced by shock synthesis, chemical vapor deposition, or a CDC process.

Nanoporous carbon A porous carbon material, which is considered to have a major part of its porosity in pores of less than 2 nm width and to exhibit apparent surface areas usually of 200 to 2000 m^2/g. Also called microporous carbon following IUPAC classification.

Physical adsorption Adsorption in which the forces involved are intermolecular forces (van der Waals forces) of the same kind as those responsible for the imperfection of real gases and the condensation vapors, and which do not involve a significant change in the electronic orbital patterns of the species involved.

Specific surface area When the area of the interface between two phases is proportional to the mass of one of the phases (e.g., for a solid adsorbent, for an emulsion, or for an aerosol), the specific surface area can be defined as the surface area can be defined as the surface area divided by the mass of the relevant phase.

Supercapacitor Electrochemical double layer capacitor. The electric energy is stored in the electric double layer from charge separation which is electrostatic force between an ionically conducting electrolyte and a conducting electrode. The ions displaced in forming the double layers are transferred between the electrodes by diffusion through the electrolyte.

Tribology The branch of engineering that deals with the interaction of surfaces in relative motion (as in bearings or gears): their design, friction, wear, and lubrication.

ACKNOWLEDGMENTS

This work was supported by DARPA via ONR contract. Y.G. would like to acknowledge productive collaboration with Professor M. J. McNallan (UIC) as well as assistance from his students and postdoctoral associates H. Ye, B. Carrol, and L. Chen at Drexel University and S. Welz at the University of Illinois at Chicago, who worked with him on development of new CDC materials.

CONTENTS

1. INTRODUCTION

The interest in ferroelectrics arises because a ferroelectric material exhibits spontaneous polarization. A ferroelectric crystal consists of positive and negative ions. For a certain temperature range, the positive and negative ions become displaced. This results in a net dipole moment. The orientation can be reversed with the application of an electric field. Entry into the spontaneous polarization temperature range requires the ferroelectric crystals to undergo a phase transition, which involves structural changes. The two phases, with and without a spontaneous dipole moment, are referred to as the ferroelectric and paraelectric respectively [1]. As the temperature decreases from above the Curie temperature, T_c, a structural phase change occurs and the crystal changes from paraelectric to ferroelectric. Since the potential energy in the ferroelectric phase of the two polarization orientations has the same energetic minimum, both polarizations are equally favored. Interest in ferroelectrics has grown rapidly because the high relative dielectric constant of a ferroelectric material can be used in dynamic random access memories (DRAM). Its capacity for being polarized in opposite directions makes it a candidate for nonvolatile random access memories. Ferroelectric thin films are also frequency agile due to the nonlinear dc electric-field dependence of their relative dielectric constant. This characteristic can be used for frequency and phase agile microwave circuits. Two popular ferroelectric thin films for frequency agile circuits are strontium titanate ($SrTiO_3$) and barium strontium titanate ($BaSrTiO_3$).

One aspect of studying particle size effects in ferroelectrics is to determine the ultimate level to which a device fabricated from these materials can be miniaturized without degrading the desirable characteristics of the material. The experimental study of size effects in ferroelectrics has gained momentum because of the advances in synthesis and material characterization techniques [2–10]. These advances provide the means for the study of size effects in nanostructured ferroelectrics.

1.1. Ferroelectric Materials

1.1.1. Dielectrics/Ferroelectrics

A dielectric material is one that is electrically insulating (nonmetallic) and exhibits, or can be made to exhibit, an electric dipole structure. There is a separation of positive and negative electrically charged particles at either a molecular or atomic level. Dielectric polarization can be visualized as the action of dipole chains, which form under the influence of an applied field. The countercharges are bound by their free ends when terminated on metal surfaces [1].

The polarization $\mathbf{P}$ ($\mathrm{C\,m^{-2}}$) induced in a dielectric by an applied electric field vector $\mathbf{E}$ ($\mathrm{V\,m^{-1}}$) is $\chi\varepsilon_0\,\mathbf{E}$, where χ ($\mathrm{F\,m^{-1}}$) is the dielectric susceptibility of the material. The total surface charge density induced by an applied electric field, $\mathbf{D}$ ($\mathrm{C\,m^{-2}}$), is given by $\mathbf{D} = \varepsilon_0\mathbf{E} + \mathbf{P}$, $\mathbf{D}$ ($\mathrm{C\,m^{-2}}$) is the dielectric displacement vector, and ε_0, given by

8.854×10^{-12} F m^{-1}, is the dielectric permittivity of vacuum. Complex permittivity $\varepsilon^* = \varepsilon' - i\varepsilon''$ is used to account for migration of charge carriers as well as any other energy-consuming process that may occur in the material. The loss tangent is defined as $\tan\delta = \varepsilon''/\varepsilon'$ and the quality factor $Q = 1/\tan\delta$ [1] (Fig. 1).

Some polar materials, called pyroelectric, display an electric dipole moment even in the absence of an external electric field. The polarization associated with a spontaneously formed dipole moment is called spontaneous polarization, P_s. Piezoelectric materials can be polarized by the application of an electric field as well as by the addition of a mechanical stress. Ferroelectric materials are both pyroelectric and piezoelectric [1].

Ferroelectric materials are polar and possess at least two equilibrium orientations of the spontaneous polarization vector in the absence of an applied electric field. The spontaneous polarization vector may be switched between these orientations by an applied electric field. Most ferroelectrics undergo a structural phase transition from a high temperature nonferroelectric (called paraelectric) phase to a low-temperature ferroelectric phase. T_c, the Curie temperature, is the temperature of the phase transition. At temperatures above T_c the dielectric permittivity falls off with temperature and follows the Curie–Weiss law [1]. For the ferroelectrics (example, $BaTiO_3$) that undergo several phase transitions into successive ferroelectric phases, only the first ferroelectric phase is called the Curie point. The ferroelectric phase transition causes anomalies in the dielectric, elastic, and thermal properties. The transition is also accompanied with changes in the dimensions of the crystal unit cell. There is a spontaneous strain, x_s, that is associated with the phase transition. It is responsible for the difference in the dimensions of the ferroelectric and paraelectric unit cells [11]. A change that can occur in a ferroelectric material is the transformation from a paraelectric cubic into a ferroelectric tetragonal phase.

In the ferroelectric phase, a crystal is spontaneously strained with $a_t \leq a_c < c_t$ where a_t and a_c are the a-axes of the tetragonal and cubic unit cell. Spontaneous polarization can arise along any of these axes with equal probability when the crystal is cooled through the ferroelectric phase transition temperature. Polarization will develop in directions dependent upon the electrical and mechanical boundary conditions imposed on the material. Regions of uniformly oriented spontaneous polarization are called ferroelectric domains. Regions between two domains are called domain walls. Domain walls oriented differently in response to the spontaneous polarization vector are called ferroelectric domain walls, and those which differ in orientation to the spontaneous strain tensor are called ferroelastic domain walls (Fig. 2). For a detailed discussion see [1].

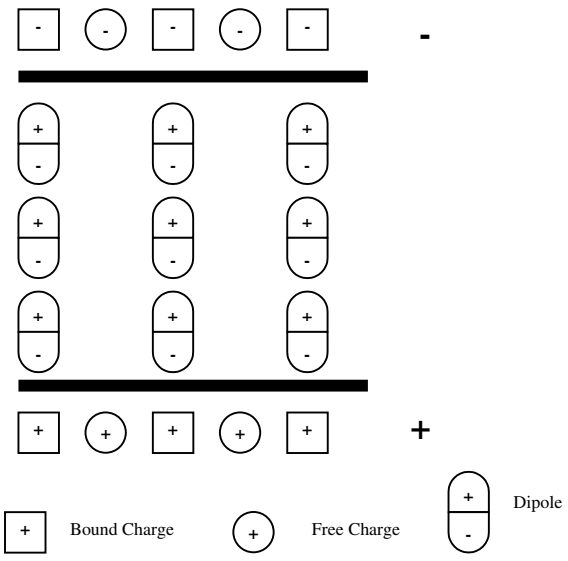

Figure 1. Dipole chains for a ferroelectric material.

The most important characteristic of ferroelectric materials is the reversal of polarization by an electric field. A consequence of the domain-wall switching in a ferroelectric materials is the ferroelectric hysteresis loop, as shown in Figure 3. At small values of the applied electric field, the polarization increases linearly. In this region the field is not strong enough to switch domains with the unfavorable direction of polarization. As the field is increased, the polarization of domains with an unfavorable direction of polarization will start to switch in the direction of the field. Zero polarization requires reversing the field.

Further increasing of the field in the negative direction will continue the realignment of dipoles until saturation. The field is then reduced to zero and reversed to complete the cycle [1]. The value of polarization at $E = 0$ is called the remnant polarization, P_r. E_c is called the coercive field, where the polarization is zero. The spontaneous polarization P_s is the intercept of the polarization axis. The coercive field, spontaneous and remnant polarization, and shape of the hysteresis loop may be affected by the film thickness, the presence of charged defects, mechanical stresses, preparation conditions, and thermal treatment [12]. The slope of the P vs E characteristics is a direct measure of ε_r of the ferroelectric material. The nonlinear P–E characteristics result in nonlinear electric field dependence of the ε_r.

When a periodically varying electric field E is applied to a ferroelectric material a hysteresis loop is obtained. This dynamic hysteresis is the representative characteristic of a ferroelectric. The hysteresis area, A, represents the energy dissipation within one period of domain reversal. The area is the characteristic parameter used to scale the dynamics of nonequilibrium first-order phase transitions in ferroelectrics. The kinetic nucleation and growth of new domains can be

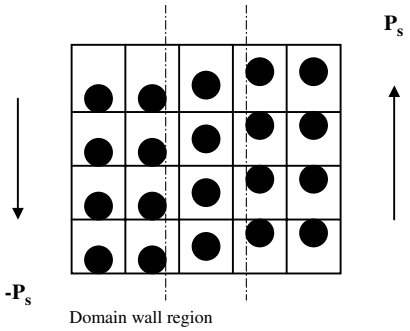

Figure 2. Ferroelectric domain regions in response to spontaneous polarization.

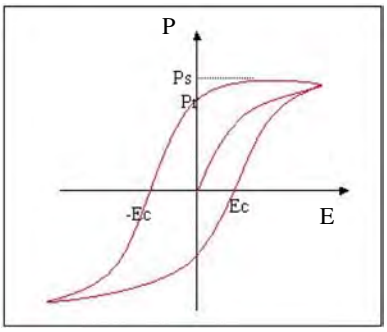

Figure 3. Hysteresis curve for a ferroelectric material under an applied electric field.

evaluated from the details of the hysteresis loop. The remnant polarization P_r and coercive field E_c can be determined from the hysteresis loop [13].

1.2. Applications of Ferroelectric Materials

1.2.1. Memory

Ferroelectric memory possesses advantages such as nonvolatility, low power consumption, high endurance, and high speed writing. The manufacturing processes for ferroelectrics are more compatible with the standard complementary metal–oxide–semiconductor (CMOS) process than traditional nonvolatile memory process. They do not require high voltage operation and the ferroelectric process does not affect characteristics of CMOS devices used in logic cells, analog cells, and core cells [14].

The importance of memory to electronic data processing drives continuous efforts to develop improved memory devices. Obstacles to very large scale integrated fabrication arise because the area of memory storage capacitance must be maintained while the device dimensions are reduced. This provides impetus to the adoption of complicated structures like the trench or the stack causing the number of processing steps to increase. The use of high dielectric constant materials has opened another avenue of DRAM development. Materials being studied in an effort to fabricate a film with a higher dielectric constant are $SrTiO_3$ and $(Ba,Sr)TiO_3$ [15].

1.2.2. Microwave

High relative dielectric constant (ε_r) ferroelectric materials are currently being employed in microelectronic, microwave, and optoelectronic applications. For example, the large capacitance per unit area requirement in high density DRAMs is accomplished using high ε_r ferroelectric materials such as $Ba_{(1-x)}Sr_xTiO_3$ (BSTO) [17]. In the past few years, the use of high-permittivity ferroelectric materials in microwave devices has been widely investigated due to the increasing need for higher power, smaller size, lighter weight, and lower cost, frequency-agile components [18–21]. Examples of applications in the area of microwave engineering include field-dependent varactors, tunable resonators, phase shifters, frequency-agile filters, variable-power dividers, and variable-frequency oscillators [18–21]. Ferroelectric materials are also being investigated for nonlinear applications such as harmonic generators, pulse shaping, mixing, and parametric amplification [22]. Electronically tunable filters can be constructed and applied to interference suppression, secure communications, dynamic channel allocation, signal jamming, and satellite and ground-based communications switching. The use of high-permittivity ferroelectric ceramics and films requires the materials possess frequency stable permittivities and low dielectric losses. For microwave applications, $\tan\delta$ is lower in the paraelectric state ($T > T_c$) due to the absence of hysteresis loop. Operating just above T_c can yield large tunabilities.

BSTO is being investigated for applications in tunable microwave devices and circuits [17–20]. BSTO is a continuous, solid-solution ferroelectric with compositions between the perovskites $BaTiO_3$ and $SrTiO_3$. For instance, the Curie temperature (T_c) of BSTO decreases almost linearly with increasing Sr concentration while the index of refraction is changed by varying the solid solution composition and the deposition rate. Their nonlinear dielectric and optical properties can be tailored over a broad range to accommodate various applications. The BSTO (60/40) thin-film ferroelectric, with a T_c of 290 K, is a promising ferroelectric for room temperature tunable devices.

1.2.3. Photonics

Ferroelectric thin films are attractive for tunable photonic circuits due to the nonlinear electric field dependence of their refractive index at optical frequencies. Bias dependent structural changes in the ferroelectric thin films (ferroelasticity) are also attractive for tunable waveguides, modulators, and second harmonic generation [25]. Electric field dependence of birefringence and ferroelasticity makes them attractive for integrated optics applications. The thin-film form of ferroelectrics reduces the voltages necessary for achieving the required electric fields, as compared to the use of bulk ferroelectrics.

1.3. Nanophase Ferroelectrics

1.3.1. Background of Nanostructures

Nanostructured materials have dimensions that are measured on the length scale of a nanometer (one billionth of a meter) and have special properties due to quantum size and surface effects [26]. The motivation behind nanostructure engineering is the development of materials with novel properties through the controlled synthesis and assembly of the material on the nanoscale. No matter what synthesis approach is used there is a common premise for the fabrication of nanostructured materials. Fabrication of nanostructured materials allows the control and potential enhancement of the properties of the material, for example, ε_r, dielectric loss ($\tan\delta$), and Curie temperature, T_c. Nanostructure engineering allows miniaturization of devices to a critical size, below which the material loses its desired characteristics. There are a variety of approaches that can be used in the synthesis of nanostructures (Fig. 4).

A bottom-up approach uses advanced chemical techniques to mix precursor materials at the molecular level. Processing then allows growth of the material for the desired nanostructure; an example is sol–gel [27]. In the top-down approach, for example pulsed laser deposition (PLD), the

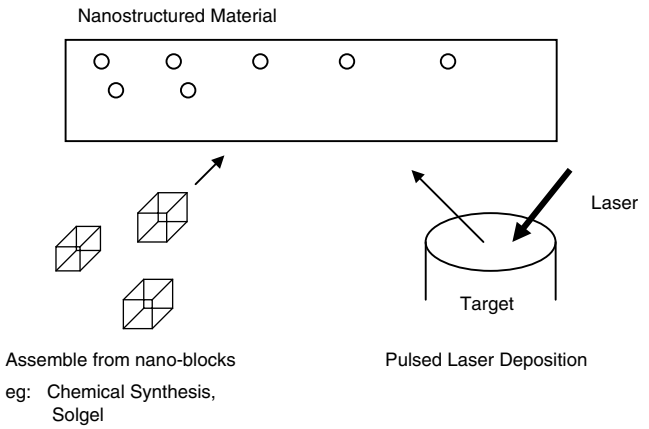

Figure 4. Synthesis of nanostructured material, the bottom-up approach, the top-down approach.

nanostructured material is deposited by the ablation of material from a target with a short laser pulse. The nanostructure of the deposited film can be controlled by varying the following PLD deposition parameters: chamber ambient gas, laser beam energy density, substrate temperature, deposition time, target system parameters, pulse repetition rate, pulse length, substrate-to-target distance, laser beam wavelength, target–substrate relative geometric arrangement, and postdeposition annealing [28–32].

Examples of materials with unusual properties at nanoscale include Si nanocrystals. Research in this area has gained momentum because of the potential of designing Si-based nanostructured materials that possess novel electronic and optical properties for use in new devices for optical communication. Quantum confinement in nanophase Si has revealed new physics for use in novel applications. Si is an indirect bandgap material and quantum confinement in this type of material can enhance luminescence, which is forbidden in bulk Si. Coalesced Si nanocrystals can be prepared by the laser vaporization-controlled condensation (LVCC) method. The Si fabricated nanocrystals have shown red photoluminescence upon excitation with visible and ultraviolet (UV) light. Since the unprecedented discovery of photoluminescence (PL) from porous Si, interest has grown in the synthesis and electrical/optical properties of Si nanocrystals because they are believed to be the luminescent centers in porous Si [33].

Very intense and highly reproducible PL spectra for SiO_x films have also been obtained by laser ablation of Si targets [34]. Patrone et al. were able to show that Si nanoclusters produced by laser ablation exhibited PL properties within a spectral region extending from the near UV to the near infrared (IR). The PL spectra were dependent on nanocluster size [35, 36]. The development of nanostructured materials has the potential to change present application of materials.

1.3.2. Size Effects in Ferroelectrics

For microwave applications, nanostructured ferroelectric films need to have a low dielectric constant ($25 < \varepsilon_r < 500$), a low loss tangent (or dissipation factor) ($0.001 < \tan\delta < 0.005$), and a high dielectric tunability [$((\varepsilon_{r0} - \varepsilon_{rV})/\varepsilon_{r0}) > 10\%$ where ε_{r0} is the ε_r at zero bias, ε_{rV} is the ε_r at a bias voltage V]. One of the methods to reduce ε_r and the $\tan\delta$ and improve tunability in BSTO is to form composites of BSTO with other nonelectrically active ceramics such as MgO and $LaAlO_3$ (LAO) [37]. One mol% Mg doped BSTO (60/40) resulted in a ε_r of 420, $\tan\delta$ of 0.022 (MHz frequencies), and tunability of more than 20% in thin films deposited by the metal organic deposition technique on Pt substrates [37]. Five mol% Mg content in BSTO reduced the ε_r to 386 and loss tangent to 0.007 (MHz frequencies) and increased tunability to 17.2% [38].

The potential for tuning the microwave properties of the ferroelectric barium titanate has been demonstrated by McNeal et al. [39]. Through the control of grain/particle size and domain state, relaxation frequencies were shown to increase and loss tangents decreased with decreasing grain/particle size. A polycrystalline ceramic ferroelectric, $BaTiO_3$, having grain sizes of 14.4, 2.14, and 0.26 μm and powder–polymer matrix composites of sizes 1.33 μm, 0.19 μm, and ~66 nm, respectively, were used.

Zhang et al. studied finite-size effects in the ferroelectric solid solution $Ba_xSr_{1-x}TiO_3$. Their samples were characterized and analyzed by scanning electron microscopy (SEM), transmission electron microscopy, and X-ray diffraction. The Curie temperature decreased with a decrease of grain size. The Curie peak became broader and eventually disappeared. Three ferroelectric critical grain sizes of 317, 246, and 176 nm for $x = 0.3$, 0.5, and 0.7, respectively, were evaluated [40].

Jiang and Bursill have proposed a new phenomenological model to study size effects on the first-order phase transition of lead titanate ferroelectric particles. The proposed model would try to explain the experimental results that show the Curie temperature, tetragonality (c/a) ratio, latent heat, and soft-mode frequency all decrease with decreasing particle size for $PbTiO_3$, $BaTiO_3$, and $PbZrO_3$ [41].

Wang et al. report on the size effects on spherical ferroelectric particles described by the transverse Ising model taking into consideration the long-range interactions [42]. In this report the authors studied the size dependence of the mean polarization, the Curie temperature, the mean susceptibility of the particle, and the critical size of the particle. The Hamiltonian of the transverse Ising model has the form

$$H = -\Omega \sum (S_i)^x - \frac{1}{2} \sum J_{ij} (S_i)^z (S_j)^z - 2\mu E \sum (S_i)^2 \quad (1)$$

Ω is the transverse field, and $(S_i)^x$ and $(S_j)^z$ are components of a spin-$\frac{1}{2}$ operator at site i. J_{ij} is the exchange strength between sites i and j. μ is the effective dipole moment of site i and E is the external electric field. The authors summarize their results: with a decreasing particle size, the mean polarization and Curie temperature of the particle decrease to zero at a critical size of the particle. Here, there is size-driven phase transition from the paraelectric phase to the ferroelectric phase. Long-range interactions are dominant contributions to ferroelectricity.

1.3.3. Why Nanophase Ferroelectrics?

Ferroelectric materials are typically multidomained as a large depolarization field (due to buildup of surface charges) forces a single crystal to divide into several domains. At microwave and optical frequencies, these multidomained materials exhibit a large dielectric relaxation characterized by a decreasing ε_r and increasing $\tan\delta$. Mechanisms attributed to dielectric relaxation include piezoelectric resonance of grains and domains, domain wall vibration, and shear waves from domain walls contributing to high frequency dispersion of ε_r $(\varepsilon_r' - j\varepsilon_r'')$ and high $\tan\delta$ $(|\varepsilon_r''/\varepsilon_r'|)$ [43]. The dielectric relaxation, which is intrinsically dependent upon domain state, is in part dependent upon the microstructure. Previous studies in size effects have shown that: (i) Relaxation frequencies increased and $\tan\delta$ decreased with decreasing grain/particle size [43]. (ii) T_c decreases with decreasing grain/particle size [43]. (iii) The peak value of ε_r decreases [44]. (iv) Lattice constants change such that the unit cell becomes more symmetric [44]. (v) There exists a critical domain size below which the ferroelectric behavior vanishes [43]. (vi) Monodomain ferroelectrics can be obtained for a grain size below 200 nm [43]. (vii) Domain switching is quicker in smaller domains compared to larger domains but requires higher electric fields [43].

2. SYNTHESIS OF NANOSTRUCTURED BSTO

2.1. Sol–Gel

Sol–gel is a chemical process that permits molecular-level mixing and processing of starting materials and precursors in a relatively easy way and permits nanostructured films to be formed at low temperatures. The process is relatively inexpensive because it does not require a vacuum for deposition. A sol–gel deposited film is amorphous, which means there is a long diffusion process with sufficient time for diffusing atoms to move into and through grains from grain boundaries. This leads to a relatively uniform distribution of diffusant [45–50]. Nanocrystalline particles of $BaTiO_3$ < 30 nm have been successfully fabricated using the sol–gel method [51]. A flow diagram for the sol–gel fabrication of $(Ba,Sr)TiO_3$ films is given in Figure 5. Precursor solutions are prepared in a nitrogen dry box at room temperature. Barium diethoxide $[Ba(OC_2H_5)_2]$ and strontium diethoxide $[Sr(OC_2H_5)_2]$ are dissolved in dehydrated 2-methoxyethanol $(CH_3OCH_2CH_2OH)$ and stirred. Titanium tetra-I-propoxide $[Ti(OCH(CH_3)_2)_4]$ will be added to the barium and strontium solutions [52].

The reaction represents the synthesis for $t \geq 0$ °C:

$$Ba(OH)_2 * H_2O + Ti(OR)_4 \rightarrow BaTiO_3 \quad \text{(I)}$$

$$Sr(OH)_2 * H_2O + Ti(OR)_4 \rightarrow SrTiO_3 \quad \text{(II)}$$

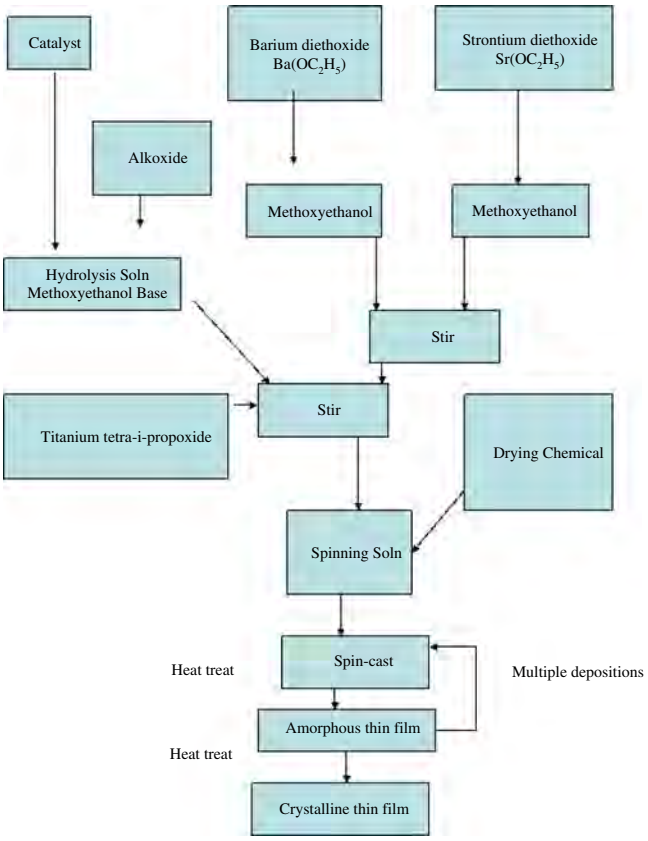

Figure 5. Flow diagram for the fabrication of sol–gel films.

2.2. PLD

PLD is recognized as a versatile and powerful technique for the fabrication of nanostructures. The principle of PLD utilizes an intense laser pulse passing through the optical window of a vacuum chamber. The laser beam is directed onto a solid or liquid target surface where it is partially absorbed. Above a threshold power density, target material is ablated and forms a highly energetic and directed luminous plume. The power density needed to produce the plume depends on the target material and its morphology as well as the laser pulse wavelength and duration. Film growth occurs at the substrate in an ambient gas environment where energetic adatoms from plume components can reproduce an epitaxial film with the same stoichiometry as the target [53, 54]. A reactive gas or ion source may be added to aid the growth process. The PLD plume can be a mixture of macroparticles, molecular species, atomic species, and ionic species. Pulsed laser deposition is popular in the deposition of oxide thin films because of the demonstrated deposition of high quality thin films and heterostructures [55]. The final quality of the deposited film depends on the complexity of the deposited material system and the ability to control approximately 17 process control variables according to a deposition recipe [56].

As in PLD of thin films as well as with PLD of nanostructures, the critical growth dynamics are controlled by the characteristics of the plume components' adatoms, the substrate/seed layer/film surface, and the ambient gas

environment. These characteristics can be summarized as follows:

1. Adatoms
   a. Mobility on film/substrate surface
      i. Kinetic energy
         1. Due to plume dynamics
         2. Due to heater temperature
      ii. Time before movement quenched by arrival of next pulse
   b. Density per laser pulse
   c. Differences between several plume component adatoms (generally they need to arrive in some order and density)
2. Substrate/seed layer/film
   a. Number and arrangement of nucleation sites on surface
   b. Lattice match of surface to desired stoichiometric growth structure
   c. Strength of component confinement inside substrate, seed/buffer and film layers (diffusion effects)
3. Ambient gas
   a. Required for incorporation into film structure (usually cannot be suitably added later)

For a more complete and detailed description of PLD, see Chrisey and Hubler [53].

2.2.1. Process Control

To adapt PLD as a manufacturing process for thin nanostructured films, the critical film-growth process variables must be identified and controlled. This permits *in-situ* control of the process which could enable intelligent processing or self-directed process control (SDC). SDC consists of making *in-situ* sensed observations of the process. Stark and Laube's [57] four steps for the development and implementation of SDC are

1. Identify appropriate sensors and the variables that control the deposition process dynamics.
2. Determine empirical relationships by experimentation, since no good analytical models exist at present.
3. Correlate test results with experimental results to develop qualitative relationships.
4. Incorporate qualitative relationships into the process baseline.

Many of the process variables in PLD, such as laser fluence and chamber ambient pressure are interdependent and are coupled to temperature-dependent variables like substrate temperature and plume velocity. Mathematically modeling the variables and their interdependence is very complex and has only partially been addressed [58–63]. Plume dynamics is one of the most important but least understood aspects of the PLD process. The plume is second only to the film growth dynamics in terms of complexity. SDC requires identification of the interrelationship of process variables involved. The 17 outer ovals in Figure 6, are at the environmental level and are considered process control variables. The three inner ovals are critical measurable parameters affected by several process-control variables. The dashed outlined process variable is a significant control variable not yet easily adjustable on excimer lasers. The octagons are subdivided regions of the deposition process where the control variables exert their effects.

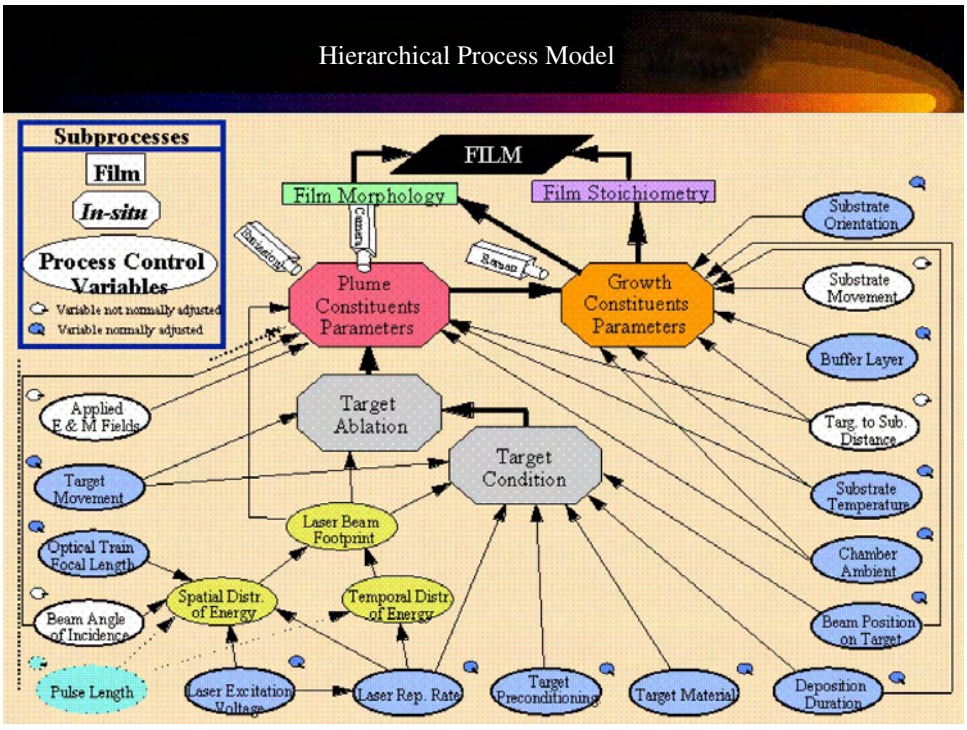

Figure 6. Hierarchial process model identifying process control variables and their complex interactions with a pulsed laser deposition system.

Appropriate sensors are positioned to monitor these critical regions. The knobs near the control variables indicate normally actuated/used when turned to a downward position. The emission sensor monitoring the plume can provide feedback activation of all but the top right three variables. These variables require a different sensor such as the Raman sensor depicted in Figure 6.

2.2.2. Versatility and Complexity of PLD

The versatility and complexity of PLD are evident by the number of process control variables that were noted in the hierarchical model. These deposition variables can be adjusted and each can strongly affect the basic components involved in the film/nanostructure growth depending on what part of deposition parameter space the deposition is in. Usually they are set according to a deposition recipe that is unique to the deposition system being utilized. Adjustment of these deposition variables is not recommended without some idea of the effect on the film growth. Biggers and Jones have developed a general list similar to that in the hierarchical model (to be published). These variables all affect the film growth through the adatoms, the substrate/seed layer/film, and the ambient gas at substrate/film and plume interface (where the film grows).

The following PLD process control variables strongly affect these adatoms, the substrate/seed layer/film, and the ambient gas environment during nanostructure growth.

1. The excitation voltage (kV) affects the target surface condition and film adatoms
   a. Controls total energy delivered to optical train. Some lasers may have a change in beam quality at a certain kV below which a current recipe will not produce quality films.

2. The optical train affects the target surface condition and film adatoms
   a. Controls the total energy (J) delivered to target
      i. Aperture reduces beam size (cm^2) and energy (J)
      ii. Affects beam quality
      iii. Each optical surface removes energy (J) from the beam
   b. Sets the beam footprint area (cm^2) on the target

3. Beam footprint (cm^2) affects the target surface condition and film adatoms
   a. At a set excitation voltage, controls power density (W/cm^2) applied to the target
   b. Affects the amount of target material removed per pulse
   c. Effects plume dynamics
      i. Expansion
      ii. Components' velocities

4. Substrate temperature (°C) above room temperature affects the film adatoms, ambient gas environment, growth surface, and diffusion effects
   a. Directly effects adatom mobility via heater surface temperature
   b. Effects plume dynamics by decreasing ambient gas density which lowers the number of component collisions with the ambient gas
      i. This decreases plume component cooling which increases arriving adatom kinetic energy (mobility)
      ii. Also increases plume expansion (reduces amount of adatoms arriving per area per pulse)
   c. Increases diffusion effects (impurity movement to grain boundaries, across interfacial surfaces, etc.)

5. Chamber ambient gas pressure (mTorr) and (type) affects the adatoms, substrate/film, and the ambient gas environment
   a. Affects the collision cross-section (probability of collisions)
   b. Affects the amount of energy transferred during collisions (cooling/slowing of plume components)
   c. May provide needed component to growing film
   d. Reduces or oxidizes the substrate surface

6. Target to substrate distance (cm) affects the adatoms and the ambient gas environment
   a. Affects kinetic energy of components (adatom mobility)
   b. Number of adatoms deposited per pulse (film growth dynamics)
   c. Plume envelope expansion (density of adatoms)

7. Deposition duration (min) affects target, film surface, and film
   a. Total amount of material delivered to substrate (thick films lose texture)
   b. Target surface dynamics (creation of cones, etc.)
   c. The diffusion range and amount of materials within the film/substrate system

8. Target system parameters include rotation rate (rpm), surface structure (polished or ablated), chemistry ($Ba_{0.5}Sr_{0.5}TiO_3$), and density (g/cm^3) which affect the film adatoms and film surface

9. Pulse repetition rate (Hz) affects film adatoms and film surface
   a. Time for adatom movement between pulses strongly affects film growth dynamics (longer times larger grains, shorter times probability of holes and outgrowth development, etc.)
   b. Amount of overlap between successive laser footprints (ablating from a solid or a liquid surface-effects kinetic energy of plume components, etc.)

10. Pulse length (ns) affects film adatoms
    a. Affects plume dynamics (longer pulses more plume initial ionization)
    b. The shorter the pulse length, the more ablative the plume generation

11. Wavelength (nm) affects film adatoms
    a. Affects the transfer of energy to target material (excimer may provide almost true ablation while IR causes target heating and material evaporation over a longer time frame)

b. Amount of energy available in beam footprint
c. Energy density and distribution available in the beam footprint

12. Postdeposition annealing affects film through diffusion effects and the ambient gas environment

2.2.3. Power and Flexibility with PLD

Grain size, surface smoothness, and film density are important characteristics for many thin film systems, especially superconducting and ferroelectric films. Many groups have been able to demonstrate some level of control over the final film characteristics to make the films more suitable for intended uses. They have utilized a subset of the deposition variables previously listed. Trananovic et al. utilized the pressure of the chamber ambient gas and the substrate temperature to control the surface morphology, grain dimensions, and grain density [64]. At low pressures (40 to 60 mTorr O_2), the YBCO *a*-axis grains were larger. The grain surfaces were flatter at 800 °C but rounded and better packed at 760 °C. Kim et al. also used ambient pressure to control film orientation and surface roughness [65]. They made a 30 nm template layer in 300 mTorr O_2 on Pt(111)/SiO_2/Si which produces an (110) orientation in the BTO film. They then deposited another 300 nm of BTO under 0.01, 100, and 400 mTorr. The orientation remained (110), the same as the seed layer, but the microstructure was quite different. The lowest pressure produced the densest and smoothest film, while the highest pressure produced the roughest surface and largest grains. Mukaida et al. used initial growth temperature to control YBCO grain size [66]. They found that grain size was logarithmically proportional to the heater temperature from 670 to 730 °C. In addition, if a desired grain size was set by an initial but short growth, then this grain size was retained if the temperature was changed for the remainder of the film growth. Biggers et al. found that laser repetition rate can strongly effect YBCO grain size and surface morphology while not diminishing other critical film characteristics such as critical transition temperature (T_c) and critical current density (J_c) [67]. The trend was that grain sizes decreased and the number of surface outgrowths increased as the repetition rate was incremented from 2 to 20 Hz. The number outgrowths continued to increase up to the limit of the laser at 40 Hz. However, the grain size slightly increased from that at 20 Hz. These are but a few examples of influencing film characteristics by manipulating the basic PLD deposition variables.

Emission Monitoring and Application of Process Control of PLD Emission spectroscopy (ES) permits the examination of plume sensitivity to almost any of the deposition process variables and is a critical element in achieving SDC. Pulsed laser deposition is very a versatile process especially for the deposition of nanophase thin films. Its potential is still constrained by the need to develop process control methodologies. Biggers et al. report the development of process control methodologies for a PLD system, Figure 7, [68] situated at the Materials Directorate, Air Force Research Laboratory, Wright–Patterson Air Force Base, Ohio. A PLD plume monitoring and control system was developed and utilizes a Lambda Physik 305i excimer laser (KrF, $\lambda = 248$ nm) with a 17 ns pulse, a variable-focus optical train, a beam scanning mirror, a Neocera vacuum chamber with multitarget holder, and substrate heater (see Fig. 7). Two optical emission sensor systems are attached to either side of the vacuum chamber to enable simultaneous monitoring of the same or different sections of the plume. The first maintains a fixed line-of-sight of a ~1 cm wide vertical slice of the passing plume manually set 38 mm from the target. The second system is similar but can be automatically positioned anywhere along the plume centerline from 11 mm away from the target all the way to the substrate heater. The two optical sensors in each system consist of photomultiplier tubes with inline narrow bandpass filters and slit arrangements to limit the viewed section of the plume. The filters are used to restrict monitored plume emissions to wavelengths associated with critical plume components (553 nm for exited Ba^* in $YBa_2Cu_3O_{7-\delta}$ depositions). The monitored emissions generate a time-of-flight (TOF) versus intensity signal as seen in Figure 8. The time difference between the start of the ablation process (the fireball) and the maximum intensity from the passing emitting plume component (main plume), the TOF setpoint, is sent to the computer.

This passed TOF provides the feedback for the computer to actuate from one to three deposition control variables (laser excitation voltage, chamber ambient pressure, and/or beam footprint size, process control variables 1, 5, and 3 respectively). Regulation of these deposition parameters once every two seconds to maintain the TOF setpoint provides the *in-situ* real-time process control. Also, linked through the computer is the control of the scanning mirror, laser repetition rate, and substrate temperature and recording of 27 deposition related variables, visible plume images, and control variable settings.

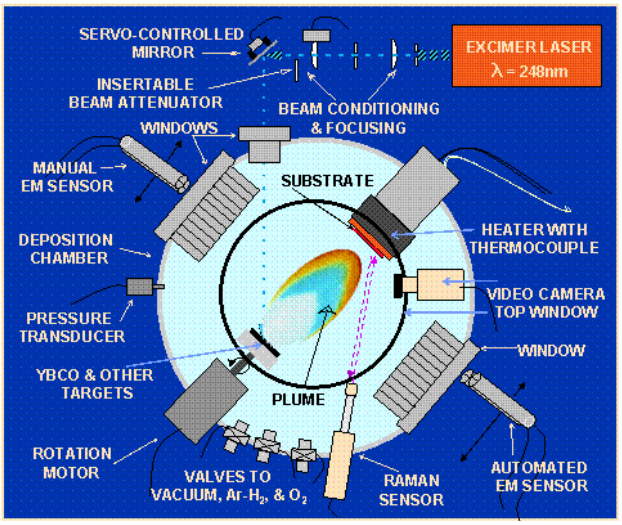

Figure 7. Automated *in-situ*, real-time, process-control pulsed-laser-deposition system. Real-time control based on feedback from emission sensors. Laser energy, chamber ambient, and/or beam footprint can be adjusted to maintain a TOF setpoint based on ES feedback.

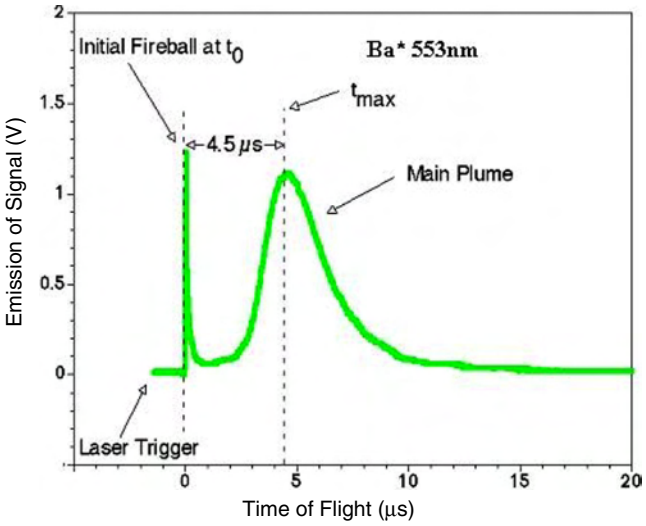

Figure 8. The emission signal from the Ba* component in the plume is generated when the material passed the monitored position. Note the sharp spike when the beam hit the target (fireball). This provides a timing mark for the start of the deposition process. The feedback TOF is the time between the fireball and the maximum intensity of the Ba* signal.

Emission Monitoring and Process Control for PLD of BSTO A number of groups have used ES to study plume dynamics [69–72] but only one group attempts *in-situ* real-time control based on ES feedback [68]. In the following figures, Biggers et al. show plumes from the deposition of BSTO on LAO substrates using the automated PLD system previously described and shown in Figure 9. A TOF of 4.5 μs, which in prior BSTO depositions [68] gave good results, was used as a starting TOF setpoint for the following depositions at different ambient O_2 pressures. TOF setpoints for various pressures from 19 to 300 mTorr were generated by attaining a TOF of 4.5 μs in 150 mTorr O_2 and then changing the pressure from 19 to 300 mTorr while recording the average TOF at each pressure, and holding a constant laser energy. Noting that 4.5 μs was recorded at 150 mTorr as the pressures were increased from 19 mTorr suggests that the desired energy density had been maintained. The TOFs and associated pressures were as follows: 3.60 μs @ 19 mTorr, 3.66 μs @ 38 mTorr, 3.95 μs @ 75 mTorr, 4.50 μs @ 150 mTorr, 4.95 μs @ 225 mTorr, and 5.45 μs @ 300 mTorr.

Figure 10 shows the variation of grain size with pressures ranging from 38 to 300 mTorr. The average grain diameters grow from ~36 nm at 38 mTorr to ~137 nm at 150 mTorr. Somewhere above 150 mTorr, the growth dynamics change and the grains begin to coalesce. Second depositions at the same deposition parameters produced similar results.

2.2.4. Nanoparticle/Nanocluster Formation within PLD Plume

The basic principles of nanoparticle formation using conventional pulsed laser ablation have been reported by Marine et al. [73]. (Haberland's description of clusters is given [74]: aggregates of atoms, or molecules, with size ranging from tens up to a few thousands of atoms.) Nanocluster synthesis using conventional PLD is usually performed at medium to high gas pressure, for example 0.2–10 Torr. Condensation starts within the plume during expansion and cooling. Within the plume condensed particles undergo multiple collisions with the ambient gas molecules. This leads to a stabilization of nanoclusters before arriving at a collection substrate surface. The size of nanoclusters can be varied by varying laser parameters of fluence, wavelength, pulse duration, ambient gas pressure, and the collection position from the plume centerline. Smaller clusters are scattered more than larger; hence more smaller can be collected off axis nearer the target. The authors [74] further define the process for nanocluster formation in four independent steps:

- *Cluster nucleation:* Nucleation is a function of the material's thermodynamic properties and the dynamic conditions of the plume and the plume components.

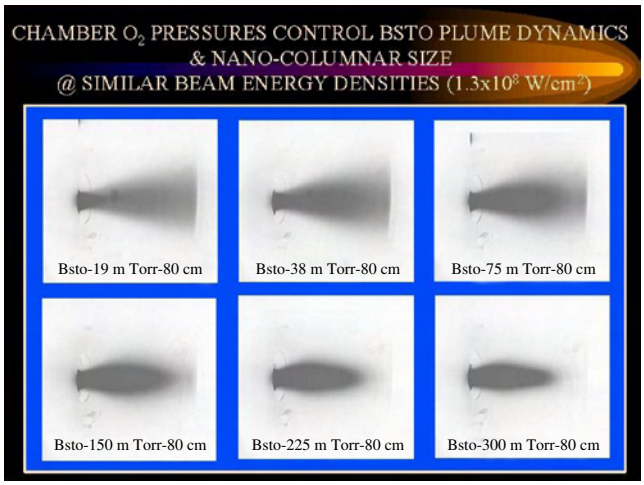

Figure 9. Visible wavelengths images of the PLD plume as the pressure was increased while holding a constant beam footprint energy density. Note the plume compacting and shortening, which is suggestive of more material being deposited per pulse and at lesser adatom energies.

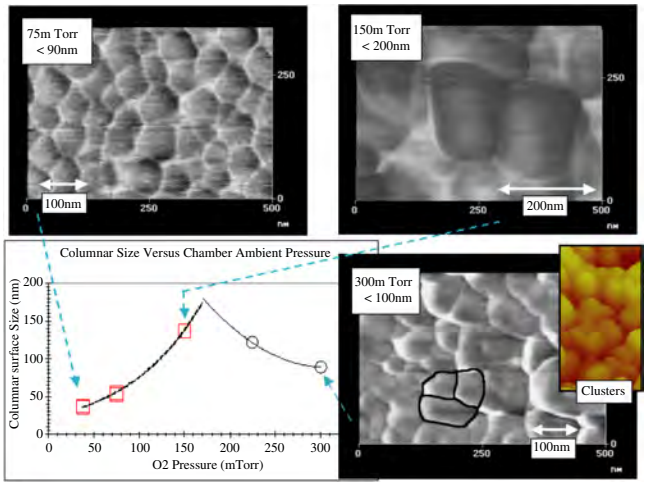

Figure 10. Frictional AFM images of BSTO surface morphologies as PLD ambient pressure increased. Note increasing grain size up to 150 mTorr of O_2, beyond which the grains begin to coalesce. The grain sizes fit a smooth curve up to 150 mTorr.

- *Growth:* Cluster growth occurs during the collisional expansion between plume particles (expansion dynamics vary with ambient gas effects). Expansion dynamics are influenced by ambient gas pressure.
- *Cluster cooling:* Because of the amount of energy generated during formation, clusters are stabilized by radiative, evaporative, and collisional cooling (collisional is the strongest with ambient gas at higher pressures).
- *Cluster deposition:* Deceleration of clusters must occur for cluster deposition or only fragments will be collected.

Deceleration is aided by growth in a background gas since this decreases significantly the kinetic energy of the ejected species by collisions with the gas species [74]. The mobility of the atoms arriving at the substrate surface is reduced relative to that in vacuum [74].

Nanocluster Size and Nanoparticle Formation It has been shown that the size of nanoclusters can be varied by the ambient gas pressure. Yoshida et al. [75] have shown that the diameter of Si particle size in the range 10–20 nm varied as a function of the pressure of the chamber ambient gas in the proportion $P^{1/2.8}$. Gonzalo et al. reported the influence of deposition parameters on nanocomposite materials produced by PLD [76]. Nanocomposite films of Cu nanocrystals embedded in amorphous Al_2O_3 were produced by PLD. The effect of laser fluence and ambient Ar gas was studied. The films were grown at room temperature using variable fluences and Ar pressures (10^{-6}–10^{-1} Torr). The authors suggested in the discussion of the experiment that nucleation and growth of the nanocrystals occurs on the substrate, not in the plume at 0.1 Torr when the diffusive region of the plume (the nucleation region) occurs at distances beyond the current substrate placement.

PLD Nanoparticle Condensation A phenomenological description of a condensation process is given by Pászti et al. for the formation of nanoparticles and nanocrystal networks prepared by PLD [77]. The authors postulate that in a high enough background pressure a shock wave is initiated by the collisions between target and gas atoms. This confines the plume and slows it down. In an inert gas atmosphere they describe four steps in nanoparticle formation:

- During the laser pulse, the plume components are emitted from the target.
- Atoms ablated from the target collide with ambient gas atoms primarily at the front of the expanding plume. Plume atoms thermalize, in 10–100 μs, after the laser pulse, while the shock wave develops.
- Nanoparticles form via homogeneous nucleation due to a supersaturation state, a result of the plume confinement and cooling behind the shock wave front.
- The first nanoparticles that are formed can coalesce incompletely which leads to the formation of aggregates in the plume and a nanocrystal network. This may coalesce completely leading to larger spherical particles. This continues until the number of primary particles become insignificant due to expansion.

This process explains the observed nanoparticle formation. There is a pressure range that accounts for thermalization in a limited volume of the plume. When decreasing the pressure, more plume component atoms avoid condensation and reach the substrate where heterogeneous nucleation begins. At the other end of the pressure range, increasing the ambient pressure increases the rate of thermalization decreasing the volume, where thermalization occurs. The level of supersaturation also increases. Thus the number and density of primarily condensed particles continues to increase. This leads to larger aggregates for incomplete coalescence and larger single particles in the complete coalescence. See [77] for a more detailed discussion.

2.3. Sputtering

Radio frequency (rf) magnetron sputtering is another popular technique in fabrication of complex dielectrics. The microstructure of the films depend on the sputtering pressure during the deposition, rf power, the target to substrate distance, and the substrate temperature. The scattering behavior of the sputtered components during deposition control the microstructure and crystal orientation of the growing film. Periaswamy et al. sputter deposited $Ba_{0.5}Sr_{0.5}TiO_3$ thin films on $Pt/TiO_2/SiO_2/Si$ substrates [78]. The films exhibited a capacitance tunability of 4:1. The higher tunability was attributed to (100) texturing of BST films and the biaxial tensile stress imposed by Si on BST making the polar axis oriented in plane [78]. Wang et al. demonstrated (111) oriented BST thin films (with 10% Sn doping in the Ti sites) on $Pt/TiO_2/SiO_2/Si$ substrates by rf magnetron sputtering [79]. The grain size increased with increasing deposition temperature, correlating with an increased dielectric constant [79].

2.4. Metal Organic Chemical Vapor Deposition

Metal organic chemical vapor deposition (MOCVD) is another powerful technique used in the semiconductor industry for large area growth of thin films. With suitable organic precursors, one can control the growth very precisely. The growth of ferroelectric thin films is dependent on the precursors and the substrate temperature. Gao et al. studied the effects of precursors and substrate materials on the microstructure and dielectric properties of BSTO thin films grown by MOCVD [80]. Two sets of precursors with quite different reactivities resulted in differing step coverage. Different reactivities apparently did not affect the microstructure, surface morphology, and dielectric properties of the stoichiometric BSTO thin films.

Tombak et al. studied BST thin films for variable capacitor (varactor) applications for rf and microwave frequencies [81]. BST films grown by the MOCVD method achieved a 71% tunability. The measured dielectric loss tangent was in the range of 0.003–0.009 at very high frequencies [81].

2.5. Molecular Beam Epitaxy

Molecular beam epitaxy is another popular process for preparing ferroelectric thin films. Ferroelectric $BaTiO_3$ (001) ultrathin film (10 nm) has been epitaxially grown on $SrTiO_3$ by laser molecular beam epitaxy [82]. The film was

observed by atomic force microscopy (AFM) and had a surface roughness of 0.2 nm.

Zhao et al. [83] report using laser molecular beam epitaxy to produce a series of $BaTiO_3$ thin films with thickness varying from 10 to 400 nm. The oxygen pressures were varied from 1.5×10^{-3} to 90 mTorr on $SrTiO_3$ (001) substrates. The films were highly *c*-axis or *a*-axis oriented with a surface root-mean-square (rms) roughness of 0.14 nm. The dependence of the crystallographic orientation on gas pressure was reported. Two mechanisms were reported as responsible for the effect: the residual hydrostatic compression from excess interstitials under low pressure and the residual hydrostatic tension resulting from excess vacancies under high pressure caused the crystallographic orientation.

3. SPECTROSCOPIC CHARACTERIZATION

3.1. X-Ray Diffraction

X-ray analysis reveals lattice structures as well as crystal structure. When X-rays are directed at a crystalline material they are diffracted by the planes of atoms or ions within the crystal. The diffraction angle depends on the wavelength of the X-rays and the distance between adjacent planes.

X-ray diffraction (XRD) analysis has been used to study tetragonality and lattice parameters of ceramic specimens of $BaTiO_3$ [84]. The ceramic materials used were prepared from commercial powders. Coarse grain $BaTiO_3$ (CGBT) polycrystalline ceramics of size 1–20 μm were processed by conventional solid state sintering. Small grain ($\sim$1 μm) ceramics of $BaTiO_3$ (SGBT) and fine grain ($\sim$0.02 μm) ceramics of $BaTiO_3$ were prepared using hydrothermal starting powders. The powders were dry pressed into pellets and further processed using cold isostatic pressing, then hot pressed, and annealed. Grain size was determined by SEM. X-ray diffraction analysis revealed a decrease in tetragonality as the grain size decreased from coarse to fine. The decrease in tetragonality was attributed to internal stress in the crystal [84]. The large grain size would allow for compensation for homogenous stress. The small grain ceramic allowed for partial internal stress relief. It was proposed that the fine grain size was probably too small to allow domain twinning to occur keeping high internal stresses throughout the grain which would reduce tetragonal distortion [84]. (Mechanical stress can be compensated for in a material through *twinning*. The stress can produce atomic displacements such that on one side of a plane, the twin boundary, atoms are located in mirror image positions of atoms on the other side of the boundary.) Diffraction peaks were obtained from $2\theta = 20°$ to 80°. The (200) reflections were observed for the three ceramic samples. The CGBT sample showed splitting of the reflection. The SGBT sample showed some splitting of the (200) reflection.

Process parameters for PLD play an important role in the microstructure of the thin film. The investigation by Kim et al. [85] reported tailoring the preferred orientation and microstructure of $BaTiO_3$ thin films deposited by PLD. The microstructure was affected by adjusting oxygen pressure during deposition. A KrF excimer laser was used with a pulse rate of 5 Hz for film deposition. A power density of 2 J/cm^2 was used. The target to substrate distance was 42 mm. The barium titanate pellets were prepared by isostatic pressing. Films were deposited on $Pt/SiO_2/Si$. Oxygen was introduced during the film deposition. Crystallographic structures and microstructures of the films were studied using XRD and SEM. The XRD patterns of $BaTiO_3$ showed that films deposited at 1 mTorr were oriented to (100). At oxygen pressure lower than 1 mTorr, dense and smooth films were obtained. Film roughness increased with increasing oxygen pressure.

Vijayalakshmi et al. [86] reported the growth properties of Si films deposited on Si substrates using PLD. A KrF excimer laser beam was focused to a 100 μm spot diameter on a Si film. Because of the directional nature of the PLD plume, the substrate samples contained regions that varied in thickness. There were three main regions, region I with estimated thickness 200 nm, region II with estimated thickness 400 nm, and region III with estimated thickness 800 nm. The three regions contained micrometer sized islands. Nanometer size clusters were scattered between larger islands. The authors report on a 2θ scan of the Si film; the XRD spectra revealed a sharp peak at 69.3° which indicates a higher order of (100) Si crystal. Approximately 83% of the crystallinity of the nanoclusters was seen to be from (111) and (220). The three regions I, II, and III of the deposited films showed the same 2θ peaks. The intensity of the XRD spectra varied. The average size of clusters increased going from region I to region III and in region II the average cluster size was 25 nm. The XRD peak intensity decreased going from region II to region III and the width of the peaks remained the same.

Pulsed laser deposition, using the system described in Section 2.2, was used to deposit 300 nm thick films of $Ba_{0.6}SrO_{0.4}TiO_3$ on substrate $LaAlO_3$. The microstructure of the film was varied by changing the ambient gas pressure while holding the energy density constant. At 38 mTorr, the particles were distinct and had average diameter 37 nm. As the pressure increased in steps from 38 to 150 mTorr the particle's grains remained distinct. However, by 225 mTorr, the nanograins began to coalese into clusterlike structures. The XRD spectra show that as the clusters form, the intensity of the (200) reflection for BSTO and the intensity for the (200) reflection of LAO reverse in relative magnitudes. The (200) reflection for BSTO is now greater in magnitude than the (200) reflection for LAO perhaps indicating the clusters form a better surface coverage of the substrate. Figures 11, 12, and 13 show the change.

3.2. Scanning Probe Microscopy

Scanning probe microscopy (SPM) is a class of surface characterization techniques utilized to study the physical, chemical, or electrical properties of surfaces and interfaces on the nanometer-to-micrometer scale [87, 88]. SPM technology provides measurement of three-dimensional surface topography, atomic resolution imaging of conductive and nonconductive materials, probing of various types of surface forces (friction, magnetic, electric) [89], unique analyses of surfaces (electrochemical reactions, surface elasticity/hardness, surface adhesion, surface charge density, surface energy, viscoelastic properties) [89], and surface

modification and manipulation [87]. The various modes of operation (scanning tunneling, contact, noncontact, tapping mode) enable the versatile nondestructive analysis of a wide variety of materials surfaces including ceramics, metals, polymers, biomolecules, semiconductors, superconductors, ferroelectrics, and composites. This makes SPM an essential tool in the characterization of nanostructures.

In general, SPM techniques involve scanning a sharp tip within a very close distance (in the near field) across a material surface, allowing the probing of specific physical, chemical, or electrical interactions that occur between the tip and the material surface [90]. The resolution of a given SPM technique depends on the size, shape, and sharpness of the tip. A smaller or sharper tip probes a smaller surface area and results in better lateral resolution [90]. Scanning probe microscopes measure and image surfaces in all three dimensions (x, y, z), with x and y topographic resolutions of 2–10 nm for AFM, 0.1 nm for scanning tunneling microscopy (STM), and a z resolution of 0.1 nm [88]. Scanning tunneling microscopy, the first SPM technique, utilizes a very sharp conductive tip to produce real space images of atomic arrangements on highly conductive flat surfaces. Typical materials for STM probes are gold, tungsten, and platinum/iridium. The STM tip is mounted on a system of piezoelectric drives, which provide movement in three dimensions [91]. In STM measurements the very sharp tip is brought within 0.1 nm of the conductive material surface while a voltage (bias) in the range of 0.1–1 V is applied between the tip and the sample. This close distance causes the outer electron orbitals of the tip and sample to overlap. The voltage causes the electrons to tunnel from the tip into the unoccupied energetic states of the sample [90, 91] producing a tunneling current, which is used to map the topography of the sample surface. The STM can be operated at either constant height mode or constant current mode. In the constant height mode the tip is scanned over the sample surface at a fixed height while the current is measured. A topographical image is obtained by mapping the current tip–sample separation relationship. In the constant current mode, the tip-to-sample separation is varied using a feedback loop to maintain a constant current as the tip scans across the sample surface resulting in a image based on the position of the tip.

The STM provides subangstrom resolution but it is limited to imaging highly conductive materials. Because of this limitation AFM was invented to map the three-dimensional topography of nonconductive samples. AFM utilizes a very sharp tip (silicon nitride or silicon) placed on the end of a cantilever to probe and map the topography of both nonconductive and conductive surfaces. The cantilever has a low spring constant on the order of 1 N/m. The most common modes of AFM are contact mode AFM and tapping mode AFM. In contact mode AFM, as the tip is scanned across a sample surface the force between the tip and the sample (10^{-9} N) is measured by monitoring the deflection of the cantilever, which occurs as a result of the tip pushing against the sample surface [87, 88]. A pieozoelectric tube scanner is utilized to either scan the tip in a raster pattern with respect to the sample or to scan the sample with respect to the tip [92]. As the scanning progresses, interactions between the tip and the sample are monitored by

reflecting a laser beam off the back of the cantilever into a four-part photodiode detector. Changes in the cantilever deflection are monitored by detecting the difference in the photodetector output voltages that result as the position of the laser beam on the photodetector changes [93]. The laser beam movement is monitored both vertically and horizontally. As the tip scans across the sample and encounters surface features, the upward and downward movements of the tip shift the reflected laser beam between the lower and upper portions of the photodetector and create voltage differences which are electronically converted into height information. A feedback loop maintains a constant cantilever deflection and thus a constant force (0.1–100 N) during scanning by moving the piezoelectric scanner vertically at each x, y datapoint, to maintain a constant voltage difference between the upper and lower portions of the photodetector [92]. The distance the scanner is moved vertically at each x, y datapoint is utilized to render a topographical image of the sample surface. Lateral movements of the beam between the left and right portions of the photodetector create voltage differences, which are converted into frictional information. In tapping mode AFM the cantilever (with a silicon tip) is oscillated at its resonant frequency and lightly taps the surface of the sample during scanning. A feedback loop maintains a constant rms oscillation amplitude by moving the piezoelectric scanner vertically at each x, y datapoint [92]. The vertical movement at each datapoint is used to render a topographical image. Tapping mode AFM is preferred over contact mode AFM when imaging soft fragile samples like polymers, biomolecules, and adhesives because of the absence of lateral shear forces encountered with the contact mode that often damage the sample. Tapping mode AFM is also an excellent tool in the imaging of other classes of materials such as silicon wafer surfaces, superconductors, metals, and insulators.

Lowndes et al. [94] report the characterization of Si and ZnTe nanoparticles produced by PLD using AFM. The size distribution measurements were made for nanostructures too small for an accurate high-resolution (field emission) scanning electron microscope (HRSEM, Philips XL30/FEG) in secondary electron mode. The heights (approximating the diameters) for nanostructures too small for accurate HRSEM measurements, all of the Si and some ZnTe, were made using the tapping mode (TM) AFM. A Nanoscope III (Digital Instruments) was used to image 500 nm^2 areas in two different regions of each substrate. The TM-AFM had vertical resolution of ~0.05 nm. The horizontal resolution in the study was limited by the size of the imaging tip. The nanoparticle size distribution was obtained by statistical analysis of the TM-AFM images [89]. The size distributions of Si and AnTe nanoparticles, produced by low energy density ArF (193 nm) pulsed laser deposition in He gas, were correlated to the gas pressure and target–substrate separation. Their AFM measurements of the Si nanoparticle size distribution showed that for He pressures in the range 1.5 to 10 Torr, larger nanoparticles were more numerous closer to the target. With increasing substrate to target distance, smaller nanoparticles formed. The authors point out that the mean Si nanoparticle size was maximized for $P \approx 6$ Torr while in contrast Yoshida et al. [95] and Makimura et al. [96] found the mean diameter of Si nanoparticles increased monotonically with the He pressure in the same pressure range. When correlated with their visual observations of the plume, the AFM data showed that for any He pressure, the largest nanocrystals were deposited beyond but close to the end of the luminescent plume. Nanocrystal size distribution shifted toward smaller average diameters for larger substrate-to-target distance. The authors note this trend had not been identified in earlier studies.

Contact mode atomic force microscope images (Fig. 18) of BSTO thin films deposited onto LaO substrates with the PLD system described in Section 4.2.4 were obtained using a Digital Instruments MultiMode SPM with a NanoScope IIIa controller in air at ambient temperatures at Wright–Patterson AFB in the Materials Directorate. Scan sizes for the images range from 500×500 nm to 167×167 μm. Scan speeds for the images were between 0.5 and 3 Hz. Images were obtained from multiple locations on each BSTO thin film sample. All analyses of the nanostructure dimensions and surface roughness measurements were performed on flattened images. Multiple 500×500 nm areas from several 1×1 μm images were used to determine nanostructure widths and heights for each thin film. Surface roughness measurements for each thin film were obtained from multiple 1×1 μm areas within several 5×5 μm images. The images in Figure 14 show the particle size increasing with increasing O_2 ambient pressure from 38 to 150 mTorr.

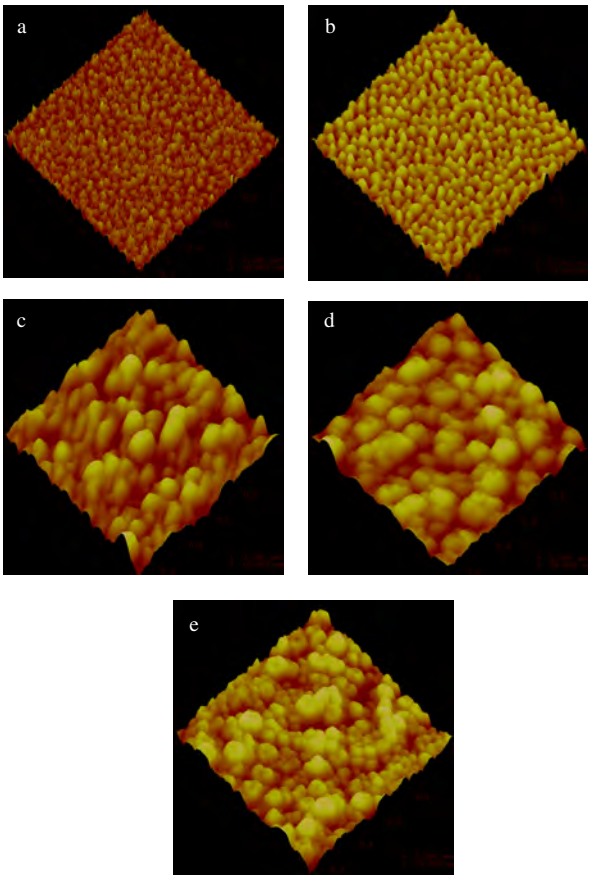

Figure 14. AFM images for (a) 38, (b) 75, (c) 150, (d) 225, and (e) 300 mTorr.

Above 150 mTorr, clustering or coalescing of the grains was observed starting at 225 mTorr.

4. PROPERTIES

4.1. Electrical Properties

4.1.1. Effect of MgO-Mixed BSTO Bulk Ceramics and Thin Films on Dielectric Properties for Tunable Microwave Applications

Chang and Sengupta investigated the dielectric properties of $Ba_{0.6}Sr_{0.4}TiO_3$ and 1.0, 20.0, 40.0, and 60.0 wt% MgO mixed with bulk ceramic and thin film BSTO [97]. The BSTO and MgO-mixed BSTO bulk ceramics were prepared by a standard solid-state reaction process described by Sengupta et al. [98]. BSTO and BSTO–MgO composite thin films (~0.03 μm) were grown on (100) MgO single-crystal substrates by PLD. The process is described by Grabowski et al. [99]. Chang and Sengupta observed that the grain size of BST bulk ceramic was relatively large (~10–20 μm) compared to 1.0 wt% MgO-mixed BSTO bulk ceramic (~3–5 μm) and added that MgO is an observed inhibitor of grain growth in titanate ceramics. The SEM images of 1.0, 20.0, 40.0, and 60.0 wt% showed no significant change in grain size. The thin films showed a similar trend as in the grain size for bulk ceramics with change in wt% of MgO. The grain size of the thin film was much smaller than the grain size of the bulk ceramics. The grain size for pure BST thin film was ~100 nm and for MgO-mixed BST was ~50 nm (seen in the SEM images).

The dielectric constant of the bulk ceramics and thin films drops at 1.0 wt% MgO-mixed BST and gradually decreases with an increase of wt% MgO. The dielectric tuning of bulk ceramics and thin films shows a similar trend with respect to the MgO mixing content. The dielectric constant and dielectric tuning for thin film remains less than bulk constants except at ~50 wt% where there is a reversal in magnitude of bulk and thin film dielectric constant. The dielectric Q of the thin films deposited using pure BST and MgO-mixed BST bulk ceramics was given as a function of applied dc electric field:

- Thin films 20.0, 4.0, and 60.0 wt% MgO-mixed bulk ceramics dielectric Q:

$$Q \sim 75 \text{ at } 0 \text{ V}/\mu\text{m to } 150 \text{ at } 16 \text{ V}/\mu\text{m}$$

- Pure BST and Mg-substituted BST thin films:

$$Q \sim 20 \text{ at } 0 \text{ V}/\mu\text{m to } 75 \text{ at } 16 \text{ V}/\mu\text{m}$$

In summary, the authors have shown that Mg substitution into BST modifies the microstructure of bulk ceramics and thin films significantly. There is a shift in the cubic-tegragonal phase transition peak (T_C) to a lower temperature. This causes an abrupt decrease in the dielectric constant and tuning.

4.2. Physical Properties

4.2.1. Effect of Porosity on Permittivity and the Effect of Temperature on Permittivity and Tunability

The influence of the microstructure (particularly porosity and grain sizes) of $Ba_{0.6}Sr_{0.4}TiO_3$ on the dielectric properties of bulk ceramics and thick films was studied by Zimmermann et al. [100]. Their paper investigates BSTO bulk ceramics and thick films with different porosities and grain sizes. Dense and porous BSTO bulk ceramics were prepared by the mixed oxide method [100]. The authors mention that it has been shown that the permittivity of barium titanate has been reduced by increasing the porosity of admixing different materials [101, 102]. The temperature dependence of permittivity has been shown to decrease by reducing grain size [103, 104].

The temperature dependence of the permittivity and loss tangent of dense and porous BSTO bulk ceramics was shown. The permittivity curve of the dense bulk ceramic showed three phase transitions from cubic to tetragonal (275 K), tetragonal to orthorhombic (220 K), and orthorhombic to rhombohedral (175 K). The permittivity curve of porous bulk ceramic showed one broad peak and reduced permittivity.

In comparing the dielectric properties of the porous ceramic with the thick film, the thick film showed significantly smaller permittivity which decreases by increasing porosity. At room temperature the porous ceramic showed a tunability of 8%. The dense bulk ceramic had ~16% tunability. The thick films were almost temperature-independent and had a tunability of 70–80% at a maximum temperature and 45–70% at room temperature.

4.2.2. Dielectric Properties of Sol–Gel-Derived $MgO:Ba_{0.5}Sr_{0.5}TiO_3$ Thin Films

Jain et al. investigated the dielectric constant and the dielectric tunability sol–gel-derived $MgO:Ba_{0.5}Sr_{0.5}TiO_3$ thin-film composites [105]. In the study, MgO:BSTO films were fabricated by sol–gel to synthesize heterostructured thin films. The X-ray diffractograms showed that both pure and heterostructured films were primarily (100) oriented and crystallized into a perovskite phase. From cross-sectional SEM micrographs, the heterostructured films showed better density and low porosity compared to pure BST thin films. The dielectric constant and the dielectric loss tangent of the heterostructured films were lower than pure BST thin films especially in the ferroelectric state [105]. The authors mentioned that the significant reduction of loss tangent in the heterostructured BST thin films is attributed to the MgO solubility in BST and microstructural modifications induced by the MgO layers [105].

4.3. Microwave Properties

Determining the dielectric properties of the ferroelectric thin films at microwave frequencies is critical for developing tunable components such as phase shifters and filters. To determine the relative dielectric constant (ε_r) and the loss tangent ($\tan\delta$) of the ferroelectric thin films, coplanar

waveguide (CPW) transmission lines and resonators (loaded as well as unloaded) have been designed for on-wafer probing. With measurements of scattering parameters on the CPW lines and resonators in conjunction with theoretical quasi-static conformal mapping analysis, one can determine the dielectric properties of the ferroelectric thin films, including the frequency dependent $\tan\delta$. The scattering parameters (S-parameters) are useful for microwave frequencies as they are based on a traveling waves concept. The S-parameters can be determined based on appropriate impedance matching at both the source and load ends. The S-parameter S_{21} is the ratio of the output power to the input power in dB and is also called the insertion loss of the circuit under measurement. S_{11} is the ratio of the reflected power to the input power in dB. The S-parameters are complex quantities with a magnitude and phase. When we measure S-parameters for a CPW line, the magnitude of S_{21} is an indication of the loss in a line, and the phase of S_{21} is an indication of the electrical length of the line. For more information on S-parameters, please refer to a modern textbook on microwave engineering.

Once the ferroelectric thin films are deposited on the substrates, test structures are either photolithographically defined or samples are coated with a silver or gold conductor by sputtering, thermal evaporation, or PLD through the shadow mask. The minimum thickness of the metal layer required is approximately three times the skin depth of the metal at the lowest frequency of measurement. The CPW lines and resonators are very easily probeable using ground–conductor–ground probes.

To understand the effect of inserting the ferroelectric thin film in the CPW structure, tunable components were modeled such as a CPW transmission line and CPW linear resonators. The cross-section of the modified CPW structure, consisting of a conductor/ferroelectric/dielectric configuration, is shown in Figure 15. The structure consists of a dielectric substrate (typically LAO of 254 μm thick), a BSTO ferroelectric thin film layer (thickness t typically 300 nm), and a 2 μm thick Au/Ag thin film for the conductor (centerline) and ground lines (adjacent parallel lines).

The important geometrical dimensions are indicated in the Figure 15. The critical design parameters for the tunable circuits are the characteristic impedance (Z_0) and the effective dielectric constant (ε_{eff}) which are both a function of the electric field dependence $\varepsilon_{r\text{FE}}$ of the ferroelectric thin film. Important geometrical parameters controlling these parameters are the width of the center conductor (W), spacing between the ground lines (S), thickness of the ferroelectric thin film (t), and the thickness of the substrate (h). The characteristic impedance of the line is inversely proportional to the ratio of W/S. The dielectric properties of the ferroelectric thin film and the thickness of the ferroelectric film are expected to determine the overall insertion loss of the circuit. The transmission lines were designed for characteristic impedance of 50 Ω in the absence of the ferroelectric layer.

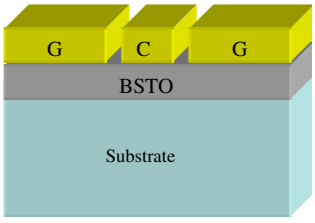

Figure 15. Cross-section of the modified ferroelectric tunable CPW configuration. The G–C–G refers to ground–conductor–ground.

The methodology in determining ε_r and $\tan\delta$ for the ferroelectric thin films at microwave frequencies is (i) Determine the effective dielectric constant of the CPW structure using the phase of the S_{21}. $\varepsilon_{\text{eff}} = [(\text{total phase of } S_{21} \text{ in degrees}) * \lambda_0/(360 * l)]^2$ where λ_0 is the wavelength in free space, and l is the length of the CPW line. (ii) Use a conformal mapping technique based on quasi-static analysis to determine the ε_r of the ferroelectric thin film [23]. Another method is to use simulation tools such as Sonnet and plot the effective dielectric constant versus the relative dielectric constant of the ferroelectric thin film, for the frequency of interest and for the specific film thickness [25]. Once we obtain ε_{eff}, we can extract the value of ε_r from such a plot. (iii) By measuring the quality factor of the CPW resonator circuit (3 dB bandwidth/center frequency), we can obtain $\tan\delta$ of the ferroelectric thin film, as the unloaded Q-factor will be inversely proportional to $\tan\delta$ (i.e., $\tan\delta \approx 1/Q_u$) [23–25].

Figure 16 shows a plot of the ε_{eff} versus $\varepsilon_{r\text{BSTO}}$ for a CPW line with 300 nm BSTO thin film, at 20 GHz. This plot is obtained using Sonnet simulation of a CPW line of 1 cm long, on a 10 mil thick LAO substrate.

Several ferroelectric tunable CPW lines were fabricated on LAO, MgO, and LSAT substrates. One BSTO tunable CPW line (4 mm long) on a 10 mil thick LSAT substrate, with a conductor width of 4 mils and the gap between the conductor and the ground line of 0.8 mils, exhibited a low insertion loss and moderate tunability, as shown in Figure 17. The BSTO film for this sample is approximately 400 nm thick. Note that as the center conductor is biased at a higher voltage level, the dc electric field changes the dielectric constant of the BSTO film. As can be seen from Figure 17, the insertion loss improves as one increases the bias voltage. The $\varepsilon_{r\text{BSTO}}$ as well as $\tan\delta$ both improve at higher bias voltage, resulting in reduced insertion loss. The $\varepsilon_{r\text{BSTO}}$ was extracted from the measurements at zero bias as

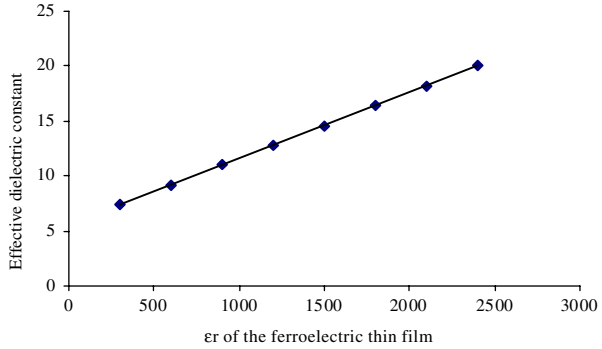

Figure 16. The ε_{eff} vs $\varepsilon_{r\text{BSTO}}$ for a 50 Ω CPW line with a ferroelectric layer thickness of 300 nm, at 20 GHz. The loss tangent of the ferroelectric thin film was assumed to be 0.001 for this simulation.

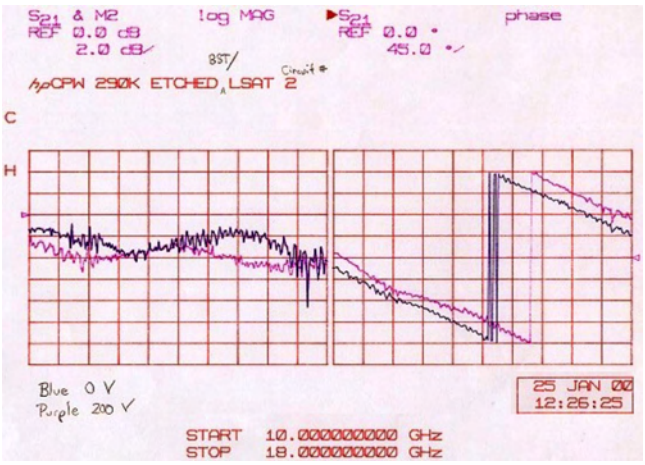

Figure 17. The swept frequency response of magnitude and phase of S_{21} at two different bias voltages applied to the center conductor, in a BSTO (400 nm) tunable CPW line of 4 mm, fabricated on LSAT substrate.

well as at 150 V bias. The measurements agreed with modeling at tuning from $\varepsilon_{r\mathrm{BSTO}}$ of 900 at zero bias to $\varepsilon_{r\mathrm{BSTO}}$ of 300 at 75 kV/cm (corresponding to a dc bias of 150 V). The dielectric tunability for this particular sample is calculated as $[\varepsilon_{r\mathrm{BSTO}}(\text{zero bias}) - \varepsilon_{r\mathrm{BSTO}}(\text{high bias})]/\varepsilon_{r\mathrm{BSTO}}(\text{zero bias})$. The dielectric tunability in this case is approximately 66.67%.

An important figure of merit for tunable microwave devices is the K-factor, defined as the ratio of the phase shift (due to dielectric tunability) to the insertion loss of the sample. The K-factor for the sample in Figure 18 is approximately 30 degrees/dB. The worst-case insertion loss needs to be taken into consideration in the frequency range of the measurements.

An example of the swept frequency measurement for a CPW resonator is shown in Figure 18. One can clearly see the resonance peak from this measurement. The loaded Q of the resonator is calculated as the ratio of the 3 dB bandwidth to the center frequency. In the example, the loaded Q is calculated as 65. The unloaded Q can be obtained from $Q_U = Q_L/[1 - S_{21}(f_0)]$, where $S_{21}(f_0)$ is the ratio of the output voltage to the input voltage as a fraction at the resonant frequency. The unloaded Q is approximately 150 for this example. Tan δ is calculated as the inverse of the unloaded Q. This is based on the assumption that the dielectric loss is primarily due to the ferroelectric thin film layer.

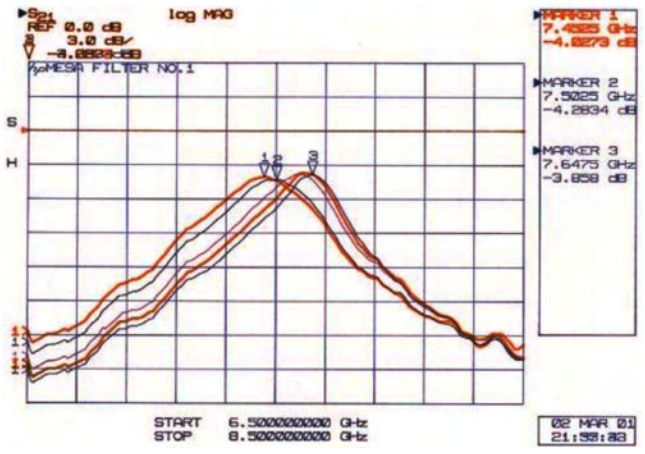

Figure 18. Frequency response of a BSTO tunable resonator showing the improvement in insertion loss as a function of biasing voltage. The left most plot is for the zero-bias voltage, and the right most for +400 V bias on the resonator.

As shown in Figure 18, the center frequency of the resonator is tunable with applied bias, because of the dielectric tunability of BSTO thin film with applied dc bias. In this example, the resonator's passband is very much the same for both 0 and 400 V applied bias. Such a condition is desirable for bandpass filtering applications. The nanophase BST thin films tested to date show that they are tunable by 20%, and the loss tangent of the films is approximately 0.025–0.05 between 1 and 25 GHz. Further studies are underway to optimize the BST thin films to yield lower loss-tangent values.

5. SUMMARY

Utilizing a repeatable and controllable process to synthesize nanocluster and nanostructured materials is essential for understanding the fundamental physics involved in the nanoscience of materials and the evolution of the science into nanotechnology. PLD provides, with established process control, a deposition TECHNIQUE required for the synthesis of high quality multicomponent thin films. As seen in this chapter, there are at least 17 PLD process variables. Most can be monitored and controlled during the synthesis of the nanostructure of a deposited film. During PLD the microstructure of a BSTO films is very sensitive to the ambient chamber pressure. Further tailoring of the microstructure should be enabled by adjusting other deposition parameters individually or combinatorially such as heater temperature or laser repetition rate. However, adjusting (increasing) the heater temperature at a setpoint TOF will change (decrease) the laser beam energy density because the plume will undergo a different amount of (less) collisions before reaching the TOF monitoring control point. An increase in heater temperature decreases the density of the ambient gas in the chamber which translates to less collisions; hence the plume components will move faster at a set energy density. Careful examination of the listed process control variables and their general affect on the critical growth dynamics should enable fabrication of films with the desired characteristics.

Emission spectroscopy permits the examination of plume sensitivity to almost any of the deposition process variables and is a critical element in developing self-directed process control for PLD. XRD reveals information about the lattice structure as well as crystal structure of the film deposited. Another critical tool in the characterization of the film's nanostructure is the SPM. It can be utilized to study physical, chemical, and electrical properties of the film surface.

Although our study on BSTO nanostructured thin films has yet to be completed, engineering the grain/particle size and the domain state of a ferroelectric material is clearly useful to obtain desired microwave properties of the material. The desired result is to produce optimum material characteristics

Table 1. Summary of important studies on bulk and thin-film BSTO.

No.	Topic	Ref.	Description
1	Ferroelectric memories	[107]	High K BST capacitors for DRAM.
2	Temperature coefficient of dielectric constant (TCK)	[108]	Adding small quantities of BSN decreases the TCK dramatically.
3	Giant effective pyroelectric coefficients in graded ferroelectrics	[109]	Pyroelectric coefficients $\sim 5\ \mu C/cm^2\ ^\circ C$ obtained from compositionally graded BST thin films on Si.
4	Effect of stress on dielectric properties of BST thin films	[110]	Stress-free capacitance was found to be 23% higher than the capacitance under residual stress.
5	Dependence of dielectric properties on internal stresses in BST thin films	[111]	BST thin films on MgO substrates, with thickness of 14 to 500 nm, were investigated. Dielectric constant drops from 2350 for highly stressed films to 1700 in relaxed thicker films.
6	Microstructure and dielectric properties of BST films on LAO	[112]	$Ba_{1-x}Sr_xTiO_3$ thin films with $x = 0.1$–0.9 were studied. At room temperature, the dielectric constant and tunability are high for $x \leq 0.4$ and decrease rapidly for as x increases.
7	Infrared optical properties of BST thin films	[113]	$Ba_{0.8}Sr_{0.2}TiO_3$ thin films grown on $Pt/Ti/SiO_2/Si$ substrates were studied in the spectral range of 2.5–12.6 μm. The refractive index decreases and the extinction coefficient increases as the wavelength increases.
8	Pyroelectric properties of sol–gel derived BST thin films	[114]	Pyroelectric coefficient of $Ba_{0.8}Sr_{0.2}TiO_3$ thin films on $Pt/Ti/SiO_2/Si$ substrates. Measured pyroelectric coefficient $> 3.1 \times 10^{-4}$ C/m^2 K from 10 to 26 °C.
9	Dielectric tunability and harmonic generation in BST thin films on LAO	[115]	Dielectric tuning is investigated at nanosecond time-scale in $Ba_{0.3}Sr_{0.7}TiO_3$ thin films at 3 GHz. Full dielectric tuning can be expected at nanosecond time scales.
10	Flexoelectric polarization of BST	[116]	Strain-gradient induced polarization (flexoelectric effect) is studied in $Ba_{0.67}Sr_{0.33}TiO_3$ bulk ceramic in the paraelectric state. The flexoelectric coefficient (μ_{12}) is roughly proportional to dielectric permittivity.
11	BST thin films on Si with Pt electrodes	[117]	$Ba_{0.6}Sr_{0.4}TiO_3$ thin films grown by PLD on $Pt/SiO_2/Si$ substrates. Measured dielectric constant for a 170 nm BST film was 400 with a loss tangent of 0.01–0.03 at 10 kHz.
12	Effect of annealing on the structure and dielectric properties	[118]	The effect of a postdeposition anneal on the structure and dielectric properties of epitaxial $Ba_xSr_{1-x}TiO_3$ thin films ($x = 0.35$–0.65) were measured. The anneal had the effect of an increased electric field dependence on dielectric tuning without increased dielectric loss.
13	Composites of BST and other nonelectrically active ceramics	[25]	Reduced dielectric constant and loss tangent for low-loss tunable dielectric materials.
14	Doped BST for microwave applications at room temperature	[119]	Dielectric properties of laser ablated Mn-doped and undoped $Ba_{0.6}Sr_{0.4}TiO_3$ thin films are compared at low frequencies and at microwave frequencies. 1% Mn doped films had large tunability of 56% at 40 kV/cm and a loss tangent of 0.006 at zero bias and 10 GHz.
15	Nonlinear properties of BST	[120]	Four types of nonlinear properties of ferroelectric materials were considered: paraelectric–ferroelectric interphase boundaries, nonlinear equilibrium excitations–domain walls, nonlinear response of domain structure near the first-order phase transition-wetting of domain walls, and nonlinear effects caused by external high magnetic fields.
16	Strain-induced ferroelectric properties	[121]	Metal–ferroelectric–insulator–semiconductor structures were formed by PLD. Mechanical strain induced a ferroelectricity in the BST films.
17	Enhanced electrical properties	[122]	Enhanced electrical performance of high-dielectric-constant BST thin films grown by *in-situ* UV-assisted PLD in comparison with conventional PLD.
18	BSTO thin films for uncooled infrared focal plane arrays	[123]	BSTO thin films prepared by improved sol–gel technique. BST15 thin film is the advanced candidate material for uncooled infrared focal plane arrays at near ambient temperature.

continued

Table 1. Continued

No.	Topic	Ref.	Description
19	Size effect and fatigue mechanism in ferroelectric thin films	[124]	Fatigue in ferroelectrics may be caused by field screening mechanism where only a fraction of the applied voltage is seen by film bulk.
20	Thickness-dependent dielectric constants of BSTO thin films	[125]	Decrease in measured dielectric constant of BSTO thin films with decreasing dielectric film thickness analyzed.
21	Thin film ferroelectrics for capacitor applications	[126]	PLD used to fabricate thin film capacitor, electrical characterization of BSTO films showed Curie point behavior independent of composition, contrasting sharply with bulk behavior.
22	Structural features and phase transition temperature of BSTO films on various substrates	[127]	BSTO films grown on various substrates by rf sputtering. Structural diagnostics of films correlated with temperature corresponding to maximum capacitance.
23	BST for tunable phase shifters	[128]	The influence of the microstructure of BST: in comparison to dense bulk ceramics, the permittivity of thick films is approximately 10 times less.
24	Advances in low loss, tunable dielectrics	[25]	Composites of BSTO fabricated in bulk ceramic, thick film, and thin film. The dielectric constant and loss tangents of the composites were reduced to enhance impedance matching and lowering overall insertion loss of devices.
25	Microwave power handling	[129]	High power handling capability of ferroelectric thin-film based circuits.
26	Coupled microstrip phase shifters	[130]	BSTO thin-film based CMPS with 60 degrees/dB *K*-factor in *Ku*- and *K*-band phase shifter circuits.
27	Distributed analog phase shifter	[131]	BST varactors periodically loading CPW lines for analog phase shift.
28	Phased array antenna based on bulk phase shifting	[132]	A new concept for phased arrays based on voltage controlled ferroelectric lens implemented using bulk ferroelectric slabs.
29	Electronically steerable reflect array antennas	[133]	Eight element reflect array demonstrated using BST thin-film based CMPS circuits.
30	Ferroelectric/ferrite hybrid circuits	[134]	Combined ferroelectric/ferrite thin films for tunable devices demonstrated.

for use in frequency and phase-agile microwave devices and also gain an understanding of the physics involved in fabricating nanostructured materials. Table 1 is provided as a summary of most important work on BSTO bulk as well as thin films. Further work will continue in our group in optimizing the process for low microwave loss and highly tunable BSTO thin films for room temperature applications.

GLOSSARY

a_t and a_c *a*-axes of the tetragonal and cubic unit cell.

Domain walls Regions between two domains.

Ferroelectric A group of dielectric materials exhibiting spontaneous polarization.

Ferroelectric domain walls Domain walls oriented differently in response to the spontaneous polarization vector.

Ferroelastic domain walls Domain walls which differ in orientation to the spontaneous strain tensor.

Hysteresis loop Consequence of the domain-wall switching in a ferroelectric materials.

Nanoclusters Aggregates of nanoparticles.

Nanostructure Material topography (physical features) consisting of structures of size less than or equal to 10^{-9} meters.

Paraelectric Dielectric material without spontaneous polarization.

Pyroelectric Dielectric displaying polarization without an electric field.

Sol–gel Chemical process for thin film deposition.

Thin film Film with crystal structure, in this case thickness less than 300 nanometers.

Twinning Atoms are located in mirror image positions of atoms on the other side of the boundary.

Nanostructured Biomaterials

R. Murugan, S. Ramakrishna

National University of Singapore, Singapore

CONTENTS

1. INTRODUCTION

Recent years have clearly shown a considerable upsurge in the number of publications concerning biomaterials engineered at the nanolevel. The field of biomaterials, a multidisciplinary subject, has developed rapidly due to its unique potential in human health care systems. According to the definition of Williams [225], a biomaterial is a substance or a combination of substances, other than drugs, derived either naturally or synthetically used to repair or replace the function of living tissues of the human. An ideal biomaterial should be highly biocompatible, bioactive, easy to fabricate, reproducible, sterilizable, nontoxic, noncorrosive, nonimmunogenic, and not cause any foreign body reactions upon implantation. The use of biomaterials in humans dates far back into ancient civilizations as Egyptians used artificial eyes, ears, teeth, and noses on mummies [224]. They used elephant's tusks, walrus teeth, and some kinds of wood to replace bone or missing teeth. As per historical evidence, the Indians and Chinese used waxes, glues, and tissues in reconstructing defective parts of the human body. Over the centuries, advancements in synthetic materials and surgical techniques have permitted the use of biomaterials in many ways to restore, maintain, or improve the functions of human tissues or organs [172].

More recently, biomaterials engineered at the nanometer scale have gained recognition in various biomedical applications owing to their potential advantages over the conventional biomaterials in terms of superior surface characteristic properties, high degree of monodispersity, flexibility to design improved biomaterials, reproducibility, and close surface contact with body environments due to a larger surface-area-to-volume ratio. A unique value of nanomaterials is their extremely high surface area having many more sites for achieving property enhancements, which makes them ideal for a wide variety of applications. Moreover, and perhaps more importantly, it provides the opportunity for the user to tailor make the desired properties of such materials according to specific needs through chemical and/or physical modifications. Nanotechnology is mainly concerned with the design and manufacture of materials to nanometric tolerances, a nanometer being equal to 10^{-9} m. Dimensions of some of the materials are given in Figure 1, with the highlights of nanometer-scale biological systems. The field of nanoscale biomaterials is an exciting multidisciplinary subject covering many areas of modern science, engineering, and medicine. The interactions between the various disciplines are where much of the novel activity resides. The scientific literature clearly shows a significant increase in the number of researchers from various disciplines entering into the nanobiomaterials field each year. This results in an increasing number of novel ideas and exciting new opportunities, which in turn impact global nanostructural science and technology. This implies the potentiality of nanostructured biomaterials to address the medical challenges facing day-to-day life.

This review is mainly intended to provide an overview of nanostructured biomaterials, in particular, ceramics and polymers, used in bone grafting, tissue engineering, and drug delivery systems. The chapter also presents the critical issues and scientific challenges that need further research and development of the nanostructured biomaterials for their enhanced acceptance in human health care. For the benefit of readers, fabrication methodology, properties, various types, and the potential of currently available biomaterials are briefly described in each section, in addition to their performance with living tissues or organs. This review, with hope, could be useful for gaining insight and knowledge on nanoscale biomaterials, and opens new avenues for further extension of research in novel and challenging areas of human health-care systems.

2. NANOMATERIALS IN BONE GRAFTING

The need to transplant bone to a deficient skeletal location has been recognized for centuries. Skeletal deficiencies from trauma, tumors, bone diseases, or abnormal development frequently require surgical procedure to restore normal bone functions. If a fracture is minor, usually bone has the capability to self-regenerate its functions in a few weeks' time. In the case of a severe fracture, a bone-grafting substitute may be needed to restore their routine functions. The terminology of bone transplantation is more complicated by the various histological types of bone grafts. Bone-grafting techniques can be grouped into four different types with respect to grafting terminology and implant materials used, namely, autograft, allograft, xenograft, and alloplast. A typical diagram of bone grafting is shown in Figure 2.

Autograft or autogenous graft is the ultimate method being considered as the gold standard as tissue transplanted from one site to another within the same individual. The concept is basically that our own bone is taken from a donor site and placed somewhere else in the same body into the recipient site. The best success rate in bone grafting has been achieved with autografts because these are essentially living tissues with their cells intact. Clinically, it has been proven that there is no chance of immune reaction using this method, and the microscopic architecture is perfectly matched with the host tissue. The only disadvantage of the autograft is that it has to be harvested from a secondary site in the body, which means more morbidity and a more complicated surgery, that is, secondary surgery is needed. For most grafting purposes confined to oral implantology, we can use another part of the jaw (i.e., chin or back portions of the jaw) as an acceptable donor site. This way, we stay surgically inside the mouth, and avoid any extra oral wounds and scarring. Sometimes, however, when there is no availability of bone volume intraorally, it is necessary to get bone from other parts of the body, for example, the hip bone or tibia (shin) bone, since these are the most accessible areas to obtain larger quantities of bone. The second method is allograft or allogenic graft, which is defined as a tissue transplant between individuals of the same species, but of nonidentical genetic composition. This method eliminates the need for a secondary surgery, but after sterilization, the donated bone loses much of its strength. In addition, when bone grafts are taken from cadavers, there is a risk of rejection or of transmitted diseases such as hepatitis B or AIDS caused by infection with the human immunodeficiency virus. Allograft procedures have been on the decline since late 1993 when the U.S. Food and Drug Administration (U.S. FDA) issued regulations governing bone and tissue banks because of the risk of transmitting infectious diseases. The third method is xenograft or xenogenic graft, which pertains to tissue transplant between two different species (e.g., bone from animal to human). Tissue banks usually stock these kinds of materials because it is possible to extract a larger amount of bone with a specific microstructure as compared to bone from human origin. However, there is a possibility of infectious disease transformation from animal bone to implant site if we use this method. Another option, which is becoming more viable, is the use of synthetic materials (biomaterials) to repair or to replace lost bone, known as alloplast or alloplastic graft. These biomaterials have the advantage of eliminating the need for surgery to claim bone for the graft procedure, and eliminating the chance for rejection or transmission of infectious disease. An additional benefit of using this kind of material lies in their availability, reduction of medical cost, and faster recovery time.

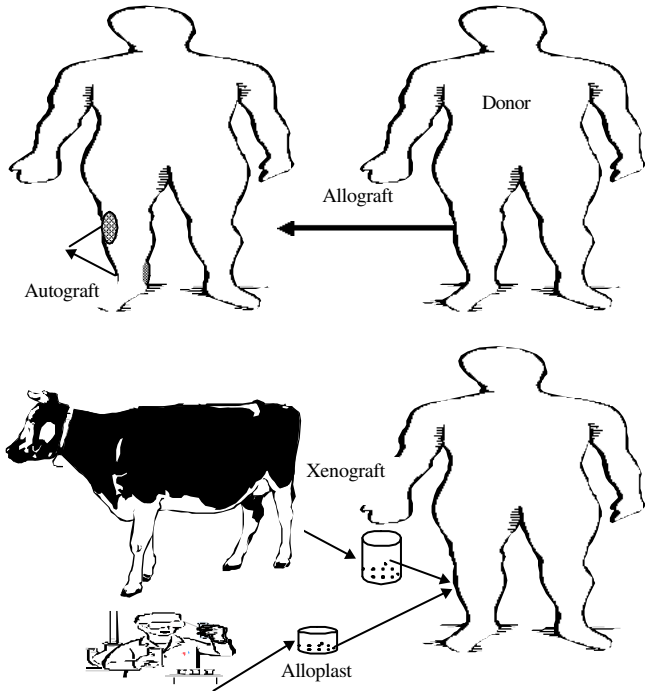

Figure 2. Schematic representation of bone grafting.

Several biomaterials have been developed for bone substitution in the past three decades, and have been used clinically [111, 209, 44, 9]. The major classifications of biomaterials are listed in Table 1 with suitable examples. The materials commonly used as bone substitutes are typical metals, ceramics, polymers, and their composites. Mostly, metals and ceramics are used in hard-tissue applications and polymers in soft-tissue applications due to their structural and mechanical properties. Among them, ceramics and polymer-based biomaterials play a key role in producing artificial bone-graft substitutes. In this topic, we address the potential of those materials in bone grafting and bone tissue engineering applications. The most commonly used

Table 1. Broad classification of biomaterials pertaining to their properties.

Biomaterials	Properties	Examples
Metals	Corrosive	Ferrous
	Noncorrosive	Stainless steel, titanium
Ceramics	Bioinert	Alumina, zirconia
	Bioactive	Hydroxyapatite, bioglass
	Bioresorbable	Tricalcium phosphate
Polymers	Biodegradable	Collagen, gelatin, PLA, PGA, PLGA, PCL
	Nonbiodegradable	PMMA, PHEMA, PEEK, PAA

ceramics and polymers in bone-graft systems include alumina, zirconia, tricalcium phosphates (TCPs), hydroxyapatite (HA), calcium carbonate, dental plaster, demineralized bone matrix, collagen, polylactic acid (PLA), polyglycolic acid (PGA), poly(lactide-co-glycolide) (PLGA), polyethylene glycol (PEG), and polycarbolactone (PCL) [36, 41, 18, 221, 186, 208], which are explained in detailed fashion in this review. The design of medical implants with surface properties similar to physiological bone, characterized by surface grain sizes on the nanometer scale, would undoubtedly help in the formation of new bone at the biomaterial–tissue interface [116]. It is possible to synthesize such materials with nanostructural characteristic features for medical applications with the aid of nanotechnology in order to mimic the natural bone [192].

2.1. Nanobioceramics

Recently, then has been an increasing demand for biomaterials at the nanolevel to assist in the repair of osseous defects caused by skeletal deficiencies in which a substantial amount of bone has been lost. Nanoscale biomaterials, in particular, bioceramics, play a pivotal role as a bone-graft substitute due to their large surface area and their particle size which resembles that of natural components of the bone. In general, ceramics used for the repair and reconstruction of diseased or damaged parts of the human organs or tissues are termed bioceramics. Bioceramics have evolved to become an integral and vital figment of today's modern health-care systems. They are the natural choice of materials with a broad range of composition. The bioceramics used in medicine are primarily classified into three groups: bioinert (e.g., alumina and zirconia), bioactive (e.g., hydroxyapatite), and bioresorbable (e.g., tricalcium phosphates). These classified bioceramics and their performance with respect to tissue reaction are briefly shown in Table 2 [49]. Often, bioceramic materials are used in hard-tissue applications (less load bearing) due to their favorable mechanical properties (Table 3). Mostly, grain sizes of those bioceramics are on the order of few microns with respect to specific site applications. More recently, the term known as nanobioceramics frequently appears in articles in almost all of the fields, particularly biomedical. This may be defined as the ceramics intended for medical applications whose particles in the range of the nanometer scale are known as nanobioceramics. It has unique advantages by having a high surface area and ultrafine structure, which are more

Table 2. Types of bioceramics with respect to their tissue reaction.

Type of bioceramics	Description of biological performance	Examples
Bioinert	Coexistence with implant without noticeable changes and separation from the implant by a layer of fibrous tissue	Single crystals and poly crystalline alumina, zirconia, titanium
Bioactive	Attachment with tissue by direct biochemical bonding, which allows bone-free growth	Hydroxyapatite, bioactive glasses
Bioresorbable	Material is gradually replaced by new bone with respect to their dissolution without any sign of toxicity	Porous hydroxyapatite, tricalcium phosphates, calcium sulfate

beneficial for cell–biomaterial interaction upon implantation. With advances in ceramics and nanotechnology, the application of nanobioceramics as bone substitute has recently received considerable attention because they are biocompatible, bioactive (i.e., direct chemical bonding with bone to biomaterial), provoke little, if any, inflammatory response, and have a large surface area [111, 116, 56, 131].

In general, nanoceramic material synthesis can be grouped into two categories, namely, gas phase and sol–gel process. The gas-phase condensation process was invented by Siegel [193, 194]. This process involves the production of physical vapor from elemental or reacted material, followed by sudden condensation and reaction of the vapor into small nanometer-scale particles. The gas-phase condensation process can be explored in the synthesis of inorganic and metal phases [20]. The sol–gel technique is a wet-chemical approach that can be used to generate nanoparticles by gelation, precipitation, and hydrothermal treatments [123]. An example of the sol–gel process is described by Wiltzius [226]. Here, a concentrated dispersion of colloid is chemically converted into a gel, and then dried, followed by sintering, which produced a ceramic or glass product. By this technique, it is possible to produce nanosize particles, fibers, films, plates, and tubes at low temperature. It is reported that nanoparticles with diameters ranging from 1 to 10 nm with consistent crystal structure, surface derivation, and a high degree of monodispersity have been processed by both the gas-phase and sol–gel techniques [155].

2.1.1. Biocompatible Alumina

Alumina (Al_2O_3) is the first of its kind of bioceramic material widely used clinically [93]. It is frequently being used in total hip prostheses and dental implants due to its multiple characteristic features, including excellent corrosion resistance, biocompatibility, being chemically inert, having low friction, high wear resistance, and high strength [167]. Alumina with an average grain size of less than 4 μm and a purity of greater than 99.7% exhibits good flexural strength and excellent compressive strength. Moreover, this kind of nanometer-scale medical-grade alumina certainly has a higher surface area for better interaction with host tissue.

Table 3. Properties of bioceramics favorable for biomedical applications [33].

Bioceramics	Young's modulus (GPa)	Tensile strength (GPa)	Compressive strength (GPa)	Fracture toughness (MPa · $m^{1/2}$)	Hardness (HV)	Applications
Alumina	366–380	0.31	3.3.8	4	2200	Orthopedic and dental implants, maxillofacial reconstruction
Zirconia	220	0.82	2	7–10	1200	Orthopedic, biocomposites
Hydroxyapatite	80–110	0.05	0.4–0.9	0.7–1.2	600	Coatings on bioimplants, bone and dental filler, periodontal pockets, alveolar ridge augmentation, maxillofacial reconstruction, tissue engineering

Nanoscale alumina is also used in corneal replacements, alveolar ridge and maxillofacial reconstructions, segmental bone replacements, ossicular bone substitutes, knee prostheses, and post-type dental implants [91, 206, 217]. Boutin et al. [19] reported that the alumina as a component of total hip prostheses outperformed other orthopedic implants such as polyethylene. They stated that the long-term success in orthopedic applications depends on its micro/nanostructure, implant geometry, and the health status of the host bone. A successful investigation of osteogenic cell–substrate interaction using nanoscale alumina was reported [217]. Webster et al. prepared nanoalumina in combination with titanium oxide (TiO_3) by compacting with different nanophase grain sizes. They followed the sterilization method for the sample preparation as similarly reported by Puleo et al. [179]. They studied the efficacy of the materials with osteoblast cells, a well-known cell pertaining to the formation of bone, and found that there was an increasing trend in osteoblast adhesion on the nanostructure of the alumina phase. This kind of investigation provided evidence that the enhanced adhesion is independent of the specific chemistry of material surface, and dependent only on the optimal surface topography of nanophase bioceramics.

The extent of osteointegration between bone and a newly implanted material is influenced by many factors, including surface topography. The surface properties of the biomaterials play a vital role in controlling the type and magnitude of cellular and molecular events at the tissue–implant interface. Hence, control and/or manipulation of the surface properties of nanoparticles are of great importance when intending the nanoceramics as medical implants. In general, there are two ways to modify the surface of nanoparticles. The first method is carried out through surface agents by a variety of functionalities depending upon the site of application [213]. The second one is based on grafting polymeric molecules through covalent bonding to the functional groups existing on the nanoparticles [120]. The advantage of the second method over the first lies in the fact that the polymer-grafted particles can be provided with the desired functional properties through a proper section of monomers for the grafting and standardizing optimal grafting condition. In this way, the structure–property relationship of the nanomaterials can be tailor made to a specific need [185]. Recently, grafting of vinyl monomers such as polystyrene and polyacrylamide onto nanometer-scale alumina was successfully carried out [184]. To enhance the interfacial interaction in alumina nanoparticles, the alumina surface was first treated with silane, followed by radical graft polymerization in aqueous and nonaqueous media using a peroxide initiator for an aqueous medium and an azobis–isobutyronitrile (AIBN) initiator for a nonaqueous medium. They tailored the structural properties of the grafts by changing reaction conditions, and found that the grafting polymer radicals and/or the grafted polymer chains had a blocking effect on the diffusion of radicals or monomers toward the surface of alumina nanoparticles. This can be because the interactions between solvent and grafted polymers were weaker as compared to the grafted polymers and the nanoparticles. Another class of materials known as nanofibers also has attracted great attention from materials researchers because of their superior properties and their potential for a wide range of applications. Recently, alumina nanofibers were synthesized at a moderate condition in an aqueous medium through a surfactant-directed crystal growth process using polyethylene oxide (PEO), which is different from the conventional crystallization and the template synthesis of nanofibers thus far studied [236, 237]. This kind of nanofiber is very useful in developing nanocomposites with desired morphology, tailorable size, porosity, and surface topography.

2.1.2. Bioinert Zirconia

Zirconia (ZrO_2), a well-known ceramic oxide, was identified as such in 1789 by the German chemist Klaproth in the reaction product obtained after heating some kind of gems, and was used for a long time blended with rare-earth oxides as a pigment for ceramics. The research and development on zirconia as a biomaterial were started only in the late 1960s, and was studied extensively by Helmer and Driskell [92]. The zirconia, either of pure form or of partially stabilized zirconia, was used for the fabrication of ball heads in total hip replacement (THR), and also recommended for various dental and orthopedic applications [31, 160]. The

basic requirements to use zirconia as medical implants are described by the International Standard Organization (ISO) [106]. More than 3,00,000 zirconia, namely, tetragonal polymorph, ball heads have been implanted [30], and only two failure cases have been reported so far [99].

In this connection, biocompatibility is one of the important parameters for the materials when considering implantation. Zirconia is a biocompatible material, but does not have any direct bonding to bone [167, 83]. There are many reports available for the biocompatibility of zirconia using different cell lines [88]. It is reported that zirconia has no cytotoxic effects when fibroblasts are cultured, and the adhesion and spreading of cells were evaluated [45, 128, 24]. On the other hand, higher inhibition of cellular growth using zirconia and tricalcium phosphate in comparison to alumina or hydroxyapatite was observed in the direct contact test, cell viability, and MTT assay [192]. Ito et al. [108] studied the cytotoxic effects on L929 fibroblasts cocultured in the presence of pseudoextracellular fluid used as a lubricant, and reported that the cytotoxicity of wear products obtained by the friction of ultramolecular-weight polyethylene (UHMWPE) against yittria partially stabilized zirconia (YPSZ) was higher than the cytotoxicity of UHMWPE/Ti-6Al-4V wear products. They found that the cytocompatibility of wear products was improved using a specific pore size filter (0.22 μm). Since toxic effects could be related neither to ion release nor to polyethylene particles less than 0.22 μm in diameter, the presence of floats on the surface of the culture medium may be considered as one of the causes of the cytotoxicity. The effect of wear products of the alumina and zirconia ceramics were evaluated using flow cytofluorimetry analysis [27]. Alumina and zirconia ceramics were tested in comparison with high-density polyethylene on macrophages J774 and RAW267.5, and it was found that polyethylene particles were more cytotoxic than ceramic particles, even if a quantity of polyethylene less than ceramic particles was phagocytosed by macrophages. These results further supported the biocompatibility of zirconia. There are many direct evidences also available for the *in vivo* biocompatibility test of zirconia implanted in bone and soft tissues. The first *in vivo* experiment onto dense zirconia in combination with Y_2O_3 was performed in a monkey's femur, and the absence of adverse tissue reactions with surrounding environments was reported [92]. Later, Hulbert et al. [97] reported the effects of disks and tubes of different composition of nanopore zirconia particles into rabbit muscles. Histological analysis of all of the implants tested nine months after implantation did not show any sign of toxic, immune, or carcinogenic effects. Another study on the biocompatibility of zirconia was performed by Bortz and Onesto [17], who introduced zirconia tubular elements into rabbits and dogs in order to develop tracheal prostheses. They observed the problems of heavy fibrous growth within the lumen of the tube, which sometimes closed it off. There was a sign of bacterial infections observed in rabbits, but never in dogs; nevertheless, prostheses were firmly attached to the trachea, even though infection was present. The *in vivo* implantation of magnesia partially stabilized zirconia (Mg–PSZ) in the paraspinal muscle of rabbits was also investigated and the biocompatibility at different time intervals of postimplantation was evaluated [71]. There was no evidence of any adverse tissue reactions using zirconia as the implant material. In an overall view, the results obtained so far suggest that the zirconia is a highly biocompatible ceramic material due to the evidence of connective tissue formation at the bone–ceramic interface.

2.1.3. Bioactive Nanohydroxyapatite

The development of calcium-phosphate-based ceramics in medical applications started almost three decades ago with the first successful publication of Levitt et al. [127]. Since then, calcium phosphates have gained much interest in biomaterials research due to their physicochemical properties as evidenced by the large number publications until today. Hydroxyapatite is a major type of calcium phosphate bioceramics, with a chemical formula of $Ca_{10}(PO_4)_6(OH)_2$, which is primarily being used in hard-tissue repair and regeneration. It is highly biocompatible, bioactive, osteoconductive, nontoxic, nonimmunogenic, has a direct chemical bonding to bone, and a structure crystallographically similar to bone mineral with an adequate amount of carbonate substitution [5]. The physicochemical properties of HA have wide biological and industrial applications [50, 87, 227, 125, 94]. Basically, it is a family of apatite phase, and the name apatite was first coined by Werner in 1786 [220]. The name was derived from the Greek word for "deceive" because it had been confused with several other minerals of similar appearance, including beryl, amethyst, olivine, and fluorite. It had been suspected earlier by some workers to be a distinct species, but its color and habit variations are distinct from similar appearing minerals. Chemical analysis in 1785 by Proust and Klaprota established apatite as a calcium phosphate, and confirmed its similarity to calcined bone, although the role of the OH, F, and Cl was not recognized at that time [196]. The name "apatite" belongs to a family of components having a hexagonal system of space group $P6_3/m$ (sixfold symmetry axis with a threefold helix and a microplane) with lattice cell dimensions $a = b = 9.42$ Å and $c = 6.88$ Å [42, 118]. The first synthesis of apatite was carried out by Daubree in 1851 [39], who obtained HA by passing phosphorus trichloride vapor over red hot lime. Since then, a number of preparation methods of HA have been reported and reviewed extensively [109]. There is a long history of preparation of HA in the micrometer scale range in various forms like powder, dense, porous, or composite for biomedical applications [93]. In the past few years, significant research efforts have been devoted to the nanostructure processing of HA and its composites as a means to achieve an ultrafine structure with adequate physicochemical and biological properties resembling those of natural bone minerals [214, 215, 37, 48]. Some of the physiochemical properties of HA are listed in Table 4. In general, the routes of HA preparation are mainly grouped as solid state, wet chemical, hydrothermal, mechanochemical, and more recently, microwave processing [126, 115, 110, 150, 151, 94, 152, 90, 161]. Solid-state reaction has generally been used for the processing of ceramic powders at high temperature. The powders prepared by this method usually have irregular shapes with a larger grain size, and often exhibit heterogeneity in the phase composition due to the informporate reaction resulting from small diffusion coefficients of

Table 4. Physical, mechanical, and chemical properties of hydroxyapatite [13, 42, 93, 126].

Properties	Measurement data
Crystal system	Hexagonal
Space group	$P6_3/m$
Cell dimensions (Å)	$a = b = 9.42$, $c = 6.88$
Young's modulus (GPa)	80–110
Elastic modulus (GPa)	114
Compressive strength (MPa)	400–900
Bending strength (MPa)	115–200
Density (g/cm^3)	3.16
Relative density (%)	95–99.5
Fracture toughness ($MPa \cdot m^{1/2}$)	0.7–1.2
Vickers harness	600
Decomposition temp. (°C)	>1000
Melting point (°C)	1614
Dielectric constant	7.40–10.47
Thermal conductivity ($W/cm \cdot K$)	0.013
Chemical composition	$Ca_{10}(PO_4)_6(OH)_2$
Ca/P molar	1.67
Color	White

ions within the solid. The second method is the wet-chemical method, which is relatively easy to conduct, even at low temperature, in contrast to the solid-state reaction. As per publications, this is one of the simplest methods frequently used to prepare HA. The materials prepared by this method are usually poorly crystallized and homogeneous in composition. Hydrothermal production methodology involves the reaction in aqueous solution of precursors at high temperature and high-pressure atmosphere. This method enables the preparation of a well-crystallized and homogeneous phase. The product obtained by this method is easily sinterable due to the effects of high-temperature high pressure aqueous solutions. More recently, ceramic powders are being prepared using microwave techniques under optimum conditions in order to minimize the reaction time, production cost, and to increase the purity of the sample [212].

One of the potential properties, namely, high surface area reactivity, associated with nanocrystals can be exploited to improve many biomedical applications [154, 51, 52, 57]. In addition, nanocrystallized characteristics have proven to be of superior biological efficiency [219]. For example, compared to conventionally crystallized HA, nanocrystallized HA promotes osteoblast cell adhesion, differentiation and proliferation, osteointegration, and the deposition of calcium-containing minerals on its surface [218], and also enhances the formation of new bone in a short period. Therefore, nanostructured HA is thought to represent a unique class of biomaterial formulations that promises enhanced implant bonding and improved overall implant efficacy. On this topic, we discuss the recent advances made on nanoscale bioactive HA. Recent publications concerning HA showed that there are few possible methods available for the preparation of nanoscale HA (Table 5). Toriyama et al. succeeded in obtaining HA by starting from brushite and calcium carbonate [207], and then Yokayama et al. [230] doped some trace elements such as Sr to HA in order to strengthen it mechanically. They obtained HA from mechanochemical treatment with low crystallinity. Further, they postheated the samples at temperatures between 500 and 1000 °C in order to promote their crystallinity. Free-standing crystalline nanostructured HA was synthesized using a wet-chemical technique [53]. They consolidated powder agglomerates into bulk form for the testing of fracture toughness, bending, and compressive strength. Their results clearly showed that the compressive strength of bulk nano-HA could be increased up to 4 fourfold in comparison to bone (879 versus 193 MPa for compact bone), whereas the bending strength was found to be much equivalent (913 versus 160 MPa in bone).

A novel method for the preparation of HA fibers was introduced using a solid phase reaction [168]. The HA fibers were fabricated by heating a compact consisting of calcium metaphosphate fibers with calcium hydroxide particles at 1000 °C in air atmosphere, and subsequently treating the resultant compact material with dilute aqueous HCl solution to remove unwanted secondary phase substitution such as

Table 5. Various methods for nanohydroxyapatite preparation.

Techniques	Grain size	General description	Ref.
Solid state	~0.5μm	Inhomogeneous, large grain size, irregular shapes, reaction condition 900–1300 °C	[168]
Wet chemical	20–200 nm	Micro- to nanograin size, low crystallinity, homogeneous, reaction condition: room temp. to 100 °C	[53, 47, 232, 170, 121]
Precipitation/ hydrothermal	11–24 nm	Homogeneous, micro/nanosize, low crystallinity, reaction condition: room temp. to 200 °C (1–2 MPa)	[234]
Hydrothermal	60–70 nm	Homogeneous, ultrafine crystals, high temperature, and high-pressure atmosphere	[107, 85]
Mechanochemical	<20 nm	Easy production, low crystallinity, ultrafine crystals, room temp. process	[230, 161]
pH shock wave	20–100 nm	High-energy dispersing, nonporous, monocrystalline particles with Ca/P molar ratio 1.43–1.66	[122]
Microwave	115–300 nm	Time and energy saving, uniformity, fine grain size	[212, 229]

CaO by acid leaching. The obtained HA fibers were characterized systematically, and the morphological structure was evaluated by SEM analysis. The structural morphology of HA fibers clearly showed nanostructural characteristic features more or less similar to natural bone mineral apatite phase. Zhang and Consalves [234] reported the thermal stability of nano-HA prepared by the precipitation method, followed by hydrothermal treatment. By this approach, the obtained HA has a rod-like shape, with an average crystal size of 11–24 nm with respect to the precursor's compositions. They produced various calcium phosphates of HA powder with respect to the starting material from 1.66 to 1.73 (Ca/P ratio). The HA also was prepared in the form of lath-like monocrystalline particles using high-energy dispersing equipment in combination with a pH shock-wake method using $Ca(H_2PO_4)_2{\cdot}H_2O$ and $CaCl_2$ with a Ca/P molar ratio of 1.66, almost similar to the stoichiometric Ca/P ratio of HA, and characterized using various analytical methods to determine their phase composition, structure, and texture [122]. They measured the Ca/P molar ratio from 1.43 to 1.66 with respect to the method of preparation of HA, and found that the pH shock-wave method produces a nonporous monocrystalline HA lath with particles with an average grain size of ~140–1300 nm in length, 20–100 nm in width, and 10–40 nm in thickness. The obtained Ca/P atomic ratio is 1.66, which is very close to the theoretical value of stoichiometric HA (1.67). Per their investigation, it seems to be a unique method since it creates the proper hydrodynamic conditions for lath-like particle growth in the [001] direction with the physicochemical characteristics that could not be obtained by using conventional mechanical stirring equipment. Ahn et al. [4] derived a bioactive nanocrystalline HA through nanostructure processing to achieve superior chemical homogeneity and microstructural uniformity in order to get high-quality apatite-based bioceramics. They attained nanostructural HA by the precipitation method, and studied the optimal conditions by changing the reaction parameters such as precursor pH, aging time, and temperature to achieve nano-HA particles with tailored composition and morphology. This investigation clearly showed that the nanostructure processing offers an alternative solution to challenges encountered in the HA processing; they also concluded that the nanostructured HA results in a 70% improvement over the best conventional HA. In 2002, Driessens et al. [47] reported a new class of nanoapatite cement having Ca/P ratio in the range of $0.8 < Ca/P \leq 1.5$, which is entirely different from the conventionally prepared calcium phosphate cement ($1.5 \leq Ca/P < 1.8$). They found that the prepared nanoapatitic calcium phosphate cement first will be transformed into CO_3–Ca deficient HA before it can be resorbed in the bone. After that, it will only be transformed into bone as a function of commercial calcium phosphate cements. However, there is no detailed report of animal experimentation on this product. The preparation and characterization of nanosized HA under microwave irradiation were investigated recently [212]. The nano-HA was synthesized by the precipitation method using $NH_4H_2(PO_4)$ and $Ca(NO_3)_2{\cdot}4H_2O$. The obtained precipitate was subjected to microwave sintering after washing with distilled water using a high-speed centrifuge. The microwave generated a power conception of 980 W and a power output of 490 W with frequency 2.45 GHz for a period of 5–15 min. This method offers advantages over normal furnace heating with respect to time and energy saving. They found that there was a slight increase in the microhardness value of the sintered material with an increase in microwave exposure time. The major problem associated with the microwave densification is in getting large samples without microcracks. This is believed to be due to the nonuniform packing of crystallite in the green compact, as well as due to the nonuniform heating profile occurring inside the microwave cavity.

After the development of nanoscale HA, its application to coating on bioimplants such as titanium alloy has been increased. The coating, conventionally and commercially, so far has been done by the thermal-spraying method, which functions as an intermediate layer between human tissues and the metal implant. This type of coating method can speed up early stages of the healing process after postimplantation, but the lifespan is very limited due to the low interfacial bond strength between the tissue and the implant, which arises from the dissolution of amorphous HA in human body fluid. To alleviate these problems associated with interfacial strength, Zang et al. [232] developed a novel room-temperature electrophoretic deposition process to fabricate nanostructural HA coating. This kind of nanostructured HA coating significantly improved the coating's bond strength up to 50–60 MPa, that is, two–three times better than the thermal-sprayed HA coating, and has excellent corrosion resistance, 50–100 times higher than the conventional HA coating. Apart from this, nanostructured carbonated HA also has been used as a coating material on titanium alloy using the plasma-spraying technique [85]. The acquired results showed that the sprayed precursors consisted of β–$Ca_2P_2O_7$, α–$Ca_3(PO_4)_2$, and $CaHPO_4$ phases, whereas the carbonated HA coatings exhibited a unique phase construction of nanostructural and needle-like crystals. They found that the dissolution and bonding strength degradation of the carbonated HA coatings were much lower than the plasma-sprayed HA coatings. The structural characterization of the carbonated HA coating obtained in this study is expected to show much more biological efficacy.

2.2. Polymeric Nanomaterials

The design of polymeric structures at the nanometer-scale level has received great attention because their submicron size particles could deliver biomolecules in a controlled fashion. The use of polymers in medical applications dates back almost to the birth of polymer science; since then, they have been used for the design of medical prostheses or implants and for the delivery of therapeutic molecules [14, 105]. The interest in polymers for various biomedical applications is mainly due to their design flexibility (because the polymer composition and structure can be tailor made to a specific need) and their biodegradation in body pH. Polymers can include chemical bonds that undergo hydrolysis upon exposure to the body's aqueous environment, and they can also degrade by cellular or enzymatic pathways. The rate of degradation can be controlled by manipulating the polymer properties such as hydrophobic and crystalline. Polymers can be broadly

classified into two groups, depending upon their degradation behavior, namely, biodegradable and nonbiodegradable polymers (Table 6). Considering the mechanical properties of the polymers (Table 7) with the host tissue, most of the polymers frequently have been used for soft-tissue applications [180]. Polymeric systems that have been investigated for hard-tissue regeneration include poly(hydroxy esters) [146–148, 204, 205, 202], polydioxanone (PD) [162], poly(propylene fumarate) (PPF) [72], poly(ethylene glycol) (PEG) [148], poly(orthoesters) [197], polyanhydrides [142], and polyurethanes (PU) [163]. Among the poly(hydroxy esters), PLA, PGA, and PLGA serve as scaffolds that have an appropriate three-dimensional (3D) structure on which osteoblast cells can grow and deposit bone extracellular matrix (osteoid). The polymers degrade after the osteoid has become established. These polymeric materials may also serve as carrier vehicles for the delivery of bioactive molecules, and at the same time, they have a structural function. In addition, poly(L-lactic acid) has the highest mechanical strength as compared to PGA and PLGA, and the same was investigated for orthopedic applications in the form of pins, screws, and plates. The nondegradable polymers also were investigated in many hard-tissue applications, including poly(methylmethacrylate) (PMMA) [46], poly(hydroxyethylmethacrylate) (PHEMA) [79], poly(acrylic acid) (PAA) [114], poly(butylmethacrylate) (PBMA) [132], and poly(glycidylmethacrylate) (PGMA) [156–159].

For the past few years, there has been growing interest in a novel polymer fiber production methodology. Polymeric fibers having a high degree of orientation along the fiber axis are fabricated from polymer melt or solution through a variety of processes, including drawing or spinning by involving a number of complex molecular processes [40, 8, 191]. These processes involve time- and temperature-dependent molecular motions, phase transitions under highstress, entanglement constraints, and various intermolecular reactions. Hence, the final state of molecular order in a fiber is a function of the process variables such as stress, strain, temperature and time, and the length and length distribution of the molecules. The polymer fibers developed by these techniques have a diameter in the range of 1–100 μm. Recent advances in the fabrication of nanofibers offer another form of building block for the nanostructure-based biomaterials [138]. Polymer nanofibers can be produced by a number of techniques such as drawing [165], template synthesis [139, 61], phase separation [136, 228], self-assembly [130, 222], and electrospinning [75, 63, 96]. Drawing is a simple method that is being explored to prepare polymeric nanofibers because it needs minimum equipment, and is also feasible for producing lengthy fibers. By this process, it is possible to create nanofibers with diameters in the range between 2 and 100 nm approximately. The only disadvantage of this process is that it produces fibers one after another. Template synthesis is also a considerably easy method to produce nanofibers. This method uses a nanoporous membrane as a template during the fiber formation. The highlight of this method is the fabrication of various sizes of solid as well as hollow-shape fibers by optimizing the experimental conditions. However, this method is limited to a few polymers only, which may be disadvantage of the template synthesis. Phase separation is an interesting method involving various processing steps, including material dissolution, gelation, solvent extraction, freezing, and drying. Of course, to carry out these steps would take a prolonged time to convert the polymer into a nano form. The advantage of this method lies in the controlling of mechanical properties of polymer nanofibers. Self-assembly is a process in which individual, preexisting components organize themselves into desired patterns and functions. It is also a time-consuming process. Ultimately, the legend of the polymer nanofiber processing technique may be termed so-called electrospinning.

Table 6. Types of polymers and their applications with respect to degradation behavior.

Materials	Applications
Nonbiodegradable polymers	
Polymethylmethacrylate (PMMA)	Bone and dental cement, intraocular lens
Polyhydroxyethylmethacrylate (PHEMA)	Drug delivery
Polybutylmethacrylate (PBMA)	Bone and dental filling, controlled release
Polyacrylic acid (PAA)	Bone plates, tissue engineering
Polypropylene (PP)	Heart valves, skin patches, sutures
Polytetrafluroethylene (PTFE)	Vascular grafts, reconstructive surgery
Polyamides	Drug delivery, catheters, syringe
Polycarbonate (PC)	Contact less, syringe, skull implants
Biodegradable polymers	
Polylactic acid (PLA)	Sutures, bone plates, screws, scaffolds
Polyglycolic acid (PGA)	Sutures, bone plates, screws, scaffolds
Polylactic-co-glycolic acid (PLGA)	Tissue engineering, drug delivery, cartilage screws, sutures, wound dressing
Polycaprolactone (PCL)	Drug delivery, bone plates, fixation device
Polyhydroxybutyrates (PHB)	Drug delivery, bone plates
Polydioxanone (PD)	Sutures
Collagen	Prosthetic heart valves, membranes, wound dressing, tissue engineering
Gelatin	Binding agent, tissue engineering, membranes

Table 7. Mechanical properties of polymeric biomaterials [59, 13].

Polymers	Tensile strength (MPa)	Tensile modulus (GPa)	Flexural modulus (GPa)	Glass transition (°C)	Melting temperature (°C)
Poly(L-lactic acid) (Mw:100,000)	50	2.7	3.0	58	169
Poly(D,L-lactic acid) (Mw:107,000)	29	1.9	1.95	51	n/a[a]
Poly(glycolic acid) (Mw:50,000)	n/a	n/a	n/a	35	210

For the past few years, there has been growing interest in novel fiber production by electrospinning. It is a unique process because it can consistently generate nanoscale fibers ranging between 50 and 500 nm in diameter [43]. The electrospinning can be considered a variation of the better known electrospray process. The electrostatic-spray techniques enable the understanding of the insights of the electrospinning process, which involves applying a high voltage to a capillary and pumping a polymer solution through it. As a result, nanofibers of a polymer collect as a nonwoven fabric on a grounded plate below the capillary. The driving force of the mechanism behind the spinning of nanofibers is when, in the absence of the electric field, the fluid forms a drop at the exit of the capillary, and its size is determined by surface tension. If an electric field is applied, it stimulates charges into the solution, and quickly relaxes to the fluid surface. The coupling of the surface charge and the external electric field creates a tangential stress, resulting in the deformation of the droplet into a conical shape, better known as a Taylor cone. Once the electric field exceeds a critical value needed to overcome the surface tension, the apex of the cone ejects a fluid jet. A schematic representation of the electrospinning process is shown in Figure 3. This process has three stages. First, there is a jet initiation and extension along a straight line. The second step pertains to growth of a bending instability and elongation of the jet, which allows the jet to become very long and thin while it follows a looping and spiraling path. This is followed by, of course, the final step, solidification of the jet into nanofibers. The background development of this electrospinning process recalls many early inventions as when Lord Rayleigh [134] studied the instability that occurred in electrically charged liquid droplets. He determined the maximum amount of charge of liquid droplets before the applied electric forces overcome surface tension of the droplets, followed by Zeleng [233], who described the phenomenon of the electrospraying technique. Later, Taylor [233] analyzed the conditions at the print of a droplet that is deformed by an applied electric field, and reported that a conical interface between two fluids is stable if the cone has a semiangle of 49.3°. These findings have a great impact on the process of electrospinning of a polymer solution or melt. However, the electrospinning of the solution of macromolecules can be traced back to 1934, when Formhals invented a process for making polymer fibers by using electrostatic force. He found that the electrostatic potential difference required depended upon the properties of spinning solution, such as molecular weight and viscosity [64–70].

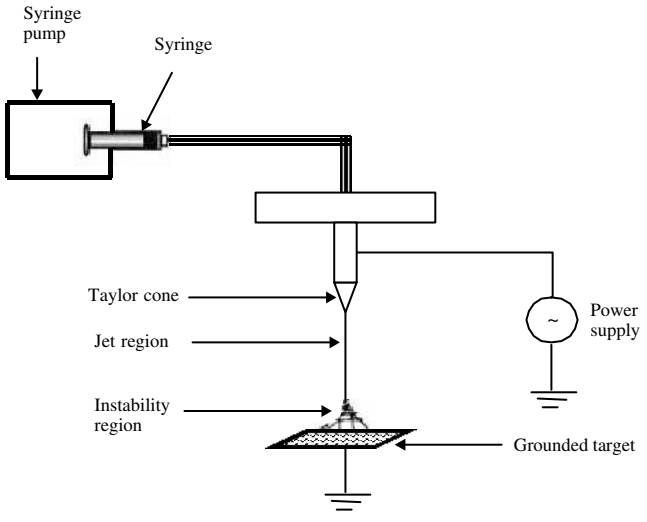

Figure 3. Schematic representation of electrospinning process.

Because of the small pore size and high surface area, electrospun nanofibers have shown promise for exploitation in protective clothing, molecular filtering [43, 183, 75, 74], and in many biomedical applications [21, 75]. In addition, polymer nanofibers are being explored in making optical and electronic devices [164, 26], and as reinforcement agents in nanocomposites [26]. The polymeric nanofibers formed by the electrospinning technique have been proposed for soft- and hard-tissue applications, depending upon their structural and mechanical properties. Also, many investigations suggested the use of polymer nanofibers as medical prostheses, including blood vessels, vascular, breast treatments [140, 141, 95, 16, 11, 189, 198], and for hard-tissue remodeling [6, 21–23]. Polyethylene oxide (PEO) was fabricated in the form of nanofibers by electrospinning for wound-healing applications [38]. Dashy and Reneker studied the processing conditions and fiber morphology, and found that the diameter of the fibers could be varied by changing the processing parameters such as electric field, distance between capillary and the collection plate, and viscosity of the polymer solution. This kind of nanofiber could

be used as a wound-dressing material and as a reinforcement agent in making nanocomposites. Hulteen et al. [98] reported the preparation method of carbon nanotubes and nanofibrils with a nominal outer diameter of 200 nm and a length of 60 μm. They characterized their products with SEM, and found that the structure was extended throughout the entire length of the membranes (~60 nm) without any sign of breakage. Carbon nanotubes can also be catalytically produced in large quantities, and have been used for the reinforcement of nanostructural composite materials [175]. Elias et al. [55] enhanced the functions of osteoblast cells on carbon nanofibers. They investigated the *in vitro* performance of osteoblasts (the bone-forming cells) onto carbon nanofibers, and found that the osteoblastic proliferation increased with decreasing carbon fiber diameters after a few days of culture. The comparative study of the carbon nanofibers prepared by electrospinning with respect to conventionally prepared carbon fibers with dimensions larger than 100 nm implies that the nanoscale fibers represent a unique and promising class of material for the cell culture of osteoblastic cells. These results explored the ability of carbon nanofibers to improve the osteointegrative properties in a controlled manner. The effect of bone-cell adhesion on novel carbon nanofibers and polycarbonate urethane/carbon nanofiber composites was investigated at the *in vitro* level [178]. The results provided the evidence that the smaller scale (nano) carbon fibers promoted the osteoblast adhesion. The adhesion of other cells was not influenced by the carbon fiber dimensions. Also, smooth muscle cells, fibroblast, and chondrocyte adhesion decreased with an increase in either the carbon nanofiber surface energy or the simultaneous change in the carbon nanofiber chemistry. The versatility of these fibers suggested that there are a large number of possibilities for future designs that could enhance the efficacy of medical implants.

3. NANOMATERIALS IN TISSUE ENGINEERING

The field of tissue engineering has emerged over the past decade by evolution of the engineering discipline in combination with materials and molecular cell biology. Tissue engineering may be defined as the application of engineering disciplines to either preserve existing tissue structures or to allow tissue growth. Although tissue engineering has multiple facets and several definitions proposed so far, it is also known as the science of persuading the body to regenerate or repair tissues that fail to regenerate or heal spontaneously [2]. Tissues are usually organized into three-dimensional structures in our body. This architecture is increasingly believed to contribute considerably to the growth of specific biological function in tissues, and it is thought to provide appropriate nutritional conditions and a spatial environment for cells [12]. All of the materials intended for human applications undergo tissue responses upon implantation into living tissue with respect to the implanted site. Recently, progress has been made in the design of nanostructural biomaterials capable of interacting very closely with the biological environment. This interaction has been accomplished by harnessing the principles involved in biological recognition between proteins and proteoglycans on a cell surface with other biological molecules normally present in the natural extracellular matrix (ECM). An ECM is a complex matrix of proteins, proteoglycans, and charged polysaccharides, which provides physical scaffolding for cells and tissues, and further helps to provide a permeability barrier between tissue compartments, and hence enables the polarization of tissue structures [82]. The ECM molecules are typically quite large, of molecular weight above 100,000, and contain several functional domains or regions, including those involved in receptor-mediated cell adhesion and regions which interact with other ECM molecules or growth factors. These biomolecules have a notable role in tissue repair or regeneration by allowing cell-free materials to elicit cellular infiltration within implanted materials, and to direct the formation of new tissues within the material at the implanted site. By this technique, the implanted biomaterial functions as a mechanical supporter, which is able to alter the track of tissue regeneration through the transmission of biological signals to cells in the surrounding tissue.

Generally, tissue can be classified into hard and soft, depending upon its mechanical and structural characteristic features. For example, bones and teeth pertain to a hard kind of tissue, which is stiffer (elastic modules) and stronger (tensile strength) than the soft tissue. Skin, blood vessels, cartilage tendon, and ligaments are a few notable examples of the latter type. Table 8 shows the major differences between hard and soft tissues in terms of mechanical properties [180]. All hard and soft tissues of our body contain differentiated cells living in an ECM elegantly designed by nature's master mind. These matrices consist of nanofibers, microfibers, sheaths of material, minerals, proteins, polysaccharides, and other essential biopolymers. The nanoscale architecture of these matrices is critical for the proper function of each tissue. It is reported that the cells can attach and organize well around fibrous scaffolds, even though the fiber diameter is smaller than the cell [124]. Hence, it is clear that the nanoscale fibrous matrix as an artificial scaffold could provide better circumstances for the growth of cells in a natural way. Progress in nanoscience and nanotechnology is expected to enable the fabrication of structurally and functionally designed artificial nanoscaffolds that will support cells to live in a natural environment with all

Table 8. List of mechanical properties of hard and soft tissues [180].

Tissues	Young's modulus (MPa)	Tensile strength (MPa)
Hard tissues		
Cortical bone	7,000–30,000	50–150
Cancellous bone	50–500	7.4
Dentine	11,000–17,000	21–53
Enamel	84,000–131,000	10
Soft tissues		
Articular cartilage	10.5	27.5
Fibrocartilage	159.1	10.4
Ligament	303.0	29.5
Tendon	401.5	46.5
Skin	0.1–0.2	7.6

of the necessary qualities. In this regard, a fundamental understanding of cell–substrate interactions is an important criterion for tissue remodeling in the development of novel biomedical implants. It has been hypothesized that cell–substrate interactions are governed by surface properties and their imperative interactions found to occur within 1 nm of the implant surface [117]. Naturally occurring biological structures appear to interact selectively with relevant biomolecules while resisting nonspecific interactions. As biological interfaces are highly dynamic, simply trapping cells at a particular point on a surface is not enough [15]. Cells must first be encouraged to differentiate, that is, change their behavior to perform as required, and once their function is complete, their activity must be turned off again. Transient interactions are thus to be encouraged, and multiple-function surfaces are likely to prove extremely important. To gain insight into these interactions, a logical approach is needed to investigate the scaffolds on which the cells attach and grow in living systems. To make this happen, material scientists, biologists, engineers, and clinicians will have to work together to create the necessary strategies to synthesize scaffolds at the nanolevel.

The scaffolds or templates can be fabricated through the use of lithographically defined patterning or processing of the substrate materials in order to achieve selective nucleation and growth of the nanostructured biomaterials similar to natural ECM. Hanarp et al. [86] studied the adsorption of 110 nm negatively charged polystyrene particles on positively charged titanium surfaces by colloidal lithography for the purpose of making surfaces with controlled nanotopography for the cells' adhering. The coverage and structure of the particle films were in good qualitative agreement with the soft sphere random sequential adsorption model. They found that the colloidal lithography is a quick and relatively simple method to produce uniform nanostructures over large surface areas. However, there is also a host of natural templating materials that researchers can avail themselves of. Recently, a biodegradable polymer nanofiber scaffold was prepared by the electrospinning process using poly(caprolactone) (PCL) for bone tissue engineering [231]. In this process, PCL fibers with diameters down to the nanometer-scale rage were formed by subjecting a fluid jet to a high electric field. The biocompatibility of these nanofibers was evaluated with mesenchymal stem cells derived from the bone marrow of neonatal rats. The cell–polymer constructs were cultured with osteogenic supplements under dynamic culture conditions. The potentiality of PCL nanofibers for tissue engineering was confirmed by the penetration of cells into the nanofibrous scaffold. This kind of scaffold provides an environment that supports mineralized tissue formations, and may also be used in the treatment of bone defects. Apart from this, other possible micro/nanostructure scaffold fabrication techniques are reviewed in a detailed manner [135, 203] as illustrated in Table 9. Carbon-based nanosystems and carbon nanotubes are another class of materials which provided a tremendously rich basis for nanostructure research. Carbon fibers are a new breed of superstructure materials mainly used in composites as reinforcing agent. Carbon fibers offer the highest specific modulus and strength of all reinforcing fibers thus far used in nanocomposites [28]. They can also serve as a precursor in the fabrication of nanomaterials such as starting material or can provide an avenue for the synthesis of natural templates of varying sizes depending upon medical applications. This kind of scaffold can also be seeded with appropriate cells, growth factors, or therapeutic macromolecules to enhance their properties, and hence widen their usage. Carbon fibers have wide medical applications, either as such or as composites, and have been investigated extensively. Their potentiality as molecular filters for the separation of biological molecules is also noteworthy. Recently, carbon fibers were produced by the electrospinning technique at the nanolevel. Wang et al. [216] prepared ultra fine fibers from a polyacrylonitrile/N,N–dimethylformamide precursor solution using electrospinning. They made carbon fibers on the order of 100 nm diameter. This study particularly emphasized the chemical analysis features of carbon nanofibers by Raman spectroscopy. This kind of carbon nanofibers could be used as cell carriers in tissue engineering applications.

Phase separation	[136]
Template synthesis	[61]
Drawing	[166]
Self-assembly	[222]
Electrospinning	[231]

As compared to other types of biomaterials, biodegradable polymers are frequently being used in tissue engineering due to easy fabrication and their potentiality in cell attachment. The list of nanostructure biomaterials used as scaffolds in tissue engineering applications is given in Table 10 with respect to the types of cells studied. The essential properties of an ideal scaffold are that it should be biocompatible, biodegradable in a controlled fashion, have an appropriate pore size with interconnective porosity to achieve better cell growth, be surface modifiable, have adequate mechanical strength, the potential to elicit an immunological or foreign body reaction, should encourage the formation of ECM by promoting cellular functions, and should possess the ability to carry biomolecular signals such as growth factors. Scaffolds intended for tissue remodeling must direct the arrangement of cells in an appropriate three-dimensional configuration, and present molecular signals in a suitable spatial and temporal manner so that the individual cells will form the desired tissue structures. This should be easily fabricable, and reproducible within economical limits. Most of the degradable polymers are at least cell adhesive [25, 35, 171, 211, 210, 54]. The scaffolds

are frequently made by using biodegradable polymers, either natural such as collagen, fibronectin, elastin, gelatin, or synthetic such as PLA, PGA, PLGA, and PCL. Some of the composite materials are also available in conjunction with HA for the purpose of bone tissue engineering. As the function of a nanofibrous scaffold is that it mimics the natural ECM, the conversion of biomaterials (in particular, polymers) as nanofibers has been enhanced rather than conventional larger diameter fibers (few microns), which do not have the morphological structure of natural tissue. Huang et al. [96] reported the high-resolution analysis of engineered type I collagen nanofibers generated by the electrospinning process. As collagen is a primary structural element in the ECM, they intended this nanofiber for tissue engineering applications. Collagen nanofibers were generated at ambient temperature and pressure by electrospinning a 1 wt% solution of type I collagen and PEO, and the fiber features were studied by a scanning electron microscope (SEM) and a transmission electron microscope (TEM). They also renewed emphasis on the use of processing of natural materials, which is the one they addressed in this experiment. This strategy may lead to the production of collagen scaffolds for the repair of connective tissue injuries, and as a matrix for cellular growth directed at organ regeneration. As collagen has a variety of tissue remolding applications, it is necessary to spin those natural polymers into nanofibers in order to widen their usage. To address this, Matthews et al. [144] fabricated a collagen nanofiber matrix using types I and III. They demonstrated the possibilities of tailor-made subtle mechanical properties into a matrix by controlling the fiber orientation. The inherent properties of the electrospinning process make it possible to fabricate complex and seamless three-dimensional structures. They proved that those natural polymers promoted cell growth, and achieved considerable cell penetration into the engineered collagen matrix. They suggested that this kind of nanofibrous matrix may represent a considerable tissue engineering scaffold due to their structural and biological features.

In the role of bioceramics, nano-HA has been used in tissue engineering applications, and a few investigations also reported its activity with cells. Yang and Ong [229] prepared nano-HA by the microwave processing technique, and cultured osteoblast-like cells on the surface of HA. They used a 115 nm particle size of HA for this *in vitro* evaluation, and observed the osteoblast cell morphology behavior. There were no significant differences of cell proliferation on the HA derived from conventional as well as microwave processes, and no sign of apparent impairment of cell physiology also was detectable. These results showed that the microwave processing condition did not have any apparent detrimental effect on the biological properties of HA. The *in vitro* response of sol–gel-derived HA with human mesenchymal stem cells was described in order to prove their enhancement of bioactivity and biocompatibility [137]. The *in vitro* results showed that the human mesenchymal stem cells adhere to aero–sol-derived HA coatings, and exhibited better proliferation signals on these surfaces. The evidence of the proliferation rate of mesenchymal stem cells was observed with a tendency to spread onto the surface as if forming groups, thus supporting the notion of not only biocompatibility, but also enhanced bioactivity of the materials at the *in vitro* level. This behavior is considered to be of great importance since it simulates in an artificial surface several steps of the cell cycle occurring in a tissue environment with no need for an interfacial protein scaffold. They concluded that these surfaces present an interaction with the mesenchymal stem cells that may be useful for tissue engineers to design an alternate to biological ECMs. A new class of nano-HA in the form of fibers is also being used in many biomedical applications, in particular, tissue engineering. The production of such a type of nanofiber was reported recently by a simple route using the reaction between calcium chloride and sodium phosphate in the presence of a surfactant [133]. Liu et al. produced a high-crystalline and fairly pure phase of HA with length and diameters of 160–220 nm and 5 nm, respectively. One more interesting publication is one in which Ioku et al. [107] reported the preparation of fibrous apatite and apatite sheet by the hydrothermal process intended for both bone filling and tissue engineering applications. Since HA is a bioactive agent, it will act both as a cell carrier and as an osteoconductive substance at the defective part of the bone tissue engineering. This kind of HA sheet could be used as a matrix for bone tissue engineering, and for the delivery of bioactive molecules due to its biocompatibility and biostability. A comprehensive article by Kizuki et al. [121] demonstrated the effect of polarization on cell behavior by cell cultivation on electrically polarized ceramic HA. The acceleration of the cell proliferation was confirmed on the surface of the polarized ceramic HA. The cell proliferation was accelerated

by the bone-like layer on the material. It was found that the bone-like layer significantly reinforced the cell adherence, and the cells on the surface of polarized HA were more proliferated than those on the ceramic HA. Porous biomaterials are of particular interest in tissue engineering as cells/tissues invade the pores for their growth upon implantation. Gibson et al. [73] addressed the porous structure biomaterials by producing an interconnected membrane-like web of small fibers with a diameter size in the range between 10 and 550 nm suitable for tissue engineering applications. Tissue reaction to the implant is determined by the combined effects of the implant material, structure, and carrier fluid. Induction or enhancement of biological reactions are achievable by bioactive implant surfaces or by bioactive substances released from the implant materials or included in the carrier fluid. For instance, the inclusion of angiogenic factors within the matrix may serve to enhance its vascularization. To induce bone in-growth into the scaffold, a bioactive agent, that is, a calcium phosphate kind of nanoscale material, can be included. Recently, research has focused on the incorporation of inorganic bone fillers such as hydroxyapatite [190] and tricalcium phosphates [102] into a polymeric matrix to produce bioactive tissue engineering materials. These inorganic fillers allow tailor-making the desired degradation and resorbtion kinetics of the polymer matrix. More importantly, the basic resorbtion products of HA or TCP would buffer the acidic resorbtion byproducts of the polymers (e.g., aliphatic polyesters), and may thereby help to avoid the formation of an unfavorable environment for the cells due to decreased pH [1]. These kinds of biomaterials improved the biocompatibility and tissue integrity upon implantation with surrounding tissues.

4. NANOMATERIALS IN DRUG DELIVERY

Over the past few years, there has been a tremendous advancement in the development of drug delivery systems. Recently, many efforts have been taken into consideration to design nanoscale biomaterials as drug carriers. It may consist of solid colloidal particles ranging from 10 to 1000 nm grain size. Nanotechnology is currently developing as an advanced conceptual approach in medical and pharmaceutical applications due to its flexibility of materials design to deliver therapeutic macromolecules or other bioactive molecules. Nanoparticles have been found to be of much use for the controlled release of therapeutic molecules such as drugs and other bioactive molecules, including growth factors [84, 103]. As nanoparticles have a large surface area, it is expected that they will release the therapeutic macromolecules or growth factors in a controlled fashion, in particular, target delivery systems. In this area, a major concern is that, when delivered, the molecules in physiological fluids such as blood, or organs like lungs, interact more with the surroundings of the body environment. As such, the surface characteristics of the particles must be properly designed to maximize the potential for favorable interactions, and their preparation procedure must be delineated accordingly. In the area of medical applications, finely dispersed pharmaceuticals offer rapid drug delivery and reduced dosages for patients [177]. Expensive health-care materials such as drugs may be efficiently dispersed in small and controlled quantities through the nanoarchitecture of carrier materials [188]. The preparation process of carrier materials is generally achieved by the liquid dispersion method. The prepared materials in this approach are being widely used to apply topical coatings to the human epidermis because they can be absorbed faster and more completely than the conventional coating method. Recently, it was found that the HA nanoparticles have good affinity in the delivery of therapeutic macromolecules and growth factors. In this direction, porous HA is used for the intestinal delivery of insulin [173]. Insulin was loaded into nanoparticles by soaking HA in a fixed amount of insulin at 2–6 °C and encapsulated with a sodium alginate solution. The insulin-loaded HA nanoparticles encapsulated in solution alginate can efficiently release the insulin in the neutral environment of simulated intestinal fluid. Hence, the delivery system with HA nanoparticles encapsulated with an alginate matrix seems to be a suitable carrier for the oral delivery of insulin.

The delivery of therapeutic macromolecules in a controlled fashion, either as a sustained release or a targeted release to a patient's body, is of great importance in drug delivery systems. Some of the researchers identified that the particle size and shape greatly influence the delivery of macromolecules. It is appreciable if the particle size is less than 5 μm to circulate through the smallest capillaries, and a particle diameter less than 200 nm is needed to avoid spleen filtering effects [149, 81]. The particulate drug carriers tend to be readily cleared, and accumulate upon delivery at the tissue sites, in particular, liver and spleen. For example, polystyrene (PS) [104], albumin [187], PLA [10], and PLGA [181, 80] are frequently used as drug carriers. These are all mainly used for target delivery systems. The potential applications of PEG-coated nanoparticles as effective drug carriers also have been studied in a detailed fashion by many researchers [169, 182, 58, 7]. Recent publications showed that a few drugs have been encapsulated in PEG-coated nanoparticles, and their release kinetics were studied. Lidocaine was successfully encapsulated as a model drug to study the possibility of controlling the rate of drug release from nanospheres of PEG–PLA, PEG–PCL, and PEG–PLGA copolymers [175]. The results obtained indicated that the drug release was governed by the nature of the core and by the coating layer of polymer, particularly PEG. Gorner et al. [78] loaded lidocaine in PLA and PEG–PLA nanospheres, and studied the drug release kinetics. They found that the drug release was directly related to the size of the nanoparticles and the dispersion of the drug inside the particles. Matsumoto et al. [143] reported the loading of progesterone into PLA and PLA–PEG–PLA copolymeric systems, and studied the rate of drug loading and release. They found that the release kinetics and polymer degradations significantly pertained to the PEG content in the copolymeric carrier. It was also emphasized that the polymer dispersity plays a notable role in the drug release mechanism. Recently, there has been a growing interest in the delivery of drugs or growth factors using polymer nanofibers. The significant role behind the delivery of the biomolecules is based on the principle that the rate of dissolution of the drug increases with the increasing surface area of the drug as well

as the carrier. As nanofibers have a large surface area, they are good to use as a drug or other biomolecular carrier to achieve efficient delivery. The tetracycline drug was delivered from polymer nanofibers using PLA, poly(ethylene–co–vinylacetate) (PEVA), and their composites [119]. Kenawy et al. evaluated the *in vitro* release kinetics of the drug from the electrospun polymer mats, and compared them with a commercially available drug delivery system. The polymer mats of PEVA and PLA/PEVA composites delivered the drug in a controlled fashion as compared to other materials used in this experiment, such as PLA and commercial drug delivery system (Actisite). With the overview of illustrated examples, nanoscience and nanotechnology will certainly provide a new tool for the delivery of biomolecules in a controlled fashion. Further, this will make it possible to do molecular-level therapeutic release to diseased parts.

5. CHALLENGES FOR NANOTECHNOLOGY

Among the challenges facing nanotechnologists for rapid progress to continue in the field are the necessary advances that must be made in several enabling technologies. There are mainly two aspects associated with identifying the critical issues of nanostructural synthesis and assembly in which the control of grain size and the composition of nanomaterials play prominent roles. Another one is the control of interfaces and distributions of the nanoparticles within the materials. The first aspect is inextricably linked; nevertheless, it is important to understand how to exercise separate control over the nucleation of the nanostructural building blocks and the growth of those components throughout the synthesis and assembly process. It is always appreciated to control and/or manipulate the size of matter at an ultrafine level, and to establish computational and mathematical approaches to direct the same in the right path. The latter issue highlights an ability to scale up synthesis and assembly strategies at low cost, large-scale production of nanostructure materials, and control the size and quality of interfaces. Thus, nanotechnology helps us to understand how the structure of biomaterials is connected to their properties at the nanolevel, and thereby enhances the design of biomaterials with special properties required for particular site applications. Sometimes, stability also needs to be considered significantly since nanostructures are often inherently unstable owing to their small constituent sizes and high chemical activity. Hence, a further challenge is to enhance the stability of these materials in terms of structural, thermal, chemical, and biological aspects. The relationship between the micro- and nanoscale properties of the biomaterials has been established to some extent. As a result, nanomaterials available today are mechanically stronger, have a larger surface area, and are more durable, reproducible, and surface modifiable to specific needs. Further investigations are needed on the biological performance of nanostructured biomaterials to understand their interactions with the body environment at molecular level, and to increase their potential as human health care substitutes.

6. CONCLUSIONS

Nature always presents challenges for materials scientists and engineers to design medical implants or scaffolds similar to natural tissue or organs with respect to their performance. With the aid of nanoscience and technology, considerable investigations on medical prosthetics have provided the opportunity to design materials at the nanolevel with all ideal characteristic features in order to function in a natural way in our body environment. Novel innovative technology for the fabrication of nanostructural biomaterials helps increase the possibility of realizing implants with enhanced quality, at both the *in vitro* and *in vivo* levels. Nanostructured biomaterials are a generous gift to humans, either as temporary or permanent substitutes for defective or degenerated tissues and organs. They represent potential breakthroughs in human health care, including the rejuvenation of bone graft materials, three-dimensional scaffolds for tissue engineering, and macromolecular delivery systems using nanoscale particles. Compared to microscale biomaterials, nanoscale biomaterials are relatively less available. Now, the trend is changing to nanoscale biomaterials in order to mimic the natural tissue functions after implantation. With the advancement of nanoscience and nanotechnology, it is expected to develop nanoscale biomaterials either in a monolithic or a composite form in human health care systems with all of the qualities of ideal biomaterials, which leads to an improved quality of human life.

GLOSSARY

Allograft Transplantation of tissue or organ between individuals of the same species, but of non-identical genetic.

Alloplastic graft The use of synthetic biomaterials to repair or replace a defective part of the body.

Artificial organ A medical device that replaces, in part or whole, the functions of the human organs.

Autograft Transplantation of tissue or organ from one part of a body to another part of the same body.

Bioactive material A material, which is capable to elicit an intended biological function.

Biocompatibility The natural ability of an implant material to perform with an appropriate host response in a specific application.

Biodegradability The susceptibility of an implant material to decompose by a living organism.

Bioimplant A scientific term representing the prosthesis made of biocompatible synthetic material.

Biomaterials Any synthetic materials which are compatible with living tissues upon implantation. They can be metals, ceramics, polymers, and their composites.

Bone A supportive rigid connective tissue consisting of collagen fibers impregnated with calcium based minerals in conjunction with metabolic cells.

Cell The fundamental structural and functional unit of all life, that is, composed of an outer membrane enclosing protoplasm and nucleus.

Collagen A fibrous connective tissue protein having triple helical structure that functions to hold tissues together.

Composite A material, which contains two or more different substances.

Compressive modulus The ratio of compressive stress to compressive strain below the proportional limit.

Compressive strength The maximum load sustained by a test specimen in a compressive test divided by the original area of the specimen.

Connective tissue Any of the tissues of the body that support the specialized elements or parenchyma.

Cortical bone The compact hard bone with functional osteons.

Drug Any substance other than food or water that is intended to be taken for the purpose of altering, sustaining or controlling the recipient's physical or mental state.

Enamel A hard white substance that covers the dentine of the crown of a tooth. It is the hardest substances in the body.

Encapsulation A process of applying a thin coating onto a substrate, which conforms to the external geometry of the article being encapsulated.

FDA An abbreviation for Food and Drug Administration, the agency formed in 1931 under the Department of Health Education and Welfare, USA. It deals with the safety and efficacy of products marketed for biomedical application.

Femur An orthopedic term of thigh bone, that is, the bone of upper leg.

Fracture The separation of a body part, characterized in either brittle or ductile.

Graft A transplant.

Growth factors A heterogeneous group of substances whose general purpose is to enhance the rate of healing.

Hardness The resistance of a plastic to indentation, compression and scratching.

Hard tissue The general term for calcified structures in the body, e.g., bone and tooth.

Hydroxyapatite An inorganic phase of calcified bone tissue. It is a type of calcium phosphate having a chemical composition of $Ca_{10}(PO_4)_6(OH)_2$.

Implant Any medical device made from single or multi phase materials intended for human health care applications.

Implantation A surgical procedure by which medical devices or prosthesis is placed, either temporarily or permanently, in human body.

Infection A disease process caused by the invasion and the damaging action of microorganisms like bacteria or virus.

In vitro A biological study performed outside the living body.

In vivo A biological study performed inside the living body.

Nanomaterials Materials composed of particles having nanometric tolerances; a nanometer is being equal to 10^{-9} m.

Organ A differentiated part of an organism adapted for a definite function.

Orthopedics The medical specialty concerned with the skeletal system.

Osteoblast Any one of the cells of mesenchymal origin concerned to the formation of bone tissue.

Osteoclast One of the large multinuclear cells found in association with the resorption of bone tissue.

Osteocyte A cell, which is responsible for the maintenance of bone tissue.

pH A numerical expression of the degree of acidity or alkalinity of an aqueous solution.

Polymer A large molecule formed by the combination of many similar smaller molecules i.e. monomers.

Porosity A ratio of the void volume to the total volume expressed in terms of percentage.

Prosthesis A device that replaces a limb, organ or tissue of the body.

Resorption Dissolution or removal of a substance.

Scaffold A biocompatible 3D structural constructs with or without cells intend as a temporary implantable tissue capable to be replaced by natural tissue.

Surface area The total area of exposed surface of a powder, form or textured material.

Tissue A collection of similar cells and the surrounding intercellular substances.

Tissue engineering The development and manipulation of laboratory grown molecules, cells, tissues, or organs to repair or replace the defective body parts.

Transplantation Surgical transfer of a tissue or organ from one pace to another.

Trauma Any injury caused by external force.

Tumor An uncontrolled growth of cells that serve no useful purpose, which may be benign or malignant.

Xenograft Transplantation of tissue or organ between two different species.

ACKNOWLEDGMENTS

Financial support of the NUS Research Project (R-398-000-002-112) is gratefully acknowledged.

Nanostructured Bipolar Organic Polymers

Antonio Cravino, Helmut Neugebauer, N. Serdar Sariciftci

Johannes Kepler University Linz, Linz, Austria

CONTENTS

1. INTRODUCTION

During the last decades, the research activity of many chemists, physicists, and material scientists has been increasingly committed to the synthesis, understanding, and applicational use of molecules with extended π-electron systems. This work not only has allowed the development of new exciting concepts, but has also boosted the utilization of organic materials like conjugated polymers [1–4] and fullerene derivatives [5–12] in fields of application that have been so far reserved to inorganic semiconductors and metals. For example, after a period of academic research, polymeric films for antistatic coatings as well as polymeric light-emitting diodes and displays have entered the market [13–16]. Moreover, the discovery of a photoinduced electron transfer from nondegenerate ground-state conjugated polymers onto fullerene derivatives [17, 18] fueled up the research on organic polymeric photovoltaics (PV). Indeed, conjugated polymers and fullerenes became potentially suitable for the cost-effective fabrication of flexible, lightweight, and large-area photovoltaic devices and photodetectors [19, 20].

Organic solar cells of the first generation were p/n-heterojunction diodes. These devices were heterojunctions between organic thin films, one consisting of an electron-donating molecule (p-type layer), and the second of an electron-accepting molecule (n-type layer), sandwiched between two metal contacts with different workfunctions. These flat heterojunctions showed rectification behavior as well as photovoltaic effects [21–27]. However, this class of devices suffered limited interaction between the p and n components, which is in them confined to a flat geometrical interface. A breakthrough has been achieved by the direct blending of a soluble p-type conjugated polymer and C_{60} fullerene, or other fullerene derivatives, as an n-type component [27, 28]. In these devices, called "bulk-heterojunction" solar cells, the effective interaction between the donor and the acceptor components can take place in the entire bulk of the photoactive layer. As such, a more efficient charge generation was attained, which in turn dramatically enhanced the short circuit current J_{SC} values, resulting in much more efficient photovoltaic devices. However, the performance of bulk-heterojunction solar cells is still affected by some critical factors. Among them are the following.

- The solid-state miscibility between the conjugated polymer and the fullerene components plays a crucial role in determining the final morphology of the blend. Phase separation and clustering of the fullerene usually occur, reducing the effective donor/acceptor interfacial area as compared to the ideal maximum value [29].
- Clustering effects, leading to a "void" between p- as well as n-type domains, are dramatically detrimental for the transport of charges [29]. In the bulk-heterojunction architecture, a balanced transport of both photogenerated electrons and holes would be highly important. For an efficient transport of holes through the donor polymer matrix and of electrons through the acceptor fullerene phase, a truly bicontinuous and nanoscaled interpenetrating network is required.

As such, it is indeed appealing to think of a single material with intrinsic donor–acceptor properties, as well as being capable of both electron and hole transport (p/n-type material).

An elegant approach to such a target is offered by the design and synthesis of p-type conjugated backbones (donor *cable*) bearing directly grafted or tethered acceptor groups such as fullerene moieties (acceptor *cable*). In this way, the

Encyclopedia of Nanoscience and Nanotechnology
Edited by H. S. Nalwa
Volume 7: Pages (615–628)

secondary structure of the macromolecule possibly might be dictated at a nanoscale level by its primary structure (double-cable polymer). The effective donor/acceptor interfacial area will be maximized, and phase separation and clustering phenomena should be prevented too. In addition, the interaction between the donor conjugated backbone and the acceptor moieties might be finely tuned by selecting the chemical structure (nature and length) of their connecting fragment [30]. Basically, the realization of effective double-cable polymers will bring the p/n-heterojunction concept at a nanoscale, molecular level. In this chapter, after a brief introduction to the photophysics of conjugated polymer:fullerene composites and to the bulk-heterojunction photovoltaic devices constructed using them, the developments of the design, characterization, and preliminary application of nanostructures consisting of a conjugated backbone bearing fullerene moieties are reviewed. Even though the search for electron-accepting components alternative to fullerenes has been pursued [31–36], the results so far obtained indicate that fullerenes are specially suitable for organic photovoltaics [27, 29, 37, 38].

2. CONJUGATED POLYMERS AND FULLERENES: PHOTOINDUCED ELECTRON TRANSFER

Most nondegenerate ground-state conjugated polymers in their photoexcited states, in which electrons are promoted to the antibonding π^* band, are electron donors. The stability of the so-called quasiparticles on conjugated polymers (e.g., radical cations such as positive polarons) [39, 40] suggested their use in combination with electron acceptor molecules. In 1992, the spectroscopic and photophysical properties of blends composed of poly((2–methoxy–5–(2′–ethylhexoxy)–*p*–phenylene) vinylene) or poly(3–octylthiophene) (MEH–PPV and P3OT, respectively; see Chart 1) and C_{60} [17, 18] were independently reported by Sariciftci et al. and Morita et al. While no ground-state interaction between the two components was observed, a strong quenching of the MEH–PPV luminescence indicated the existence of a subpicosecond photoinduced electron transfer [41]. The same behavior was observed later in a number of conjugate polymer/fullerene composites. Very recently, the transfer of electrons from photoexcited conjugated polymers onto 1–(3–methoxycarbonyl)–propyl–1–1–phenyl–(6, 6)C_{61} (PCBM, see Chart 1) has been studied by pump–probe measurements with the unprecedented time resolution of 10 fs [42]. The photoinduced electron transfer time was resolved with about 40 fs after an initial Kasha relaxation [42]. This high forward transfer rate results in a very efficient process, with a quantum yield that approaches unity. Finally, direct and definitive evidence for an electron transfer from photoexcited conjugated polymers onto fullerenes, leading to long-living charged states, was obtained by steady-state light-induced electron spin resonance (LESR) experiments. As an example, upon illumination of MDMO–PPV/PCBM composites (MDMO–PPV stands for poly((2–methoxy–5–(3, 7–dimethyloctyloxy)–*p*–phenylene) vinylene); see Chart 1), two light-induced electron spin resonance signals can be resolved: one at $g = 2.0026$, assigned to positive polarons on the conjugated backbone, and one at $g = 1.9997$, assigned to $PCBM^{\bullet -}$ radical anions [43, 44].

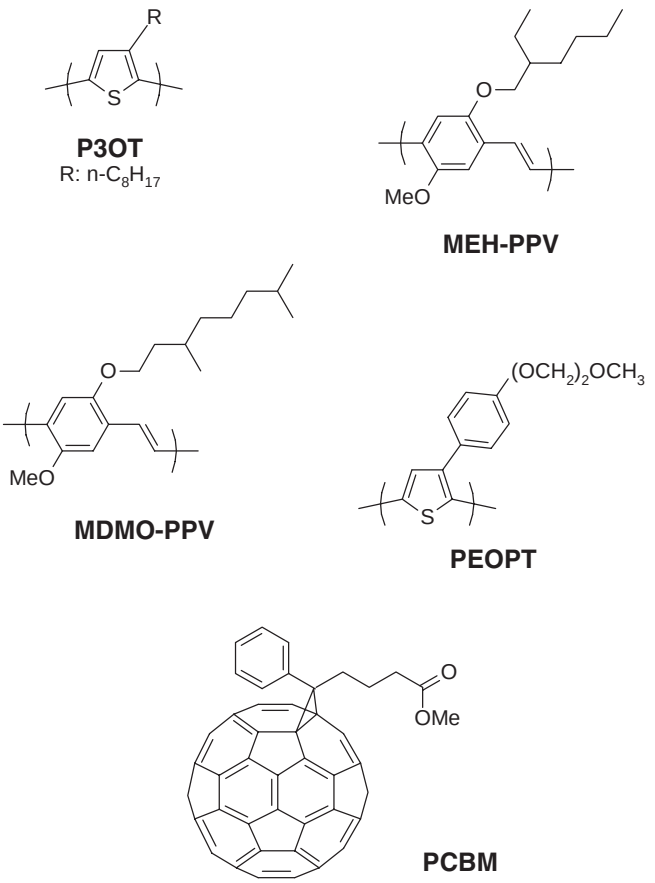

Chart 1

The long-lived nature of the charge carriers photogenerated within conjugated polymer:fullerene composites allows their collection at electrodes via diffusion (as well as field-induced migration), and their use to provide electrical power to an external utilizer. As such, these materials are rather attractive for PV solar energy conversion, and have been used for the preparation of plastic solar cells, as described in the next section.

3. ORGANIC BULK HETEROJUNCTIONS

In this section, we introduce the bulk-heterojunction solar cells, with the only aim to clarify the relationship between the morphology of the photoactive layer and the device's performance. Reference [27] gives a general and updated overview on organic, plastic PV. A discussion of the working principle and origin of the open-circuit voltage (V_{OC}) of conjugated polymer/fullerene bulk-heterojunction solar cells can be found in [37] and [45].

Extensive literature exists on the realization of bilayer photovoltaic elements based on small organic molecules, conjugated polymers, and fullerenes [21–26, 46, 47]. Although, as mentioned above, the internal quantum efficiency of photoinduced charge separation approaches unity for each

donor/acceptor pair, the power conversion efficiency of these devices is limited by the fact that only a small fraction of impinging photons is absorbed near the heterojunction interface. Charge separation occurs only at the flat geometrical interface, within the exciton diffusion length. Photoexcitations created far away from the heterojunction undergo recombination prior to reaching the electrodes. To overcome these problems, bulk-heterojunction solar cells, whose photoactive layer consists of a conjugated polymer/fullerene blend, have been designed [27, 28].

3.1. Morphology of Bulk Heterojunctions

Recently, it has been demonstrated that the efficiency of bulk-heterojunction plastic solar cells can be improved by manipulating the *morphology* within the photoactive blend [29]. Conjugated polymer:fullerene composites are, in fact, juxtapositions of domains with different compositions. Figure 1 shows images of the surfaces of MDMO–PPV/PCBM blends spun cast from a toluene solution (a) and a chlorobenzene solution (b), respectively, obtained by atomic force microscopy (AFM). The images show that a much more homogeneous mixing of the two components is obtained if chlorobenzene is used as the processing solvent. Recent morphological studies, performed by comparing AFM surface images and cross-sectional transmission electron microscopy (TEM) images of these blends, clearly corroborate this observation [48]. The impact of these two highly different morphologies to the PV device performance was studied by fabricating solar cells under identical conditions, except for the choice of the solvent. The open-circuit photovoltages for the two types of devices are nearly identical, while the device fabricated from the chlorobenzene solution exhibits more than a twofold enhancement in the J_{SC} as compared to the device cast from the toluene solution (5.25 versus 2.33 $mA \cdot cm^{-2}$). This high J_{SC} value, combined with a fill factor (FF) as high as 0.61, results in a power efficiency η of 2.5% under AM1.5 illumination [49]. The optical absorption spectra of the active layers are almost identical in the two cases, while the incident photons to current efficiency (IPCE, also called external quantum efficiency, EQE) of the device made from chlorobenzene is higher over the whole absorption spectrum. It is therefore clear that the difference in the device efficiencies must be related to the different morphologies shown in Figure 1. Shrinking both the interpenetrating two phases' domain size leads to an increase of the donor–acceptor interfacial area, as well as a decrease of the spatial separation between fullerene domains. Indeed, the increase in efficiency also relies on the increased mobility of the charge carriers of both signs, as indicated by field-effect measurements on the single components, as well as on the composite, spun cast from different solvents [50].

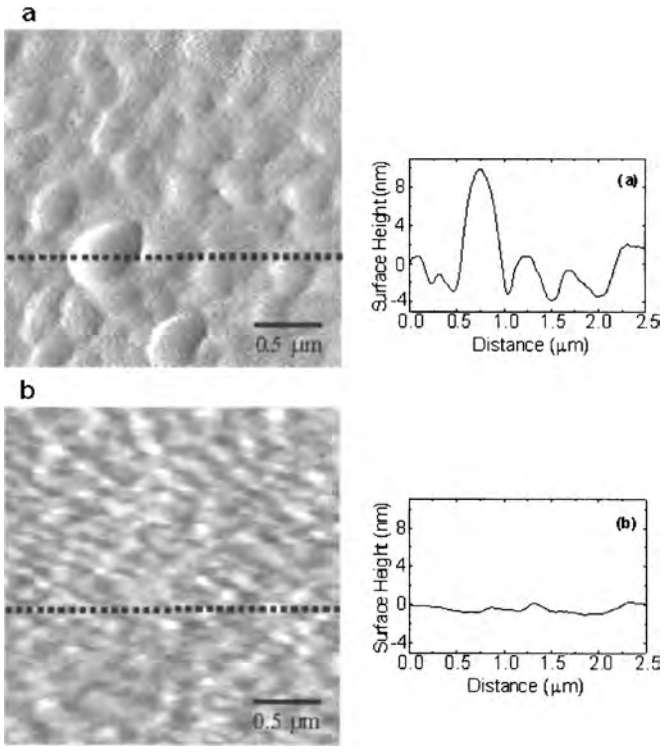

Figure 1. AFM images showing the surface morphology of MDMO–PPV/PCBM (1:4-w) blend films with thickness of about 100 nm and the corresponding cross section. (a) Film spun cast from solution in toluene. (b) Film spun cast from solution in chlorobenzene. The images show the first derivative of the actual surface heights. The cross sections of the true surface heights were taken horizontally from the points indicated by the dotted lines. Reprinted with permission from [27], C. J. Brabec et al., *Adv. Funct. Mater.* 11, 23 (2001). © 2001, Wiley-VCH.

Different strategies to improve the processability of fullerenes and/or to obtain a predetermined nanoscopic phase-separated polymer:fullerene network have been developed. For instance, systems such as diblock copolymers (conjugated donor blocks plus not conjugated fullerene-bearing blocks) [51] and conjugated oligomer–fullerene dyads have been prepared [52–60]. Peters et al. utilized an oligo(*p*–phenylene vinylene)–fulleropyrrolidine dyad to fabricate solar cells which exhibited efficiencies comparable to those of other previously reported bulk-heterojunction solar cells [59]. However, for several donor–acceptor dyads, it was found that, depending on a number of factors (e.g., aggregation state, conjugation length of the donor unit, etc.), photoinduced energy transfer can compete with photoinduced electron transfer [58–61]. Conjugated oligomer–fullerene dyads, containing donor moieties with different conjugation lengths, also have been tested as embedded components in an MDMO–PPV matrix. By comparing the performance of the obtained PV devices, it seems that dyads capable of intramolecular electron transfer (those with longer conjugated oligomer moieties) also enhance geminate carrier recombination [62, 63]. This appears plausible since, on dyads, separated charges can escape recombination only by intermolecular hopping processes. On the contrary, in systems with a long conjugated donor backbone bearing a number of acceptor fullerene moieties—such as double-cable polymers—it can be expected that holes (the positive polarons) first migrate away from electrons by a very fast intrachain diffusion process, preventing recombination. As such, double-cable polymers appear as very appealing materials that may retain the favorable electronic and photophysical properties of conjugated polymer/fullerene composites, but in which phase separation and clustering phenomena cannot occur.

4. DOUBLE-CABLE POLYMERS

A conjugated polymer/fullerene blend (a) (the occurrence of fullerene clustering is emphasized for clarity), an ideal double-cable polymer chain (b), and a more realistic picture in which the continuous pathway for the transport of electrons is also given by intermolecular contacts (c) are schematically sketched in Figure 2. Apart from aspects like the relative positioning of the polymer chains, as well as the positioning of a fullerene moiety with respect to its neighbors, a double-cable polymer for PV applications must posses the following properties:

- mutually independent ground–state electronic properties of the donor backbone and of the fullerene acceptor moieties
- as a prerequisite for photogeneration of free charge carriers, a photoinduced electron transfer from the electron-donating backbone onto the electron-accepting fullerene moieties must occur, and lead to metastable long-lived charged states.

Moreover, since the easy and cost-effective preparation of thin-film devices involves processing from solutions, solubility in common organic solvents is also a determinant factor.

A widely used route toward conjugated polymers is the electropolymerization of suitable aromatic monomers. The electropolymerization process is via electrogeneration of radical cations as reactive species and their subsequent coupling, followed by rearomatization steps [64, 65]. Several conjugated polymers, some of them carrying electroactive moieties [66], were made by synthesizing molecules specifically designed as substrates for electropolymerization [65]. Furthermore, electropolymerization allows the growth of polymeric thin films onto transparent electrodes, leading to samples suitable for most spectroscopic techniques. This is a clear advantage when the solubility of a novel conjugated polymer cannot be expected or obtained. As mentioned before, it has been reported that, in molecular donor–acceptor dyads, photoinduced energy transfer can take place in competition with intramolecular charge transfer, and geminate recombination may also be enhanced. Analougus effects, which are detrimental at least for organic PV, could occur, even in double-cable polymers (a double-cable polymer can be indeed regarded, formally, as a "polydyad"). Therefore, for the design of polymers and supramolecular structures for photovoltaic materials [67], the electrochemical approach was selected as a first step toward the preparation of double-cable polymers, as well as for the study of their electronic and photophysical properties. However, as explained above, solubility is an important requirement for practical applications. Based on the encouraging results obtained with electropolymerized insoluble double-cable polymers, the chemical synthesis of soluble and more defined double-cable nanostructures is nowadays proceeding worldwide [68].

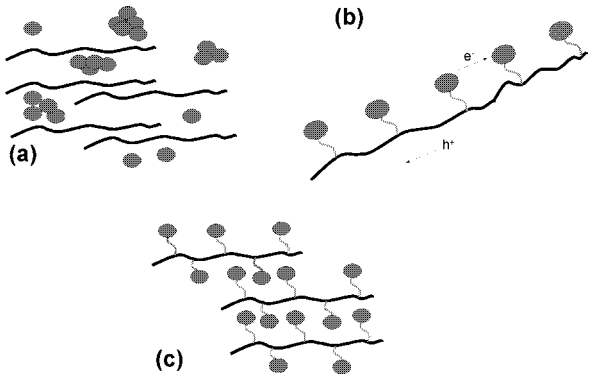

Figure 2. (a) Schematic representation of a bulk-heterojunction. Clustering of the fullerene component is emphasized. (b) An ideal, ordered double-cable polymer, and (c) a more realistic picture where interchain interactions are considered. Reprinted with permission from [68], A. Cravino and N. S. Sariciftci, *J. Mater. Chem.* 11, 1934 (2002). © 2002, Royal Society of Chemistry.

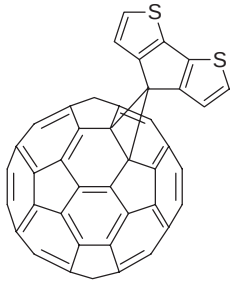
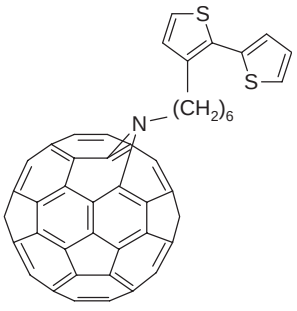
4.1. Electropolymerized Double-Cable Polymers

The first conjugated polymeric materials bearing fullerene side groups were reported by Benincori et al. and Ferraris and co-workers [63–71]. The direct grafting of C_{60} at the bridging carbon of cyclopentadithiophene, leading to compound **1** which was suitable for electropolymerization, was described in 1996 [69]. Due to its low solubility in mixtures containing acetonitrile, the anodic electropolymerization of **1** was possible only in chlorobenzene. After electrochemical compensation (dedoping), poly-**1** showed an absorption spectrum with a maximum at about 440 nm (onset above 600 nm). This λ_{max} value, which is almost 100 nm blue shifted as compared to that of electropolymerized unsubstituted cyclopentadithiophene, was explained as a consequence of the poor solubility mentioned above, leading to relatively short chains (and, therefore, to a short effective conjugation length). The electrochemical properties of poly-**1** films were studied by cyclic voltammetry in monomer-free conditions. One anodic reversible wave corresponding to the electrochemical oxidation/rereduction (*p* doping/dedoping) of the polyconjugated chain was observed at a potential 0.55 V more positive than that of the corresponding process in polycyclopentadithiophene. This result was explained as being due to the electron-withdrawing effect of the fullerene moieties. However, is worth mentioning that such an effect might originate from the short effective conjugation length as deduced from the absorption spectrum. By scanning the negative potential, three reversible waves, assigned to the multiple fullerene substituent reduction/reoxidation steps, were observed [72].



1

One year later, Ferraris et al. reported the synthesis and electrochemical polymerization of a bithiophene carrying a fullerene group through a flexible alkyl chain spacer (**2**) [70, 71]. The choice of **2** was motivated by the easier and superior electropolymerizability of bithiophenes as compared to thiophenes [64, 65]. Moreover, the flexible alkyl spacer was introduced to improve the solubility of the monomer, as well as to reduce the electron-withdrawing effect of the fullerene moiety. 2–bromo–3–(6–bromohexyl)thiophene was obtained by bromination of 3–(6–bromohexyl)thiophene with NBS in a chloroform/acetic acid solution. 3′–(6–bromohexyl)–2–2′–bithienyl was prepared by coupling the Grignard's reagent obtained from 2–bromothiophene and 2–bromo–3–(6–bromohexyl)thiophene. The reaction of the bithienyl derivative with sodium azide in DMSO afforded bythienyl azide in quantitative yeld. Treatment of the latter with C_{60} in refluxing chlorobenzene gave the monoadduct **2**, which was purified by column chromatography. In contrast to C_{60} and **1**, bithiophene **2** was indeed soluble in several organic solvents such as chloroform, dichloromethane, and THF. These improved characteristics resulted in an electropolymerized material that showed, after dedoping, an absorption maximum at $\lambda = 480$ nm. This value is comparable to that of most electrochemically synthesized polythiophenes, indicating almost no electronic or steric perturbation of the conjugated chain. Similarly, electrochemical and *in-situ* UV–vis spectroelectrochemical measurements revealed that the polymeric chain of poly-**2** behaves as common polythiophenes do. In the cathodic region of the cyclic voltammogram (CV) of poly-**2**, four fullerene reduction/reoxidation waves were observed [72]. These results indicated that, in double-cable polymers, both the donor polyconjugated chain and the fullerene acceptor moieties can mantain, to different extents, their individual electronic and electrochemical properties. In particular, by using flexible spacers of the proper length, the donor and acceptor moieties can be electronically isolated in order to prevent ground–state interactions. As such, these early works already showed that double-cable polymers could meet the first requirement for PV applications.



2

Polythiophene P3OT in combination with C_{60} or PCBM also has been utilized for the construction of promising bulk-heterojunction solar cells [73, 74], suggesting polythiophene–fullerene based double cables for further studies on PV applications. The preparation of bithiophene–fulleropyrrolidine dyad **3** was reported recently by Cravino et al. [75, 76]. The reaction of 4–hydroxybenzaldehyde with 1, 2–bis–(iodoethoxy)–ethane and K_2CO_3 afforded 4–{2–[2–(2–iodoethoxy)–ethoxy]–ethoxy}–benzaldehyde. Substitution of iodine with the potassium salt of 4–[2, 2′]bithiophenyl–4–yl–phenol gave the corresponding functionalized bithiophenyl benzaldehyde that was used in the 1, 3–dipolar azomethine ylide cycloaddition to [60]fullerene with sarcosine to afford **3** in 49% isolated yield.

Similar to the criteria already exploited by Ferraris et al. [66, 71], fulleropyrrolidine–bithiophene **3** was designed as a substrate for a relatively facile anodic electropolymerization. Both dichloromethane and toluene/acetonitrile mixtures were suitable as solvents. As a major result, the obtained poly-**3** films allowed the first observation of a photoinduced electron transfer from the polythiophene backbone to the pendant fullerene moieties within a double-cable polymer, as discussed in the following.

The cyclic voltammogram of **3** is illustrated in Figure 3. The first scan shows one irreversible wave peaking at about +1.3 V, corresponding to the oxidation of **3**. Recurrent potential scanning leads to the rising of a new redox wave around +0.8 V, corresponding to the *p* doping/dedoping process of a freshly formed poly-**3** film. Analogous results were obtained using different solvents (toluene/acetonitrile mixtures). Poly-**4** was also electrochemically prepared as reference material following the same procedure [38, 75]. The CV of poly-**3** films in a monomer-free electrolyte solution is depicted in Figure 4(a). In the positive region, one reversible process, corresponding to *p* doping/dedoping of a polythiophene backbone, was observed by the redox wave at about +0.75 V. The relationship between the maximum current peak value and the scan rate (varied from 25 to

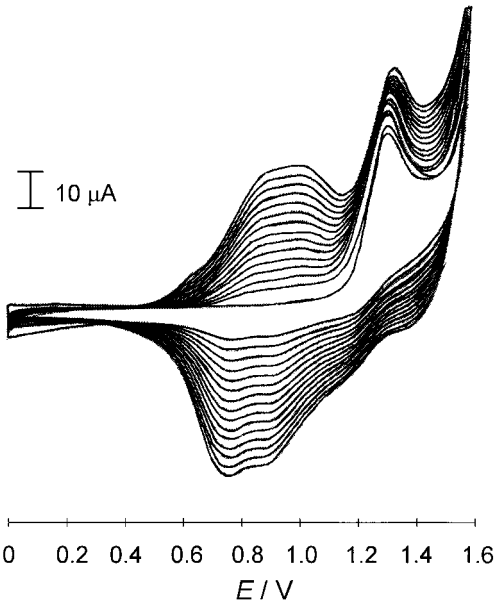


Figure 3. Anodic cyclic voltammogram of **3** (0.1 M Bu_4NPF_6in CH_2Cl_2). Working electrode: Pt foil; quasireference electrode: Ag/AgCl wire (−0.44 V versus ferrocene). 200 mV/s) was found to be linear [Fig. 4(b)]. A linear relationship indicates a redox-active polymer attached to the electrode, and exemplifies the stability of poly-**3** films toward *p* doping [64]. Scanning negative potentials up to −2.0 V shows several redox waves related to the multiple reduction of the fullerene moiety [72]. The irreversible peak at −0.74 V, with no clear origin, was seen only during the first cycles [Fig. 4(a)] [74]. Similar to the properties described by Ferraris et al. [70, 71], these results confirmed that both the polythiophene backbone and the pendant fullerene moieties can substantially retain their single individual electrochemical properties. Films of neutral poly-**3** were yellow–brownish, not soluble, and not photoluminescent. Their UV–vis absorption spectra showed a broad absortpion feature ranging from about 600 nm to the ITO–glass cutoff, with a pronounced shoulder at about 460 nm. As observed with poly-**1**, this value is significantly blue shifted as compared to the λ_{max} of reference poly-**4**, seen at 530 nm [75]. Again, this has been explained as an effect of the relatively low solubility of monomer **3** (as well as that of its oligomer intermediates involved in the electrochemical polymerization process), leading to a lower molecular weight for the corresponding polymer. According to the conclusions from electrochemical characterization, no hints for ground–state donor–acceptor interactions were observed.

3 4

The nature of the photoexcitations in poly-**3** solid films was investigated by means of photoinduced absorption (PIA) in the vis–NIR. The PIA spectrum, taken at an excitation wavelength of 476 nm, is shown in Figure 5. Two electronic photoinduced absorption bands are observed, one with a maximum at 1.48 eV, and one peaking below 0.6 eV. These features compare very well with PIA spectra of long oligothiophenes, and were assigned to positive polarons on a thiophene-based conjugated backbone [41, 77]. To shed light on the relaxation kinetics of the photoinduced charged states, both the intensity and modulation frequency of the pump beam were varied [78, 79]. The polaronic features, estimated by the signals at 1.38 and 0.62 eV, showed a square-root excitation intensity dependence. This dependence corresponds to a nongeminate bimolecular recombination of the photoinduced charges, suggesting the migration of charge carriers with opposite sign to different sites within the films. From the modulation frequency dependence, a broad distribution of charged state lifetimes was observed in the range from 0.8 to 10 ms.

Chem.* 11, 1934 (2002). © 2002, Royal Society of Chemistry.

While these results proved the photoinduced generation of metastable positively charged states on the polythiophene backbone, definitive evidence of a photoinduced electron transfer to the pendant fullerene moieties was obtained by

steady-state LESR spectroscopy. The LESR spectrum, calculated by subtracting the "light-off" signal from the "light-on" signal, shows the photogeneration of two paramagnetic species (Fig. 6). The positive polarons on the conjugated backbone were seen by the signal at a g factor of 2.0022, while the signal observed at a lower g factor, 2.0004, is typical of fullerene radical anions [43, 44]. As such, it was concluded that, in double-cable poly-3, a photoinduced electron transfer from the conjugated backbone to the pendant fulleropyrrolidine moieties leads to long-lived and mobile charge-separated states, as observed earlier in conjugated polymer/fullerene composites.

4.2. Processable Double-Cable Polymers

As already discussed, soluble double-cable polymers are required specifically for PV or other electronic applications in thin-film cost-effective devices. The attachment of fullerene moieties to conjugated backbones, which generally have low solubility, decreases the solubility even more. Therefore, the design of soluble double cables loaded with an adequate number of fullerene moieties (e.g., a fullerene concentration that allows perculation of electrons) is therefore a very challenging task for synthetic chemists. Processable double cables have been synthesized following two different strategies:

- the direct reaction of C_{60} with soluble and specifically functionalized conjugated polymers
- the copolymerization of two monomers, one carrying the fullerene moiety, and one carrying flexible chains in order to impart solubility.

The first approach has been reported by Ferraris et al. in parallel with the electrochemical preparation of poly-**2** [70]. In this work, head-to-tail copolyalkylthiophenes functionalized with azido- or primary amino groups were prepared at first. After treatment with C_{60}, soluble double cables bearing azafulleroid moieties in different percentage (**5a, b**) were obtained and isolated by extraction. The solution of these copolymers showed absorption spectra peaking at about 438 nm. This value is in rather good agreement with that of standard polythiophenes, and again, no absorption at longer wavelengths was observed. *In-situ* UV–vis absorption spectroelectrochemical measurements upon reduction of polymer **5b** showed the spectroscopical features of the fullerene moiety radical anions and, at more negative potential, of dianions, according to the results previously reported for fullerenes and azafulleroids [72, 80]. At even more negative potentials, the behavior of copolymer **5b** was similar to that reported for poly-**2**. In the anodic region, the polymer showed the typical p doping/dedoping wave of polythiophenes. As already observed with poly-**2** and poly-**3**, no hints for a ground–state interaction between the donor and the acceptor moieties were observed.

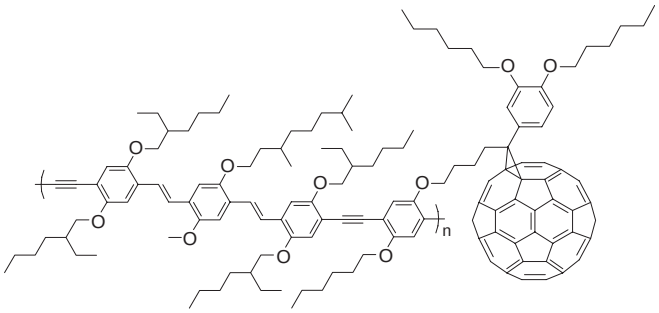
5a, b

The second approach has been used recently by Marcos Ramos et al., who reported the preparation of the first PV device based on a soluble double-cable polymer [81, 82]. They synthesized a conjugated backbone hybrid of poly(p–phenylene vinylene) and poly(p–phenylene ethynylene), with covalently linked methanofullerene moieties (**6**). The polymer was synthesized under inert atmosphere in o–dichlorobenzene/triethylamine (7:3 v/v) via a palladium-catalyzed cross coupling of a diiodobenzene derivative, bearing a pendant methanofullerene, and oligo(p–phenylene vinylene) units end capped with reactive ethynylenes. A polymer similar to **6**, but lacking the methanofullerene moieties, was used as a reference for spectroscopic investigations. The effective conjugation length of the two materials was found to be nearly identical: the λ_{max} of the double-cable polymer, found at 468 nm, was only 6 nm shifted to blue as compared to that of the reference polymer. The molecular weight of **6** was M_W = 16,200 (PDI = 2.82), as estimated by means of size-exclusion chromatography. However, the authors report a behavior indicating that this value could be underestimated [80]. Spectroscopic measurements were carried out both in solution and in thin solid films. The photoluminescence of polymer **6** in a toluene solution was quenched by two orders of magnitude as compared to that of the reference polymer. The quenching of the photoluminescence in an apolar solvent probably involves a singlet–singlet energy transfer from the photoexcited conjugated backbone to the fullerene moieties, as known from studies on oligo(p–phenylene vinylene)–fulleropyrrolidine dyads [59]. However, photoluminescence quenching was also observed in thin solid films. In this case, the quenching mechanism is the photoinduced electron transfer, as discussed before. Accordingly, the photoinduced vis–NIR absorption spectrum of **6** in the solid state

exhibits a band typical of methanofullerene radical anions at about 1.2 eV (this fullerene radical-anion feature was not seen in the poly-**3** spectrum due to the concomitant presence of the broad and much more intense polaron absorption band of the polymer) accompanied by two broad bands, seen at 0.62 and 1.53 eV, characteristic of positive polarons on a conjugated chain (Fig. 7). As reported for poly-**3**, the photoinduced charge recombination was found to follow a nongeminate bimolecular mechanism. The lifetime of the photogenerated charges in **6** also extends to the millisecond time domain.



6

Photovoltaic elements were prepared by spin coating **6** from a chloroform solution [82]. The current–voltage (I/V) characteristic curves of the device recorded in the dark and under white-light illumination ($100\ \mathrm{mW \cdot cm^{-2}}$) revealed a J_{SC} value of $0.42\ \mathrm{mA \cdot cm^{-2}}$, a V_{OC} of 830 mV, and an FF of 0.29. The IPCE showed an onset at 550 nm, and a maximum of 6% at 480 nm. It is noteworthy that this performance, even though obtained with the first example of not optimized double-cable based solar cells, is already competitive with that of devices prepared following the more established p/n-heterojunction and bulk-heterojunction approaches [27, 83, 84]. Moreover, this performance was given by a double-cable polymer with a fullerene content of 31.5%-w, a value considerably smaller than that used commonly in bulk-heterojunction solar cells (about 75%-w).

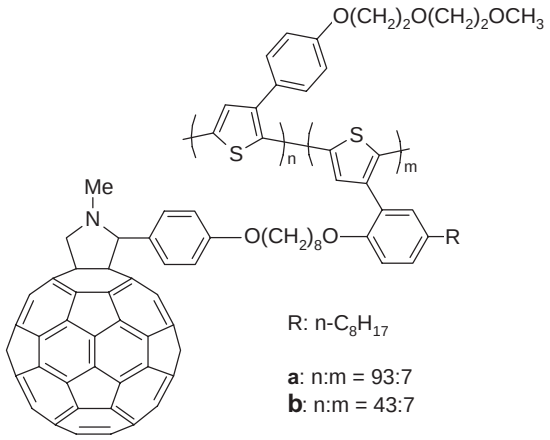
Another family of soluble double-cable copolythiophenes carrying fulleropyrrolidine moieties as well as solubilizing chains (**7a, b**) was reported recently by Zhang et al. [85]. These random copolymers were prepared by chemical oxidative coupling, adding a slurry of $FeCl_3$ in chloroform to the monomers dissolved in the same solvent. Two copolymers with different fullerene loadings were prepared by using two different solubilizing-monomer/fullerene-bearing monomer (prepared via the Prato reaction) ratios in the feed. After dedoping and removal of low-molecular-weight fractions and byproducts, the copolymers were found to contain about 7%-mol (corresponding to 14.5%-w, **7a**) and 14%-mol (corresponding to 24.2%-w, **7b**) of monomer-containing fullerene, respectively. Size exclusion chromatography in chloroform gave the following molecular weights: $M_W = 48{,}000$, $M_N = 28{,}000$ for **7a**, and $M_W = 39{,}000$, $M_N = 26{,}000$ for **7b**. Attempts to increase the fullerene loading were made: when higher percentages of monomer-containing fullerene were placed in the feed, an intractable material was obtained. When the solubilizing monomer used in excess in this preparation is used alone, a polythiophene known as PEOPT is obtained (see Chart 1). PEOPT spin coated from a chloroform solution leads to an orange phase. This phase can be converted to a more ordered blue phase with extended effective conjugation by thermal annealing or by chloroform vapor exposure [46, 86]. It is of interest to note that **7a** and **7b** retain this property, despite the presence of the bulky fullerene moieties. Both copolymers undergo a color change from orange to blue upon exposure to chloroform vapors at room temperature. In this blue phase, both copolymers display a broad electronic absorption band covering a wide range of the solar spectrum, which is in itself an interesting property for PV materials.



7a, b

The solubility of **7a** and **7b** allowed the preparation of photodiodes [85]. The devices based on the double cable with the higher fullerene loading **7b** showed an IPCE more than twofold higher as compared to that of the devices prepared with **7a** (Fig. 8). In both cases, a significant

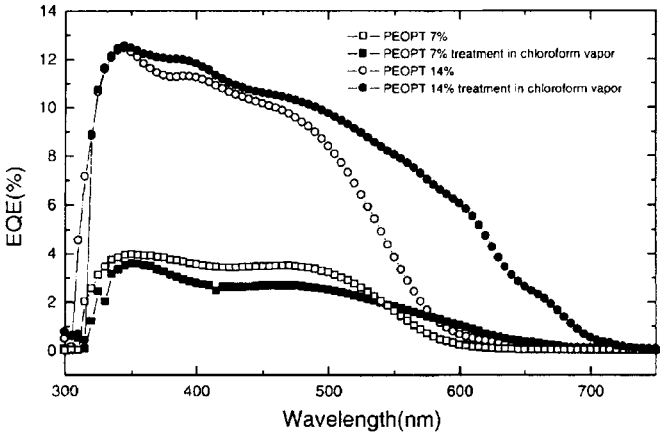


Figure 8. External quantum efficiency (IPCE) of ITO/PEDOT:PSS/**7a** or **7b**/Al photodiodes under monochromatic light illumination prior to and after conversion from the orange to the blue phase. Reprinted with permission from [85], F. Zhang et al., *Adv. Funct. Mater.* 13, 171 (2001). © 2001, Wiley-VCH.

improvement of the IPCE was obtained after treatment of the photoactive films with chloroform just before evaporation of the Al electrode. This effect reflects the change in the absorption spectra while going from the orange to the blue phase of the copolymers. The devices prepared using **7b** where characterized under monochromatic light (λ = 505 nm) illumination with an intensity of 0.1 $mW \cdot cm^{-2}$. The FF was 0.25, and the power conversion efficiency was 0.6% [49]. The diodes not treated with chloroform vapor gave the highest photovoltages, V_{OC} = 750 mV. This value is higher than that reported for PEOPT/C_{60} bulk-heterojunction solar cells [46]. After treatment with chloroform vapors, the V_{OC} of the device dropped to 450 mV. This behavior is a consequence of the altered energy levels between the orange and the blue phases [37, 45, 85].

Another class of soluble double cables was described by Xiao and by Wang et al. [87, 88]. Based on the well-known photoconducting as well as electrochemical properties of carbazole, they synthesized a soluble regular copolymer containing *p*–phenylene vinylene and carbazole units, the latter bearing a pendant azido functionality. The reaction with C_{60} in chlorobenzene gave a soluble fraction (CCl_4 as solvent) with a fullerene percentage estimated spectroscopically as 19.9%-w (**8**). Similarly, they synthesized a double cable also containing triphenylamine moieties (**9**). In this case, the fullerene content was about 21%-w. The weight-average M_w values were determined by means of gel permeation chromatography as 3810 for **8** and 5051 for **9**. Based on these limited values, it is clear that these double-cable materials consist of only a few repeating units. Highly fullerene-loaded double cable **10** was prepared by the same group [88]. In this latter material, the fullerene percentage was estimated as high as 68.8%-w. This value seems to be overestimated since, based on the repeating unit, the calculated maximum fullerene loading is about 57%-w. Nevertheless, this is a high fullerene loading, approaching those of conjugated polymer/fullerene composites used for the fabrication of bulk-heterojunction solar cells with improved efficiency. By means of thermal gravimetric analysis, these copolymers have been found to be stable up to about 350 °C, and moderate weight losses occurred just within the temperature range 380–460 °C. Spectroscopic and electrochemical studies allowed the authors to conclude that the electronic properties of the fullerene moieties were substantially preserved in all cases. Photoinduced electron transfer has been claimed to occur due to the photoluminescence quenching observed in chloroform solutions. These double-cable polymers are currently being tested as material for plastic PV energy conversion [88].

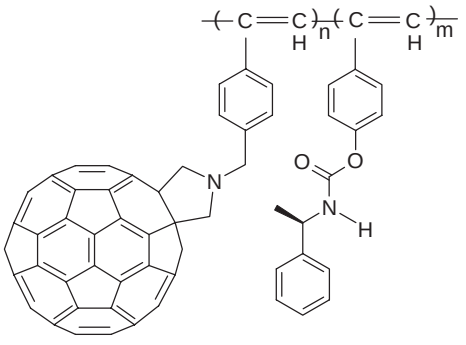
4.2.1. An Optically Active Double-Cable *Polymer*

Nishimura et al. synthesized and characterized optically active helical polyphenylacetylenes carrying tethered achiral fullerene groups (**11**) [89]. The latter arrange in

a helical array with a predominant screw sense along the conjugated backbone. Optically active *cis-transoidal* polyphenylacetylene double cables **11** were prepared by rhodium-catalyzed copolymerization of an achiral fulleropyrrolidine phenylacetylene, synthesized using Prato's reaction, and an optically active phenylacetylene with an (*R*)–[(1–phenylethyl)carbamoyil]oxy unit on the phenyl group. The fullerene homopolymer was insoluble, whereas the copolymers with a fullerene unit content of 10, 20, and 30%-mol were partially soluble in THF or chloroform. The circular dichroism (CD) and absorption spectra of the copolymer containing 10%-mol of fullerene monomer are shown in Figure 9. This copolymer exhibited an intense induced CD in the region where the main conjugated backbone absorbs, the magnitude of which increases monotonically with decreasing temperature. The same effect also can be observed with the homopolymer containing no fullerene monomer. In dilute solutions, the copolymer does not exhibit detectable absorption and CD above 500 nm due to the low fullerene content. At higher concentrations and at a temperature below −40 °C, remarkable CD induction was observed in the characteristic region of the fullerene chromophore (over 700 nm), and the induced CD intensity further increased at −80 °C (see inset in Fig. 9). This behavior indicates that the achiral fullerene units of the copolymer arrange in a helical array with a one-handed screw sense. Similar results were found with the copolymers containing higher fullerene percentages. This seems to be the first example of an induced chirality upon achiral fullerene units, derived from their induced helical arrangment *along a conjugated backbone*. As such, this work demonstrates that the proper design of the double-cable primary structure allows the attainment of a defined nanostructure, both in terms of distance between the acceptor units and the conjugated polymer skeleton, as well as of the positioning of the single acceptor moieties with respect to their neighbors. In fact, the authors have proposed a helical structure (Fig. 10) which suggests similar approaches as a way to improve the intercontact between fullerene moieties of a double-cable polymer, even with relatively low fullerene loading.



11

5. ALTERNATIVES TO FULLERENE-CONTAINING POLYMERS

Fullerene derivatives so far have been the most promising electron acceptor materials for donor–acceptor polymeric solar cells, as well as electron-transporting components

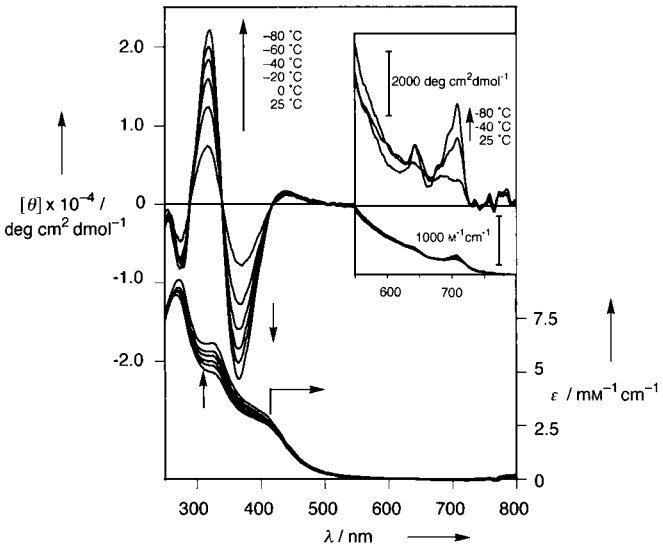


Figure 9. CD and absorption spectra of poly-**11** with a fullerene fraction of 20%-mol in THF solution (0.11 mg · mL^{-1}) at various temperatures. The inset shows the corresponding CD and absorption spectra in the fullerene region in THF at a higher concentration (4.6 mg · mL^{-1}). The molar concentrations were calculated based on the monomer units and C_{60} units (inset). Reprinted with permission from [89], T. Nishimura et al., *Angew. Chem.* 114, 3754 (2002). © 2002, Wiley-VCH.

in organic electronic devices. However, a vast range of electron acceptor molecules are known, which are readily available and could be preferred species to fullerenes, especially from the preparative, cost-effective, and tunable viewpoints. Zerza et al. prepared and characterized a double-cable polymer where the electron acceptor moieties were of the tetracyanoanthraquinone type [35]. This polythiophene-based double-cable polymer was synthesized electrochemically, starting from the bithiophene derivative **12**. As observed for fullerene-containing double-cable polymers, the electrochemical and electronic properties of the individual conjugated chain and of the tethered tetracynoanthraquinone-type moieties in poly-**12** were nicely preserved [35]. Again, a photoinduced electron transfer from the polythiophene chain to the acceptor moieties, leading to long-lived charged states, was demonstrated by comparing electrochemical and photoexcited spectroscopy results.

Finally, a quite different approach was proposed by Skabara et al. [36]. The authors reported the chemical and electrochemical preparation of a donor–acceptor noncomposite polymeric material consisting of a polythiophene incorporating π-conjugated 1, 3–dithiole–2–ylidenefluorene (**13**). Different from the materials described above, the donor and the acceptor components (the polythiophene chain and the 1, 3–dithiole–2–yledenefluorene fragments, respectively) of this nanostructure are connected through sulphur bridges which allow electronic interactions between them. Indeed, internal charge transfer occurs in the monomer as well as in **13**, as seen by electronic absorption measurements. However, despite the occurrence of this ground–state electronic interaction, polymer **13** undergoes photoinduced charge separation, as seen by photoinduced IR absorption [36].

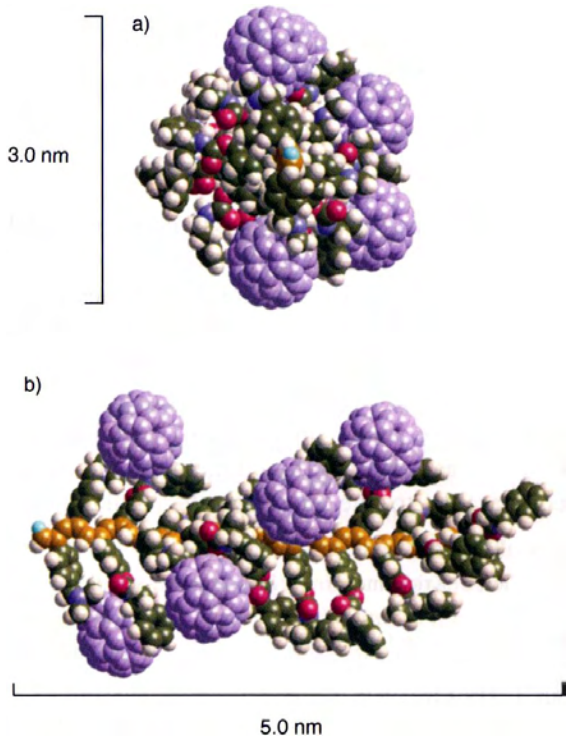

Figure 10. Possible helical structure of poly-**11** with a fullerene fraction of 20%-mol (20-mer). Space-filling models are shown in the top (a) and side views (b). The fullerene units are assumed to arrange in a left-handed helical array along the right-handed polyacetylene main chain. The helix sense is tentative, but the copolymer should have a helical conformation (either a right- or left-handed helix), as it exhibits an ICD in both the main chain and the fullerene chromophoric regions. 13

6. SUMMARY

The preparation and properties of a novel class of fullerene functional materials such as double-cable polymers have been reviewed. These nanostructures consist of a hole-conducting, conjugated backbone (*p* cable) with covalently bound fullerene moieties (*n* cable). By the choice of the proper covalent linkage, both in terms of chemical nature and length, the donor and the acceptor moieties can be electronically "isolated" to exclude ground–state interactions. As such, double-cable polymers are attractive for all organic electronic applications in which bipolar transport is required. Photoexcitation spectroscopic investigations have shown that double cables in their solid state undergo photoinduced electron transfer, leading to long-lived, mobile charge carriers, as observed earlier in conjugated polymer/fullerene composites. Since, in double-cable polymers, phase separation cannot occur, these materials are indeed appealing as a way to control both electronic and nanostructural properties within the photoactive layer of plastic solar cells. The very important technological issue is processability, which is certainly the major challenge toward practical application of double-cable polymers in thin-film devices. With the few soluble double-cable polymers prepared so far, the fabrication of prototype photodiodes and solar cells has been demonstrated. However, so far, a compromise between the fullerene loading (for the transport of electrons) and solubility has been made. In this respect, the following hold.

- Improving the chemical design of a double cable may allow the preparation of processable materials with an acceptably high fullerene moieties percentage as well as acceptable solubility.
- Fullerene content as high as 14%-mol (24.2%-w) has been obtained in a soluble random copolymer (**7b**), and a loading of 31.5%-w already has been obtained, even in a polymer with a well-defined backbone (**7**).
- Balberg et al. described bipolar transport in a poly(3–hexylthiophene)/C_{60} composite with a fullerene fraction of 10%-mol [90]. Indeed, it should be taken into account that the volume fraction occupied by the fullerene moieties could be enhanced by minimizing the volume occupied by the solubilizing but electrically inactive side chains.
- The double-cable concept may lead to bipolar transport properties, even in guest–host systems where the double-cable polymer is embedded within processable polymers as matrices.
- Synthetic strategies toward fullerene derivatives able to self-assemble in well-defined nanostructures with suitably designed conjugated polymers should be considered as an alternative to covalently bound double cables, too. To this end, self-assembly strategies based on electrostatically driven or other key/lock interactions will be possible [91–93].

In addition, to gain additional control of the final morphology by their tertiary structure, covalently linked double-cable polymers also could be further functionalized [91–94].

GLOSSARY

AM1.5 illumination conditions Sunlight radiating through an air mass 1.5 times greater than the vertical case (typical standard definition for specific solar radiation conditions).

Bipolar organic polymer An organic polymer able to stabilize and transport both positive and negative charge carriers.

Conjugated polymer A polymer whose backbone consists of unsaturated carbon atoms or of the repetition of unsaturated units which may allow π-electron delocalization. Well known conjugated polymers are, for instance, polyacetylene $(—CH=CH—)_n$ and polythiophene $(—Th—)_n$.

Doping of conjugated polymers Term developed in analogy with the terminology used in the field of inorganic semiconductors. In conjugated polymers, and more generally in organic semiconductors, doping is a chemical or electrochemical process (mostly of redox type) upon which charged species (for instance polarons) are generated. As result the conductivity of the material is increased. Since photoexcitation may lead to substantially similar results, the term photodoping is also used often.

Double-cable polymer A bipolar conjugated polymer consisting of a conjugated backbone, which acts as electron donor and transporting moiety ("*p*-cable"), bearing tethered or grafted substituents that act as electron acceptor and transporting moieties ("*n*-cable").

Fill factor (of a photovoltaic element) The fill factor (FF) of a solar cell is determined as $FF = I_{mpp}V_{mpp}/I_{SC}V_{OC}$, where I_{mpp} and V_{mpp} are the current and voltage at the maximum power point in the fourth quadrant of the I/V curve and I_{SC}, V_{OC} are the short circuit current and the open circuit voltage, respectively.

Incident photons to converted electrons (IPCE) Ratio of the number of electrons collected at the electrodes versus the number of incident photons; also called external quantum efficiency (EQE).

Photoinduced electron transfer A photoinduced redox reaction between an electron donor, which acts as reducing species, and an electron acceptor, which acts as oxidizer. After photoinduced electron transfer the two species are positively and negatively charged.

Polarons Radical-ions on systems with extended π-electron delocalization. Due to the strong electron-phonon coupling in these systems, an electronic perturbation is usually accompanied by a considerable distortion of the molecular geometry.

Polymer:fullerene plastic solar cells Photovoltaic devices constituted of a conjugated polymer and a fullerene derivative sandwiched between electrodes. After photoinduced electron transfer from the conjugated polymer onto the fullerene, the separated charge carriers are collected at the electrodes and used to deliver power to an external utilizer. These solar cells can be fabricated by well developed coating techniques (e.g. spin coating from solution) on flexible and light weight plastic substrates coated with conductive materials. Thus, they are often called plastic solar cells.

Power efficiency of a photovoltaic element The power-in to power-out conversion efficiency η is given by $\eta = I_{SC} \cdot V_{OC}FF/I_{light}$, where I_{light} is the power of the incident light.

49. The fill factor (FF) of a photovoltaic element is determined as $FF = I_{mpp}V_{mpp}/I_{SC}V_{OC}$, where I_{mpp} and V_{mpp} are the current and voltage at the maximum power point in the fourth quadrant of the I/V curve. The power-in to power-out conversion efficiency η is given by $\eta = I_{SC}V_{OC}FF/I_{light}$, where I_{light} is the intensity of the incident light. AM1.5 illumination conditions correspond to the global sun light spectrum, with $I_{light} = 860\ W \cdot m^{-2}$. An interesting discussion on the usefulness of different kinds of given efficiency values can be found in [25].

Nanostructured Chalcogenide Glasses

Keiji Tanaka

Hokkaido University, Sapporo, Japan

CONTENTS

1. INTRODUCTION

Nanostructures can be defined as having a typical length scale between 1 nm and a few 100 nm. As shown in Figure 1, this scale covers molecular and cluster dimensions, and it is clearly greater than the atomic distance of approximately 0.2 nm. On the other hand, this scale is substantially smaller than the submicrometer wavelength of visible light, which can be regarded as a macroscopic scale. The nanostructure may also be defined as the structure in which material properties depend on the sample size. For instance, in a cubic solid with a side length of 10 nm, the number n_s of atoms located at the surface is nearly equal to that n_b included in the interior, and the ratio n_s/n_b dramatically increases with a decrease in the side length. In such small solids, the surface, not the bulk, may govern material properties.

For amorphous materials, the control of nanoscale structures could be an ultimate research subject. This situation is in contrast to that of single crystalline materials, in which *atomic* structures can be controlled. For instance, we can prepare atomically flat surfaces, where atoms can be controlled one by one. In contrast, in amorphous materials such atomic manipulations are meaningless, since the amorphous structure is disordered at the atomic level. Instead, the structure may be controlled in cluster units.

Can nanostructure science and technology be promising subjects for chalcogenide glasses? Until now, several scientific problems have attracted considerable interest, while applications have been limited. Accordingly, the answer remains. We can see, however, that, in comparison with oxide and halide glasses, chalcogenide glass has two characteristic features, that is, low-dimensional (molecular) structures and semiconductor properties [1, 2], which provide unique subjects for nanostructure science and technology as follows.

The low-dimensional structure presents several topics. First, the chalcogenide glass shows clear signatures of the medium-range structural order of 1–5 nm, while real structures are still controversial [1, 2]. Accordingly, artificially produced chalcogenide nanostructures could be investigated for obtaining insight into the medium-range structure. For instance, it will be interesting to examine how the first sharp diffraction peak and the boson peak [1, 2] change with decreasing size of the chalcogenide glasses. Second, as shown in Figure 1, the molecular structure has nanometer scales, so that the chalcogenide could be a good test material for investigating the relationship among molecules, crystals, and bulk glasses. How the glass transition and thermal crystallization behave in nanoscale chalcogenides is an intriguing problem. Third, the low-dimensional structure can have a few dangling bonds at the surface, which may be favorable for examining some inherent properties in nanostructures.

As a semiconductor having an energy gap of 1–3 eV, the chalcogenide glass may show notable electronic properties when nanostructured. One is the quantum effect, which is familiar in nanostructured crystalline semiconductors. Also, in a-Si:H (hydrogenated amorphous Si), some quantum effects have been reported, and, accordingly, comparative studies for chalcogenide glasses are important. The other is the photoinduced phenomenon. It is known that chalcogenide glasses exhibit a variety of photoinduced phenomena [3–5], and the behavior in nanostructured samples is interesting from fundamental and applied points of views.

This review is intended to be a summary of nanostructured chalcogenide glasses at the present stage and could also be an embryo for future studies. Section 2 focuses on nanoscopic inspections of chalcogenide glasses. Sections 3–5

Encyclopedia of Nanoscience and Nanotechnology
Edited by H. S. Nalwa
Volume 7: Pages (629–640)

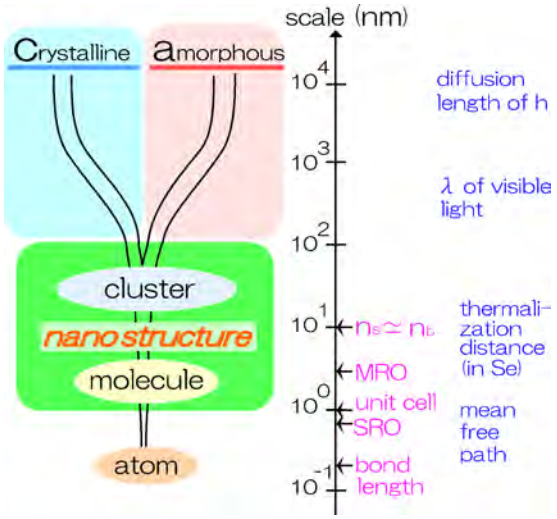

Figure 1. Schematic definition of a nanostructure. Related lengths are also shown. SRO, short-range order; MRO, medium-range order; n_s, number of atoms at the surface: n_b, number of atoms in the interior.

are organized according to the form of the nanostructures: Section 3, zero- and one-dimensional molecular structures; Section 4, two-dimensional nanostructures such as ultrathin films and multilayers; and Section 5, nanostructures produced by modification with radiation and by using scanning-probe microscopy. Since phase-change memories, the so-called Ovonic memories, are growing in use as DVDs (digital video/versatile discs) and the mark size is decreasing to the nanoscale, this topic is treated separately in Section 6. The last section gives a future perspective.

2. NANOSCOPIC INSPECTION

2.1. Transmission Electron Microscopy and Scanning Electron Microscopy

Direct inspections of nanometer-scale structures in chalcogenide films have been carried out using TEM (transmission electron microscopy) and SEM (scanning electron microscopy). Several studies have taken images of inhomogeneous structures greater than about 10 nm in evaporated As_2S_3 and $GeS(Se)_2$ films [6–10]. For instance, in obliquely deposited films, slanted columnar structures have been imaged [11–13], as shown in Figure 2 [10]. The slanted angle changes with the deposition angle, following the so-called tangent law, $\tan\alpha = 2\tan\beta$ [14], where α and β are the vapor incidence angle and the column inclination angle, both measured with respect to the substrate normal. The oblique deposited films may have anisotropic physical properties such as optical birefringence, which remain to be studied.

However, we should be careful of electron-beam effects in TEM and SEM observations. For instance, the small electrical conductivity of chalcogenide glasses may cause image distortions due to charge accumulation. In addition, the chalcogenide glass is liable to undergo structural changes upon irradiation of electron beams [15], and, accordingly, fresh images may not be obtained.

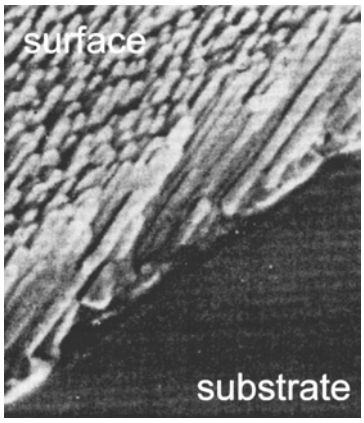

Figure 2. SEM image of an obliquely deposited 1-μm-thick As_2S_3 film [10], which is prepared with a vapor incidence angle of 80°. Note that the column tilt angle is about 45°. Adapted from [10], N. Starbov et at., *J. Non-Cryst. Solids* 139, 222 (1992).

2.2. Scanning Tunneling Microscopy and Atomic Force Microscopy

The surface structures of amorphous chalcogenides have been investigated using STM (scanning tunneling microscopy) and AFM (atomic force microscopy) with nanometer resolution. Note that, in contrast to oxide glasses, some chalcogenide glasses have finite electrical conductivity ($\geq 10^{-6}$ S/cm), which is needed for STM inspections. Ichikawa has examined $Ge_{20}Te_{80}$ bulk glass using STM [16] and AFM [17] at 1 atm. The glass surface is disordered, as expected, while an annealed sample at 100 °C (T_g = 160 °C) for 1–3 days shows atomically ordered regions and some structures that may correspond to a medium-range order. Peled et al. investigated a-Se and its crystallization behavior under laser heating using AFM at 1 atm [18]. They showed an image that may be identified with disordered chain molecules with a scale of 1 nm. Tanaka and co-workers studied the initial stages of photosurface deposition [4] in $Ag_{20}As_{32}Se_{48}$ films, which were exposed to 633 nm light, using STM [19]. Interestingly, in contrast to previous macroscopic observations [4], Ag nanocrystals grow upon illumination in such an Ag-deficient glass. Scanning tunneling spectroscopy with nanoscale spatial resolution has also demonstrated nanoscopic movements of Ag ions in Ag–As–Se glasses [20, 21].

In these studies, however, it may be fair to state that *atomic* images of glass surfaces have not been obtained. The reason is ascribed to the disordered structures. As illustrated in Figure 3, it is plausible that the surface of amorphous materials is irregular with a typical roughness of 1–5 nm, the scale of medium-range orders, and the apex of the STM tips has a curvature of about 5 nm. In such cases, atomic images cannot be obtained, since the tunneling current does not necessarily flow from an apex atom of the tip. Clustering of electron wave functions in disordered glass surfaces may also limit atomic resolution [22]. To obtain atomic images, we need atomically flat *facets*, the size being much greater than the dimension of the tip apex. However, the existence of such facets must be very exceptional in disordered structures [23]. In addition, it is difficult to distinguish real amorphous

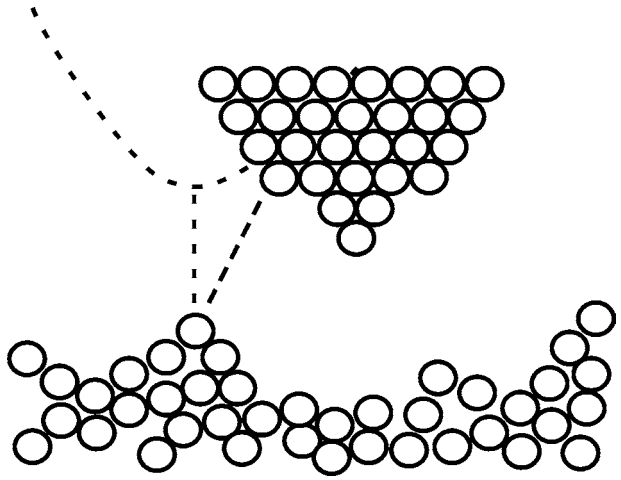

Figure 3. Schematic illustration of a crystalline STM tip and a clean surface of amorphous materials.

structures from contaminated structures, since we cannot identify atomic species using STM. Both real amorphous structures and contaminated surfaces may appear as irregular. Therefore, it will be difficult to get convincing insight into the atomic structure of chalcogenide glass surfaces.

However, it may be valuable to note that, in some molecular and crystalline chalcogenides, clear atomic images have been obtained at 1 atm. Peled et al. presented an AFM image of trigonal Se [18], and Ohto and Tanaka provided STM images of crystalline Ag_2Te surfaces in ordered (20 °C) and superionic (170 °C) phases [24]. Czajka et al. studied the structure of vacuum-evaporated Se molecules onto highly oriented pyrolytic graphite (HOPG) substrates (see the next section) [25].

3. ZERO- AND ONE-DIMENSIONAL MOLECULAR STRUCTURES

Dot structures embedded in wide-gap materials have been studied for chalcogenide materials. However, for amorphous chalcogenide dots, little work has been reported. For instance, Yumashev et al. studied induced optical absorption in a-Se particles (~20 nm) embedded in a polymer [26]. On the other hand, substantial studies have been reported for crystalline chalcogenide dots, for example, CdS(Se) particles in SiO_2 matrices (see, e.g., [27–30]). These studies concern mostly optical properties, which may be promising for filters and nonlinear devices. CdS(Se) crystals have direct bandgaps, in which the optical absorption edges are sharp and excitons can easily be excited. However, the atomic bonding structure is tetrahedral, and, accordingly, when the crystals are nanostructured, many dangling bonds are liable to exist at the surface. On the other hand, in materials such as Se and As_2S_3, in which chalcogen atoms are twofold coordinated, such surface defects can be fewer, so that the intrinsic dot properties can be investigated.

Chalcogen molecules incorporated into nanoscale channels and cavities (see Fig. 4) have attracted substantial scientific interest. Physical studies were pioneered by Bogomolov and co-workers at the Ioffe Institute around 1980 [31–35]. Incorporated molecules are Se [33–55], which has

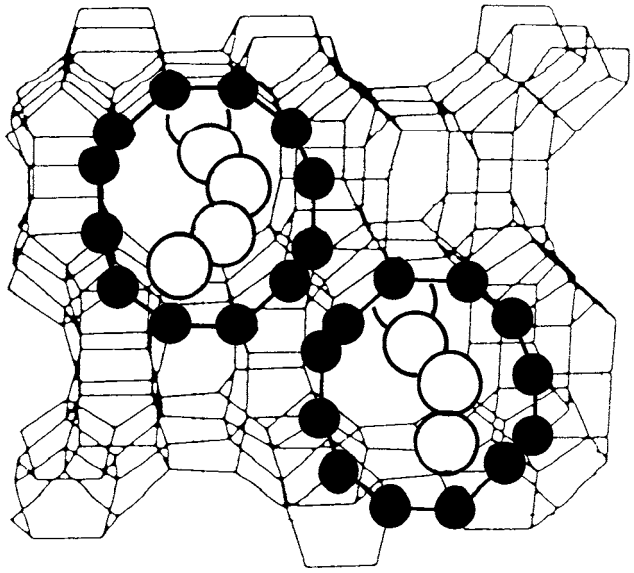

Figure 4. Illustration of Se molecules incorporated in zeolite channels.

been extensively studied, S [31, 50, 54], Te [32, 33, 50], and As–S [56]. On the other hand, porous matrices are mostly a variety of zeolites (crystalline $M_{2/n}O/Al_2O_3/xSiO_2/yH_2O$, where M is a cation such as Na^+, n is the valence number, $x \geq 2$, and $y \geq 0$) [57], and porous glasses [38]. These materials can be prepared in powder form with a size of 0.1–1 μm or as small crystals with a size of 5–50 μm, in which channels and/or cavities with diameters of approximately 1 nm are arranged periodically (zeolites) or nonperiodically (porous glasses). Incorporation of molecules has been done as follows: First, porous materials are dehydrated by heating. Then, the materials are sealed with chalcogenide pellets in an evacuated glass ampoule. Finally, the ampule is heated, which incorporates chalcogenide molecules into the porous structures through thermal diffusion.

Since a variety of zeolites are available (at least 135 kinds) [57], the molecular systems produced are also fond of variety. Structural studies have been done using TEM [37, 43], extended X-ray absorption fine structure (EXAFS) [36, 39, 51, 55], X-ray diffraction [45, 48], Raman scattering [34, 35, 43, 44, 47, 52, 54–56], and electron spin resonance (ESR) [39]. For instance, for Se, not only Se chain molecules, which form the trigonal crystal, but also Se_2 anions [45, 51] and rings such as Se_6, Se_8, and Se_{12} [50, 54] are identified as being incorporated. Photoinduced structural changes have been investigated [34, 39, 42], and some theoretical calculations have also been reported [58–60].

The thermal properties of these molecules are interesting. Matsuishi et al. investigated glass-transition and crystallization behaviors, the results being shown in Figure 5 [49], which will be discussed in Section 4.2.2. Poborocci et al. demonstrated that the molecular shape of Se in a zeolite undergoes a phase transition at certain temperatures [52].

Among many physical properties, optical absorption spectra are the ones most extensively studied [33, 34, 36, 39, 40, 44, 46]. It is amply demonstrated that the optical absorption edge of molecules blueshifts from that of the corresponding amorphous films (see Fig. 6b). This is reasonable since the intermolecular interaction, which governs the width of the

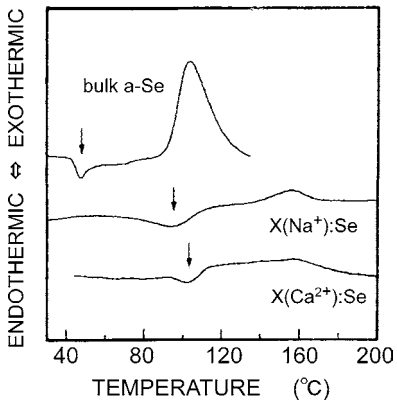

Figure 5. Thermograms obtained using differential scanning calorimetry for amorphous Se (upper) and Se in two kinds of zeolites (lower two) [49]. The arrows indicate the glass transition temperatures.

valence band in chalcogenide glasses [1, 2], is absent in the molecular structures consisting of single molecules. On the other hand, when incorporated into anisotropic matrices such as single crystals of natural mordenite, a kind of zeolite, the optical spectra appear to be highly anisotropic [33]. Studies on photoluminescence [53] and electrical conductivity are relatively limited [32].

The properties of single molecules may be investigated in this way, while the interpretation of experimental results should be done carefully for two reasons. One is a surface effect. That is, in the case of powdered zeolites, chalcogen atoms may be deposited as films also on the powder surface, which will be undesired components, giving rise to noisy properties. The other is a channel effect. For instance, there is direct evidence obtained through TEM images that single Se molecules are incorporated into the narrow channels in zeolite [37]. However, there is also substantial evidence that the molecules interact with the inner walls of the channels [48, 51]. As suggested by theoretical studies, the wall–molecule interaction has a crucial effect on the structural and physical properties [58–60]. Accordingly, if we really want to examine the properties of single molecules, the molecule should be laid on an inert surface or should be produced in free space.

Such studies have been carried out. Czajka et al. prepared, using vacuum evaporation, periodically located monolayers of Se_n rings (where n may be 5–8), the average diameter being approximately 0.5 nm, onto HOPG substrates [25]. STM inspection at 1 atm demonstrated that the ring plane is parallel to the HOPG substrates. The molecules were stable when imaged under tip voltages of −0.7–+0.3 V. However, application of +0.7 V to the STM tip collapsed the molecules, producing oval and round-shaped islands with a diameter of about 5 nm. They interpreted this phenomenon as electronically induced molecular breaking [61], while no explanations were given for, for example, the polarity dependence. On the other hand, Nagata et al. produced neutral clusters of Se_2, Se_5, and Se_6 in vacuum using a supersonic jet expansion method [62]. They found that Se_5 is unstable when ionized by electrons of 14 eV and irradiated by laser light with an intensity of 0.7 W and a wavelength of 488 nm. The instability of odd-membered rings seems to be consistent with theoretical calculations [61, 62]. It is mentioned

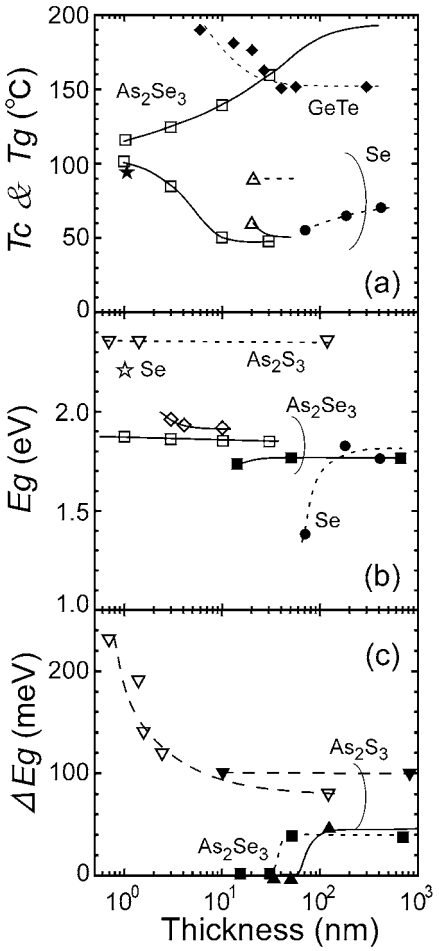

Figure 6. Dependence of thermal and optical properties on the sample dimension such as film thickness and multilayer period. (a) shows the crystallization temperature T_c (dashed lines) of Se and GeTe and the glass transition temperature T_g (solid lines) of Se and As_2S_3. (b) shows the optical gap E_g of Se, As_2Se_3, and As_2Se_3. (c) shows the reversible photodarkening ΔE_g in As_2S_3 at room temperature (solid line) and 80 K (dashed lines) and in As_2Se_3 at room temperature (dotted line). Solid symbols are obtained for films (● [64], ■ [72], ▲ [68], ▼ [71]), open symbols are for multilayers (▽ [75], □ [79], ◇ [80], Δ [115]), and stars (☆ [36], ★ [49]) are for Se in zeolites. Since the details of measurements are different among the results cited, absolute magnitudes are less valuable, and only the trends should be compared.

here that nanoscale powders of a- and c-Se have been prepared through evaporation of Se in Ar gas [63]. The work is intended to show the formation mechanism of amorphous interstellar grains.

4. TWO-DIMENSIONAL NANOSTRUCTURES

4.1. Ultrathin Films

Several kinds of ultrathin films have been prepared, and the thickness dependence of the physical properties has been investigated. These include crystallization kinetics [64, 65], electrical resistance [66], optical absorption [64, 67–72], and photodarkening [69–72]. For instance, Chaudhuri et al. [64]

showed for a-Se films with thickness of 70–180 nm that thermal crystallization occurs at lower temperatures in thinner films (see Fig. 6a). In addition, as shown in Figure 6b, the optical gap decreases from 1.8 to 1.4 eV with a decrease in the film thickness. They interpret these observations as resulting from higher defect densities in thinner films. On the other hand, Chopra and Bahl demonstrated that the crystallization temperature in GeTe films increases in thinner films [65]. These characteristics are discussed in comparison with those in multilayers in Section 4.2. For ultrathin films, however, we should be careful of surface effects, such as oxidation and moisture [73]. Also, it is plausible that the substrates have appreciable effects [10, 69, 74].

The dependence of the photodarkening on film thickness is intriguing, as summarized in Figure 6c. Tanaka and co-workers found that reversible photodarkening [3] disappears in As_2S_3 films thinner than approximately 50 nm when illuminated at room temperature by bandgap light [68]. At about 80 K, it appears as demonstrated in successive studies [70–72]. Nonstoichiometric films ($As_{43}S_{57}$ and $As_{20}S_{80}$) do not show such anomalous thickness dependence [68]. The room-temperature characteristic has been confirmed recently by Hayashi and Mitsuishi using As_2Se_3 films with a thickness of 15–700 nm [72]. They also found that the thickness dependence arises from the initial state, that is, the annealed state before illumination. That is, the optical absorption edge of annealed films redshifts in thinner films (see Fig. 6b), which may be consistent with the result reported by Chaudhuri et al. [64]. Hayashi and Mitsuishi proposed a model as follows [72]: Since the films are attached on oxide glass substrates and the film/substrate combination is annealed before illumination, thermal stresses, which can darken the film, arise. Such a mechanism is possibly more effective in thinner films, so that the photodarkening becomes smaller. On the contrary, Indutnyi et al. [75, 76] showed that much thinner As_2S_3 films (0.7–2.5 nm in thickness), which are embedded in transparent SiO layers, give greater (∼3 times) photodarkening at 80 K than that in thick films. In their result, the annealed state is not dependent on the film thickness (see Fig. 6b), and, instead, the illuminated state changes with the thickness. They interpret this result as arising from the higher density of self-trapped excitons in thinner films, which is assumed to enhance the photodarkening. It is also mentioned that Sainov et al. have reported that refractive-index changes can be photoinduced in thin (10–20 nm) As_2S_3 films [77]. Further studies remain.

4.2. Multilayers

4.2.1. Historical

After the pioneering work on semiconductor superlattices by Esaki and Tsu [78], similar structures have been explored for amorphous semiconductors. Since the constraint of unit-cell matching in crystalline superlattices does not exist in amorphous structures, preparations of amorphous multilayers by repeating depositions are straightforward. However, the boundary between two layers in amorphous multilayers cannot be atomically flat, due to disordered structures, which may cause some unique features. Fundamental problems concern the formation and stability of multilayer structures upon thermal treatment and light illumination. Quantum effects also become to be interesting topics.

As far as we know the first study on amorphous-semiconductor multilayers was reported in the beginning of the 1980s for chalcogenide glasses in Japan, independently from two groups at Hitachi [79] and NTT (Nippon Telephone and Telegram Corp.) [80]. The Hitachi group prepared Se/As_2Se_3 multilayers through vacuum evaporation in the development of highly sensitive vidicon targets. The NTT group tried to see, using sputtered $As_2Se_3/GeSe_3$ multilayers, what occurs when long-range multilayer periodicity is incorporated into amorphous semiconductors. They measured several physical properties such as optical absorption, electrical conductivity, glass-transition temperature, and infrared (IR) spectra.

Afterwards, the work by Abeles and Tiedje [81] triggered extensive studies on a-Si:H, which may stimulate further investigations of chalcogenide multilayers. Trodal and Wright prepared Ge/Se multilayers, and discovered photoinduced diffusion of Se atoms into Ge using Raman scattering spectroscopy [82, 83].

However, in these studies of chalcogenide multilayers, it was not explicitly demonstrated if long-range structural periodicity was really formed. Since the initial stage of evaporation starts with the formation of island structures due to the surface tension of the deposited clusters [74, 83], repeated deposition cannot necessarily produce multilayers. In addition, there is a possibility that interdiffusion occurs at multilayer interfaces, so that homogeneous structures may be produced [85]. Actually, Tanaka et al. tried to prepare multilayers of Se/As_2S_3, but they could not detect X-ray Bragg peaks originating from multilayer periodicity [86]. Proper selection of materials and deposition conditions is required.

The first structural evidence of chalcogenide multilayers was given by Shirai et al. for Se/Cd–Se multilayers with periodicities of 4–40 nm [87]. Later, a Bulgarian group obtained similar results for evaporated Se/CdSe multilayers [88], which are shown in Figure 7. In these studies, the researchers detected clear X-ray Bragg peaks originating from the long-range periodicity, when the layers are thicker than 2–3 nm. These results mean that the thickness of interfacial regions can be estimated at 1–2 nm. We note here that in ideal crystalline superlattices, the interfacial thickness is nominally equal to the atomic distance, approximately 0.2 nm. On the other hand, in amorphous multilayers, we can assume that, due to disordered structures, rough interfaces and interfacial strains necessarily produce the interfacial region of 1–2 nm thickness.

The Bulgarian group has continued the most active research on chalcogenide multilayers using Se(Te)/CdSe and SeTe/Se combinations [89–104]. In addition to thermal vacuum evaporation systems having rotating substrate holders, they have also employed laser ablation [100].

Others have studied some properties of several kinds of multilayers. For instance, Imamura et al. investigated carrier transport in SeTe/Se multilayers [105], and Hamanaka et al. measured photoluminescence in As_2Se_3/As_2S_8 [106]. For photoinduced interdiffusion, Se/As_2S_3 [107–111], $SeTe/As_2S_3$ [112], and Ag/AsS_2 [113] have been examined. Here, the last combination has shown a substantial increase in photodoping efficiency [4] by multilayering, which may

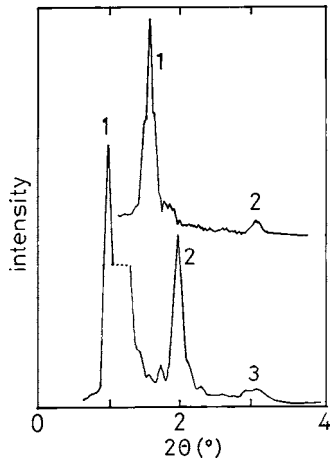

Figure 7. X-ray Bragg peaks obtained for Se/CdSe multilayers with periodicity of 5.7 nm (upper) and 9.2 nm (lower) [89]. The number indicates the diffraction index. In the lower trace, the fundamental peak is weakened.

be promising for some applications. Indutnyi et al. [75, 76] investigated the photodarkening in As_2S_3/SiO as already noted in Section 4.1, and Kim et al. measured thermal boundary resistance in $Ge_2Sb_2Te_5$/ZnS multilayers with an emphasis on to phase-change memories [114].

4.2.2. Thermal Stability

Studies on thermal stability are limited, probably because the sensitivity of thermal analyses is not sufficient for thin films. Actually, a few direct thermal analyses have been reported [49, 79], while indirect analyses using structural and optical measurements also provide additional insight [103, 115]. Vateva investigated thermal modifications of Se(Te)/CdSe multilayer structures using X-ray diffraction [100]. Thermal annealing can provide conventional intermixing (positive interdiffusion) as well as phase separation (negative interdiffusion) at multilayer interfaces, which occur depending on several conditions such as annealing temperatures and periods [100].

Results for the thermal crystallization are summarized in Figure 6a. We see that the observations appear to be controversial. Popescu et al. showed that, in the multilayered samples of Se/CdSe with a layer periodicity of about 20 nm, the crystallization temperature (90–100 °C) of Se is similar to that in bulk Se [115]. In contrast, it can be pointed out that no clear Se crystallization is detected in Se/As_2Se_3 multilayers with periodicities of 1–30 nm [79] and in Se/zeolite (see Fig. 5) [49]. For the crystallization to occur, the scale of the Se films (clusters) should be greater than the size of the crystallites or should be much greater than the crystalline unit-cell dimension, which is approximately 1 nm. These conditions may not be satisfied in these two kinds of nanostructured samples, and, accordingly, Se crystallization cannot occur. On the contrary, it has already been mentioned in Section 4.1 that, in Se films with a thickness of 70–180 nm, the crystallization occurs at lower temperatures [64]. Such thermal instability is commonly observed for the melting temperature T_m, which is understood theoretically using the Thomson–Frenkel relation given as $T_m - T_m(t) \propto 1/t$, where t is the thickness. The weaker bonding of atoms located at and near the free surface is assumed to govern these decreases in characteristic temperatures. How can we reconcile these contrasting behaviors? It is plausible that the difference between multilayers and films, that is, the existence of interfacial layers, has some effect on these characteristics [103].

For the glass transition, as shown in Figure 6a, the results also appear to be diverse. In the Se/As_2Se_3 multilayers [79] and Se/zeolite [49] samples, the glass-transition temperature of Se increases in more spatially restricted samples. On the other hand, the temperature of As_2Se_3 in the Se/As_2Se_3 decreases in samples with smaller periodicities. In addition, it is interesting to note that, in the multilayer samples, the temperature increase in Se and the decrease in As_2Se_3 occur at a thickness of approximately 50 nm [79].

The glass transition is still a matter of controversy in solid-state science, and this behavior remains to be studied. Recent studies on other materials in confined geometries show that T_g increases in more confined samples if there are no interfacial interactions for the confinement. This behavior is understood as a manifestation of collective molecular motions of the glass transition [116–118].

4.2.3. Electronic Quantum Effect

Although multilayer structures have been demonstrated in X-ray diffraction patterns [87, 88, 94], phonon spectra [92], and SEM images [106], electronic quantum-size effects still remain vague. It is well known that an electron confined in a one-dimensional square well with infinite potential walls has an energy of $E_n = (\hbar^2/2m)(n\pi/L)^2$, where m is the electron mass, n the positive integer, and L the well thickness. Accordingly, we may expect blueshifts ($\propto 1/L^2$) of the optical absorption edges and stepwise ($\propto n^2$) absorption spectra in thin films. Actually, as shown in Figure 6b, in some systems the blueshifts of the optical absorption edges are reported [80–82, 87]. In others, however, the edges do not shift [75, 79]. In addition, we have already seen in Section 3 that ultrathin Se and As_2Se_3 films even exhibit red shifts when the film thickness is decreased [64, 72]. For the stepwise optical spectra, the Bulgarian group reported some traces in SeTe/CdS and SeTe/Se systems having a periodicity of 4–7 nm [92, 94, 100].

However, when interpreting these optical results, we should be aware of several points. First, since we are dealing with thin films, optical interference fringes inevitably appear on optical transmission spectra. This optical effect should be clearly separated when evaluating absorption spectra. Second, for the blueshift, interfacial layers (~2 nm thick) can be responsible, which is also inferred from carrier-transport behavior [87, 105]. This structural effect becomes progressively greater in thinner films, and, accordingly, it is very difficult to separate the quantum effect from the interfacial effects. Third, we should note that, in formulations of the quantum effect, it is implicitly assumed that the mean free paths of electrons and/or holes are much longer than the well thickness. Taking the small mobility in amorphous semiconductors into account, we can assume that the mean free path is, at most, 2 nm [119], which is comparable to the interfacial layer thickness [88, 94]. Therefore, it seems difficult to obtain unambiguous signatures of the quantum effects. Fourth, for the case of SeTe/CdS multilayers [93],

it is a pnpn-type system. That is, electrons in the valence band in SeTe should be excited into the conduction band in CdS. The two states are spatially separated, and, accordingly, the transition probability must be very small. Such a situation probably makes the observation of quantum effects nearly impossible. As far as the author knows, among many studies of amorphous semiconductor multilayers, including chalcogenide and tetrahedral materials, the clearest quantized (stepwise) absorption spectrum is the one obtained by Hattori et al. [120] for a-Si:H/a-SiC:H with layer thicknesses of 2–5 nm at 100 K.

5. STRUCTURAL MODIFICATIONS

5.1. Radiation Effects

Chalcogenide nanostructures can be produced using a variety of radiation such as X-ray, electron beams, and ion beams. Soft X-ray exposures upon Ge–Se films have produced microscopic structures with scales down to 10 nm [121–123] through photodoping processes [4]. On the other hand, electron [124–127] and ion beams [127] can produce nanostructures in chalcogenide films such as Ag/As–S without using patterned masks. These studies aim at developing novel lithographic techniques having ultrahigh resolutions.

For visible light, nanostructures can be prepared using near-field optics. Such trials have been reported for photodarkening [3], photochemical modification [4], and phase-change phenomena, the last being treated separately in Section 6.1. For photodarkening, Isbi et al. demonstrated, using $As_{50}Se_{50}$ films and an SNOM (scanning near-field optical microscope), that dark lines of about 100 nm width can be recorded using green light [128]. They also mentioned that Al-coated fiber tips are liable to break upon light illumination of 10 nW, which corresponds to 1 W/mm^2, through thermal vaporization of the Al film. For photochemical modification, Gotoh and Tanaka showed, using Ag–As(Ge)–S and an SNOM providing 0.1–1 nW of blue-laser illumination, that convex deformations with a diameter of 100–300 nm can be produced [129, 130]. The deformation is assumed to be a manifestation of the accumulation of Ag^+ ions [4].

5.2. STM-Produced Structures

STM is capable of producing surface modifications with nanoscale resolution at *room temperature* [131]. The modification may be topological or compositional, in which case continuous compositional modifications can be induced, in principle, only in amorphous materials such as chalcogenide glasses, which are thermodynamically quasistable [1, 2]. Since some chalcogenide glasses containing Se and Te possess proper electronic conductivity, and Ag-chalcogenide glasses have finite ionic conduction, the nanoscale STM modification appears to be an interesting subject. (Note that these features are in contrast to atomic manipulation of crystalline surfaces, which can be performed in vacuum at low temperatures.) However, the application of STM modifications of chalcogenide glasses has been rather limited. Comparative studies using electrical AFM may also be valuable. The work on Se molecules [25] has already been described in Section 3.

The first demonstration of nanoscale modifications of chalcogenide films was reported by Utsugi [132]. He showed, using $GeSe_9$ films coated with Ag–Se, that STM is capable of producing grooves approximately 10 nm wide and 3 nm deep through an electrochemical reaction. That is, when the bilayer film consisting of Ag–Se/$GeSe_9$ is subjected to tip voltages of about +4 V, Ag^+ ions in Ag–Se layers migrate into $GeSe_9$, and, as a result, Se atoms remain at the surface. Then, if the sample is treated in H_2 gas ambient, the Se atoms react to form H_2Se, which evaporates, giving rise to the narrow grooves. Using this phenomenon, he could draw nanoscale patterns such as shown in Figure 8. Later, Ohto and Tanaka reported that, also in Ag–As–Se glass, Ag^+ ions migrate under STM electric fields [133], which is consistent with the observation by Utsugi.

Different processes of STM modifications appear in other materials. In Cu–As–Se glasses, as shown in Figure 9, sombrero-shaped modifications have been produced by applying negative tip voltages of about −5 V [133, 134]. In contrast, Cu_3AsSe_4 crystal does not show such deformations, the phenomenon being inherent to glasses. It seems that injected electrons from the tip to the glass induce appreciable fluidity, which may be similar to the fluidity induced by electron beams [15] and light [135]. In addition, Coulomb attractive forces between the tip and the glass possibly govern the shape, which resembles that of a Taylor cone. Curiously, in As_2Te_3, which has a similar electrical conductivity to that of Cu–As–Se, only conventional field evaporation was induced under tip voltages higher than ±6 V [134]. The reasons of these different features remain to be studied.

6. OVONIC MEMORIES

Optical phase-change memories were commercialized in the middle of the 1990s, which has accelerated intensive research and development. The memory utilizes reversible structural changes between amorphous and crystalline phases in telluride films such as Ge–Sb–Te, which are

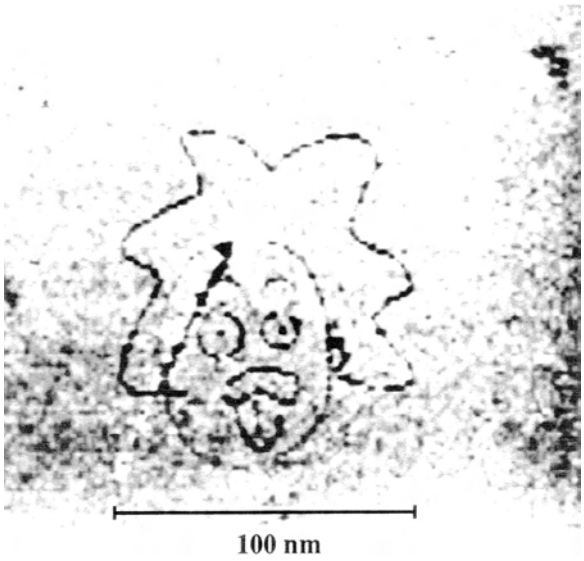

Figure 8. Smallest Einstein. Courtesy of Y. Utsugi.

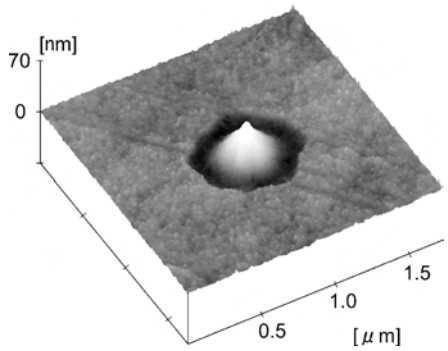

Figure 9. A sombrero structure in $Cu_{30}As_{28}Se_{42}$ glass after an application of −5 V for 1 s with an STM tip [134].

induced by temperature rises produced by light pulses. The bit size is now submicrometer, which is decreasing to the nanoscale [136]. Film structures were inspected using TEM with 1–10 nm resolution [137] and AFM [137, 138].

These studies shed light, not only on applications, but also on fundamental problems. For instance, what are the smallest amorphous or crystalline marks that can be written in phase-change films? We can assume that, if the dimensions are the same, crystalline spots in amorphous phases are more stable than amorphous spots in crystalline phases, since the crystal has a smaller free energy. Therefore, in a feature, alternatively to the present scheme, the crystalline mark may be written and erased in amorphous films.

6.1. Optical

At least two trials have been reported for nanoscale optical phase-change recordings. Hosaka et al. demonstrated the production of 60-nm marks in 30-nm-thick amorphous $Ge_2Sb_2Te_5$ films using an SNOM and 785-nm light pulses with widths of 0.5 and 5 ms [139]. Written marks are read as reflection SNOM images. They expect that a high-speed reading of 10–100 Mbit/s will be achieved. On the other hand, Tominaga and co-workers produced 90-nm marks in $Ge_2Sb_2Te_5$ films using 686-nm light in combination with a nonlinear transmission phenomenon in thin Sb films [140, 141]. Their sample consists of a triple-layer structure, Sb(15 nm)/SiN(20 nm)/$Ge_2Sb_2Te_5$(15 nm). Then, intense laser pulses produce optical pinholes in the Sb film with a diameter smaller than the light wavelength, and evanescent light from the film induces a phase change in the chalcogenide film. In this experiment, the Sb film works as a nonlinear optical switch, while its behavior has not been analyzed.

Here, we should make two points. One is that, in these studies, as-deposited amorphous films are employed for recording, and amorphous-to-crystalline phase changes are induced. The other is that mark erasing has not yet been demonstrated, which is probably more difficult, since we should manage more intense light pulses. However, intense light may destroy SNOM tips or produce larger optical pinholes. Therefore, much work will be needed for practical applications of these optical nanoscale memories.

6.2. Electrical

Electrical Ovonic devices of nonvolatile RAM (random access memory) type are currently being revived. The Ovshinsky group reported on a new memory utilizing Ge–Sb–Te films 50 nm thick, in which active bit sizes are as small as 200 nm [142, 143]. Nakayama et al. employed As–Sb–Te films 200 nm thick, in which the bit size is 300 nm [144]. These bit sizes are determined predominantly by bit-cell lithography techniques, and further reduction will be possible.

On the other hand, electrical Ovonic memories utilizing AFM have also been explored. Kado and Tohda tried to induce phase changes using an AFM having conducting cantilevers [145]. Their samples have a two-layer structure consisting of $GeSb_2Te_4$ (20 nm thick) and Pt films (200 nm thick), which are sputtered onto Si wafers. Mark writing can be made by applying positive pulses with widths of 10 μs–5 ms, voltages of 2–10 V, and currents of 10–20 nA to the $GeSb_2Te_4$ film through Au-coated Si_3N_4 cantilevers. Written data are read under a positive direct-current (dc) bias of 0.5–1 V. Drastic changes (∼100 times) in electrical conductivity of the film have been detected, which accompany no topological changes, within spots as small as 10 nm. This size corresponds to a data storage density of 1 Tbit/cm^2. In a more recent work [146], they succeeded in mark erasing by scanning the cantilever, which applies −1 V. However, this polarity dependence, that is, writing by positive voltages and erasing by negative voltages, strongly suggests that the change is electronic, not thermal, accompanying structural phase changes [146]. Actually, Gotoh et al. demonstrated recently that such marks are unstable, spontaneously disappearing within 1 day [147].

Gotoh et al. also demonstrated that erasable amorphous-to-crystalline phase changes are possible using similar samples to that of Kado and Tohda [147]. An important difference is that their cantilevers are made from PtIr wires, which permit high-current flows. Then, crystalline marks with a diameter of approximately 50 nm can be written by electrical pulses of 1.5 V (∼1 mA) and 2 μs and erased by 2 V and 20 ns (see Fig. 10). No polarity dependence has been observed for the writing and erasing. In addition,

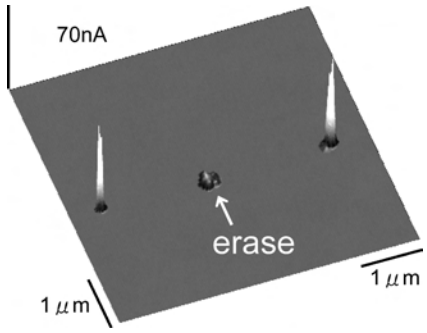

Figure 10. Erasable nanoscale phase changes produced by electrical AFM in a 50-nm-thick $GeSb_2Te_4$ film. In the three marks, the left hand and right hand are written by single pulses of 1.5 V and 2 μs, while the central mark is written by the pulse and then erased by a pulse of 2 V and 20 ns. This current image is obtained by luster scanning a conductive cantilever with 10 mV. Courtesy of T. Gotoh.

X-ray diffraction measurements detected crystalline peaks for written marks. These facts show that structural phase changes governed by Joule heats are electrically induced. This may be the first demonstration of *erasable nanoscale* Ovonic memories.

Similar trials have been done using STM, although the results are still preliminary. Saluel et al. demonstrated, using 30-nm-thick Ge–Sb–Te fillms, that voltage pulses greater than 3 V and 10 ns produce holes with a diameter of approximately 200 nm [148]. On the other hand, Sugawara et al. applied dc voltages to $GeSb_2Te_4$/Pt/Si samples [149]. Three kinds of deformations are produced. That is, the tip voltage of -10 V gives prominent expansions, $+2$ V gives depressions with peripheral mounds, and $+10$ V gives depressions with no peripheral deformations. The shape of depressions by $+2$ V suggests that these are produced by tip scratching. On the other hand, the ± 10-V deformations appear only when ambient humidity is higher than approximately 50%, which implies some roles of thin ($\sim$1 nm) water layers on the $GeSb_2Te_4$ films. Anodic oxidation and electrochemical decomposition seem to be responsible for the expansion and the depression.

7. CONCLUSIONS

Intensive motivation is needed for advancing nanostructural studies, since the experiments are more or less difficult due to limited sample sizes. Among such motivation,

PC, phase change; PL, photoluminescence; PI, photoinduced changes.

undoubtedly, nanoscale phase-change memories are the biggest at present. The study will produce terabyte memories and also provide fundamental insight into the nanoscale phase change and mark stability. On the other hand, chalcogenide photoresists have been demonstrated to possess 10-nm resolution, which will be competitive with that of conventional organic resists. Nanoscale dots and linear channels of chalcogenides appear to give interesting optical properties such as anisotropy and nonlinearity. The system can be regarded as a kind of artificially controlled nanocomposite, which is analogous to dye molecules in organic polymers.

As for fundamental problems, further studies are need for gaining deeper understanding of the scale dependence. Most observations reported so far are preliminary and, in some cases, controversial. For instance, behaviors of the glass transition remain to be studied in more detail. In addition, if electronic quantum effects really exist in chalcogenide nanostructures is ambiguous. Optical absorption and Raman scattering spectra have been investigated, while few studies have been reported for photoluminescence. As for materials, further studies on Se, which is the simplest chalcogenide system, may be valuable.

Table 1 summarizes the current state of the art of a variety of chalcogenide glass nanostructures.

GLOSSARY

a- Abbreviation for amorphous. The amorphous material is defined as a noncrystalline solid. The glass is a kind of amorphous material, which is produced through quenching of the corresponding liquid. Accordingly, the glass exhibits the glass transition.

c- Abbreviation for crystalline.

T_g The glass transition temperature. The temperature that separates a glass from the corresponding supercooled liquid state. This is not a temperature indicating a phase transition, since the glass is not a thermally equilibrium phase.

ACKNOWLEDGMENT

The author thanks K. Sugawara for preparing the illustrations.

Nanostructured Extracellular Matrix

Zuwei Ma, S. Ramakrishna

National University of Singapore, Singapore

CONTENTS

1. INTRODUCTION

In tissue engineering, cells are seeded into a biodegradable scaffold to obtain a cell-scaffold complex, which then will be implanted into patients to replace diseased or damaged tissue. In this process, the cells in the scaffold should be induced to proliferate and differentiate in a manner that mimics the natural process of tissue regeneration in the human body. To do so, the scaffold should be made an analog of the natural environment of the cells *in vivo*.

In human and animal bodies, tissues are not solely made up of cells. The insoluble noncellular material present between the cells throughout the tissue is known as the extracellular matrix (ECM), which is composed of various biomacromolecules secreted by the cells themselves. There are three major functions of the ECM. First of all, they provide structural support and tensile strength. Second, they provide substrates for cell adhesion and a highway for cell migration. Third, the ECM regulates cellular differentiation and metabolic functions, for example, by modulation of cell growth by the binding of growth factors. Not only the ECM composition, but also the three-dimensional organization of the biomacromolecules in ECM, of which the dimension is typically in the nanoscale, influence cellular behavior significantly. So, the mimic of the tissue-engineering scaffold to the natural ECM should be made not only in terms of the chemical composition, but also in terms of the 3D nano/microphysical structures. Here, the ECM analogs (scaffolds) are called synthetic ECM, to be distinguished from the natural ECM.

It is not difficult to prepare synthetic ECM with similar chemical compositions as natural ECM. For many years, biomacromolecules derived from ECM such as collagen [2], chitosan [3], hyaluronan [4], alginate [5], and so on, have been extracted, modified, and processed to prepare tissue-engineering scaffolds for the regeneration of skin, cartilage, liver, and many other human tissues. ECM-derived biomacromolecules or specific polypeptides have also been used to modify the surface of the synthetic biodegradable polymers such as PLLA, to obtain an ECM-mimic surface, while remaining the good mechanical properties of the bulk materials. For example, tripeptide RGDs, which can combine specifically with integrins on a cell membrane, have been introduced on the surface of many polymeric biomaterials to enhance cell adhesion [6].

Compared to the chemical modification of the synthetic ECM, fewer works have been done to prepare scaffolds with similar morphological characters with natural ECM. In addition, more attention has been paid to the influences of material chemical compositions on cell behavior than to the influences of material physical morphologies. The reason may be that there are many more difficulties in controlling material morphologies than in controlling chemical compositions. Scaffolds with precise micro- or nanostructures cannot be easily produced by some traditional technologies such as particulate leaching and the foaming method.

In this chapter, the relationships between the material morphologies and the cell behaviors in ECM and synthetic ECM will be reviewed. First, the chemical composition and the 3D morphology of ECM and the interactions between cells and ECM will be discussed to explain why nanoscale structures are so important to cell behavior. Then, nano- or microsurface patterns, which have been developed in recent years as a powerful tool for the fundamental research of interactions between surface morphologies and cells, will be discussed. Finally, nano- or microscale polymer fibers and nonwoven polymer meshworks used as tissue-engineering scaffolds will be introduced.

It should be noted here that many previous works have demonstrated that the dimensions of the physical structures

Edited by H. S. Nalwa
Volume 7: Pages (641–655)

that cells react to is about from 30 nm to 20 μm. Due to this reason, literature involving the structures with dimensions in this range will all be discussed in this review to provide a complete and comprehensive understanding, although the structures in natural ECM are mainly in the nanoscale.

2. COMPONENTS AND STRUCTURE OF EXTRACELLULAR MATRIX: NANOSCALE STRUCTURES

An extracellular matrix is composed of versatile biomacromolecules, of which there are three important classes. The first class is called glycosaminoglycans (GAGs), which belong to polysaccharide chains. The second class is fibrous proteins, such as collagen, elastin, and fibronectin. The third class is nonfibrous proteins, such as growth factors and cytokines.

Most of these biomacromolecules are secreted locally by the cells. Here, the synthesis and secretion of the collagen will be described briefly as an example. Genes encoding for the α chains of precollagen in DNA are transcripted to mRNA in the cell nucleus. The mRNA is translated by ribosomes on endoplasmic reticulum to synthesize the α chains. Modifications of the α chains such as hydroxylation of proline, hydroxylation of lysine, and glycosylation of some hydroxlysine are made, and the α chains assemble into triple helix precollagen molecules in golgis. Finally, the procollagen molecules are secreted by exocytosis into the ECM space. In ECM, "registration peptides" in precollagen molecules are cut down by precollagen peptidases, resulting in collagen molecules, which are one of the most important proteins in ECM.

2.1. GAGs

GAGs are unbranched polysaccharide chains composed of repeating disaccharide units. One of the two sugar residues in the repeating disaccharide is always an amino sugar (*N*–acetylglucosamine or *N*–acetylgalactosamine), which in most cases is sulfated. The second sugar is usually an uronic acid (glucuronic or iduronic). Four main groups of GAGs most frequently found in an ECM are: (1) *hyaluronan*, (2) *chondroitin sulfate* and *dermatan sulfate*, (3) *heparan sulfate* and *heparin*, and (4) *keratan sulfate*. In most cases in an ECM, large numbers of GAG chains are covalently bonded with a protein core to form proteoglycan, called aggrecan (Fig. 1 [7]). The molecular weight of the protein core is only a very small fraction of the total molecular weight of the proteoglycan. It should be noted that hyaluronan does not bind with proteins to form proteoglycans.

Due to the plentiful sulfate or carboxyl groups in GAG chains, the proteoglycan molecules are highly negatively charged, and combine large amounts of water to form gel-like hydrogels. In the ECM of articulate cartilage, proteoglycan molecules are noncovalently connected with hyaluronan to form huge polysaccharide aggregates (Fig. 1 [7]). The strongly hydrophilic aggregates combine huge amounts of water to form hydrogels, in which the GAG chains adopt highly extended conformations that occupy a huge volume relative to their mass. Moreover, the high density of negative charges in GAG chains attract a cloud of cationic ions, such as Na^+, that are osmotically active, causing large amounts of water to be sucked into the matrix. This creates a swelling pressure that enables the matrix to withstand very strong compressive forces, which is one of the most important functions of the articulate cartilage.

2.2. Fibrous and Nonfibrous Proteins

The proteins in an ECM come in a great variety of shapes and sizes. Most of these proteins are in fibrous forms, while a small part are in nonfibrous forms. There are two functional types of fibrous proteins: the ones that are mainly structural, like collagen and elastin, and the ones that are mainly adhesive, like fibronectin and laminin. Growth factors in an ECM, which have a crucial effect on the cell growth and differentiation, belong to nonfibrous proteins.

The most important fibrous protein in human and animal ECM is collagen. About 15 types of collagen molecules have been found. The main types of collagen are type I, II, III, V, and XI. Type II collagen is the principal collagen in cartilage tissue, while type I collagen is by far the most common, and is the principal collagen of skin and bone. The collagen fiber network in an ECM provides the tensile strength for the tissue. Another important structural protein is elastin fibers, which provide the elasticity for the tissue. Fibronectin and laminin belong to the adhesion proteins, and are also in a fibrous form. The fibronectin or laminin fibers have specific biding sites, either for other matrix biomacromolecules or for receptors on the cell surface. These protein fibers thus contribute to both organizing the biomacromolecules in an ECM and helping attach the cells to the ECM. Recent research has demonstrated that collagen also has cell-binding sites in their molecules [8]. So collagen belongs to both structural and adhesion proteins. Table 1 summarizes some main components of the extracellular matrix and their function.

2.3. 3D Organization of Biomacromolecules in ECM

Once secreted into the ECM, the biomacromolecules will be orientated and assembled into an organized 3D meshwork, either by cell orientations or by self-assembly. In different

Table 1. Main components of the extracellular matrix and their function.

Components	Structure	Function
Collagen	Triple helical glycoprotein. Molecules are mainly composed of proline, hydroxyproline, and glycine.	Provides tensile strength to tissues; support and structure for tissues and organs; mediates cell adhesion to ECM.
Elastin	Stretchable hydrophobic protein interacting with glycosylated microfibrils.	Provides tissue with elasticity; allows for expansion and contraction of the tissue.
Fibronectin	Specialized adhesive glycoprotein.	Mediates cell–ECM adhesion by binding with cells and other biomacromolecules in ECM.
Laminin	Large, complex adhesive glycoprotein.	Mediates cell–ECM adhesion in connective tissue; binds cells to type IV collagen and heparin sulfate in basal laminae.
Proteoglycans	Heterogeneous, long glycosaminoglycans (GAG) chains covalently linked to a core protein.	Combines with large amounts of water to form hydrogels, shock absorption, sequestration of growth factors, and cytokines.
Hyaluronic acid	A very large, specialized, nonsulfated GAG. Does not form proteoglycan.	Provides a fluid environment for cell movement and differentiation; binds the growth factors and cytokines.
Growth factors and cytokines	Protein molecules, embedded in ECM. Combined with protein fibers or proteoglycan hydrogels by noncovalent interactions.	Regulation of cell functions and gene expressions.

tissues, variations in the relative amounts of the different types of biomacromolecules and the way they are organized give rise to an amazing diversity of ECM morphologies, each adapted to different particular functional requirements.

However, there are some common characteristics in the structure of various ECMs. Here, connective tissue can be used to describe the 3D structure of an ECM. In connective tissue, such as skin, cartilage, liver, tendons, and corneas, there is many more plentiful ECMs than cells. In an ECM of connective tissues, both the fibrous and nonfibrous proteins are embedded in the large volume of hydrogels composed of proteoglycan and waters. The fibrous proteins, such as collagen, elastin, fibronectin, and laminin fibers, penetrate through the hydrogels to form a 3D network (Fig. 2 [9]). The growth factors, cytokines, and other nonfibrous proteins are dispersed in the hydrogel or combined with the fibrous proteins.

The discussion of the ECM structure above has focused on the volume-filling ECM between cells. But in certain places, especially beneath epithelia, the ECM can also be organized as a thin tough sheet–basal lamina, or basement membrane. Basal laminae are flexible, thin (40–120 nm thick) mats of specialized ECM that underlie all epithelial cell sheets to separate them from the underlying connective tissues. Most mature basal laminae contain mainly type IV collagen, laminin, and the large heparan sulfate proteoglycan, perlecan. The type IV collagen and laminin form a dense mesh, which is embedded in the perlecan hydrogel. In some cases, such as in kidney glomerulus, the basal lamina lies between two epithelial cell sheets, and functions as a highly selective filter [10]. Basal laminae serve in more than simple supporting and filtering roles. They influence cell metabolism, organize the proteins in adjacent cell membranes, induce cell differentiation, and serve as specific highways for cell migration. Figures 3 [11], 4 [12], and 5 are schematic diagrams of the structures and locations of basal laminae.

2.4. Nanoscale Structure of ECM

Until now, the diameter of the fibers embedded in the proteoglycan hydrogel in an ECM have not been mentioned. It has been pointed out that the most common protein fiber in an ECM is collagen fiber. The characteristic feature of a typical collagen molecule is its long, stiff, triple-stranded helical structure, in which three collagen polypeptide chains, called α chains, are wound together to form a rope-like superhelix, the collagen molecule. After being secreted into the extracellular space, the collagen molecules assemble into ordered polymers called collagen fibrils (10–300 nm in diameter, Fig. 6), which can aggregate further into larger, cable-like collagen fibers with diameters of several hundred nanometers or several microns (Fig. 7 [13, 14]). Nishida et al. [15] observed the protein matrix composed largely of collagen fibers in the cornea of a rat after the hydrogel in the rat cornea was removed by enzyme and acid treatment.

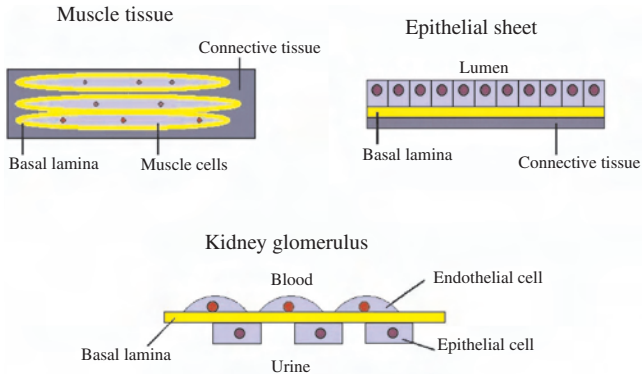

Figure 5. Locations of basal lamina.

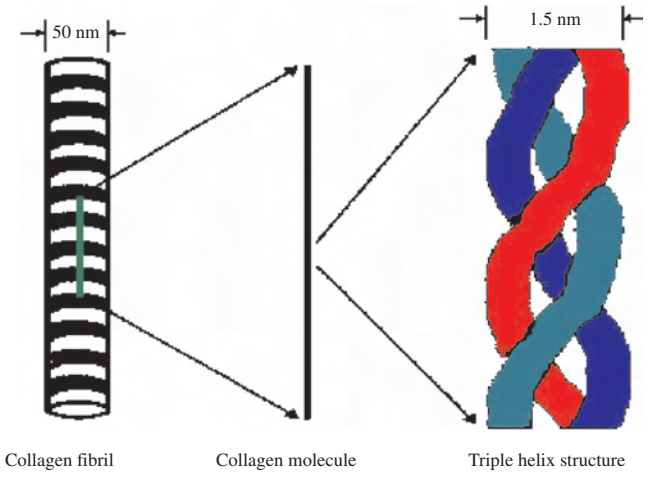

Figure 6. Schematic representations of a collagen molecule and a collagen fibril.

The diameter of collagen fibers in a rat cornea was about 100–400 nm.

The fiber diameters in the basal laminae are also in the nanometric range. Research has shown that basal laminae are comprised of a complex mixture of pores, ridges, and fibers [16]. Shirato et al. [17] studied the glomerular basement membrane of the rat kidney, in which the fibrils are 5–11 nm thick and the pores are 10–30 nm wide. Yamasaki and co-workers examined the pores and fibers in bovine glomerular and tubular basement membranes [18]. The pore diameter is about 10–12 nm, and the fiber diameter is 3–15 nm. Another study by Hironaka et al. found that the glomerular, tubular, and Bowman's capsule basement membranes of the rat kidney all had mean fiber diameters of 6–7 nm and mean pore diameters of 10–13 nm [19]. Using SEM, TEM, and AFM, Abrams et al. [20] measured the feature sizes on the surface of corneal epithelial basal laminae of the Macaque monkey. The average feature heights were from 147 to 191 nm, and the average fiber width was 77 nm. They found that pores made up 15% of the total surface area of the membrane, and had an average diameter of 72 nm. Similar features were observed on the human corneal epithelial basement membrane and on Matrigel™, a commercially available basement membrane matrix [21].

Mosler and N. B. Larsen.

A scanning electron micrograph of a corneal epithelial basement membrane is shown in Figure 8 [16].

Now, it can be concluded that, in a natural ECM, protein fibrils and fibers with mainly nanometric-scale diameters entangle with each other to form a nonwoven meshwork, which is embedded in proteoglycan hydrogel. In basal laminae, the meshwork is much denser and the fibers much thinner than in other ECMs in common connective tissue. Due to this characteristic of the ECM, in recent years, much interest has been focused on the fabrication of biodegradable polymeric nanofibers and nonwoven meshworks to be used in the field of tissue engineering and artificial organs [22].

3. CELL INTERACTIONS WITH EXTRACELLULAR MATRIX AND BIOMATERIALS

The interactions between cells and their ECMs are mediated by a process called biorecognition. In this process, the transmembrane proteins called receptors on the cell membrane combine specifically with the corresponding ligands in the ECM, causing a series of events in the signal transduction cascade within the cells, and eventually influencing their gene expression. For example, growth factors such as FGF combine with their receptors on the cell surfaces, and stimulate their proliferation and differentiation.

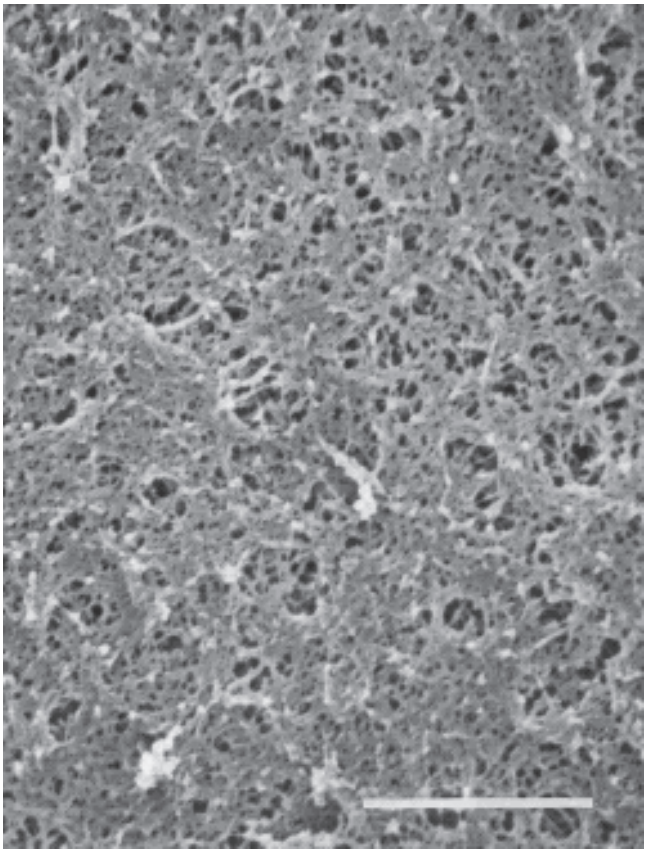

Figure 8. Scanning electron micrograph of a corneal epithelial basement membrane of Macaque monkey. After the corneal epithelium was stripped, the cornea was fixed in 2% glutaraldehyde, dried by the critical point method, and imaged on a Hitachi S-900 scanning electron microscope (bar=1 m). 3.1. Integrins

Many kinds of receptors exist on a cell membrane, among which the integrins are the most important. The interactions between the integrins and their ligands in an ECM are the main ways that cells bind to and respond to the ECM. This process is involved in a variety of cellular functions such as wound healing, cell differentiation, and apoptosis.

Integrins belong to a large family of cell adhesion receptors involved in cell–ECM and cell–cell interactions. Functional integrins consist of two transmembrane glycoprotein subunits, called α and β, which are noncovalently bound (Fig. 9 [23]). Both of the subunits contribute to the binding of the ligands. Until now, 16 alpha and 8 beta subunits have been identified. From these subunits, only 22 integrins are formed in nature, which implies that not all possible combinations exist. The ligands of integrin are mainly adhesion proteins, including fibronectin, laminin, vitronectin, and collagens. The biding sites for integrins in adhesion proteins are relatively small, typically five amino acid residues in length or less. The first integrin-binding site to be identified was the tripeptide RGD (arginine–glycine–aspartic acid). Figure 10 [24] is a schematic diagram illustrating the interactions between integrins and fibronectin fibers in an ECM.

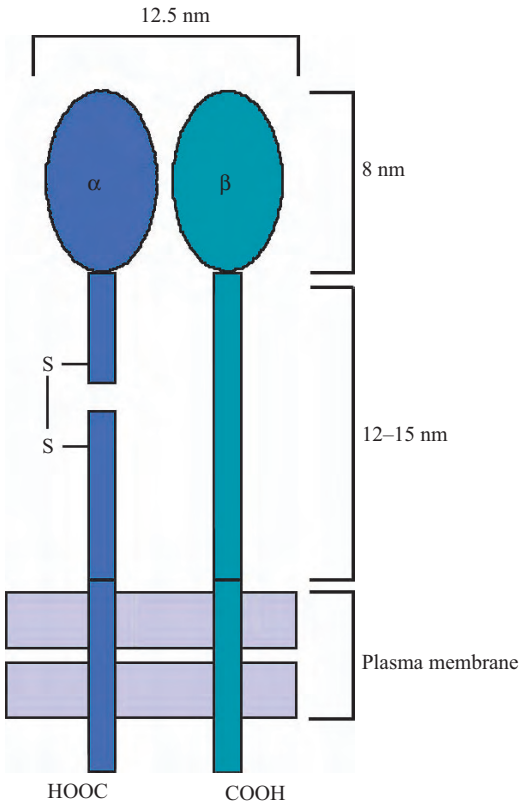

Figure 9. Integrin structures.

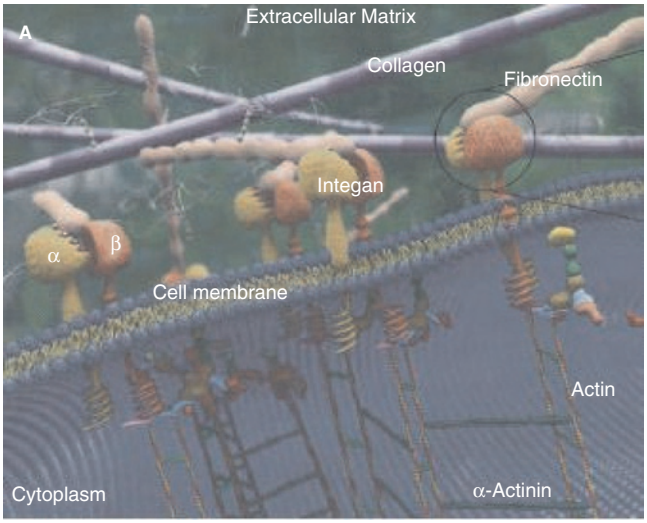

Figure 10. Interactions of integrins and their ligand, adhesion proteins in ECM. Reprinted with permission from [24], M. Tirrell et al., *Surf. Sci.* 500, 61 (2002), © 2002, Elsevier Science.

Another adhesion receptor important for cell–ECM adhesion is cell surface proteoglycans, which are present on cell surface and serve as adhesion receptors with a lower specificity than integrins. The negative charges of GAG chains in the cell surface proteoglycan can interact with regions of clustered positive charges on adhesion proteins such as fibronectin. Other key adhesion receptors on cell surfaces include cadherins, selectins, and Ig superfamilies like NCAMs (neural cell adhesion molecules) and ICAMs (intercellular adhesion molecules). They are all transmembrane proteins, and are important to cell–cell junctions. Cadherin on a cell surface can bind another cadherin on another cell. Selectin on a cell surface can bind some specific oligosaccharides on another cell surface. NCAM can bind two nerve cells through interactions between two NCAMs. Integrins are also involved in cell–cell interactions through the binding of an integrin on a cell surface to its ligand on another cell surface.

3.2. Focal Contact

Focal contact, also called focal adhesion, is formed when a cluster of integrins accumulate in a relatively small spot on the cell membrane and interact with adhesion proteins in an ECM. Focal contact is the main way in which cells attach onto the ECM. The extracellular part of the integrin combines with the adhesion proteins in ECM, while the intracellular part of the integrin combines with the cytoskeleton (actin filament) through other cytoskeletal proteins such as α-actin, vinculin, and talin. By doing so, the cytoskeleton of a cell is attached physically to the ECM. However, one integrin cannot bind its ligand strongly. This is because the affinity between the integrin and its ligand is much lower than that of other cell-surface receptors. When the integrins are evenly distributed over the cell surface, no adhesion will occur. But the integrins are usually present at 10–100-fold higher concentration on the cell surface than other receptors. In an integrins-clustering focal contact, the combined weak affinities can give rise to a spot on the cell surface that has enough adhesive (sticking) capacity to adhere to the extracellular matrix (Fig. 11 [25]). In this way, cells can bind simultaneously, but weakly to large numbers of matrix molecules, and still have the opportunity to explore their environment without losing all attachment to it. If the receptors were to bind too strongly to their ligands, cells would probably be irreversibly bound to the matrix, depriving it of motility.

Through the formation of focal contacts, dynamic sites are built to mechanically bind the cytoskeleton to the ECM. The mechanical signal can be transferred into the cytoskeleton, and sensed by some stretch receptors that can help to reorganize the cytoskeleton structure, and eventually regulate the shape and migration of the cell. Produced by the clustering and activation of the integrins on the cell surface, focal contact also mediates the transduction of other extracellular signals into the intracellular signal transduction pathways. Focal adhesion kinase (FAK), mitogen-activated protein kinase (MAPK), and integrin-linked kinase (ILK) are often involved in the signal transduction mediated by the focal contact (Fig. 12).

FAK is a tyrosine kinase commonly found in integrin-mediated focal adhesions. Upon activation and phosphorylation of FAK, this kinase may phosphorylate other signaling proteins in a signal transduction cascade. Paxillin, for example, a protein involved in cytoskeletal reorganization, is a target of FAK. The activation of MAPK occurs after integrin binding RGD peptides in fibronectin or laminin, resulting in the translocation of MAPK from the cytoplasm to the nucleus. MAPK can also be activated by integrin-linked kinase (ILK) in a FAK-independent pathway.

3.3. Why Nanometric Scale Structure?

From Figure 9, it can be seen that the diameter of one integrin is about 10–15 nm, while the focal contact will be much larger. No works have been done to study how many integrins there are in a focal contact, probably because that interactions between integrins and their ligands is in a dynamic equilibrium. However, some works mentioned that the diameter of a focal contact is about 0.5–2 μm in width and 5–10 μm in length [26, 27]. Another work pointed that the dimension of an individual focal adhesion is about 3–5 μm [28]. It can be hypothesized that the dimension of the protein fibers in the ECM, which is typically from several

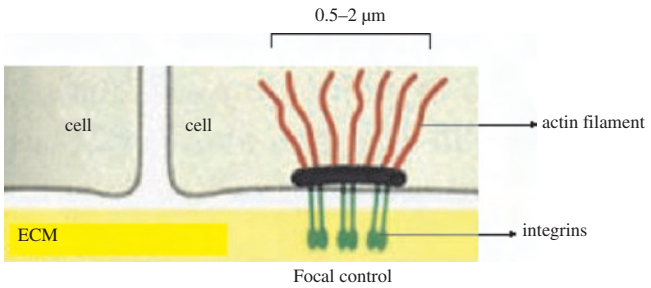

Figure 11. Focal contact formation. Reprinted with permission from [25], http://www.virtuallaboratory.net/BioFun-KFI/lectureNotes/Topic6-3_Adhesion.htm. © M. W. Klymkowsky.

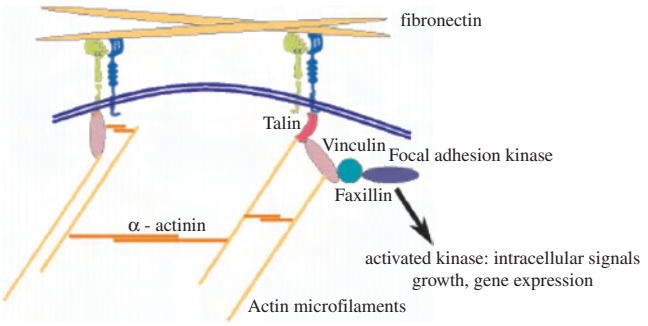

Figure 12. Integrin-mediated cell adhesion and signal transduction.

ten to several hundred nanometers, is the minimum for the formation of a focal contact. The focal contact formed on a protein fiber can extend along the fiber, and can be several micrometers in length. This feature may be very important and useful. The cells may be very easily induced to adhere, spread, and orient along the nanoscale fibers. Due to this kind of induction, protein fiber networks in an ECM can act as highways for the migration of the cells.

3.4. Cell Interactions with Biomaterial Surface

Cells interact with biomaterials in the same way as they interact with the ECM *in vivo*. Some adhesion proteins such as fibronectin, laminin, and vitronectin are soluble in blood plasma and other body fluids. The adhesion proteins also can be found in the cell culture media in which fetal bovine serum is frequently added. Upon contacting the biomaterials, the adhesion proteins are spontaneously adsorbed on the biomaterial surface, and act as ligands for cell integrins. As in an ECM, the cells also adhere on the biomaterial surface through the formation of focal contacts.

4. NANO- AND MICROSURFACE PATTERNS

Both the chemical compositions and physical structures in the ECM have great influences on the cell behavior, the mechanism of which is far from being well understood. Except for the adhesion proteins, many other ligands, such as hyaluronan and growth factors, exist in an ECM. They can also bind the receptors on the cell surface to adjust cell functions. Moreover, the physical morphologies of an ECM have great variety. Protein fiber meshworks with different nano- or microtextures in the ECM have different effects on cell adhesion, orientation, and migration. All of these chemical and physical factors entangle together, often synergistically, to affect cell behavior. In this process, so many factors are involved that it is impossible to study the effect of a single factor *in-situ* in an ECM because one cannot change one factor without altering the others.

However, using plane surfaces with specific chemical or physical properties, the research work can be greatly simplified. The cells can be cultured on the surfaces *in vitro*, and the adhesion, proliferation, migration, and differentiation can be observed. Thousands of experiments have been done using the plane surface as a research model in the last 20 years. The results showed that surface energy [29, 30], hydrophilicity [31, 32], surface charge [33–35], functional groups [36, 37], surface roughness [30, 38, 39], and surface topographical properties [40] affect the cell behavior significantly, and can be used to control the bioreactions on biomaterial surfaces. For example, immobilizing the adhesive proteins or peptides on a biomaterial surface has already been a traditional method to enhance cell adhesion on biomaterial surfaces [6].

In recent years, surfaces with defined chemical or physical patterns have been used as a much more powerful tool than homogeneous surfaces to study the relationships between the chemical or physical properties and the cell behavior. Much more information can be obtained using patterned surfaces compared to using homogeneous surfaces. The techniques for producing surface patterns are not new, however. Microfabrication technologies, which have been widely used in the microelectronics industry, are now gaining more and more attention in biomedical studies. These technologies allow the production of defined physical and chemical features on different substrates. The feature size, shape, and distribution on the surfaces can be precisely controlled and systematically changed. Photolithography and microcontact printing methods are the two most frequently used technologies to prepare surface patterns on biomaterial surfaces.

In this part, the preparation of the micro- or nanoscale surface patterns and their effect on cell functions will be introduced. Here, all kinds of surface patterns, no matter whether they are topographical or chemical, and no matter whether they are in the nanoscale or microscale, will be discussed.

4.1. Random Roughness

Almost any material has a surface with random roughness. For fundamental research, materials with different degrees of roughness can be made by sandblasting or a chemical/physical etching treatment. Lampin et al. [38] prepared a PMAA surface with different degrees of roughness (average roughness, $Ra = 0.07$–$3.3\ \mu$m) by a sandblasting treatment with alumina grains. Cell culture experiments showed that the adhesion and migration of cells on the PMMA surface increased with the degree of roughness. Similar results were also reported by Hallab [30] and Deligianni [39]. Fan et al. [41] prepared an Si wafer with different degrees of nanoscale roughness ($Ra = 2$–100 nm) using an HF or HF/HNO_3 etching treatment. More neural cells adhered on the surfaces with Ra ranging from 20 to 50 nm than on the surfaces with Ra less than 10 nm or higher than 70 nm. The viability of the cells was affected in a similar manner. The neural cells have higher tyrosine hydroxylase activity on the surfaces with Ra ranging from 20 to 50 nm than on other surfaces.

4.2. Regular Patterns

UV photolithography, which is widely used in the microelectronics industry to produce micropatterns on silicon wafer, is now being used to prepare morphological patterns on different material surfaces. The process of photolithography is schematically diagrammed in Figure 13. Surface-patterned

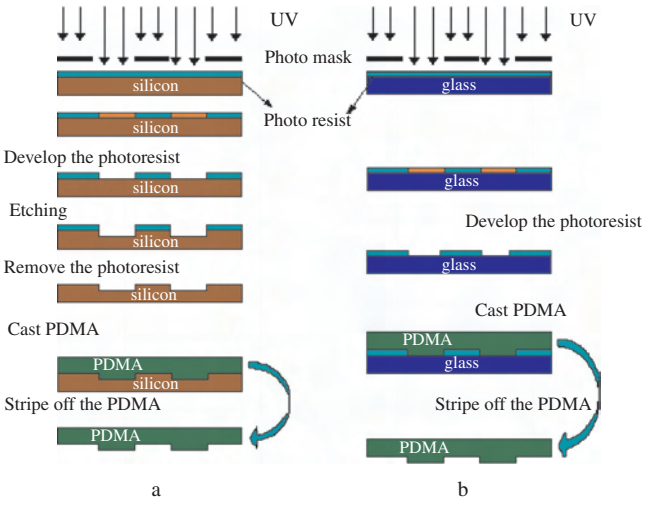

Figure 13. Photolithography technology to prepare surface-patterned PDMA. The PDMA stamp can be used as a master to prepare other surface-patterned materials.

silicon wafers are often produced first to be used as masters to replicate the surface pattern on other materials. In Figure 13(a), a photoresist-coated silicon wafer is exposed to UV light through a photomask. Then the photoresist is developed and the wafer is subjected to the etching, either by chemical erosion or by ion or electron-beam treatment. The depth of the pattern can be controlled by changing the etching time. Upon removing the remaining photoresist, topographical patterns can be produced on the silicon wafer. The surface-patterned silicon wafer can be used as a master to make polydimethylsiloxane elastomer (PDMS) duplicates. The surface-patterned PDMS has excellent thermal and chemical stability, and can be subsequently used as a master to produce topographical or chemical patterns on other material surfaces [42]. To cast a replica, the desired polymer solution is allowed to dry on the top of the PDMS master, and then the polymer film is stripped off and used. The PDMS can also be pressed into the polymeric material which has been heated to soften it. In Figure 13(b), no silicon wafer is used; the photoresist is directly coated on a glass substrate, irradiated by UV light, and developed. The macromonomer of PDMS is then cast on it and cured to obtain PDMS masters. Although many kinds of surface-patterned polymers can be made by photolithography, the most commonly used materials in research work are silicon, PDMS, or photoresist material.

Grooves and ridges (Fig. 14) are among the most studied topographical patterns related to cell morphology control, of which very excellent reviews have been made by Curtis, Wilkinson, and Flemming [40, 16]. Microgroove/ridge surfaces have shown significant control over cellular behavior, of which the most important phenomenon is that the cell spreading, alignment, and migration can be obviously oriented along the grooves/ridges (Figs. 15 [43] and 16 [44]). Wojciak-Stothard et al. [45] reported that murine P688DI macrophages were well oriented along the multiple grooves/ridges (0.5, 5 μm in depth, and 10 μm in width) on silica substrata. Moreover, they migrated mainly along the groove/ridge edges.

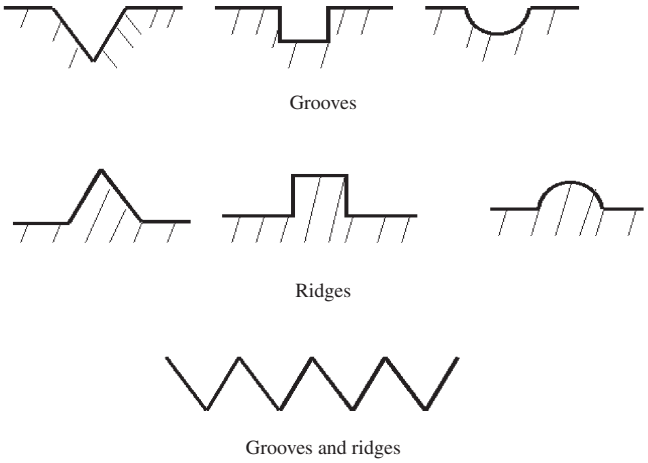

Figure 14. Grooves and ridges.

One theory that accounts for the cell orientation on the topographical surface is called the "contact guide effect." Integrins in focal contact transfer the variable degrees of tension or compression into the cytoskeleton. Cell stretch receptors subject to these stresses will be activated and reorganize the cytoskeleton according to the surface topography [40]. Curtis et al. put forward the idea that cells react to discontinuities. Focal contacts [46], vinculin [44], and F-actin [44, 45] are found to align over or close to the groove/ridge contact. Another theory [47] is that the changes of surface free energy due to the edges and disruptions may be the reason for the cell orientation.

The cellular alignment along the surface topographies is dependent on the dimensions of the surface features, a complex situation, varying with the cell types, cell–cell interaction, as well as substrate composition and topography. Clark et al. [48] reported that BHK cells and chick embryonic neural cells react to a single step, and the extent of the reaction increases with the increasing step height in the range of 1–20 μm. In another work, Clark et al. [49] cultured three cell types (BHK, MDCK, and chick embryo cerebral neurons) on multiple microgroove surfaces with varying height and width (4–24 μm repeat, 0.2–1.9 μm depth). It was found that repeat spacing (width) had a small effect (alignment is

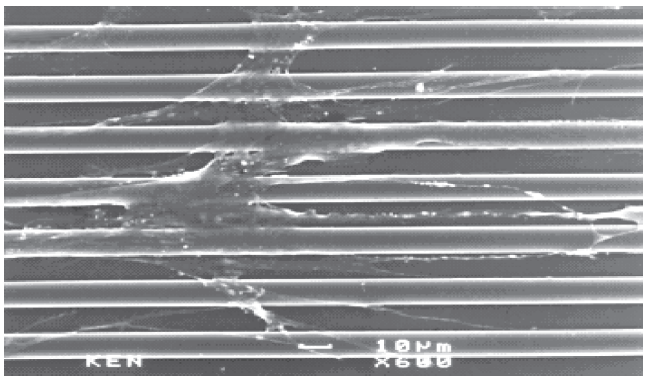

Figure 15. Osteoblasts oriented on microgrooved PS surface. Reprinted with permission from [43], K. Matsuzaka et al., *Biomater.* 20, 1293 (1999). © 1999, Elsevier Science.

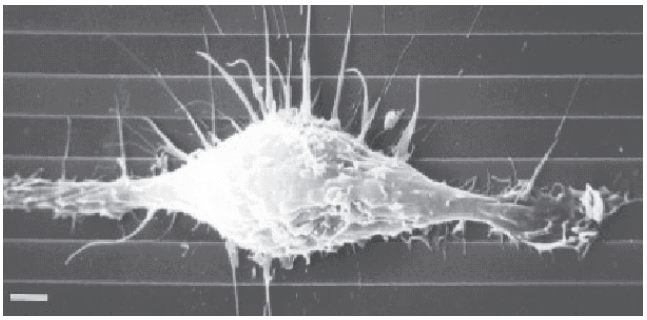

Figure 16. Well-spread macrophage with numerous microvilli on microgrooved substratum, groove depth 71 nm (bar is 5 μm). Reprinted with permission from [44], B. Wojciak-Stothard et al., *Exp. Cell Res.* 223, 426 (1996). © 1996, Elsevier Science.

inversely proportional to the spacing), but that the groove depth was much more important in determining cell alignment, which increased with the groove depth. Curtis and Wilkinson pointed out that, generally, the extent of cell orientation increases with groove depth from topographies of about 1 μm relief up to about 25 μm relief [40]. However, different results have also been reported. Wojciak-Stothard et al. [45] studied the orientation and migration of murine P688DI macrophages on a silica surface with microgrooves/ridges (0.5, 5 μm in depth and 10 μm in width). The results showed that cells speared and oriented better on the shallower (0.5 μm in depth) grooves/ridges. The macrophage migration on the shallower groove (0.5 μm in depth) was slightly faster, and had a longer persistent time than on the deeper grooves (5 μm in depth).

The smallest depth that a cell can sense has been studied, and found to be related to cell types. Clark et al. [50, 51] studied the elongation of BHK cells, MDCK cells, and chick embryo cerebral neurones on 260 nm period grating surfaces (130 nm grooves separated by 130 nm) of various depths (100, 210, and 400 nm). Only the BHK cells are aligned precisely by the grooves, while the other two kinds of cells were unaffected by the gratings. Wojciak-Stothard et al. [44] discovered that P388D1 macrophage-like cells could sense dimensions as small as 70 nm (Fig. 16). Casey et al. [52] reported that biological cells respond to topographic features in their environment at least as small as 30 nm. Such small topographies approach the dimensions of larger molecules, which are typically from several to several tens of nanometers. The groove width also affects the cell orientation degree [40]. When the grooves or ridges are appreciably wider than the cells, the effects on orientation are not very marked, although a cell may align to an edge. As the groove/ridge width is reduced to the width of the cells or less, the effects on cell orientation become more marked. No work has yet discovered the minimum width of topography to which a cell can react.

Other cell behavior such as cell adhesion and differentiation is also affected by groove/ridge patterns. Using UV photolithography and reactive ion etching, Wilkerson et al. [42] prepared rectangular ridges on the silicon wafer. Polystyrene solution was cast on the silicon wafer master to obtain a negative replication, and then PDMS was cast and polymerized on the polystyrene master to obtain a positive replication on the PDMS surface. On the surface-patterned PDMS, the 5 μm wide ridges (1–5 μm high) enhanced the adhesion of a kind of marine spore, the *Enteromorpha* spore, while they decreased the adhesion of endothelial cells. Matsuzaka et al. [43] prepared micropatterns with groove depths of 0.5, 1.0, and 1.5 μm and widths of 1, 2, 5, and 10 μm on PLA or PS surfaces by directly casting the polymer solution on micropatterned silicon wafers. Rat bone marrow cells were cultured on the microgrooved surfaces. Alignment of the cells along the grooves was observed (Fig. 15), and more mineralized ECM was formed on the microgrooved surfaces than on the smooth ones. PLA surfaces with a groove depth of 1.0 μm and a width of 1 and 2 μm induced the most mineralized ECM. The alkaline phosphatase activity of the cells was also higher on the microgrooved surfaces compared to the smooth ones.

Except for grooves and ridges, other topography was also prepared. Mata et al. [53] produced micropillars 6 μm in height and 5, 10, 20, and 40 μm in diameter on the surface of PDMS. Human bone-marrow-derived connective tissue progenitor cells (CTPs) spread, and adhered more on the micropillared PDMS than on the smooth PDMS. Tan et al. [54] fabricated polyimide (a kind of photoresist) pillars on glass and holes in polyimide film using UV photolithography. Arrays of the pillars and the holes with 2 μm, 4 μm height (or depth) separated by 10 μm had obvious effects on the cell spreading and migration. Neutrophils attached and spread on the smooth glass surface and surfaces with pillars. In contrast, cells were rounded, and did not adhere to either smooth polyimide film or microholed polyimide films. The migration of neutrophils was much faster on holes than on the polyimide surface, but it was significantly slower on pillars than on glass.

In addition to physical topography patterns, chemical patterns were fabricated to affect cell reactions. Mircocontact printing (μCP) is widely used in fabricating chemical patterns on biomaterial surfaces. This technique is outlined schematically in Figure 17 [55]. A PDMS stamp with the desired physical surface patterns is coated with the solution containing the substance that will be printed, such as adhesion protein. By contacting the stamp and the substrate, the substance can be printed on the substrate with the same patterns of the PDMS template. Physical interactions such as the strong adsorption between proteins and hydrophobic surfaces or chemical reactions such as that between an —SH group and gold surface can be used in μCP to maintain the stability of the micropatterned surfaces.

The patterning of adhesion proteins using μCP on biomaterial surfaces is an effective approach to control cell adhesion, spreading, orientation, and to obtain cell mircopatterns. Singhvi et al. [56] imprinted the hydrophobic compound $HS(CH_2)_{15}CH_3$ on a gold surface with a micropatterned PDMS stamp, then hydrophilic thiol compound $HS(CH_2)_{11}(OCH_2)_6OH$ was reacted with the remaining gold surface. The selective adsorption of laminin on the hydrophobic domain can be used to obtain rectangular islands of laminin with different sizes (40/15, 60/15, 70/20, 80/20 μm) to control the cell extension degree. DNA synthesis of hepatocytes increased greatly with the cell extension degree, while the albumin secreted into the medium decreased with the cell extension degree.

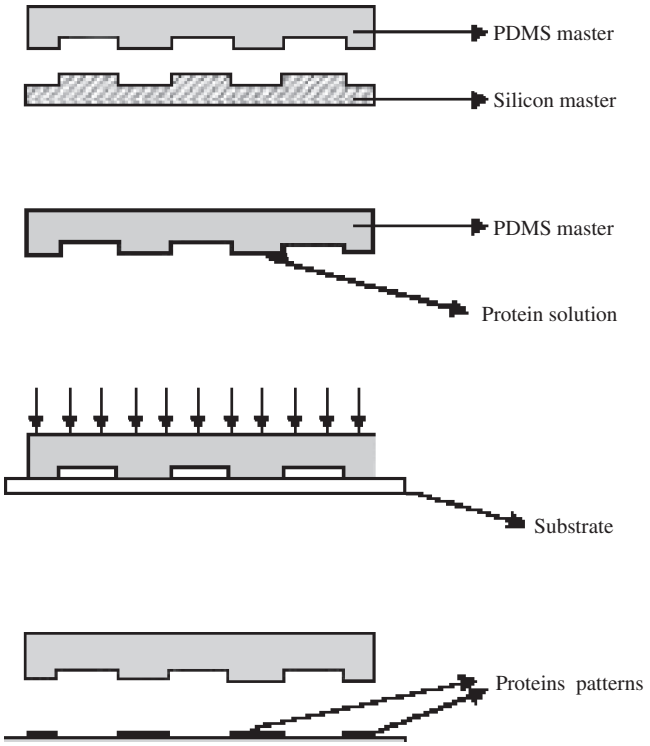

Figure 17. Schematic presentation of protein patterning process using microcontact printing technology. Reprinted with permission from [55], L. Kam et al., *Biomater.* 22, 1049 (2001). © 2001, Elsevier Science.

Fibronectin islands were also imprinted on the gold surface using the same method, and similar results on endothelia cells were obtained [28]. Kam et al. [55] prepared a honeycomb-like hexagonal micropattern of polylysine-conjugated laminin on a borosilicate glass surface using μCP technology. The hippocampal neurons selectively adhered to the polylysine-conjugated laminin area, and could be guided with high precision by polylysine-conjugated laminin patterns as narrow as 2.6 μm in width.

The self assembly monolayer (SAM) is another important technology to prepare surfaces with precise chemical or physical patterns. Self-assembly is the autonomous organization of components into patterns or structures without human intervention [57]. A SAM of amphiphilic molecules formed by hydrophobic interactions as in phospholipid cell membranes has been used to form surface patterns. Zhang et al. [58] prepared patterns of a kind of adhesion peptide (RADS) on the gold surface using a combination of a self-assembly oligopeptide monolayer and microcontact printing. Oligopeptides containing a cell adhesion motif (RADS) at the *N* terminus, followed by a hydrophobic oligo–alanine linker and a cysteine residue at the *C* terminus were prepared. By μCP, a patterned SAM of the oligopeptides was formed on the gold surface. The —SH group can react with the gold to attach the oligopeptide monolayer covalently to the gold surface. Hexaethylene glycol thiolate was used to produce antiadhesive domains. Microscale RADS tracks were prepared to guide cell adhesions and orientations precisely (Fig. 18 [58]).

5. NANOFIBERS AND 3D NANOSCALE SYNTHETIC EXTRACELLULAR MATRIX

The ideas that use biodegradable 3D nonwoven meshworks fabricated with synthetic polymeric nanofibers as tissue-engineering scaffolds have been attracting more and more interest in recent years. This is for three reasons: (1) polymeric fibers are usually strong in tensile strength, so the scaffold can have good mechanical properties and excellent flexibility; (2) research showed that cells attach and organize well around fibers with diameters smaller than the diameter of the cells [59]; and (3) a nonwoven polymeric meshwork mimics the nanoscale protein fiber meshwork in natural ECM.

5.1. Cells and Fibers

Wan et al. [60] studied the fibroblast adhesion and proliferation on four different multifilament materials with diameters less than 20 μm: Kevlar 29 (K), silicon carbide (SiC), nylon 66 (N), and polyethylene terephthalate (PET). The results showed that fibroblasts adhered and grew very well on all fiber surfaces, although fewer cells were observed on PET. Significant orientational behavior of the cells was found on all fiber surfaces from the SEM and CLSM analysis, independent of the bulk chemistry of the fibers. To study the effects of nanofiber diameter on osteoblast proliferation and differentiation, carbon fiber nonwoven mesh with different fiber diameters (from 60 to 200 μm) were synthesized [61]. Osteoblast proliferation increased with decreasing carbon fiber diameters after three and seven days of culture. Moreover, compared to larger diameter carbon fibers, osteoblasts synthesized more alkaline phosphatase and deposited more extracellular calcium on the carbon fibers with smaller diameters.

5.2. Electrospinning

One of the most important technologies to prepare polymeric nanofibers is electrostatic spinning (electrospinning). Electrospinning is not a new technology for polymer fiber production. It has been known since the 1930s [62]. In recent years, special needs of military, medical, and filtration applications have stimulated renewed interests and studies in the process of electrospinning. The principle of electrospinning is to use an electric field to draw a positively charged polymer solution or melt from an orifice to a collector (Fig. 19 [63]). This creates a jet of fluid that is drawn down by acceleration from the orifice to the grounded collection device. The process use high voltages (10–20 kV) to generate sufficient surface charge to overcome the surface tension in a pendant drop of the polymer fluid. The diameters of electrospun fibers are at least one order of magnitude smaller than those made by conventional extrusion techniques. When the jet dries or solidifies, an electrically charged fiber remains. This charged fiber can be directed by electrical forces, and then deposited in sheets or other useful geometrical shapes in the form of a nonwoven fabric. Due to the small fiber diameters and the porous structure of a nonwoven meshwork, electrospun products possess a high surface-to-volume ratio that renders them attractive for a variety of applications, such as a biodegradable nonwoven meshwork for tissue engineering. Figures 20 [64] and 21 [65] are SEM photographs of polymeric nanofibers prepared by the electrospinning method.

Reneker et al. [66] prepared nanofibers of more than 20 kinds of polymers, including polyethylene oxide, nylon, polyimide, DNA, polyaramid, and polyaniline using electrospinning. Most fibers were spun from polymer solution. In another work by Fong and Reneker et al. [67], styrene–butadiene–styrene triblock copolymers were electrospun to obtain elastic nanofibers with diameters around 100 nm. Separated phases of styrene and butadiene blocks were observed using TEM. The single-phase domains were irregular in shape, but elongated along the axis of the fiber. Biodegradable amorphous poly(D,L–lactic acid) (PDLA)

and semicrystalline poly(L–lactic acid) (PLLA) nanofiber nonwoven membranes for biomedical applications were fabricated by Zong et al. [68] using the electrospinning method. Bognitzki et al. [65] prepared PLLA, PC, and polyvinylcarbazole nanofibers with pores on fiber surfaces. The pore morphology can be controlled by the rapid phase separation induced by the evaporation of the solvent and a subsequent rapid solidification. Not only synthetic, but also natural polymers such as protein, have been made into nanofibers. Huang et al. [22] employed a kind of elastin-mimic protein that was processed into fibers by an electrospinning technique. The 81 kDa recombinant protein based upon the repeating elastomeric peptide sequence of elastin (Val–Pro–Gly–Val–Gly)(4)(Val–Pro–Gly–Lys–Gly) was obtained through bacterial expression of the gene

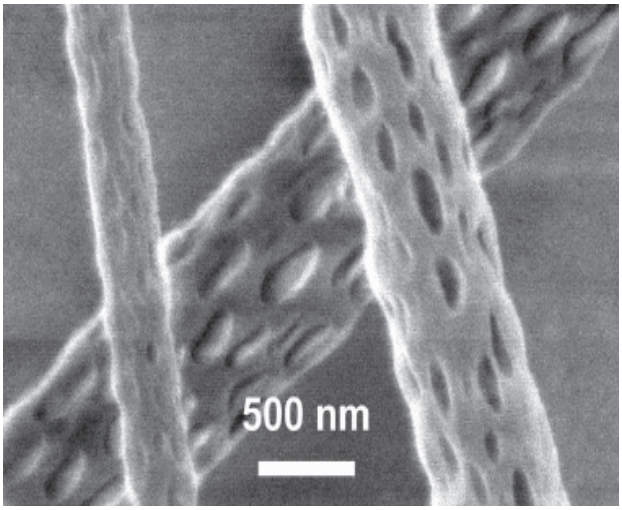

Figure 21. SEM micrographs of porous PLLA fibers obtained via electrospinning of a solution of PLLA in dichloromethane. Reprinted with permission from [65], M. Bognitzki et al., *Adv. Mater.* 13, 70 (2001). © 2001, Wiley-VCH.

coding for tandem repeats of the monomer. Processing parameters were changed to influence the fiber diameter (200–3000 nm) and morphologies. Three kinds of morphologies, beaded fibers, thin filaments, and broad ribbon-like structures, were obtained with varied processing parameters.

Using a PEO/water system, Deitzel et al. [69] studied the effects of the two most important parameters, spinning voltage and solution concentration, on the morphology of the fibers formed. In addition, electrostatic effects also are found to influence the macroscale morphology of the electrospun textiles, and may result in the formation of heterogeneous or three-dimensional structures. Mo et al. [70] found that the diameter of PLLA–co–PCL nanofibers decreased with decreasing polymer concentration and increasing electrospinning voltage. Other affecting parameters include polymer solution vescoelasticity, polymer solution feeding rate, and ionic slat addition [68].

One of the characteristic features of electrospinning is the onset of a chaotic oscillation of the electrospinning jet. This instability of the polymer solution jet can cause the formation of beaded fibers. Fong and Reneker [71] demonstrated that electrospun fibers often have beads in regular arrays (Fig. 22 [71]). The viscoelasticity of the solution, charge density carried by the jet, and the surface tension of the solution are the key factors that influence the formation of the beaded fibers. Reneker et al. [72] studied the bending instability of the electrically charged liquid jets of polymer solutions using a mathematical rheological model. Deitzel et al. [73] overcame the instability by using an electrostatic lens element and a collection target of opposite polarity to control the deposition of PEO fibers (diameters <300 nm) on a substrate.

5.3. Phase Separation

Phase separation method has been used to prepare 3D nanofiber meshworks. Using this technique, Ma et al. [74] prepared biodegradable 3D meshworks composed of PLLA, PDLA, and PLGA nanofibers with diameters ranging from 50 to 500 nm. The process involved thermally induced gelation (phase separation), solvent exchange, and freeze drying. It should be noted that a sponge-like porous matrix could also be obtained by the phase separation method [75]. Preparing parameters such as gelation temperature, gelation time, solvent, and polymer concentration should be well controlled to make proper conditions for the formation of nanofibers in the phase separation to obtain a nanofiber meshwork morphology.

The main advantage of the phase separation method is that it is easy to fabricate meshworks that are isotropic in all three dimensions. It is also a simple process requiring little equipment. However, the fibers produced are relatively short, and do not have a uniform cross-sectional geometry or porosity along their lengths. Hence, the scaffolds lack mechanical strength, and it may be difficult to produce scaffolds with consistent and controlled architecture.

5.4. Nonwoven Meshworks as Tissue-Engineering Scaffolds

Nonwoven meshes of PLGA or PGA fibers with a diameter of 10–15 μm have been widely used in cartilage tissue engineering [76]. Cao et al. [77] seeded chondrocytes isolated from bovine articular cartilage into PGLA nonwoven meshworks with the shape of a human auricle. The cell-seeded nonwoven meshworks were subsequently implanted on the dorsa of athymic mice. New cartilage tissue was generated in the meshworks. The three-dimensional structure of the meshworks was well maintained in the process of the cartilage tissue regeneration after the removal of the external stents. PGA nonwoven mesh with a diameter of 12–15 μm has also been used for cardiovascular tissue engineering by first seeding the fibroblast and then epithelia cells on the mesh [78]. Microscopic examination of the seeded mesh demonstrated that the human fibroblasts attached to the polymeric fibers, and spread out and proliferate in the meshwork. The seeded endothelial cells formed a monolayer on the fibroblasts (Fig. 23 [78]). Finally, a homogeneous scaffold resembling a solid sheet of tissue was obtained. Li et al. [79] developed a thermal compression method to prepare a nonwoven polyethylene terephthalate (PET) meshwork with a fiber diameter of about 20 μm. The effects of preparation parameters including temperature, pressure, and compression duration on the mechanical property, pore size, and porosity of the meshworks were studied. Human trophoblast ED_{27} and NIH 3T3 cells were cultured and adhered on the PET fibers (Fig. 24 [79]). This thermal compression method can be used to prepare other biodegradable polymer nonwoven mesh, and to modify their microstructure. Altman et al. [80] used a natural silk cord matrix (5–20 μm in diameter) as a scaffold for the tissue engineering of anterior cruciate ligaments. The silk fiber matrix promoted the adhesion, spreading, and differentiation toward the human ligament lineage (Fig. 25 [80]).

Fewer works have been reported to prepare nonwoven meshworks using nanoscale fibers for tissue engineering, probably due to the fact that fibers with such small diameters are very difficult to easily manipulate. Mo et al. [70] found that smooth muscle cells (SMCs) and endothelia cells

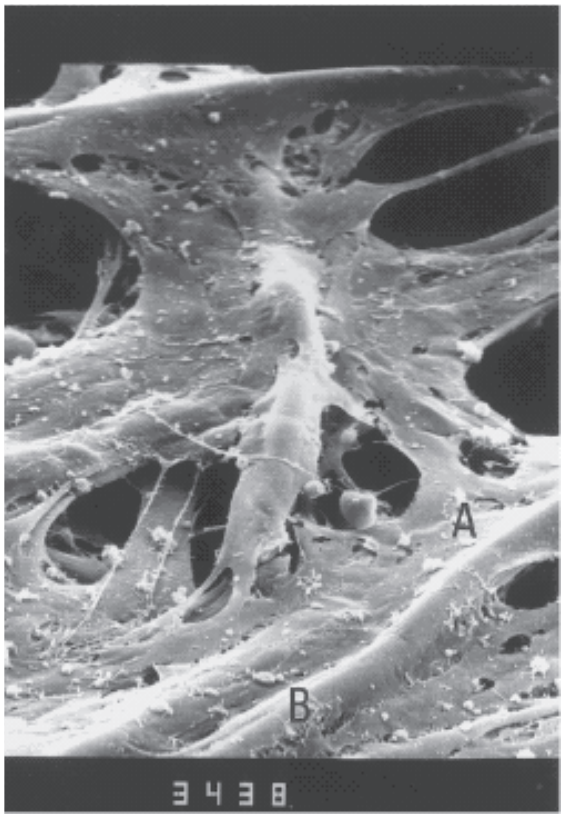

Figure 23. Continuous formation of fibroblasts. was studied for its potential in bone tissue engineering. Mesenchymal stem cells (MSCs) derived from the bone marrow of neonatal rats were cultured, expanded, and seeded on the PCL meshwork. The cell–meshwork construct was then cultured in a culture medium supplemented with osteogenic factors under dynamic culture conditions for more than four weeks *in vitro*. The cells penetrated into the meshwork and secreted ECM during the culture. After four weeks of culture, collagen type I and mineralized ECM were found in the cell–meshwork construct, which indicated that the electrospun PCL is a potential candidate scaffold for bone tissue engineering.

It can be expected that, in the future, nonwoven meshworks composed of nanoscale fibers will be more and more widely used as ECM analogs in the field of tissue engineering and artificial organs.

6. CONCLUSION

In natural ECM, protein fibers with nanoscale diameters form a nonwoven meshwork penetrating through and embedded in the proteoglycan hydrogel. In common connective tissue, the fiber diameter is from several hundred nanometers to several microns, while in basal lamina, the fibers are thinner (several to several ten nanometers in width) and the meshwork is denser (several nanometers in pore diameter). The interactions between the cells and the ECM are mainly mediated by the integrin-clustered focal contacts, of which the dimensions are also from several hundred nanometers to several microns. These nanometric characteristics of an ECM can be used to prepare ECM-mimic synthetic materials. Nano/micropatterns can be produced on plane biomaterial surfaces using several kinds of microconstruct technologies such as photolithography, microcontact printing, and self-assembly monolayer. The nano/microsurface patterns have significant influences on

cell behavior. Polymeric nanofibers can be obtained successfully by electrospinning technology, and fabricated into nonwoven meshworks. These nonwoven meshworks have a potential application in tissue engineering in the future due to their great similarity with the nonwoven meshworks in a natural ECM.

GLOSSARY

Adhesion proteins (also called adhesive proteins) Fibrous proteins in ECM which promote cell adhering on ECM by specifically binding cell membrane receptors called integrin. Adhesion proteins mainly include fibronectin, laminin and vitronectin etc. Collagen is also a kind of adhesion proteins due to its ability to bind with some integrins.

Biomaterials Materials which directly contact physiological environments like cells, blood and human tissues.

Electrospinning A polymer processing method to produce ultra-fine polymer fibers. The principle of electrospinning is to use a high electric field to draw a positively charged polymer solution or melt from an orifice to a collector, producing ultra-fine fibers with diameters ranging from several microns down to several tens of nanometers.

Extracellular matrix (ECM) A complex structural entity surrounding and supporting cells that are found within mammalian tissues.

Focal contact (focal adhesion) Focal contact, also called focal adhesion, is formed when a cluster of integrins accumulate in a relatively small spot on the cell membrane and interact with adhesion proteins in ECM. Focal contact is the main way for cells to attach onto the ECM and to respond to outer signals.

Glycosaminoglycans (GAGs) Long unbranched polysaccharides containing a repeating disaccharide unit. The disaccharide units contain either of two modified sugars—*N*-acetylgalactosamine (GalNAc) or *N*-acetylglucosamine (GlcNAc) and a uronic acid such as glucuronate or iduronate. The majority of GAGs in ECM are linked to core proteins, forming proteoglycans.

Integrin Tans-membrane heterodimeric receptor proteins on cell surface. There are about 22 different kinds of integrins on cell surface. The binding of integrins with the adhesive proteins lead to the forming of focal contact, which is the main way for cell to adhere onto the ECM.

Nanofiber Fibers with diameter ranging from several nanometers to several hundred nanometers are called nanofiber in this chapter.

Proteoglycan Macromolecules that are composed of a protein core to which is attached many GAGs chains. Proteoglycan hydrogels provide pressure resistance properties for ECM.

Structural proteins Fibrous proteins in ECM which provide tensile strength and elasticity for ECM. Structural proteins mainly include collagen and elastin. Collagen is the most abundant protein in ECM.

Surface patterning Surface treatment of materials which can produce micro- or nano-scale texture with a random or regular geometric pattern on the material surfaces. The most common surface patterning techniques include photolithography electrobeam-lithography, neutron-lithography, self-assembly and microcontact printing, etc.

Synthetic ECM Artificial materials that can support the growth of cells, just as the native ECM does.

Tissue engineering A new approach to repair and regenerate damaged human tissues. The procedure include seeding the cells into a 3-D porous biodegradable scaffolds, culturing the cell-scaffold construct *in vitro*, and transplanting the cell-scaffold construct into human body. The scaffold will be degraded and removed, and finally replaced by new generated tissue, living no foreign materials *in vivo*.

Tissue engineering scaffold 3-D porous biodegradable biomaterial used as supports for cells in tissue engineering.

Nanostructured Hybrids from Layered Double Hydroxides

Toshiyuki Hibino

National Institute of Advanced Industrial Science and Technology, Tsukuba, Japan

CONTENTS

1. INTRODUCTION

Layered double hydroxides (LDHs) are a class of lamellar solids, other examples of which include smectite clays, zirconium phosphates, layered titanium dioxides, transition-metal chalcogenides, layered perovskites, graphites, and graphite oxides. LDHs are made up of hydroxide layers with anions and water sandwiched between them. The hydroxide layers vary in composition, and in composition ratio. The weakly interacting regions between the layers are called the "interlayer" or "gallery" regions. LDHs, which are rare in nature but relatively simple and inexpensive to synthesize, are sometimes called "anionic clays," owing to their structural similarity to smectite clays and their anion exchange capability. LDHs go by numerous other names—such as hydrotalcite, manasseite, pyroaurite, sjögrenite, takovite, meixnerite, reevesite, iowaite, and honessite—depending on the composition and polytype form of the minerals. The term "green rust" is used for some natural LDHs found in anoxic environments [1–3]. LDHs are also widely known as "hydrotalcite-like compounds."

LDHs have found a variety of practical applications in industry. Calcination of LDHs at temperature depending on the particular cations in the layers and anions in the interlayers leads to mixed oxides characterized by structural homogeneity and the absence of chemical segregation. Catalysts obtained in this way have been thoroughly investigated, and many papers and reviews have been published [4–6]. LDHs are also being used as antacid agents for gastritis, as stabilizers in poly(vinyl chloride), and as components of flame retardants for plastics. However, all these uses of LDHs are related to either their thermal properties or their basicity and do not take advantage of their two-dimensional lamellar structure.

The technique of delaminating or exfoliating lamellar compounds into single lamellae or packets of a few lamellae is the key route for assembling nanostructured hybrids. Designing and building new materials on a nanometer scale are currently topics of intense research. Single layers of lamellar compounds can be considered as anisotropic inorganic macromolecules, and can serve as well-defined building blocks for the synthesis of heterostructured nanohybrids. For example, smectite clays have found practical use in polymer/clay nanocomposite materials in which the clays have been delaminated into single sheets within polymer matrices [7]. Furthermore, delamination has been reported for several other classes of lamellar compounds, such as zirconium phosphates, layered titanium dioxides, transition-metal chalcogenides, and graphite oxides. These compounds have been thoroughly investigated and have been developed into nanocomposite materials that have already attained success in the experimental stage [8–23]. On the other hand, most of the nanocomposite materials successfully fabricated from LDHs have been obtained by means of techniques other than delamination, as will be discussed later in this review. However, the first example of delamination of an LDH was reported in 2000 [24].

In addition to describing the synthesis and fundamental properties of LDHs, this review compares nanocomposite materials made from LDHs with nanocomposite materials made from other lamellar compounds, focusing on the delamination process.

2. LAYERED DOUBLE HYDROXIDES

2.1. Structure

As we have seen, LDHs consist of positively charged hydroxide layers with interlayer spaces filled with anions and water molecules (Fig. 1) [25, 26]. LDHs can be usually represented

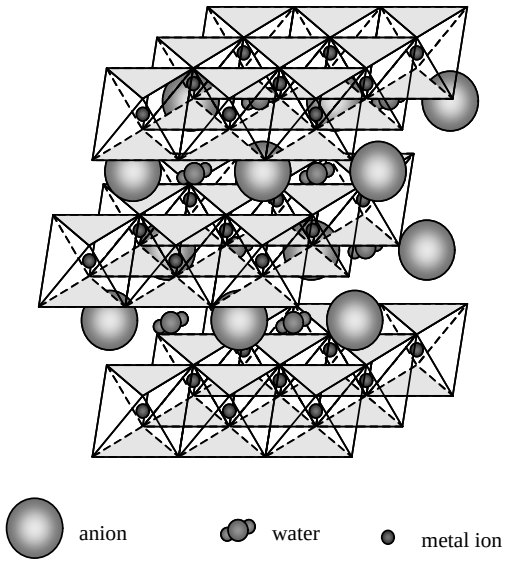

Figure 1. Structure of LDHs.

by the general formula $[M^{2+}_{1-x}M^{3+}_{x}(OH)_2]$ $[A^{n-}_{x/n} \cdot mH_2O]$, where x normally varies between 0.20 and 0.33, M^{2+} and M^{3+} are di$^-$ and trivalent metal ions occupying octahedral positions within the hydroxide layers, A^{n-} is an interlayer anion that compensates for the charge on the layers, and m is the number of interlayer water molecules. Each M^{2+} ion is octahedrally surrounded by six OH^- ions, and adjacent octahedra share edges to form infinite sheets that resemble $Mg(OH)_2$ (brucite) sheets. Isomorphous replacement of some of the M^{2+} ions with M^{3+} ions creates the positive charge on the hydroxide layers. The layers can be stacked in either rhombohedral or hexagonal symmetry. In the rhombohedral stacking sequence, the c parameter of the unit cell is $3c'$, where c' is the combined thickness of one hydroxide layer and one interlayer. In the hexagonal stacking sequence, the c parameter is $2c'$. Synthetic LDHs are normally rhombohedral, and some minerals in nature are hexagonal [4, 5].

In addition to the LDHs represented by the general formula given above, Li–Al LDHs, $[Li^{+}_{1/3}Al^{3+}_{2/3}(OH)_2][A^{n-}_{1/3n} \cdot mH_2O]$, have also been reported [27]. In this case, the metal ions in the host layers are mono- and trivalent cations. Li^+ ions occupy the vacant octahedral sites within the $Al(OH)_3$ (gibbsite) layers in this compound. When Li–Al LDHs are included, the extended general formula for LDHs becomes $[M^{z+}_{1-x}M^{3+}_{x}(OH)_2]^{b+}$ $[A^{n-}_{b/n} \cdot mH_2O]$, where M is a metal ion, A is an anion, and $b = x$ or $2x - 1$ for $z = 2$ or 1, respectively. Intriguingly, although Li–Al LDHs are synthetic, they have hexagonal symmetry, unlike M^{2+}–M^{3+} LDHs.

The phenomenon in which the interlayers of lamellar compounds are partially filled with guest ions or molecules in an ordered way is known as staging. Many examples of staging are found for graphite. Although staging are not commonly found for LDHs, some LDHs have been found to show second-stage intermediate phases when some organic anions are intercalated between the layers [28, 29].

2.2. Synthesis

In general, LDHs are synthesized by coprecipitation [4, 5, 30, 31]. For example, one can obtain a typical Mg-Al-CO_3 LDH by adding an aqueous solution of magnesium and aluminum salts (chloride, nitrate, sulfate, etc.) dropwise to an aqueous solution of sodium carbonate at a constant pH of 10 while simultaneously adding a sodium hydroxide solution [32]. The pH range at which coprecipitation occurs depends on the nature and concentration of the metal ions used (Table 1). The precipitation pH value for the metal ion is calculated from the solubility product (K_{sp}) of $M^{2+}(OH)_2$ or $M^{3+}(OH)_3$ and can serve as a reference for the choice of pH for synthesis. Usually, M^{2+} and M^{3+} double hydroxides coprecipitate in pH titration at pH values between the values at which pure M^{2+} and M^{3+} hydroxides precipitate [4, 33, 34]. The coprecipitation method can be performed at ambient temperature and pressure, and these environmentally benign conditions are one of the virtues of LDHs.

Another virtue of LDH synthesis is the fact that a large variety of compositions are possible, depending on the choice of metal ions and anions. In the coprecipitation synthesis, pure LDH phases are usually obtained at x values ranging from 0.20 to 0.33, and the M^{2+}/M^{3+} atomic ratios in the products are almost the same as those in the initial solutions. There are practically no limitations on the nature of the anions. However, contamination by carbonate anions is likely to occur because LDHs have a high affinity for carbonate anions and because the basic solutions used for LDH preparations easily absorb carbon dioxide from the air [4, 5, 31, 35–37]. When LDHs other than carbonate forms are prepared, measures to avoid carbonate anion contamination should be taken; for example, the synthesis can be carried out under an inert gas like nitrogen or in a glovebox.

2.3. Physical and Chemical Properties

2.3.1. Thermal Behavior

When LDHs are heated, the evolution of interlayer water occurs first and is followed by decomposition to mixed oxides. In the case of the well-studied Mg–Al–CO_3 LDHs

Table 1. Precipitation pH values for metal hydroxides.

		Precipitation pH	
Cation	pK_{sp}	at $[M^{2+\text{ or }3+}] = 0.1$ mol/L	at $[M^{2+\text{ or }3+}] = 0.01$ mol/L
Al^{3+}	32.90	3.4	3.7
Cr^{3+}	30.20	4.3	4.6
Fe^{3+}	37.40	1.9	2.2
Mg^{2+}	10.74	9.1	9.6
Zn^{2+}	16.92	6.0	6.5
Ni^{2+}	14.70	7.2	7.7
Fe^{2+}	15.10	7.0	7.5
Co^{2+}	14.80	7.1	7.6
Cu^{2+}	19.66	4.7	5.2
Ca^{2+}	5.26	11.9	12.4
Mn^{2+}	12.72	8.1	8.6

[4, 32, 33, 38–45], the loss of interlayer water occurs at 100–250 °C and is observed as an endothermic peak in the differential thermal analysis (DTA) curves in Figure 2. This initial loss of water is not accompanied by collapse of the layered structure, and rehydration of the interlayer water occurs reversibly. The second endothermic peak, at 300–400 °C, corresponds to the loss of structural water from the hydroxide layers, as well as decarbonation. At this stage, the layered structure collapses to an amorphous phase, as evidenced by the difference between the X-ray diffraction (XRD) patterns shown in Figure 3a and b. The second endothermic peak in the DTA curves splits into two peaks when the aluminum content increases (Fig. 2). This split is due to the fact that the dehydroxylation of the hydroxyl group bound to aluminum occurs at a lower temperature than the dehydroxylation of the hydroxyl group bound to magnesium. At temperatures higher than 400 °C, a MgO phase begins to appear, and aluminum ions enter the MgO lattice. The calcination materials obtained between 500 °C and 800 °C are NaCl-type Mg–Al oxide solid solutions, as shown in Figure 3c. When the temperature is elevated still further, aluminum ions migrate from the solid solutions to spinel ($MgAl_2O_4$) phase, and at temperatures higher than 900 °C, pure MgO and spinel appear in the XRD pattern (Fig. 3d).

2.3.2. The Memory Effect

When oxide solid solutions obtained by thermal decomposition of Mg–Al–CO_3 LDHs at about 500 °C are exposed to water, the original LDH structure is restored. This reconstruction process, depicted schematically in Figure 4, is termed the "memory effect" [4]. LDHs with volatile interlayer anions, such as chloride and hydroxide anions, also exhibit the memory effect. Because the oxide solid solutions adsorb anions as well as water from the aqueous solution, a great variety of anions can be intercalated by means of the reconstruction method, and numerous LDH intercalates have been reported [4, 30, 31, 46–49]. However, the spinel phase that forms at temperatures higher than 900 °C cannot be reconstructed to LDHs by means of this method.

The reconstruction reaction is mainly governed by the nature of the divalent metal ions in the hydroxide layers of the LDHs. Oxide solid solutions obtained from LDHs based on Mg or Zn hydroxides are easy to reconstruct at room

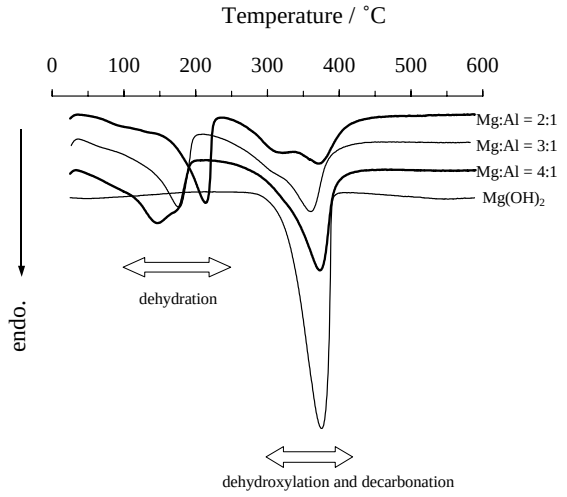

Figure 2. DTA curves of Mg–Al–CO_3 LDHs with various Mg:Al atomic ratios.

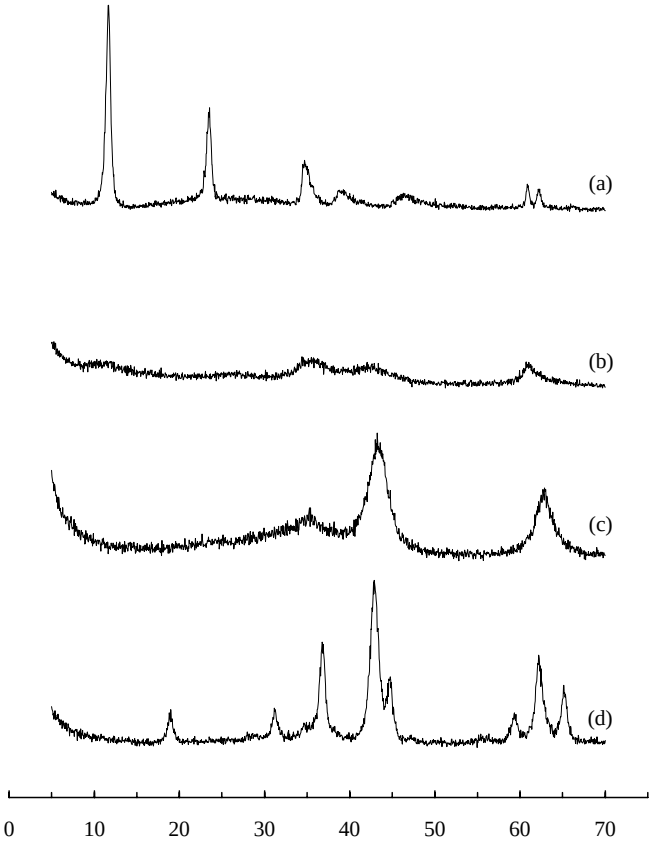

Figure 3. XRD patterns of Mg–Al–CO_3 LDHs (Mg:Al = 2:1) heated at various temperatures: (a) unheated, (b) 350 °C, (c) 500 °C, and (d) 1000 °C.

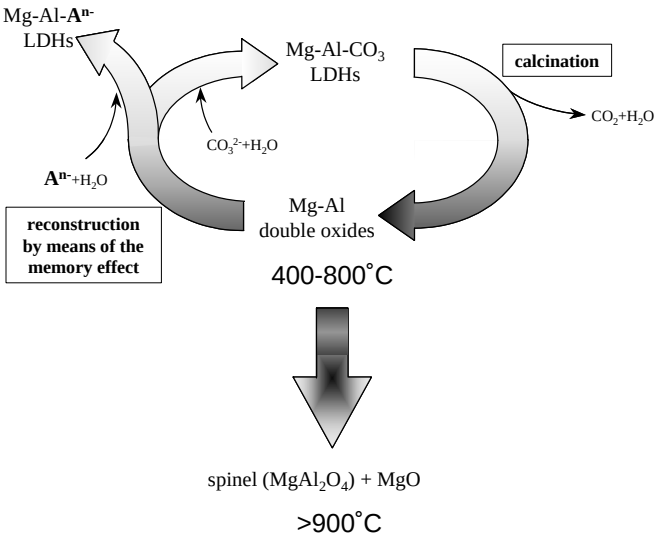

Figure 4. Thermal decomposition and reconstruction of LDHs.

temperature [39, 46–52]. However, reconstruction of oxide solid solutions obtained from LDHs based on Ni hydroxide requires a hydrothermal treatment [52, 53]. Some extent of ZnO-like phase remains after reconstruction at room temperature in the case of Zn-based LDHs, but hydrothermal treatment for Zn-based oxide solid solutions predominantly produces highly crystalline ZnO, and reconstruction into LDHs does not occur [50].

2.3.3. Anion Exchange

One of the most important properties of LDHs is their high anion exchange capacity, which is related to their lamellar structure. When LDHs are dispersed in aqueous solutions containing anions, this capacity allows the exchange of the LDHs' original anions with those present in the solution. This is, of course, one route for making nanostructured hybrids. Anion exchange capacity values ranging from 1.8 to 4.5 mequiv/g have been reported [5, 36, 54, 55], depending on the x value in the general formula. The selectivity of the exchange decreases with decreasing anion charge density. Therefore, LDHs containing monovalent anions, such as chloride and nitrate anions, should be good precursors for ion exchange reactions.

Although carbonate forms of LDHs are easier to synthesize than other anion forms, carbonate anions in LDHs cannot be exchanged with other anions by simple dispersion of a CO_3-LDH in an aqueous solution, because of the high affinity of carbonate for LDHs. Treatment with a diluted acid solution, however, makes the exchange of carbonate anions with other anions possible [37, 56–58]. Chloride and nitrate anions are intercalated when hydrochloric and nitric acids, respectively, are used.

For confirming the presence of anions or polymeric anions in LDHs and determining their environment, IR spectroscopy is a useful technique. For example of Mg–Al–CO_3 LDH, an intense absorption band for carbonate anions appears at 1350-1380 cm^{-1}. After loss of interlayer water, the band splits into two bands, at 1330 and 1540 cm^{-1}, owing to the change of symmetry of the carbonate anions (see Fig. 5).

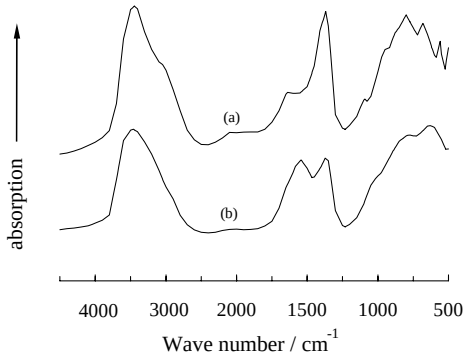

Figure 5. IR spectra of Mg–Al–CO_3 LDHs (Mg:Al = 2:1): (a) unheated and (b) dehydrated at 250 °C. The ν_3 bands of carbonate are labeled with solid circles.

3. NANOSTRUCTURED HYBRIDS FROM LAYERED DOUBLE HYDROXIDES

3.1. Delamination Techniques

Delamination, a process that is unique to lamellar compounds, is the most useful technique for building nanocomposite materials. As we have seen, lamellar compounds allow intercalation of ions or polar molecules into interlayer galleries with the layered structure intact, owing to the considerable anisotropy in the chemical bonding. Large guests open up the interlayer galleries, but the lamellar solids remain crystalline because of the attractive interactions between the guests and the sheets of the host. In some cases, the intercalation process allows large amounts of solvent to penetrate the interlayer region, in a process known as swelling. Delamination or exfoliation of lamellar solids into single sheets can be thought of as the extreme case of swelling, in other words, infinite swelling, as illustrated in Figure 6. The delaminated single sheets can be seen as giant planar macromolecules and as building blocks for new materials that cannot be prepared by means of other processes. This feature of delamination has prompted use of the lamellar solids as precursors for polymer/solid sheet nanocomposite materials [8–16], self-assembled multilayers [17, 18], and pillared porous materials [19–23].

The delamination of lamellar solids other than LDHs has been extensively investigated. Delamination has been reported for smectite clays [14, 59–61]; graphite oxides [9, 10, 62]; dichalcogenides (MoS_2 [11, 63–65], WS_2 [64], and $NbSe_2$ [8]); metal phosphates (α-metal phosphates [18, 66–74], γ-zirconium phosphates [20, 21, 75], and vanadium phosphorus oxides [76]); and layered oxides (layered titanate [16, 17, 22, 77–84], perovskites [85–88], MoO_3 [12, 13], and $K_4Nb_6O_{17}$ [89]). Smectite clays are a typical example, and delamination occurs when suspensions of their sodium

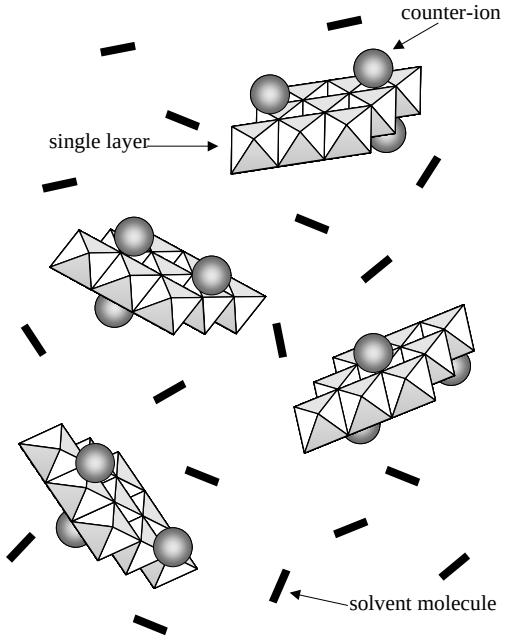

Figure 6. Delamination of LDHs in solvent.

forms are stirred in water. The exfoliation of graphite oxides easily occurs in dilute alkaline aqueous solution. The lithium forms of dichalcogenides have been shown to exfoliate into single sheets upon reaction with water. As for metal phosphates, α-M^{4+} phosphates (M^{4+} = Zr, Sn, and Ti) are known to delaminate in aqueous solutions of alkylamines or tetra-*n*-butylammonium hydroxide (TBA^+OH^-). Layers of γ-zirconium phosphates have been found to delaminate in aqueous alkylamine solutions and in a 50% (v/v) water/acetone mixture at 80 °C. Vanadium phosphorus oxides, $VOPO_4 \cdot 2H_2O$ and $VOHPO_4 \cdot 0.5H_2O$, are reportedly intercalated with 4-butylaniline, and the intercalates are delaminated in tetrahydrofuran (THF). In addition, some layered oxides can be also delaminated. Perovskite oxides such as Dion-Jacobson and Ruddlesden-Popper phases have been successfully delaminated in aqueous solutions of organic bases (amines or amino acids), and delaminations of layered titanates and acid-exchanged $K_4Nb_6O_{17}$ by reaction with aqueous TBA^+OH^- solutions have been confirmed. Some Aurivillius-type perovskite oxides and MoO_3 exfoliate in water after being converted to their lithium forms.

Despite the importance of delamination, techniques for characterizing the process have not been established yet, owing to the difficulty of measuring nanometer-scale phenomena in solutions. XRD measurement of the colloidal solutions in which the lamellar solids are delaminated can sometimes give useful information, although the small and weak peaks of the lamellar compounds are difficult to distinguish from the large and broad peaks from the media. In spite of these difficulties, the XRD pattern of single layers of MoS_2 in water [65] and the XRD patterns of intermediate states such as osmotically swollen layered titanates [82, 84] have been reported. Osmotic swelling had been observed only for smectite clays before being found in layered titanates [59–61, 90]. In the state of osmotic swelling, uptake of much larger volumes of water takes place than does in crystalline swelling.

In addition to XRD, transmission electron microscopy (TEM) and atomic force microscopy (AFM) are other possible characterization methods for delamination. Single sheets obtained by dipping TEM grids or substrates into colloidal solutions in which the lamellar solids are delaminated have been observed by TEM and AFM, and their thickness has been measured by AFM [18, 66, 78, 88]. In the case of tin phosphates, the absence of free phosphoric acid in the colloidal solutions obtained by delamination has been confirmed by ^{31}P NMR spectroscopy, which suggests exfoliation rather than chemical decomposition [91].

Investigation of the delamination of LDHs began only recently. Although the high charge density on LDH layers makes delamination difficult, LDHs have been delaminated by modification of interlayer galleries with organic anions. Delamination of dodecyl sulfate intercalates of Zn–Al LDHs has been reported to occur in refluxing alcohols at 120 °C [24]. A method whereby LDHs containing glycine are delaminated in formamide at room temperature has also been reported [92]. Intercalation of glycine, the simplest amino acid, creates an interlayer region that is attractive to polar solvents, owing to the strong hydrogen bonding between the intercalated anions and the solvents. After publication of these two studies ([24] and [92]), delamination of LDHs has been achieved by means of the shearing of dodecyl sulfate-LDHs in an acrylate monomer at 70 °C and subsequent polymerization of the monomer [93]. Delamination by means of these techniques is becoming a route for the construction of nanocomposite materials from LDHs.

3.2. Polymer/Layered Double Hydroxide Nanocomposite Materials

3.2.1. Synthesis

Nanocomposites composed of polymers and lamellar compounds have been extensively studied with the goal of finding novel functionalities that result from synergistic effects between the polymers and hosts. Novel anisotropic materials, battery cathode materials, electrochromic displays, microelectronic devices and sensors, mechanically reinforced polymers, and systems for the study of polymerization processes have been reported [8–14, 94, 95]. Synthetic methodologies vary with the combination of guest and host but can be placed in four principal categories [96] (see Fig. 7):

(1) *in-situ* polymerization methods
(2) template methods
(3) delamination–reaggregation methods
(4) melt intercalation methods.

Although all four methods should be applicable to LDHs, the first two have been the main processes for LDHs up to now. The *in-situ* polymerization method is feasible only when appropriate monomers are available. In the case of LDHs, monomer anions can be intercalated by ion exchange. Intercalated monomers can then be polymerized by a thermal, photoinduced, or redox treatment. There are two possibilities for the timing of polymerization: polymerization after intercalation of the monomers, and concomitant polymerization during intercalation of the monomers. The template method involves the synthesis of lamellar compounds in solutions in the presence of polymers. During the nucleation and growth of the lamellar host crystals, polymers get trapped within the interlayer regions. LDHs are remarkably suitable for this technique because they can be synthesized at room temperature, whereas other lamellar compounds must be prepared at high temperatures, at which polymers would decompose. In the delamination–reaggregation method, lamellar compounds are delaminated in solvent, and then solutions of polymers are added. Nanocomposites are obtained after evaporation of the solvents, or when resulting nanocomposites are insoluble, they are obtained as precipitates during the reactions. In the melt intercalation method, which has been widely used for smectite clays, lamellar compounds are mixed with melted polymers, and polymer chains diffuse into the interlayer regions.

3.2.2. Nanocomposites

Conventional composites have been prepared with a variety of inorganic additives as stabilizers, extenders, or reinforcements for improving the stiffness and strength of polymers. However, these additives sometimes have drawbacks, such as brittleness or opacity. In these conventional composites,

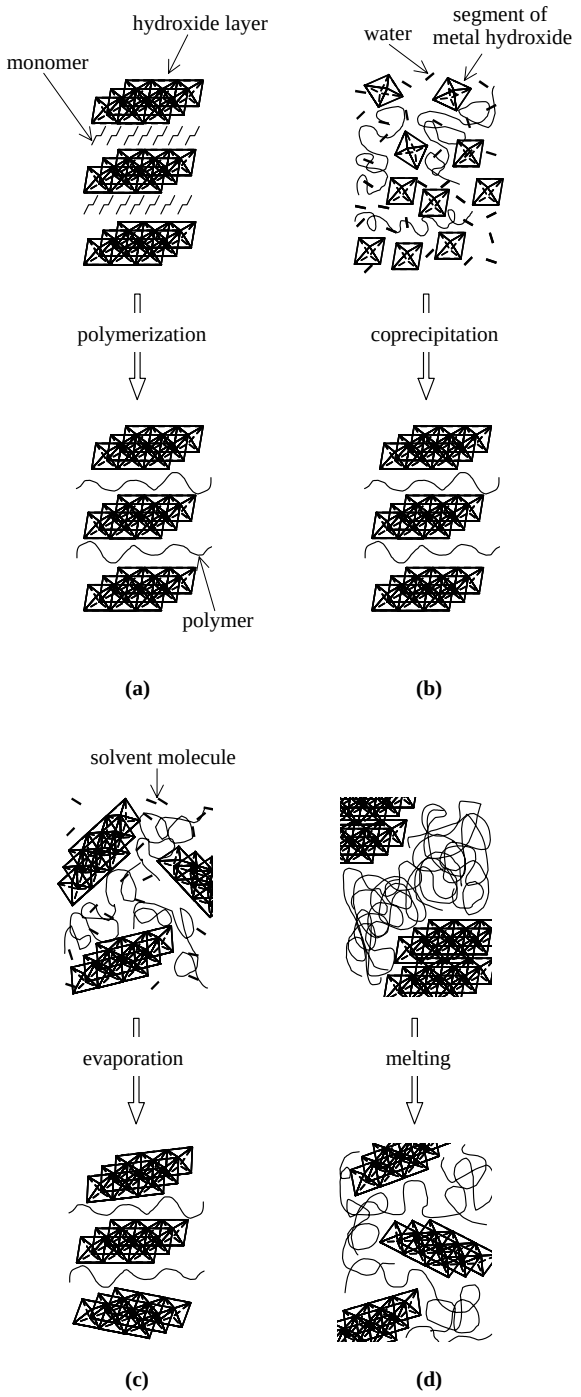

Figure 7. Synthetic routes to polymer/lamellar solid nanocomposites: (a) *in-situ* polymerization method, (b) template method, (c) delamination–reaggregation method, and (d) melt intercalation method.

phase mixing occurs on a macroscopic scale, and the inorganic additives are not homogeneously dispersed at the microscopic level (Fig. 8a). In contrast, nanocomposites are a new class of materials with ultrafine phase dimensions on the nanometer scale, and owing to intimate mixing and improved interfacial properties, they perform better than conventional composites.

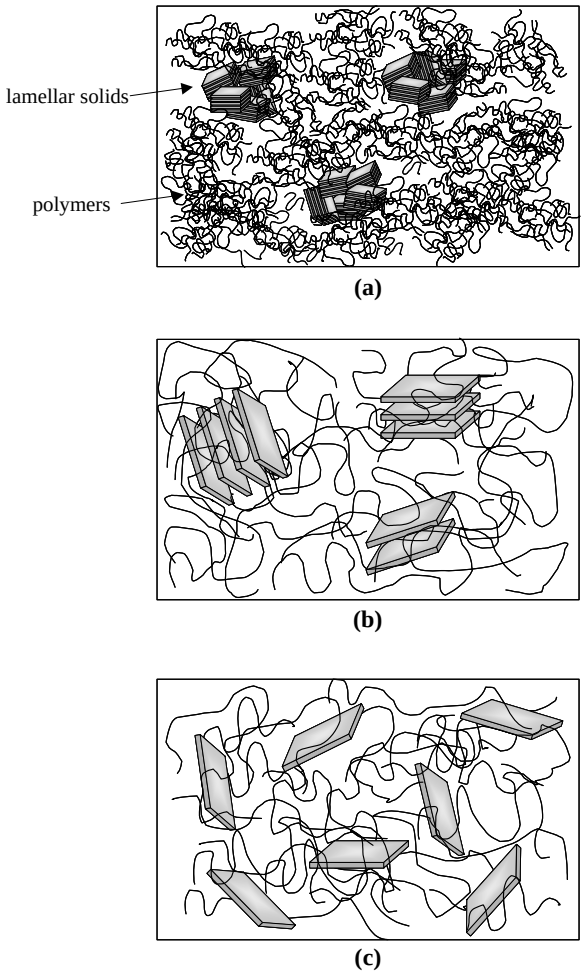

Figure 8. Types of polymer/lamellar solid composites: (a) conventional composite, (b) intercalated nanocomposite, and (c) delaminated nanocomposite. Panel a is drawn on a reduced scale relative to panels b and c.

From a structural viewpoint, there are two types of nanocomposites of lamellar compounds. In intercalated hybrids, a single polymer layer or a few layers are intercalated into the interlayer galleries (Fig. 8b). In delaminated hybrids, single layers of lamellar solids are uniformly dispersed in polymer matrices (Fig. 8c).

Historically, LDHs have been used as flame retardants and as acid neutralizers in stabilizer packages for polymers [97–100]. In these cases, polymers and LDHs form conventional composites. As for nanocomposites of LDHs, they are still at the experimental stage. Most of the polymer/LDH nanocomposite materials reported to date can be categorized as intercalated hybrids. Chemical compositions, basal spacings, and synthetic methods for polymer/LDH nanocomposite materials are summarized in Table 2.

The *in-situ* polymerization method is widely employed for various lamellar materials, such as smectite clays [101–111], graphite oxides [112], zirconium phosphates [113], $RuCl_3$ [114], $HNbMoO_6$ [115], MoO_3 [116, 117], V_2O_5 [118, 119], and FeOCl [120, 121]. Several studies related to LDHs have been also reported; polyacrylate, polyaniline, poly(aminobenzoate), and poly(α,β-aspartate) have been

Table 2. Polymer/LDH nanocomposite materials.

Composition of host layer	Polymer	Basal spacing / Å	Method	Ref.
Mg–Al	polyacrylate	13.4	*in-situ*	[56]
Mg–Al	polyacrylate	poorly crystalline	*in-situ*	[93]
Mg–Al	polystyrene oligomer	23.2	ion exchange	[94]
Li–Al	poly(aminobenzoate)	15.5	*in-situ*	[122]
Ni–Fe	polyacrylate	12.6	template	[125]
Ni–Fe	polyacrylate	12.6	*in-situ*	[125]
Cu–Cr	polyaniline	13.3	*in-situ*	[126]
Cu–Al	polyaniline	13.5	*in-situ*	[126]
Mg–Al	poly(α, β-aspartate)	9.0	*in-situ*	[127]
Mg–Al	poly(α, β-aspartate)	15.1	template	[127]
Mg–Al	poly(styrenesulfonate)	21.0	template	[131]
Mg–Al	poly(vinyl sulfonate)	12.7	template	[131]
Ca–Al	poly(vinyl alcohol)	18.0	template	[132]
Mg–Al	poly(styrenesulfonate)	20.8	template	[133]
Zn–Al	poly(styrenesulfonate)	21.6	template	[133]
Mg–Al	poly(styrenesulfonate)	20.8	template	[134]
Mg–Al	poly(vinyl sulfonate)	13.1	template	[134]
Mg–Al	polyacrylate	12.0	template	[134]
Ca–Al	poly(styrenesulfonate)	19.6	template	[134]
Ca–Al	poly(vinyl sulfonate)	13.2	template	[134]
Ca–Al	polyacrylate	12.4	template	[134]
Zn–Al	poly(styrenesulfonate)	21.6	template	[134]
Zn–Al	poly(vinyl sulfonate)	13.3, 13.0	template	[134]
Zn–Al	polyacrylate	12.4	template	[134]
Co–Al	poly(vinyl sulfonate)	13.3	template	[134]
Zn–Al	poly(styrenesulfonate)	poorly crystalline	delamination–reaggregation	[135]

intercalated into LDHs by *in-situ* polymerization [56, 93, 122–127]. LDHs intercalated with monomers are generally obtained in crystalline phases, and polymerization is usually initiated thermally. Transformation from monomers to polymers is often confirmed by IR analysis [56, 122, 125, 126]. XRD analysis is not suitable to confirm the polymerization because the basal spacing changes are very small.

Other intriguing uses of LDHs have been also reported related to *in-situ* polymerization method [94]. During the polymerization of styrene in aqueous emulsions, LDHs have been added to trap the anionic oligomers for the purpose of monitoring the intermediate states. Moreover, investigation of photoinduced isomerization and polymerization of organic guests is another interesting study [128]. Polymerization and isomerization of muconate anions have been controlled by media used for suspension.

The template method is an advantageous technique for use with LDHs. (There have been only a few reports about the use of this method for lamellar compounds other than LDHs [129, 130].) Poly(α, β-aspartate), poly(styrenesulfonate), polyacrylate, poly(vinyl sulfonate), and poly(vinyl alcohol) have been intercalated into LDH hosts by means of coprecipitation or soft chemistry preparation [125, 127, 131–134]. This method can be used only with water-soluble polymers. The capture of polymer chains by means of the memory effect could also be categorized as a template method [135]. Calcined LDHs have been reconstructed in the presence of anionic polymers, and ordered hybrids have been obtained.

The delamination–reaggregation method is new to LDHs. Delamination followed by restacking has been investigated recently [136]. A possible approach to the fabrication of polymer/LDH nanocomposites via a delamination and reaggregation process has also been reported [135]. The nanocomposite obtained via this approach shows a poorly crystalline phase. Numerous nanocomposites composed of polymers and other lamellar compounds, such as smectite clays, MoO_3, and graphite oxides, have been obtained by this method, and the products are usually intercalated hybrids rather than delaminated hybrids [8–18].

Finally, the melt intercalation method is a practical one because a conventional polymer extrusion or injection molding process can be used. This method has been established for smectite clays with polymers of nylon 6, epoxy, rubbers, and polyolefins [7, 95, 103, 137–147]. Although this method has not yet been applied to LDH nanocomposites, reactions of carbonate LDHs with molten organic acids, such as sebacic, capric, decanoic, and phenylphosphonic acids, have been tested, and it has been found that the organic moieties are partly inserted into the interlayer regions [148–151].

3.3. Nanocomposite Materials from Layered Double Hydroxides

In this section, we review other nanocomposite materials made from LDHs, focusing on the immobilization of guest molecules in the interlayers of LDHs. Through anion

exchange or memory effect processes, a wide range of functional materials can be encapsulated within the nanometer-scale texture of LDHs. The charge density and chemical composition of LDHs can easily be controlled by means of the simple synthetic methods used to prepare them. Control of the charge density permits regulation of the number of guest anions, and compositional diversity can be used to impart electrochemical or redox properties to LDHs. In combination with intercalation reactions, and control of the chemical composition of LDHs should lead to a variety of applications for LDH-based nanocomposites.

LDHs have been used to immobilize biomimetic catalysts [152–155] and photocatalysts [156]. Porphyrins or phthalocyanines, an example of the former, have been confirmed to serve as homogeneous catalysts in aqueous solutions. However, the use of homogeneous catalysts in environmental remediation technologies is impractical because separation of the aqueous catalysts, reactants, and products is difficult. Porphyrins or phthalocyanines intercalated into LDHs by anion exchange, memory effect, and template methods have been verified to be active and separable from the reaction solutions, although some inevitable drop in activity is observed, owing to hindered access to intercalated porphyrins or phthalocyanines.

Polyoxometalate photocatalysts, such as $[W_7O_{24}]^{6-}$, $[W_{10}O_{32}]^{4-}$, $[PW_{12}O_{40}]^{3-}$, $[SiW_{12}O_{40}]^{4-}$, and $[P_2W_{18}O_{62}]^{6-}$, effectively degrade organochlorine pesticides. Again, these polyoxometalates are water soluble, and water-insoluble supports are necessary for recycling of the catalysts. LDHs intercalated with $[W_7O_{24}]^{6-}$ anions have been synthesized via anion exchange, and they show photocatalytic activity against hexachlorocyclohexane.

The creation of novel microporous materials by means of intercalation of polyoxometalates into LDHs has also been intensively studied [19, 47–49, 157, 158]. These polyoxometalate- LDHs are synthesized by means of anion exchange, memory effect, and template methods. However, a delamination method like the one used to intercalate bulky inorganic ions into zirconium phosphates [20, 21, 67, 68] might be a better method for intercalation of polyoxometalates into LDHs.

Immobilization of electroactive anions in LDHs has been also reported. LDHs containing transition metals such as Ni, Co, and Mn have been found to be redox active [159, 160]. When these LDHs are used as electrode modifiers, they immobilize electroactive anions in the interlayers and enhance the electron-transfer rate toward the intercalated ions. Thin hybrid films of an amphiphilic anionic Ru(II) complex with Ni–Al LDHs have been prepared by the Langmuir–Blodgett (LB) method [161]. The nickel sites in the LDH layers act as mediators, oxidizing the Ru(II) cyano complex in the interlayers. The hybrid films may thus be used as electrochemical sensors of, for example, bimolecular materials. However, these hybrid films are composed of 30–70 LDH layers, not single layers, because LDHs are not delaminated under the preparation conditions used. In contrast, layer-by-layer assemblies have been developed for other lamellar compounds. Single layers of titania or zirconium phosphate and polycations have been alternately deposited on substrates [17, 18], and LB films prepared with delaminated smectite clay layers have been also reported [162]. The delamination techniques recently elaborated for LDHs may also provide a method for fabricating well-structured thin LDH hybrid films.

There have also been reports of the incorporation of C_{60} into LDHs by anion exchange with C_{60} charged by chemical reduction or by co-intercalation with organic anions and solvents [163, 164]. The interaction between LDH layers and C_{60} alters the photophysical properties of C_{60} and enhances its photoluminescence. There have also been attempts to intercalate a range of biochemical substances into LDHs, mainly by anion exchange, with the aim of developing pharmaceutical or cosmetic uses [165–172]. Amino acids, vitamins, enzymes, nucleosides, and adenosine triphosphate (ATP) have reportedly been used for this purpose. The modification of LDHs by organic surfactants and various organic anions has been intensively studied with the goal of changing the surface properties of the LDHs [173–176]. In addition, such organic anion intercalates of LDHs have been subjected to calcination, which produces carbon/LDH nanocomposites, and the catalytic activity or porosity of these composites has been evaluated [177–179]. Polymerization of silicates in LDHs has been also studied [180, 181] and appears to be a new synthetic approach to the preparation of smectite-like clays via a chimie duce route.

4. SUMMARY

LDHs are versatile compounds for fabricating nanocomposites with a wide range of materials. The lamellar nature of LDHs permits host–guest chemistry and intercalation reactions, which invoke considerable attention from material designers.

Delamination technique is one of the most versatile routes to fabricate nanocomposites. The novel delamination techniques for LDHs that have been reported should trigger the development of a variety of new nanocomposites of LDHs. Moreover, the synthetic route of LDHs is environmentally benign, which has become increasingly important recently. There are many other valuable features of LDHs, such as facileness in synthesis, anion exchange ability, versatility in chemical composition, and memory effect as an intercalation method. The number of reports about LDHs has considerably increased during the past decade, and the above-mentioned useful characteristics of LDHs for fabrication of new functional materials including nanocomposites should stimulate even more research.

GLOSSARY

Delamination Phenomenon that layers of lamellar solids come apart into single layers or packets of a few layers in appropriate solutions or media.

Exfoliation Has the same meaning as delamination.

Hydrotalcite-like compound Other general term for layered double hydroxide.

Intercalation Insertion of molecules or ions into interlayers in lamellar solid.

Interlayer The weakly interacting region between the stacked sheets in lamellar solid.

Lamellar solids Compounds that possess layered structure.

Layered double hydroxides A class of lamellar solids, consisting of positively charged hydroxide layers with charge-balancing anions and water molecules in interlayers.

Layered structure The structure in which basal sheets of atoms that are tightly bonded within the sheets but relatively weakly bonded in the direction perpendicular to the sheets are stacked on top of one another.

Nanostructured Metals and Alloys

Dmitri Valentinovich Louzguine, Akihisa Inoue

Tohoku University, Aoba-Ku, Sendai, Japan

CONTENTS

1. INTRODUCTION

Nanostructured metals or more widely speaking metallic materials with a nanoscale size microstructure are relatively new and prospective types of substances that demonstrate superior properties in a wide range. Among them are materials with exclusively high mechanical, enhanced magnetic, electronic, and optical properties. Such properties were obtained due to a very small structure unit (grain, particle, layer) size ranging from 1 to 100 nm, much smaller than that obtained in conventional metallic materials or alloys. Such a unit can have a crystalline, quasicrystalline, or amorphous structure. Due to a small structure unit size these materials are often in highly nonequilibrium state, although lots of them exhibit remarkable stability against structural coarsening. Current and potential applications of nanocrystalline materials are structural materials, different electronic, magnetic, and optical devices, filters, batteries, displays, biomaterials, and protective coatings.

Nanostructured metallic materials (here also called nanomaterials) can be obtained as a group of separated particles or as a polycrystalline sample in a bulk form. The development of age-hardened Al–Cu alloys, discovered by Wilm in the beginning of the 20th century [1], with nanoscale Guinier–Preston zones, θ'' and θ' phases, can be considered one of the first examples of use of the nanocrystals in materials for practical purpose [2]. Several decades later, synthesis of new materials by tailoring of structure at the submicronic, nanoscale, and atomic or molecular scale has become an important interdisciplinary field.

In this chapter we will emphasize metallic nanostructured materials and will not pay much attention to semiconductors, nonmetallic materials, ceramics, and oxides which, however, also produce a large group of technologically important nanomaterials.

2. PRODUCTION

At an early stage of nanomaterials studies ultrafine particles, for example, Pd with face centered cubic (fcc) structure equal to that of the bulk specimen and a mean size of 2 nm, were prepared by a vacuum evaporation method [3]. Fine gold particles were prepared by a gas evaporation technique [4]. Considerable progress of the processing procedure for obtaining nanomaterials has been achieved in the last decade. At present nanomaterials can be produced using various methods from vapor phase (inert gas condensation [5], vapor deposition, sputtering [6, 7]), liquid phase (rapid solidification [8], electrodeposition [9]), or solid phase (mechanical attrition [10], severe plastic deformation [11, 12], devitrification of glassy alloys [13], pulse plating by nanoscale deposits [14], laser beam treatment of the surface, etc.).

The processing procedure can be separated into single-step and double/multistep processes. The former it preferable if the properties are not worsened. Very important from a practical viewpoint, bulk nanomaterials can be produced in a single-step process by casting, for example, or a double-step process like compaction of the preprepared particles.

The same material can be produced by different techniques. For instance, pure nanocrystalline hexagonal close packed (hcp) Co with a grain size below 15 nm has been produced by inert gas condensation [15] and a ball milling technique [16] respectively. However, the method of production often has a significant influence of the properties of nanomaterials.

Mechanical attrition and severe plastic deformation offer the possibility of production of nanomaterials in commercial quantities. The influence of high energy [17] and low energy [18] ball milling on the crystallite size and lattice strain was studied. However, during mechanical attrition the

Encyclopedia of Nanoscience and Nanotechnology
Edited by H. S. Nalwa
Volume 7: Pages (669–697)

problems of powder contamination from milling device and atmosphere, as well as a problem of powder consolidation without coarsening, are still to be solved. Fundamental studies of the microstructural development in ball-milled pure elements have defined the sequence of events leading to nanocrystalline grains with average grain size from 2 to 20 nm [19, 20]. The grain size is found to decrease with milling time down to a constant value. There is a balance between defect creation and recovery during deformation. At the same time, amorphous alloys can also be prepared by ball milling [21].

Nanostructured metals, and even metalloids, can also be produced by severe plastic deformation. For example, nanostructured Si with a mean grain size of less than 20 nm was obtained by torsion straining [22]. The structure is characterized by a small grain size and a specific structure of grain boundaries. A high level of elastic strain and significant microdistortions of the crystal lattice were also observed.

Deformation mechanisms during mechanical milling and a severe plastic deformation process leading to the formation of ultrafine grains require investigation. It is considered that shear processes requiring crystal rotation are required for nanocrystal formation and disclinations may contribute to this process [23]. Very recently high resolution transmission electron microscopy (HRTEM) observation showed partial disclination dipoles in body centered cubic (bcc) Fe that had undergone severe plastic deformation by mechanical milling [24]. It was shown that the formation and migration of such partial disclinations during deformation allow crystalline grains to rotate and rearrange at the nanometer level. The formation of partial disclination dipoles and other disclination defects facilitating deformation under high stresses can also cause considerable strengthening, owing to the interaction of their elastic stress fields with each other and with grain boundaries.

Nanoparticles of crystalline or quasicrystalline phase can be produced directly from the liquid on rapid solidification by the cooling rate-controlled process [25]. For example, the size of the icosahedral particles homogeneously distributed in Zr–Pt [26] alloy is below 10 nm. The formation of the nanoscale icosahedral phase indicates that the icosahedral short-range order exists in the melt of Zr–Pt binary alloy.

Nanoscale particles of a crystalline or quasicrystalline phase can be easily produced by devitrification of the glassy alloys. This indirect method of production of nanostructure requires formation of the glassy phase in the initial stage and its subsequent full or partial devitrification on heating. However, as has been mentioned such a structure can also be obtained directly during rapid solidification or casting by the control of cooling rate.

If the process involves nucleation and growth then a high nucleation rate and low growth rate of the precipitating phase are required in order to obtain a nanostructure. Such conditions are usually obtained under primary devitrification with long-range diffusion controlled growth [27]. For example, Al-rich amorphous alloys with high Al concentrations above 85 at%, in general, suffer double or multistage devitrification in which the first-stage exothermic reaction is due to the precipitation of fcc-Al and the other exothermic peaks result from the decomposition of the residual amorphous phase to intermetallic compounds. Nevertheless, nanocrystalline structure was also obtained after eutectic [28] and polymorphous [29, 30] devitrification of glassy alloys. Another type of phase transformation in amorphous solid leading to formation of a nanostructure is spinodal decomposition [31, 32].

Al–RE–TM (RE—rare earth metals, TM—transition metal) system glassy alloys, produced in late 1980s in Japan [33, 34] and the United States [35], belong to one of the most important groups of Al-based metallic glasses discovered to date. These alloys were obtained by adding TM to binary Al–RE alloys produced shortly before [36, 37]. Simultaneous alloying with RE and TM caused drastic widening of the composition range of the amorphous single phase. These alloys are usually produced in a ribbon shape by the melt spinning technique [38] or in a powder one by gas atomization [39]. It is important that amorphous alloys in the ternary Al–RE–TM system, for example, Al–Y–Ni, in addition to their high strength possess good bend ductility, that is, show the ability to be bent 180° without fracture [40, 41]. An addition of Co partially replacing Y in the $Al_{85}Y_{10}Ni_5$ [here and elsewhere alloy compositions are given in nominal atomic percents (at%)] increased tensile fracture strength, for example from 920 to 1250 MPa in the case of $Al_{85}Y_8Ni_5Co_2$ metallic glass, without worsening of bend ductility [42]. At the same time, the addition of 2 at% Co to $Al_{85}Y_{10}Ni_5$ alloy also caused drastic increment of the glass-forming ability. Critical ribbon thickness being still less than 1 mm increased from 120 to 900 μm [42]. Moreover, high-strength quaternary $Al_{85}Y_8Ni_5Co_2$ alloy shows one of the widest supercooled liquid regions on heating among Al-based metallic glasses.

However, ease of devitrification of the Al-based glassy samples connected with high density of so-called quenched-in nuclei in some glasses as well as low reduced glass-transition and devitrification temperature in other glasses [43] imposes a limit on the sample's critical thickness below 1 mm. At the same time $Al_{85}Ni_{10}Ce_5$ bulk amorphous samples of high relative density were obtained by warm extrusion of atomized amorphous powder [44].

Different Al–RE–TM glasses containing about 85 at% Al show primary precipitation of Al solid solution (α-Al) nanoparticles on heating [45, 46] with extremely high nucleation rate [47, 48] of above 10^{20} $m^{-3}\,s^{-1}$. Fcc α-Al lattice parameter measurements and atom probe ion field microscopy investigation [49] showed a very low concentration of the alloying elements in nanocrystalline Al in accordance with phase diagrams [50] of Al–RE and Al–TM. Segregation of the RE metal having low trace diffusivity in Al on the α-Al/amorphous phase interface is considered to be one of the most important reasons for the low growth rate of α-Al. Nearly the same effects were observed during formation of the α-Fe nanocrystals [51]. It is also important that primary devitrification requires long-range diffusion that impedes crystal growth [52].

One should mention that the devitrification behavior of various Al–Y–Ni–Co alloys has been also studied, and at definite compositions formation of the α-Al was observed at the primary stage [53, 54]. Y-, Sm-, Gd-, and Dy-bearing metallic glasses of the $Al_{85}RE_8Ni_5Co_2$ composition showed precipitation of the α-Al nanoparticles after continuous

heating using differential scanning calorimetry (DSC) at a high enough heating rate (0.67 K/s and higher) or annealing at the temperature above T_g. For the aforementioned alloys a heating rate of 0.67 K/s is high enough to prevent devitrification below T_g. At the same time, Y-, Gd-, and Dy-bearing metallic glasses [55] as well as $Al_{85}Y_4Nd_4Ni_5Co_2$ [56] showed simultaneous formation of the intermetallic compound(s) and α-Al nanoparticles, or primary formation of the intermetallic compound only after annealing below T_g. For example, the $Al_{85}Y_8Ni_5Co_2$ alloy shows formation of an unknown intermetallic compound conjointly with α-Al nanoparticles after annealing up to the completion of the primary phase transformation. After the completion of the primary phase transformation a lot of relatively small intermetallic compound particles below 50 nm size exist in the structure of the $Al_{85}Y_8Ni_5Co_2$ alloy. The intermetallic compounds are metastable and have a multicomponent composition. The volume fraction of the intermetallic compound is higher than that of α-Al and the fraction of α-Al depends upon annealing temperature below T_g. It should be also noted that the multicomponent intermetallic phase is a leading phase during isothermal devitrification of $Al_{85}Y_4Nd_4Ni_5Co_2$ below T_g (i.e., starts to precipitate prior to α-Al).

It has been also reported that in some Al–TM–RE glasses devitrification appears to be preceded by amorphous phase separation that leads to formation of a nanostructure [57].

Devitrification of nanocrystal-forming Ti-based alloys, for example, the $Ti_{50}Ni_{20}Cu_{23}Sn_7$ alloy, begins from the primary precipitation of a nanoscale equiaxed, almost spherical particles of Ti_2Ni solid solution (other alloying elements are partially dissolved in this phase) with a lattice parameter of 1.138 nm (Fig. 1) [58]. Although only Ti_2Ni solid solution phase was observed to precipitate during the primary devitrification reaction the trace of heat release corresponding to primary devitrification reaction studied by DSC and isothermal calorimetry (Fig. 2) has a complicated shape. This demonstrates a change of the growth rate during primary crystallization according to Kolmogorov [59], Johnson and Mehl [60], and Avrami [61], and Kelton [62]. The general exponential equation for the fraction transformed is

$$x_e(t) = \frac{4\pi}{3V_0}\int_0^t I(\tau)\left[\int_\tau^t g(t')\,dt'\right]^3 d\tau \qquad (1)$$

where $I(\tau)$ and $g(t')$ are time-dependent nucleation and growth rates, respectively. This feature has also been observed in Zr-based alloy [63]. Difficulty of nucleation of the Ti_2Ni solid solution having a large lattice parameter and complicated composition is one of the reasons for the elevated glass-forming ability of the Ti–Ni–Cu–Sn amorphous alloy studied.

The largest Ti_2Ni particle size in the beginning of the transformation and after its completion is plotted versus transformation time in Figure 3. Crystal size (average of three measurements for the largest particle) versus transformation time (without incubation period) dependence has a nonlinear character and indicates a diffusion-controlled growth. Cu atoms are mostly rejected into the residual glassy matrix.

Formation of the nanoscale icosahedral phase was observed in Zr–Cu–Al, Zr–Al–Ni–Cu [64], and Zr–Ti–Ni–Cu–Al [65] glassy alloys containing an impurity of oxygen above about 1800 mass ppm, although no icosahedral phase is formed if the oxygen content is lower than 1700 mass ppm. Recently the nanoscale icosahedral phase was obtained in Zr–Al–Ni–Cu–Ag [66], Zr–Al–Ni–Cu–Pd [67], Zr–Ni–NM [68] (NM-noble metals), Ti–Zr–Ni–Cu [69], Zr–Cu–Ti–Ni [70], Zr–Al–Ni–Cu–(V, Nb, or Ta) [71], Zr–Pd [72], and Zr–Pt [73, 74] system alloys at much lower (typically about 800 mass ppm) oxygen content. The icosahedral phase is also formed in $Zr_{70}Cu_{29}Pd_1$ alloy at very low Pd content [75]. It is also noted that the Zr-based amorphous alloys containing the NM elements exhibit the glass transition followed by the supercooled liquid region and hence the icosahedral phase precipitates from the supercooled liquid. At the same time, recently the nanoscale icosahedral phase has been produced in Zr–Al–Ni–Cu glassy alloys with low oxygen content below 500 mass ppm [76].

The study of the amorphous → icosahedral phase transformation in a $Zr_{65}Al_{7.5}Ni_{10}Cu_{7.5}Ag_{10}$ showed that the quasilattice constant decreases with annealing time and the

zirconium and silver content in the icosahedral particles differs from those in the remaining amorphous matrix [77]. It confirms that this is a nonpolymorphous, rather primary-type reaction.

The local atomic structures around Pt as well as Zr in the amorphous and quasicrystalline $Zr_{70}Al_6Ni_{10}Pt_{14}$ alloys have been determined by the anomalous X-ray scattering method [78]. The existence of chemical short range order clusters was found around Pt atoms in the glassy state as well as in the quasicrystalline phase.

Two very important parameters of such composite nanomaterials are grain (particle) size and its volume fraction. Primary devitrification of highly supercooled liquid or amorphous phase often has the following unique features, that is, high nucleation frequency, low crystal growth rate, high concentration gradient of solute element at liquid/solid interface resulting from low atomic diffusivity, formation of metastable phases by the control of redistribution of solute elements, formation of a residual amorphous phase with high solute concentration, defect-free nanocrystalline particles with low residual strain, highly dense packed structure at liquid/solid interface, nanoscale interparticular spacing, and size and shape effects of nanoscale spherical particles. By utilizing these features, new nanoscale mixed-phase alloys containing a residual amorphous phase were obtained by devitrification of glassy alloys [79].

Various Ge–Cr–Al–RE amorphous alloys show a wide exothermic DSC peak preceding crystallization (Fig. 4). After the completion of this heat effect the structure remains almost amorphous, although medium range order zones below 1 nm in size were observed in heat treated as well as in the as-solidified state (Fig. 5, encircled).

The nature of the broad exothermic peak has been studied in the $Ge_{70}Cr_{16}Al_{10}Nd_4$ alloy by differential scanning calorimetry and X-ray diffraction [81]. The resultant coordination numbers for the first and second peaks of ordinary radial distribution function in the as-solidified state are 2.8 at 0.258 nm and 4.4 at 0.310 nm, respectively. The corresponding coordination numbers for the sample heat-treated up to the completion of the first broad heat effect are 3.3 at 0.250 nm and 2.9 at 0.308 nm, respectively [81]. The ratio between the second and the first nearest neighbor distances (0.41 and 0.250 nm, respectively) of 1.64 is almost identical with the value of 1.63 for *a*-Ge and *c*-Ge. The results indicate that during heat treatment tetrahedral configuration of Ge atoms which is close to the configuration observed in pure amorphous and crystalline Ge was formed. Formation of Ge-enriched zones precedes devitrification.

Finely dispersed nanoscale fcc Ge precipitates upon solidification of Ge–Al–TM–RE rapidly solidified alloys (Fig. 6) or upon devitrification of Ge–Al–TM–RE amorphous solids (Fig. 7) [82].

In Ge-based alloys one of the reasons for a nanoscale Ge particle size except for the diffusion-controlled growth discussed previously is elastic strain arising from volume changes upon precipitation. Tetrahedrally bonded crystalline Ge has higher specific volume compared to metallic liquid with a higher coordination number.

Precipitation of the nanoscale Ge–Si solid solution finely dispersed particles induced by Ge addition was observed in rapidly solidified $Si_{55-x}Ge_xAl_{20}Fe_{10}Ni_5Cr_5Zr_5$ alloys (Figs. 8 and 9) [83]. Average particle size of nanoscale Ge calculated

from the broadening of the diffraction peaks increases with increase in Ge content and was found to be in good agreement with that obtained from TEM observations (Fig. 10). The smallest Ge particle size was obtained in $Si_{48}Al_{20}Fe_{10}Ge_7Ni_5Cr_5Zr_5$ alloy and these particles are finely dispersed (see Fig. 8).

The Ge diffraction peaks are shifted to higher 2θ angle values and lower interlattice distances d_{hkl} by the dissolved Si. The amount of Si dissolved in Ge decreases and the lattice parameter of Ge solid solution increases with increasing Ge concentration in the alloy as shown in Figure 11 [83]. Such a material consisting of nanosize particles of crystalline Ge solid solution (semiconductor with high electrical resistivity of about 4.7×10^5 $\mu\Omega$ m) in Si-based amorphous matrix has a resistivity of 11–13 $\mu\Omega$ m depending on the composition and can be possibly applied in electronic materials.

Structure types that can be obtained in rapidly solidified Si, Ge, Al, and TM containing alloys are summarized in Table 1 [84].

3. CLASSIFICATION

As the first approximation dimensionality of nanomaterials (in how many of three dimensions a material has a nanoscale size) can be used for their classification. Thin layers, multilayers, coatings, and quantum well structures can be treated as one-dimensional nanomaterial; thin wires [85, 86] or nanotubes (carbon [87] or BN [88], for example) as two-dimensional nanomaterial; and submicrometer grains, isolated particles, fullerenes [89], and quantum dots as three-dimensional nanomaterials, that is, they have a nanoscale size in any of the three dimensions (atomic clusters can also fit into this group). However, nanoscale coatings and films on the surface of bulk materials being actually one-dimensional can be considered as a special class of nanomaterial. Bulk polycrystalline nanostructured materials having a size exceeding 1 mm in any dimension nevertheless consist of nanoscale grains. Nanocomposites [90] are another quickly developing branch in the field of nanomaterials. A classical example is age-hardened Al-based alloys consisting of an aluminum solid solution matrix reinforced with dispersed (tens of nanometers in size) nanoparticles.

H. Gleiter, one of the founders of the nanomaterials field, proposed another classification scheme consisting of three categories [91]. The first category contains materials or devices with reduced dimensions in the form of (isolated, substrate-supported, or embedded) nanometer-sized particles, thin wires, or thin films. The second category comprises materials in which the nanometer-sized microstructure is

limited to a thin (nanometer-sized) surface region of a bulk material. Third category includes bulk solids with a nanoscale microstructure grain, crystallite, dendritic cell size, etc. There are two classes of such solids. In the first class, the atomic structure and/or the chemical composition varies in space continuously throughout the solid on an atomic scale. Glasses, gels, supersaturated solid solutions, or implanted

materials are examples of this type. A second class of materials with a nanoscale microstructure are assembled of nanoscale size structure units, mostly crystallites. These structure units may differ in their atomic structure, their crystallographic orientation, and/or their chemical composition. If the units are crystallites, incoherent or coherent interfaces may be formed between them, depending on the atomic structure, the crystallographic orientation, and/or the chemical composition of adjacent crystallites. In other words, materials assembled of nanometer sized structure units are microstructurally heterogeneous consisting of the grains (crystallites) and the regions between adjacent grains (e.g., grain boundaries). This inherently heterogeneous structure on a nanometer scale is crucial for many of their properties and distinguishes them from glasses, gels, etc. that are microstructurally homogeneous. One should also say that glassy alloys phase separated by a spinodal mechanism represent a nanomaterial with two kinds of glassy phases.

Although nanostructured materials are mostly in nonequilibrium state equilibrium nanomaterials also exist as self-assembled structures. Supramolecules are produced by the intermolecular association of receptors and substrates following an inherent assembling pattern based on the principles of molecular recognition. Supramolecular self-assembly concerns the spontaneous association of a number of components resulting in the generation of supermolecules or extended polymolecular assemblies such as molecular layers and films [92, 93]. However, in this chapter we will focus on nanostructured metals and alloys only.

4. STRUCTURE

Knowledge of the structure of nanomaterials, especially their grain boundaries, is critical for understanding their properties. Among the techniques used for structure characterization of nanomaterials are X-ray diffractometry (XRD), TEM, including (HRTEM) imaging, Mössbauer spectrometry, etc. [94]. HRTEM is a direct and extremely powerful method for observation of nanostructure. The atom probe technique also has been used for materials characterization and demonstrated a unique capability of characterizing local chemical compositions of nanoscale metallic microstructures. In particular, the three-dimensional atom

probe (3DAP) technique gives three-dimensional mapping of all alloying elements in a real space with a near atomic resolution. Thus, HRTEM and 3DAP are the most suitable techniques for analyzing composition of nanoscale precipitates, zones, or clusters. Devitrification in Zr-based bulk metallic glasses has been directly detected using high intensity, high energy monochromatic synchrotron beam diffraction in transmission during *in-situ* heat treatment [95].

4.1. Nanocrystalline Alloys

An important problem is precise determination of the nanocrystal size. TEM allows direct imaging and calculation of the grain size and is one of the most powerful techniques for structural investigation of nanomaterials. Moreover, nanobeam electron diffraction and energy dispersive X-ray spectrometry (EDX) allow direct analysis of the crystal structure and chemical composition of nanoparticles. However, the grain overlap problem sometimes produces difficulties in determination of the average grain size. Analysis of the broadening of the diffraction peaks obtained by XRD gives an average crystal size of the whole sample [96]. However, broadening of the XRD diffraction peaks is caused by both small grain size and microdeformation. Although there are several methods to analyze and separate an income of the grain size and microdeformation to the broadening of the diffraction peak [97–99] the resulting grain size differs from method to method [100].

X-ray-diffraction measurements performed on a nanocrystalline Cu sample made by severe plastic deformation showed that the shape of the diffraction peaks was found to be represented primarily by a Lorentzian function. A small difference was revealed between the integrated intensities from the nanocrystalline and a reference Cu sample. The broadening of the diffraction peaks of the nanocrystalline Cu sample was induced by both small crystallite size and microstrain inside the grains [101]. Although at the grain size below 50–100 nm dislocations easily annihilate on the grain boundaries the lattice of nanomaterials obtained by severe plastic defloration is heavily distorted elastically. It was found that the grain sizes of nanocrystalline Cu in different crystallographic orientations are essentially the same, while the microstrain exhibits a significant anisotropy. Nanomaterials obtained by severe plastic deformation show a high level of elastic strain in the grains and in the areas close to grain boundaries the elastic strain level is much higher than in the central regions.

Due to a very small grain (structure unit) size nanostructured materials have a high fraction of grain boundaries. The volume fraction of atoms directly influenced by grain boundaries can be estimated by the formula $V_g = 3e/\langle d \rangle$, where e is an average effective thickness of the zone of influence of grain boundaries and $\langle d \rangle$ is the average grain size [102]. For $e = 1$ nm and $\langle d \rangle = 10$ nm V_g is $\sim$30%. High volume fraction of atoms at grain boundaries gives a large contribution to Mössbauer spectra. Although Mössbauer spectrometry is a less direct technique than HRTEM it provides complementary information on statistical features which are difficult to obtain using TEM [103]. It has been also shown that the coordination number of nanostructured Pd as a function of the interatomic spacing is different from that of a conventional polycrystalline Pd [104] which is also connected with the high volume fraction of grain boundaries.

The grain boundaries in nanomaterials have been also studied by TEM. Initially it was considered that grain boundaries in nanomaterials are thicker than those of the conventional alloys [91]. However, high resolution TEM studies (Fig. 12) showed that thickness of grain boundaries, for example in nanostructured Pd [105], does not exceed 1–2 interatomic distances.

An important question is do grain boundaries in nanomaterials differ from that in conventional materials? As reported in [106, 107] grain boundaries in nanomaterials have the short range order of grain boundaries formed in conventional polycrystalline materials. However, other studies showed that the grain boundaries in nanomaterials, especially obtained by plastic deformation, contain defects and thus have high energy and nonequilibrium character [108, 109]. One can say that the type of grain boundary (equilibrium or nonequilibrium [110]) also depends upon the production method of the nanomaterial.

All the aforementioned also supports the idea that nanostructured materials are different from conventional polycrystalline materials.

4.2. Nano-Quasi-Crystalline Alloys

An icosahedral phase is formed in rapidly solidified Al–TM based alloys containing Mn [111], Cr [112], and V [113, 114] as TM elements. It is possible to obtain nanostructure by using a high cooling rate or severe plastic deformation. The Al–TM base icosahedral structure has been presumed [115] to consist of Mackay icosahedral clusters containing 54 atoms which are arranged through glue atoms into a three-dimensional quasiperiodic structure. Nanomaterial consisting of icosahedral almost spherical particles with diameters below 10 nm was obtained in Zr–Pt alloy [26] by casting. The formation of the nanoscale icosahedral phase during casting indicates that the icosahedral short-range order exists in the melt of the Zr–Pt binary alloy. For example, the structure of the $Zr_{65}Al_{7.5}Ni_{10}Cu_{12.5}Pd_5$ alloy annealed for 18 s at 725 K is shown in Figure 13.

Local atomic structures around NM as well as Zr in amorphous and quasicrystalline Zr-based alloys have been

determined by anomalous X-ray scattering. The existence of chemical short range order clusters that are formed around the NM atom in the amorphous as well as in the quasicrystalline phase [78] is confirmed.

Quasicrystals can often coexist with rational approximant crystalline structures. A multiple twinning around an irrational axis of the approximants has been reported in an aggregate of fine size cubic crystallites. The crystalline aggregate symmetry is linked to the icosahedral point group symmetry ($m\bar{3}\bar{5}$) [117].

4.3. Nanostructured Alloys with Mixed Glassy and (Quasi)Crystalline Structure; Nanocomposites

Nanoscale particles of a crystalline or quasicrystalline phase can be easily produced by devitrification of glassy alloys. Figure 14 summarizes the features of the microstructure of nonequilibrium Al-based alloys. The nonequilibrium structures for Al-based alloys are classified into the following six types, (1) amorphous single phase, (2) nanostructure consisting of Al and compounds obtained by devitrification of amorphous phase, (3) partially crystallized structure of nanoscale fcc-Al particles embedded in an amorphous matrix, (4) nanoquasicrystalline structure consisting of nanoscale quasicrystalline particles surrounded by Al phase without grain boundary, (5) coexistent nanogranular amorphous and Al phases, and (6) nanogranular Al phase surrounded by an amorphous network.

The structure types of Zr-based nanostructured alloys with mixed glassy and (quasi)crystalline structure are shown in Figure 15.

One should also mention that some bulk glassy alloys, for example $Zr_{55}Co_{20}Al_{12}Cu_5Nb_8$, contain medium-range order (MRO) zones and nanoscale particles in as-solidified state (Fig. 16) even though these precipitates do not produce

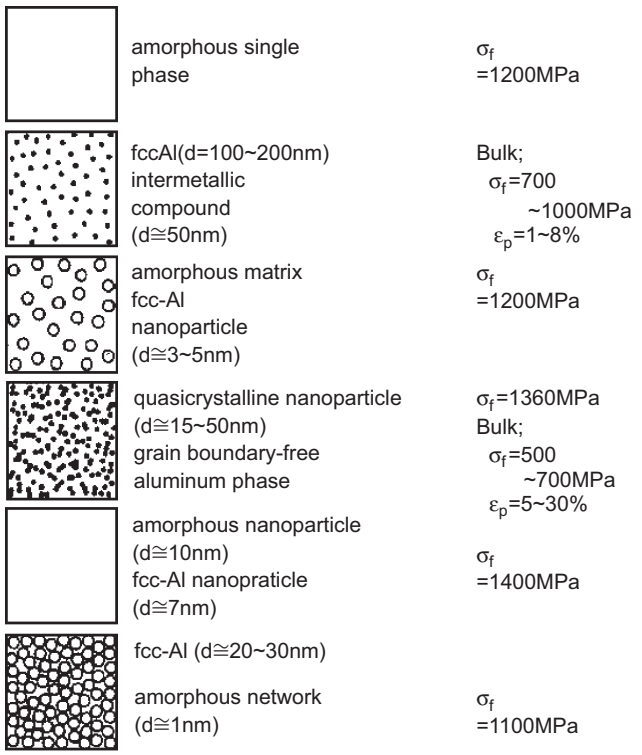

Figure 14. Microstructure and mechanical properties of nonequilibrium Al-based alloys. Reprinted with permission from [118], A. Inoue and H. M. Kimura, *J. Metastable Nanocryst. Mater.* 41 (2001). © 2001, Trans Tech.

diffraction peaks in the XRD and selected-area electron diffraction pattern due to their low volume fraction.

4.4. Grain Growth and Other Structure Changes on Heating Except for Phase Transformations

The driving force of grain growth in metal or alloy is the excess of free energy. Although nanoscale grains in nanostructured metals and alloys usually contain no dislocations they have an extremely large fraction of atoms in grain boundaries. In nanomaterials obtained by severe plastic deformation these grain boundaries have a nonequilibrium nature and have grain boundary dislocations [121]. These dislocations cause a high level of elastic strain.

Grain growth in nanostructured materials obtained by severe plastic deformation having highly nonequilibrium grain boundaries starts at quite a low reduced temperature [122, 123].

Grain growth in nanostructured metals and alloys has been studied [124, 125]. Structure changes in nanocrystalline Fe on heating were studied by X-ray diffraction and DSC [126] and it is found that the n exponent in the equation [127, 128]

$$D^{1/n} - D_0^{1/n} = k't \tag{2}$$

for a mean grain diameter D after time t where k' is the rate constant deviates from (0.5) what it should be in the

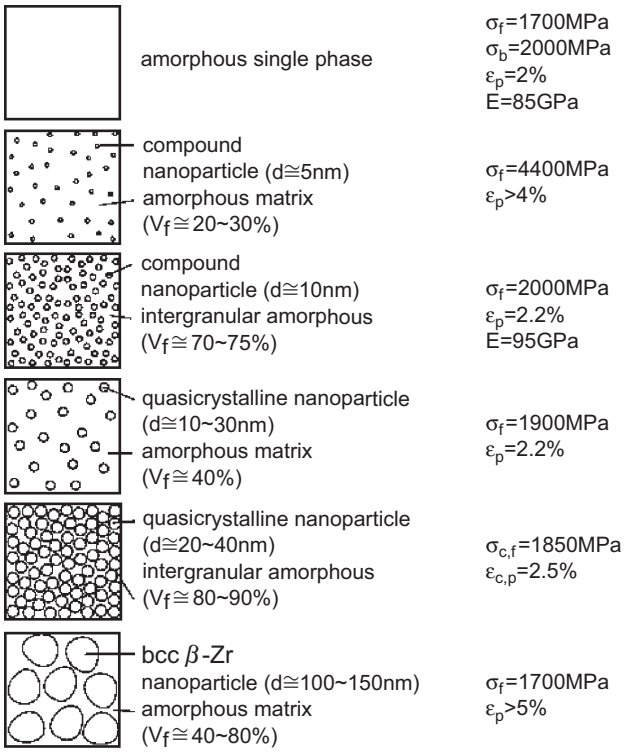

Figure 15. Microstructure and mechanical properties of nonequilibrium Zr-based bulk alloys in Zr–Al–Ni–Cu and Zr–Al–Ni–Cu–M (M = Ag, Pd, Au, Pt, or Nb) systems. Reprinted with permission from [119], A. Inoue et al., *Sci. Technol. Adv. Mater.* 1, 73 (2000). © 2000, Elsevier Science.

case of parabolic growth. The same results were obtained by other researchers [129, 130].

Another process taking place on heating is the relaxation process leading to reduction of dislocation density. For example, this process took place under heating of nanostructured Ni obtained by severe plastic deformation and was followed by recrystallization [131].

Nanoparticles obtained by devitrification of glassy phase in many cases show quite high thermal stability against coarsening [132]. The grain growth curve of cF96 Ti_2Ni crystalline nanoparticles in Ti-based glassy matrix shows significant retardation of the particle growth rate when they reach a size of about 20 nm (Fig. 3) due to diffusion controlled growth. At the diffusion controlled growth a particle radius r or diameter D is proportional to $t^{1/2}$. Fitting of the particle size versus time curve (Fig. 3) gives an exponent value of 0.25. Such a low value is possibly due to rejection of Cu from the Ti_2Ni phase forming a Cu-enriched layer in the Ti_2Ni/residual glassy matrix interface. The residual glassy matrix further forms γTiCu phase.

Inclusions of nanoparticles in large grains as well as segregation of some atoms on the grain boundaries hampers grain growth. Grain growth of pure Ni and Ni–Si solid solution was studied by DSC [133]. It was found that the segregation of Si atoms on the grain boundaries impedes growth of the nanocrystals. It has been also shown that [134] nanoscale grains may reach a metastable state where the structure is stable with respect to variation of its total grain boundary area and the grain boundary free energy is significantly reduced.

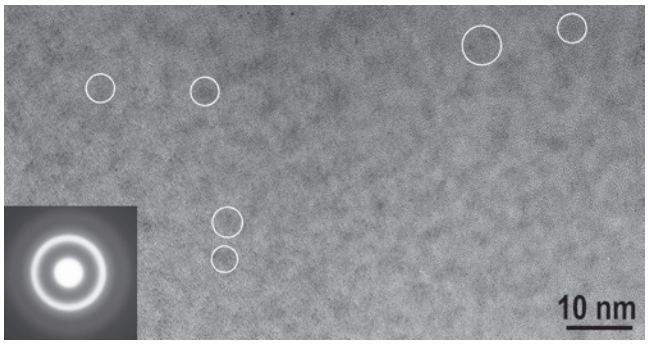

Figure 16. HRTEM image of rod-shaped bulk (2 mm in diameter) $Zr_{55}Co_{20}Al_{12}Cu_5Nb_8$ glassy alloy containing MRO zones and nanoscale particles in as-solidified state. 5. PROPERTIES

Properties of nanomaterials are quite different from those of conventional crystalline alloys as well as from the amorphous and glassy solids. For example, due to high fraction of grain boundaries nanocrystalline materials have lowered density compared to that of conventional polycrystalline materials. It has been shown that Curie temperature and other magnetic properties of nanostructured Ni also change when a grain size becomes nanoscale [135]. Not only are mechanical strength and ductility of Cu strongly affected when grain size reaches nanoscale values but also such a non-structure-sensitive properly as Young's modulus [136]. The aforementioned supports an idea of separating nanomaterials into a special class of solid substances. In the present section we will consider mechanical and magnetic properties of metallic nanomaterials.

5.1. Mechanical Properties

Nanostructured metals and alloys exhibit mechanical properties which are significantly different from the properties of conventional polycrystalline alloys. They possess high hardness, tensile, and compressive strength values and exhibit superplastic behavior at low reduced temperature.

5.1.1. General Description of Deformation Behavior on the Basis of Crystalline Single-Phase Nanostructured Alloys

A number of works are dedicated to theoretical and experimental understanding of mechanical behavior of nanostructured metals and alloys. In general bulk nanostructured materials were found to exhibit low ductility at room temperature that imposes a limit on their practical applications [137]. For example, pure copper which is naturally very ductile became quite brittle when its grain size decreased below 50–100 nm. Especially low plastic elongation values of 1–2% are obtained for materials with a grain size below

25 nm. For example, electrodeposited nanocrystalline Ni with a mean grain size of 10 nm showed yield strength, ultimate tensile strength, and elongation to fracture of 900 MPa, 2000 MPa, and 1%, respectively compared to 100 MPa, 400 MPa, and 50%, respectively, for polycrystalline Ni with 10 μm grain size [138, 139]. The major reasons for brittleness of bulk metallic nanomaterials are connected with the porosity, weak bonding of the grains/particles and other artifacts, as well as instability of crack nucleation and propagation. Limited ductility and toughness of nanomaterials is closely connected to the absence of any significant work hardening. However, recent studies on nanocrystalline pure metals showed that quite high ductility values on tensile test can be obtained at a definite grain size after proper treatment [140]. For example, nanocrystalline hcp Co samples with a mean grain size of 12 nm produced by pulse electroplating on Ti substrate followed by a thermomechanical treatment showed an ultimate tensile strength of 1865 MPa and yield strength of 1000 MPa at 7% elongation which is an example of a very good combination of strength and ductility [141].

Mechanical yield strength of conventional polycrystalline materials obeys the well-known Hall–Petch relationship that has been extrapolated to nanomaterials as well [142]. The Hall–Petch relation states that the yield strength σ_y increases monotonically with decreasing the average grain size d as

$$\sigma_y = \sigma_0 + kd^{-1/2} \tag{3}$$

where σ_0 is the friction stress needed to move dislocations and k is a material dependent constant. Considerable strengthening is achieved on reducing the grain size from the macro- to the micro- and finally to the nanoscale size. However, different types of strength variation with nanoscale grain size have been reported, ranging from respecting the Hall–Petch relationship to showing a saturation of strength or even fall of strength at the finest grain sizes. Several Hall–Petch plots of yield stress or hardness against the reciprocal of the square root of the average grain size show a deviation from straight line behavior when grain size is lower than 25 nm [143–145].

A number of models have been proposed to interpret the inverse Hall–Petch behavior. Some calculations [146] based on the idea that very small grains cannot sustain significant dislocation activity indicate that Hall–Petch behavior should cease when the average grain size is below 10–20 nm. Numerous models have been devised and molecular dynamics simulations have been carried out to explain deformation when the grain size falls below the cutoff value for significant dislocation activity. It is frequently predicted by a mechanism based on grain boundary sliding accommodated by diffusion or by the emission of dislocations into the grains [147, 148]. However, recent *in-situ* observations of deformation behavior in nanocrystalline Cu by TEM have shown dislocation motion mechanism of plastic deformation [149]. No evidence for grain boundary sliding or rotation in the range of grain sizes that could be studied in the present experiment was observed. The inverse Hall–Petch relation is also explained by the size dependent line tension where the dislocation elastic strain is assumed to be screened within the distance of the grain diameter [150]. The existence of a Frank–Read source in large grains in nanocrystals was also assumed [151]. On the basis of the composite model involving a crystalline matrix and intercrystalline layers, the yield stress of nanocrystalline materials can be expressed as the sum of the matrix contribution and the intercrystalline contribution, both of which are assumed to be linearly connected with the corresponding shear module and to be functions of the grain size [152]. An attempt was also done to explain the inverse Hall–Petch relation by the change of the deformation mechanism from a dislocation glide process to the Coble creep [153]. In this model the shape of the yield stress against grain size curve depends on the relative values of Hall–Petch slope, the conventional Coble constant, the threshold constant, and the width of the grain size distribution.

Creep behavior of nanocrystalline Cu and Pd has been studied over a range of temperatures (0.24–0.64 T_m) on the samples prepared by inert gas condensation and compaction [154]. The measured creep rates were found to be two to four orders of magnitude smaller than the values predicted by the equation for Coble creep. At the same time a low temperature tensile creep test of nanoscale Cu with an average grain size of 30 nm prepared by electrodeposition and investigated in the temperature range of 0.22–0.24 T_m showed that the creep rates are of the same order of magnitude as those calculated from the equation for Coble creep [155]. The results suggest that the creep can be attributed to the "interface controlled Coble creep." The difference in creep behavior between electrodeposited Cu and that produced by inert gas condensation can be attributed to different preparation techniques. Once again one can point out that the preparation method has an influence on the properties of the product.

Fatigue properties of nanocrystalline Cu prepared by inert gas condensation [156] (an increase of grain size by 30% is observed after cycling) and severe plastic deformation [157] have been also studied. No cycling softening and high saturation stress were observed. However, nano-submicrometer-scale Cu produced by severe plastic deformation in [158] tested in tension–compression fatigue under strain control showed significant softening during testing.

5.1.2. Crystalline Multiphase (Two and More) Nanostructured Alloys

Commercial materials usually have a multiphase microstructure.

When the extrusion temperature is raised to the second-stage exothermic reaction range, one can easily produce a fully dense nanocrystalline alloy consisting of fine compounds with a size of about 50 nm embedded in an Al matrix with a grain size of 100 to 200 nm [159]. The nanocrystalline alloys exhibit a good combination of high tensile strength above 900 MPa and high fatigue strength of 300 to 350 MPa which are much superior to those for conventional Al-based alloys as well as for new Al-based alloys [160] developed by rapid solidification and powder metallurgy techniques. Figure 17 shows the relation between the yield strength ($\sigma_{0.2}$) and the grain size of the fcc-Al matrix phase for the

nanocrystalline Al-based alloys, together with the data of conventional crystalline Al-based alloys. The present high tensile strength has been interpreted to result from the combination of two mechanisms of dispersion strengthening and grain size refinement strengthening. The combination of the two strengthening mechanisms is attributable to the formation of the unique mixed structure in which intermetallic compounds disperse homogeneously within the Al grains and on the grain boundaries. The dispersion density of the compounds is not high enough to suppress all the dislocations and a significant part of dislocations is hindered at grain boundaries of Al phase. Figure 17 also shows that the increase in the yield strength by the dispersion strengthening and grain size refinement strengthening is approximately 400 and 390 MPa, respectively. When the dispersion strengthening is attributable to the Orowan mechanism [161], the increase in the yield strength is evaluated by

$$\Delta\tau = 0.81Gb/\{2\pi(1-\nu)^{1/2}\} * \ln(2r_s/r_0)/(\lambda_s - 2r_s) \quad (4)$$

Here, G is shear modulus of Al (27 GPa), b is Burger's vector of Al (2.86×10^{-10} m), ν is Poisson's ratio of Al (0.345), r_s is particle radius $\{2/3(r)\}$, r_0 is core dislocation radius for Al (2.86×10^{-10} m), λ_s is $1.25r(2\pi/3f)^{1/2}$, and f is volume fraction of the dispersoids. The r and f for the present alloy are measured to be 2.5×10^{-8} m and 0.34 [162], respectively. The $\Delta\tau$ is calculated to be 129 MPa and the resulting increase of yield stress $\Delta\sigma$ is 395 MPa.

Furthermore, the increase in σ_y by the grain size refinement strengthening is expressed by the Hall–Petch relation (3). Here, σ_0 is yield strength of a single grain due to all strengthening mechanisms except grain boundary contributions [163], k is a constant relating to how effective the grain boundaries are in increasing yield strength, d is grain or subgrain size, and n is an exponent in the range 0.5 to 1 and is assumed to be 0.5 [162]. The σ_0 is due to solid solution strengthening and strain strengthening up to 0.2% elongation and included into the dispersion strengthening. The k value has been reported to be 75 MPa $\mu m^{1/2}$ for commercial pure Al [164], 120 MPa $\mu m^{1/2}$ for optimally aged 7075 [165], and 220 MPa $\mu m^{1/2}$ for underaged 7091 [166]. In the calculation, the k value was assumed to be 135 MPa $\mu m^{1/2}$. The resulting kd^{-n} value is 426 MPa for $d = 100$ nm and 302 MPa for $d = 200$ nm. Consequently, the yield strength ($\sigma_{0.2}$) evaluated by the summation of the dispersion strengthening and grain size refinement strengthening is 821 MPa for $d = 100$ nm and 697 MPa for $d = 200$ nm. These calculated $\sigma_{0.2}$ values agree with the experimental results shown in Figure 17, indicating an appropriateness of the strengthening mechanisms.

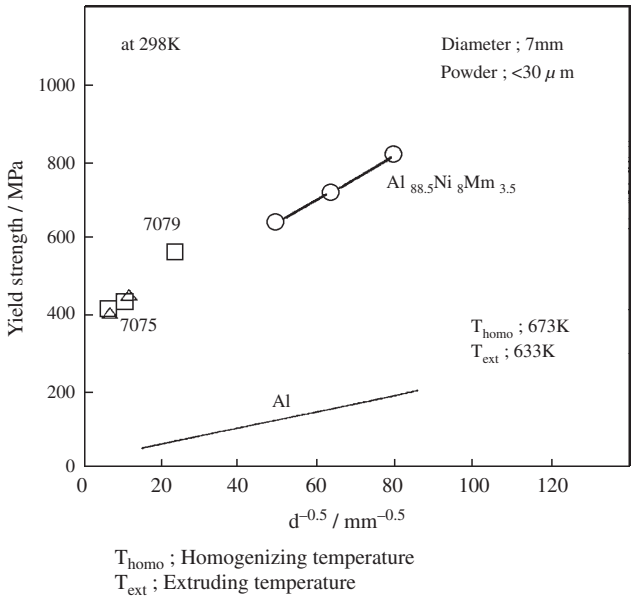

Figure 17. Relation between the yield strength ($\sigma_{0.2}$) and the grain size of Al matrix phase ($d^{-1/2}$) for nanocrystalline Al–Ni–Mm base alloys prepared by the powder metallurgy technique. The data of conventional Al-based alloys are also shown for comparison. Reprinted with permission from [167], A. Inoue and H. Kimura, *J. Light Metals* 1, 31 (2001). © 2001, Elsevier Science.

Mg-based solid solutions with high Mg content above 90 at% were produced by warm extrusion of gas atomized powders [rapid solidification powder metallurgy (RS P/M)] [168]. The structure of these high-strength RS P/M Mg-based alloys consisted of hcp solid solution containing fine compounds [169]. However, the resulting mixed phase alloys exhibit low elongation less than 3% and the poor ductility has prevented the progress of the Mg-based alloys as structural materials.

The compositional dependences of microstructure, Vickers hardness, and bend ductility for melt-spun Mg–Ln–TM and Mg–Y–Mm alloys were examined with the aim of finding an alloy composition with higher hardness at a good ductility. By choosing alloys with good bend ductility and higher hardness number consolidated bulk alloys were produced by warm extrusion of high pressure gas atomized alloy powders, that is, RS P/M process. The process consisted of the production of alloy powders by high-pressure gas atomization, followed by collection, sieving, precompaction, sealing into a Al can, and then extrusion at an extrusion ratio of 10 in the temperature range of 573 to 723 K [169].

The tensile yield strength at room temperature for the bulk $Mg_{95.5}Mm_2Y_{2.5}$ alloys produced at different extrusion temperatures ranging from 573 to 698 K exceeds 500 MPa in the extrusion temperature range of 573 to 648 K, but the elongation is less than 1.0% [170]. The consolidated bulk alloys of $Mg_{95.5}Y_2Mm_{2.5}$ alloy made from the atomized powders have two kinds of structure: (1) hcp solid solution single phase and (2) a mixed structure consisting of fine compounds embedded in hcp-Mg matrix phase. The low elongation is a disadvantage for the bulk hcp Mg-based alloys in Mg–Mm–Y and Mg–Ln–TM systems. On the contrary, the Mg-based solid solution alloys exhibit very high elevated temperature strength. For $Mg_{95}Mm_3Zn_2$ and $Mg_{95.5}Mm_2Y_{2.5}$ alloys the high yield strength above 400 MPa is kept in the temperature range up to 523 K and the strength level is 2 to 3 times higher than that [171] for the commercial WE54A-T6 alloy in a wide temperature range below 550 K. A similar high elevated temperature strength was also obtained for extruded bulk $Mg_{95}Ca_{2.5}Zn_{2.5}$ and $Mg_{96.5}Ca_1Zn_{2.5}$ alloys, though their elongation is also lower than 3% [172].

Based on the previous knowledge that the low elongations below 3% prevent practical uses of the Mg-based

alloys, a completely new Mg-based alloy with much higher $\sigma_{0.2}$ and larger δ values was developed [173]. In the development, the attention was paid to new ternary Mg-based systems which satisfy the following three criteria: (1) a multicomponent system consisting of more than three elements, (2) significant atomic size ratios above about 12% among the three elements, and (3) suitable negative heats of mixing among their elements. It has generally been approved that the three criteria are very effective for the stabilization of metallic supercooled liquid [174]. The effect of the stabilization is expected to cause the formation of a solid solution with a higher degree of nonequilibrium state. Mg–Al–Zn, Mg–Ca–Al, and Mg–Zn–Y systems satisfy the three criteria. The composition dependence of H_v and bend ductility were examined systematically in the annealed states for the melt-spun Mg–Ca–Al and Mg–Zn–Y alloys. The higher H_v value at the maintenance of good bend ductility was obtained for $Mg_{85}Ca_5Al_{10}$ and $Mg_{97}Zn_1Y_2$ alloys.

By choosing these two alloys, alloy powders with an average size of about 25 μm were produced by high pressure gas atomization. The atomized powders were subsequently collected, sieved, precompacted, sealed into a Al can, and then extruded at an extrusion ratio of 10 in the extrusion temperature range of 573 to 723 K.

The atomized $Mg_{85}Ca_5Al_{10}$ powder with a size below 25 μm consisted of hcp-Mg, Al_2Ca, and unknown nonequilibrium phases. The structure changed to hcp-Mg and Al_2Ca phases for the bulk alloy obtained by extrusion at 623 K. The extruded bulk alloy exhibited rather good mechanical properties. The tensile yield strength varied from 420 to 500 MPa at 5 to 8% elongation. It is noticed that the ductility value increases significantly without detriment to the high strength. The bulk Mg–Ca–Al alloy has a mixed structure of fine hcp–Mg grains with a size of about 400 nm including much smaller precipitates with an average size of about 50 nm.

A similar experiment was made for the $Mg_{97}Zn_1Y_2$ and $Mg_{96}Zn_1Y_3$ alloys [175]. The atomized $Mg_{97}Zn_1Y_2$ powder with an average size below 32 μm had a mixed structure consisting mainly of hcp-Mg and $Mg_{24}Y_5$ phases. The Mg–Zn–Y alloy powder can be easily consolidated into a bulk form with high density. The density is 1.84 g/cm^3 for the 2% Y alloy and 1.86 g/cm^3 for the 3% Y alloy. Figure 18 shows the $\sigma_{0.2}$ and δ values as a function of extrusion temperature for the RS P/M $Mg_{97}Zn_1Y_2$ alloy. As the extrusion temperature rises, the $\sigma_{0.2}$ decreases from 600 to 420 MPa while the δ increases from 5% to 15%. It is noticed that the $\sigma_{0.2}$ and δ values are about 1.5 times higher than those for the former Mg–Y–Mm and Mg–Zn–Ln alloys. The specific yield strength values of the present Mg–Zn–Y and Mg–Ca–Al alloys are in the range of 2.7×10^5 to 3.3×10^5 Nm/kg which is about 1.2 to 4 times higher than those for the conventional Mg, Al, and Ti alloys [176].

One can note that one of the national projects is the development of Al-based amorphous alloys with higher specific strength of 300 to 400 MPa/(Mg/m^3) and higher specific modulus of 20 to 30 GPa/(Mg/m^3). The specific strength and specific modulus of the extruded bulk $Mg_{85}Ca_5Al_{10}$, $Mg_{97}Zn_1Y_2$, and $Mg_{96}Zn_1Y_3$ alloys were compared with the data of conventional Al-, Mg-, Ni-, and Ti-based alloys. The newly developed Mg-based alloys had higher specific strength of 270 to 330 MPa/(Mg/m^3) and high specific modulus of 19 to 23 GPa/(Mg/m^3). It is noticed that the specific strength values of the new Mg-based alloys are much superior to those for all the conventional metallic materials. RS P/M $Mg_{97}Zn_1Y_2$ alloy also exhibits high elevated temperature strength above 400 MPa in the temperature range up to 473 K and the further increase in testing temperature to 523 K causes a significant decrease in $\sigma_{0.2}$ to 130 MPa accompanying a significant increase in δ to 135%. It is also confirmed that the $\sigma_{0.2}$ values in the temperature range up to 473 K are much superior to those for the conventional heat resistant type Mg-based alloys of WE54-T6 and TMT-WE43.

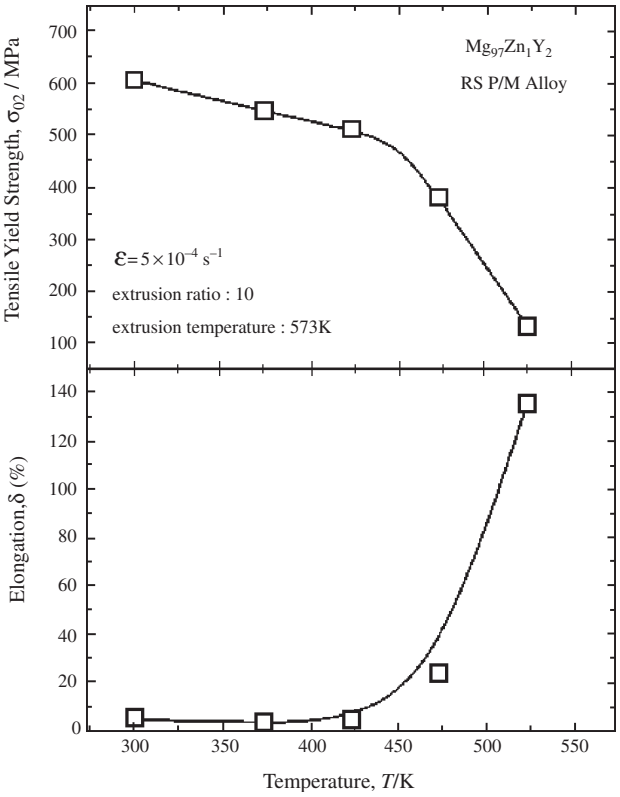

Figure 18. $\sigma_{0.2}$ and δ values as a function of extrusion temperature for the RS P/M $Mg_{97}Zn_1Y_2$ alloy. Reprinted with permission from [173], Y. Kawamura et al., *Mater. Trans.* 42, 1172 (2001). © 2001, Japan Institute of Metals.

The choice of Mg-rich compositions in the Mg–Zn–Y system causes a simultaneous increase in strength and ductility presumably because of the formation of a novel long periodic hexagonal matrix phase with much smaller grain sizes of 100 to 150 nm and the decrease in volume fraction of another phase. Figure 19 shows the TEM image of the RS P/M $Mg_{97}Zn_1Y_2$ alloy obtained by extrusion at 573 K. The alloy consists of fine grains with grain sizes of 100 to 150 nm. In addition, each grain contains a high density of stacking faults as well as very fine precipitates with a size of about 10 nm. In the selected-area electron diffraction pattern shown in Figure 19, one can see extra reflection spots at the positions of $1/3(0001)_{Mg}$ and $2/3(0001)_{Mg}$, indicating the formation of a long-periodic structure in which the periodicity is longer than that for the ordinary hcp-Mg phase.

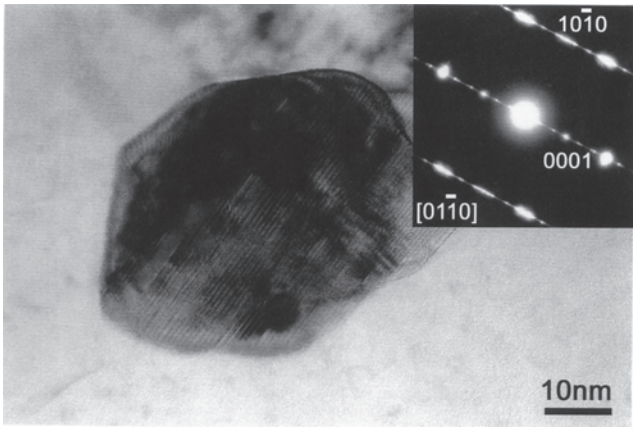

Figure 19. TEM image of the RS P/M $Mg_{97}Zn_1Y_2$ alloy obtained by extrusion at 573 K. Reprinted with permission from [173], Y. Kawamura et al., *Mater. Trans.* 42, 1172 (2001). © 2001, Japan Institute of Metals.

With the aim of clarifying in more details the long-periodic hexagonal structure, high-resolution TEM was used. One can see in Figure 20 an atomic configuration of ABACAB type which is three times longer than the ABABAB type atomic configuration [177] which is typical for the ordinary hcp-Mg phase. A novel long-period ordered structure is formed in the alloy, whose unit cell is composed of six close-packed planes of the magnesium crystal with a stacking sequence of ABCBCB′ where A and B′ layers are significantly enriched by Zn and Y. However, an atomic structure model of the Mg–(Zn, Y) long-period ordered structure was constructed based on a monoclinic lattice with $\gamma = 88°$, $a = 0.56$, $b = 0.32$, $c = 1.56$ nm, by discerning the lattice distortion from the ideal 6H-type structure. The lattice is distorted from an ideal hexagonal lattice of 6H-type (ABCBCB), which is probably due to an asymmetry of the chemical order with respect to the 6H-type stacking order.

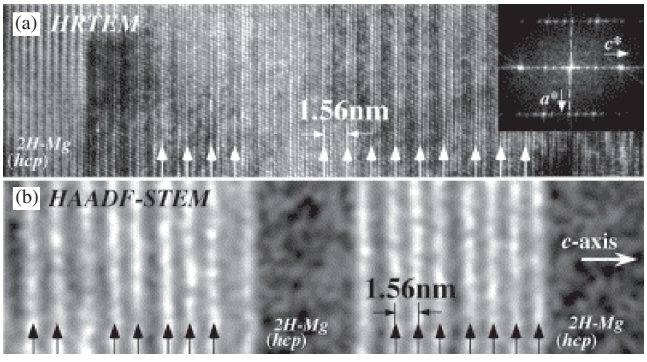

Figure 20. (a) HRTEM and (b) HAADF-STEM images showing the distribution of the long-period ordered structure in the fine-lamellar grain. HRTEM image of (a) reveals a periodic contrast with an interval of six close-packed planes (1.56 nm) at some places. Fourier transform obtained from the periodic contrast region is inserted in (a). HAADF-STEM image of (b) exhibits significant lamellar *Z*-contrasts with the same interval of 1.56 nm at some places, directly representing a chemical order of the structure with this correlation length. Reprinted with permission from [177], E. Abe et al., *Acta Mater.* 50, 3845 (2002). © 2002, Elsevier Science.

The present results demonstrate that the additional elements of a few atomic percent to Mg lead to formation of a long-period chemical-ordered as well as stacking-ordered structure. It is therefore concluded that the Mg–Zn–Y solid solution has a novel atomic configuration which is significantly different from that for hcp-Mg phase.

In addition to the change in the structure of the matrix phase, homogeneous dispersion of fine precipitates with cubic lattice and a size of about 7 nm was observed. These precipitates were characterized as a $Mg_{24}Y_5$ phase with a cubic structure of a lattice parameter of 1.1 nm, on the basis of the data on the high-resolution TEM image, the nanobeam electron diffraction pattern, and the nanobeam EDX profile [177].

In an equilibrium phase diagram in a Mg–Zn–Y system [178], there is no appreciable solid solubility limit of Zn and Y elements in hcp-Mg phase at room temperature. Consequently, the present Mg phase can be identified to be a reinforced solid solution saturated with Zn and Y elements. Such a reinforced solid solution generates significant strains because of significant atomic size ratios of 14% for Y/Mg and 20% for Mg/Zn. The high density of precipitates and stacking faults leads to significant strengthening. The mechanisms for the high strength and high ductility for the RS P/M Mg–Zn–Y alloys are thought to result from the combination of the following four factors: (1) nanograin hexagonal structure with grain sizes of 100 to 150 nm, (2) reinforced solid solution of Y and Zn elements with significantly different atomic sizes, (3) existence of a high density of stacking faults in the hexagonal Mg phase leading to significant change in the atomic configurations, and (4) homogeneous precipitation of cubic $Mg_{24}Y_5$ particles with a size of about 10 nm in the hexagonal Mg matrix.

5.1.3. Bulk Nanostructured Alloys Containing Quasicrystals

Quasicrystals not only attract interest themselves as a new type of solid. Being produced in the shape of nanoparticles with common boundaries or embedded in the amorphous matrix, they are used for strengthening of bulk samples and enhancing ductility of the metallic glasses. For example, a large number of such alloys have been recently produced in Al, Zr, and Hf based systems [44].

The icosahedral phase can contain dislocations [179]. However, it is very difficult for dislocations to move in the icosahedral phase because the movement of the dislocations demolishes the quasiperiodic lattice at room temperature and elevated temperatures. A single icosahedral $Al_{70}Pd_{10}Mn_{20}$ quasicrystal [180] prepared by the Chochralskii method has a high Young's modulus of 200 GPa, a high rigid modulus of 72 GPa, and a high Vickers hardness of about 750 at room temperature, even though it is extremely brittle [181]. The quasicrystal also exhibits high elevated temperature compressive strength of about 650 MPa at 1000 K, accompanying a significant elongation. By utilizing the high Young's modulus, high hardness, and high elevated temperature strength, an icosahedral base Al alloy with high strength were developed. The key point in the development is attributable to the possibility of synthesizing an icosahedral base alloy with good ductility.

High strength and good ductility for the icosahedral base alloys can be obtained in a nanostructure state where the icosahedral phase coexists with fcc α-Al phase and has a spherical morphology, small grain size, and homogeneous dispersion. The nanostructure state is also expected to be obtained by the increase in the stability of supercooled liquid against the transition to a crystalline phase. Significant attention has been paid to Al–Mn–RE and Al–Cr–RE systems because Al–Mn and Al–Cr alloys are well-known icosahedral-forming systems and Al–RE binary alloys are a good glass-forming system. The mixed structure consisting of icosahedral + α-Al phases is formed in the Al-rich melt-spun Al–Mn–RE alloys in the composition range above 92 at% Al and the mixed phase alloys have good bending ductility and high fracture strength reaching 1320 MPa. The high-strength $Al_{92}Mn_6Ce_2$ alloy consists of spherical icosahedral particles of about 50 nm size surrounded by a fcc-α-Al layer with a thickness of 5 to 10 nm. The halo-like reflection rings result from the icosahedral particles and the particles have random orientation because of the primary precipitation of the icosahedral phase, followed by the solidification of Al phase from the remaining liquid. The volume fraction of the icosahedral phase is as high as about 60 to 70%. A similar nanoscale mixed structure is also formed in rapidly solidified Al–Cr–Ce–Co alloys [182]. In the structure of $Al_{94.5}Cr_3Ce_1Co_{1.5}$ alloy the icosahedral particles with a size of 20–40 nm are homogeneously dispersed in the Al phase. The icosahedral phase alloy also exhibits a high fracture strength of 1340 MPa. The similar high fracture strength values exceeding 1000 MPa combined with high Vickers Hardness (H_v) above 400 are also obtained for rapidly solidified $Al_{93.5}Cr_3Ce_1Co_{1.5}TM_1$ alloys containing various transition metals [183]. The icosahedral phase based alloys also have good cold deformability and can be cold rolled up to a significant reduction ratio in thickness above 70% [184]. Besides, the cold-rolled alloy has a much finer mixed structure consisting of an icosahedral phase with a size of 5 to 10 nm coexistent with nanoscale fcc α-Al phase.

Here, it is important to point out that the high tensile strength combined with good ductility is obtained only for the mixed phase alloys prepared through the unique solidification process in which the nanoquasicrystalline phase precipitates as a primary phase, followed by the solidification of Al from the remaining liquid. On the other hand, when the Al-based alloys have the other type of solidification processes in which an Al solid solution is formed, followed by the precipitation of an icosahedral phase within Al grains and along Al grain boundaries or in which primary fcc-Al particles precipitate, followed by the solidification of an intergranular quasicrystalline phase from, the remaining liquid the alloys cannot have high tensile strength and good ductility.

In addition the same mixed structure of nanoscale icosahedral phase surrounded by fcc α-Al phase is also formed for atomized powders in Al–Mn–RE and Al–Cr–RE–TM systems as well as in Al–Mn–TM and Al–Cr–TM systems without RE elements [185]. When the atomized powders are extruded in the temperature range below 673 K, which is lower than the decomposition temperature of the icosahedral phase, one can obtain fully dense bulk icosahedral base alloys which have the same mixed structure as that for the atomized powders. Figure 21 shows the relation between tensile strength and plastic elongation for the extruded bulk icosahedral base alloys [154, 185, 186] in comparison with the data of conventional Al-based alloys obtained from the JIS handbook. The bulk icosahedral-based alloys have high σ_f values of 500 to 850 MPa combined with large elongation of 5–25% which are much superior to those for the conventional Al-based alloys. Furthermore, the bulk icosahedral base alloys can be divided into the following two kinds: (1) high-strength type for Al–Mn(Cr) alloys containing RE elements and (2) high ductility type for Al–Mn(Cr)–TM alloys without RE elements. The Al–Cr and Al–Mn base alloys containing RE elements also exhibit rather high elevated temperature strength of 350 MPa at 473 K and 200 MPa at 573 K, in addition to a high Young's modulus of about 100 GPa at room temperature. The bulk icosahedral based $Al_{94}Cr_{2.5}Co_{1.5}Mm_1Zr_1$ alloy also exhibits high fatigue strength values of 240 MPa at room temperature and 210 MPa at 423 K which are much higher than those (175 and 125 MPa) for conventional Al-based alloys in Al–Si–Fe systems. On the other hand, the bulk icosahedral base alloys without RE elements in $Al_{93-95}(Cr,Mn,Ni)_{5-7}$ and $Al_{93-95}(Cr,Mn,Cu)_{5-7}$ systems exhibit large elongation reaching 30% and high impact fracture energy reaching 160 kJ/m^2 combined with high tensile strength of 500 to 800 MPa [187]. All the values of tensile strength, elongation, and impact fracture energy are much higher than those for the 7075-T6 alloy.

More recently, a mostly single icosahedral phase was obtained at a new composition of $Al_{84.2}Fe_{7.0}Cr_{6.3}Ti_{2.5}$ in the melt-spun state [188]. There have been no data on the formation of an icosahedral phase in Al–Fe base alloys and hence the present formation of the mostly single icosahedral phase is believed to be the first evidence. Based on the previous data [189] that all the solute elements of Fe, Cr, and Ti have very low diffusivity in the fcc-Al phase, the

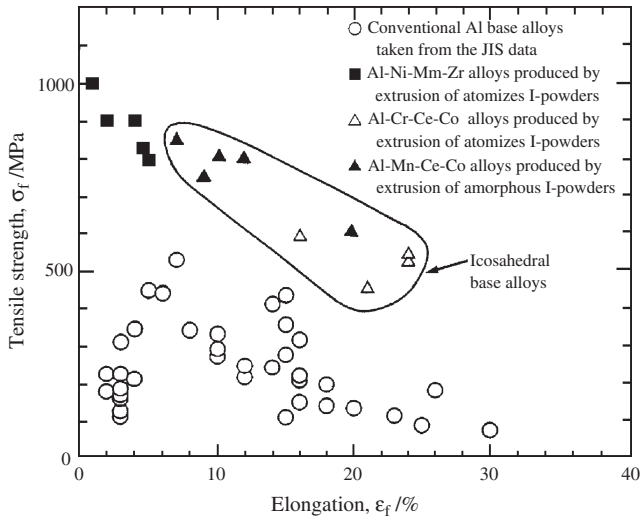

Figure 21. Relation between tensile strength and plastic elongation for the extruded bulk icosahedral base alloys. The data of conventional Al-based alloys are also shown for comparison. Reprinted with permission from [44], A. Inoue and H. M. Kimura, *J. Light Metals* 1, 31 (2001). © 2001, Elsevier Science.

icosahedral base alloys are expected to exhibit higher elevated temperature strength. Even for an $Al_{93}Fe_3Cr_2Ti_2$ alloy with a further Al-rich concentration, a similar mixed structure consisting mainly of icosahedral + Al is formed in the atomized powders with a particle size fraction range below 125 μm. The resulting bulk alloys prepared by extrusion of the atomized powders also consist mainly of icosahedral + Al phases. The new Al–Fe–Cr–Ti alloys exhibit excellent elevated temperature strength of 400 to 460 MPa at 473 K and 350 to 360 MPa at 573 K which exceed the air-force goal level. It has further been confirmed that the high elevated temperature strength level of the extruded $Al_{93}Cr_3Fe_2Ti_2$ alloy is maintained even after annealing for 1000 h at 573 K. The annealed alloy also keeps a fine mixed structure consisting of fine icosahedral particles with sizes less than 400 nm and fine Al grains with a size of about 500 nm.

Thus, the icosahedral based Al alloys can be classified into three groups: (1) high-strength type alloys in Al–Mn–RE and Al–Cr–RE–TM systems, (2) high ductility type alloys in Al–Mn–Cu–TM and Al–Cr–Cu–TM systems, and (3) high-elevated temperature strength type alloys in Al–Fe–Cr–Ti system. When the mechanical properties are compared with those for the 7075-T6 alloy (Fig. 22), one can notice that the present nanoquasicrystalline Al alloys exhibit a much better combination for almost all properties including tensile strength, elevated temperature strength, Charpy impact fracture energy, cold workability, elongation, and Young's modulus except thermal expansion. The excellent characteristics are quite attractive for future applications as a new type of Al-based alloy with high fracture strength, high ductility, and high elevated temperature strength.

Fine-grained magnesium alloys reinforced by quasicrystalline particles were developed by thermomechanical processes for as-cast $Mg_{96}Zn_{3.4}Y_{0.6}$ and $Mg_{94.8}Zn_{4.3}Y_{0.7}Zr_{0.2}$ alloys [190]. The $Mg_{96}Zn_{3.4}Y_{0.6}$ alloy shows a yield stress of 210 MPa and an ultimate tensile strength of 355 MPa, similar to those for an AZ91 alloy, and a large elongation of around 23%. The yield strength of Mg–Zn–Y alloys is relatively high due to the strengthening effect of the quasicrystalline particles [191]. However, at high temperature the level of flow stress of Mg–Zn–Y alloys is lower than that of commercial magnesium alloys due to the softness of the eutectic and fine grains. Furthermore, icosahedral phase particles in the Mg–Zn–Y alloy are stable against coarsening during deformation near the melting temperature of the eutectic, forming a stable quasicrystalline particle/matrix interface. This stability provides a large elongation with no voids opening at the interface between the quasicrystalline particle and the Mg matrix.

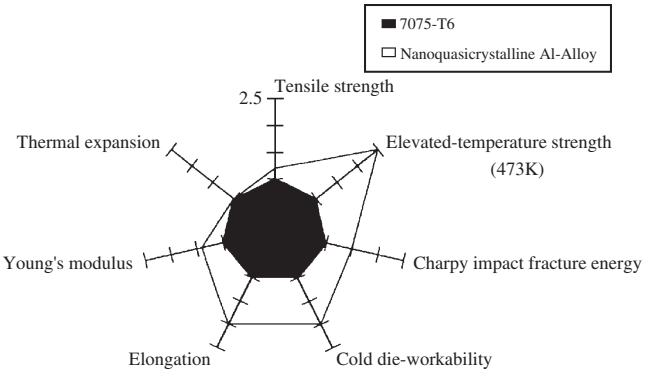

Figure 22. Comparison of mechanical properties of the icosahedral base bulk alloys with those for the commercial 7075-T6 alloy. Reprinted with permission from [44], A. Inoue and H. M. Kimura, *J. Light Metals* 1, 31 (2001). © 2001, Elsevier Science.

5.1.4. Nanostructured Alloys with Glassy Phase: Nanocomposites

As has been mentioned such materials can be produced using a single-step process, for example on rapid solidification by controlling cooling rate, or using a double-step one like devitrification of the glassy matrix.

Ductility of bulk glassy alloys can be drastically improved by precipitates of nanocrystalline or nanoquasicrystalline phase [119]. For example, in 1988 Al-based amorphous alloys with high tensile strength exceeding 1200 MPa were produced [192]. Subsequently, it has been noticed [193] that the homogeneous dispersion of nanoscale fcc α-Al particles in an amorphous matrix causes a drastic increase in tensile fracture strength to 1560 MPa which is three times higher than the strength level of conventional high-strength type Al-based alloys. For example as well as in the case of the ternary Al–Y–Ni alloys fine precipitates of fcc-Al formed by devitrification of the $Al_{85}Y_8Ni_5Co_2$ glassy matrix strengthen the alloy without reduction of bend ductility [194]. An optimum strength value was obtained for a crystalline phase volume fraction ranging from 5 to 25%. These nonequilibrium Al-based alloys exhibit much better mechanical properties compared with conventional crystalline alloys developed to date [195]. The volume fraction of the fcc-Al phase is controlled by changing the rotation speed of wheel and is evaluated by the change in the exothermic heat release due to crystallization. The tensile fracture strength increases from about 1100 MPa at volume fraction (V_f) of fcc-Al V_f = 0% to 1560 MPa at $V_f = 25\%$, accompanying an increase in Vickers hardness from 280 to 400 and Young's modulus from 63 to 71 GPa [196]. The significant decrease in tensile fracture strength by the further increase in V_f is due to the embrittlement of the remaining amorphous phase by the progress of structural relaxation and the enrichment in the solute elements [197]. A similar nanoscale mixed structure is also formed by annealing in the first-stage exothermic reaction range and the mixed phase alloys exhibit high tensile strength exceeding 1400 MPa which is about 1.4 times higher than that for the corresponding amorphous single phase alloys [198].

$Al_{88}Y_2Ni_9Fe_1$ amorphous alloy containing 7% volume fraction of the fcc-Al particles with a size of about 3–4 nm has a high tensile fracture strength of 1320 and 1260 MPa with volume fraction of 24%, respectively [199]. It is notable that these values for the former alloy are higher than the highest values of Al-based amorphous single-phase alloys. The high strength is combined with good bend ductility.

The deformation of amorphous materials is concentrated on the shear band of maximum shear stress which maintains about 45 degrees with the load (tensile or compressive) direction. The width of the shear band in Al alloys is about 20 nm.

Table 2. Alloy system, microstructure, and mechanical properties for the quasicrystalline (Q) phase bearing bulk Al-based alloy.

Type	Alloy system	Structure	Mechanical properties
High-strength alloy	Al–Cr–Ce–TM, Al–Mn–Ce	Al + Q	$\sigma_f \sim$ 600–800 MPa, $\varepsilon_p \sim$ 5–10%
High ductility alloy	Al–Mn–Cu–TM, Al–Cr–Cu–TM	Al + Q	$\sigma_f \sim$ 500–600 MPa, $\varepsilon_p \sim$ 12–30%
High elevated temperature strength alloy	Al–Fe–Cr–Ti	Al + Q + $Al_{23}Ti_9$	$\sigma_f \sim$ 350 MPa at 573 K

Source: Reprinted with permission from [44], A. Inoue and H. M. Kimura, *J. Light Metals* 1, 31 (2001). © 2001, Elsevier Science.

An $Al_{88}Ni_{10}Ce_2$ glassy alloy primarily transformed from an amorphous to an amorphous plus fcc α-Al state exhibited a large elongation reaching 45% in the temperature range of 450 to 465 K. In this temperature range primary fcc-Al particles with a size of about 12 nm precipitate homogeneously in the amorphous matrix with an interparticular spacing of about 6 nm. The appearance of the significant elongation is due to a crystallization-induced elongation phenomenon. The process occurs through inhomogeneous deformation along shear plane, followed by deformation-induced preferential precipitation of Al particles on the shear plane and then propagation of the deformation site to other site resulting from the precipitation-induced strengthening in the deformed area [200].

The increase in strength by the dispersion of nanoscale fcc-Al particles in the amorphous matrix has been thought [44] to result from the combination of the following three effects: (1) the defect-free effect of nanoscale fcc-Al particles, because the Al particles are too fine to contain dislocations, (2) the interface effect, because the amorphous/Al particle interface has a highly dense packed structure without excess vacancies due to a low interfacial energy, and (3) the nanoscale effect, because the Al particle size is smaller than the width of the inhomogeneous shear deformation region and hence the nanoscale Al particles can act as an effective barrier against the shear deformation of amorphous matrix [201]. It also explains maintenance of a good bend ductility.

At the same time, it was also suggested [202] that the hardening could be attributed mainly to solute enrichment of the residual glassy matrix due to lowering of the Al content. This theory well describes hardening of the material. As the hardness of fully amorphous or partially crystalline alloys correlates well with solute content in the amorphous phase it is suggested [203] that not only Al particles but also the amorphous matrix has some role in the hardening and embrittlement of the alloy.

A model of the ductile–brittle transition of partially crystallized amorphous Al–Ni–Y alloys was proposed in [204]. The maximum strength of the partially crystalline Al–Ni–Y alloys was obtained when the size of Al particles is 10 nm. However, partially crystallized Al–Ni–Y alloys become brittle when the size and the volume fraction of the Al particles exceeded the optimum values. The reactions in three regions, Al particles, Y accumulated interface layers, and amorphous matrix, were derived by balancing the quantity of each element. It is assumed that the Al–Ni–Y alloys become brittle when the solute content of the interface layers reached the critical value (20%). The predictions were found to be in good agreement with the published data. However, the tensile strength is too high to get a consolidated bulk alloy by warm extrusion in a relatively low temperature range where the nanoscale mixed structure is maintained.

Bulk $Al_{88.5}Ni_8Mm_{3.5}$ alloy having a mixed structure consisting of amorphous and fcc-Al phases was produced by extrusion of atomized powders at an extrusion ratio of 10 and at 633 K and was found to exhibit high tensile strength of 940 MPa at room temperature, 700 MPa at 423 K, and 520 MPa at 473 K [205]. Similarly, the yield strength is also as high as 845 MPa at room temperature and 420 MPa at 473 K. The high values of strength remain unchanged even after annealing for 100 h at these testing temperatures. The fatigue limit after the cycles of 107 is also as high as 330 MPa at 293 K and 220 MPa at 473 K. The fatigue limit at room temperature is also 1.2 times as high as the highest value for conventional Al-based alloys.

In the historical progress of the high-strength Al- and Zr-based alloys, a drastic increase in tensile strength is recognized for the recent nonequilibrium alloys including an amorphous phase (Figs. 14 and 15).

However, in some cases formation of the primary α-Al particles worsens the mechanical properties of Al-based alloy. For example, partial replacement of Ni by Cu in the $Al_{85}Y_8Ni_5Co_2$ metallic glass caused formation of the nanoscale α-Al particles that resulted in sharp drops in tensile strength, hardness, crystallization temperature, and disappearance of the supercooled liquid prior to crystallization (Fig. 23) [206]. Cu has a much lower absolute value of heat of mixing with Al, Y, and Co than Ni [207] which leads to a decrement of the interatomic constraint force. Thus, Cu may weaken the interaction needed for the stability of the glass, thus resulting in the disappearance of T_g and precipitation of α-Al nanocrystals. In addition the volume fraction of the α-Al nanocrystals in $Al_{85}Y_8Ni_3Co_2Cu_2$, for example, is much lower than that in the primarily devitrified $Al_{85}Y_8Ni_5Co_2$ metallic glass [208, 209]. α-Al interparticular distances in the $Al_{85}Y_8Ni_3Co_2Cu_2$ metallic glass significantly exceed the particle size (Fig. 24). Thus, α-Al particles cannot act as an effective barriers against the shear deformation of amorphous matrix as was supposed for the $Al_{85}Y_8Ni_5Co_2$ metallic glass.

At the same time existence of the MRO zones and nanoscale particles in as-cast rod-shaped bulk (2 mm in diameter) $Zr_{55}Co_{20}Al_{12}Cu_5Nb_8$ glassy alloy (see Fig. 16) enhances its ductility leading to appearance of a plastic deformation region of about 1% deformation as shown in Figure 25.

It can be shown that the cylindrical bulk sample of $Zr_{65}Al_{7.5}Cu_{7.5}Ni_{10}Pd_{10}$ alloy, the structure of which consists of an almost single icosahedral phase with nanoscale grain sizes of 20–40 nm, shows a better combination of

mechanical properties compared to the as-cast glassy sample. The Young's modulus, ultimate tensile strength, 0.2% proof stress, and total percentage elongation including elastic elongation are 85 GPa, 1750 MPa, 1640 MPa, and 2.2%, respectively, for the glassy alloy and 88 GPa, 1780 MPa, 1830 MPa, and 3.1%, respectively, for the icosahedral phase-based alloy [210]. However, it is well known that stoichiometric icosahedral phase-based alloys have high hardness and are extremely brittle [211] and it is difficult to consider that the icosahedral phase itself in the present alloys has plastic deformability. The good mechanical properties are attributed to the residual existence of an intergranular glassy phase, though the volume fraction of the glassy phase is estimated to be less than 5%. The deformation of the icosahedral-based alloy takes place in the intergranular glassy phase along the maximum shear plane. The existence of the icosahedral particles can act as a resistant medium against the shear deformation (Fig. 26). The good ductility of the glassy layer is also attributed to the localization effect of deformation. The localization generates the multiaxis stress condition as well as the increase in temperature.

A nanocrystalline bulk $Zr_{55}Al_{10}Cu_{30}Ni_5$ alloy containing nanoscale crystals embedded uniformly in a glassy matrix also has both a high tensile strength of 1.7 GPa and good ductility [212].

Deformation behavior of partially crystallized Zr-based glassy alloys consisting of a metallic glass matrix with crystallite precipitates of different shape and size was studied [213].

However, although a finely dispersed structure consisting of a glassy phase and nano-submicron-sized $Ni_{33}Cr_{33}P_{34}$

crystalline particles (≈500 nm in size) with a volume fraction of 9–13% was formed in $Pd_{40}Cu_{29}Ni_{10}P_{20}Cr_1$ alloy prepared by copper-mold casting [214] its mechanical strength is lower than that of $Pd_{40}Cu_{30-x}Ni_{10}P_{20}$ glassy alloy. This result supports the proposed strengthening mechanism of nanocomposite materials by blocking of deformation share bands of 20–50 nm in width depending upon alloy composition in glassy matrix by the precipitated nanoparticles. Particles of 500 nm are too large to be the barriers blocking deformation.

Bulk composite Zr-based alloys consisting of a $Zr_{55}Cu_{30}Al_{10}Ni_5$ glassy matrix reinforced with micrometer size ZrC particles exhibited high strength and good ductility [215, 216]. The Young's modulus, compressive strength, and Vickers hardness of the composite alloys increase almost linearly from 103 to 125 GPa and 1820 to 2170 MPa and 488 to 563, respectively, with increasing volume fraction of ZrC from 0 to 17 vol%. The plastic elongation also increases from nearly zero at 0 vol% of ZrC to 0.5% at 10 vol% of ZrC.

5.1.5. Superplasticity

Superplastic flow in an alloy is achieved at a sufficiently small-micrometer and submicrometer grain size [217]. Recently this phenomenon has been extended to nanomaterials. The large volume fraction of grain boundaries and their small size are believed to enhance superplastic behavior.

The Al–Ni–Mm alloy with nanocrystalline structure has been found [218] to lead to a high-strain-rate superplasticity which is evidenced from a high-strain-rate sensitivity exponent (m value) of 0.5 as well as a large elongation reaching about 670% at a high strain rate of 1.0 s^{-1}.

A nanocrystalline Ni_3Al with a grain size of about 50 nm processed by severe plastic deformation exhibited superplasticity under tensile test at 923–998 K and a strain rate of 1×10^{-3} s^{-1}. The total elongations for as-processed specimens were 380 and 560% at 923 and 998 K, respectively, which is really impressive for the intermetallic phase. Nanocrystalline Ni_3Al showed quite low reduced superplastic temperature, a large strain hardening stage, and high flow stresses. The tensile elongation of 560% at 998 K was obtained, whereas 640% elongation at nearly the same strain rate was reported for the polycrystalline Ni_3Al with a 6 μm grain size doped with boron [219] when the testing temperature was 1373 K, that is, more than 300 K higher.

The mean grain size of nanocrystalline Ni_3Al after deformation increased up to about 100 nm while no trace of dislocation activity was found by TEM. It is suggested that the deformation took place by intergranular sliding. The role of transformations of grain boundary dislocation pile-ups at triple junctions of grain boundaries in plastic deformation processes in nanocrystalline materials with special attention paid to competition between different deformation mechanisms has been discussed in [220].

High elongation above 175% was obtained in nanosubmicron-grained Ti-45Al-2.4 Si alloy at 800 K [221, 222]. High-strain-rate superplasticity was also obtained in nanocrystalline Al-based 1420 alloy [223].

Low-temperature superplasticity has been reported in nanocrystalline Ni, nanocrystalline Al-based alloy (1420-Al), and nanocrystalline Ni_3Al [224]. Nanocrystalline electrodeposited Ni exhibited an elongation of 295% achieved at 623 K which is 0.36 of the melting temperature of Ni. A maximum elongation of 895% at a strain rate of 10^{-3} s^{-1} was obtained at a temperature of 693 K [225].

RS P/M $Mg_{97}Zn_1Y_2$ alloy also exhibited the high strain rate superplasticity as is evidenced from large δ above 700% at 623 K in the vicinity of the high strain rate of 0.1 s^{-1} as well as high strain rate sensitivity exponent of 0.4. It is recognized that the sample with the largest elongation at the high strain rate of 0.10 s^{-1} was elongated through a homogeneous deformation mode. Figure 27 shows the relation between elongation (δ) and strain rate for the RS P/M $Mg_{97}Zn_1Y_2$ alloy. The δ value is the highest for the Mg–Zn–Y alloy and the strain rate leading to the highest δ value is also located at the high strain rate side. Thus, the RS P/M $Mg_{97}Zn_1Y_2$ alloy has excellent mechanical properties as well as high strain rate superplasticity [226].

The Mg–Ca–Al alloy also exhibits a very large elongation above 700% at 723 K and at a very high strain rate of 0.2 s^{-1} [39, 227]. It is also reported [227] that a nearly linear relation exists between flow stress and strain rate. From the linear relation, the strain rate sensitivity exponent (m value) was evaluated to be 0.45 in the vicinity of 0.2 s^{-1}. These data

indicate the achievement of high strain rate superplasticity for the extruded Mg–Ca–Al bulk alloy.

The deformation behavior of a bulk $Cu_{47}Ti_{33}Zr_{11}Ni_6Sn_2Si_1$ bulk glassy alloy (Fig. 28) in the supercooled liquid region has been studied in [228]. It is suggested that the alloy devitrifies during deformation while no structure data except for the XRD are given in the as-solidified state. However, the shape of the X-ray diffraction pattern in Figure 28 assumes the possible existence of nanocrystals in an as-solidified sample. Two broad peaks in the XRD pattern in the as-cast state (Fig. 28) might be likely caused by nanocrystals. Nevertheless, the sheet shows large elongation around 450% at temperatures of 745 and 750 K (2×10^{-3} s^{-1}) and more than 650% at a strain rate of 1×10^{-2} s^{-1} (750 K) [228]. TEM images (Fig. 29) show nanocrystalline particle bands aligned along the loading direction.

5.2. Magnetic Properties

Magnetic material is another very important and dynamically developing field of the application of nanostructured metallic materials and the connection between nanostructure and magnetic properties is a topic of intensive investigations.

5.2.1. Soft Magnetic Alloys

Classical examples of Fe-based soft magnetic materials with mixed nanocrystalline and amorphous structure are Finemet $Fe_{73.5}Cu_1Nb_3Si_{13.5}B_9$ [229] and Nanoperm

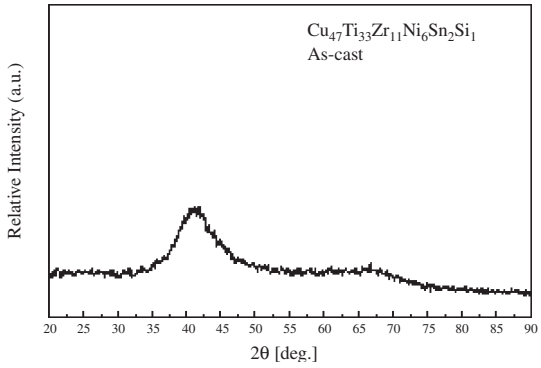

Figure 28. X-ray diffraction pattern of an as-cast $Cu_{47}Ti_{33}Zr_{11}Ni_6Sn_2Si_1$ alloy sheet. Reprinted with permission from [228], D. H. Bae et al., *Acta Mater.* 50, 1749 (2002). © 2002, Elsevier Science.

$Fe_{84}Zr_{3.5}Nb_{3.5}B_8Cu_1$ [230] alloys, the structure of which consists of bcc-Fe nanocrystals of below 20 nm in size finely dispersed in the amorphous matrix. Hitperm $Fe_{44}Co_{44}Zr_7B_4Cu_1$ [231] alloy has an α'-FeCo phase. Cu, Nb, or Zr, despite on their low content, are responsible for bcc-Fe grain

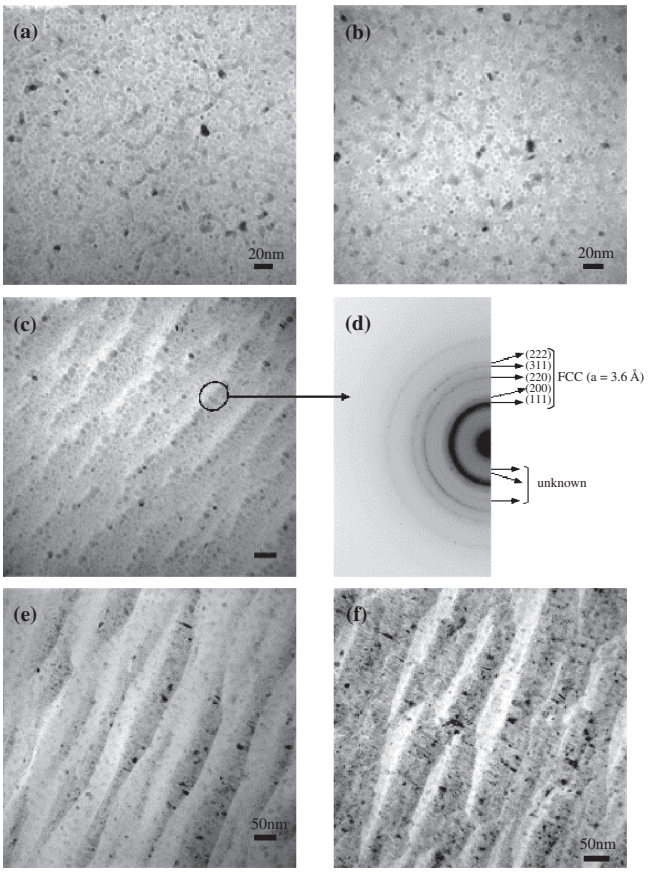

Figure 29. Bright-field TEM images of the alloy tested at a strain rate of 2×10^{-3} s^{-1} and a temperature of 750 K in which (a), (b), and (c) are taken from the specimen deformed to $\varepsilon = 0.5$ and (e) and (f) are taken from the specimen deformed to $\varepsilon = 1.0$. Also the electron diffraction pattern obtained from the crystals marked in (c) is given in (d). Reprinted with permission from [228], D. H. Bae et al., *Acta Mater.* 50, 1749 (2002). © 2002, Elsevier Science.

refinement and formation of a nanostructure in these alloys. The best results were obtained for alloying with two minor alloying elements like Cu and Nb or Cu and Zr (Fig. 30), for example.

Cu has a very low solid solubility in iron and as has been shown by means of atom probe field ion microscopy and high resolution transmission electron microscopy [233] forms nanoclusters in the $Fe_{73.5}Si_{13.5}B_9Nb_3Cu_1$ amorphous matrix which works as a heterogeneous nucleation site for bcc-Fe particles on devitrification. X-ray absorption fines structure studies also showed that Cu clusters with near-fcc structure were present from very early stages of the devitrification process [234]. The density of the clusters estimated by a three-dimensional atom probe is on the order of 10^{-24} m^{-3} at the average cluster size of about 2 nm [235]. Structure evolution in $Fe_{73.5}Si_{13.5}B_9Nb_3Cu_1$ alloy under primary devitrification is shown in Figure 31. Extended X-ray absorption fine structure analysis of grain boundaries in nanocrystalline $Fe_{85}Zr_7B_6Cu_2$ alloys showed very low Fe content in the grain boundaries between bcc-Fe nanograins.

These alloys show high permeability (μe) and low magnetic losses [236]. $Fe_{84}Zr_{3.5}Nb_{3.5}B_8Cu_1$ alloy shows a very high μe of 100,000 combined with the high magnetization (B_s) of 1.53 T [237]. This excellent μe is comparable to those of nanocrystalline $Fe_{73.5}Si_{13.5}B_9Nb_3Cu_1$ and the zero-magnetostrictive Co based amorphous alloys, and the high B_s is comparable to other Fe-based amorphous and nanocrystalline alloys with good soft magnetic properties.

It has also been found that the nanoparticles in partially crystallized $Fe_{73.5}Si_{13.5}B_9Nb_3Cu_1$ (Finemet) and $Fe_{92-x}B_xZr_{7-y}Nb_yCu_1$, with $x = 2$, 4, 6, 8, 10, 12 and $y = 0$, 3.5 at% (Nanoperm-type) nanostructured soft magnetic alloys show a superferro–superpara- and a superpara–paramagnetic transition at high temperature [238]. The transition temperatures depend on the annealing conditions.

Fe–Zr–B soft magnetic materials also exhibit high magnetization of 1.60–1.70 T under an applied field of 800 kA/m as well as high effective permeability (μe) of 13,000–15,000 at 1 kHz [183]. Typical nanocrystalline bcc $Fe_{89}Hf_7B_4$ and $Fe_{84}Nb_7B_9$ alloys subjected to the optimum annealing exhibit high magnetization above 1.5 T as well as high effective permeability (μe) at 1 kHz above 20,000. The bcc Fe–M–B (M = Zr, Hf, or Nb) alloys also show low core losses (W)

from 1.4×10^{-1} to 2.1×10^{-1} W/kg at 50 Hz and 1.4 T and from 1.70 to 2.50 W/kg at 1 kHz and 1.0 T [239].

Annealed $Fe_{82}(Zr,Hf,Nb)_7B_{10}Cu_1$ alloys exhibit good soft magnetic properties especially in the high-frequency range [240]. The high concentration of boron suppresses growth of bcc-Fe grains and stabilizes the amorphous matrix. The result reveals that the reason for good soft magnetic properties is associated with the reduction of the magnetic anisotropy by rather strong exchange energy when annealing temperature is increased.

Nanocrystalline $Fe_{42.5}Co_{42.5}Nb_7B_8$ alloy with a structure consisting of nearly spherical bcc grains with size from 5 to 10 nm dispersed in the residual amorphous matrix was obtained by annealing of the amorphous alloy at 873 K for 3.6 ks and exhibits a high saturation magnetization (I_s) of 1.90 T and a low coercivity (H_c) of 60 A/m [241]. It also exhibits a very high Curie temperature (T_c) more than 1173 K. The segregation of the Nb element in the intergranular amorphous phase increases the thermal stability of the amorphous phase and suppresses the grain growth of the bcc phase. The high thermal stability of the structure and the high Curie temperature are promising for soft magnetic materials for high temperature applications.

The origin of the good soft magnetic properties is as follows: (a) The apparent anisotropy is decreased by the combined effects of the formation of the nanoscale bcc structure and the achievement of rather strong magnetic coupling between the bcc grains through the intergranular ferromagnetic amorphous phase. (b) The small saturation magnetostriction (λ_s) results from the nonequilibrium bcc phase. The solute-rich intergranular amorphous phase with high Curie temperature (T_c) and high thermal stability plays an important role in the achievement of the good soft magnetic properties through the attainment of the rather strong magnetic coupling between the bcc grains.

5.2.2. Hard Magnetic Alloys

Two types of permanent magnetic materials consisting mainly of Fe_3B with $Nd_2Fe_{14}B$ phase were obtained by annealing melt-spun $Nd_{4.5}Fe_{77}B_{18.5}$ flakes [242]. The microstructure is composed of nanoscale grains of magnetically soft Fe_3B and magnetically hard $Nd_2Fe_{14}B$ phases. High remanence of 0.8 Ms is obtained due to the remanence enhancement effect of exchange-coupled magnetic

grains. $J_r = 1.2$ T and $(BH)_{max} = 97$ kJ/m^3 while the coercivity, $H_c = 240$ kJ/m, is slightly low. Influence of heating rate on the microstructure of $Fe_3B/Nd_2Fe_{14}B$ nanocomposite magnets has also been recently studied [243]. Attempts to improve the coercivity of this type of magnet were made [244]. With increasing Cr content in $Nd_{4.5}Fe_{77-x}Cr_xB_{18.5}$ alloy, the intrinsic coercivity (H_{cI}) increased; however, the remanence (B_r) decreased considerably [245]. High coercivity values exceeding 300 kA/m were obtained in amorphous $Nd_5Fe_{72}Cr_5B_{18}$ crystallized into $Fe_3B/Nd_2Fe_{14}B$ state [246].

Low coercivity of $Fe_3B/Nd_2Fe_{14}B$ magnets impedes a limit on their application. The bcc-$Fe/Nd_2Fe_{14}B$ nanomaterials have higher coercivity than those for $Fe_3B/Nd_2Fe_{14}B$ magnets. H_c of 480 kA/m and $(BH)_{max}$ of 160 kJ/m^3 are reported for bcc-$Fe/Nd_2Fe_{14}B$ nanomaterials. The structure consist of two phases: magnetically hard $Nd_2Fe_{14}B$ with nanoparticles of α-iron on grain boundaries. Grain size of the $Nd_2Fe_{14}B$ is below 30 nm and particle size of the α-iron is below 10 nm [247].

α-$Fe/Nd_2Fe_{14}B$ nanostructured magnet of $Fe_{89}Nd_7B_4$ composition contains residual amorphous phase and shows $B_r = 1.22$ T, $H_c = 240$ kA/m, and $(BH)_{max} = 130$ kJ/m^3. This alloy has high iron and low boron concentrations [248].

Rapidly quenched Sm–Fe–N powders show high remanence values. The structure consists of a nanoscale mixture of $SmFe_7N_x$ phase and α-Fe with a size of 20–30 nm [249]. High remanence is due to the small crystal size and exchange coupling at interphase boundaries.

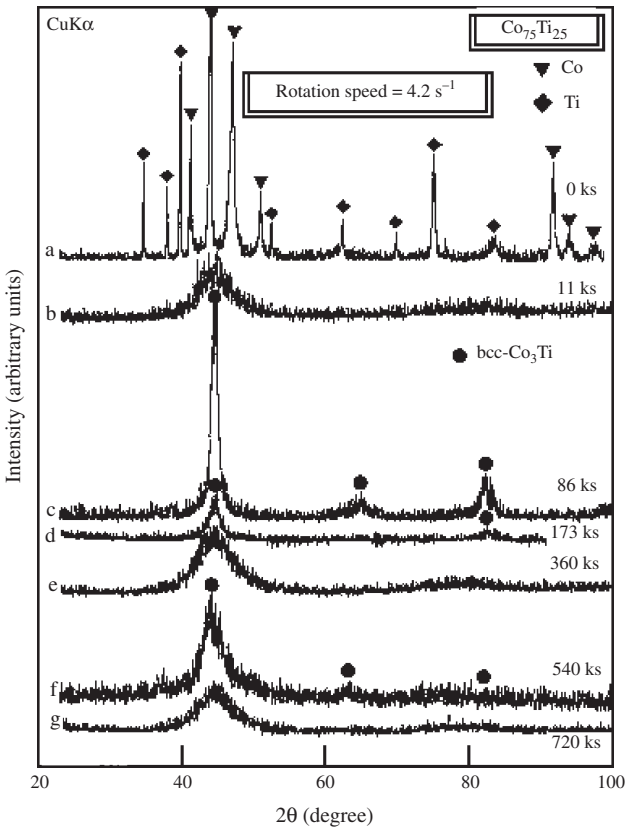

Figure 32. XRD patterns of ball-milled $Co_{75}Ti_{25}$ powders after (a) 0, (b) 11, (c) 86, (d) 173, (e) 360, (f) 540, and (g) 720 ks of milling time, using a rotation speed of 4.2 s^{-1}. 6. SOLID STATE PHASE TRANSFORMATIONS IN NANOSTRUCTURED ALLOYS

Most nanostructured materials, being metastable, transform on heating. In this section we will also show the examples of phase transformations in nanomaterials that have not been included in other sections.

6.1. Cycling Transformations

Cycling amorphous-to-crystalline phase transformations were observed in different binary TM–TM alloys [250]. For example, cycling phase transformations were observed during ball milling of elemental $Co_{75}Ti_{25}$ powder. After a few kiloseconds of milling, a solid-state reaction takes place at the fresh interfaces of Co/Ti layers and an amorphous phase of $Co_{75}Ti_{25}$ is formed after 11 ks (Figs. 32 and 33). This amorphous phase transforms into an ordered fcc-Co_3Ti upon heating to 880 K (crystallization). Further milling (86 ks) also leads to an amorphous–crystalline transformation (crystallization) and the formed phase is metastable bcc-Co_3Ti nanocrystalline powders. This transformation is attributed to the inability of the formed amorphous phase to withstand the impact and shear forces that are generated by the milling media (balls). When the milling time is increased (360 ks), the crystalline phase is subjected to several defects (points and lattice defects) that raise the free energy of bcc-Co_3Ti to a less stable phase (amorphous). Here, the crystalline–amorphous transformation which takes place is similar to the mechanical grinding method [251] in which the amorphization occurs by relaxing the short-range order without any compositional changes. Further milling leads to the formation of crystalline and/or amorphous phases depending on the milling time.

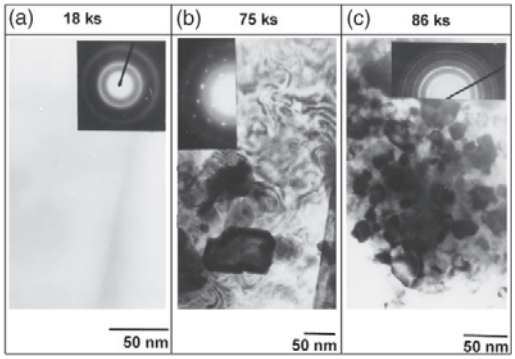

Figure 33. Bright-field TEM images and the corresponding selected-area electron diffraction patterns of as-ball-milled $Co_{75}Ti_{25}$ powders after (a) 18, (b) 75, and (c) 86 ks of milling time using a rotation speed of 4.2 s^{-1}. Reprinted with permission from [250], M. Sherif El-Eskandarany et al., *Acta Mater.* 50, 1113 (2002). © 2002, Elsevier Science.

6.2. Phase Transformation in Ge–Al–La Alloy

The structure of the as-solidified $Ge_{60}Al_{25}La_{15}$ alloy is a mixture of amorphous and metastable nanocrystalline phase [252]. It consists of colonies of needle-shaped crystalline phase with a nanoscale size in two dimensions crystallized within the amorphous matrix, as shown in Figure 34. Some nanoscale crystalline particles are also present in amorphous matrix, but their volume fraction is low.

The $Ge_{60}Al_{25}La_{15}$ alloy has a heating-rate-dependent transformation behavior [252]. Being heated using DSC at a heating rate of 0.33 K/s and higher this alloy showed the only single exothermic peak up to melting, whereas at lower heating rates of 0.17 and 0.08 K/s for example, as shown in Figure 35, about three heat effects are seen. It is important to note that total heat released during a single thermal effect of 85.7 J/g observed at a heating rate of 0.33 K/s is almost equal to total heat effects of 83.7 and 86.2 J/g observed at 0.17 and 0.08 K/s, respectively, calculated as a sum of all three effects [252].

The reaction related to the first DSC peak scanned at heating rates of 0.17 K/s or less was found to be "Amorphous phase + unknown crystalline phase 1 → unknown phase 2." This reaction is similar to the peritectic reaction in binary systems with amorphous phase instead of the liquid one. During subsequent two reactions pure *Fd3m* Ge precipitates from amorphous matrix and an unknown phase 2 transforms into unknown phase 3. This phase is stable in the $Ge_{60}Al_{25}La_{15}$ alloy. In accordance with equilibrium Ge–Al–La phase diagram it can be identified as Ge_2AlLa phase of unknown structure observed in [253].

The structure of the $Ge_{60}Al_{25}La_{15}$ alloy after the first strong heat effect changes greatly. The inhomogeneous as-solidified structure consisting of separate amorphous and crystalline phases (see Figs. 34 and 36a) transforms to a relatively uniform one (Figs. 36b and 37) in which needle-shaped particles of GeAlLa phase of about 10 nm in thickness are homogeneously distributed in the residual amorphous matrix. Due to the small crystal thickness diffraction peaks belonging to unknown phase 2 (marked by ▼ in Fig. 38) are broadened. Residual crystalline phase 1 is also seen in Figure 38.

Such a structural change takes place at a relatively short period of time of 2.4 ks at 578 K isothermally (Fig. 39) and of 42s at the range from 598 to 605 K during continuous heating at 0.17 K/s. Moreover, the unknown crystalline phase 1 has a wide area of homogeneity. Composition of crystalline particles determined by EDX analysis varied significantly ($Ge_{56-72}Al_{15-33}La_{12-17}$) whereas composition of amorphous phase ($Ge_{58.2}Al_{26.3}La_{15.6}$) was close to the alloy's composition. Thus, the transformation should be diffusive type. The thickness of the unknown phase 1 particle is about 50 nm on average while the size of the whole crystalline colony exceeds 10 μm. Simple calculation of the diffusion coefficient D using diffusion length l and time τ according to the relation $D \approx l^2/2\tau$ gives D values of about 1×10^{-18} and 3×10^{-17} m^2/s for single crystalline particles or 4×10^{-14} and 1×10^{-12} m^2/s for the whole colony at 578 and 598–605 K, respectively. Relatively high D values of alloying elements in the amorphous matrix obtained for the whole crystalline colony suggest an important role of grain boundary diffusion which can go much faster than the volume one.

The metastable nanocrystalline phase 2 was found to have a tetragonal lattice with lattice parameters of $a = 0.559$ nm and $c = 0.528$ nm [254]. According to EDX

analysis (beam size 3 nm) compositions of three different crystals of crystalline phase 2 were found to be $Ge_{52}Al_{31}La_{17}$, $Ge_{64}Al_{20}La_{16}$, and $Ge_{59}Al_{25}La_{16}$ [254]. The average composition ($Ge_{58}Al_{26}La_{16}$) is very close to the alloy's composition and can be written as $Ge_{12}Al_5La_3$.

In order to study the details of the first phase transformation in the $Ge_{60}Al_{25}La_{15}$ alloy (i.e., amorphous phase + unknown crystalline phase 1 → unknown phase 2), an isothermal differential calorimetry was carried out at 573 and 578 K. Fraction transformed versus annealing time dependence is shown in Figure 39. The volume fraction transformed at the time t is assumed to scale with the fraction of the total heat released. The transformation kinetics can be described on the basis of Eq. (5) [255] for volume fraction (x) transformed as a function of time (t):

$$x(t) = 1 - \exp[-kt^n] \tag{5}$$

k is an effective rate constant and n is Avrami exponent [255]. This is a simplified case of Eq. (1). The Avrami plot of $\ln[-\ln(1-x)]$ vs $\ln(t)$ yields a straight line with slope n and intercept $n\ln(k)$. From the data shown in Figure 39 the average slope is calculated to be $n = 2.7$. The slope value slightly changes with temperature being 2.6 at 578 K and 2.8 at 573 K. Thus, the volume fraction transformed as a function of time can be described on the basis of Eq. (5)

Reprinted with permission from [252], D. V. Louzguine and A. Inoue, *Mater. Res. Bull.* 34, 1991 (1999). © 1999, Elsevier Science.

with $n = 2.7$. Such a value of the exponent n corresponds to accelerated nucleation and three-dimensional crystal growth by volume diffusion. The data show that the reaction is of diffusion-controlled type.

6.3. Complex Devitrification of Glassy Alloys

The $Ge_{68}Cr_{14}Al_{10}Ce_4Sm_4$ amorphous alloy was found to have a multistage crystallization behavior [256]. Four clearly separated heat effects marked as A, B, C, and D are observed in the DSC trace (see Fig. 4a). As has been mentioned the first prolonged heat effect A is related to the process of the short-range order change in the amorphous matrix leading to the segregation of the Ge atoms forming Ge-enriched zones prior to crystallization. However, the size of such zones is not larger than that of the medium-range order zones observed in the as-solidified state. As shown in Figure 40 no crystallinity is seen in the sample heat treated up to the completion of reaction A (see Fig. 4a).

The type of reaction B is the most interesting in the present alloy. In the sample heat treated in DSC up to 660 K reaction B is complete, but reaction C has not started yet (see Fig. 4a). Three broadened diffraction peaks belong to pure *Fd3m* Ge. As shown in Figure 41 the structure of the sample heat treated up to the completion of the reaction B at 0.083 K/s consists of the equiaxed nanoscale Ge particles with the size of about 3–20 nm homogeneously distributed in the amorphous matrix (Fig. 41a, b) and relatively large dendrites of an unknown multicomponent $Ge_{18}Cr_4AlCeSm$ crystalline phase of about 0.5 μm in size (Fig. 41d, e). Thus, precipitation of Ge nanoparticles as well as nucleation

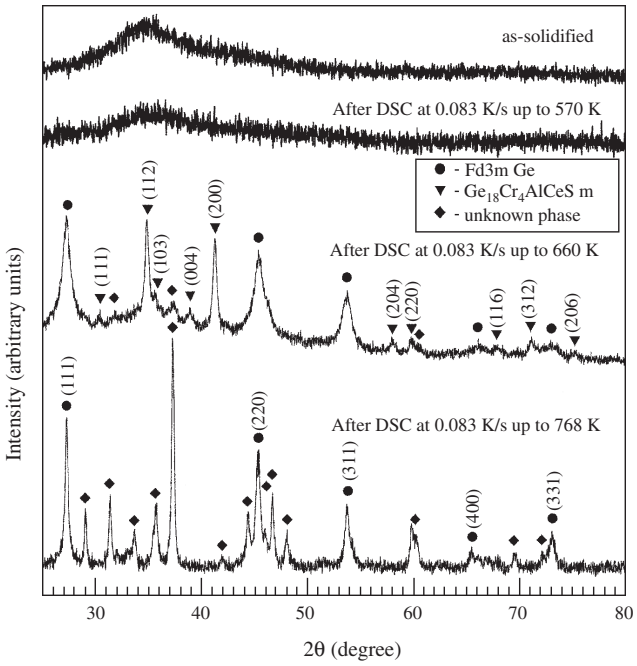

Figure 40. X-ray diffraction patterns of the $Ge_{68}Cr_{14}Al_{10}Ce_4Sm_4$ alloy in as-solidified and heat-treated using DSC state. Reprinted with permission from [256], D. V. Louzguine et al., *J. Mater. Sci.* 35, 5537 (2000). © 2000, Kluwer Academic.

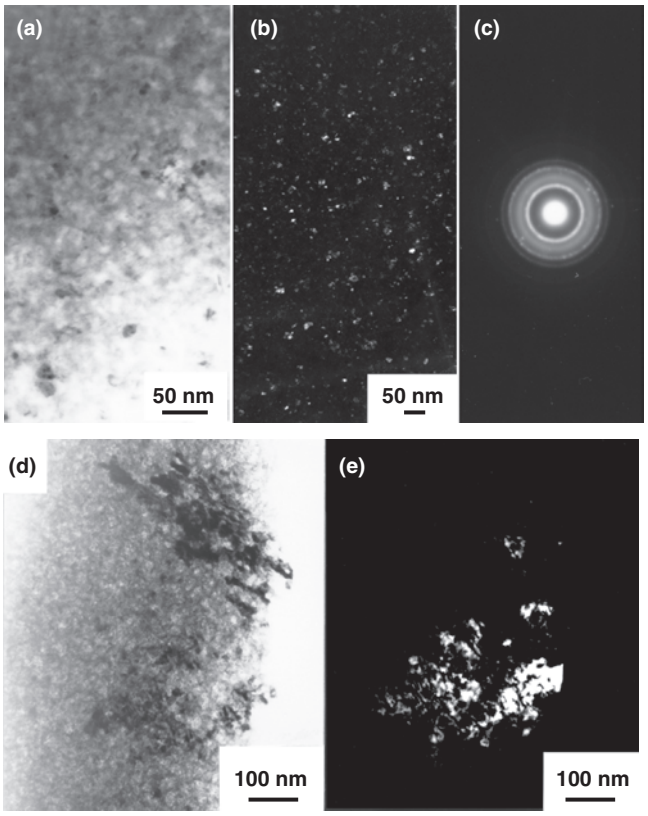

Figure 41. Microstructure of the $Ge_{68}Cr_{14}Al_{10}Ce_4Sm_4$ amorphous alloy. (a), (b), and (c) are bright-field and dark-field images and selected-area electron diffraction patterns, respectively, of the Ge nanoparticles embedded in an amorphous matrix. (d) and (e) are bright-field and dark-field images, respectively, of the $Ge_{18}Cr_4AlCeSm$ phase. Reprinted with permission from [256], D. V. Louzguine et al., *J. Mater. Sci.* 35, 5537 (2000). © 2000, Kluwer Academic.

and growth of the multicomponent $Ge_{18}Cr_4AlCeSm$ phase go simultaneously during a single heat effect B, although no eutectic-type coupled growth was observed. These two phases often have no common interface and are separated by the amorphous matrix (Fig. 41). Moreover, the size and volume fraction of the multicomponent phase depend on heating rate whereas the size and distribution of the Ge particles are independent of the rate. It can be suggested that Ge nanoparticles grew from the Ge—enriched zones formed during structural relaxation. As chemical composition of the $Ge_{18}Cr_4AlCeSm$ phase is close to composition of the amorphous matrix it likely nucleates by a polymorphous mechanism. $Ge_{18}Cr_4AlCeSm$ phase was found to have a tetragonal lattice of $a = 0.438$ nm and $c = 0.925$ nm [256]. This phase is a metastable one and disappears by reactions C and D (see Fig. 40 sample heat treated up to 768 K).

6.4. Solid-State Transformations Involving Quasicrystals

Mechanical alloying leads to formation of metastable and stable quasicrystalline phases in different alloy systems [257, 258]. For example, different structures including quasicrystals were obtained by heating a mechanically alloyed $Al_{65}Cu_{23}Fe_{12}$ powder mixture [259]. Solid-state reactions in mechanically alloyed nanocrystalline $Al_{65}Cu_{23}Fe_{12}$ powder were also studied [260]. A metastable disordered nanocrystalline phase forms as a result of mechanical alloying. Upon heating this phase undergoes a complex transformation, followed by partial decomposition and ordering. A metastable cubic phase transforms into an icosahedral quasicrystal in the temperature region 773–873 K [260].

In Al-based alloys an ordering transformation of the icosahedral phase at room temperature was observed. A transformation from higher symmetry of quasicrystals results in several variants of the product phase; for example, six variants of the decagonal phase are produced on transformation from the icosahedral phase [261]. The transformation of quasicrystalline phases to crystals involves the production of a high density of planar faults which produce streaking of reciprocal spots. The quasicrystals may transform into several intermediate metastable phases before transforming into the stable crystalline phase.

7. APPLICATIONS

Metallic nanomaterials are mostly used for structural and magnetic applications.

There are some reasons to believe that the problem of low ductility of nanostructured metallic materials subjected for structural applications will be solved in the near future and the production cost factor will be the critical one limiting their application. Nevertheless, nanostructured Ti could be used to replace commercial Ti-6Al-4V alloy in biomedical applications as an implantate. High mechanical properties were recently obtained in nanostructured Ti obtained by

severe plastic deformation [262]. Nanostructured Ti is also suitable for use in microthreaded connections.

The nanocrystalline Al-based alloys exhibiting high tensile strength of about 1 GPa have been already commercialized under the commercial name GIGAS. The GIGAS alloys also have higher specific strength and higher specific Young's modulus which are superior to those for conventional Al-based and Ti-based alloys. These advantages are already used in materials for some application fields such as rapidly repeating machinery parts requiring high specific strength and high specific modulus, main construction parts in robots, and high elevated temperature die casting materials, etc. [167].

The martensitic 9Cr-ODS (of Fe–9Cr–0.13C–2W–0.2Ti–$0.35Y_2O_3$ (mass%) composition) and ferritic 12Cr-ODS steels reinforced with stable Y_2O_3 oxide particles on a nanoscale are promising fuel cladding materials in fast nuclear reactors [263]. Oxide particles serve as blocks for mobile dislocations and as sinks for radiation defects at the particle–matrix interfaces resulting in high values of high-temperature strength and ductility. The alloys are produced by powder metallurgy and consolidation by hot isostatic pressure or hot extrusion.

Finemet $Fe_{73.5}Cu_1Nb_3Si_{13.5}B_9$, Nanoperm $Fe_{84}Zr_{3.5}Nb_{3.5}B_8Cu_1$, and Hitperm $Fe_{44}Co_{44}Zr_7B_4Cu_1$ alloys are used as soft magnetic materials. The feature limiting their application is low critical thickness.

Planar micromotors have the potential for high-speed control applications. These systems require closed loop control and therefore involve not only the motor but also associated high-speed control circuitry. Magnetic micromotors have been constructed by using deep X-ray lithography and metal plating. The devices consist of a stator that is rigidly attached to the substrate and a rotor that is fabricated as a fully released, free part made of Ni of 100 μm in thickness. The rotor is assembled onto the stator shaft with submicrometer tolerances. The structure is driven by an external rotating magnet or a fixed electromagnet. It is reported that rotational speeds of up to 8000 rpm have been obtained and maintained for several days [264]. Modulating the spectral properties of synchrotron radiation, different regimes of X-ray lithography lead to the mass fabrication of nanostructure as high resolution X-ray lithography or classical X-ray lithography is able to obtain a nanometer resolution below 50 nm [265].

Materials with reduced dimensions in the form of isolated nanoparticles, thin wires, or thin films are used in catalysts and semiconductor devices utilizing single or multilayer quantum structures.

Nanostructured surfaces with enhanced corrosion resistance, hardness, and wear resistance can be used as protective coatings in which the properties of a thin surface layer are improved by means of creating a nanoscale microstructure in a thin surface region.

Materials in the form of an array of quantum dots connected by nanowires synthesized by nanolithography [266], the tip of a tunneling microscope, or electron or ion beams are expected to play a key role in the production of the next generation of electronic devices such as terrabit memories [267], quantum computers, etc.

Nanostructured materials offer potential applications for hydrogen storage materials. High absorption–desorption rates can be achieved by decreasing the grain size [268].

High localized corrosion resistance of nanocrystalline Fe–18%Cr–8%Ni stainless steel prepared by sputter deposition [269] offers another possibility of usage as a corrosion resistant material.

In conclusion one must say that although in our days applications of metallic nanomaterials, especially as structural materials, are still very limited without any doubt nanostructured materials and nanocomposites will play a leading role in the materials science of the present century.

GLOSSARY

3DAP Three-dimensional atom probe technique.

Bs Saturation magnetic flux density.

Devitrification Solid-state reaction related to the formation of a phase with a long-range order from a glassy (amorphous) phase with a short-range order. Can be also called "crystallization" but "devitrification" is more precise term as there is the possibility of confusion with crystallization reaction from the liquid. Process opposite to vitrification (glass formation).

Hc Coercivity.

hcp Hexagonal close packed lattice.

MRO Medium-range order zones, typically 0.5–2 nm in size or a few interatomic distances. An intermediate ordered state between glassy (disordered on a long-range-scale) and long-range ordered crystalline state. MRO is characterized by a diffuse boundaries between ordered regions.

n Avrami exponent.

SAED Selected-area electron diffraction pattern. Taken via TEM of the local area.

UTS Ultimate tensile strength, close on meaning to σ_f.

Nanostructured Metals in Surface Enhanced Raman Spectroscopy

Helena I. S. Nogueira, José J. C. Teixeira-Dias, Tito Trindade

University of Aveiro, Aveiro, Portugal

CONTENTS

1. INTRODUCTION

Since the 19th century, a few pioneering scientists have dedicated efforts to understand the physical and chemical properties of metal colloids, in particular of gold colloids. Michael Faraday was probably the first nanochemist, in the sense that he employed chemical reasoning in the synthesis of stable gold colloids and correctly assigned their unusual optical properties to size effects occurring in particles of very small dimensions [1]. On his own words: "Agents competent to reduce gold from its solution are very numerous, and may be applied in many different ways, leaving it either in films, or in an excessively subdivided condition. Phosphorus is a very favourable agent when the latter object is in view. If a piece of this substance be placed under the surface of a moderately strong solution of chloride of gold, the reduced metal adheres to the phosphorus as a granular crystalline crust. If the solution be weak and the phosphorus clean, part of the gold is reduced in exceedingly fine particles, which becoming diffused, produce a beautiful ruby fluid" [1]. Gustav Mie is still one of the most cited authors in the scientific literature due to his work on the optics of turbid media (and metal colloids in particular) [2]. The Nobel Prize laureate in chemistry in 1925 was Richard Zsigmondy for his contributions to the foundation of modern colloid chemistry. Among numerous contributions, Zsigmondy was able to measure particle sizes of gold colloids using one of his inventions, an ultramicroscope. Other outstanding and pioneering scientific contributions could be named to demonstrate that nanometals have been a scientific issue for a long time. Nevertheless, as it is generally recognized today, the term nanometal (or nanomaterial in a broad sense) has never been so frequently used in diverse innovative contexts as it is today. There are a number of factors which may explain this upsurge on this class of materials, which include: the recognition that nanomaterials have properties different from those of the macrocrystalline analogues; the advent of characterization techniques at an atomic scale; the increase of computing power allowing the simulation of larger scale nano-objects, and the tendency to achieve better performances in miniaturized devices.

The main focus in this chapter will be on the application of nanostructured materials in surface enhanced Raman scattering (SERS) studies. The surface-enhanced Raman effect has been known since the studies of Jeanmaire and VanDuyne [3] and Albrecht and Creighton [4] on the adsorption of pyridine on a rough silver electrode. This spectroscopic method differs from other types of techniques in that the relevant physico-chemical phenomena occur at the surface of a solid phase when interacting with specific adsorbates. Moreover, it is a spectroscopic tool generally applied to very dilute samples of the adsorbate. Notably these two factors are of great interest for nanosciences and, in particular, for the chemical manipulation of metal nanoparticles and the study of its surfaces.

Nanometals are of great interest because they show unique properties related to their small size and large surface-to-volume ratio. The fabrication of nanodevices using chemical methods will be dependent on the ability to control the chemical surface in nanoparticles, which may be regarded as the building blocks for novel nanostructures. Contrary to the understanding of their bulk properties, the chemistry of nanoparticles surfaces is less understood. Therefore, a nondestructive technique, such as Raman spectroscopy, which can give information on the type of interactions occurring between molecular species

Volume 7: Pages (699–715)

and metal nanoparticles, is scientifically valuable in the context of nanotechnology.

Most of the work reported so far on the SERS effect has involved silver and gold colloids and, though in considerably less number, other noble metals such as platinum. To understand the importance of SERS in the study of metal nanoparticles and their assemblies, it is relevant to be aware of some fundamental properties of metal nanocrystals. Therefore, this chapter starts with a summary of some basic concepts involved in the synthesis, surface derivatization, and assembly methods of metal nanocrystals. These nanostructures are zero-dimensional (i.e., they correspond to systems that are finite in all directions). SERS as a Raman spectroscopic method will then be reviewed and elucidative examples will be given. Finally we will note some perspectives of development of this technique taken in consideration of its applications to nanosciences. Since the authors have a chemical background the emphasis will be on chemical nanostructures, which are nano-objects prepared by chemical methods. For more extensive discussions on nanometals the reader is referred to [5–11].

2. CHEMISTRY OF METAL NANOPARTICLES

2.1. General Concepts

Metal nanocrystals show distinct properties from those of the macrocrystalline counterparts due to their reduced particle size and larger surface to volume ratios. Since the semantics in nanosciences literature vary widely, it is important to make clear the terminology used here which follows closely the criteria adopted by Kreibig and Vollmer in defining the different classes of metal clusters [11]. These authors distinguish metal clusters according to the dimensions of the particles and they have used the general term "cluster" to define those particles. For the purposes of this chapter, the term "nanocluster" will be used here to mention nanoparticles composed of up to hundreds of atoms, with dimensions typically less than 3 nm in diameter, which includes the "very small clusters" and "small clusters" mentioned by those authors [11]. Here, the "larger clusters" will be generally referred as "nanocrystals"; this includes the larger nanoparticles forming most of the metal colloids employed in SERS which may have dimensions even superior to 100 nm. In metal nanocrystals the internal crystalline structure is similar to the macrocrystalline lattice but they show distinct physical and chemical properties from the bulk materials and from nanoclusters of metallic atoms.

Chemists have long recognized the importance of the availability of a large surface area in nanometals, for example in heterogeneous catalysis [12]. Surface chemistry controls to a large extent the properties of catalysts, quantum semiconductor devices, and bioprobes, to mention just a few examples. Due to the large surface energy, nanoparticles are thermodynamically unstable and with time tend to coalesce into the stable bulk structure. To prevent agglomeration, the metal surfaces are molecularly tailored using Lewis bases which render to the nanoparticles steric hindrance. Unless otherwise stated, it is assumed that the metal nanocrystals and nanoclusters reported here are generated by chemical means leading to surface protected nanostructures. From a chemical perspective there is an obvious resemblance between the nanoclusters and the larger nanocrystals, in the sense that organic ligands are used to stabilize the metal core.

It is now well established that the intrinsic properties of metals change as the particle size is reduced from the bulk material to the nanocluster scale. A few selected examples will be given which clearly elucidate this important point. A fundamental aspect, which immediately arises, is related to the structure development from an assembly of a few metallic atoms in a nanocluster to a typical macrocrystalline lattice. Although this topic is still a matter of intense investigation there are some related important points to be addressed. First, it should be kept in mind that nanoclusters are in fact quantum-sized objects. Therefore their stable structures are governed by quantum mechanics; *ab initio* methods have been employed to predict the structures of small nanoclusters [11]. The structural patterns observed in very small nanoclusters may no longer be related to the typical geometrical arrangement of the atoms observed in the bulk lattice. Schmid and co-workers have reported a series of giant metal nanoclusters whose cores correspond to geometrical arrangements containing a specific number of atoms, often called magic atom-number clusters [6, 7]. These nanoclusters seem to be built by the progressively addition of shells of identical atoms to a central atom. For example, it has been shown that gold clusters, which in the bulk crystallizes with a face centered cubic lattice, adopt specific geometrical arrangements depending on the number of atoms forming the nanocluster [6, 7]. The experimental identification of metal nanoclusters with a specific number of atoms (magic atom-numbers) has also been reported for example for sodium and gold [13, 14].

The structural transformations occurring as the particle size reduction proceeds down to the nanocluster regimen are accompanied by dramatic changes in the electronic, magnetic, catalytic, and thermodynamic properties [10]. A first effect of reducing particle size is the creation of more surface sites. An elucidative example of these changes is exemplified by the dramatic decrease on the melting temperature of metals as the particle size is reduced to a few nanometers. The melting temperature of metal nanoclusters decreases with particle size and the rate of decrease increases drammatically at very small sizes [10]. In terms of the electronic structure of the metal nanoclusters, the energy levels forming a continuum half-filled conduction band in a bulk metal become more discrete, approaching the molecular-like description based on more localized molecular bonds [8, 11]. In these nanoclusters very strong size effects govern their electronic and structural properties; therefore theoretical models derived from quantum mechanics should apply to have a complete understanding of this behavior. Measurements on the ionization potentials show that depending on the number of metal atoms composing the nanoclusters there are specific sizes and geometries which are the most stable; as mentioned these correspond to specific atom-numbers. Due to confinement of the electron wavefunction by the particles dimensions, the bands in these systems become best described as sets of discrete energy levels [8].

The average spacing within successive quantum levels is known as the Kubo gap and is given by

$$\delta = 4E_F/3n \quad (1)$$

where E_F is the Fermi energy of the bulk metal and n is the number of valence electrons in the nanoclusters [8]. The properties of nanoclusters, such as electrical conductivity and magnetic susceptibility, may present quantum size effects due to the existence of the Kubo gap. In certain conditions, low temperatures for instance, the metal nanoclusters may exhibit nonmetallic behavior since this gap is comparable to the thermal energy necessary to promote electrons across successive energy levels.

SERS studies on nanostructured metals are usually performed on metal colloids whose dimensions are typically in the 10–200 nm range. These nano-objects have dimensions larger than those of the nanoclusters mentioned previously and show extrinsic effects, which are size-dependent responses to external fields or forces irrespective of the intrinsic effects observed for nanoclusters [11]. The optical properties of metal nanocrystals and nanoclusters are size-dependent and distinct from the bulk metals. For example, it is well known that macrocrystalline metals are highly absorbent in the infrared region of the electromagnetic spectrum; in contrast metal nanoparticles are transparent in this wavelength region. Gold and silver nanoparticles, the most used metals in SERS studies, have characteristic optical spectra [16, 17], showing strong bands in the visible (Fig. 1). The incidence of ultraviolet (UV)/visible light in metal nanocrystals originates an absorption band due to the spatial confinement of the electrons of the conduction band. Due to this confinement effect, the plasmon oscillations become restricted to a narrow frequency range located in the visible [11]. The optical spectra of metal nanocrystals can be predicted using the Mie equations. For isolated spherical particles with dimensions much smaller than the wavelength of the incident light, the absorption band due to the dipolar surface plasmon is observed at a frequency ω_0 such that [2, 9, 11]

$$\varepsilon_1(\omega_0) = -2\varepsilon_m \quad (2)$$

where

$$\varepsilon(\omega) = \varepsilon_1(\omega) + i\varepsilon_2(\omega) \quad (3)$$

$\varepsilon(\omega)$ is the dielectric function of the metal particles and ε_m is the dielectric function of the surrounding medium. By varying the nanoparticle dimensions there are shifts on the resonance band compared to the classical Mie frequency which can be interpreted using Mie's theory [11]. From a chemical point of view, it is of interest to consider surface coated metal nanocrystals. The optical spectra of coated nanoparticles can be obtained using the Mie formalism and the appropriate methodologies [9]. The ligands at the nanoparticles surface form a dielectric cap whose electric insulation can be varied for instance by varying the length of the alkyl chains of the ligand.

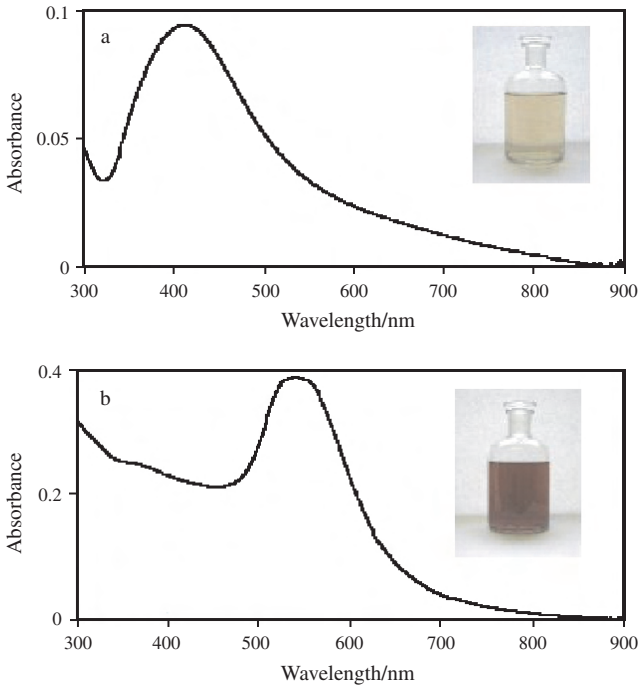

Figure 1. Absorption by silver (a) and gold (b) hydrosols.

2.2. Chemical Synthesis

Although the synthesis of metal colloids has been investigated since the work of Faraday, the interest in chemical methods to yield reasonable amounts of functional and highly stable nanometals is recent. Within the variety of synthetic methods developed during the last two decades, the need to prepare nanoparticles which are morphologically uniform, have the ability for surface functionalization and may be further used to fabricate nanostructured devices becomes clear. In general, metal nanoparticles have been prepared using the chemical strategy delineated by pioneering colloidal chemists (i.e., the addition of a reducing agent to a solution containing the metal salt). These methods vary essentially on the type of the reducing agent used, the solvent medium, the order/amount of reagent addition, and the chemical conditions employed to stabilize the as-prepared nanoparticles.

The preparation of gold nanoparticles using the citrate method, still one of the most popular chemical methods to obtain gold colloids, involves the reduction of the $[AuCl_4]^-$ complex by citric acid [18]. Similarly, Ag colloids can be prepared by this method using silver nitrate or acetate as the starting salt. The metal particles are electrostatic stabilized in solution, during a relatively long period of time, due to a citrate rich surface which avoids nanoparticle coalescence. In aqueous solution, electrostatic stabilization of metal nanocrystals has been commonly used. The stability and quality of these colloids for SERS can be easily evaluated by their optical spectra, which should be dominated by the characteristic surface plasmon sharp bands (Fig. 1). Broadening of the bands is associated with agglomeration processes. In some situations this agglomeration step might be important to record good SERS spectra. The SERS activity/sensitivity of these nanoparticles is strongly dependent on their morphological characteristics. In other words, in

a nanoparticle ensemble, not all the particulates will have the same SERS sensitivity. This was shown by investigating the SERS activity of silver colloids which had been size fractionated from a morphologically heterogeneous sample [19]. In a typical silver colloid prepared by the standard citrate-reduction procedure of Lee and Meisel, only about 0.1–1% of particles are highly SERS sensitive. These particles are large faceted nanocrystals (80–100 nm) which can be concentrated in a colloid to about 10–15% in relation to the starting sample, using size-selective fractionation methods [19]. Morphological modifications on the generally spheroidal metal nanoparticles may be obtained by modifying the chemical speciation during the synthesis. Gold nanorods have been reported via photochemical synthesis which involved reducing $[AuCl_4]^-$ in the presence of $AgNO_3$ and organic surfactants [20]. The gold nanorods have diameters of 12.6, 15, and 18 nm, depending on the amount of silver nitrate used during the synthesis. Gold nanoparticles spherical in shape were mainly obtained in the absence of silver ions [20].

The synthesis of metal nanocrystals can be carried out in a solvent medium which acts as the reducing agent of the metal salt [21–23]. Organic solvents such as ethanol [21], ethylene glycol [22], and dimethylformamide [23] have been used to obtain metal nanocrystals with distinct particle sizes and morphological properties. These methods involve some sort of external energy (e.g., heat) to promote the reduction of the metal salt. It should be noted that although SERS studies on metal colloids involve frequently an aqueous medium, there are reports on SERS spectra obtained in other solvents [24]. Good quality SERS spectra of organic adsorbates have been reported, using silver colloids dispersed in organic solvents such as dimethylformamide and acetonitrile [24].

In the chemical synthesis of metal nanocrystals, experimental conditions are set up so that the particle growth process is terminated abruptly and a stable sol is formed in the liquid medium. The stability of the as-formed particles against agglomeration can be attained by surface capping or by electrostatic repulsion. This general idea is behind many synthetic methods in which polymers, surfactants, or Lewis bases have been used to surface cap the small particles formed (nanocrystals). An elucidative example of this concept is the reduction of a metal salt in confined spaces such as reverse micelles [25]. Reverse micelles have nonpolar tail groups forming an interface with the bulk hydrocarbon solvent. The polar head groups are directed toward the interior of the micelle, which contains a droplet of a polar solvent, usually water. The formation of the metal phase occurs inside this nanoreactor by reduction of a metal salt. The aqueous droplet is capable of solubilizing the starting metal salt and also provides the medium in which nucleation and growth occurs during the reduction of the metal salt. In the context of this chapter, it is important that the metal nanocrystals surfaces can be modified using either organic ligands or a second inorganic phase to replace the surfactant molecules. One of the major advantages of metal reduction inside reverse micelles is its simplicity associated to two important requirements on metal nanoparticle preparation. These are (i) size-tuning and size polydispersity control (by varying $w = [\text{water}]/[\text{surfactant}]$) and, (ii) surface modification, since the surfactant molecules at the nanocrystals surface can be replaced by other chemical capping agents, such as thiols or amines. A simple relation was deduced to predict the water pool radius in reverse micelles using bis(2-ethylhexyl)sulfosuccinate (AOT) as the surfactant [25]:

$$R_w(\text{Å}) = 1.5w \tag{4}$$

The use of confined spaces in organized amphiphilic structures has been employed in the synthesis of several metals in quite distinct contexts. These include the formation of ultrathin particulate Ag films [26], local control of the shape of Cu particles [27, 28], and the formation of monodispersed nanoparticles for a wide range of metals, including bimetallic systems [25, 29]. In these few examples the subject of study is related to the metal nature surface and in particular to the type of chemical bonding occurring between the capping agent and the metal sites. It should be noted that usually the capped nanometals can be isolated as powders and redispersed in solvents for further chemical or physical treatments. In order to obtain narrow particles size distributions the nanodispersed metal can be further subjected to size-selected precipitation methods [30].

Other confined spaces have been used in the preparation of metal nanoparticles. Polymers, for example, are interesting stabilizers to produce metal nanoparticles with controlled shape and size. The reduction of $[AuCl_4]^-$ to yield gold nanoparticles has been performed at room temperature in the presence of poly(vinylpyrrolidone) as the stabilizer using the oxygen-free solvent formamide [31]. As mentioned, this is a situation in which the solvent formamide is the reducing agent. Nonspherical Pd nanocrystals have been prepared using surfactant micelles and a polymer gel [32]. In this regard, the UV photolysis of $Pd(acac)_2$ previously solubilized in anionic SDS (sodium dodecyl sulfate) micelles and poly(acrylamide) gel yielded faceted Pd nanocrystals (tetrahedral or octahedral shaped). Although the mechanism of formation of these Pd nanoparticles is not known, there is a synergistic effect involving both the micelles and the polymer, in a process possibly mediated by the type of interaction occurring at specific metal surfaces with the chemical sites of the polymer matrices. The polymer gel confers some rigidity to the confined spaces limiting the shape changes occurring on the SDS micelles due to thermal motion. The synthesis in the absence of the polymer did not yield nonspherical Pd nanocrystals, revealing the importance of the polymer gel to influence the faceted final morphology of the particles. Fine divided Pd is a very important heterogeneous catalyst; the knowledge of which surfaces are active in chemical catalysis may be inferred during the synthetic process, including *in-situ* spectroscopic analysis of the particle formation. Therefore, Raman spectroscopy is a potential tool to investigate the interaction of well-defined Pd nanoparticles, as well as other faceted noble metal particles, with adsorbates in other media, including hard matrices such as pillared clays [33, 34], metal oxides [35], or silica spheres [36]. Synthesis in large quantities is also a major limitation on most of the chemical methods employed to produce nanometals. Although for SERS applications scale-up synthesis is not needed, this point should

be considered for the use of nanometals in the large-scale production of devices or in catalytic processes. A possible strategy to overcome this limitation involves the synthesis of nanometals in confined spaces of solid polymer matrices. The matrix acts as an active template preventing nanoparticle agglomeration and promoting surface passivation. An important aspect in this strategy is the possibility to redisperse the nanometals allowing further chemical manipulation. This method has been employed in the preparation of Pt nanoparticles in the solid state via a polymer matrix [poly(*N*-vinyl-2-pyrrolidone)] effect [37].

The reduction of metal salts in order to produce nanosized metals has also been accomplished using other strategies and a few more will be briefly mentioned. Copper nanoparticles have been prepared by thermal reduction and sonochemical reduction of the precursor copper(II) hydrazine carboxylate [38]. Despite the use of the same copper precursor, under an argon atmosphere, the chemical composition of the final products differs depending on the method used. Hence, whereas the thermal reduction yielded pure irregularly shaped Cu nanoparticles (200–250 nm), a mixture of the metal phase and Cu_2O was obtained when the sonochemical method was applied. The presence of the oxide phase was attributed to the generation of OH· radicals that are formed during the sonolysis of water. The sonochemical synthesis under a mixture of argon and hydrogen atmosphere led to pure aggregated copper nanoparticles (50–70 nm). This work also highlights the importance of the preparative method for the final properties of the nanometals, and their use in processes in which the surface plays an important role, such as catalysis. In fact, the thermal derived nanoparticles are faceted and dense while the sonochemical derived nanoparticles are porous. Both syntheses yielded Cu nanoparticles showing superior catalytic activity (Ullmann reaction) as compared to the analogous commercial powders. Copper and palladium form alloys over their entire composition range. Bimetallic palladium–copper nanoparticles stabilized by poly(vinylpyrrolidone) (PVP) have been prepared by thermoreduction (135 °C) of Pd and Cu acetates in 2-ethoxyethanol [39]. Poly(vinylpirrolidone) was used here to surface cap the metal nanoparticles allowing the formation of highly monodispersed PdCu/PVP bimetallic particles (30–50 Å ± 10%).

Electrochemical methods have been shown to meet two important criteria in nanoparticle synthesis, particle size control and surface stabilization [40]. Hence, tetraalkylammonium-stabilized Pd and Ni nanoparticles have been reported by a simple electrochemical method. Size tuning is achieved by variation of the current density and high yields of the nanometals are obtained [40]. The formation of the metal powders is avoided due to the presence of tetraalkylammonium or phosphonium salts. The observed particle sizes are in accordance with the equation for the critical radius (R_{crit}) of adatoms formed at the cathode interface [40],

$$R_{crit} = \frac{2M\gamma}{nF\eta\rho} \tag{5}$$

where M is the molecular weight, γ is the surface tension, F is the Faraday constant, η is the overpotential, ρ is the density of the nanoparticles, and n is the valency. Equation (5) shows that the particle critical radius is inversely dependent on the applied overpotential and therefore the current density. Note that numerous studies on SERS have been performed on metal electrodes and this type of chemical synthesis may constitute an interesting bridge to nanoparticle formation and mechanisms for surface detection.

Rigorous size tuning and surface tailoring are still the major challenges in the chemical synthesis of metal nanoparticles. The delineation of diverse chemical strategies to provide useful alternatives in the synthesis of various metals is still a very active research area. Associated with the chemical synthesis of nanometals, there are in some cases postpreparative methods, such as size-fractionation procedures and surface modification methods. The main idea is to end up with a quasi-monodispersed nanometal with functionalized surfaces. These particles will form the basis of devices in which the properties related to the dimensions and high surface area of the building units are fully exploited. The use of nanocomposite particles containing a SERS active metal as one of the components should also be pointed out. As will be seen later this may prove interesting to expand the studies of SERS to various types of surfaces.

2.3. Surface Modification and Assembly

The ability to control the chemical surface in nanometals is essential to the fabrication of nanodevices. This is directly related to the use of assembly methods to produce organized nanostructures using highly stable passivated nanocrystals, here regarded as the building blocks. The surface derivatization of the metal particle surface should not disturb the integrity of the metal core. The particle surface can be derivatized by either an inorganic layer, an organic layer, or both. Only the organic surface derivatization of nanometals will be mentioned here. The silica encapsulation of semiconductor and metal nanocrystals has been reviewed [41]. The type of organically capped surface allows the control of the geometrical arrangement and spacing of the nanometal particles, as well as of the higher order structure observed in the final assembly.

Thiol or ammine passivated metal nanocrystals have been the most investigated organically capped systems. The surface passivation of gold nanoparticles with thiol compounds (e.g., alkanethiols with long alkyl chains) has been widely used since the work of Brust and co-workers [42, 43]. These authors have reported the formation of dodecanethiol passivated gold nanoparticles by reducing $[AuCl_4]^-$ in a toluene solution, using aqueous $NaBH_4$ as the reducing agent, after phase transfer using the cationic surfactant tetraoctylammonium [42]. The high affinity of the alkanethiol molecules to the gold surfaces prevents the coalescence of the gold nanoparticles into the bulk phase and also allows the isolation of the nanometal as a powder, which is redispersible in a wide range of organic solvents. The overall reaction is summarized by [42]

$$AuCl^-_{4\,(aq)} + N(C_8H_{17})^+_4(C_6H_5Me) \longrightarrow N(C_8H_{17})^+_4AuCl^-_4(C_6H_5Me) \tag{6}$$

$$m\mathrm{AuCl_4^-(C_6H_5Me)} + n\mathrm{C_{12}H_{25}SH(C_6H_5Me)} + 3me^- \longrightarrow 4m\mathrm{Cl^-_{(aq)}} + (\mathrm{Au}_m)(\mathrm{C_{12}H_{25}SH})_n(\mathrm{C_6H_5Me}) \quad (7)$$

By varying the length of the alkyl chain, the diameter of the gold nanocrystals can be varied within the nanosize regimen. This type of Au nanocluster contains 200–1000 atoms as determined by mass spectrometry and electron microscopy [14, 44]. The aurothiol nanoclusters reversibly condense to form films or powders [14, 44]. An interesting feature of these Au nanoclusters relies on the possibility of self-assembly into ordered close-packed structures due to steric hindrance of the long alkyl chains. X-ray diffraction performed on these superstructures revealed that in addition to the diffuse peaks due to the Au atoms within individual nanoclusters, there are sharp features in the small angle region attributed to three-dimensional (3D) superlattice formation [44]. The nanoclusters assemblies seem to consist of compact crystalline Au cores capped at the surface by thiolates bound to Au sites through the sulfur atoms. The *n*-alkyl chains tend to organize and fill the voids within the nanoclusters to obtain maximal dense packing. The observed high symmetry structures, hexagonal close-packed and cubic close packed, observed for the 3D superlattices become destabilized as the *n*-alkanethiol monolayers become thicker in relation to the core dimensions, leading to more open structures such as the body-centered cubic structure. This has been described as an increase of the softness of the Au nanoparticles which results in superstructures of lower symmetry and lower coordination numbers [44]. These nanostructures are of great interest not only from the academic point of view but also to fabricate nanodevices, since they can be functionalized and integrated into other surfaces and solid state structures [45, 46]. There have been various adaptations to the method initially proposed by Brust et al. to produce thiol-cappped nanometals. One interesting example consists of the formation of nanoparticles and the surface passivation with thiols in a one-pot method [47]. Such a method consists on the preparation of a hydrosol of Au (it works also for Ag or Pt) nanoparticles, by reducing $[AuCl_4]^-$ with tetrakis(hydroxymethyl) phosphonium chloride. A toluene solution containing the alkanethiol is added to the hydrosol; further addition of HCl to the biphasic mixture led to the migration of the metal nanoparticles to the organic phase. This is also an interesting experiment to show the aurifilicity of sulfur compounds.

The self-assembly of *n*-alkanethiolate monolayers has been used on other metal nanostructures, for example silver nanocrystals [48, 49]. These monolayers encapsulate the Ag nanoparticles, prepared electrochemically, protecting the metal sites from further reactions for example by the anodic dissolution in pure water. Using this strategy, self-assembly and chemical protection have not been observed in using long-chain *n*-alkyl amines [49]. However, these compounds have been used as efficient surface passivating agents on gold nanoparticles (25–70 Å) [50]. These amine-capped Au nanocrystals have been prepared by the reduction of $[AuCl_4]^-$ by $NaBH_4$ in the presence of a series of *n*-alkylamines. Therefore, a method similar to the original method proposed by Brust et al. was employed with the main exception that *n*-alkylamines were used instead of *n*-alkanethiols. The amine/gold surface interaction is charge-neutral via weak covalent bonds. The hydrophobic character of the amine-capped Au nanoparticles allows dispersion in a range of organic solvents although this behavior strongly depends on the synthetic method used in their preparation [50].

In principle, hybrid superlattices composed of metal and semiconductor nanocrystals could be obtained by the assembly methods employed for the single components. The appropriate tailoring of the nanocrystal surfaces should be viewed as an influential parameter for obtaining well-organized hybrid nanostructures. For example, layered nanocomposites of close-packed gold nanoparticles and TiO_2 layers have been reported [51]. The gold nanoparticles were prepared by reduction of $HAuCl_4$ by $NaBH_4$ in the presence of the disulfide $HO(CH_2)_{11}SS(CH_2)_{11}OH$, which acts as the nanocrystal surface stabilizer. The modified gold nanocrystals have surface hydroxyl groups being chemically compatible to participate in the sol–gel process used to generate the TiO_2 particles from metal alkoxide hydrolysis. A general procedure to obtain hybrid superlattices, of metal–metal or metal–semiconductor type, has been reported [52]. These heterostructures may consist of alternate layers of semiconductor (CdS) and metal (Pt) nanocrystals obtained from layer-by-layer deposition by using dithiols as cross-linkers.

The mechanism of assembly of nanoparticles involves nanocrystal-specific interactions still not fully elucidated, both in terms of capping agent/nanoparticle interactions and interparticle (surface capped) interactions. Hence, the amine-capped Au particle stability with respect to agglomeration was attributed to kinetic factors [50] whereas the alkane-capped Au particles were shown to possess thermodynamic stability. With respect to the interparticle interactions involved in the formation of larger nanostructures, besides the type of capping agent, the possible mechanism seems to depend on the exact nature of the particle core. In the formation of thiol capped Ag nanocrystal superlattices [53], the capped inorganic nanocrystals were described as soft balls, the organic ligands filling the voids between the Ag cores, hence determining the interparticle spacing. Entropy effects at high particle volume fractions drive the well positioning of the capped Ag nanocrystals into an extended face centered cubic structure. More recently, it was reported that the incorporation of carboxylic groups in thiolate capping agents allows controllable interparticle packing, ordering, and branching of Au nanostructures [54]. A model involving both hydrogen bonding at the carboxylic groups and cohesive van der Waals interdigitation of the thiolate molecules was proposed to explain the interparticle assembling forces.

A number of methods have emerged recently in order to produce metal nanoparticles with a variety of functional groups other than thiolates. Although the fundamental goals on these procedures are generally similar, [i.e., surface tailoring for nanometal protection and further assembly into larger (and distinct) nanostructures], the fact is that depending on the type of capping, chemical selectivity can be attained. A fundamental idea in this approach aims to make use of the particular molecular shape of the cap to bind to metal sites. Calix[4]arene type molecules have been particularly investigated as metal receptors [55, 56]. Gold-thiol

monolayers of calix[4]resorcinarenes for molecular recognition and sensing have been used. For example the calix-4-resorcinarene molecules can anchor to the gold surface using the thiol terminated alkyl chains, leading to well-packed monolayers (each 22–24 ± 2 Å) at 60 °C [55]. In these monolayers the bowl type structure formed by the phenol rings may act as molecular receptors for specific adsorbates. Other examples of the preparation of nanostructured functional materials due to chemical selectivity are the preparation of cyclophane receptor–Au nanoparticles for electrochemical sensing [57] or the photoinduced charge separation in fluorophore–gold nanoparticles [58]. Table 1 summarizes some systems in which organic compounds have been used to surface passivate metal nanoparticles in order to form functional superstructures. It should be noted that SERS studies have rarely been used in the characterization of these hybrid systems which open up interesting possibilities to develop this spectroscopic method in the field of the nanosciences.

3. SURFACE ENHANCED RAMAN SPECTROSCOPY (SERS)

3.1. Fundamentals of Raman Spectroscopy

In the issue of *Nature*, March 31, 1928, a scientific note entitled "A new type of secondary radiation" was published, signed by Raman and his student Krishnan [60]. Using an analogy with X-ray scattering, it was claimed that "also in the case of ordinary light two types of scattering, one determined by the normal optical properties of the atoms or molecules, and another representing the effect of their fluctuations from their normal state" should be expected. A simple experiment with a beam of sunlight, a liquid sample in between two light filters—a blue–violet filter and a green–yellow one—and a light detector supported those conclusions. In a subsequent issue of *Nature* (April 21), another paper entitled "A change of wavelength in light scattering" was published, this time signed only by Raman [61]. It is interesting to note the worries of Raman at the time and his reasoning to convince himself that the observed secondary radiation was not a fluorescence. The "excessive feebleness" of this "modified scattering" and its "polarization characteristics" were pointed out. A month later, in yet another issue of *Nature* (May 5), Raman and Krishnan published an explanatory note of the observed effect, entitled "The optical analogue of the Compton effect" [62].

Table 1. Examples of organic ligands used in nanometal passivation.

Compound	Nanometal (typical dimensions)	Ref.
Dodecylamine ($C_{12}H_{25}NH_2$) Oleylamine ($C_{18}H_{35}NH_2$)	Au (2.5–7 nm)	[50]
Calyx[4]resorcinarenethiols	Au (film)	[55]
	Au (film)	[56]
Dodecanethiol	Ag (<10 nm)	[53]
Decanethiol+α, ω-mercapto-alkanoic acids	Au (6.2 ± 0.5 nm)	[54]
Pyrene+dodecathiol	Au (2–3 nm)	[58]
C-undecylcalix[4]resorcinarene	Co (27 ± 4 nm)	[59]
Decanedithiol	Au (6 nm) and Pt (5 nm)	[52]

When monochromatic light of frequency ν_0 is incident on a transparent sample and the scattered light is dispersed by a monochromator and subsequently measured in intensity, the spectrum of inelastically scattered radiation, the Raman spectrum of the sample, is obtained. A dispersive instrument for Raman spectroscopy includes a source of monochromatic radiation, a sample device, a dispersing system, and a detection/recording system. An adequate choice of the frequency of the laser is required to fulfill the objectives of the experiment. In particular, fluorescence may be avoided if a sufficiently long laser wavelength, preferably 752.5 nm, is selected [63]. Modern Raman spectrometers are usually equipped with both a macro sample compartment and a microscope. In fact, so important is the possibility of studying microscopic samples that Raman microspectroscopy is a new experimental field on its own [64]. The dispersing system consists of a monochromator to disperse the light scattered by the sample. Through scattering at optical surfaces, particularly at the gratings, a small fraction of light at the laser frequency appears in the output focal plane, at positions corresponding to other frequencies in the neighborhood of the excitation frequency. In order to improve stray light rejection, double or preferably triple dispersion should be used [65]. At the detection stage, monochannel and multichannel detectors can be employed. Comparison of the quantum efficiency curves of a photomultiplier tube and a charge-coupled device, in the studied wavelength region, should be done before one of these detectors is selected [66].

The total scattering intensity I_S in photons per molecule per second, for a transition from the initial ground state, $|G\rangle$, to the final state, $|F\rangle$, is given by

$$I_S \propto \omega_S^4 I_L \phi(\omega_S, \Gamma) \Sigma |(\alpha_{\rho\sigma})_{GF}|^2 \tag{8}$$

where the symbol $\propto$ should be read "proportional to," indicating that uninteresting constants were intentionally omitted; I_L is the incident intensity at the laser frequency ω_L, ω_S is the scattered frequency, $\phi(\omega_S, \Gamma)$ is the bandshape function, and $(\alpha_{\rho\sigma})_{GF}$ is the polarizability tensor for the transition from $|G\rangle$ to $|F\rangle$, with scattered and incident polarizations indicated by ρ and σ, respectively, and the summation extending over the polarization subscripts. Use of perturbation theory shows that the second order perturbation expression for $(\alpha_{\rho\sigma})_{GF}$ is approximately given by

$$(\alpha_{\rho\sigma})_{GF} \propto \Sigma \langle F|\rho|I\rangle\langle I|\sigma|G\rangle(\omega_{GI} - \omega_L - i\Gamma)^{-1} \tag{9}$$

where Γ is the linewidth of the intermediate state $|I\rangle$ and the summation extending over intermediate states. In (2), the term associated with the $|I\rangle$-to-$|F\rangle$ downward transition—the nonresonance term—was neglected, because its denominator, $(\omega_{IF} + \omega_L)^{-1}$, which excludes the possibility of resonance due to the plus sign, is always comparatively large.

For convenience, the scattering may be classified into three excitation frequency regions: normal (off-resonance) *Raman scattering*, for incident frequencies well away from resonance with any allowed transition; *discrete resonance Raman scattering* (DRRS), for excitation near or in resonance with a discrete transition; *continuum resonance*

Raman scattering (CRRS), for excitation resonant with continuum transitions, that is, excitation above a dissociation limit or into a repulsive electronic state [67]. In CRRS, the summation in (9) should be replaced by an integration, and the corresponding density of states of the continuum, $\rho(\omega_i)$, used.

After substitution of (9), expression (8) enables us to assess the effect of varying the frequency of the exciting radiation, thus accounting for the scattering properties of the sample. In particular, when the laser frequency approaches resonance with a real discrete transition, a single excited rovibronic state is discriminated against all the others, since the denominator in (9) is drastically reduced for that particular rovibronic state as the intermediate state and the polarizability value increases abruptly. In DRRS, the overtones may be of intensity comparable to the fundamental transition and, in fact, as strong as the Rayleigh line. The ratio of the intensity of one overtone to the next varies erratically and a small shift in frequency of the excitation line may cause drastic intensity variations. On the other hand, in CRRS, a small shift in frequency will cause a gradual variation in intensity as, within a continuum, a small frequency shift will not destroy the resonance condition.

When the intensity of a given Raman mode is plotted against the excitation frequency, an excitation profile is obtained. If this profile is compared with the absorption spectrum of the molecule, the agreement is usually good. However, in some cases, the peak of the excitation profile exhibits a redshift from the absorption maximum, as for the fundamental vibration mode of Br_2 isolated in a rare-gas matrix [68]. This effect has been studied and explained through consideration of the excitation frequency dependence of the factors involved in the intensity of a Raman transition as compared with the intensity of an absorption transition [68].

The bandshape function in (1) can be represented by the general expression

$$\phi(\omega_S, \Gamma) = \delta(\omega_L - \omega_S - \omega_{GF}) + L(\omega_S, \Gamma) \qquad (10)$$

where the L-function represents a Lorentzian, the linewidth is given by

$$\Gamma = \gamma_n + \gamma_e + \gamma_i \qquad (11)$$

and subscripts n, e, and i refer, respectively, to natural linewidth and elastic and inelastic collisions [67]. At sufficiently low pressures, both γ_e and γ_i are negligible, and the second term in (10) almost vanishes. On the other hand, if the pressure increases, the second term in (10) becomes progressively important and a Lorentzian bandshape is then obtained. Hence, a pressure increase in DRRS leads to a Γ increase and, at sufficiently high pressures, eventually leads to a change from DRRS to CRRS, where the denominator in (9) no longer discriminates against nearby states [69, 70]. It is worth pointing out that when a phase interruption occurs in the excited state, the underlying unit of the Raman process no longer prevails and one may then speak of an absorption followed by an emission (i.e., fluorescence) [67].

When the frequency of a single-mode 514.5 nm incident laser was tuned away from resonance with a discrete transition in molecular iodine, a significantly shortened scattering lifetime was observed [71]. This experiment used incident laser pulses of rectangular shape with time widths of ≈100 ns. The observation of a shortened scattering time is an indication of what is conventionally called a normal Raman process. In this case, an upper limit to the re-emission time can be estimated from

$$(\Delta\omega^2 + \Gamma^2)^{-1/2} \qquad (12)$$

For a 647.1 nm laser wavelength ($\omega_L \approx 2911$ Trad s^{-1}) and a sample with gaseous molecular iodine ($\omega_{GI} \approx 3315$ Trad s^{-1}, i.e., 568.2 nm on-resonance wavelength), $\Delta\omega \approx 404$ Trad s^{-1} and $1/\Delta\omega \approx 2.5$ fs [Γ in (12) is negligible]. On the other hand, if the laser frequency is tuned with a discrete transition in molecular iodine, a re-emission lifetime of the order of 10^3 ns is obtained [71].

3.2. The SERS Effect

Surface-enhanced Raman scattering refers to the observation that for certain molecules adsorbed on specially prepared metal surfaces a Raman spectrum is obtained whose intensity is enhanced by a factor of up to 10^6 [72]. For most surfaces the intensity of Raman bands from the surface monolayer is very low and is normally undetectable. If the surface is a suitably roughened (e.g., roughened electrodes) or there is a finely divided surface (e.g., colloids) of copper, silver or gold, however, the SERS effect then amplifies the Raman scattering, giving easily detectable Raman signals specifically from the first monolayer. The SERS effect was discovered in 1977 [3, 4] and there was strong research interest in the 1980s [73], which settled until another more recent burst of interest came out in association with research on metal nanoparticles and application to single-molecule detection [74, 75].

The large enhancement factors in SERS are obtained through a combination of an electromagnetic effect and chemical interactions between the adsorbate molecule and the surface [76]. The nature of the signal enhancement has been thoroughly studied but aspects such as the relative contribution of the electromagnetic and chemical enhancements are not fully understood. The electromagnetic effect depends on the response of the conduction electrons of the metal surface to the electromagnetic field of the incident and scattered light, being related to the excitation of localized surface plasmons [76–78]. The chemical enhancement mechanisms are related to the formation of a molecule–surface complex and charge transfer transitions between the surface and the adsorbed molecule [76, 79]. It is this chemical effect that gives the high degree of specificity of SERS to the first monolayer.

The scattering intensity in normal Raman scattering, I_{NRS}, is proportional [75] to the Raman cross section, σ^R_{free}, the excitation laser intensity, $I(\omega_L)$, and the number of molecules in the probed volume, N,

$$I_{\mathrm{NRS}}(\omega_S) \propto N \cdot I(\omega_L) \cdot \sigma^R_{\mathrm{free}} \qquad (13)$$

where the symbol $\propto$ should be read "proportional to." The surface-enhanced Raman signal, I_{SERS}, is proportional [75] to the Raman cross section of the adsorbed molecule, σ^R_{ads}, the excitation laser intensity, $I(\omega_L)$, and the number of molecules which are involved in the SERS process, N':

$$I_{SERS}(\omega_S) \propto N' \cdot I(\omega_L) \cdot |A(\omega_L)|^2 \cdot |A(\omega_S)|^2 \cdot \sigma^R_{ads} \quad (14)$$

The field enhancement factors at the laser and Stokes frequency are given by $A(\omega_L)$ and $A(\omega_S)$, respectively. The chemical enhancement is included in σ^R_{ads} which describes the increased Raman cross section of the adsorbed molecule. The SERS effect allows one to overcome the extremely small cross section for Raman scattering, typically 10^{-31}–10^{-29} cm^2/molecule (the large values occurring only under resonance Raman conditions). Raman enhancement factors on the order of 10^{14} made possible the optical detection and spectroscopic studies of single molecules and single nanoparticles, at room temperature with the use of SERS [80, 81].

3.2.1. Surface Selection Rules

The relative intensities of different vibrational modes in the Raman spectrum of a molecule will be dramatically changed when it is placed near a metal surface; the intensity of some modes may even be almost totally suppressed. This phenomenon is usually referred to as a "surface selection rule." The orientation of molecules adsorbed at metal surfaces can be deduced from the observed intensity distribution of SERS bands, based on surface selection rules [82, 83]. A number of surface selection rules for SERS have been proposed, in particular by Creighton [78, 84] and Moskovits et al. [76, 85–87]. The least enhanced vibrational modes are those whose Raman tensor components involve the two axes in the plane of the surface [76, 78]. The relative enhancements for normal modes can be classified into three groups in terms of the polarizability tensor elements. Normal modes associated with the tensor element α_{33} are the most enhanced, modes associated with α_{13} or α_{23} are less enhanced, and modes associated with α_{11}, α_{12}, or α_{22} are the least enhanced. The subscripts 1 to 3 refer to the orthogonal axes parallel (1 and 2) and perpendicular (3) to the surface.

A set of generally accepted rules is usually followed by authors to judge the molecular orientation on the surface from SERS. The rules presented next are used in the particular case of substituted benzenes.

For substituted benzenes, the presence or absence of the benzene ring C–H stretching vibration has been used [83, 88, 89] as an indicator in SERS for the perpendicular or parallel orientation of the benzene ring with respect to the surface. According to the surface selection rule proposed by Creighton [78] and by Moskovits and Suh [90], the C–H stretching vibration should be relatively more enhanced when the C–H bond is perpendicular to the surface plane than when it lies parallel to the surface.

According to the surface selection rule [91, 92], for benzene derivatives the out-of-plane vibrations should be more enhanced than the in-plane ones when the benzene ring assumes a parallel position with respect to the surface and the opposite should occur when the ring lies perpendicular to the surface. Changes in the bandwidth of benzene ring modes have been used [88, 93, 94] to judge the presence of surface–ring π interaction for benzene derivatives adsorbed on silver or gold.

SERS spectra have been reported for a large number of substituted benzenes [83, 95] and other aromatic compounds. SERS spectra of benzoic acid adsorbed on silver colloids [89, 96] and at silver electrodes [89, 97] have been studied. Carboxylic acids can bind to silver either via the oxygen lone pair electrons or the carboxylate π system [98], thereby assuming different orientations on the silver surface. It was suggested [89] that the benzoate species adopted a flat or tilted orientation on the silver colloid surface but assumed a perpendicular orientation with respect to a silver electrode surface. SERS studies on 3-aminosalicylic and 2-mercaptonicotinic acid in silver colloids [82] show examples of flat and perpendicular adsorption, respectively. The SERS of these two compounds [82] show how the Raman spectra can be affected when the molecules adsorb with the aromatic ring either parallel or perpendicular to a silver surface (Figs. 2 and 3). For 3-aminosalicylic acid a flat orientation on the silver surface was suggested [82], based on the following evidence in the SERS spectrum (as shown in Fig. 2): (i) the out-of-plane bending mode $\gamma_s COO^-$, 727 cm^{-1}, was relatively much more enhanced than the symmetric stretching mode $\nu_s COO^-$, 1392 cm^{-1}, suggesting that the carboxylate group should be flat on the surface instead of perpendicular; (ii) the band assigned to the amine asymmetric bend $\delta_{as}NH_2$, 1120 cm^{-1}, was quite intense and broad, suggesting that the amine group interacts directly with the surface; (iii) the absence of the C–H stretching vibrations; (iv) the strong increase in the bandwidth for the benzene ring vibrations; (v) the presence of two strongly enhanced bands for out-of-plane ring modes γCCCH, 894 cm^{-1}, and τCCCC, 438 cm^{-1}.

Evidence was obtained for the perpendicular adsorption of 2-mercaptonicotinic acid on silver from the SERS spectrum [82], in particular from its similarities with the conventional Raman spectrum of the silver complex (as shown

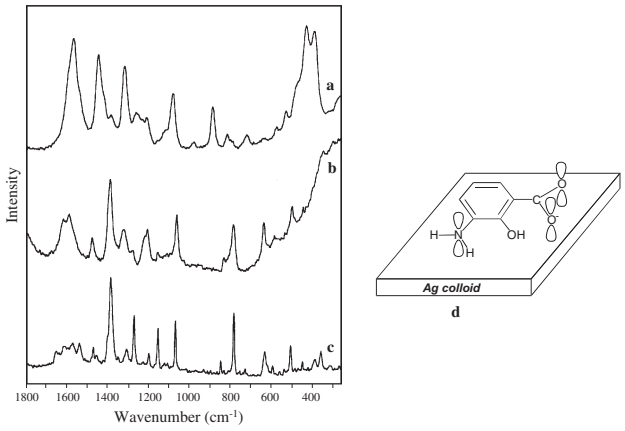

Figure 2. (a) SERS spectrum of 5×10^{-4} M 3-aminosalicylic acid solution in aqueous silver–citrate colloid, pH 6.0; (b) conventional Raman spectrum of 3-aminosalicylic acid in 3M aqueous NaOH solution; (c) conventional Raman spectrum of solid 3-aminosalicylic acid; (d) flat adsorption of 3-aminosalicylic acid on silver. in Fig. 3): (i) the carboxylate group vibrations for the in-plane $\nu_s COO^-$ stretch at 1393 cm^{-1} and δCOO^- bend at 849 cm^{-1} were seen in the SERS spectrum as strong and broad bands; the relatively much stronger enhancement of $\nu_s COO^-$ suggested that this group was in a perpendicular position to the silver surface; (ii) the in-plane ring vibrations ν_{as}CX at 1123 cm^{-1}, νCC at 1078 cm^{-1}, and δCC at 664 cm^{-1}, involving also the stretching of the C–S band, were stronger in the SERS spectrum; (iii) the absence of the out-of-plane τCCCC, seen at 733 cm^{-1} in the conventional Raman spectrum of the silver complex, and the relatively weaker enhancement in the SERS spectrum of τCCCC at 470 cm^{-1}; (iv) the C–H stretching was seen as a strong peak at 3068 cm^{-1}; (v) all the other enhanced modes in the SERS spectrum were in-plane modes, consistent with a perpendicular position to the silver surface; (vi) the shoulder at 245 cm^{-1} in the SERS spectrum was assigned to the Ag–S stretch, seen in the spectrum of the Ag complex as a stronger band at 257 cm^{-1}. Comparisons of the conventional Raman spectra of metal complexes (in particular of the silver complex) with the SERS spectra of the ligands have shown that there is a close relationship between complexation and adsorption (in particular for the case of a perpendicular orientation on the metal surface), as reported for 1,8-naphthyridine [99], *o*-mercaptobenzoic acid [100], and 1,2-benzenedithiol [88].

SERS studies on other substituted benzenes include salicylic acid [101], anthranilic acid [102], *p*-aminobenzoic acid [103, 104], 2-aminophenol [83], 1,2- and 1,4-benzenedithiol [88, 105]; many SERS studies were also reported on other aromatic compounds such as 1,1′-bi-2-naphthol [106], 4,4′-dicyanobiphenyl [107], quinoline derivatives [108], pyridine carboxylic acids [109], and other pyridine derivatives [110]. The first SERS reports were made on the study of pyridine; the report made by Fleischmann et al. [111] in 1974, on the Raman spectrum of a monolayer of pyridine adsorbed on a silver electrode surface, was actually the first SERS observation.

3.2.2. SERS as a Tool for Trace Detection

The strong enhancement of the normally weak Raman signals makes SERS an interesting technique for detecting low concentration samples or unknown low level contaminants in a sample [104, 112, 113]. SERS reports are found in the literature related to the detection of several organic compounds with specific interest, such as drugs and biological materials (the anti-HIV drug AZT [114], amphetamine drugs [115], sulphur- and nitrogen-containing drugs [116, 117]); detection and analysis for monitoring water contamination [118]; detection and identification of very low gas concentrations of substances that are adsorbed irreversibly at silver surfaces [119]; detection of trace amounts of atmospheric contaminants in aerosols [120]; detection of trace organic pollutants in aqueous systems [121]; and spectral fingerprinting of stereoisomer drugs at trace concentration levels [122]. The use of colloids in nonaqueous solvents allows an expansion of the organic compounds that may be detected by SERS [123].

The potential of colloidal silver and gold sols for the purpose of semiquantitative trace analysis of organic molecules by SERS has been investigated. The value of colloidal SERS for analytical purposes, in particular when employing silver sols, is described in one report to be limited to qualitative analysis [124]. Another study [125] has, for example, shown that the dye nuclear fast red can be detected and determined semiquantitatively by SERS in the concentration range of 10^{-8} to 10^{-6} M. Though the use of SERS for quantitative analysis is controversial, it has been demonstrated that it is a good technique for trace detection. SERS is important mostly with respect to the low limits of detection that can be obtained (e.g., 10 ppb for the sensitivity limit of cyanide detection in water [118], or 10^{-8} M for the dye nuclear fast red [125]).

Surface-enhanced resonance-Raman scattering (SERRS) combines two previously known effects, namely resonance-Raman scattering and SERS. The enhancement in SERRS is very much greater than either resonance-Raman or SERS enabling lower detection limits. SERRS is obtained by using a molecule with a chromophore as the adsorbate and selecting the excitation frequency to match or nearly match that of the chromophore. With SERRS, sensitivities down to 6.87×10^{-18} M were obtained using rhodamine dye [112].

4. SERS STUDIES USING NANOPARTICLES AND ITS ASSEMBLIES

Nanotechnology aims to fabricate functional devices in which their size decreases down to the nanometer range and molecular dimensions. In particular, scanning probe microscopies provide the tools to investigate the properties of functional nanodevices. More recently, new developments have been achieved with the use of Raman spectroscopy to probe surface properties with molecular resolution. It is particularly interesting to explore these findings in correlation with measurements of electron transport properties through

molecular frameworks, or for optical detection using single molecules. SERS has been generally performed on metal colloids; however, even when nanoparticles with low standard deviations are used, the spectrum of single particles has to be obtained to get optical information as a function of particle size. The use of Raman spectroscopy coupled with the use of well defined metal nanocrystals is a valuable tool which complements the single molecule detection performed by other techniques such as scanning tunneling microscopy, fluorescence measurements, or electrochemical methodologies.

4.1. SERS Substrates Based on Metal Nanoparticles

The preparation of substrates for SERS has many variations, but essentially a very finely divided sample of the metal is used either pure or in a support. The most common substrates are silver and gold colloids, but other sorts of substrates have been developed. SERS has been observed on, for example, cellulose acetate films doped with Ag fine particles [126], silver hydrosols on filter paper [120], or silver-coated alumina/glass substrates [127]. Figure 4 shows a diagram of a few examples of substrate types that can be used in SERS studies. Modification of the substrates can also be achieved by chemical coatings that can be either passive or active [119]. The passive coatings simply provide an affinity for the analyte and can act as an internal standard for normalizing the signal. Active coatings exhibit a different Raman spectrum in the presence of the analyte.

Research on metal nanoparticles led to its use as SERS substrates, in particular for silver and gold. Metal particle size and shape and the possibility of formation of nanoparticulate aggregates contribute to distinct characteristics as SERS substrates. Also, the development of a variety of solid surface-based probes based on metallic nanostructures gave a high degree of reproducibility to SERS that could not be achieved with the use of colloids [128]. The strict control of surface parameters is possible through the use of solid materials yielding the metallic nanostructures. Several types of metallic nanostructures have been developed (Fig. 4) such as metal nanoparticle island films, metal-coated polymer nanospheres, or metal-coated nanoparticles (of alumina, titanium oxide, and other oxides).

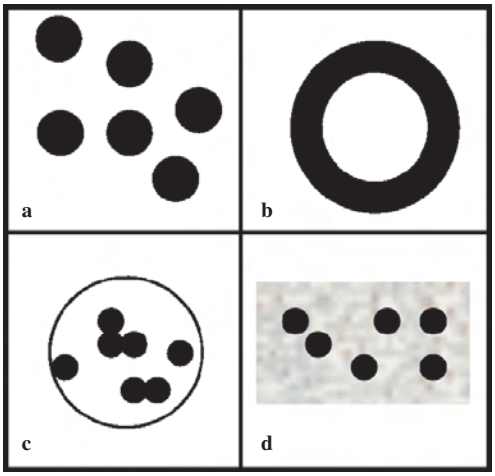

Figure 4. Diagram representation of substrates containing SERS active metal nanoparticles. (a) SERS active metal nanoparticles; (b) metal coated particles; (c) metal nanoparticles clustered into islands; (d) metal nanoparticles dispersed in a polymer substrate.

Nanostructured materials have recently been prepared by mixing silica and silver. Stable substrates were obtained by impregnating silica with silver in water followed by calcination [129], or by deposition [130] or evaporation [131] of silver over silica nanospheres. In the preparation of SERS substrates by the impregnation of silica with silver [129], the solid silica support was applied not only to disperse the metal but also to stabilize the metallic phase (by preserving the aggregation state of the Ag particles) making the SERS activity stable. A silver particle size of 6–16 nm was found to be effective for SERS. In another study [132], SERS substrates were prepared by photoreduction of silver ions onto silica colloidal nanoparticles. Silver photoreduction was achieved by irradiation with a 514.5 nm laser; the same laser radiation was employed in the SERS measurements. One advantage of the colloidal dispersions over the solid substrates is the resistance to damage caused by laser irradiation, due to the continuous agitation of the colloidal particles in the aqueous environment. Other potential SERS substrates were obtained using hybrid particles in colloidal suspensions, such as Ag–CdS [133], Ag–ZnO [134], Ag–TiO_2 [135, 136], and Ag–SiO_2 [137]. Core–shell nanoparticles have been tested as SERS substrates, using both metallic core and shell [138], or a dielectric core and a metallic shell [139]. Au/Ag core–shell nanoparticles were prepared by growing an Ag shell onto a 12 nm Au core; the SERS activity was investigated by using 2,4-dimethylpyridine as the probe [138]. A series of silica core–silver shell nanoparticles were constructed [139] using 65 and 79 nm cores, upon which silver layers ranging from 5 to 20 nm were deposited. Systematic variation of the internal geometry of the silica core–silver shell nanoparticle allowed the local electromagnetic field at the nanoparticle surface to be precisely controlled, as monitored by SERS. The SERS enhancement appears to be directly and exclusively due to nanoparticle geometry [139].

A solution method to obtain silver nanostructured thin films was reported [140], using a silver complex as the starting compound. This method consisted of the reduction of a silver complex to obtain the silver metal particles. The coordinated ligand in the starting silver complex (e.g., 2,2′-dithiodipyridine, 2dtpy, in the complex [Ag(2dtpy)]NO_3) functions as a capping agent to the Ag particle surface, avoiding the agglomeration of the nanoparticles formed, and, simultaneously, may act as a linker to the Ag nanoparticles, hence promoting the formation of a three-dimensional network. Compared to the thin film deposition of metal nanoparticles formed from conventional reductive techniques, this method offers the potential to design metal nanostructures using the coordinating organic ligand as an active template. In this sense, this preparative approach is strongly dependent on the adsorption modes of the organic ligand at the metal nanoparticle surface. SERS studies were performed [140] to investigate the adsorption of the 2dtpy ligand on the Ag nanoparticles that constitute the film. The Raman spectra of the film Ag/2,2′-dithiodipyridine, the starting solid Ag(I) complex, [Ag(2dtpy)]NO_3, and the solid

2dtpy ligand are shown in Figure 5, together with the SERS spectrum of 2dtpy in a silver aqueous colloid. The Raman spectrum of the film Ag/2,2′-dithiodipyridine (Fig. 5b) is remarkably similar to the SERS spectrum of 2dtpy (Fig. 5a) in the Ag colloid. This similarity indicates that the interaction mode of 2dtpy with silver in both cases should be very close with respect to both the atoms bound to silver and the adsorption position of the 2dtpy molecules. The transmission electron microscope images of the film showed spheroidal Ag nanocrystals (typically less than 15 nm diameter) evenly distributed, in agreement with the formation of an hybrid inorganic/organic structure of interacting Ag/2dtpy clusters.

Silver and gold nanoparticle monolayers deposited on silanized glass surfaces, have been used as SERS active substrates [141, 142]. The localized surface plasmon resonance on such arrays can be tuned to a variety of wavelengths by varying the particle shape, size, and spacing. Tunable localized surface plasmon resonance of silver nanoparticle arrays has also been achieved by nanosphere lithography [143]. The wavelength corresponding to the extinction maximum of the localized surface plasmon resonance could be systematically tuned from 300 to 6000 nm, by using precise lithographic control of nanoparticle size, height, and shape, and dielectric encapsulation of the nanoparticles in SiO_x [143].

Nanostructured thin-film materials have been prepared [144] by using size-fractionated colloidal silver nanoparticles, in the size ranges of 30–50, 50–80, 80–100, and >100 nm. Figure 6 presents an atomic force microscope (AFM) image of a nanostructured thin film prepared from 50–80 nm silver colloidal particles, showing the presence of distinct nanoparticles in an uneven distribution. These nanostructured films provide a reproducible SERS substrate for ultrasensitive detection and spectroscopy of native biological molecules [144]. As shown in Figure 7, the SERS signal intensities using this type of substrate are 5 to 10 times higher than those obtained with alternative methods [144]. Nanoparticles have already been used together with SERS, for DNA and RNA detection [145]. Several recent SERS studies on molecules of biological interest using metal nanoparticles as substrates, can be found [146–149] including SERS in single living cells [150].

4.2. Probing Single Molecules Coupled to Metal Nanoparticles Using SERS

Ultrasensitive Raman spectroscopy at the single-molecule level has been achieved in the last five years [75, 80, 81, 151–153] by exploiting the SERS effect together with the large field enhancements obtained with single nanoparticles or aggregates of nanosized metal particles. The extremely large SERS enhancement [75] seems to be a very local effect with high spatial confinement, and the single analyte has to find a special hot area (for strong field enhancement) or a hot site (for electronic enhancement). Two methods have been used to achieve single-molecule sensitivity in a SERS experiment: nonresonant near-infrared experiments on single molecule attached to silver or gold colloid nanoparticle aggregates in solution [81, 154, 155] and resonance studies performed on fixed single silver nanoparticles [80, 156]. In the nonresonant method, extremely low concentrations (on the order of 10^{-12} to 10^{-14} M) and small probed volumes (on the order of femtoliters to picoliters) ensure that only one target molecule, on average, can be probed at one time; enhancement factors on the order of 10^{14} were obtained [81]. Figure 8 shows a scheme of a typical single-molecule

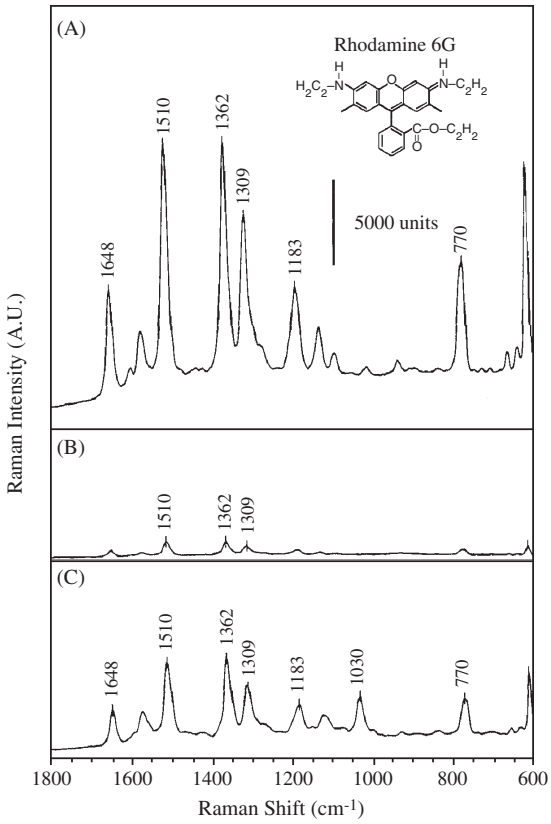

Figure 7. Comparison of SERS intensities between nanostructured thin films and colloidal nanoparticles immobilized on chemically modified surfaces. (A) Film prepared from fractionated Ag colloids (>100 nm fraction); (B) unfractionated colloids immobilized on a glass slide surface by using mercaptopropyl trimetroxysilane; and (C) unfractionated colloids immobilized on a glass surface by using polylysine. Laser wavelength = 633 nm; excitation intensity = 3 mW; data integration time = 1 s; and R6G concentration = 1×10^{-7} M. Reprinted with permission from [144], D. J. Maxwell et al., *Chem. Mater.* 13, 1082 (2001). © 2001, American Chemical Society.

SERS experiment performed in silver or gold colloidal solution [75, 149]. Spectra were excited by an argon-ion pumped continuous wave Ti:sapphire laser operating at 830 nm with a power of about 100–200 mW at the sample. A microscope attachment was used for laser excitation and collection of the Raman scattered light. The analyte was provided as a solution at concentrations smaller 10^{-11} M, which was added to the solution of small colloidal clusters [75].

In the single-particle SERS studies [80], nanometer-sized silver particles were used to amplify the spectroscopic signatures of adsorbed single molecules enormously. Simultaneously, the size-dependent properties of the nanostructures could be examined at the single-particle level. A silver colloid with adsorbed rhodamine 6G molecules was used [80], immobilized on polylysine coated glass surfaces (average silver particle size of about 35 nm). A very small number of Ag nanoparticles, called "hot particles," exhibited unusually high enhancement efficiencies. For single rhodamine 6G molecules adsorbed on the selected nanoparticles, the intrinsic Raman enhancement factors were on the order of 10^{14} to 10^{15}. Based on these findings, a SERS screening and enrichment method was reported for exploring the size and shape

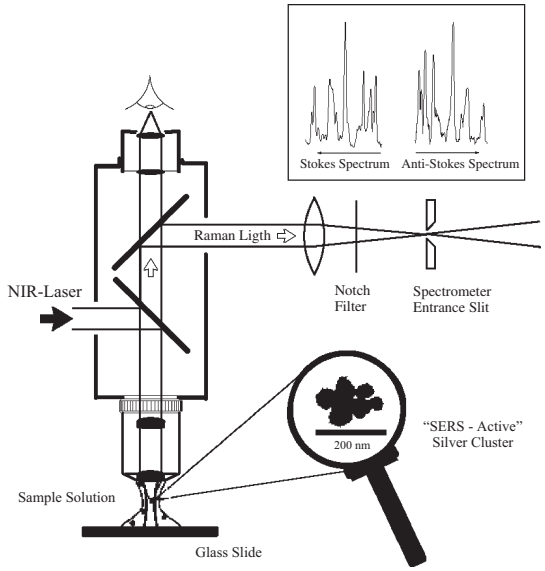

Figure 8. Schematic diagram of a single-molecule SERS experiment; a microscope is used for laser excitation and collection of the Raman scattered light. The inset shows an electron micrograph of typical SERS-active colloidal clusters. Reprinted with permission from [149], K. Kneipp et al., *J. Phys.: Condens. Matter* 14, R579 (2002). © 2002, Institute of Physics Publishing.

diversities of nanometer-scale colloidal particles [19]. The described highly active nanoparticles can be used in single-molecule spectroscopy, ultrasensitive chemical analysis, and nanomaterials design [144].

4.3. SERS as a Probe to the Chemical Nature of the Nanoparticle Surface

There is a complementary effect on SERS studies in the sense that it can be focused on the study of the internal modes of the adsorbates or on the adsorbate–metal surface modes, providing information on the type of surfaces of a specific nanometal. The correlation between the optical enhancement with the morphological characteristics of metal nanoparticles makes SERS a potential technique for nanomaterials design [80]. In this sense, standard molecular adsorbates can be used to discriminate specific particles sizes of nanoparticles assemblies.

In this context, there is interest to extend SERS studies to a variety of metal surfaces. This is particularly interesting when associated with the study of catalytic processes occurring at various metal surfaces. A possible approach which has been investigated involves the use of ultrathin metals coating a SERS active substrate (Ag or Au) [157]. Although in these cases valuable information about the metal surfaces can be obtained, there is also the possibility to have enhancement of the Raman signal from the adsorbate in contact with the active SERS substrate or at the metal/metal interface. The ideal situation, and also the most difficult to obtain, is to get the SERS spectrum on a wide range of bare metal surfaces (i.e., in a situation analogous to the SERS obtained when Ag and Au substrates are used). This has attracted considerable attention since the observation of the C–O stretching band from CO adsorbed

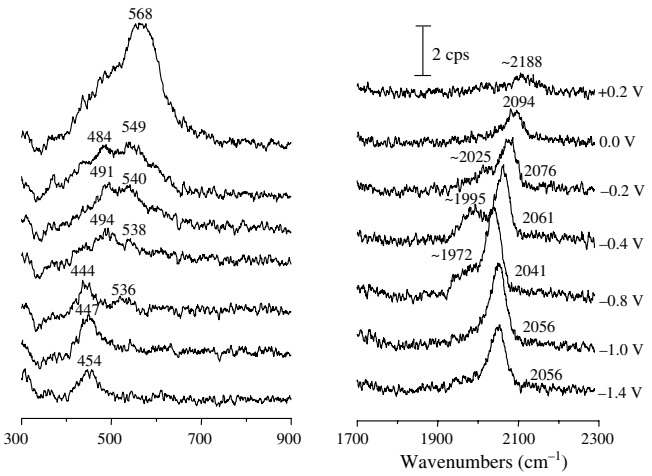

Figure 9. Potential-dependent surface Raman spectra from CO adsorbed irreversibly at a roughened Pt electrode. Reprinted with permission from [157], Z. Q. Tian et al., *J. Phys. Chem. B* 101, 1338 (1997). © 1997, American Chemical Society.

on a platinized Pt electrode [158]. Since then considerable efforts have been made to obtain SER spectra using bare Pt electrodes, although low signal intensities were generally observed [157]. Some of these limitations will tend to be overcome with advances in Raman instrumentation. An elucidative example of this was the use of confocal microprobe Raman spectroscopy and a electrochemical pretreatment of Pt electrodes to extend the detailed surface Raman studies to bare Pt substrates, using SCN^- and CO as the adsorbates (Fig. 9) [157].

Another approach to extend SERS studies to other metal surfaces involves the nanoengineering of specific metal substrates. For example, metal nanorod arrays with high SERS activity have been used as a diagnostic tool to metal nanowires with specific cross sections [159]. By analysis of SERS spectra, namely the band frequency shifts and the intensity of specific probe molecules (e.g., pyridine, SCN^-) adsorbed onto metal surfaces, one may conclude with special electronic properties of the metal nanostructures [159]. A major drawback that has limited SERS as a tool for nanometal design is that the high Raman enhancement has been limited to silver, gold, and, to a lesser extent, to copper. It should be noted that in the latter case [159], due to the nanorod morphology, SERS activity was observed even for metals which usually are non-SERS active such as in the case of several transition metals, including nickel and cobalt. In this case, two-dimensional arrays of metal nanowires (15–70 nm) were prepared by a template synthesis method involving the electrodeposition of the respective metal into nanoholes of the anodic aluminum oxide, followed by removal of the film. SERS on net transition metals has been studied [160] (e.g., Pt, Ru, Rh, Pd, Fe, Co, Ni, and their alloys) by developing various roughening procedures. An approach that replaces the randomly roughened surface with ordered nanorod arrays of transition metals was introduced as a promising class of highly SERS-active substrates [160].

5. PERSPECTIVES

The chemical control of the properties of metal nanostructures associated with recent developments on Raman spectroscopic methods has increased the possibility to apply this technique in innovative contexts. For example, the extension of SERS studies to other metal surfaces rather than Ag and Au, by tailoring specific metal nanostructures, will provide new insights about the mechanisms behind the SERS effect. The study of size-dependent properties of nanometals by SERS screening at the single-molecule level will provide novel knowledge on the understanding of the mechanisms behind surface modification and self-assembly methods. Using single-molecule SERS, the size-dependent properties of the nanostructures can be examined at the single-particle level, and, simultaneously, the spectroscopic features of adsorbed single molecules are enormously amplified. The combination of these complementary effects will give an increasing importance of single-molecule SERS for future research in the fabrication of nanodevices containing nanometals and molecular units.

GLOSSARY

Metal nanoclusters Nanoparticles composed of up to hundreds of atoms, with dimensions typically less than 3 nm in diameter, which are stabilized with capping organic ligands.

Metal nanocrystals Large nanoparticles which may have dimensions superior to 100 nm, constituents of most of the metal colloids employed in SERS. In metal nanocrystals the internal crystalline structure is similar to the macrocrystalline lattice but it shows distinct physical and chemical properties from the bulk materials and from nanoclusters of metallic atoms.

Raman spectrum When monochromatic light of frequency ν_0 is incident on a transparent sample and the scattered light is dispersed by a monochromator and subsequently measured in intensity, the spectrum of the inelastically scattered radiation (the Raman spectrum of the sample) is obtained.

Single-molecule SERS SERS measured on a single molecule using single-metal nanoparticles or aggregates of nanosized metal particles, giving stronger enhancement of the Raman signal up to 10^{14}. The extremely large SERS enhancement seems to be a very local effect with high spacial confinement, and the single analyte has to find a special hot area (for strong field enhancement) or a hot site (for electronic enhancement).

Surface enhanced Raman scattering (SERS) Refers to the observation that for certain molecules adsorbed on specially prepared metal surfaces a Raman spectrum is obtained whose intensity is enhanced by a factor of up to 10^6. The large enhancement factors in SERS are obtained through a combination of an electromagnetic effect and chemical interactions between the adsorbate molecule and the surface.

Surface modification Derivatization of the metal particle surface using either an inorganic phase, an organic ligand, or both. The derivatization process should not disturb the integrity of the metal core.

CONTENTS

1. INTRODUCTION

Light emission from organic materials has been known for a long time. One of the most amazing examples of organic light comes from a small insect known as a firefly. It emits light by a chemical process produced by its own biochemistry and the light emission is then called *bioluminescence*. What is remarkable is the efficiency of the conversion process, which is very high, close to unity, and at this stage it is not possible for scientists to obtain a similar performance with all the techniques they have. Some fish living in deep oceans can also emit light by bioluminescence.

Light can be also generated in organic materials by other conversion processes. When the excitation source is light, the process is called *photoluminescence*. Similarly, if the origin of the excitation is chemical, thermal, or electrical, the terms *chemiluminescence*, *thermoluminescence*, or *electroluminescence* are used to designate the light emission.

In electroluminescent devices, the electrical excitation of the material is provided by an external voltage source. A current flows through the device and, at a sufficient level of supplied energy, the light emission process starts in the emitter and the device emits light to the external environment. Electroluminescence in organic materials was first done experimentally in 1963 on anthracene monocrystals by Pope et al. [1] who obtained light emission by using a high applied voltage (400 V). Such a bias was considered too high and the materials were therefore not suitable to be used for everyday-use applications. In 1987, Tang and Van Slyke [2] using thin film deposition techniques and organic materials fabricated the first light emitting diodes (LEDs), which operated at low bias. A few years later, in 1990, Burroughes et al. [3] demonstrated that a well known conjugated polymer, poly(*p*-phenylene vinylene) (PPV), could emit light in a diode configuration with an applied voltage less than 20 V. Since those first experiments, the science of polymer and organic LEDs has progressed greatly. Talented chemists, physicists, and engineers have contributed to the development of new materials and new device designs, enabling the fabrication of devices with high performance: various colors, low turn-on voltage, long lifetime, low energy consumption, and great brightness. The physics of these new electronic devices have also been intensively studied and during the last decade; many new concepts were built using the basic knowledge from classical semiconductor devices. In parallel, nanotechnology science has emerged and is advancing constantly. In the late 1960s, Moore's law predicted that the number of transistors on a chip would roughly double every 18 months and that was verified over four decades. At the beginning of 2000, we have entered in the nanosize era. Advances in manipulating nanosized materials have already allowed improvements in electronic devices such as computer data storage, batteries, solar cells, and light emitting diodes. Understanding the potential market of nanosized devices, many countries have concentrated their efforts in developing research programs in nanoscience.

Encyclopedia of Nanoscience and Nanotechnology
Edited by H. S. Nalwa
Volume 7: Pages (717–739)

The conjugation of both technologies led to a new field of research: that of nanosized polymer and organic LEDs (OLEDs). In reality, the devices studied have a size ranging from several nanometers (nm) to several micrometers (μm). Classical photolithography used in computer chip industry can provide a common size of 200 nm and is still very popular in designing electronic devices. Recent progress in patterning techniques has allowed features as small as 10 nm to be obtained with high definition and ordering. Such a tiny object is not easy to handle and even if several devices could be produced, the mass production still needs further investigation to control them, especially in the design of the surface on which will be implanted the nanocomponents and the electrical connection between them.

With the development of nano-objects, the electronic properties of the materials will change from classical physics to the less familiar quantum physics. New optical and electrical properties of nanosize materials have been discovered and more are expected to be found in the near future. Study of micro- and nano-OLEDs has only been investigated for a few years, starting with composites made of a polymer matrix containing inorganic nanoparticles. These systems were first fabricated to obtain the light emission of both the electroluminescent polymer and the nanoparticles. The second generation of small OLEDs has benefitted from the progress in patterning technology to allow fabrication of ordered arrays of pixels.

This chapter is organized as follows. In the first section, we shall give the state of the art of OLEDs showing different aspects: materials, physical processes including the light emission, charge carrier transport, and degradation mechanisms. The second section deals with the nano-OLEDs where different technologies will be described. Some aspects of the physical processes in nanosize materials will be treated. In the last part, the potential applications of nano-OLEDs are discussed.

2. ORGANIC ELECTROLUMINESCENCE

The aim of this section is to present the current state of the art in organic electroluminescence. Emphasis will be given to the way the device works and to the various issues that govern its operating process.

2.1. Operating Mode

Electroluminescence (EL) is a nonthermal emission of light from a solid traversed by an electrical current. EL in organic materials was first observed in anthracene single crystals as early as 1963 [4]. The crucial issues of the process and in particular the requirement of a double injection of charge (electrons and holes) were identified two years later [5]. Today, the most generally accepted mechanism for describing organic EL does not fundamentally differ from this early analysis. The basic device for organic EL is the diode, composed of one or several organic layers sandwiched between two conducting electrodes. The sequential steps of the conversion of electricity to light in an OLED are schematized in Figure 1. At the outset of the process, there is an injection of electrons and holes from the electrodes at each side of the diode. The carriers are then driven toward the interior of the organic layer by the electric field generated by the voltage applied to the device. Recombination of charges of opposite sign occasionally occurs when these charges meet, leading to the formation of electron–hole pairs, which rapidly decay to bound excitons. At this stage, a crucial parameter is the exciton bounding energy; excitons in organic materials are generally regarded as strongly bound excited molecules, but this is still controversial, as will be detailed in the following. Light is eventually emitted when excitons deactivate to ground state. The overall efficiency of the diode results from that of each step; therefore, each of them needs to be optimized. The steps will now be analyzed in more detail.

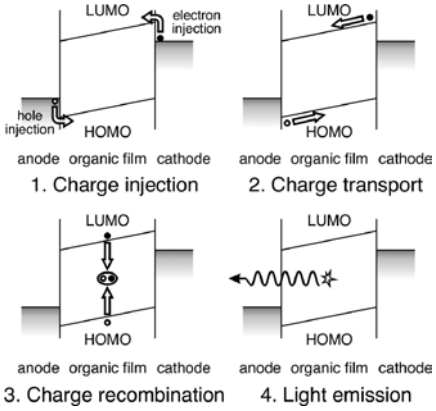

Figure 1. The four steps of the conversion of electricity to light in an organic light-emitting diode.

2.1.1. Charge Injection

Injecting charge from a highly conducting (the electrodes) into a poorly conducting (the organic layer) medium is a difficult task. In principle, charge transfer between two media occurs isoenergetically. Accordingly, there are two elementary issues in charge injection: energy level alignment and injection processes.

Energy Level Alignment This subject has been recently reviewed in detail by Ishii et al. [6]. The levels implied in charge injection from a metal into an organic layer are not of the same nature at both sides of the interface. When gathered together to from a solid, atoms and molecules see their discrete quantum energy levels widening into alternatively allowed and forbidden bands. In metals and degenerate semiconductors, the highest energy allowed band is only partially filled with electrons up to the so-called Fermi level, which constitutes therefore the level of interest in this case. The corresponding energy is the work function, Φ_m, which measures the distance between the Fermi level and the vacuum level (VL), the latter being defined as the energy of an isolated electron at rest at infinite distance from the solid. In a molecular solid, molecules interact only through weak van der Walls forces, so that it is generally accepted that bands are narrow and the highest occupied molecular orbital (HOMO) and lowest unoccupied MO (LUMO) are only slightly displaced from their value in individual molecules.

The number of interest is therefore the distance that separates the HOMO and LUMO levels from the vacuum level, that is, the ionization potential IP and electron affinity EA. Because IP and EA are very sensitive to surface state, their estimation is a difficult task. Several techniques require ultra high vacuum, such as ultraviolet (UV) photoelectron spectroscopy. Other techniques comprise Kelvin probe and electrochemical measurements. In the latter case, care must be taken because several corrections, involving solvatation effects, must be brought to the crude data. Finally, we have to mention internal photoemission, which is in principle a direct method but presents a major drawback: it requires the fabrication of a metal–semiconductor junction and its reproducibility is often uncertain.

In principle, the value of EA can be obtained directly by inverse photoemission spectroscopy, a method that suffers from radiation damage of the organic material. Nevertheless, the most popular way for estimating EA consists of subtracting from IP the HOMO–LUMO gap as deduced from optical absorption measurements (optical gap E_g^{OPT}). However, it must be noted that the optical gap may differ from the true energy gap (corresponding to the energy required to promote an electron from the HOMO to the LUMO level). To understand this difference, we have to go a little deeper in the description of energy levels in a molecular solid. As stated, the IP and EA of the solid slightly differ from that of the isolated molecule. The difference comes from the polarization energy (P_+ and P_- for holes and electrons, respectively) induced by the ionized molecule in the surrounding molecules. This energy is sometimes referred to as the "polaron binding energy." Similar stabilization energy exists for an electron–hole pair (or exciton), which is also often called the exciton binding energy. Only if this exciton binding energy strictly equals $P_+ + P_-$ does the optical gap equal the electronic gap.

When the metal and the organic layer are put in contact, the VL at the interface is shared by both media and barriers for hole (of height Φ_B^p) and electron injection (of height Φ_B^n) appear. For the perfect contact depicted in Figure 2a, the magnitude of the barrier height follows the Schottky–Mott rule, where Φ_m is the work function of the metal:

$$\begin{aligned} \Phi_B^p &= \mathrm{IP} - \Phi_m \\ \Phi_B^n &= \Phi_m - \mathrm{EA} \end{aligned} \tag{1}$$

In molecular solids, which are primarily insulators, the Fermi level is located somewhere in between the HOMO and LUMO levels. With a Fermi level at exactly midgap, we see that the junction in Figure 2a is not in electrical equilibrium. However, equilibration would require charge redistribution, which is difficult in practice because the number of available mobile charges in the organic layer is very low. This is the more true as most OLEDs are made of very thin organic layers, which reduces further the amount of charge available. For these reasons, the simple scheme of Figure 2a remains the one most usually adopted to describe energy level alignment in organic diodes.

Nevertheless, Figure 2a only corresponds to the ideal case. In actual systems, a dipole layer may form at the interface. Possible origins of this dipole are chemical reaction, charge transfer across the surface, or rearrangements of electronic charge. An abrupt shift Δ of the energy levels is associated with this dipole layer, as shown in Figure 2b, which leads to a similar change of the barrier heights. Note that this shift can also be viewed as a change of the metal work function that can be used to purposely adjust the energy level alignment.

From the previous analysis, it emerges that several strategies can be envisioned to tune the energy levels at both sides of a metal–organic junction.

- Interpose a buffer layer between the electrode and the electroluminescent layer to reduce the barrier height. In practice, a hole injecting material presents a high ionization potential, while an electron injecting material is characterized by a low electron affinity. This strategy was proposed in 1987 by Tang and Van Slyke [2] and many of such materials have been identified since then.
- Modify the work function of the electrode by an appropriate surface treatment. Various examples of such treatments will be described in the following.

The energy scheme of a typical multilayer OLED is shown in Figure 3. The terms "hole transport layer" (HTL) and "electron transport electron" (ETL) were first introduced by Adachi et al. [7] in 1988 and are widely used today to designate the two buffer layers. However, we note that these terms are somewhat confusing because these layers *inject* rather than transport the charges from the electrodes to the light-emitting medium. These injecting layers may also play the role of blocking layers for the charges of opposite sign.

Figure 3 does not account for the electric field that appears in the device when applying an external voltage. This is shown in Figure 4 in the case of a one-layer device. The far right image of this figure corresponds to forward bias where emission of light occasionally occurs.

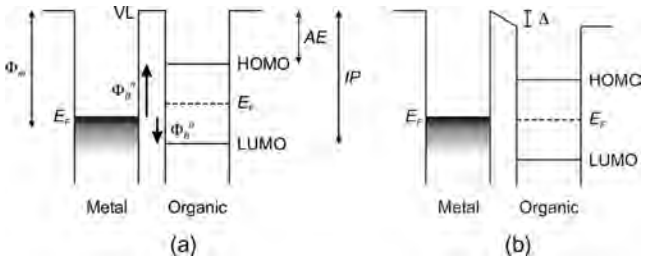

Figure 2. Energy level alignment at a metal/organic interface: (a) ideal case; (b) in the presence of a surface dipole.

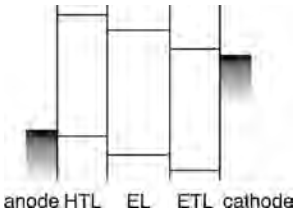

Figure 3. Energy diagram of a multilayer OLED. HTL: hole transport layer; EL: emissive layer; ETL: electron transport layer.

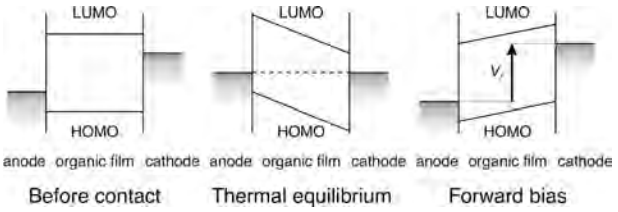

Figure 4. Energy diagram of an unbiased and biased one-layer OLED.

Injection Processes The ideal case of perfect energy alignment at both interfaces is practically never fulfilled in practice. In most real cases, charges have to pass a potential barrier before penetrating the organic layer. This interfacial process must not be confused with charge transport, which will be dealt with in a following section. As most organic semiconductors (SCs) actually behave as insulators, there are basically two injection processes: Schottky emission and field emission. The former corresponds to thermionic emission across the metal–insulator interface. The corresponding current density is given by Eq. (2). Here, A^* is the effective Richardson constant, F is the electric field, q is the absolute electron charge, ε is the permittivity of the organic layer, k is Boltzmann's constant, and T the absolute temperature. β is a characteristic factor given by $\beta = \sqrt{q/4\pi\varepsilon}$, where ε is the permittivity of the medium. (Note that the same constant is encountered in the Poole–Frenkel effect that will be dealt with in the next section.)

$$j = A^* T^2 \exp\left(-\frac{q\Phi_B}{kT} + \frac{q}{kT}\beta\sqrt{F}\right) \tag{2}$$

The second mechanism, which is often referred to as the Fowler–Nordeim process, occurs under high applied electric field. In that case, electrons can tunnel through the triangular barrier that forms when the diode is polarized. The probability for tunneling depends strongly on the height and width of the barrier but is independent of the temperature. The corresponding current density is given as follows, where m^* is the charge effective mass:

$$j \propto F^2 \exp\left(-\frac{4\sqrt{2m^*}(q\Phi_B)^{3/2}}{3e\hbar F}\right) \tag{3}$$

A useful way of checking whether field-induced injection is involved consists of plotting the logarithm of I/F^2 as a function of the reversed electric field.

The main difference between the two mechanisms resides in their temperature dependence; the tunnel process is temperature independent, while the Schottky mechanism is thermally activated. It must be pointed out that, because parameters involved in Eqs. (2) and (3) such as the Richardson constant and effective mass are not well known in most organic SCs, a quantitative check of the charge injection process remains hazardous.

2.1.2. Charge Transport

Although organic SCs have been identified for more than 50 years, charge transport in these materials is still the subject of great debate. A prominent issue of charge transport in organic SCs is the very low mobility of the charge carriers. The main methods for measuring charge carrier mobility are time of flight (ToF), analysis of the current–voltage curves of single carrier diodes in the space charge-limited current (SCLC) regime, and fabrication of a field-effect transistor (FET) structure. As shown in Table 1 for the typical case of PPV, the hole mobility stands in the 10^{-8}–10^{-6} cm^2/V s range. Even lower values have been reported for electron mobility.

This low mobility implies that the corresponding mean free path is substantially shorter than the intermolecular distance, which excludes the dominant charge transport mechanism encountered in most metals and conventional semiconductors, that is, diffusive transport in delocalized states. Among the various models that have been put forward to explain this very low mobility, two classes emerge. One covers the models based on trapping, which assumes that charge transport is limited by a given distribution of traps in the energy gap. Second are the field-dependent mobility models, which implies an exponential dependence of the mobility on the square root of the electric field. The mobility model was first set on the basis of the observed mobility-field dependence of time-of-flight data. As the general dependence resembles that of the Poole–Frenkel mechanism, the model is often referred to as the "Poole–Frenkel-*like*" law because experimental data do not quantitatively agree with the classical Poole–Frenkel emission model.

Because the density of mobile charges in organic SCs is extremely low, the current rapidly becomes limited by charges injected from the electrodes. In this space charge limited regime, the current density is given as follows, where μ is the charge mobility and d is the thickness of the organic layer:

$$j = \frac{9}{8}\mu\varepsilon\frac{V^2}{d^3} \tag{4}$$

The SCLC is strongly affected by the presence of charge traps. The expression depends on the energy distribution of the traps. One of the most frequently invoked distributions is the exponential distribution. If the density of trapped charges largely exceeds that of free charge and the Fermi occupancy function is a step function, the SCLC is given by [11]

$$j = q^{l-1}\mu N_c\left(\frac{2l+1}{l+1}\right)^{l+1}\left(\frac{l}{l+1}\frac{\varepsilon}{H_b}\right)^{l}\frac{V^{l+1}}{d^{2l+1}} \tag{5}$$

Here, H_b is the density of traps and $l = T_c/T$, where T_c is a characteristic temperature that describes the steepness of the distribution.

Table 1. Hole mobility of undoped PPV determined by various methods.

Polymer	Mobility (cm^2/V s)	Method [Ref.]
PPV	10^{-8}	ToF [8]
PPV	10^{-7}–10^{-8}	FET [9]
MEH-PPV[a]	5×10^{-6}	SCLC [10]

[a] MEH-PPV—poly[2-methoxy,5-(2′-ethylhexyloxy)-1,4-phenylene vinylene].

The field-dependent mobility model dates back to the 1970s [12]. It has become common practice to analyze mobility data in terms of the empirical equation due to Gill [13]:

$$\mu(F) = \mu(0)\exp\left(-\frac{\Delta_0}{kT} + \frac{q}{kT_{\text{eff}}}\beta\sqrt{F}\right) \qquad \frac{1}{T_{\text{eff}}} = \frac{1}{T} - \frac{1}{T_0} \tag{6}$$

T_0 is the temperature at which Arrhenius plots of $\mu(T)$ intersect and β is the previously defined Poole–Frenkel factor. The physics of the field dependence relies on disorder-induced localization of charges. The field-dependent term arises from the fact that charge transport is governed by tunneling from one localized state to another; the transfer occurs through tunneling, a process that can be assisted by the electric field. Such a mechanism is similar to the Poole–Frenkel effect. However, the exact expression for β strongly depends on the distribution of the traps, so that it noticeably differs from the conventional Poole–Frenkel factor. Furthermore, the derivation of the constant cannot be carried out by analysis. A widely used expression is that derived by Bässler [14] by performing a statistical Monte Carlo computation based on a Gaussian distribution of localized levels. The *energetic* disorder is depicted by the standard deviation σ, while that of the *geometric* dispersion is given by Σ. The general expression of the field-dependent mobility is given by

$$\mu = \mu_0 \exp\left[-\left(\frac{2}{3}\frac{\sigma}{kT}\right)^2\right] \exp\left\{C\left[\left(\frac{\sigma}{kT}\right)^2 - \Sigma^2\right]\sqrt{F}\right\} \tag{7}$$

More recently, Garstein and Conwell [15] and Novikov et al. [16] have proposed an alternative approach to the problem. The model, termed the correlated disorder model, assumes that the potential viewed by a charge carrier presents slowly varying spatial fluctuations. These variations occur because the energy of neighboring sites is correlated; that is, the energy of one site depends on the energy of the nearest sites. Because of these correlations, the energy difference between two sites is limited by an effect of spatial averaging. As in the case of the model of Gaussian disorder presented previously, the mobility is calculated through numerical Monte Carlo simulation:

$$\mu = \mu_0 \exp\left[-\left(\frac{3}{5}\frac{\sigma}{kT}\right)^2\right] \exp\left\{C_0\left[\left(\frac{\sigma}{kT}\right)^{3/2} - \Gamma\right]\sqrt{\frac{aF}{\sigma}}\right\} \tag{8}$$

Here, $C_0 = 0.78$ in a three-dimensional case, Γ measures the energy disorder ($\Gamma = 2$), and a is the intersite distance.

2.1.3. Charge Recombination and Light Emission

Charge Recombination The problem of charge recombination has received much less attention than charge injection and light emission. Charge recombination is a bimolecular reaction that obeys a second order kinetic of the following form, where n and p are the density of electron and holes, respectively [17]:

$$\frac{dn}{dt} = \frac{dp}{dt} = \gamma np \tag{9}$$

The most widely recognized mechanism of charge recombination is of Lagevin type, that is, diffusion controlled [18]. Such a mechanism is characteristic for materials in which the charge carrier mean free path is smaller than a critical distance defined by the Coulombic capture radius $r_c = q^2/4\pi\varepsilon kT$. For typical organic emitting materials, r_c amounts to around 20 nm at room temperature, while the mean free path compares to the distance between conjugated sites, which is of the order of a few nanometers. The recombination factor in Eq. (9) is given as follows, where μ_n and μ_p are the electron and hole mobility:

$$\gamma = \frac{q}{\varepsilon}(\mu_n + \mu_p) \tag{10}$$

From Eqs. (9) and (10) it can be seen that increasing recombination can be obtained by increasing charge mobility but also requires the density of electrons and holes be as close to each other as possible. The latter issue demands a balanced injection rate for both charges, which is probably one of the more difficult requirements for high performance devices.

Light Emission Charge recombination leads to the formation of electron–hole pairs that rapidly decay to excitons. The nature of the excitons in conjugated organic materials is the subject of great controversy that is still alive today. The debate has been the subject of a whole volume [19] published in 1997, which develops the two opposing aspects of the controversy. In essence, an exciton is an electron–hole pair where the two charges are linked together through Coulomb interaction. The strength of the link, also called exciton binding energy, is strongly material dependent. In conventional inorganic semiconductors the effective mass is lower than the free electron mass and the dielectric constant is high, so the binding energy is weak (that is, comparable to kT at room temperature) and the exciton extends over several lattice sites. (This weakly bond exciton is frequently termed Wannier exciton.) Hence, exciton effects are unimportant except at low temperature. On the other hand, excitons in molecular crystals are tightly bound and are localized on a single molecule, thus forming a so-called Frenkel exciton [20]. Because of the weakness of intermolecular interactions, the Frenkel exciton model is widely accepted in materials made of small molecules. This is not the case for polymers, where there exists a conflict between strong *intra*chain and weak *inter*chain interactions. Estimating the exciton binding energy is in principle quite simple [21]; it merely amounts to the difference between the energy gap and the optical gap. However, there are several difficulties hidden behind this simple definition. The first one is that both quantities are chain length dependent. Only for sufficiently long chains do they come to limiting values independent of the length. Another problem arises from the tendency of conjugated chains to relax when charges are added. This point has already been evoked earlier in this chapter. A consequence of this relaxation is that the energy gap is reduced by a quantity $P_+ + P_-$, where P_+ and P_- are

polarization energies, also called polaron binding energies. Because the polarization energies amount to tenths of an electronvolt, the estimation of the exciton binding energy may substantially differ depending on whether, on breakup, the exciton dissociates directly into a pair of polarons rather than a free electron and a free hole that subsequently relaxes into polarons. Part of the controversy rests on this still unresolved point.

Frenkel excitons in organic semiconductors can also be viewed as excited molecules that can travel over the solid through a mechanism of energy transfer. Because the Frenkel exciton propagates, it can generate energy bands, the width of which is determined by the transfer rate from one molecule to the next.

Frenkel excitons can be singlet or triplet, depending on the respective spin parity of its constituents. During the mechanism of electroluminescence, excitons are a result of the recombination of two charges of reverse sign, the spin of which is distributed at random. A generally accepted concept is that this feature limits the electroluminescence yield to 25%. The argument is based on simple spin multiplicity; for recombination of a pair of charges, they are four microstates in total, with three triplet states and only one singlet state. As the ground state is usually singlet, radiative decay from a triplet state is spin forbidden, so that the theoretical quantum yield of OLEDs is limited to 25%. However, quantum efficiency up to 50% has been recently reported in MEH-PPV based diodes [22]. Two kinds of argument have been invoked to explain this behavior.

The first one is to assert that excitons in some organic semiconductors (mainly polymers) are weakly bound (Wannier excitons). In that case, exciton effects can be neglected and quantum yields up to 100% be envisioned, like in the case of inorganic LEDs. Such an argumentation falls within the general controversy evoked previously.

The second analysis assumes Frenkel-type excitons [23]. The ratio between the number of singlet excitons and the total number of excitons can be expressed as $\eta = \sigma_S/(\sigma_S + 3\sigma_T)$, where σ_S and σ_T are the cross sections for singlet and triplet formation. The quantum mechanical argument is that interchain correlation effects of bond-charge type distinguish the cross sections for singlet a triplet states. Calculations show that in the case of PPV, the ratio σ_S/σ_T may be as high as 3, thus leading to a quantum yield of 50%.

An alternative approach to improve quantum efficiency consists of using phosphorescent materials [24]. In these materials, the luminescence comes from the radiative decay of the triplet state. In that case, the theoretical limit of the quantum yield is 75%. One way would therefore consist of adding phosphorescent compounds to the luminescent layer of the diode. However, this method has many problems. Because the decay from a triplet state is forbidden by selection rules, the lifetime of triplet excitons is very long. This means that all the phosphorescent sites may become occupied and therefore unavailable for energy transfer. Moreover, the long lifetime also increases the risk of nonradiative deactivation at some defect, or through triplet–triplet interactions.

A group at Princeton University [25] has used a different methodology where both singlet and triplet excitons transfer energy from the electron–hole pairs. As shown in Figure 5,

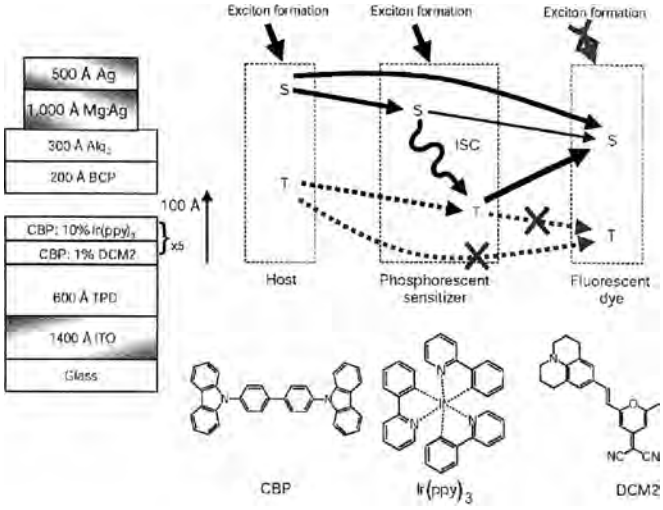

Figure 5. Phosphorescent sensitized OLED. Left: schematic structure of the device. The structure comprises a HTL (TPD), a hole blocking layer (BCP) and an ETL (Alq_3). The emitting layer is made of 10 layers of CBP alternatively doped with $Ir(ppy)_3$ (10%) and DCM2 (1%). Right: proposed transfer mechanism in the emitting layer. S stands for singlet, T for triplet, and ISC for intersystem crossing. Förster transfers are represented by solid arrows and Dexter transfers by dotted arrows. Reprinted with permission from [25], M. A. Baldo et al., *Nature* 403, 750 (2000). © 2000, Macmillan Magazines Ltd.

the emissive layer is made of a set of alternating layers that contain either a phosphorescent sensitizer or a fluorescent dye embedded in a host material. As a result, both singlet and triplet excitons are generated. Moreover, the energy of the triplet state in the phosphorescent dye is higher than that of the singlet in the fluorescent dye, so that energy transfer occurs from the triplet to the singlet, which then emits light. A quantum yield of nearly 100% thus has be obtained. However, the system presents several drawbacks. One is the need for a number of downhill energy steps, which results in the energy of the emitted light being much lower than that of the charge pair. For this reason, green or blue light would be difficult to obtain. The second problem concerns the energy transfer. Energy transfer between molecules in a solid may occur through two basic mechanisms: dipolar (Förster) or contact (Dexter). The former is long range and authorizes change of spin configuration, while the latter is short range and an exciton transferred this way retains its spin multiplicity. This second mechanism should therefore be avoided because it would lead to the formation of the nonemitting triplet exciton in the fluorescent dye.

2.2. Materials

One of the unique aspects of organic chemistry is its ability to produce new molecules at a high rate. Organic electroluminescence is a very active research topic that involves a great number of teams in both academic and industrial laboratories worldwide. Since the emergence of organic electroluminescence, dozens of new compounds aimed at being used in OLEDs have been synthesized each year. For these reasons, a comprehensive review of the materials used in organic LEDs would be far beyond the scope of this chapter. It would also not be very helpful, because it is difficult

to predict which compounds will lead to real applications. We will therefore restrict ourselves to a few representative molecules. Note that many of them are already commercially available.

2.2.1. Emitting Materials

Emitting materials can be sorted into polymers and short molecules. Recall that organic electroluminescence was first observed in a molecular crystal, anthracene, in 1963. This early device already presented encouraging quantum efficiency. However, its operating voltage of around 1000 V made its development unlikely. It is only with the advent of thin film devices that commercial application could be envisioned. Polymers [26] and small molecules [27] based devices emerged almost simultaneously at the turn of the 1980s. This breakthrough was actually made possible after the synthesis of the first conducting polymer in 1977: polyacetylene (PA) [28]. At that time, the unique property that fascinated chemists and physicists was the ability of the polymer to become conducting upon doping by a charge donating of withdrawing agent, hence the name "conducting" polymers. PA has a serious drawback: it is highly unstable in ambient air, but many other conjugated polymers were soon discovered. Their molecular formula is given in Figure 6. The finding of electroluminescence in one of them, PPV, drastically changed the perspective. The more promising property of this class of materials moved from "being a conductor when doped" to "being a semiconductor when undoped." A very interesting issue in conducting polymers is the possibility of substituting side groups to the main chain in order to modify some of its physical properties. For example, unsubstituted PPV is infusible and insoluble in most organic solvents, thus making it very difficult to process in thin solid films. Some of its substituted compounds are sketched in Figure 7. Now the most popular, MEH-PPV, which is soluble, has largely helped in developing OLEDs based on PPV. Similarly, it has been theoretically predicted that substitutions with electron donating or withdrawing groups could allow a tuning of the frontier (HOMO and LUMO) levels [29], thus favoring energy level alignment at one or both electrodes. The HOMO and LUMO shifts calculated for compounds **I** and **II** in Figure 7 are displayed in Table 2.

Substitution with a donor group (OCH_3, compound **I**) leads to a destabilization (positive shift) of the levels, while substitution with an acceptor group (CN, compound **II**) induces stabilization (negative shift).

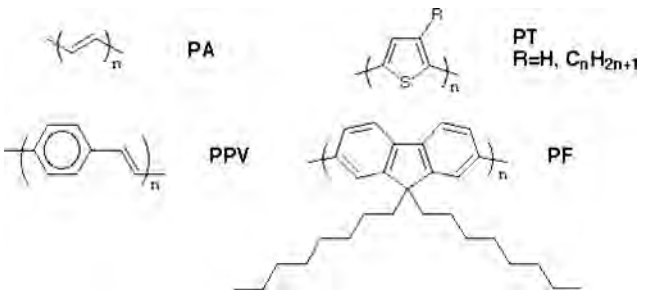

Figure 6. Molecular structure of most popular conducting polymers. *Trans*-PA; polythiophenes; PPV; poly-dialkyl-fluorene.

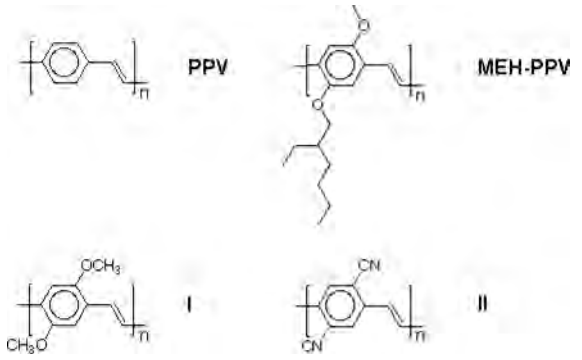

Figure 7. Molecular structure of PPV and poly[2-methoxy,5-(2′-ethylhexoxy)-1,4-henylene-vinylene] (MEH-PPV). Compounds **I** and **II** are models used to see the effect of electron donor and acceptor on the frontier levels (see Table 2).

A critical issue with low molecular weight organic compounds stems from their tendency to crystallize readily and hence form polycrystalline layers when deposited in thin films. This has the following detrimental effects on the performance of EL diodes: (1) exciton recombination occurs at grain boundaries, which considerably reduces the quantum yield; (2) films are not free of pinholes, leading to short circuits; (3) although data on that matter are relatively scarce, the polycrystalline structure might also be responsible for the lack of long-term stability of the devices. The original structure developed by Tang and van Slyke was made of two layers. The first one was an aromatic diamine and the second one was tris(8-hydroxyquinoline) aluminum (Alq_3). The morphology of the films, as measured by transmission electron microscopy, was found to be amorphous for the first layer and microcrystalline for the second one. This probably explains the tremendous success of Alq_3 as an emissive layer in OLEDs made of small molecules. The molecular structure of Alq_3 is given in Figure 8. More recently, Shirota [30] developed a general strategy to conceive and synthesize amorphous molecular materials. Starting from the simple picture that nonplanar structures should prevent crystal packing, Shirota proposed a new concept, the π-electron starburst, for the design of amorphous molecular materials. Typical examples are shown in Figure 9. (Note that Alq_3 also presents a nonplanar configuration.)

2.2.2. Electrodes

The basic rules for choosing materials for electrodes are quite simple: high work function for the anode (hole injecting) and low work function for the cathode (electron injecting). To that, we must add an obvious requirement; that is,

Table 2. Calculated shifts (in eV) of the HOMO and LUMO levels for derivatives **I** and **II** with respect to the unsubstituted PPV.

Derivative	HOMO	LUMO	E_g
PPV			3.24
I	+0.27	+0.08	3.06
II	−0.99	−1.17	3.11

Note: The energy gap E_g reported in the last column corresponds to the difference between the HOMO and LUMO levels (after [29]).

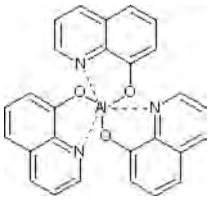

Figure 8. Molecular structure of tris(8-hydroxyquinoline aluminum).

at least one of the electrodes must be transparent to let light get out of the device. Transparent conducting materials mainly include degenerate oxides. Although there have been some reports on OLEDs with aluminum-doped zinc oxide (AZO) [31], practically all OLEDs use indium-tin oxide (ITO) as the anode. A probable reason for that is that ITO coated glass is also widely used in liquid crystal displays. In most cases, the organic layers are deposited on top of ITO during the fabrication of the device. In the course of the process, the surface state of the electrode is of primary importance because it controls crucial parameters such as energy level alignment and the absence of short circuits. In a recent paper, Kim and co-workers have investigated how surface treatments modify the performance of OLEDs [32]. The various treatments and their effect on the work function and roughness are summarized in Table 3.

The desired issues are (1) high work function to improve hole injection in the organic layers; (2) low sheet resistance to reduce ohmic losses; (3) low average roughness to avoid short circuits. An analysis of the data in Table 3 shows that the oxygen plasma treatment appears to be the best one. This was further confirmed by measuring the lifetime of the diode, which was substantially improved after an oxygen plasma treatment of the ITO surface.

Conducting polymers such as polyaniline [33] have been envisioned as alternative transparent anodes. The polymers present the advantage of a better interfacial matching with organic semiconductors. However, the sheet resistivity of these polymers remains too high for practical use. Hybrid anodes that combine the higher conductivity of ITO with the properties of the polymer have been shown to bring improvements in terms of efficiency, lifetime, and turn on voltage. The best example is the ITO/poly(3,4-ethylene dioxythiophene) (PEDOT) anode. PEDOT is now a commercially available polymer. In its most widely used form,

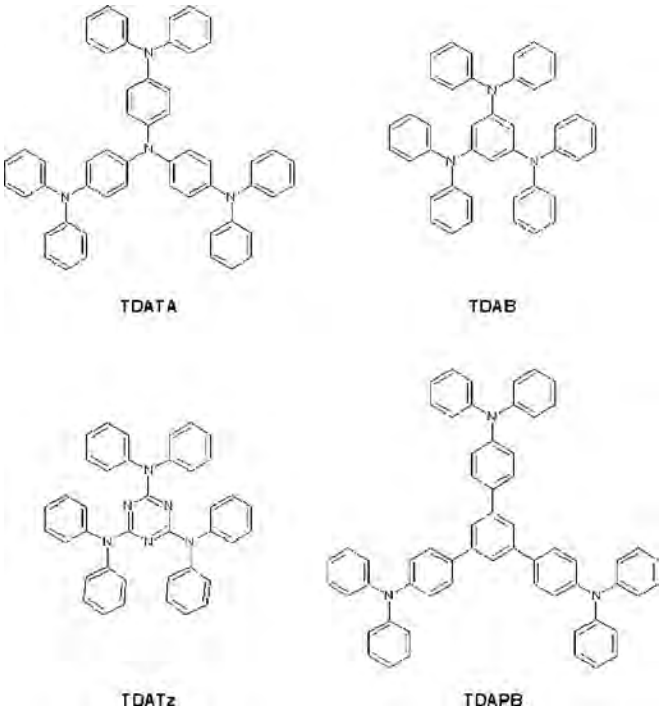

Figure 9. Molecular structure of typical amorphous molecular materials: 4;4′,4″-tris(diphenylamino)triphenylamine (TDATA); 1,3,5-tris(diphenylamino)benzene (TDAB); 2,4,6-tris(diphenylamino)-1,3,5-triazine (TDATz); 1,3,5-tris(4-diphenylaminophenyl)benzene (TDAPB).

the polymer is doped with another polymer, polystyrenesulfonate (PSS), Figure 10. A unique feature of this mixture is its large stability under its doped conducting form. Electroabsorption measurements [34] have shown that the improvements partly originate from an increased work function, so that PEDOT also plays the role of a hole injecting material.

An alternative way of modifying the work function of ITO is the use of self-assembled monolayers (SAMs). The principle of this modification rests on the use of dipolar molecules. Molecules used in SAMs also comprise a functional group prone to induce chemisorption on the surface. In the case of ITO, it has been shown that both carboxylic acid and preferably phosphonic acid can induce the formation of SAMs [35]. Both types of SAMs have been used to modify the ITO

Table 3. Work function, sheet resistance, and roughness of variously treated ITO substrates.

	Surface treatment	Work function (eV)	Sheet resistance (Ω/□)	Roughness (nm)
	as-received	4.5	16.1	2.6
Mechanical	paper rubbing	4.2	16.3	2.3
	Teflon rubbing	4.2	16.5	2.4

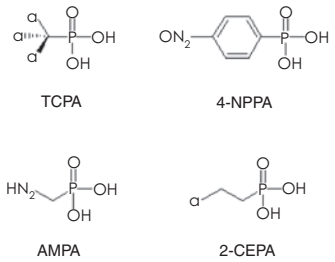

Figure 11. Molecular structures of the SAMs used to modify ITO electrodes: (tirchloromethyl)phosphonic acid (TCPA); (4-nitrophyl)phosphonic acid (4-NPPA); (aminomethyl) phosphonic acid (AMPA); (2-chloroethyl) phosphonic acid (2-CEPA).

electrodes in OLEDs [36, 37]. The shift in work function is interpreted as originating from the dipole moment induced by the SAM. According to this model, the work function shift $\Delta\varphi$ is determined by the change in electrostatic potential ΔV created at the surface by the dipolar moment μ,

$$\Delta\varphi = -q\Delta V = -qN\frac{\mu}{\varepsilon} \tag{11}$$

Here, N is the surface density of molecules and ε the permittivity of the SAM. Table 4 compares the calculated and measured work function change by four various molecules adsorbed on ITO. The measurements were performed with a Kelvin probe. The molecular structures of the SAMs are given in Figure 11.

Because the cathode is most generally deposited at the end of the fabrication process, surface treatments cannot be performed and the only criterion for selecting a metal for the cathode is its work function, which must be as low as possible (electronegative metal). Table 5 gives the work function of various metals used as cathode. According to Table 5, metals such as calcium or sodium appear to be the best choice. Unfortunately, these metals are also highly reactive and making devices with them requires a very efficient protection against ambient air. To date, the best compromise seems the use of an alloy between low work function and noble metal, such as Mg:Ag.

Improved electron injection was obtained by inserting a thin (0.5–10 nm) insulating film of lithium fluoride (LiF) between a stable metal cathode (mainly Al) and the emitter layer. The mechanism behind the enhanced injection is not fully understood. Interpretations include tunnelling [38], removal of interface states at the cathode–organic interface, and reduction of the barrier height to electron injection [39].

2.2.3. Charge Transport Agents

Although the terms "electron transport" and "hole transport" layers are universally used in the community of organic light-emitting diodes, it must be stressed that these expressions are somewhat misleading. In essence, an electron (hole) transport material would be that in which high electron (hole) mobility is encountered. This is not the case in OLEDs. Instead, ETLs and HTLs are made of chemical agents that favor electron (hole) injection. For this reason, some recent papers make a contradistinction between charge *transport* and charge *injecting* materials. In reality, both terms designate the same class of materials, since charge carrier mobility is low in practically all these organic semiconductors.

One of the most widely used electron transport agent remains the already invoked Alq_3, which is most often used as both ETL and emissive layer. A few alternatives have been proposed since then. At present, the main representatives of electron transport agents are derivatives of oxadiazole. One of these, PBD, is shown in Figure 12. The difficulty in finding organic electron transport materials probably comes from the fact that low electron affinity is usually associated with high chemical reactivity. Note that some polymers, such as polypyridine [40], have also been reported as electron transporting agents.

Hole transport materials are much more common. These comprise both short molecules and polymers. A very popular hole transport agent is N,N'-diphenyl-N,N''-bis(3-methylphenyl)(1,1′-biphenyl)-4,4′-diamine or TPD [7], the molecular formula of which is indicated in Figure 13.

Table 4. Calculated and measured work function shift (in eV) of ITO modified by SAMs.

SAM	Dipole moment (D)	Calculated	Measured
4-NPPA	5.73	0.303	0.720
TCPA	1.76	0.185	0.221
2-CEPA	1.69	0.179	0.212
AMPA	−1.43	−0.140	−0.179

Note: The molecular structure of the SAMs is shown in Figure 11. Dipole moments are calculated at the PM3 semi-empirical method (taken from [37]).

Table 5. Typical low work function metals.

Metal	Work function (eV)
Al	4.28
Ca	2.87
In	4.12
Li	2.9
Mg	3.66
Na	2.75
Sm	2.7

2.3. Performance

To conclude this section, we give here a brief outlook of the current performance of organic light emitting diodes.

2.3.1. Color

It is often claimed that one of the unique advantages of OLEDs is the possibility of generating practically all colors. However, this statement must be somewhat tempered. A characteristic of organic luminophores is to present a wide emission spectrum. This is detrimental when dealing with color displays, where red, green, and blue emitters with well-defined chromaticity are needed, but turns out to an advantage in the case of white light emission. These two extreme cases will now be dealt with in sequence.

The development of color displays based on inorganic light-emitting diodes has long been impeded by the lack of blue emitting devices. By contrast, blue OLEDs have been realized since the early beginning [41]. To date, dozens of blue light emitting molecules and polymers have been identified. Strangely enough, the problem with OLEDs concerns the red emitters; most of them are actually orange, which is not favorable for making good quality color displays. Two approaches have been used to overcome this difficulty. One is to use organometallic complexes based on rare earths, mainly europium, which is one of the best-known red emitters [42, 43] with four sharp emission peaks, the dominant one being centered at 618 nm. It is worth pointing out that in this case, the emitting element is the rare earth ion, which is at variance with other organometallic complexes such as Alq_3 where the emitting part is the ligand. The sharp emission in rare earths comes from electron transitions between $4f$ bands. For symmetry reasons, these transitions are forbidden in the free ions but may become allowed when the symmetry of the ion is removed by an asymmetrical external crystal field such as that provided by an appropriate ligand. Generally, the complex is embedded in a polymer matrix that can act as an energy transferring system for the complex. After exciting the polymer, energy cascades through the ligand to the central rare earth ion, which eventually emits light. We note that organic diodes have also be made with another rare earth, erbium [44, 45], that emits in the near infrared at 1.54 μm, a wavelength of importance in telecommunications because it corresponds to a minimum of losses in optical fibers.

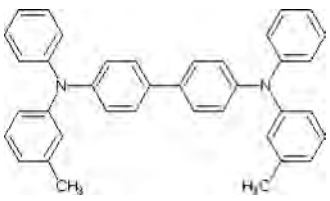

Figure 13. Molecular formula of N,N'-bis(3-methylphenyl)-N,N'-diphenylbenzidine.

The second strategy for red light devices is the use of small amounts of an efficient luminophore for this color dispersed in an electroluminescent material that emits at higher energy. One speaks in that case of "dopant" (or guest) in a host material. Representative examples of doping materials are laser dyes such as 4-dicyanomethylene-2-methyl-6-(*p*-dimehylaminostyryl)-4H-pyran (DCM) [46]. Like in the case of the rare earth complexes, emission results from a Förster energy transfer from the matrix (typically Alq_3) to the dye.

The first report on white OLED was published in 1994 [47]. White light is obtained by mixing several (most often three) emitting materials with complementary emitting spectra. In this configuration, the wide luminescent spectra of organic compounds become advantageous. Various structures have been used to realize white OLEDs, among them blends, multiple layers, and doped matrices. In essence, the basic principles that govern the operating mode of these diodes do not differ from those of the one-color diodes. Note that white phosphorescent diodes have also been reported [48].

2.3.2. Yield

The yield of an electroluminescent device can be defined in various ways. The quantum yield η_q represents the ratio of the number of emitted photons to the number of injected charge carriers. The overall yield can be decomposed into a product of factors that mirror the yield of each step of the process; hence $\eta_q = \eta_1\eta_2\eta_3$, where η_1 = (number of emitted photons)/(number of singlet excitons), η_2 = (number of singlet excitons)/(total number of excitons), and η_3 = (number of excitons)/(number of injected carriers). The first term corresponds to the photoluminescence (PL) quantum efficiency of the emitting material. Note that high PL yield (higher than 50%) can be achieved in organic solids. As discussed, the second term is in principle limited to 25%, but there is both experimental and theoretical evidence for possible higher yields. Finally, the third term mainly depends on the rate of carrier recombination. A crucial issue for high recombination rate is a balanced injection of electrons and holes.

A distinction has been made by Greenham et al. between the *internal* and *external* yield [49]. To understand this concept, one must recall that all photons produced in the diode do not actually leave the emitting layer; some of them are trapped by a process of total internal reflection. Using Snell's law, they determined that the internal quantum yield, which accounts for the total number of photons produced, is greater than the external quantum yield, for directly emitted light, by a factor of $2n^2$ where n is the refractive index of the emitting material. Note that this correction is much more important in inorganic semiconductors than in the organic ones, the refractive index of which generally ranges between 1.5 and 2.

However, the technologically important parameter is the power efficiency, that is, the ratio of the output light power (in lumens) to the input electrical power (in watts). It is worth noting that the early device of Pope and co-workers made of an anthracene single crystal presented a reasonably good quantum yield of a few percent but a desperately

poor power efficiency because its operation required very high voltages. Current OLEDs operate at low voltage, which considerably increases the power yield of the diodes. Among other issues, high power yields are obtained by using very thin films; the overall thickness of current diodes does not exceed 100 nm.

2.3.3. Degradation

Device stability is a major concern for OLEDs. This problem has known increased interest, as the development of organic electroluminescence is becoming an industrial challenge. Studies have focused on two widely used structures: ITO/poly(para-phenylenevinylene)/Ca and ITO/Alq_3/(Al or Mg:Ag) (with occasionally TPD as hole transport layer). Two different degradation mechanisms have been identified [50]. The first corresponds to a uniform long-term decay in electroluminescence yield. The half-time of the best current OLEDs, defined as the time elapsed before the luminance of the device falls to half its initial value, may amount to up to a few thousands of hours. In the second process, the degradation manifests itself through the formation of dark (i.e., nonemissive) spots that gradually cover the surface of the diode [51]. The formation of these dark spots is greatly reduced when the device operates in an inert atmosphere. For this reason, great care must be taken to avoid exposure of OLEDs to oxygen or moisture during their fabrication. Among the various origins for degradation that have been put forward, we can mention:

- Crystallization of the charge transporting layers [52] may occur. As stated, the best performance is obtained with amorphous materials. A likely origin for crystallization is Joule heating. Note that an improvement of the luminescence yield also results in a reduction of the Joule current.
- Evidence has been given that the dark spot formation is associated with the cathode/Alq_3 interface [53]. A major cause is cathode delamination. Another origin for dark spots is oxidation of the cathode/organic interfacial region. The role of traces of oxygen in this process is strongly suspected.
- Degradations may also occur at the ITO/organic interface. The main cause is diffusion of indium out of the oxide electrode. It has been suggested to replace the ITO anode with AZO [31], another transparent conducting oxide. Diffusion of zinc also occurs in this case, but to a lesser extent than indium out of ITO.

A general conclusion of these degradation studies is that preventing exposure of the device to oxygen and moisture during its entire fabrication process is of primary importance. It is also worth pointing out that any improvement in the performance of a device most generally comes with an increase of its lifetime.

3. NANO-ORGANIC LIGHT-EMITTING DIODES

The term "nano-OLEDs" designates organic light emitting diodes having nanometric size (i.e., from several nanometers to several tens of nanometers). Making such devices with controlled properties is still difficult because the fabrication technique of OLEDs has not yet been entirely mastered. Moreover, the technology for nanosize classical semiconductors is still in the process of development, despite remarkable progress made in this field in recent years. Several researchers, however, have tentatively fabricated OLEDs of submicrometer size with moderate success. The basic techniques are borrowed from semiconductor technology, although the particular properties of organic materials could allow special preparation and applications of devices. In 2001, the limiting size for nanodevices was reported to be about 250 nm [54] although it recently has been demonstrated that nanocontacts of 10 nm could be realized by nanoimprint technology [55].

We shall first review the different techniques used in conventional semiconductor technology to fabricate nanosize devices.

3.1. Technology of Nanostructures

3.1.1. Lithography

The key drivers for semiconductor industry have been lithography. This technique employs optical projection printing: the image of the mask is projected on a semiconductor wafer that has been coated with a photosensitive layer or photoresist (Fig. 14). After exposure to UV light, this layer, which becomes soluble in a developing fluid, is removed so that a pattern emerges on the substrate upon development by appropriate solvents. This pattern is a resist layer for further etching or ion implantation process and allows defined geometries for the devices to be obtained. The resolution of the pattern depends on the quality of both the resist material and the mask fabrication. The former should exhibit high imaging contrast whereas the latter should be well defined, resolved, and placed with accuracy.

The resolution of a lithography system is usually expressed as a function of the wavelength λ of the radiation used to

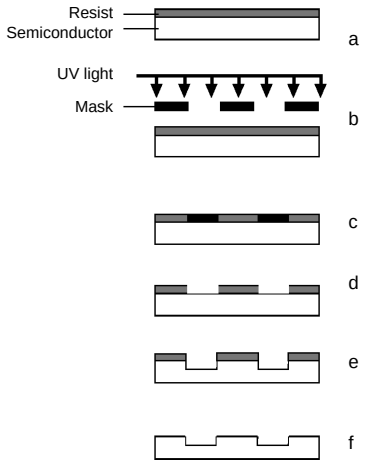

Figure 14. Schematic overview of an optical lithography process: (a) semiconductor covered with light sensitive resist; (b) exposure to UV light; (c) the expose region becomes soluble; (d) reproduction of the pattern on the resist layer; (e) etching of the semiconductor; (f) washing of the resist; the pattern is transferred to the substrate.

project the image and the numerical aperture F,

$$d = k_1 \frac{\lambda}{F} \tag{12}$$

where k_1 is a constant whose value depends on the process being used, typically 0.5 for integrated circuit manufacturing, and F varies in the range of 0.5–0.6. To achieve a low resolution, short wavelengths are used, for instance, with excimer laser sources or very short wavelengths from ultraviolet radiation (100–140 nm). The main drawback of these techniques is a large absorption of the radiation used by the materials, and the resist layer should be relatively thick.

Alternative technique consists of using an electron beam as a radiation source and a membrane with holes in it as a mask (electron beam lithography). The electron beam is absorbed by the solid part of the membrane and passes through the holes in the membrane. In this way, patterns can be designed on the resist layer. The resolution limit is based on the intermolecular force between exposed and unexposed molecules, which prevents the exposed molecules from being dissolved in the developer solution. Heating of the mask by the electron beam may cause distortion in the final pattern, which can be defined with a resolution lower than 100 nm.

3.1.2. New Technologies

The conventional lithography techniques provide highly resolved geometries to devices but require specific preparation steps, which are not always convenient for the fabrication processes. Several techniques recently developed can be used in replacement of traditional lithographic processes with success, especially for organic and polymer based devices.

(a) *Scanning probe arrays:* This technique makes use of the scanning probe of a scanning force microscopy system to pattern the surface of a layer by affecting its surface chemistry. A bias current is applied to the tip of the probe and generates an electrical field in the surface under test and modifies its structure. This modification produces relief images that can be used for circuit pattern. A large number of scanning tips in array arrangement would be needed to design circuits by this technique.

(b) *Nanoimprinting lithography* (*NIL*): This technique uses a stamping or moulding process to replicate a pattern from a master. It consists of transferring a pattern by a mechanical mold to a layer deposited on a hard substrate (Fig. 15). A stamp with the desired nanofeatures is usually fabricated by a conventional lithography technique. The material to be printed is a polymer, which is deposited on a substrate. The stamp and the substrate are put into conformal contact and the system is molded by heating it at a temperature above the glass temperature T_g of the polymer. The stamp and the substrate are then cooled down to a temperature just below T_g and separated. The polymer film left on the substrate can be used as a device or a mask for further patterning operation. Several commercial products are fabricated by using this process, for instance, compact disks. Resolution as small as 10 nm over large areas could be realized by this technique [56]. For practical use, there are two considerations. The first one is the alignment accuracy of the patterns, which can be important especially for small size and highly resolved circuits. The second issue is the accuracy in the size of the mold that should be as good as that of the pattern.

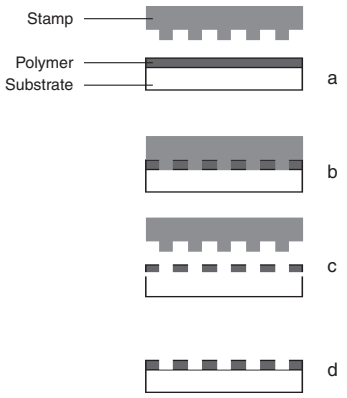

Figure 15. Schematic overview of the nanoimprint technique: (a) initial setup; (b) conformal contact; (c) cooling and mold removal; (d) patterned polymer layer.

3.2. Polymers in Nanotechnology

Polymers are perfectly adapted for nanotechnology because of the length scale of their chains. In addition, ease of processing and the ability to incorporate chemical functionality to the backbones make polymers ideal building blocks for nanosize systems [57].

In the NIL technique, a polymer such as poly(methyl methacrylate) or PMMA is used as a thin thermoplastic film to pattern nanosized designs on semiconductor substrates. After imprinting the polymer film, the pattern is transferred to the substrate by etching. The quality of the process depends on several parameters such as T_g temperature, viscosity of the polymers, and adhesion of the polymer to the substrate [58].

An alternative technique using polymer to design patterns is microcontact printing (μCP). Because the process does not employ hard polymers, it is called a soft lithography technique. It consists of printing a monolayer of a material from a stamp [made of poly(dimethyl siloxane) or PDMS] on a substrate (Fig. 16). The background or left space on the substrate can be later filled with a self-assembled monolayer, producing a patterned surface. The resolution obtained by this technique can reach 100 nm [59].

Several other particular techniques have been developed to pattern electroluminescent devices. They will be described in the next section. We mention here a special technique using an electrical field to pattern thin polymer film [60]. It consists of depositing a thin film on an electrode and then applying an electrical field to the polymer through another electrode, kept at a distance of 100 nm from the surface at the film, the system being kept at a temperature above the T_g temperature of the polymer. The electrical field will induce displacement charge density at the surface of the polymer, producing a periodic pattern.

3.3. Dispersed Nano-OLEDs

Making nanosized LEDs can be carried out by using a polymer host matrix in which electroluminescent nanoparticles are incorporated. These devices are known as hybrid structures and the nanoparticles are responsible for the light emission. The nanoparticles may be organic or inorganic. Guha et al. [61], for instance, used fluorescent dyes such as 3-(2′-benzothiozolyl)-7-*N*,*N*-diethylaminocoumarin (coumarin 7), 3-(2′-benzothiozolyl)-7-diethyl-aminocoumarin (coumarin 6), and DCM dispersed in a PMMA matrix. The thin films obtained by conventional deposition techniques were brought into contact with a GaN based LED. Light emission from the inorganic material is absorbed by the organic particles, which in turn emits light. Alternatively, inorganic nanocrystals can also be used in a electroluminescent polymer to obtain light emission from both materials. Schlamp et al. [62] deposited cadmium selenide (CdSe) or cadmium sulphide (CdS) nanocrystals from a chloroform solution onto a PPV thin film to form a disordered matrix of nanocrystals. Devices made with the combination of the two layers show either nanocrystal-only EL or a combination of nanocrystals and polymer EL, depending on the nanocrystal layer thickness. Several other inorganic nanoparticles have also been used in a polymer matrix in order to fabricate electroluminescent devices: ZnS [63], ZnS:Mn [64], porous silicon [65], carbon nanotubes [66], etc. Generally speaking, such a composite used as an emitter exhibits a higher conductivity than that of the polymer film alone. Charge carrier mobility is also improved in the composite. However, it is rarely possible to obtain light emission from both materials when using an electroluminescent polymer matrix. On the other hand, the nanocomposite systems show significant porosity [67], which may be a drawback for the fabrication of flexible devices.

Another technique to fabricate micro- and nano-OLEDs was proposed by Granström et al. [68] using poly[3-(4octylphenyl)-2,2′-bithiophene] or PTOPT as an emitter. This technique consists in filling the pores of a microfiltration membrane with PEDOT, which is a conducting polymer. The filled pores then will be used as an electrode with a defined size (10–14 nm). The emitting polymer is spin-coated on top of the membrane-contact structure and a metal is evaporated onto it to form the diode (Fig. 17). Light emission has been obtained from the polymer with dot size of about 100 nm. It should be noted that only 20 to 25% of the diodes fabricated by this technique have worked and the quantum efficiency was estimated to be less than 0.1%. A second diode structure has also been realized by the same authors using the same emitting polymer [69]. The nanosize of the diode in this case was obtained by taking advantage of the phase separation in polymer blends. The size of the emitting polymer islands was experimentally determined by varying the proportion of the components. PTOPT was mixed with PMMA in proportion of 5% PTOPT and 95% PMMA by weight and the solution was spin coated on the PEDOT contact. The size of the nanodiodes is comparable to that obtained by the previous technique.

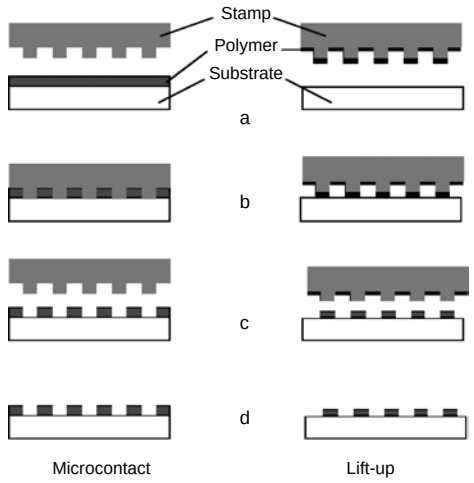

Figure 16. Schematic overview of the microcontact printing techniques: (a) initial setup; (b) conformal contact; (c) stamp removal; (d) patterned polymer. In the microcontact technique, the stamp is dipped in the polymer solution before contact with the substrate. In the lift-up technique, the polymer film is deposited on the substrate before contact with the stamp.

3.4. Ordered Nano-OLEDs

The realization of dispersed nanodiodes has demonstrated that it is possible to fabricate nano-OLEDs, but in practice, a better organization of the devices is needed for displays. Therefore, the conventional techniques used in semiconductor technology are applied to pattern the polymer emitting films. In standard photolithography, the use of solvents to remove the soluble part of the photoresist film may dissolve and swell the organic layer. In addition, UV light can damage the emitter. Methods that do not require lithography have been recently developed for patterning polymer thin films. These methods can be classified into two principal categories: soft lithography and inkjet printing. Other techniques are also available but their applications are limited.

3.4.1. Masking Technique

This technique is the simplest way to produce arrays of OLEDs. A metal mask is put in contact with the substrate and the organic layer is evaporated through the slits of the

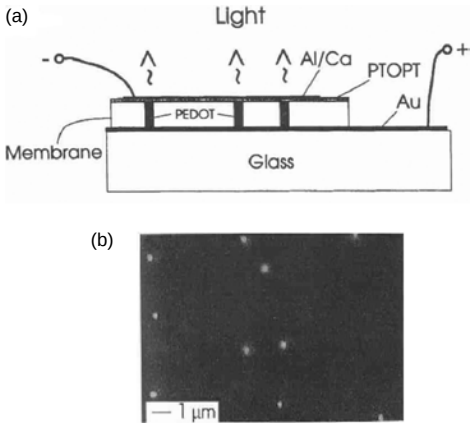

Figure 17. Fabrication of nanodiodes using PTOPT as an emitter, deposited into a polycarbonate membrane: (a) diode structure; (b) photograph of emitting nano-LEDs. Reprinted with permission from [69], M. Granström et al., *Synth. Met.* 76, 141 (1996). © 1996, Elsevier Science.

mask and forms a well defined pattern on the substrate. Generally, there is a close but not direct contact between the mask and the substrate in order to avoid scraping of the organic layer. The formed thin films have high definition geometry but their size is important. Simple pixel arrays of Alq_3 based diodes were fabricated by Jabbour et al. [70] using an electrochemically patterned mask or an electron microscope grid. Mori et al. [71] used a simple sliding mask to fabricate RGB (red green blue) pixels, each of them is 120 μm wide (Fig. 18).

The masking technique was used to fabricate planar OLEDs or surface cells [72]. In this configuration, electrodes were deposited on a polymer substrate with a gap in between using a shadow mask. The cell configuration can be a single gap cell [73] or interdigited one [74, 75]. The gap between the electrodes is a few micrometers wide and the light intensity is proportional to the total length of the electrode. In poly(3-(2′,5′-bis(1″,4″,7″ trioxaoctyl)phenyl)-2,2′-bithiophene) planar based diodes, a turn-on voltage of 6 V was sufficient to run a device with an electrode separation of 10 μm. The major advantage of such diodes over sandwich ones is that they are less sensitive to pinhole formation and may avoid electrical short in operation. However, the width of the LEDs is relatively large, of the order of a few micrometers, and it is not possible at this stage to reduce further the size of devices. Nevertheless, these diodes could be used to realize dot matrix displays.

3.4.2. Standard Lithography

The technique conventionally used in inorganic device manufacture was successfully applied to polymer LEDs by several authors to fabricate microsize diodes. For instance, Lidzey et al. [76] deposited a photoresist layer onto the emitting layer [poly(2,5-dialkoxy-*p*-phenylene vinylene)] and exposed the film to UV radiation through a contact mask. After development and washing, the exposed resist was removed and metal electrode was deposited forming micropatterned arrays of 5 μm diameter devices on a 7 μm pitch. The authors reported a loss of 35% of the photoluminescence efficiency that they attributed to the modification of the polymer during the photoprocessing. To avoid such a problem, a solution was proposed by Nagayama et al. [77] who have used a conventional lithographic method but instead of depositing the resist on the emitting layer, they fabricated arrays of cathode separators directly on the ITO substrate. These arrays of 30 μm width will act as a shadow masks in the vacuum evaporation process of the organic layer and the cathode to form the devices. The principle of the process is shown in Figure 19. This method can be also applied to fabricate polymer based diodes [78]. In this case, the polymer films were cast before patterning the cathode separation barriers. An insulator can be inserted between the emitter and the substrate to prevent edge defects, which may lead to electrical shorts between the cathode and the anode.

Standard lithography is also applied to pattern the anode, especially the ITO substrate. The cathode cannot be patterned the same way because the organic layer would be damaged under the high temperature at which the photoresist is baked. The emitting layer usually dissolves in developers. After deposition of the emitting layer by a conventional technique on the patterned ITO film, the cathode layer is evaporated through a mask to form the diodes. The size of the ITO pattern and that of the metallic electrode define the diode size. This technique was used for fabrication of photodiodes with poly(3-hexylthiophene) and 1-(3-methyoxycarbonyl)propyl-1-phenyl(6,6)C_{61} blend as an active layer [79]. The ITO layer was patterned into strips 450 μm in width and aluminum was deposited on a strip 635 μm wide forming an array of small pixels that could be deposited onto a flexible substrate material. Hosokawa et al. [80] used a similar technique to fabricate RGB multicolor displays, but instead of sizing the diode by fixing the size of the cathode layer, they used the photolithographic process to form ribs on the ITO substrate for the electrode separation. Next, organic layers and cathodes were

sequentially deposited on the ITO film within the space left between the ribs. Resolution less than 100 μm could be obtained using this technique. Based on the same principle, Tian et al. [81] fabricated Alq_3 devices of 300 μm width using oblique deposition of the cathode to avoid overheating of the emitting layer. The lifetimes of these diodes were found to be significantly improved. An original technique of shadow masking was proposed by Py et al. [82], who fabricated the mask directly on the inorganic substrate with overhanging edges. They used a stack of dense SiO_2, porous SiO_2, and Si_3N_4, deposited on a ITO substrate. To obtain the mask, a photoresist layer was patterned on the stack and was transferred by acid etching. Because of the different rates of dissolution of the insulators, the porous SiO_2 will be undercut and an overhanging profile is formed under the Si_3N_4 layer, which acts as an integrated mask. Rows of 1.54 μm width could be filled with Alq_3 to form an array of OLEDs by this technique.

These techniques are convenient for most of the soluble polymers or evaporated organic materials. For polymers such as PPV, which need a thermal conversion process at high temperature, these techniques are not adapted because of the possible damage of the resist. Visconti et al. [83] used a method based on UV holographic lithography and plasma etching to produce patterning of PPV. This technique consists of making a mask pattern by holographic lithography using an argon laser (363.8 nm) on the resist layer, which is deposited on the polymer film. By rotating the interferometer around the laser axis, the authors could obtain planar arrays of squares, triangles, and diamonds on the resist layer. Next, the patterns are transferred to the PPV film by a reactive ion etching process. By carefully controlling the etching rate, the resist layer was removed and continuous PPV stripes with a width of 200 nm could be formed.

3.4.3. Soft Lithography

Standard lithography has disadvantages in OLED fabrication, mainly because it cannot provide efficient control over the chemistry of patterned organic surfaces. A number of techniques have been developed for fabricating micro- and nanostructures using an elastomeric stamp or mold to transfer the pattern to a substrate. The elastomer stamp is usually fabricated by patterning a silicon substrate with a prepolymer of PDMS. After curing, the stamp is peeled off from the substrate. These techniques, called soft lithography, include μCP, microinjection molding in capillaries (MIMIC), replica molding, and microtransfer molding [84]. To minimize the defects of the pattern, the soft lithography techniques make use of the self-assembly of the molecules. This property of the molecules to be organized into stable configuration is based on the principle that at a final state, their organization is at thermodynamic equilibrium and therefore tends to reject any defect that could be formed. One of the best-known examples of self-assembly is the self-assembled monolayer, which is formed by self-organization of functionalized organic molecules on an appropriate surface.

Soft lithography techniques have been used by Grandlund et al. [85] to fabricate arrays of OLEDs. The arrays were formed by patterning the conducting polymer PEDOT/PSS layer deposited on an ITO substrate using the μCP technique. After deposition of the active polymer layer [poly(3-(2-butyloxy-5-octylphenyl))], they used the MIMIC technique to pattern the polymer film, and finally, a layer of aluminium was deposited over the active layer to form arrays of OLEDs. The size of each diode was 100×100 μm^2, which has a similar performance to that of standard devices.

A similar technique has been used by Nüesch et al. [86] to pattern the ITO anode (Fig. 20). A elastomeric PDMS stamp was fabricated to the desired pattern and then immersed in a 3×10^{-3} M solution of (tetrabutylammonium) hydroxide in ethanol or water. The stamp is then pressed onto the ITO substrate. The base will react with the conducting oxide film, resulting in the formation of a solid ionic double layer at the oxide surface and leading to a change in its work function [87]. The devices were obtained by depositing a TPD/Alq_3 double layer onto the ITO film and the cathode LiF/Al was finally evaporated to form the diodes. The patterned ionic layer will inhibit the positive charge injection from the anode and only the organic film corresponding to the unpatterned parts of the ITO substrate will emit light. A luminance of about 100 cd/m^2 was obtained with a driving bias of 6.5 V for such a diode. This method has the advantage in that it will avoid handling of the organic film, which may cause damage to the devices.

Arrays of OLEDs with a period of 200 nm were reported by Wang et al. [88], who used nanoimprint lithography at 150 °C in vacuum. The emitting layer was Alq_3 doped with 2 wt% DCMII dye molecules, which has high luminescence efficiency. The patterning process in vacuum was found to preserve the optical property of the organic layer by preventing the residual oxygen from contaminating it. Arrays of about 400 nm width were realized by Nyberg et al. [89] using poly(3-(2′-methoxy-5′-octylphenyl)thiophene) as an emitting layer. Making use of this method, an insulating layer was use to separate the cathode from the anode, the pattern being obtained on the insulating layer and the cathode. The emitting film was deposited in the space left between two

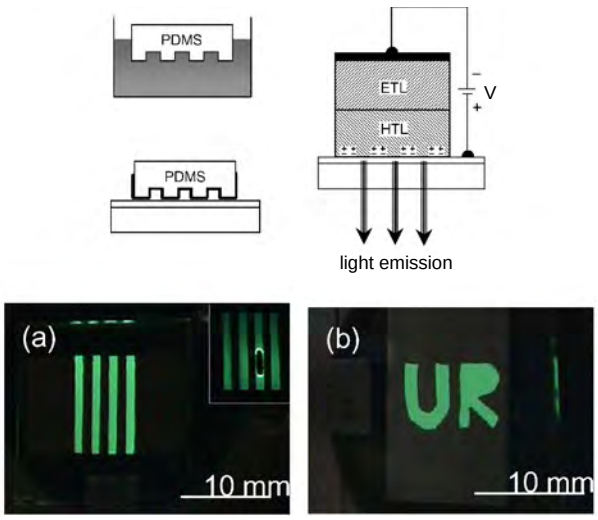

Figure 20. Fabrication of nano-OLEDs with Alq_3 as an emitter, using a soft-lithography technique to pattern the ITO substrates. Reprinted with permission from [86], F. Nüesch et al., *Appl. Phys. Lett.* 75, 1799 (1999). © 1999, American Institute of Physics.

successive arrays and the diodes have a quantum efficiency similar to standard sandwich devices (0.002%).

It is also possible to pattern the metal cathode layer directly using soft lithography. This technique makes use of silicon stamp to pattern the cathode layer by applying pressure onto the surface of the diodes (cold-welding process [90]). The stamp was previously patterned with raised areas in the shape of the regions on the electrode that were to be removed. When this was done, the left areas on the substrate can be used as arrays of LEDs. The active material used in this fabrication was Alq_3 with an electron transport layer made of 4,4′-bis(*N*-naphthyl)-(*N*-phenyl-amino)biphenyl. The measured performance on 1 mm diameter diodes is comparable to those obtained in Alq_3 based LEDs and no apparent degradation of the emitting layer was observed during the cathode patterning process.

The different soft lithography techniques have demonstrated that they can be applied to the OLED technology without producing significant damage to the organic layer and the performances of the nano- and microdiodes are generally comparable to those of standard ones. Devices of small size and high definition could be obtained by these techniques as compared to standard lithography. Recent investigations have demonstrated that patterns with 10 nm features could be prepared [91]. However, it should be noticed that industrial production requires rapid and reproducible patterning, and parallel techniques of fabricating devices are more adequate for manufacturing nanostructures. Soft lithography methods are well adapted to serial fabrication of devices in laboratory research work or lithographic masks.

3.4.4. Inkjet Printing

This technique is particularly adapted for solution processable materials and appears to be the most interesting for fabrication of devices with highly resolved patterns [92, 93]. The emitting layer can be produced by two different methods. For the first technique, the film is directly deposited by printing on the substrate. For the second, the polymer is preliminarily spin-coated onto the substrate. Then a solution containing the dopant is dropped over the films, allowing the dye diffusion into the host layer.

Inkjet printing can be performed in a continuous way or in a drop-on-demand (or impulse) mode. The difference between the two modes is in the pattern size and the printing accuracy, the drop-on-demand mode allowing smaller size patterning and a better accuracy. This process can be performed by using either a bubble jet or a piezoelectric technique. In the bubble jet technique, the ink droplet is pulled out of the nozzle by the pressure of a vapor bubble that is locally formed by thermal heating. This technique therefore needs water as a solvent for the material. In the piezoelectric technique, the ink droplet is mechanically pumped out of the nozzle by applying a voltage to a piezoelectric crystal. This technique can be applied to polymers dissolved in organic solvents. Notice that many nozzles can operate in parallel to achieve high speed printing, resulting in a low cost production of devices.

Most of the materials used for inkjet printing belong to the polycarbazole (PVK) and the phenylene vinylene families. Light emitting diodes with low turn-on voltage were fabricated by Hebner et al. [94] using PVK doped with coumarin dyes. Soluble derivatives of PPV such as MEH-PPV [95] and poly[5-methoxy-(2-propanoxysulfonide)-1,4-phenylene vinylene] [96] also used successfully make use of the printing technique. Figure 21 shows the polymer light emitting fabrication process and a logo created by inkjet printing using MEH-PPV as an active layer.

The size and the quality of the printed pattern depend on several factors. First, the size of standard nozzles is in the range of 20–30 μm, which produces at best dots of about 25 μm in size [97]. Second, the resolution of the pattern depends greatly on the viscosity of the ink and its ability to bind to the substrate. Generally, a low viscosity is needed to prevent rapid drying of ink and clogging of nozzles. Therefore, additives should be incorporated to the ink when using soluble dyes for color emission. On the other hand, ink droplets should not spread on the substrate before they are absorbed and dried (few seconds to several minutes). This condition implies that the ink viscosity should be sufficiently high and the surface of the substrate should be rough enough to limit spreading of the ink and blurring of the image. Finally, the printed pattern should be of a uniform thickness to avoid possible electrical shorts and the uniformity of the layer depends greatly on the quality of the material used. Indeed, the pinhole formation in printed patterns is usually observed and to improve the quality of the emitting devices, additional layers are used. These layers of course have their usual function but are useful to prevent shorts. For instance, PEDOT doped with PSS was used

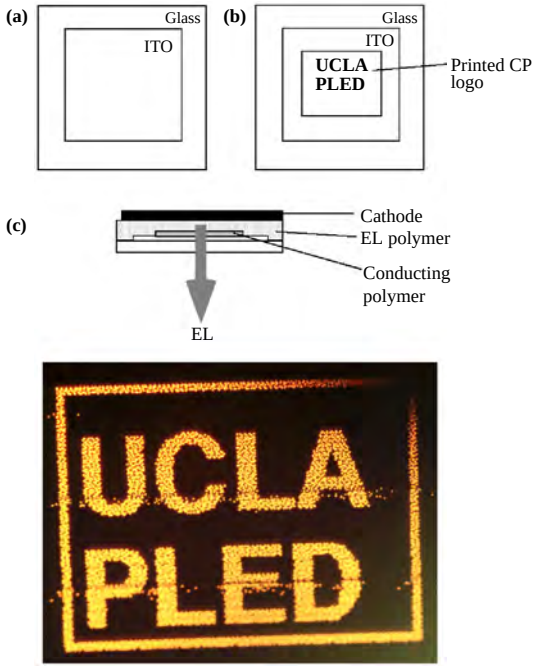

Figure 21. Fabrication of nano-OLEDs with MEH-PPV as an emitter, using an inkjet printing technique to design a logo. Reprinted with permission from [95], J. Bharathan and Y. Yang, *Appl. Phys. Lett.* 72, 2660 (1998). © 1998, American Institute of Physics.

as a hole transport layer in printed OLEDs with polyfluorene and PPV as emitters [98]. Improved techniques and materials [regioregular poly(3-hexylthiophene-2,5 dyil)] have demonstrated that good quality patterns could be realized without buffer layers [99].

The inkjet technique has several undeniable advantages in that a pattern of any size and/or shape can be reproduced directly on the substrate. Problems encountered in the technique include uniform thickness of the printed layer, pinhole formation, and viscosity of the solution. Even with these problems, the technique appears to be one of the most promising for patterning organic devices in the future.

3.4.5. Special Techniques

Besides the techniques currently used for fabrication of small devices previously mentioned, several others have been also carried out with success to pattern organic diodes.

First, a variation of the lithography technique was used by Noach et al. [100], who used a 193 nm excimer laser to ablate first the ITO substrate through a mask. After deposition of the polymer film and the metal electrode, the grid was then rotated orthogonally to the direction of the ITO strips and the laser was used to ablate the metal layer and partially the polymer. Arrays of 20 μm square pixels were reported with improved luminance as compared to standard thin film LEDs. This technique requires, however, careful control of the laser operation to obtain the desired results.

For printing techniques, an alternative method has been applied by Pardo et al. [101] to fabricate logos using MEH-PPV as an emitter (Fig. 22). This technique, called screen-printing, consists of using a nylon fabric as a screen through which the ink (solution) is deposited on an ITO substrate. The screen is in direct contact with the ITO film or close to it ($\approx$1 mm). The shape of the screen can be defined by using an epoxy to hide parts of the fabric that will not be printed. Multilayer diodes can then be formed on the screen by conventional deposition techniques. The technique is relatively simple and allows a high printing speed with a good resolution, below 100 μm. Birnstock et al. [102] reported that very a low turn-on voltage (3 V) was obtained in screen-printed OLEDs using a polyfluorene derivative, without pattern caused by the fabric.

More specific techniques have been recently developed to obtain nanosize OLEDs. These techniques can be divided into two main categories: the first one uses optical means to obtain a light emission from the organic material and the second is a special preparation of the substrate to pattern the devices.

The nanodevices can be patterned by light [103]. The technique used consists of fabricating a standard diode and then irradiating it by an intense light beam (laser) through the transparent substrate. An alternative voltage is simultaneously applied to the device during the irradiation (several minutes). It was observed in Alq_3 based diodes that electroluminescence was induced by the light beam irradiation and a memory effect was obtained: the device continued to emit light during a week. This observation suggests that the illumination facilitates the charge injection and their transport through the device, leading to the formation of excitons. However, the memory effect induced by the light is not well understood. This technique allows patterning the diodes by moving the light beam on the surface of the substrate.

A variation of the previous technique was used by Micheletto et al. [104] with a laser light of a modified scanning near field optical microscope setup. The device studied was a ITO/poly-3(2-(5-chlorobenzotriazolo)-ethyl)thiophene/Al diode. The cathode is the tip of the microscope, which acts as a nanosize electrode. It allows stimulation of very small areas of the active polymer and locally complete LEDs are formed. By this technique, it was possible to study diodes of size about 100 nm and significant differences in the light emission of these diodes with that of standard devices were observed. It should be noticed that the technique does not allow one to obtain permanent devices but may be helpful for studying properties of small size diodes. Based on the same principle, other optical instruments were modified and used to study very small areas of OLEDs. For instance, diaminotofluorbiphenyl based diodes were studied with a scanning tunneling microscope [105] and 1,3,4-oxadiazole moiety modified alkoxy ring substituted poly(*p*-phenylene vinylene) LEDs by atomic force microscopy [106].

Highly ordered OLED heterostructures were fabricated by Marks et al. [107] using a special preparation of the

substrate. This technique is called nanosphere lithography (NSL). It consists of making a special mask deposited directly on the substrate (Fig. 23). First, a self-assembled layer of triarylamine was deposited on the ITO substrate in order to obtain a smooth and uniform surface. Then a layer of hexagonally close-packed carboxy-terminated polystyrene beads was formed on the obtained surface, playing the role of a mask. Diodes were fabricated by evaporation of Alq_3 as an emitting layer and TPD as a hole transporting layer. Regular pattern prismatic posts with 90 nm sides were obtained, which emit a light similar to that of macroscopic diodes without a significant shift of the EL maximum. However, an overall light intensity was found to be two orders lower than that of standard diodes, working in similar bias conditions. This technique provides very regular small size diodes.

3.4.6. Concluding Remarks

Many techniques have been invented or borrowed from the inorganic material technology to fabricate nano-OLEDs. The size of the devices ranges from several tens of nanometers to several micrometers. Generally, the performance of small size diodes is similar to that of conventional ones. However, it should be noted that the size of the devices can influence the physical process involved in transport and light emission of the diodes. These particular aspects will be examined. Moreover, although most of techniques used give reliable and reproducible results, only a few of them are suitable for industrial fabrication, which requires low cost, mass production, and high performance devices. Finally the technique used should also suit most of the organic materials to allow the fabrication of multiplayer and multicolor devices, which are necessary for the realization of displays.

3.5. Applications: Matrix Displays

Applications of OLEDs in the field of displays can be divided into two types: active matrix and passive matrix. These displays differ from each other in their structure and in the controlling process. A passive matrix has a simpler structure than an active matrix, but its control is less efficient than that of an active one.

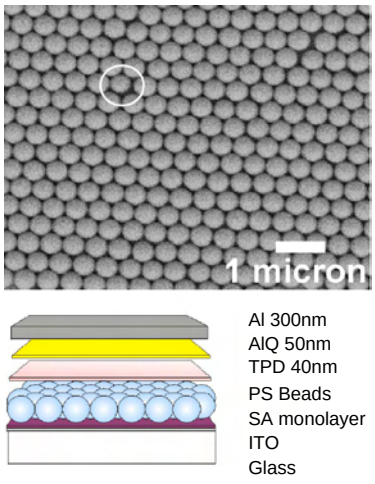

Figure 23. Schematic overview of the NSL. Reprinted with permission from [107], T. Marks et al., *Synth. Met.* 127, 29 (2002). © 2002, Elsevier Science.

3.5.1. Passive Matrix Displays

Principle Passive matrix displays consist of an array of picture elements or pixels deposited on a substrate. The pixels are patterned by one of the techniques described in previously. They are formed at intersections of rows (X horizontal) and columns (Y vertical) lines. To switch on a particular pixel (X, Y), electrical signals are applied to the X and Y lines, with a positive bias to the anode and a negative bias to the cathode. Each pixel is composed of a light emitting diode, whose color is designed by the choice of the emitting material. For a white pixel, three red, green, and blue subpixels are necessary. The brightness of a pixel is controlled by setting the current through each individual diode to the desired value.

Current Cross-Talk The circuit scheme of a OLED passive matrix is shown in Figure 24. Each pixel is switched on when a bias higher than its turn-on voltage is applied. However, because of the electrical connections between the diodes, which are connected to the same row or to the same column, parallel conduction paths occur when a selected pixel is switched on. In other words, a dc current cross-talk exists and may cause unwanted light in the matrix. There are several sources of cross-talk [108]: (i) the display resolution which creates more conduction paths when it is high, (ii) the diode rectification ratio, which reduces the cross-talk when it is high, and (iii) the diode reverse leakage current, which increases the stray light when it is high. Circuit simulation performed by Braun et al. [109] indicates that a current driver is more suitable than a voltage driver to address pixels. Furthermore, the electrode resistance, the diode leakage current, and the location of faulty pixels will strongly influence the image uniformity and the power consumption of the display. The cross-talk problem can be minimized by using a carbon underlayer placed between the ITO and the hole transport layer [110]. This layer insulates the electrodes and thus lowers the leakage current, preventing the occurrence of cross-talk.

Design Aspects for Displays In a passive matrix display, each line of the picture is addressed sequentially for a short time. The forward biased pixels will emit light while those nonaddressed are kept at zero or reverse bias. To avoid possible flicker effects, the scanning period should

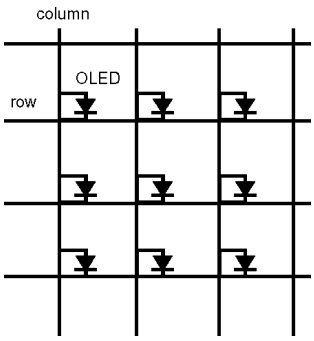

Figure 24. Schematic circuit of an OLED passive matrix.

be smaller than $1/XV_r$ sec, where V_r is the video rate (V_r = 25 images sec^{-1} for PAL standard). However, because the scanning period is very short, the emitted light intensity should be high enough to allow the eye to see a picture with a normal brightness. This condition implies that the average luminance perceived on the screen should be multiplied by a factor equal to the number of lines (X) to obtain the real luminance of the diodes. Beside this consideration, other factors should be taken into account in the calculation of the device luminance. For a monochrome display, one should compensate the loss in emission due to the use of a contrast filter and to the faulty pixels [111]. For instance, to obtain an average of 100 cd/cm^2 in a display of 120 lines, with 20% of faulty pixels, the required luminance of the diodes is 37,500 cd/cm^2. For a color display, a factor of 12 higher peak luminance would be needed because each pixel is composed of three RGB subpixels that have a reduced area, a reduced scanning time, and an increased number of lines. Of course, such a high luminance of the devices will require a high power consumption leading to a high power dissipation by Joule effect that should be reduced, for instance, by dividing the anode line into different sectors, each driven by independent synchronous circuitries.

Displays Passive matrix displays were fabricated and studied by using polymer or organic materials as an emitter. They utilize a simple structure, which is suited for low cost, low information applications such as alphanumeric displays. The techniques for the realization of the devices are different depending on the material used. For polymers, standard and soft lithography are well adapted for making small size pixels. Inkjet printing is also convenient for polymers, especially soluble ones, which can be deposited into determined size pixels. For organic materials, vacuum evaporation with the use of a special masking technique is often adopted.

Monochrome displays are currently fabricated by many companies. The first realization was the seven-segment prototype fabricated by Cambridge Display Technology using a PPV derivative. In 1997, Pioneer launched their passive matrix displays of 256 × 64 dots for automotive applications, based on Alq_3 diodes. In 2000, Motorola fabricated a cellular phone screen with passive matrix OLED displays (Timeport P8767) from Pioneer. Researchers from Huyndai LCD presented a 2.4 in. blue monochrome display for mobile application, with 160 × 160 pixel resolution and an average brightness of 30 cd m^{-2} [112]. High resolution and full color displays have been developed in recent research. In 1997, Hosokawa et al. [80] fabricated an organic display of 5 in. with 320 × 240 pixels (256 gray scale) which was followed by a full color display of 10 in. with VGA resolution [113]. The pixel surface was 330 × 320 μm^2. Pure RGB color passive matrix displays were developed by Pioneer with 320 × 240 pixels of size of 330 × 330 μm^2 and a luminance of 150 cd m^{-2} [114, 115] using a high accuracy moving system mask to deposit RGB emitters.

Despite the progress made in this field, the passive matrix displays need to be driven under pulsed conditions at high current density, which is not suitable for high resolution and high information content applications such as videos or graphics. For such applications, active matrix displays are used.

3.5.2. Active Matrix Displays

Principle In an active matrix display, each pixel element can be addressed independently via the associated thin film transistors (TFTs) and capacitors in the electronic backplane (Fig. 25). There are two TFTs employed for driving an OLED: a drive transistor and an address transistor. To address a particular pixel, the proper row is switched on and then a charge is sent down to the correct column. A storage capacitor at the designated pixel receives this charge and is able to hold the charge until the next refresher cycle. The addressed transistor acts as a switch for the drive transistor by holding a voltage on the gate of the latter. The OLED pixel has to be biased with a constant current and is thus connected to the drain of the drive TFT mounted in series with the diode. The current can be supplied to the diode during the whole frame time and the current density is much smaller than that needed to drive a passive matrix display. Other advantages of the active matrix are no cross-talk problems, continuous excitation, low power consumption, and integrated drive electronics.

Design Aspects for Displays Active matrix displays are currently fabricated using amorphous or polysilicon deposited on glass or plastic substrates although conjugated polymer has been also proposed to drive OLEDs [116, 117]. Poly-Si can be deposited at low temperature but has several drawbacks, including low electron mobility and variation in electrical properties, leading to difficult control of the current density at each pixel. Several techniques can be used to improve the performance of Si TFTs, including low temperature crystallization or excimer laser annealing [118, 119]. However, these techniques require drastic control of the substrate, which make them difficult to put into practice. A four-transistor circuit has been proposed to remedy these drawbacks [120, 121] (Fig. 26). This circuit makes use of the gate voltage of a TFT to control the data current level at a given value, regardless the TFT voltage threshold, resulting in constant output current density which switches on the pixel. A luminance uniformity and an improved performance at low luminance levels were obtained in the 16 × 16 pixel display prepared for this study. It should be noted that *p*-type TFTs are more adapted for driving OLEDs due to the fabrication process used for the organic diodes. In fact, the use of an *n*-type TFT would require the anode (ITO) of the diode to be deposited on the organic layer, which can damage the emitter.

Displays Although the feasibility of OLED active matrix displays was demonstrated a few years ago [122, 123], it is known that one TFT pixel electrode configuration cannot be used because of the continuous excitation during the frame period. Therefore, a production of TFT substrates is needed

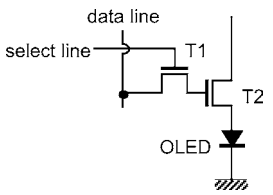

Figure 25. Schematic circuit of an OLED active matrix.

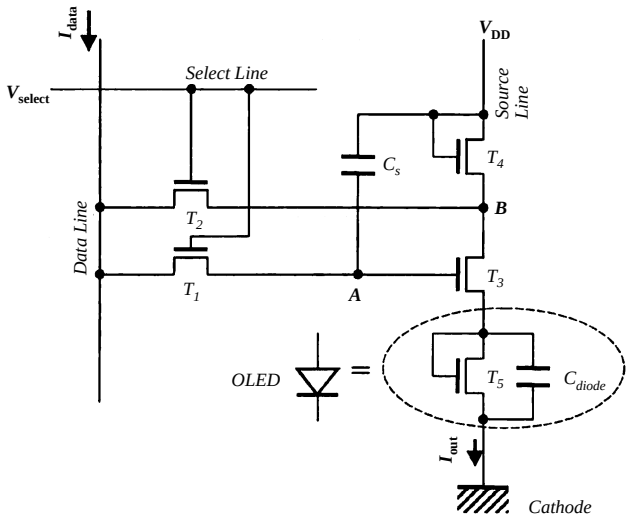

Figure 26. Schematic circuit of a four-TFT OLED active matrix. Reprinted with permission from [121], Y. He et al., *Jpn. J. Appl. Phys.* 40, 1199 (2001). © 2001, Institute of Pure and Applied Physics.

to develop active matrix displays. Using organic materials, Pioneer Corp. has fabricated a 2 in. device with 176 × 192 dots targeted at mobile telephones and a 3 in. device with 320 × 320 dots targeted at personal digital assistants (PDAs) [124]. A 160 × 160 pixel display is usually considered sufficient for a square PDA screen. Dawson et al. [125] described a prototype of QVGA screen (320 × 240 pixels) using a four-transistor autozeroing pixel driver. An alternative approach has been proposed by eMagin by fabricating OLEDs on silicon microdisplays [126]. Instead of low temperature polysilicon or amorphous silicon, the driving circuit is directly integrated within the silicon wafer using CMOS technology. Full color SVGA (852 × 3 × 600 pixels) displays have been realized with a high brightness (>100 cd m^2) and a high lifetime (>10,000 hrs) and can be used in applications such as wearable PCs, cell phones, and digital cameras. Another technique for driving the pixels has been proposed by Seo et al. [127] using a simple circuit (capacitance and rectifying diode) and providing a good control of the gray scale. Attempts to fabricate active matrix displays on flexible substrates have been performed by several research teams but no prototype has yet been proposed. These realizations need a low temperature process to implant TFT on plastic substrates (150 °C for polyethylene terephthalate and 200 °C for polyethersulphone).

3.6. Physics of Nanosize Devices

It is tempting to believe that the background we know from conventional solid-state physics can be applied without difficulty to nanodevices. However, the size of the objects involved in nanotechnology is such that the structure may significantly influence the physical processes that occur in devices [128]. In the field of OLEDs, several aspects can be considered.

First, from the electrical point of view, because of the small size of the devices, the current density would be very large. There will be a problem of energy dissipation (intensity and mechanisms) inside the structure which at this time is not clearly understood. On the other hand, the charge injection processes are believed to dominate in molecular OLEDs contrarily to molecular junctions [129], in which injection cannot occur because of the minute thickness involved (a few nm). Nevertheless, it is known that the injected charges modify the electrostatic potentials at the interface and chemical interactions can occur between the organic material and the electrode. The effects of these processes on the transport can be enhanced in very small size devices and this still needs to be elucidated [130, 131].

Second, from the optical point of view, the size of the devices may influence the emission properties of the organic materials. In the nanometer range, quantum confinement effects are expected to blueshift the optical absorption edge with decreasing material size. Small Si crystallites of 5 nm are found to emit intense blue light [132]. The optical response and charge transport in electronic polymers can be drastically changed by a small variation in local order in the materials, for instance by modifying the substituent group [133]. Experiments performed in Alq_3 of 10–15 nm sizes clearly show that the PL spectra of the material are blueshifted and the shift direction depends strongly on the size of the sample [134]. In large size samples, the formation of dimers or multimers is probable and their strong interaction results in an increase of the gap between the excited states, producing a redshift of the PL. In smaller size samples, the organic molecules would resemble monomers and the PL spectra are blueshifted.

The effects of the intermolecular interactions on the photophysical and transport properties of organic semiconductors can also be investigated through the nanoengineering of the materials, by modifying the structure of conjugated dendrimers [135] so as to understand the physical mechanisms involved within the nanostructures.

The miniaturization of the devices requires much research on new physical issues, which include, among others, the hot electron effect, the phonon effect, the quantum noise effect, the purity effect, and those effects already mentioned.

4. CONCLUSION

With the intensive research of recent years, the development of organic devices has attained a level which allows industrial applications to be commercialized, especially in the display field. Electronic companies have started to fabricate small screens for cell phones and handheld computers which compete with those using conventional techniques. Organic materials have several undeniable advantages over classical semiconductors. In particular, their very high luminance is a definite asset in display applications. These materials are also well adapted to nanotechnology, resulting from the ease of the deposition technique, which allows any shape and size of the devices to be manufactured. Not only can conventional methods developed for semiconductor technology be applied to polymers and organic materials, but also new ones (inkjet, screen printing) have been invented to fabricate nanosize devices. These techniques benefit from the unique physical properties of the materials (solution, flexibility) that are not evident in conventional semiconductors.

High-resolution displays need very small size pixels. Technically speaking, organic diodes of submicrometer size can already be fabricated with an acceptable performance. However, the question of tolerance still remains a problem. Fluctuations in size and in structural properties of the emitting layer may severely affect the quality and performance of the diodes and need to be limited to an acceptable level. Furthermore, under normal working conditions, the tiny devices have to dissipate a considerable amount of energy in regard to their size. The stability of the emitting materials is therefore the key for the fabrication of reliable displays. For the commercialization of these products, mass production would need a simple, low cost, and reproducible process for fabricating the emitting layer. At present, inkjet or screen-printing using polymers appears to be the best technique for making emitting devices.

Another concern in the field of nano-OLEDs is the interconnections. The devices in matrix displays need to be driven by appropriate circuits that require reliable electrical contacts. Although this problem can be solved by techniques used in conventional electronics, it has been proved that a number of faulty pixels exist because of failure in electrical connection.

The development of organic nanodiodes has been accompanied by new physical issues that have to be further investigated. In addition to the power dissipation in these devices, the electrical transport process, the light emission, and the interface between the emitter and the electrodes have a new and different aspect as compared to conventional and standard diodes. Not only does the size influence these properties, but also new phenomena occur, especially in the optical processes, which are not yet clearly understood.

According to many observers, the recent progress in microelectronics technology has confirmed Moore's law and this trend will continue to obey the law until the year 2010. Projections will then have to be reformulated. Further research and development appear necessary to replace the conventional semiconductors in the near future. Organic materials are good candidates, at least in the field of optoelectronics, due to their excellent emission properties. As regards nanotechnology, they are quite suitable to the processes and technologies used for the fabrication of nanodevices. There is great expectancy that these materials will have a bright and brilliant future in a new nanoelectronics era, when the ultimate limitations of the component size will be reached.

GLOSSARY

Electroluminescence Emission of light from a material when excited by an electrical mean (applied voltage). The light is generated by recombinations of excitons.

Exciton A pair of electron-hole generated in a material by an external source (light, electrical mean) and bound together by electrostatic attraction. An exciton can be a singlet (the electron and hole have spins in opposite directions) or a triplet (the electron and hole have spins in the same direction).

Lithography Printing technique that puts detailed patterns on a flat surface of a substrate. In the classical photolithographic process, an image of the desired pattern is projected onto the surface of the substrate, which is coated by a thin layer photosensitive resist. The bright parts of the resist film become soluble by a chemical reaction with the light, whereas the dark parts remain insoluble. After contact with a developer solution, the soluble part of the resist is removed. The pattern is transferred onto the substrate by a chemical etching of its surface, which preserves the protected parts by the resist film. Other lithographic techniques include electron-beam lithography, soft X-ray lithography, atomic-beam holography.

Nanoimprint Printing technique using a stamp of nanometer size to transfer a polymer film onto a solid substrate surface. The formed polymer film is then used either as an active layer in devices or as a mask in a conventional lithographic process.

Pixel A picture element. In OLED technology, a pixel is determined by the part of the emitting layer where the cathode and anode overlap. A high display resolution needs small size and closely spaced pixels.

Nanostructured Surface Modifications for Biomedical Implants

Shane A. Catledge, Marc Fries, Yogesh K. Vohra

University of Alabama at Birmingham, Birmingham, Alabama, USA

CONTENTS

1. INTRODUCTION

With the advancement of modern materials science, many times a single material does not possess the desired properties for certain applications. For example, some materials have desired bulk properties (chemical, mechanical, electrical, etc.) but their surface properties are inadequate. In these cases, a combination of two or more materials or a modification of the bulk material is adopted. Surface modification is basically a process in which the surface of a material is chemically, physically, or mechanically altered so that the surface properties are changed from that of the original bulk. Materials surfaces are commonly modified by techniques involving, for example, deposition of some additional material as a thin coating or implantation of energetic ions to alter the local atomic bonding. In addition, multilayer or functionally graded structures can be engineered to provide a more viable transition from the bulk to the surface.

Novel materials whose microstructure can be engineered to contain features with nanometer-scale dimensions have become quite popular, especially in the last two decades. These "nanostructured" materials can exhibit enhanced mechanical, electrical, magnetic, and/or optical properties compared to their conventional micrometer-scale (or larger) counterparts. Nanostructured (NS) materials contain a large volume fraction (greater than 50%) of defects such as grain boundaries, interphase boundaries, and dislocations, and this strongly influences their chemical and physical properties. The Vickers hardness of electrodeposited nickel, for example, increases from 140 to 650 when the grain size is reduced from the microcrystalline range to about 10 nm [1]. Similarly, NS ceramics tend to be tougher and stronger than coarser grained ceramics. The synthesis and control of materials in nanometer dimensions can provide access to new levels of material properties and device characteristics that were previously unattainable, and work is rapidly expanding worldwide in attempts to exploit the opportunities offered through nanostructuring.

Terms with the prefix "nano"—nanostructured, nanocrystalline, and nanophase, for example—have often been used interchangeably to describe materials with nanometer-scale dimensions. However, it is important to distinguish between different structural forms of materials containing nanometer-size features. Defined broadly, the term *nanostructured* is reserved for materials characterized by structural features of less than 100 nm in average size. Nanostructured materials can take the form of powders, dispersions, coatings, or bulk materials. One rapidly evolving class of NS materials is that of nanocomposites in which nanometer-size particles or whiskers act as reinforcements in a matrix composed of conventional-size grains or amorphous material. For example, hard composite coatings composed of nanocrystalline (10–50 nm) TiC grains imbedded in an amorphous carbon matrix (about 30 vol%) have shown a fourfold increase in toughness compared to nanocrystalline single-phase TiC [2]. Such coatings can be designed to provide adequate compliance through the controlled formation of dislocations and nano- and microcracks once stresses exceed the elastic limit, while still maintaining high hardness and eliminating catastrophic failure typical of hard, brittle materials. For purposes of this chapter and to avoid confusion with other "nano" terminology, we define *nanocrystalline* as a more specific subcategory of NS materials characterized by nanometer-size grains without the presence of conventional-size grains or an intergranular amorphous phase.

Encyclopedia of Nanoscience and Nanotechnology
Edited by H. S. Nalwa
Volume 7: Pages (741–762)

The tremendous impact on the biomedical community by the unique properties offered by NS materials has stimulated intense research to evaluate the possibility of using them in the design of orthopedic and dental implants.

1.1. Orthopedic Implants

Over 450,000 total knee and total hip replacement operations were performed in the United States in 1994 with an anticipated increase of 10% per year [3]. The typical useful life for a replaced joint is between 10 and 15 years [4]. Complications arising from wear include component loosening, deleterious biological responses, osteolysis, mechanical instability, decreased joint mobility, increased pain, and ultimately implant failure. Therefore, revision surgery is frequently necessary, particularly in younger, more active patients. If the useful life of the implant were extended (to upward of 40 years) considerable patient suffering could be eliminated and a substantial amount of health care dollars could be saved. It has been shown [5] that the wear rate of implant components is noticeably lower when articulated against ceramic materials such as zirconia than for metallic materials. Unfortunately, zirconia devices are three times more expensive than their metallic counterparts. Common drawbacks to ceramic devices are brittleness, geometrical limitations, and catastrophic failure modes. These physical limitations have made manufacture of hips difficult and knees impossible; there are currently no available femoral knee components made from solid ceramics. Thus, the major goal is to develop coating technology that can reduce the friction and wear in mating total joint replacement components, thus contributing to their significantly improved function and longer life span.

1.2. Dental Implants

It is estimated that currently there are approximately 10 million people in America, the majority of them women, who suffer pain and dysfunction in and near the temporomandibular joint (TMJ). In previous decades, TMJ implants were fabricated of polymeric materials, including the Vitek and Silastic TMJ implants. The primary problem area with these implant systems was wear and deterioration of the components. The almost 100% failure rate of these implants after 3 years lead to a recall of these devices. Revision surgery is needed in most of these patients due to excessive loss of bone and function, and there is currently no fully successful implant system available. Currently, the two devices most commonly used for TMJ restoration are: (1) cobalt–chrome metal on metal devices and (2) polyethylene condyle on a titanium alloy shaft articulating against a curved cobalt–chromium plate (glendoid-fossa component) as shown in Figure 1. Although the patient's own bone can be used to rebuild a portion of the deficient area around the TMJ, lost function is not restored in many cases and an artificial device is necessary. Metal-to-metal TMJ implants fabricated to date have also exhibited loosening problems because of the type of sliding and rotational motions involved, and metal debris is seen in fairly high amounts in the joint area. Another problem with the TMJ devices which leads to higher than expected wear (primarily the fretting type) is the lack of stable fixation in bone, as retaining screws can come loose allowing the implant move out of its ideal position. The ceramic coatings discussed in this chapter will address the issues of wear and loosening in these devices by nanostructural modification of the implant surfaces, which will allow improvement of existing articulations utilizing metal–metal and metal–polymer implants. This approach will enhance screw and component fixation through bone-to-hydroxylapatite interactions and hopefully lead to the development of a more successful TMJ implant design. Further background can be obtained from reviews on the subject (see [6, 7]).

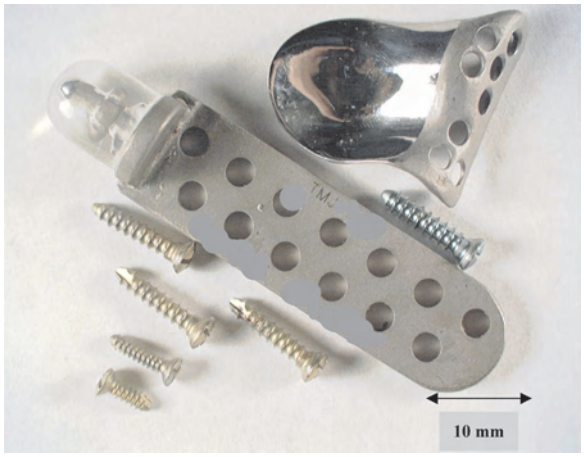

Figure 1. The components of a temporomandibular joint dental implant. The photograph shows a long titanium alloy shaft with a round condylar head made out of polyethylene. This polyethylene condyle articulates against a cobalt–chromium curved metal plate (glendoid-fossa component) shown in the top right hand corner of the photograph. The Ti-alloy screws shown are used to attach the shaft to the supporting bone. We have selected this device as a case study for nanostructured bioengineered diamond and calcium phosphate ceramic coatings. Reprinted with permission from [148], S. A. Catledge et al., *J. Nanosci. Nanotechnol.* 2, 293 (2002). © 2002, American Scientific Publishers.

In this chapter, we focus on the following areas of cutting edge research:

1. Nanostructured bioengineered diamond coatings on cobalt–chrome and titanium alloys that will increase the life span of a variety of implant devices to upward of 40 years. Nanostructured diamond and diamondlike carbon coatings have great potential for use as biomedical implants due to their extreme hardness, wear resistance, low friction, and biocompatibility characteristics. Nanostructured diamond produced by chemical vapor deposition (CVD) techniques and comprised of nanosize diamond grains has particular promise because of the combination of ultrahigh hardness, improved toughness, and good adhesion to titanium alloys. The structure and properties of these coatings are easily tailored to the desired application by appropriate choice of feedgas chemistry and other deposition conditions.
2. Nanostructured hydroxyapatite coatings on metals that will promote better attachment to the bone while optimizing abrasion resistance, bond strength, and the dissolution rate. Hydroxyapatite (HA) is a bioactive

ceramic with a crystal structure similar to native bone and teeth minerals. It has generated great interest in the search for advanced orthopedic and dental implant materials as it elicits a favorable biological response and forms a bond with the surrounding tissues. However, applications of HA are currently limited to powders, coatings, porous bodies, and non-load-bearing implants due to processing difficulties and the poor mechanical properties of conventional HA. Nanostructured processing applied to hydroxyapatite-based materials is used to achieve the desired mechanical characteristics and enhanced surface reactivity for multifunctional implant systems tailored toward different hard tissue replacements. It has allowed chemical homogeneity and microstructural uniformity to be achieved for HA so that fully dense bioceramics can be generated at low sintering temperatures with a significant reduction in flaw size. The nanometer-sized grains and high volume fraction of grain boundaries in nanostructured HA have been found to increase osteoblast adhesion, proliferation, and mineralization.

3. Nanostructured metalloceramic coatings that will provide continuous variation from a nanocrystalline metallic bond at the interface to the hard ceramic bond on the surface. Bonding of functionally graded, NS metalloceramic coatings gradually changes from metallic to primarily covalent with increasing ceramic material toward the surface. One advantage of the graded bonding structure is the ability to overcome adhesion problems associated with ceramic hard coatings on metallic substrates while exhibiting enhanced surface hardness and wear resistance. The NS metalloceramic coatings have a smooth surface finish that is retained *in vivo*, leading to a higher wear resistance.

2. NANOSTRUCTURED DIAMOND COATINGS

Diamond growth from the gas phase was reported as early as 1911 by von Bolton [8] using acetylene in the presence of mercury vapor at 100 °C. However, the first documented report of diamond growth at low pressures, which was subsequently confirmed by others, was the work of William G. Eversole at the Union Carbide Corporation. In the period between 26 November 1952 and 7 January 1953, Eversole achieved diamond growth on a diamond seed crystal using carbon monoxide as a source gas. These findings were documented in 1956 [9]. This predates the first documented, reproducible synthesis of diamond by a high pressure, high temperature process by scientists at the General Electric Company in 1955 [10]. The enormous success of this technique of producing diamond where it is thermodynamically stable, along with the impractically low growth rates initially observed for low pressure synthesis of diamond, delayed further development of the low pressure techniques. There also still remained a strong feeling that diamond grown at pressures where it is a metastable phase was somehow thermodynamically forbidden. It was not until the late 1970s, when advances were made in the USSR [11, 12] for yielding continuous films using hydrogen and methane mixtures and in Japan [13] for rendering economically viable growth rates, that the scientific community was finally convinced of the feasibility of low pressure diamond synthesis.

It is well known that diamond is the hardest known material. In fact, it is in the market of abrasives and cutting tools that diamond has found its most prominent and economically sustaining niche. Other conventional, hard bulk materials such as cubic boron nitride can reach, at best, about 47 GPa (only about 47% diamond hardness). Granted, appropriate engineering of the chemistry and microstructure of materials has led to a new class of synthetic superhard materials with exciting potential. For example, epitaxial [14] and polycrystalline [15] superlattices of transition metal nitrides can reach hardness of 50 GPa when the lattice period decreases to 5–7 nm. Carefully designed composites containing nanocrystals of a hard transition metal nitride imbedded into an amorphous silicon nitride matrix has led to claims of achieved hardness greater than 50 GPa with the possibility of approaching the 70–100 GPa range for diamond [16, 17]. However, the extremely wide range of synthetic carbon structures attainable by low pressure deposition techniques has resulted in coatings with measured hardness ranging from 10 (amorphous carbon) to 100 GPa (crystalline diamond) [18–20]. For this reason, carbon-based coatings with a myriad of different structural forms and ascribed names such as diamond, diamondlike carbon, nanostructured diamond, and tetrahedral amorphous carbon continue to dominate the superhard material arena. It is not surprising that these coatings are particularly suited for, and to some extent already commercially realized, in wear resistant applications such as in the machining of nonferrous materials using diamond-coated carbide cutting tools. Recent advances have led to NS diamond coatings exhibiting a unique combination of high hardness, high toughness, and low friction. These and other carbon coatings continue to be actively investigated with respect to the scientific issues (growth mechanisms, structure, etc.) and technological issues (large-area deposition, adhesion onto metallic substrates, etc.) involved. While there are several deposition techniques for producing hard carbon films (e.g. ion beam, pulsed laser, cathodic arc, etc.), we will focus on the use of CVD as it pertains to NS diamond growth.

Chemical vapor deposition using hydrogen-rich, hydrocarbon-containing gases has been the most successful method of producing metastable diamond films of high crystallinity. Work by Lander and Morrison [21] at Bell Labs showed in 1966 that a diamond surface saturated with hydrogen maintains the bulk terminated diamond lattice to the outermost surface layer of carbon atoms. Without the hydrogen atoms to terminate the carbon dangling bonds, the surface reconstructs into more complex structures. In 1971 Angus et al. [22] showed that atomic hydrogen could be used as a cyclic etching step to remove unwanted graphite deposited during CVD of diamond. However, the importance of atomic hydrogen used during the diamond growth process itself was realized predominantly by Fedoseev et al. [23] in the USSR, during the mid to late 1970s. In this way, atomic hydrogen could simultaneously (i) stabilize the diamond growth surface, (ii) preferentially etch graphitic and other nondiamond carbon, and (iii) create new growth sites on the surface via hydrogen-abstraction reactions.

This allowed much higher growth rates and permitted the nucleation of new diamond crystallites on nondiamond substrates. The reader is referred to a review by Angus and Hayman [24] for a more comprehensive description of the diamond growth process involving hydrogen-rich, hydrocarbon-containing gases and the corresponding roles of atomic hydrogen.

2.1. Structure

A conventional mixture used to produce high phase purity microcrystalline diamond films by CVD using hydrocarbon-containing precursors is about 1 to 3% methane in a balance of hydrogen. Other deposition parameters such as substrate and gas-phase temperature, as well as the choice of substrate material and how it its surface is prepared, can affect the film structure and morphology. However, the former mixture will typically produce a rough, faceted diamond surface comprised of micrometer-size grains. For many applications, a rough surface is undesirable as it can cause severe abrasion during sliding against other materials. By appropriate choice of feedgas types and concentrations, it is possible to manipulate the diamond growth process to produce NS films with high hardness and smooth, wear-resistant surfaces. Figure 2 shows an example of the difference in microstructure between microcrystalline and NS diamond films produced by microwave plasma CVD. Both films were grown by Catledge and Vohra [25] on a titanium alloy (Ti-6Al-4V) using an unconventionally high methane concentration of 15%. The microcrystalline film was grown under plasma conditions allowing sufficient production of atomic hydrogen via elevated gas pressure (125 Torr), along with very low levels of nitrogen impurity in the feedgas. In this way, the high methane concentration can lead to an increase of nucleation and growth rates without a substantial decrease in diamond quality. An added benefit of the high methane concentration is an improvement of diamond-to-titanium adhesion when compared to the more conventional 1 to 3% mixture [25, 26]. Adhesion of conventionally grown diamond films on metallic substrates is a concern because large thermally induced residual stresses provide a critical driving force for the propagation of cracks in the rather unforgiving and brittle nature of the film. In this example, the nanostructured nature of the film shown in the right side of Figure 2 is induced by the addition of large amounts (10% of methane flow) of nitrogen to the feedgas mixture. The grain size of the NS film as measured by X-ray diffraction is 15 nm and the surface roughness is 27 nm root-mean-squared (rms) value, an order of magnitude less than the microcrystalline film. By improving the surface finish of the initial predeposited substrate to within 10 nm (rms value), we have achieved NS diamond films with surface roughness as low as 15 nm [26]. As compared to the microcrystalline film, the Raman spectrum of the NS film reveals a weaker diamond peak (ca. 1332 cm^{-1}), pronounced scattering in the 1350–1550 cm^{-1} region associated with an increase of sp^2-bonded carbon, and an additional peak at 1140 cm^{-1}. It should be noted that the intensity scales on the Raman spectra of Figure 2 are not the same and that the diamond peak intensity for the NS film is a factor of three lower than that for the microcrystalline film. It has been shown that the weaker diamond peak is caused by a reduction of grain size to the nanometer scale [27], and that the increased sp^2-bonded carbon is due to increasing π-bonds at the grain boundaries in the nanocrystalline films [28]. The additional peak at 1140 cm^{-1} has been attributed to scattering from nm-sized diamond grains [29].

As measured by X-ray photoelectron spectroscopy (XPS), the NS diamond films grown by adding large amounts of nitrogen to the feedgas mixture do not contain a substantial nitrogen concentration. The elemental depth profile by XPS is shown in Figure 3 for a NS diamond film grown on Ti-6Al-4V alloy. Each scan step included oxygen 1*s*, vanadium 2*p*, titanium 2*p*, nitrogen 1*s*, bulk carbon, carbidic carbon, and aluminum 2*p* specific scans. The collected data

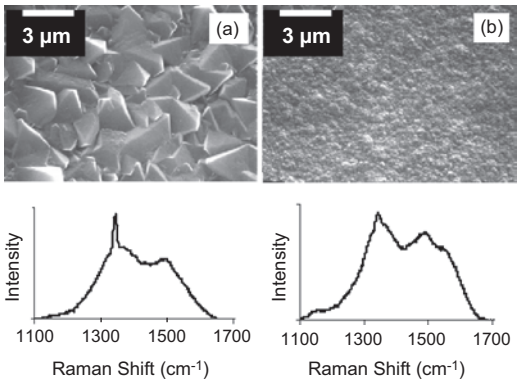

Figure 2. Scanning electron microscope images and Raman spectra of CVD diamond films grown with mixtures of (a) H_2/CH_4 with flow ratio of 500/88 and (b) $H_2/CH_4/N_2$ with flow ratio of 500/88/8.8. Both films were grown using a chamber pressure of 125 Torr and an unconventionally high CH_4 fraction (15 vol%). The smooth nanostructured film in (b) results from the addition of nitrogen to the feedgas mixture. Reprinted with permission from [148], S. A. Catledge et al., *J. Nanosci. Nanotechnol.* 2, 293 (2002). © 2002, American Scientific Publishers.

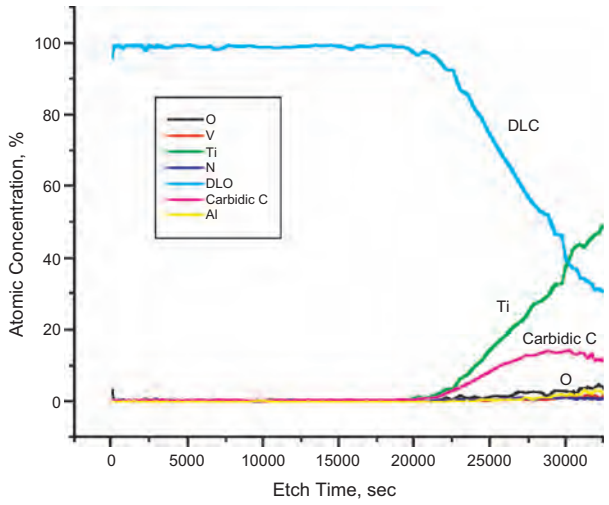

Figure 3. Elemental concentration depth profile of NS diamond film measured by XPS. The three predominant elements in the interface region on the right side of the graph include film carbon (labeled "DLC" here), Ti, and carbidic carbon. The profile represents a diffuse film/substrate boundary.

show the classic pattern for a diffuse interlayer boundary, with bulk carbon decreasing in proportion to TiC and metallic titanium with increasing depth. The proportion of carbidic carbon in the sample decreases starting at the point where bulk titanium overtakes bulk carbon as the primary species detected. The ratio of titanium to carbidic carbon is roughly 2:1 from the onset of detection of titanium up to the point where it makes up about 30% of the total volume, indicating that metallic titanium is present along with TiC throughout the interface region. Oxygen is present in the interface region at a mean value of 3% for the last 8160 s of sputtering time. This finding indicates that the titanium surface is not completely etched bare during exposure to the hydrogen plasma. It is likely that amorphous, nonstoichiometric titanium oxides exist within the interface as has been detected in other diamond/titanium systems. The XPS data reveal only trace quantities of nitrogen, suggesting that the dramatic changes observed in film morphology and structure with nitrogen feedgas addition are due not to nitrogen incorporation, but to the result of gas-phase and surface reactions involving nitrogen related species such as CN.

Due to the small grain size of NS diamond films, a significant fraction of the carbon atoms is situated in the grain boundaries. It is believed that the grain boundary carbon is responsible for the absorption and scattering of light in these films, their electrical conductivity, and their electron emission properties [30]. Simulations by Keblinski et al. [31] have revealed important structural differences between the grain boundaries of phase pure nanocrystalline diamond and those of silicon, and these findings may partially explain the remarkable properties of nanocrystalline diamond films. In contrast to silicon, carbon can form both sp^2- and sp^3-hybridized electronic states. The greater bond stiffness of diamond combined with its ability to change hybridization in a disordered environment results in more ordered grain boundary structures in diamond than in silicon. This comes at the expense of many carbon atoms in the grain boundary (typically 70–80%) being only threefold-coordinated. The competition between structural disordering and local hybridization change, which is absent in silicon, implies that the high degree of structural disorder in the mostly fourfold-coordinated silicon grain boundaries is replaced by bond-coordination disorder in the mostly threefold-coordinated, structurally less disordered diamond grain boundaries. Due to the different numbers of bonds per unit area across the grain boundary and degrees of sp^2 hybridization on high and low energy grain boundary planes, it was shown that nanocrystalline diamond (likely to contain a large fraction of high energy grain boundaries) may be mechanically stronger than coarser grained diamond (containing a significant fraction of low energy grain boundaries) or even perfect crystal diamond. The implication of this is that the dominating brittle-fracture mode in nanocrystalline diamond might be intra- rather than intergranular. Finally, Keblinski et al. showed that the threefold-coordinated grain boundary carbon atoms were poorly connected to each other, and therefore any type of graphitelike electrical conduction through the boundaries is not likely unless "bridging" impurities provide the missing connections.

A final note regarding structure involves a discussion of how the nm-sized diamond grains may be distributed in the film and whether a second or third phase is present beyond the grain boundaries. In other words, it may be possible to have a nanocomposite film comprised of nm-sized diamond (and perhaps also graphitic) grains imbedded in a surrounding amorphous carbon matrix. Such films, if designed properly, could be remarkably hard and tough. To the authors' knowledge, the only reported nanocomposite-like films based purely on carbon have been achieved through postdeposition annealing of diamondlike amorphous carbon (*a*-C) films [32]. This results in nm-sized regions of high density *a*-C embedded in a lower density *a*-C matrix. The hardness in this case was reported to increase by 15% (to 88 GPa) due to the nanocomposite structure. A few other reports have shown diamond nanocrystallites sporadically imbedded within amorphous carbon [33, 34]. However, a uniform microstructure with controlled dispersion of a nanodiamond phase within a surrounding amorphous carbon matrix is not yet reported.

2.2. Processing Routes

A range of processing routes to CVD NS diamond films exist, but they all have in common the deposition of nanometer-size grains and a film surface roughness that is typically about an order of magnitude lower than that of microcrystalline diamond films. It is possible that early observations of nanocrystallinity, or at least of the apparent degradation of diamond film quality resulting from nanocrystallinity, was concluded to be a result of gas-phase contamination by nitrogen. It is well known that nitrogen is a common impurity in natural diamond and that it can influence physical properties such as optical transparency as well as electrical and thermal conductivity [35]. In 1993, Badzian et al. [36] reported deliberate use of N_2 in place of H_2 to determine its effect on CVD diamond growth. They concluded that the mixture of $CH_4 + N_2$ resulted in a disordered diamond structure likely to be caused by surface processes involving atomic nitrogen. Nitrogen was not incorporated into the film to the amount detectable by Auger electron spectroscopy and XPS. Although not identified as containing nanocrystalline diamond grains, Raman spectroscopy of the films produced by Badzian et al. have similar features to those of NS diamond. In addition, their diamond X-ray diffraction (XRD) peaks were broad, suggestive of reduced grain size. Work by Locher et al. [37] and Jin and Moustakas [38] followed to study the influence of varying amounts of nitrogen in conventional $CH_4 + H_2$ mixtures for CVD diamond growth and revealed dramatic changes in structure and morphology. The addition of small amounts (40–200 ppm) of nitrogen results in a pronounced $\langle 100 \rangle$ texture with nearly coplanar surface facets and improved crystalline diamond quality as determined by Raman spectroscopy. It was established that much higher nitrogen additions led to a deterioration of film quality which according to Locher et al., became "nanocrystalline." The potentially beneficial properties of such films (such as improved wear resistance and electron emission) appear not to have been recognized at that time. In fact, the films may have been determined to be inferior due to the apparent lack of diamond phase purity.

Since the work of Locher et al., many researchers have investigated the influence of nitrogen addition on CVD diamond growth and realized that unique properties (such as enhanced electron field emission [39] and improved toughness [26]) can result from the nanostructured films. The evolution from micro- to nanocrystalline diamond grains has prompted considerable investigation into the mechanisms responsible for the nitrogen-induced transformations. For hydrogen-rich reactant gases, the importance of methyl radicals to the diamond growth process is well known [40]. It is likely that the relative concentration of CH_3 and CN species is of crucial importance to the growth mechanism and observed changes in morphology. According to Bohr et al. [41], for small N_2 additions CN and HCN can efficiently abstract adsorbed H atoms creating vacant growth sites and improving diamond crystal quality by reducing carbon supersaturation. With larger N_2 additions, the increased supply of CN and HCN enhances the abstraction of adsorbed H leading to reconstruction of the diamond surface, because adsorbed CN or nitrogen species are not able to stabilize the diamond structure at the surface efficiently. This "reconstruction" appears to manifest itself as a reduction of crystal size with a corresponding increase of sp^2-bonded carbon, most of which is presumably located at the grain boundaries. Recent gas-phase simulations [42] indicate that there exists a critical N_2/CH_4 feedgas concentration, above which changes in the CH_3/CN ratio are minimal. The trend in the modeled CH_3/CN ratio corresponds well to the experimentally observed changes in diamond crystallinity and surface roughness [25]. This suggests that above a critical N_2/CH_4 ratio, saturation of CN will not induce any further change in the surface structure. While it has been shown that nitrogen incorporation is higher in {111} growth sectors than in {100} sectors by a factor of 3–4 leading to different growth rates of these faces [43], the overall low level of nitrogen incorporation ($<9 \times 10^{20}$ cm^{-3}) into the diamond [36, 38] suggests that the roles nitrogen play on the growth surface are responsible for the observed changes in structure and growth rates. Possible nitrogen-related surface processes include an increase in the generation of growth steps [44] (especially on {100} faces} or multiple twinning [45] of diamond crystals.

A unique processing route to diamond film growth by CVD was reported by Gruen et al. [46] in 1994 using argon-rich plasmas with fullerenes, but without hydrogen addition. These films were initially characterized as containing phase-pure, fine-grained (0.05–0.3 μm grain size) diamond without graphitic or amorphous phases. Nanocrystalline films were also grown using $Ar/H_2/C_{60}$ [47, 48], $Ar/H_2/CH_4$ [49, 50], Ar/CH_4 [51], N_2/CH_4 [39], and $Ar/CH_4/N_2$ [52] plasmas resulting in grain sizes from 3 to 20 nm and surface roughness as low as 18 nm. Figure 4 shows a plan-view transmission electron microscope (TEM) image of a typical nanocrystalline diamond film produced using 1% CH_4 + 99% Ar. According to Gruen et al., the grain size of this film ranges from 3 to 20 nm. It was observed for argon-rich (>90% Ar) plasmas and elevated reactant gas pressures (100 Torr) that the C_2 concentration is extremely intense compared to atomic hydrogen, while the concentration of methyl radicals is immeasurably low [53]. This is in contrast to the case of conventional (hydrogen-rich, low methane) plasmas

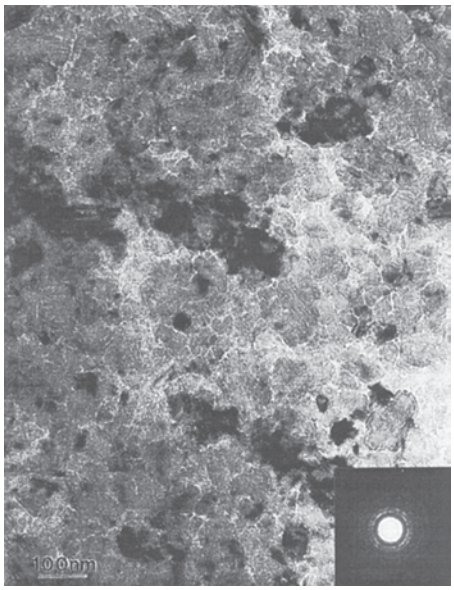

Figure 4. Plan-view TEM image of a diamond film prepared from an Ar/CH_4 plasma at 100 Torr showing that the diamond film consists of nanocrystalline grains ranging from 3 to 20 nm. The inset image shows a sharp ring pattern of selected area electron diffraction, indicating that the diamond grains have a random orientation. Reprinted with permission from [51], D. Zhou et al., *J. Appl. Phys.* 83, 540 (1998). © 1998, American Institute of Physics.

in which the CH_3 radical predominates. The relatively high C_2 plasma emission compared to atomic hydrogen or CH species is illustrated in an optical emission spectrum (Fig. 5) for an Ar-rich plasma (99% Ar, 1% CH_4) at a gas pressure of 100 Torr. The film growth rate and C_2 emission intensity were also observed to increase with increasing reactant gas pressure. These results, along with the fact that the films can be grown in hydrogen-poor or hydrogen-free plasmas, led to a modified explanation for growth involving the carbon dimer C_2, which is believed to be the precursor for nucleation and growth of nanocrystalline diamond in this composition regime. It was suggested that with C_2 as the growth species, no hydrogen abstraction reactions are required, partly because insertion of C_2 into surface C–C bonds is energetically favorable with low activation barriers.

Growth rates for the nanocrystalline diamond films produced from argon-rich plasmas tend to be low, especially for compositions considered to be optimum for yielding small grain size and low surface roughness. For example, conditions required to reduce the rms surface roughness of the film to about 30 nm (e.g., 97% Ar, 2% H_2, 1% CH_4) yield a growth rate of only about 0.3 μm/hr [50]. According to Gruen, the reduction in growth rate may be due in part to the activation energy associated with forming a nucleus of critical size [54]. In order to produce NS diamond films at significantly higher growth rates, and to achieve better adhesion and toughness to metal-carbide forming substrates, Catledge and Vohra developed a process [55] using a mixture of unconventionally high CH_4 concentration (15% of total flow) with N_2 (1.5% of total flow) in a balance of H_2 at a reactant gas pressure of 125 Torr and substrate temperature of 800–850 °C. In this way, NS diamond films with rms roughness of as low as 15 nm can be grown [26]. The C_2

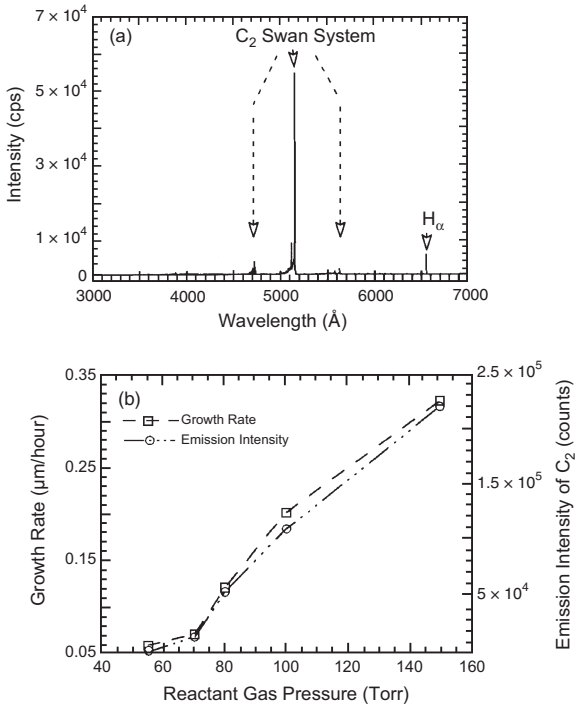

Figure 5. An optical emission spectrum of an Ar/CH_4 plasma running with 1 vol% CH_4 and 99 vol% Ar as the reactant gas at a chamber pressure of 100 Torr; (b) plots of growth rates of nanocrystalline diamond films and emission intensities of C_2 from the Ar/CH_4 plasmas vs reactant gas pressures ranging from 55 to 150 Torr. emission was found to increase with increasing CH_4 flow and with increasing gas pressure [56], leading to higher nucleation and growth rates. The growth rates for micro- and nanostructured films grown with the 15% CH_4 concentration were 2.4 and 1.8 μm/hr, respectively [57]. The strong influence of the CN radical in causing nanocrystallinity was confirmed by the correlation of its modeled composition in the gas phase [42] with the degree of nanocrystallinity as determined experimentally [18] for diamond films grown with different N_2 additions. For a given CH_4 feedgas concentration, there exists a critical N_2 feedgas concentration, above which the change in the CH_3/CN ratio is minimal. The change in the CH_3/CN ratio with increasing N_2/CH_4 ratio is shown in Figure 6 and illustrates a "knee" in the curves, defining the critical N_2 concentration. The knee becomes more evident when using a higher CH_4/H_2 feedgas ratio. It was observed experimentally that the same critical N_2 feedgas concentration exists, above which a further decrease in diamond crystallinity and surface roughness of the grown diamond films is minimal.

Recently, Sharda et al. [58] have produced NS diamond films with surface roughness in the 15–30 nm range by using biased enhanced growth (BEG) in a microwave plasma CVD system. This unique technique relies on a combination of two growth processes acting simultaneously during deposition. One process involves the surface-related hydrogen abstraction reactions typical for diamond deposition using conventional hydrogen-rich plasmas. In addition, shallow

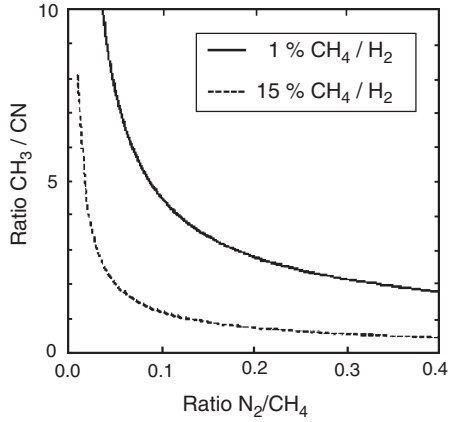

Figure 6. Gas-phase equilibrium plot of the ratio of CH_3 to CN as a function of N_2/CH_4 feedgas ratio as simulated for conditions of diamond growth using an $H_2/CH_4/N_2$ mixture with 1 and 15 vol% CH_4. The chamber pressure was 125 Torr. Reprinted with permission from [42], R. Corvin et al., *Appl. Phys. Lett.* 80, 2550 (2002). © 2002, American Institute of Physics.

subsurface implantation of energetic carbon ions caused by the continuous application of a dc bias voltage to the substrate produces a disordered structure containing a high concentration of sp^3 carbon in the films. The BEG process takes advantage of subsurface implantation of carbon ions to produce a smooth NS diamond film while the process involving hydrogen abstraction reactions helps to etch away graphitic carbon deposits. Relatively low substrate temperatures (400–700 °C) were shown to be useful for this growth regime in obtaining optimal NS diamond content and film hardness.

While the three major processing routes for NS diamond growth discussed in this chapter can be used to produce hard and smooth films, there are likely to be differences in structure, primarily with regard to the relative amounts of sp^3- and sp^2-bonded carbon, the degree of crystallinity, and the amount of hydrogen incorporation in the film. These factors will no doubt influence the mechanical properties of the film such as hardness, adhesion, and wear resistance.

2.3. Mechanical Properties

As grain size decreases to the nm range, the mechanisms for plastic deformation change. In particular, dislocation activity is reduced and the creation of new dislocations is made difficult as the grain size reaches the lower end of the nanoscale (<10 nm). Stresses needed to activate dislocation sources, such as the Frank–Reed source, are inversely proportional to the distance between dislocation pinning points. Since nanoscale grains will limit the distance between such pinning points, the stresses needed to activate dislocation sources can reach the theoretical shear stress of a dislocation-free crystal at the smallest grain sizes (~2 nm). Therefore, current deformation models cannot simply be scaled, but instead new models have to be developed which take the special microstructural features of NS materials into account. It has been suggested that the new deformation mechanisms acting for nanoscale materials may involve grain boundary sliding and formation of mesoscopic glide planes [59].

According to the empirically based Hall–Petch effect, which is due to dislocation motion/generation in materials that exhibit plastic deformation, the strength and hardness of polycrystalline materials increases with decreasing crystallite size. It is well established that as grain size is reduced through the nanoscale regime (<100 nm), hardness typically increases and can be factors of 2 to 7 times higher for pure nanocrystalline metals (10 nm grain size) than for large-grained (>1 μm) metals [60]. For typical ceramics, of course, strength is particularly influenced by Griffith "flaws" such as pores or other heterogeneities common to the manufacturing process. The so-called inverse Hall–Petch effect has been observed for some nanocrystalline materials and results in a decrease in hardness with decreasing grain size below about 10 nm. The transition from the conventional to inverse Hall–Petch effect may be attributed to a competition between dislocation dominated processes and grain boundary sliding controlled processes [59]. These are two independent mechanisms and the one that requires less stress (energy) will be the favored mode of deformation. The softening of some materials below a grain size of about 10 nm may also logically be explained by the strong increase in the amount of disordered grain boundary material, whose strength is lower [61].

The importance of NS composites in improving not only strength and hardness but also fracture toughness has become increasingly recognized. Veprek et al. [17] have developed new superhard nanocrystalline coatings consisting of about 4 nm or less nanocrystals of a hard transition metal nitride embedded into <1 nm thin matrix of amorphous silicon nitride. Unlike pure nanocrystalline materials which show softening when the crystallite size decreases below about 5 nm, the hardness of these nanocomposites strongly increases with decreasing crystallite size in that range and approaches the hardness of diamond. The high hardness observed for many nanocomposite materials appears to be due to the harder phase acting as an obstacle to dislocation movement and grain boundary sliding. This, in turn, is influenced by the number and dispersion of the harder phase. Other nanocomposite coatings such as those based on TiC crystals of 10–50 nm in size embedded into an amorphous carbon phase have shown hardness of 32 GPa and a fourfold increase in toughness in comparison with nanocrystalline single-phase TiC [2]. Clearly, the high hardness/strength and toughness/ductility that appear to be characteristic of recently studied multiphase ceramic nanocomposites are leading to very exciting engineering of material structures.

With regard to diamond films and measurement of their mechanical properties, a critical issue involves how to obtain accurate, reproducible data that are not influenced by the deformation (elastic or plastic) of the testing apparatus itself. However, if one is careful to monitor changes in the surfaces involved, useful data can be obtained. The large variation in film structure that can occur using different processing routes for NS diamond growth requires measurements of film hardness, wear resistance, adhesion, fracture toughness, and friction coefficient.

Catledge et al. [18] have recently studied changes in NS diamond structure and hardness for films produced on Ti-6Al-4V using different N_2/CH_4 feedgas ratios. The relative concentration of CH_4 and N_2 (in a balance of H_2) is shown to strongly influence film structure, hardness, and adhesion. For high CH_4 concentration (15% by volume), NS diamond films with roughness of 20–30 nm, good adhesion, and high hardness (85 GPa) are obtained. As shown in Figure 7, a distinct correlation was found between the nanoindentation hardness of the deposited film and the N_2/CH_4 ratio in the plasma as well as correlation of hardness to the ratio of the Raman peak intensities (1332 and 1555 cm^{-1}). The most abrupt changes in film structure occur in the low N_2/CH_4 ratio range less than 0.10. Above this ratio, the crystalline diamond component does not change significantly and the surface roughness and friction coefficient are not lowered any further. This may be explained by observations that the concentration of CN radical in the plasma saturates above a N_2/CH_4 feedgas ratio of 0.10.

The measured hardness of the biased enhanced growth of NS diamond films produced by Sharda et al. [58] is shown in Figure 8 as a function of substrate temperature. Also plotted with temperature is the Raman intensity ratio of nanocrystalline diamond (I_n @ 1150 cm^{-1}) and graphitic (I_g @ 1580 cm^{-1}) components. Substrate temperature is found to play a crucial role in the growth of nanocrystalline diamond by this technique and the maximum hardness (~40 GPa) is reached at about 600 °C. It is suggested that higher temperatures cause the implanted carbon atoms to migrate back to the surface resulting in domination of surface processes in the growth, which in turn results in an increase in the graphitic content of the film. By optimizing the growth parameters in this technique, film hardness can be increased to above 75 GPa.

The adhesion of diamond films to the substrate is a very important issue, especially for deposition on metallic substrates where thermally induced residual film stress can provide a large driving force for delamination. Several techniques have been used to evaluate adhesion and fracture toughness of diamond films [62–65]. Adhesion and toughness of the NS diamond films produced from $N_2/CH_4/H_2$ plasmas with high CH_4 concentration were investigated by indentation testing up to 150 kg load with a 1/8 inch diameter tungsten carbide ball [26]. This results in significant

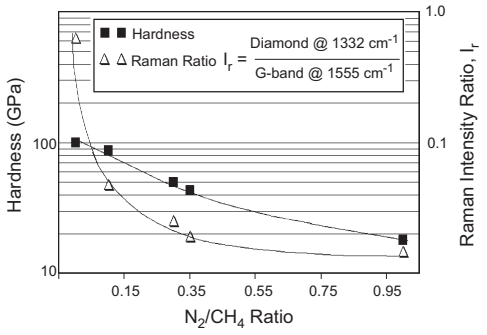

Figure 7. Nanoindentation hardness and Raman intensity ratio ($I_r = I_{1332}/I_{1555}$) vs N_2/CH_4 ratio. The hardness value for the N_2/CH_4 ratio of 0.0 was not measured but was estimated as 100 GPa (a value representative of high phase purity crystalline diamond). plastic deformation of the film as well as the underlying substrate and can provide a semiquantitative measure of film adhesion and toughness [62, 66]. An optical micrograph of the indentation craters is shown in Figure 9 for indentation loads of 294, 588, 980, and 1470 N. No delamination of the film was observed even for testing at the highest load. However, scanning electron microscopy revealed the presence of circumferential microcracks in the film around the edge of the indents. The strain to cause microcracking was estimated to be as high as 1.9%, which represents a significant improvement in toughness over other ceramic coatings. The cracks clearly did not result in catastrophic failure of the coating but are stable and likely responsible for the observed ductility. Similar tests performed on conventional diamond films (with micrometer-size grains) resulted in complete film spallation at the lowest loads used [25]. These results suggest that NS diamond films can be tailored with excellent adhesion on metallic surfaces and have hardness ranging from 10 (medium-hard) to 100 GPa (superhard).

In addition to high hardness and good adhesion, low coefficient of friction is necessary for many coating applications in which surfaces are in sliding contact with each other. Extensive work by Erdemir et al. [48, 67] to characterize friction and wear behavior of nanocrystalline diamond films grown in Ar–C_{60} and Ar–CH_4 plasmas has shown very low friction coefficients (0.04 in dry N_2; 0.1–0.15 in air) and wear rates, essentially comparable to those of natural diamond. The friction fluctuated substantially when tested in dry N_2, especially during long duration tests. This was attributed to transformation of the diamond surface into sp^2-bonded amorphous carbon wear debris particles that get trapped at the sliding interface.

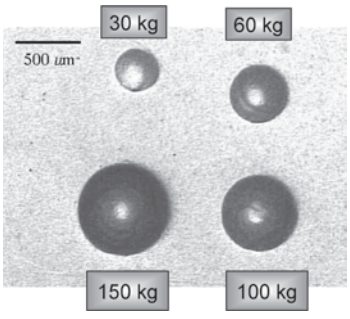

Figure 9. Optical micrograph showing a set of four indentations made on a nanostructured diamond-coated titanium alloy using a 1/8-in. diameter tungsten carbide ball indenter and loads of 30, 60, 100, and 150 kg. No delamination of the film was observed, indicating excellent film adhesion and toughness. Reprinted with permission from [148], S. A. Catledge et al., *J. Nanosci. 2.3.1. Wear of TMJ Implants

Wear of articulating surfaces is a major problem in orthopedic devices such as total hip and knee replacements. In dentistry, wear of the TMJ implant (shown in Fig. 1) is a concern. It has been estimated that more than 10 million people suffer from TMJ-related disorder symptoms in the United States alone [68]. The human TMJ, as diagrammed in Figure 10, has proven to be difficult to replace with a reliable artificial implant [69, 70]. This is due in part to the sliding/rotating articulation of this joint [71], which requires a component geometry that is more complex than those found in most other artificial joints. In addition, TMJ implants are small and reside in close proximity to the eye, the ear, various nerves, and the brain with very little bone available for fixation. As a result, TMJ implant service lifetimes have historically been short compared to other common joint replacements, and implants have even been the subject of product recall.

Very little basic science has been performed on such fundamental issues as the articulation mechanics of the

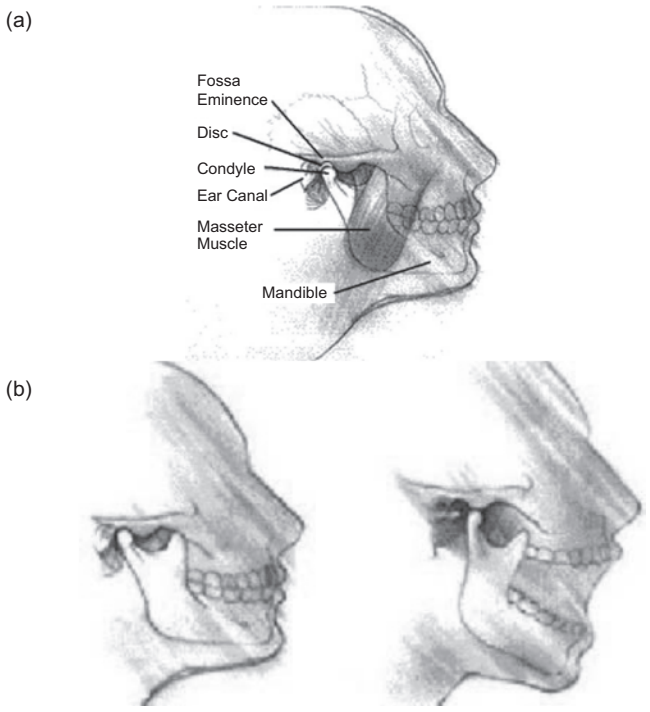

Figure 10. Diagrams showing TMJ anatomy and articulation motion. Notice the sliding/rotating articulation of the condyle and how it dislocates from the fossa eminence. TMJ and disorder causes or progression. The basic structure of the TM joint is also poorly understood, as little research has been performed on typical TMJ loading forces, or on anatomical differences between genders and race. It is believed that the root cause of TMJ implant failure is a lack of understanding of the forces present during articulation [72]. Failure of joint prostheses typically occurs by one of three general conditions: (1) surgical error during placement, (2) postoperative infection, or (3) osteolysis [73] of the surrounding bone due to wear particle generation. Condition (3) results from a long-term failure mode, is least understood, and warrants intense investigation with regard to cause and prevention. During this failure mode, surface roughening of articulating implant components leads to increased wear particle generation from the polymer implant components that implant condyles articulate against [74, 75]. Polymer particles, in turn, cause osteolysis in the bone proximal to the implant [76, 77]. The implant then loosens leading to improper joint articulation, progressively severe implant wear, and accelerating bone loss. This third, long-term failure mode is dependent upon design of the implant, including the choice of materials used. Since long-term implant failure has its roots in the wear properties of the articulating components of the implant, an improvement of wear behavior should result in longer service lifetime for the implant and greater comfort and utility for the patient. It is hoped that a significant improvement can be achieved by coating implant articulation surfaces with a very hard, smooth layer of nanostructured diamond.

Nanostructured diamond films, 3 μm thick, were deposited on TMJ condyle simulants made from Ti-6Al-4V alloy. This alloy exhibits excellent mechanical properties [77] and superb resistance to electrochemical corrosion [78]. However, Ti-6Al-4V also shows poor wear resistance *in vivo* and the resulting titanium particles can cause bone resorption proximal to the implant [77]. For this reason, most metallic implant condyles are made almost exclusively of Co–Cr–Mo alloy today. Some patients, however, are especially sensitive to the nickel found in Co–Cr–Mo, and so a small number of implants are fashioned out of Ti-6Al-4V for these patients. NS diamond deposition on Ti-6Al-4V alloy has been studied extensively and is known to exhibit high hardness and low roughness [18, 26]. Since Ti-6Al-4V is acceptable as an articulating component in all terms but wear resistance, coating Ti-6Al-4V implant condyle components with NS diamond may result in a component that is acceptable for use as an implant in terms of wear resistance and biocompatibility.

Figure 11 shows images of two condyles, one with and one without the diamond coating, as well as a schematic of their dimensions. The coated TMJ simulants were evaluated for their wear resistance properties using a custom-built manibular movement simulator (MMS) developed by Dr. Camillo Machado at the University of El Bosque, Columbia. This is shown in Figure 12 [79]. This device is designed to accurately reproduce the normal articulation of a human jaw and is adapted to mount TMJ simulants in place of the natural TMJ anatomy. The MMS is a fiberglass reproduction of an actual human skull and so it closely mimics the mechanical movement and anatomical structure of a typical patient. The test is performed using a cyclic chewing

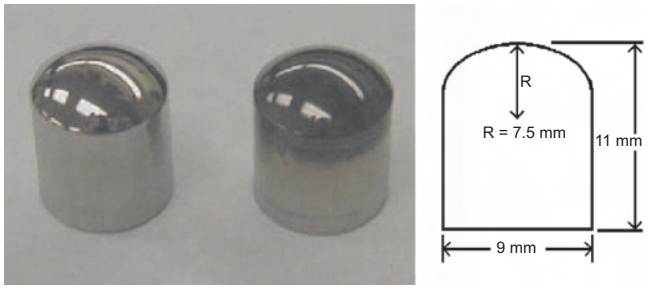

Figure 11. Ti-6Al-4V TMJ simulants uncoated (left) and coated with a 3 μm NS diamond (right), along with dimensions as they were measured from a commercially available implant.

motion of the mandible, with maximum chewing forces measured at the teeth of 200 N during testing. The NS diamond-coated TMJ stimulant was mounted in the anatomically correct temporomandibular position, opposite a 2.54-cm-diameter NS diamond-coated Ti-6Al-4V disk. The simulant was subjected to 500,000 loaded cycles in the MMS, which is equivalent to 4.4 years of typical use. It should be noted that the conditions of this test are considered to be much more extreme than those experienced by an actual implant because in this test the TMJ articulates against a flat plate in a point wear mode. An actual implant would articulate against a conformal fossa component that would increase the articulating surface area, thereby greatly decreasing the pressure at any point of the film in contact. Eventually, a NS diamond-coated fossa component will be fabricated to produce a more realistic TMJ couple and the wear test will be repeated.

A separate experiment was performed by Machado et al. [79] using uncoated Ti-6Al-4V condyles with NS diamond-coated Ti-6Al-4V flat disks. A control disk (uncoated Ti-6Al-4V) was also tested for comparison. The samples were subjected to 400,000 cycles at 1.2 Hz in the MMS. Surface profilometry of the wear tracks on the disks was performed to determine the extent of wear by measuring surface roughness. The rms surface roughness of the

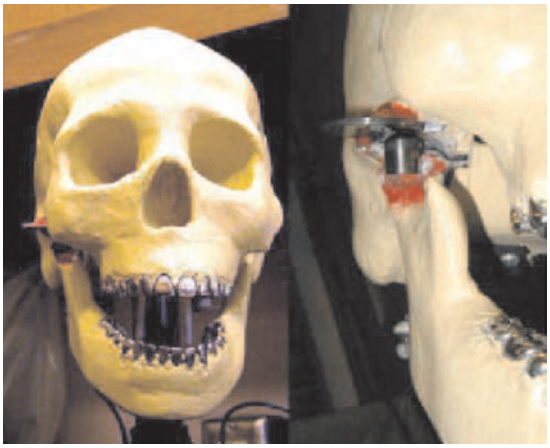

Figure 12. Mandibular movement simulator. The MMS (left image) is based on a composite replica of a human skull to replicate the natural motion of the TMJ. The image on the right shows detail of a TMJ condyle stimulant and wear test disk in position and prior to fixation.

uncoated control disk changed from 50.3 nm to 248.4 nm. In comparison the rms roughness of the NS diamond-coated disk changed from 61.5 to 122.7 nm. SEM also confirmed that damage to the uncoated Ti surfaces was much more extensive than for the diamond-coated surfaces.

2.4. *In Vivo* Biocompatibility

Lemons et al. have recently performed a study to assess the biocompatibility of NS diamond-coated Ti-6Al-4V alloy *in vivo* using animal models [80]. This work is complementary to the diamond-coated TMJ study in that it shows quite clearly that the animal models respond favorably to implantation of NS diamond materials on Ti-6Al-4V. These results show that NS diamond materials exhibit excellent biocompatibility and are therefore well suited as implant materials.

In the study, eight 7 mm diameter, 2 mm thick disks of Ti-6Al-4V alloy were coated with NS diamond to a thickness of 3 μm. The samples were seeded ultrasonically using 1–2 μm diamond powder and then diamond deposition was performed using a feedgas mixture of 500 sccm H_2, 88 sccm CH_4, and 8.8 sccm N_2. The uncoated side of each sample was then carefully polished to a mirror finish. The diamond coated samples were implanted into four New Zealand white rabbits, two samples in each rabbit. One sample was implanted into the tibial proximal condyle and one into the femoral distal condyle of the same leg on each rabbit. The rabbits were examined clinically and radiographically to ensure proper placement of the implant, and the rabbits were euthanized at times up to 8 weeks. The femoral and tibial condyles with implanted samples were excised and sectioned, five per sample, by the Exakt system. The Exakt system is a standard, commercially available process whereby the biological material is dehydrated with a series of alcohols and infused with xylenes to improve monomer penetration into the sample. The sample is then soaked in polymethylmethacrylate under vacuum at reduced temperature to allow the methylmethacrylate monomer to saturate the sample. The sample is then warmed to room temperature to allow the polymer to set, cut into thin sections with a diamond-blade band saw, and polished on a polishing wheel. The sections were then observed and photographed by an optical microscope.

Figure 13 shows a cross-section image of an implanted NS diamond-coated disk after retrieval. Living bone tissue had grown across both the NS diamond and Ti-6Al-4V surfaces. The retrieved samples showed no foreign body reactions, fibrous granulation tissue, or abnormal characteristics within the bone/marrow spaces. Both compact and trabecular bone are found to be directly associated with both the titanium alloy surface and the NS diamond-coated surface without the presence of fibrous tissue at the interface. Results were consistent throughout the retrieved samples. These findings show that NS diamond thin films perform at least as well as Ti-6Al-4V in terms of general and histological biocompatibility. Given the excellent biocompatibility properties of Ti-6Al-4V [81, 82], this finding identifies NS diamond thin films as a material well suited to long-term use in the human body.

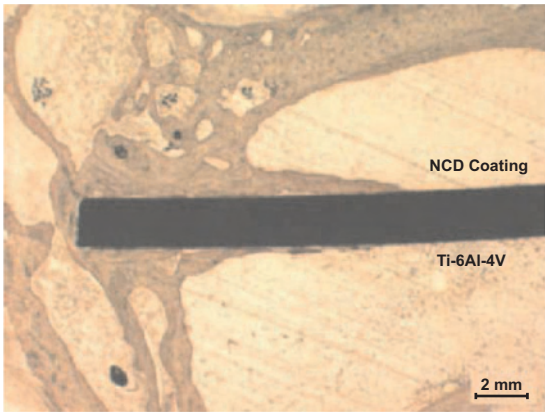

Figure 13. Cross section image of implanted NS diamond-coated disk. Living bone tissue has grown across both the NS diamond and Ti-6Al-4V surfaces. No immune response occurred in the marrow tissue adjoining the implant.

2.5. Corrosion Resistance

Biomedical implants and their components must operate in a corrosive environment, without maintenance or added lubrication, over service lifetimes that are expected to cover decades. As a result, there are stringent demands placed on these components in terms of high corrosion resistance and minimal wear particle generation. Nanostructured diamond films must meet these requirements in order to effectively perform as protective coatings. In terms of electrochemical resistance, they are uniquely suited to do so.

The use of diamond films as a protective coating for biomedical implants is an application with great promise. Currently, most articulating surfaces in human artificial joints are made of wrought Co–Cr–Mo alloy, which is chosen for its excellent mechanical wear and electrochemical corrosion properties. Much of the nonarticulating mass of implants is composed of Ti-6Al-4V alloy primarily due to this alloy's lower cost and excellent bone ingrowth behavior [83]. While Ti-6Al-4V would be preferable to Co–Cr–Mo in terms of bone/implant bulk modulus mismatch and cost, the poor mechanical wear properties of Ti-6Al-4V preclude its use in articulating components. The addition of a hard, smooth NS diamond coating to implant articulation surfaces may ameliorate this shortcoming. Previous work has shown that Ti-6Al-4V is especially well suited to the NS diamond deposition process and hard, smooth films over curved substrates made of this alloy can be reliably produced [84].

One aspect of NS diamond-coated Ti-6Al-4V that must be investigated is the electrochemical corrosion behavior of the coated alloy system. The electrochemical properties of diamond have been closely scrutinized, and in fact products based on diamond thin films have reached commercial production for the electrochemical research market. The primary attributes that draw attention to these films are their large potential window and excellent chemical stability [85–93], allowing for electrochemical measurements over a comparatively wide voltage range in caustic environments. Boron doping of diamond films can result in semimetallic electrical behavior, and Fausett et al. [93] report similar behavior for nanocrystalline diamond films grown in Ar-rich

gas mixtures without hydrogen. Studies have shown diamond electrodes to be stable in corrosive environments such as anodic polarization in acidic fluorine, and alkaline, neutral, and acidic chlorine [90]. To date, most electrochemical studies of diamond films have focused on defining their behavior for electronic applications and have not closely examined electrochemical corrosion behavior. However, Dowling et al. [94] used a scanning reference electrode technique to examine diamondlike carbon on AISI 316L stainless steel and found that coated samples could sustain a bias of 2400 mV without breaking down. By comparison, bare stainless steel control samples reached breakdown potential between 200 to 600 mV.

Biocompatibility tests performed by Mitura et al. [95] show that NS diamond coatings are very strongly resistant to chemical attack by Tyrode's solution (an aqueous solution with the addition of salts with properties similar to that in the human body) as well as to some HCL-based acids. Biotolerance was investigated by coating AISI 316L stainless steel disks with NS diamond and subcutaneously implanting them into the chest muscles of guinea pigs according to ASTM 98186 standards. It was found in the subcutaneous tissue, muscles, and bones that thin connective tissue capsules built from fibrocytes and collagen fibers were formed. In the wall of the capsule, no phagocyte reactions were observed and no products of corrosion were found. In addition, no pathomorphological changes were observed in the internal organs (liver, kidneys, and spleen). The study illustrated that NS diamond coatings exhibit good biotolerance and biocompatibility and effectively protect against corrosion and metalotoxemie.

Ti-6Al-4V is considered to be an excellent material for biomedical applications in terms of corrosion resistance due to its protective native oxide [96–98]. From a corrosion standpoint any surface treatment would be considered well suited for biomedical use if it were to preserve the corrosion properties of the alloy, much less improve upon it. To test this supposition, experiments were performed on passivated and NS diamond-coated Ti-6Al-4V substrates [99]. The substrates were polished to an rms roughness of 20–30 nm and then passivated following ASTM specifications (F 86) for implant materials. Three samples were coated with the NS diamond films to a thickness of 3 μm. The control and coated samples were subjected to potentiodynamic polarization in deaerated Hank's balanced salt solution. The counterelectrodes were platinum metal cylinders. All potentials were expressed with reference to a standard calomel electrode (SCE). The solution was purged with nitrogen gas from half an hour prior to immersion of the sample to the end of the test. The test procedure consisted of monitoring the rest potential for 1 hour, followed by generating cathodic and anodic polarization curves. Data were generated by conducting a forward scan from 100 mV more cathodic than the corrosion potential (E_{corr}) to a threshold anodic current density, and then reversing until the open circuit potential was reached. Tafel extrapolation and Stern–Geary currents were used to calculate the corrosion current density (I_{corr}) in A/cm^2 at the E_{corr}. The E_{corr} and the I_{corr} values obtained for the two sample groups are presented in Table 1. The E_{corr} values for the control samples were significantly more active (negative) than those exhibited by the NS diamond-coated samples. The noble E_{corr} values exhibited by the coated samples must have resulted from the protection provided by the insulating NS diamond film. I_{corr} values for the NS diamond-coated samples were an order of magnitude lower than those exhibited by the Ti-6Al-4V control samples. These E_{corr} values were also significantly more noble and were two orders of magnitude lower than those exhibited by a passivated Co–Cr–Mo alloy implant bearing surface evaluated in an earlier study under similar experimental conditions [100]. It should also be noted that the NS diamond-coated samples exhibited a significantly larger range of passive behavior than the control Ti-6Al-4V samples.

Table 1. Potentiodynamic polarization test results for NS diamond-coated Ti-6Al-4V in deaerated Hanks salt solution.

Sample	E_{corr} (mV vs SCE)	I_{corr} (nA/cm^2)
Ti-6Al-4V control	-96 ± 19	9.85 ± 5.86
NS diamond-coated	154 ± 13	0.93 ± 0.86

Figure 14 shows potentiodynamic polarization curves for passivated and NS diamond-coated Ti-6Al-4V, and Table 2 shows the calculated values of corrosion rate, I_{corr}, and open circuit potential (E_{OCP}) for the coated and control groups. No sign of electrochemical breakdown behavior all the way up to a potential of 1600 mV is observed for the uncoated Ti-6Al-4V material. This suggests that a very stable, well-adhered oxide coating is protecting the bulk Ti-6Al-4V from chemical attack. The NS diamond-coated samples also show no sign of breakdown behavior over the range of the experiment and the material becomes more noble as seen from the more positive open circuit potential (E_{OCP}). The corrosion rate of the system is correspondingly decreased approximately sevenfold. A one-way ANOVA test performed at $P = 0.05$ indicates that the mean corrosion rate values for NS diamond-coated Ti-6Al-4V and wrought Co–Cr–Mo are statistically indistinguishable. The mean corrosion rate of wrought Co–Cr–Mo was taken from a separate experiment

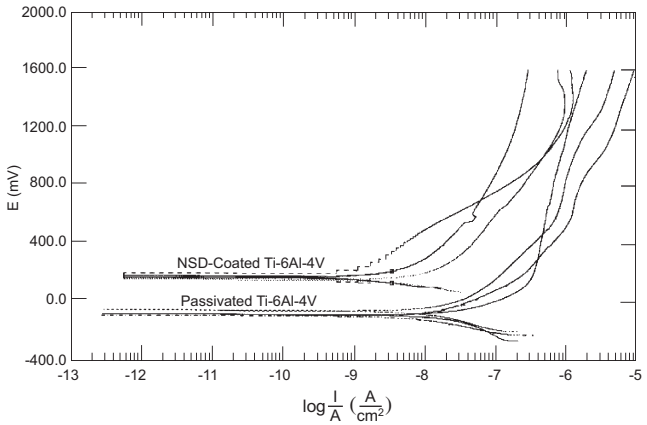

Figure 14. Potentiodynamic polarization curves for passivated and NS diamond-coated Ti-6Al-4V. Note the higher, more noble open circuit potential of the NS diamond-coated samples and the lack of breakdown behavior in any sample to 1600 mV.

Table 2. Measured values from potentiodynamic polarization for NS diamond-coated Ti-6Al-4V.

	Corrosion rate (mm/yr)	I_{CORR} (nA/cm^2)	E_{OCP} (mV)
Passivated Ti-6Al-4V	449.2E-6 +/− 269.9E-6	27.06 +/− 16.26	−93.4 +/− 19.2
NCD-coated Ti-6Al-4V	63.2E-6 +/− 87.8E-6	3.81 +/− 5.29	153.6 +/− 10.1
Wrought Co–Cr–Mo	24.8E-6 +/− 13.1E-6	94 +/− 0.79	−171 +/− 4.7

performed with the same apparatus and under the same conditions as this experiment [101].

The passivated, uncoated Ti-6Al-4V samples show a single curve in the Nyquist plot (Fig. 15) indicative of a protective oxide layer, as is typical for Ti-6Al-4V. The results are summarized in Table 3. The polarization resistance (R_P) value of 5.00×10^6 Ω measured from these data is very high and in agreement with the good corrosion resistance attributed to this alloy. In the case of the coated samples, the Nyquist plot shows a pair of impedance curves. These data are consistent with the behavior of microcrystalline, nanocrystalline, and single-crystal diamond thin films and are regarded as an intrinsic property of diamond [102, 103]. The Nyquist curves are also in agreement with the equivalent circuit proposed by van de Lagemaat et al. [103]. We believe that the native oxide does not survive the MPCVD deposition process as a result of exposure to hydrogen plasma during the thin film deposition step and so the oxide does not play a role in electrochemistry of the NS diamond-coated samples. Overall, the potentiodynamic polarization and electrochemical impedance spectroscopy data indicate that the film is an electrochemically protective material with high polarization resistance.

3. NANOSTRUCTURED HYDROXYAPATITE COATINGS

Some of the most chemically stable biomaterials used are ceramics. The surface and bulk chemistry can be controlled to tailor strength, hardness, wear resistance, and thermal expansion to each application individually. Along with the natural ability to promote tissue in-growth via a porous surface, the high compressive strength of ceramic materials lends itself for use as implants. Because of these properties, ceramics have been used as crowns, bridges, and false teeth in dental applications, in mandibular jaw reconstructions, as orthopedic load-bearing hip prostheses, and as coatings for porous tissue in-growth.

Hydroxyapatite $[Ca_{10}(PO4)_6(OH)_2]$ is the primary ceramic coating material used for both dental and orthopedic implant devices. HA is very similar to the mineral or inorganic portion of bone and has been shown to have good osteoconductive properties (i.e., to be conducive to bone formation around the implant). However, the low toughness (0.8–1.2 MPa $m^{1/2}$) and low flexural strength (<140 MPa) of bulk synthetic HA material precludes its use as a load-bearing implant [104]. Therefore, its primary use is either in the form of small filler particles for placement in bone-deficient areas or as coatings on stronger implant materials such as titanium and cobalt–chromium alloys. Calcium phosphate coatings (usually containing about 70% HA) are commonly deposited by the plasma spray process onto endosseous (i.e., into bone) dental implants in order to speed up formation of bone around the devices, thus allowing earlier stabilization in a patient [105]. Studies have shown that in cases of poor bone quality in a dental patient's implant site, a coating of HA is especially desirable, and coated devices are usually preferred over uncoated titanium implants. HA coatings have gained wider acceptance in dentistry as compared to orthopedics, but the potential for increased use in both fields is high if superior coatings can be developed.

The importance of the nanostructure of HA coatings for biomedical devices has not been realized until the last 10 years or so, as thin film deposition processes have been adapted from the electronic industry and employed in an attempt to produce superior HA implant coatings. Nanostructure processing of HA-based composites has allowed for the design of structural and surface features inspired by the architecture of bone. It has allowed chemical homogeneity and microstructural uniformity to be achieved for HA so that fully dense bioceramics can be generated at low sintering temperatures with a significant reduction in flaw size. HA powders can be easily densified to greater than 98% theoretical density, resulting in an ultrafine-grained (125 nm) compact that exhibits superior compressive and

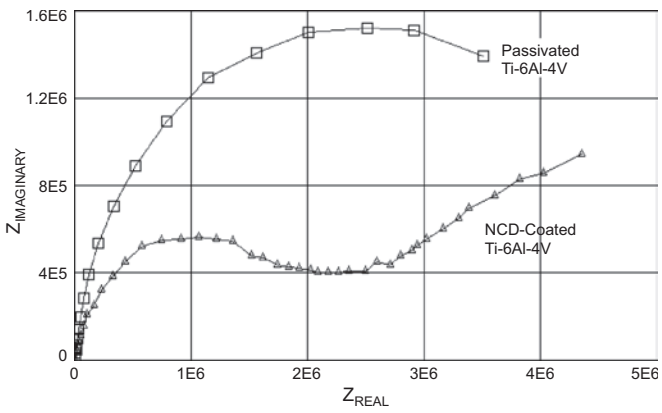

Figure 15. Nyquist plot of EIS data mean values for passivated and NS diamond-coated samples. Polarization resistance (R_P) and maximum frequency (ω_{MAX}) values taken from these data are reported in Table 3.

Table 3. Polarization resistance (R_P) and maximum frequency (ω_{MAX}) values for NS diamond-coated Ti-6Al-4V as measured from EIS data.

	R_P (Ω)	ω_{MAX}
Passivated Ti-6Al-4V	5.00E + 06	9.42E + 06
NS diamond-coated Ti-6Al-4V		
First curve	2.07E + 06	3.14E + 06
Second curve	1.24E + 07	7.85E + 06

bending strengths and fracture toughness. The nanometer-sized grains and high volume fraction of grain boundaries in nanostructured HA can increase osteoblast adhesion, proliferation, and mineralization. Zirconia nanocrystals have been added to further toughen the HA matrix. The resulting nanocomposite can achieve greater than 98% theoretical density with grain size less than 125 nm by pressure- and temperature-assisted sintering. The incorporation of highly dispersed zirconia significantly enhances the fracture toughness and bending strength of the HA-based bioceramics for load-bearing implant applications.

Almost all commercial bioceramic coatings placed on dental implants at this time are plasma sprayed, but these coatings have numerous limitations, such as inherent fractures, porosity, and unpredictable chemistry. These relatively thick (40–80 μm) coatings are subject to fracture or fragmentation during insertion and service and have unpredictable rates of dissolution. One of the primary reasons for the lack of control with the use of the plasma spray process is that extremely high temperatures must be employed in melting the starting powder (in excess of 10,000 °C), thus making it difficult to obtain the proper chemistry and structure of the resulting coating [106, 107].

Although calcium phosphate exhibits desirable properties such as biocompatibility, osteoconductivity, bioactivity, and direct bonding to bone interface, the bulk ceramic lacks the fracture toughness and flexural strength necessary for most load-bearing applications. However, the potential for HA coatings on metallic implants has resulted in a recent surge in mechanical property studies for this material [98–113]. Figure 16 shows an example of a commercially pure titanium implant screw (10 mm long, 3.75 mm diam) coated with 50 μm of plasma-sprayed HA. The HA coating extends from below the head of the screw to the insert-end base and is observed as an off-white color. X-ray diffraction confirmed the crystalline component of the coating to be hydroxyapatite [$Ca_{10}(PO_4)_6(OH)_2$] with hexagonal structure, space group $P6_3/m$, and measured lattice parameters $a = 9.393 \pm 0.003$ Å and $c = 6.885 \pm 0.003$ Å [114]. Nanoindentation testing was performed on the screw to yield measurements of coating hardness and Young's modulus. Hardness and Young's modulus measurements can provide a useful comparison to the mechanical properties of the surrounding bone and underlying implant. Figure 17 shows hardness and
