Oxide Nanowires and Nanorods

Guozhong Cao, Steven J. Limmer

University of Washington, Seattle, Washington, USA

CONTENTS

1. INTRODUCTION

Oxides possess many important physical properties conducive to a wide range of applications. Examples include electronic or ionic conductors, semiconductors, dielectrics, ferroelectrics, piezoelectrics, pyroelectrics, electro-optics, ferrites, and high T_c superconductors. In addition, they offer excellent thermal and chemical stabilities. The physical properties of these materials are sensitively dependent on the chemical stoichiometry, crystallinity, and microstructure and thus can be tailored by doping or alloying, or control of crystal structure and microstructures. There is, therefore, no doubt that nanostructured oxides would play a very important role in nanotechnology. Nanostructured materials can be generally grouped into (1) zero-dimensional structures (i.e., quantum dots and core-shell nanostructures), (2) one-dimensional structures (i.e., nanorods and nanowires), (3) two-dimensional structures (thin films), and (4) three-dimensional structures (bulk materials with nanoscale building blocks).

In this chapter, we discuss the synthesis and fabrication of one-dimensional structures. Although the focus is on the oxide nanorods and nanowires, significant attention has been paid to the review of fundamental concepts, which determine the synthesis and fabrication of one-dimensional nanostructures. For the completeness of the discussion, a large number of nonoxide nanorods and nanowires have been discussed in detail to illustrate the practical approaches, when no suitable examples of oxide nanorods are available. It should be noted that it is not our intention to exhaust all the work on the synthesis and fabrication of oxide nanorods and nanowires published in the open literature, and therefore, many excellent works have not been included in this chapter. The aim of the chapter is to provide the reader a systematic and fundamental understanding of various methods applied in the fabrication of one-dimensional nanostructures of all types of materials, albeit with more emphasis on oxides.

One-dimensional nanostructures have been called a variety of names including whiskers, fibers or fibrils, nanowires, and nanorods. In many cases, nanotubules and nanocables are also considered one-dimensional structures. Although whiskers and nanorods are in general considered to be shorter than fibers and nanowires, the definition is often a little arbitrary. In addition, one-dimensional structures with diameters ranging from several nanometers to several hundred micrometers were referred to as whiskers and fibers in early literature, whereas nanowires and nanorods with diameters not exceeding a few hundred nanometers are used predominantly in recent literature. One will find, from reading this chapter, the fact that many fundamental understandings and techniques of growth of one-dimensional nanostructures are based on the early work on the growth of whiskers and fibers, albeit with less emphasis on nanometer scale. In this chapter, various terms of one-dimensional structures will be used interchangeably, though nanowires in general have a higher aspect ratio than that of nanorods.

Many techniques have been developed in the synthesis and formation of one-dimensional nanostructured materials, though some techniques have been explored extensively, while other techniques attracted far less attention. These techniques can be generally grouped into three categories:

1. Spontaneous growth

   a. evaporation (or dissolution)–condensation
   b. vapor (or solution)–liquid–solid (VLS or SLS) growth
   c. stress–induced recrystallization

2. Template-based synthesis

   a. electroplating and electrophoretic deposition
   b. colloid dispersion, melt, or solution filling
   c. conversion with chemical reaction

3. Lithography

Spontaneous growth and template-based synthesis are considered bottom-up approaches, whereas lithography is a top-down technique. Spontaneous growth commonly results in the formation of single crystal nanowires or nanorods along a preferential crystal growth direction depending on the crystal structures and surface properties of the nanowire materials. Template-based synthesis mostly produces poly-crystalline or even amorphous products. All the above techniques for the preparation of one-dimensional nanos-tructured materials will be discussed in this chapter, following the above order just for the sake of clarity. Further, lithography will be discussed briefly only, considering the maturity of the technique.

2. SPONTANEOUS GROWTH

Spontaneous growth is a process driven by the reduction of Gibbs free energy or chemical potential. The reduction of Gibbs free energy is commonly realized by phase transformation or chemical reaction or the release of stress. For the formation of nanowires or nanorods, anisotropic growth is required (i.e., the crystal grows along a certain orientation faster than other directions). Uniformly sized nanowires (i.e., the same diameter along the longitudinal direction of a given nanowire) can be obtained when crystal growth proceeds along one direction, whereas there is no growth along other directions. In spontaneous growth, for given material and growth conditions, defects and impurities on the growth surfaces can play a significant role in determining the morphology of the final products.

2.1. Evaporation (Dissolution)–Condensation

The evaporation–condensation process is also referred to as a vapor–solid (VS) process; however, the discussion in this section will not only be limited to the simple evaporation–condensation process. Chemical reactions among various precursors may be involved to produce desired materials. Of course, the growth of nanorods from solution is also included. The driving force for the synthesis of nanorods and nanowires by spontaneous growth is a decrease in Gibbs free energy, which arises from either recrystallization or a decrease in supersaturation. Nanowires and nanorods grown by evaporation–condensation methods are commonly single crystals with fewer imperfections. The formation of nanowires, nanorods, or nanotubules through evaporation (or dissolution)–condensation is due to the anisotropic growth. Several mechanisms are known to result in anisotropic growth, for example:

1. Different facets in a crystal with different growth rates. For example, in silicon with a diamond structure, the growth rate of {111} facets is smaller than that of {110}.
2. Presence of imperfections in specific crystal directions such as screw dislocation.
3. Preferential accumulation of or poisoning by impurities on specific facets.

Before discussing the growth of various nanowires by the evaporation–condensation method in detail, let us first review the fundamentals of crystal growth. Crystal growth can generally be considered as a heterogeneous reaction, and a typical crystal growth proceeds following the sequences:

1. Diffusion of growth species from the bulk (such as vapor or liquid phase) to the growing surface, in general, is considered to proceed rapidly enough, and thus is not a rate-limiting process.
2. The adsorption and desorption of growth species onto and from the growing surface can be rate limiting, if the supersaturation or concentration of growth species is low.
3. During surface diffusion, an adsorbed species may either be incorporated into a growth site, which contributes to crystal growth, or escape from the surface.
4. Surface growth can occur by irreversibly incorporating the adsorbed growth species into the crystal structure. When a sufficient supersaturation or a high concentration of growth species is present, this step will be the rate-limiting process and determines the growth rate.
5. If by-product chemicals were generated on the surface during the growth, by-products would desorb from the growth surface, so that growth species can adsorb onto the surface and the growth process can continue.
6. By-product chemicals diffuse away from the surface so as to vacate the growth sites for continuing growth.

For most crystal growth, the rate-limiting step is either adsorption–desorption of growth species on the growth surface (step 2) or surface growth (step 4). When step 2 is rate limiting, the growth rate is determined by condensation rate J (atoms/cm^2 sec), which is dependent on the number of growth species adsorbed onto the growth surface, which is directly proportional to the vapor pressure or concentration, P, of the growth species in the vapor as given by

$$J = \alpha\sigma P_0(2\pi mkT)^{-1/2} \tag{1}$$

where α is the accommodation coefficient, $\sigma = (P - P_0)/P_0$ is the supersaturation of the growth species in the vapor in which P_0 is the equilibrium vapor pressure of the crystal at temperature T, m is the atomic weight of the growth species, and k is the Boltzmann constant. Here, α is the fraction of impinging growth species that becomes accommodated on the growing surface and is a surface specific property. A surface with a high accommodation coefficient will have a high growth rate as compared with low α surfaces. A significant difference in accommodation coefficients in different facets would result in anisotropic growth. When the concentration of the growth species is very low, the adsorption is more likely a rate-limiting step. For a given system, the growth rate increases linearly with the increase in the concentration of growth species. Further increase in the concentration of growth species would result in a change from an adsorption limited to surface growth limited process. When the surface growth becomes a limiting step, the growth rate becomes independent of the concentration of growth species as schematically shown in Figure 1. A high concentration or vapor pressure of growth species in the vapor phase would increase the probability of defect formation, such as impurity inclusion and stacking faults. Further, a high concentration may result in a secondary nucleation on the growth surface
Figure 1. A schematic of crystal growth when the surface growth is rate limiting. At higher concentrations of growth species, the reaction rate is independent of the concentration.

or even homogeneous nucleation, which would effectively terminate the epitaxial or single crystal growth.

An impinging growth species onto the growth surface can be described in terms of the residence time and/or diffusion distance before escaping back to the vapor phase. The residence time, τ_s, for a growth species on the surface is described by

$$\tau_s = \frac{1}{\nu} \exp\left(\frac{E_{des}}{kT}\right) \qquad (2)$$

where ν is the vibrational frequency of the adatom (i.e., adsorbed growth species) on the surface (typically 10^{12} sec^{-1}), and E_{des} is the desorption energy required for the growth species escaping back to the vapor. While residing on the growth surface, a growth species will diffuse along the surface with the surface diffusion coefficient, D_s, given by

$$D_s = \frac{1}{2} a_0 \nu \exp\left(\frac{-E_s}{kT}\right) \qquad (3)$$

where E_s is the activation energy for surface diffusion and a_0 is the size of the growth species. So the mean diffusion distance, X, for a growth species from the site of incidence is

$$X = \sqrt{2} D_s \tau_s = a_0 \exp\left(\frac{E_{des} - E_s}{kT}\right) \qquad (4)$$

It is clear that in a crystal surface, if the mean diffusion distance is far longer than the distance between two growth sites such as kinks or ledges, all adsorbed growth species will be incorporated into the crystal structure and the accommodation coefficient would be unity. If the mean diffusion distance is far shorter than the distance between growth sites, all adatoms will escape back to the vapor and the accommodation coefficient will be zero. The accommodation coefficient is dependent on desorption energy, activation energy of surface diffusion, and the density of growth sites.

When step 2 proceeds, sufficiently rapid surface growth (i.e., step 4) becomes a rate-limiting process. Different facets in a given crystal have different atomic densities and atoms on different facets have a different number of unsatisfied bonds (also referred to as broken or dangling bonds), leading to different surface energy. Such a difference in surface energy or number of broken chemical bonds leads to different growth mechanisms and varied growth rates. According to periodic bond chain (PBC) theory developed by Hartman and Perdok [1], all crystal facets can be categorized into three groups based on the number broken periodic bond chains on a given facet: flat surface, stepped surface, and kinked surface. The number of broken periodic bond chains can be understood as the number of broken bonds per atom on a given facet in a simplified manner. Let us first review the growth mechanisms on a flat surface.

For a flat surface, the classic step growth theory was developed by Kossel, Stranski, and Volmer, which is also called the KSV theory [2]. They recognized that the crystal surface, on the atomic scale, is not smooth, flat, or continuous, and such discontinuities are responsible for the crystal growth. To illustrate the step growth mechanism, we consider a {100} surface of a simple cubic crystal as an example and each atom as a cube with a coordination number of six (six chemical bonds). When an atom adsorbs onto the surface, it diffuses randomly on the surface. When it diffuses to an energetically favorable site, it will be irreversibly incorporated into the crystal structure, resulting in the growth of the surface. However, it may escape from the surface back to the vapor. On a flat surface, an adsorbed atom may find different sites with different energy levels. An atom adsorbed on a terrace would form one chemical bond between the atom and the surface; such an atom is called an adatom, which is in a thermodynamically unfavorable state. If an adatom diffuses to a ledge site, it would form two chemical bonds and become stable. If an atom were incorporated to a ledge–kink site, three chemical bonds would be formed. An atom incorporated into a kink site would form four chemical bonds. Ledge, ledge–kink, and kink sites are all considered as growth sites; incorporation of atoms into these sites is irreversible and results in growth of the surface. The growth of a flat surface is due to the advancement of the steps (or ledges). For a given crystal facet and a given growth condition, the growth rate will be dependent on the step density. A misorientation would result in an increased density of steps and consequently lead to a high growth rate. An increased step density would favor the irreversible incorporation of adatoms by reducing the surface diffusion distance between the impinging site and the growth site, before adatoms escape back to the vapor phase.

The obvious limitation of this growth mechanism is the regeneration of growth sites, when all available steps are consumed. Burton, Cabrera, and Frank [3] proposed that screw dislocations serve as a continuous source to generate growth sites so that the stepped growth would continue. The crystal growth proceeds in a spiral growth, and this crystal growth mechanism is now known as BCF theory. The presence of screw dislocation will not only ensure the continuing advancement of the growth surface but also enhance the growth rate. The growth rate of a given crystal facet under a given experimental condition would increase with an increased density of screw dislocations parallel to the growth direction. It is also known that different facets can have a significantly different ability to accommodate dislocations. The presence of dislocations on certain facets can result in anisotropic growth, leading to the formation of nanowires or nanorods.

The PBC theory offers a different perspective in understanding the different growth rates and behavior in different facets. Let us take a simple cubic crystal as an example to illustrate the PBC theory as shown in Figure 2. According to the PBC theory, {100} faces are flat surfaces (denoted as F-faces) with one PBC running through one such surface, {110} are stepped surfaces (S-faces) that have two PBCs, and {111} are kinked surfaces (K-faces) that have three PBCs. For {110} surfaces, each surface site is a step or ledge site, and thus any impinging atom would be incorporated wherever it adsorbs. For {111} facets, each surface site is a kink site and would irreversibly incorporate any incoming atom adsorbed onto the surface. For both {110} and {111} surfaces, the above growth is referred to as a random addition mechanism and no adsorbed atoms would escape back to the vapor phase. It is obvious that both {110} and {111} faces have a faster growth rate than that of the {100} surface in a simple cubic crystal. In general terms, S-faces and K-faces have a higher growth rate than F-faces. For both S- and K-faces, the growth process is always adsorption limited, since the accommodation coefficients on these two type surfaces are unity, that all impinging atoms are captured and incorporated into the growth surface. For F-faces, the accommodation coefficient varies between zero (no growth at all) and unity (adsorption limited), depending on the availability of kink and ledge sites.

The above theories enable us to understand better why some facets in a given crystal grow much faster than other facets. However, facets with fast growth rates tend disappear (i.e., surfaces with high surface energy will disappear). In a crystal at thermodynamic equilibrium, only those surfaces with the lowest total surface energy will survive. Therefore, the formation of high aspect ratio nanorods or nanowires entirely based on different growth rates of various facets is limited to materials with special crystal structures. In general, other mechanisms are required for the continued growth along the axis of nanorods or nanowires, such as defect-induced growth and impurity-inhibited growth.
Figure 2. The types of crystal faces in PBC theory. Reprinted with permission from [1], P. Hartman and W. G. Perdok, *Acta Cryst.* 8, 49 (1955). © 1955, International Union of Crystallography.

It should be noted that for an anisotropic growth, a low supersaturation is required. Ideally, the concentration is higher than the equilibrium concentration (saturation) of the growth surface, but equal or lower than that of other nongrowth surfaces. A low supersaturation is required for anisotropic growth, whereas a medium supersaturation supports bulk crystal growth, and a high supersaturation results in secondary or homogeneous nucleation leading to the formation of polycrystalline or powder samples.

Sears [4] was the first one to explain the growth of mercury whiskers (or nanowires, with a diameter of ∼200 nm and a length of 1–2 mm) by axial screw-dislocation induced anisotropic growth in 1955. The mercury whiskers or nanowires were grown by a simple evaporation–condensation method, with a condensation temperature of −50 °C under vacuum, and the estimated axial growth rate was of approximately 1.5 μm/sec under a supersaturation of 100, which is defined as a ratio of pressure over equilibrium pressure. However, it was found that the whiskers or nanowires remained at constant radius throughout the axial growth and thus implied that there was no or negligible lateral growth. In a subsequent article, Sears [5] also demonstrated that fine whiskers of other materials including zinc, cadmium, silver, and cadmium sulfide could be grown by the evaporation–condensation method. The experimental conditions varied with the material in question. The growth temperature varied from 250 °C for cadmium to 850 °C for silver whiskers, with a supersaturation ranging from ∼2 for cadmium sulfide to ∼20 for cadmium.

Subsequently, a lot of research has been devoted to confirm the presence of axial screw dislocation for the growth of nanowires; however, in most cases, various techniques including electron microscopy and etching all failed to reveal the presence of axial screw dislocation [6]. Microtwins and stacking faults are observed in many nanowires or nanorods grown by the evaporation–condensation method and are suggested to be responsible for the anisotropic growth [7]. However, many other researchers revealed no axial defects at all in the grown nanorods and nanowires. Such an anisotropic growth is also not possible to explain by means of anisotropic crystal structures. Obviously, more work is needed to understand the growth of nanowires and nanorods by the evaporation–condensation method.

Another related issue is the fact that the observed growth rate of the nanowires exceeds the condensation rate calculated using the equation for a flat surface [Eq. (1)], assuming the accommodation coefficient is unity. That means the growth rate of nanowires is faster than all the growth species arriving at the growth surface. To explain such a significantly enhanced growth rate of a whisker or nanowire, a dislocation–diffusion theory was proposed [8]. In this model, the fast growth rate was explained as follows: the depositing materials at the tip originated from two sources: direct condensation of growth species from the vapor and the migration of adsorbed growth species on side surfaces to the growth tip. However, an adatom migrating over an edge from side surfaces to the growth surface on the tip is unlikely, since the edge serves as an energy barrier for such a migration [9–11].

Pan et al. [12, 13] reported the growth of single crystal nanobelts of various semiconducting oxides simply by

evaporating the desired commercially available metal oxides at high temperatures under a vacuum of 300 Torr and condensing on an alumina substrate, placed inside the same alumina tube furnace, at relatively lower temperatures. The oxides include zinc oxide (ZnO) of wurtzite hexagonal crystal structure, tin oxide (SnO_2) of rutile structure, indium oxide (In_2O_3) with C-rare-earth crystal structure, and cadmium oxide (CdO) with NaCl cubic structure. Figure 3 shows the scanning electron microscope (SEM) and transmission electron microscope (TEM) pictures of SnO_2 nanobelts. We will just focus on the growth of ZnO nanobelts to illustrate their findings, since similar phenomena were found in all four oxides. The typical thickness and width-to-thickness ratios of the ZnO nanobelts are in the range of 10 to 30 nm and ∼5 to 10, respectively. Two growth directions were observed: [0001] and [0110]. No screw dislocation was found throughout the entire length of the nanobelt, except a single stacking fault parallel to the growth axis in the nanobelts grown along [0110] direction. The surfaces of the nanobelts are clean, atomically sharp, and free of any sheathed amorphous phase. Their further TEM analysis also revealed the absence of amorphous globules on the tip of nanobelts. The above observations imply that the growth of nanobelts is not due to the VLS mechanism, which will be discussed later in this chapter. The growth of nanobelts cannot be attributed to either screw dislocation induced anisotropic growth, nor impurity inhibited growth. Furthermore, since four oxides in question all have different crystal structures, it is not likely that the growth of nanobelts is directly related to their crystal structures. It seems worthwhile to note that the shape of nanowires and

nanobelts may also depend on growth temperature. Early work showed that single crystal mercury grown at different temperatures would have either a platelet shape or a whisker form [4, 14]. CdS ribbons were also grown by the evaporation–condensation method [5].

Liu et al. [15] synthesized SnO_2 nanorods by converting nanoparticles at elevated temperatures. The nanoparticles were chemically synthesized from $SnCl_4$ by inverse microemulsion using nonionic surfactant, have an average size of 10 nm, and are highly agglomerated. SnO_2 nanoparticles are likely amorphous. When heated to temperatures ranging from 780 to 820 °C in air, single crystal SnO_2 nanorods with rutile structure were formed. These nanorods are straight and have uniform diameters ranging from 20 to 90 nm and lengths from 5 to 10 μm, depending on annealing temperature and time. Figure 4 shows SnO_2 nanowires grown by this method.

Silicon nanowires could be synthesized by thermal evaporation of silicon monoxide under a reducing environment [16]. SiO powder was simply heated to a temperature of 1300 °C, and the vapor of silicon monoxide was carried by a mixture of argon and 5% hydrogen. The (100) silicon

Figure 4. SnO_2 nanorods grown by heating of powders nanoparticles. Reprinted with permission from [15], Y. Liu et al., *Adv. Mater.* 13, 1883 (2001). © 2001, Wiley-VCH.

substrate was maintained at 930 °C for the growth. It was found that the as-grown nanowires of 30 nm in diameter consist of a silicon core of 20 nm in diameter and a shell of silicon dioxide of 5 nm in thickness. The silicon core is believed to form through the reduction of silicon monoxide by hydrogen. The silicon dioxide shell may serve as a stopper for the side growth, resulting in a uniform diameter throughout a nanowire.

Although it is known that the impurities have differential adsorption on various crystal facets in a given a crystal and the adsorption of impurity would retard the growth process, no nanorods have been grown by vapor condensation methods based on impurity poisoning by design. However, impurity poisoning has often been cited as one of the reasons for anisotropic growth during the synthesis of nanowires and nanorods.

The dissolution–condensation process differs from evaporation–condensation in growth media. In the dissolution–condensation process, the growth species first dissolve into a solvent or a solution and then diffuse through the solvent or solution and deposit onto the surface resulting in the growth of nanorods or nanowires.

Gates et al. [17] prepared uniform single crystal nanowires of selenium by dissolution–condensation methods. In the first step, spherical colloidal particles of amorphous selenium with sizes of ~300 nm in aqueous solution were prepared through the reduction of selenious acid with excess hydrazine at 100 °C. When the solution was cooled to room temperature, some nanocrystalline selenium with trigonal structure precipitated. In the second step, when the solution aged at room temperature in dark, amorphous selenium colloid particles dissolved into the solution, whereas the selenium crystallites grew. In this solid–solution–solid transformation, the morphology of the crystalline selenium products was determined by the anisotropic growth, which is attributed to the one-dimensional characteristics of the infinite, helical chains of selenium in the trigonal structure. Trigonal Se crystals were found to grow predominantly along the [001] direction [18]. Se nanowires grown by this method were found free of defects, such as kinks and dislocations.

The chemical solution method was also explored for the synthesis of nanorods of crystalline Se_xTe_y compound [19]. In an aqueous medium (refluxed at ~100 °C), a mixture of selenious acid and orthotelluric acid was reduced by excess hydrazine [20]

$$xH_2SeO_3 + yH_6TeO_6 + (x + 3y/2)N_2H_4$$
$$\rightarrow Se_xTe_{y(s)} + (x + 3y/2)N_{2(g)} + (x + 3y/2)H_2O \quad (5)$$
Tellurium could easily precipitate out as crystalline hexagonal nanoplatelets under the experimental conditions through a homogeneous nucleation process [21]. It is postulated that the selenium and tellurium atoms subsequently produced by the above reduction reaction would grow into nanorods on the nanoplatelet tellurium seeds with a growth direction along [001]. The as-synthesized nanorods typically have a mean length of <500 nm and a mean diameter of ~60 nm, with a stoichiometric chemical composition of SeTe, and a trigonal crystal structure, similar to that of Se and Te. Hydrazine can also promote the growth of nanorods directly from metal powders in solution; for example, single crystal

ZnTe nanorods with diameters of 30–100 nm and lengths of 500–1200 nm were synthesized using Zn and Te metal powders as reactants and hydrazine hydrate as solvent by a solvothermal process [22]. It was postulated that hydrazine could promote anisotropic growth in addition to its role as a reduction agent.

Wang et al. have grown single crystal Mn_3O_4 nanowires of 40–80 nm diameter and lengths up to 150 μm in a molten NaCl flux [23]. $MnCl_2$ and Na_2CO_3 were mixed with NaCl and nonylphenyl ether (NP-9) and heated to 850 °C. After cooling, the NaCl was removed by washing in distilled water. NP-9 was used to prevent the formation of small particles at the expense of nanowires. The nanowires are believed to grow through Ostwald ripening, with NP-9 acting to reduce the eutectic temperature of the system, as well as stabilizing the smaller precursor particles. This technique has been applied to a wide variety of single crystal oxide nanorods.

Nanowires can grow on alien crystal nanoparticles, which serve as seeds for heteroepitaxial growth, by solution processing. Sun et al. [24] synthesized crystalline silver nanowires of 30–40 nm in diameter and ~50 μm in length using platinum nanoparticles as growth seeds. The growth species of Ag is generated by the reduction of $AgNO_3$ with ethylene glycol, whereas the anisotropic growth was achieved by introducing surfactants such as polyvinyl pyrrolidone in the solution. Polymer surfactants adsorbed on some growth surfaces, kinetically blocking (or poisoning) the growth, resulting in the formation of uniform crystalline silver nanowires. TEM analyses further revealed that the growth directions of face-centered-cubic silver nanowires were [211] and [011]. Figure 5 shows the silver nanowires grown in solution using Pt nanoparticles as growth seeds. Dissolution–condensation can also grow nanowires on a substrate. Govender et al. formed ZnO nanorods on glass substrates from a solution of zinc acetate or zinc formate and hexamethylenetetramine at room temperature [25]. These faceted nanorods were preferentially oriented in the [0001] direction (that is, along the c-axis), with diameters of about 266 nm and a length of ~3 μm.
Figure 5. Silver nanowires grown from solution. Reprinted with permission from [24], Y. Sun et al., *Nano Lett.* 2, 165 (2002). © 2002, American Chemical Society.

Hydrothermal growth is another method being explored in the formation of nanorods from inorganic salts. $CdWO_4$, with a monoclinic crystal structure, nanorods were synthesized directly by the reaction of cadmium chloride ($CdCl_2$) and sodium tungstate ($NaWO_4$) at 130 °C under pressure at a pH ranging from 3 to 11 for 5 hours. Such grown cadmium tungstate nanorods have diameters of 20–40 nm and lengths ranging from 80 to 280 nm [26]. The growth of nanorods is attributed to anisotropic growth, though no specific growth direction was identified. Nanotubes of $H_2Ti_3O_7$ have been hydrothermally synthesized from TiO_2 powder dissolved in a NaOH aqueous solution at 130 °C by Chen et al. [27]. The synthesized products were hollow tubes about 9 nm in diameter, with lengths from 100 to several hundred nanometers.

Nanowires or nanorods by the evaporation (dissolution)–condensation deposition most likely have faceted morphology and are generally short in length with relatively small aspect ratios, particularly when grown in liquid medium. However, anisotropic growth induced by axial imperfections, such as screw dislocation, microtwins, and stacking faults, or by impurity poisoning, can result in the growth of nanowires with very large aspect ratios.

2.2. Vapor (or Solution)–Liquid–Solid Growth

In VLS growth, a second phase material, commonly referred to as either impurity or catalyst, is purposely introduced to direct and confine the crystal growth on a specific orientation and within a confined area. Catalyst forms a liquid droplet by itself or by alloying with growth material during the growth, which acts as a trap of growth species. Enriched growth species in the catalyst droplets subsequently precipitates at the growth surface resulting in the one-directional growth. Wagner et al. [28, 29] first proposed the VLS theory over 40 years ago to explain the experimental results and observations in the growth of silicon nanowires or whiskers that could not be explained by the evaporation–condensation theory. These phenomena include:

1. There are no screw dislocations or other imperfections along the growth direction.
2. The growth direction $\langle 111 \rangle$ is the slowest as compared with other low index directions such as $\langle 110 \rangle$ in silicon.
3. Impurities are always required.
4. A liquidlike globule is always found in the tip of nanowires.

Wagner summarized the experimental details, results, and the VLS theory in a truly elegant way in a classical paper [30], and Givargizov [6] further elaborated the experimental observations, models, and theories developed regarding the VLS process. The readers who want to learn more about this subject are strongly recommended to read those literatures. Although extensive research in this field has been carried out in recent years, fundamentals of the VLS method have not been changed significantly. Wagner summarized the requirements for the VLS growth 30 years ago [30], which are still valid in today's understanding.

1. The catalyst or impurity must form a liquid solution with the crystalline material to be grown at the deposition temperature.

2. The distribution coefficient of the catalyst or impurity must be less than unity at the deposition temperature.
3. The equilibrium vapor pressure of the catalyst or impurity over the liquid droplet must be very small. Although the evaporation of the catalyst does not change the composition of the saturated liquid composition, it does reduce the total volume of the liquid droplet. Unless more catalyst is supplied, the volume of the liquid droplet reduces. Consequently, the diameter of the nanowire will reduce and the growth will eventually stop, when all the catalyst is evaporated.
4. The catalyst or impurity must be inert chemically. It must not react with the chemical species such as by-products presented in the growth chamber.
5. The interfacial energy plays a very important role. The wetting characteristics influence the diameter of the grown nanowire. For a given volume of liquid droplet, a small wetting angle results in a large growth area, leading to a large diameter of nanowires.
6. For a compound nanowire growth, one of the constituent can serve as the catalyst.
7. For controlled unidirectional growth, the solid–liquid interface must be well defined crystallographically. One of the simplest methods is to choose a single crystal substrate with desired crystal orientation.

In VLS growth, the growth species is evaporated first and then diffuses and dissolves into a liquid droplet. The surface of the liquid has a large accommodation coefficient and is therefore a preferred site for deposition. Saturated growth species in the liquid droplet will diffuse to and precipitate at the interface between the substrate and the liquid. The precipitation will follow first nucleation and then crystal growth. Continued precipitation or growth will separate the substrate and the liquid droplet, resulting in the growth of nanowires.

Let us take the growth of silicon nanowires with gold as a catalyst as an example to illustrate the experimental process of the VLS growth. A thin layer of gold is sputtered on a silicon substrate and annealed at an elevated temperature (above the eutectic point of ~360 °C of the silicon–gold system), which is typically the same as the growth temperature. During the annealing, silicon and gold react and form a liquid mixture, which forms a droplet on the silicon substrate surface. During the growth, an equilibrium composition is reached at the growth temperature as determined by the binary phase diagram. When silicon species is evaporated from the source and preferentially condensed at the surface of the liquid droplet, the liquid droplet will become supersaturated with silicon. Subsequently, the supersaturated silicon will diffuse from the liquid–vapor interface and precipitate at the solid–liquid interface resulting in the growth of silicon. The growth will proceed unidirectionally perpendicular to the solid–liquid interface. Once the growth species is adsorbed onto the liquid surface, it will dissolve into the liquid. The material transport in the liquid is diffusion-controlled and occurs under essentially isothermal conditions. At the interface between the liquid droplet and growth surface, the crystal growth proceeds essentially the same as that in the Czochraski crystal growth.

The catalyst can be introduced *in-situ* as well. In this case, the growth precursor is mixed with the catalyst and evaporated simultaneously at a higher temperature. Both the growth precursor or species and the catalyst condense at the substrate surface when supersaturation is reached at a temperature lower than the evaporation temperature. The mixture of the growth species and catalyst reacts either in the vapor phase or on the substrate surface to form a liquid droplet. The subsequent nanowire growth would proceed as discussed before.

Crystalline defects, such as screw dislocations, are not essential for VLS growth. However, defects present at the interface may promote the growth and lower the required supersaturation. From the above discussion, it is clear that the growth of nanowires by the VLS method is not restricted by the type of substrate material and the type of catalysts. The nanowires can be single crystal, polycrystalline, or amorphous depending on the substrates and growth conditions.

The preferential adsorption of growth species onto the liquid droplet surface can be understood. For a perfect or an imperfect crystal surface, an impinging growth species diffuses along the surface. During the diffusion, the growth species may be irreversibly incorporated into the growth site (ledge, ledge–kink, or kink). If the growth species did not find a preferential site in a given period of time (the residence time), the growth species will escape back to the vapor phase. A liquid surface is distinctly different from a perfect or imperfect crystal surface and can be considered as a "rough" surface. Rough surface is composed of only ledge, ledge–kink, or kink sites. That is, every site over the entire surface is to trap the impinging growth species. The accommodation coefficient is unit. Consequently, the growth rate of the nanowires or nanorods by the VLS method is much higher than that without liquid catalyst. Wagner and Ellis [31] reported that the growth rate of silicon nanowires using a liquid Pt–Si alloy is about 60 times higher than directly on the silicon substrate at 900 °C. It is likely that in addition to acting as a sink for the growth species in the vapor phase, the catalyst or impurity forming the liquid with the growth material can act as a catalyst for the heterogeneous reaction or deposition.

Bootsma and Gassen compared the axial (V_{II}) and lateral ($V_\perp$) growth rates for Si and Ge nanowires as well as the substrate (i.e., film) growth rate of these materials, with SiH_4 and GeH_4 as precursors and numerous metals (Au, Ag, Cu, Ni, Pd) as catalysts [32]. They found that the lateral and the substrate growth rates are essentially the same, whereas the axial rates by the VLS process for both Si and Ge nanowires are approximately two orders of magnitude higher than the VS growth rates under the same conditions.

The enhanced growth rate can also be partly due to the fact that the condensation surface area for the growth species in the VLS growth is larger than the surface area of the crystal growth. While the growth surface is the interface between the liquid droplet and the solid surface, the condensation surface is the interface between the liquid droplet and vapor phase. Depending on the contact angle, the liquid surface area can be several times the growth surface.

Growth of elementary Si and Ge nanowires has been well established [33–35]. Although gold was initially used for the growth of silicon nanowires with the VLS method, other catalysts have been found to be effective in the formation of nanowires of various materials. For example, Si nanowires can be synthesized using Fe as a catalyst [36, 37] at a relatively high growth temperature of 1200 °C. A mixture of silicon powder with 5 wt% Fe was ablated by either laser or simple heating to 1200 °C, which was also the growth temperature. The nanowires have nominal diameters of ~15 nm and a length varying from a few tens to several hundreds micrometers. An amorphous layer of silicon oxide of ~2 nm in thickness overcoated the outside of silicon nanowires. The amorphous oxide layer was likely formed during the growth at high temperature, when a small amount of oxygen leaked into the deposition chamber.

The size of nanowires grown by VLS method is solely determined by the size of the liquid catalyst droplets. To grow thinner nanowires, one can simply reduce the size of the liquid droplets. A typical method used to form small liquid catalyst droplets is to coat a thin layer of catalyst on the growth substrate and to anneal at elevated temperatures [38]. During annealing, catalyst reacts with the substrate to form a eutectic liquid and further ball up to reduce the overall surface energy. Au as a catalyst and silicon as a substrate is a typical example. The size of the liquid catalyst droplets can be controlled by the thickness of the catalyst film on the substrate. In general, a thinner film forms smaller droplets, giving smaller diameters of nanowires subsequently grown. For example, 10 nm Au film yields single crystal germanium nanowires of 150 nm in diameter, while 5 nm Au film results in the growth of 80 nm sized germanium nanowires [39]. However, further reduction in the catalyst film thickness did not result in a decreased diameter of germanium nanowires [39]. No further reduction in diameter of nanowires indicated that there is a minimum size of liquid droplets achievable by applying thin films.

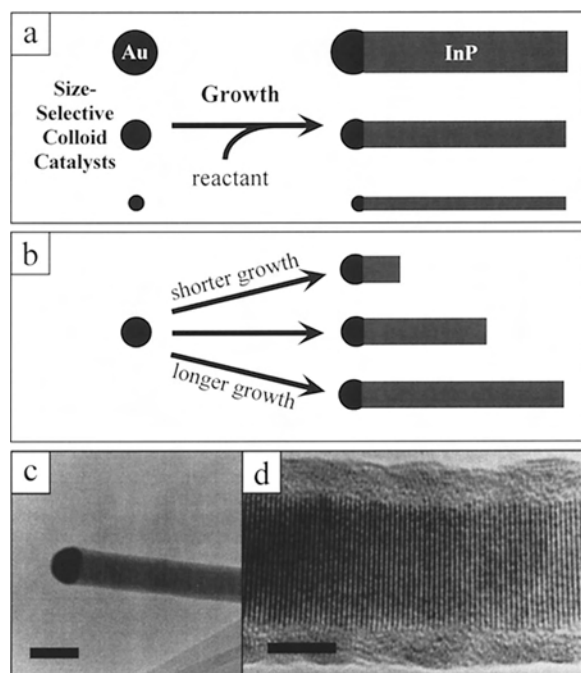
Further reduction of diameters of nanowires could be achieved by dispersing monosized catalyst colloids on the substrate surface, instead of a thin film of catalyst [40, 41]. GaP nanowires were grown by a laser catalytic growth synthetic method [35] using gold colloids [41]. Gold colloids or nanoclusters were supported on a silica substrate and the reactants Ga and P were generated from a solid target of GaP by laser ablation. Single crystal GaP nanowires show a growth direction of [111] and have a stoichiometric composition of 1:0.94 confirmed by energy dispersive X-ray analysis (EDAX). The diameters of GaP nanowires were determined by the size of the catalyst gold nanoclusters. GaP nanowires grown from 8.4, 18.5, and 28.2 nm diameter gold colloids were found to be 11.4, 20, and 30.2 nm, respectively. A similar technique was applied to the growth of InP nanowires [40]. The growth substrate temperature was controlled to be approximately 500–600 °C, and a constant flow of Ar at 100 standard cubic centimeters per minute under a pressure of 200 Torr was maintained during the growth. The laser for ablation used was an ArF excimer laser with a wavelength of 193 nm. InP nanowires were found to be single crystal and grew along the [111] direction. Figure 6 shows the general concepts of control of the diameters and length of nanowires grown by catalyst colloids [40]. Detailed analysis further revealed an amorphous oxide layer of 2–4 nm in thickness presented on all nanowires. The existence of an


Figure 6. Length and diameter control in nanowires grown from colloidal catalysts. Reprinted with permission from [40], M. S. Gudiksen et al., *J. Phys. Chem. B* 105, 4062 (2001). © 2001, American Chemical Society.

amorphous oxide layer was explained by the overgrowth of an amorphous InP on the side faces and subsequent oxidation after the samples were exposed to air. The overgrowth on side faces is not catalyst activated and implies supersaturated vapor concentrations of growth constituents in the system.

The equilibrium vapor pressure or solubility is dependent on the surface energy and a radius (or curvature of a surface) at a given condition defined by the Kelvin equation

$$\ln\left(\frac{P}{P_0}\right) = -\frac{2\gamma\Omega}{kTr} \tag{6}$$

where P is the vapor pressure of a curved surface, P_0 is the vapor pressure of a flat surface, γ is the surface energy, Ω is the atomic volume, r is the surface radius, and k is the Boltzmann constant. For the growth of nanowires, if facets are developed during the growth, longitudinal and lateral growth rates of nanowires or nanorods will be solely determined by the growth behavior of individual facets. However, if nanowires were cylindrical in shape, the lateral growth rate would be significantly smaller than the longitudinal one, assuming all surfaces have the same surface energy. Convex surfaces (the side surface) with very small radius (<100 nm) would have a significantly higher vapor pressure as compared with that of a flat growing surface. A supersaturated vapor pressure or concentration of the growth species for the growing surface may be well below the equilibrium vapor pressure of the convex surface of thin nanowires. For the growth of uniform high quality crystalline nanowires or nanorods, in general supersaturation should be kept relatively low, so that there would be no growth on the side surface. A high supersaturation would result in growth of other

facets, just as in the vapor–solid growth discussed before. Further high supersaturation would lead to secondary nucleation on the growth surface or homogeneous nucleation, resulting in termination of epitaxial growth.

Since the diameters of nanowires grown by the VLS method are solely controlled by the size of the liquid catalyst droplets, thinner wires can be grown by using smaller liquid droplets. However, this approach has its limit. From Eq. (6), we already know that the equilibrium vapor pressure of a solid surface is dependent on the surface curvature. The same dependence is found for a solubility of a solute in a solvent. As the size of the droplets is reduced, the solubility would increase. For the growth of very thin nanowires, a very small droplet is required. However, a convex surface with a very small radius would have a very high solubility. As a result, a high supersaturation in the vapor phase has to be generated. A high supersaturation in the vapor phase may promote the lateral growth on the side surface of nanowires with the vapor–solid mechanism. Therefore, a conical structure may be developed instead of uniformly sized nanowires. Further, a high supersaturation may initiate homogeneous nucleation in the gas phase or secondary nucleation at the surface of nanowires.

Another characteristic in the VLS method should be noted. According to the Kelvin equation, an equilibrium solubility and supersaturation of growth species in larger liquid catalyst droplets can be obtained more easily than in smaller droplets. The growth of nanowires will proceed only when the concentration of growth species is above the equilibrium solubility. When the concentration or supersaturation in the vapor phase is appropriately controlled, vapor pressure could be kept below the equilibrium solubility in small liquid droplets, and the growth of nanowires of thinnest nanowires would terminate. When the growth proceeds at high temperatures and the grown nanowires are very thin, radial size instability is often observed as shown in Figure 7. Such instability is explained by the oscillation of the size of the liquid droplet on the growth tip and the concentration of
Figure 7. Radial size instability in nanowires grown by VLS. Reprinted with permission from [6], E. I. Givargizov, "Highly Anisotropic Crystals." Reidel, Dordrecht, 1986. © 1986, Kluwer Academic Publishers.

the growth species in the liquid droplet [6]. Alternately, this instability may be thought of as similar to the necking of thin streams of liquids [42]. The instability is only observed in very thin wires, where the surface energy is quite high, and at high temperatures where roughening may occur. Such instability could be another barrier for the synthesis of very thin nanowires, which may require high deposition temperatures.

The diameter of nanowires grown by the VLS method is determined by the minimum size of the liquid catalyst droplet under the equilibrium conditions [30]. Methods to achieve small sizes of liquid catalyst droplets are straightforward. For example, laser ablation can be used to deposit catalytic material on a heated substrate to form nanometer diameter clusters with controlled pressure and temperature [43]. In a similar manner, many other evaporation techniques could be used to deposit nanometer catalyst clusters on substrates for the growth of nanowires. Controlling the catalyst placement on the substrate can be used to achieve other novel morphologies. For example, patterned arrays of ZnO nanorods on a surface have been grown, simply by patterning the Au catalyst film prior to VLS growth [44].

Nanowires or nanorods grown by the VLS method in general have a cylindrical morphology (i.e., without facets on the side surface and having a uniform diameter). The physical conditions of both Czochraski and VLS methods are very similar; growth proceeds very close to the melting points or liquid–solid equilibrium temperature. Surfaces may undergo a transition from faceted (smooth) to "rough" surface, known as the roughening transition [45]. Below the roughening temperature, a surface is faceted, and above this temperature, thermal motion of the surface atoms overcomes the interfacial energy and causes a faceted crystal to roughen. From melt, only a restricted group of materials including silicon and bismuth can grow faceted single crystals [46]. However, facets may develop if there is VS deposition on the side surface. Although the VS deposition rate is much smaller than the VLS growth rate for a given temperature, it is still effective in controlling the morphology. Since the difference in the two deposition rates decreases with increasing temperature, the VS deposit will greatly influence the morphology in the high temperature range. It is noted that the diameter of the nanowire may change if the growth conditions vary or the catalyst evaporates or is incorporated into the nanowires.

Numerous precursors have been used for the VLS growth as evaporation–condensation methods. Gaseous precursors such as $SiCl_4$ for silicon nanowires [38] are convenient sources. Evaporation of solids by heating to elevated temperatures is another common practice [47]. Laser ablation of solid targets is yet another method used in generating vapor precursors [35, 48]. To promote the evaporation of solid precursors, formation of intermediate compounds may be an appropriate approach. For example, Wu et al. [39] used a mixture of Ge and GeI_4 as precursors for the growth of Ge nanowires. The precursors evaporated through the formation of volatile compound via the following chemical reaction

$$Ge_{(s)} + GeI_{4(g)} \rightarrow 2GeI_{2(g)} \qquad (7)$$

The GeI_2 vapor was transported to the growth chamber, condensed into the liquid catalyst (here is Au/Si) droplets, and disproportionated according to

$$2GeI_{2(g)} \rightarrow Ge_{(l)} + GeI_{4(g)} \qquad (8)$$

Other precursors have also been explored in the VLS growth of nanowires including ammonia and gallium acetylacetonate for GaN nanorods [49], closo-1,2-dicarbadodecaborane ($C_2B_{10}H_{12}$) for B_4C nanorods [50], and methyltrichlorosilane for SiC [51].

Other materials can be used as catalysts as well. For example, silicon nanowires were grown using iron as a catalyst [35]. Any material or mixture can be used as catalyst as long as they meet the requirements described by Wagner [30]. For example, a mixture of Au and Si was used for the growth of germanium nanowires [39].

ZnO nanowires have been grown using the VLS method [52] on Au-coated (thickness ranging from 2 to 50 nm) silicon substrates by heating a 1:1 mixture of ZnO and graphite powder to 900–925 °C under a constant flow of argon for 5–30 min. The grown ZnO nanowires vary with the thickness of the initial Au coatings. For a 50 nm Au coating, the diameters of the nanowires normally range from 80 to 120 nm and their lengths are 10–20 μm. Thinner nanowires of 40–70 nm with lengths of 5–10 μm were grown on 3 nm Au-coated substrates. The grown ZnO nanowires are single crystal with a preferential growth direction of $\langle 001 \rangle$. The growth process of ZnO is believed to be different from that of elementary nanowires. The process involves the reduction of ZnO by graphite to form Zn and CO vapor at high temperatures (above 900 °C). The Zn vapor is transported to and reacted with the Au catalyst, which would have already reacted with silicon to form a eutectic Au–Si liquid on silicon substrates, located downstream at a lower temperature to form Zu–Au–Si alloy droplets. As the droplets become supersaturated with Zn, crystalline ZnO nanowires are formed, possibly through the reaction between Zn and CO at a lower temperature. The above process could be easily understood by the fact that the reaction

$$ZnO + C \leftrightarrow Zn + CO \qquad (9)$$
is reversible at temperatures around 900 °C [53, 54]. Although the presence of a small amount of CO is not expected to change the phase diagram significantly, no ZnO nanowires were grown on substrates in the absence of graphite.

Single crystal monoclinic gallium oxide (β-Ga_2O_3) nanowires were synthesized with a conventional dc arc-discharge method [55]. GaN powder mixed with 5 wt% of transition metal powders (Ni/Co = 1:1 and Ni/Co/Y = 4.5:4.5:1) was pressed into a small hole of the graphite anode. A total pressure of 500 Torr of argon and oxygen gases in a ratio of 4:1 was maintained during the growth. The typical diameter of the nanowires is about 33 nm with a growth direction of [001], and no amorphous layer was founded on the surface. A possible chemical reaction for the formation of Ga_2O_3 is proposed to be

$$2GaN + \left(\frac{3}{2} + x\right)O_{2(g)} \rightarrow Ga_2O_3 + 2NO_{x(g)} \qquad (10)$$
Single crystal GeO_2 nanowires were grown by evaporation of a mixture of Ge powder and 8 wt% Fe at 820 °C under a flow (130 sccm) of argon gas under a pressure of 200 Torr [56]. The nanowires have diameters ranging from 15 to 80 nm. Although Fe was added as a catalyst to direct the growth of nanowires, no globules were found in the tips of grown nanowires. The authors argued that the GeO_2 nanowires were grown by mechanisms other than the VLS method. It is also noticed that during the experiment, no oxygen was intentionally introduced into the system. Oxygen may leak into the reaction chamber and react with germanium to form germanium oxide.

Yu et al. [57] reported the synthesis of amorphous silica nanowires by the VLS method. A mixture of silicon with 20 wt% silica and 8 wt% Fe was ablated using an excimer laser of 246 nm wavelength under flowing argon at 100 Torr. Fe was used as a catalyst and the growth temperature was 1200 °C. The nanowires have a chemical composition of Si:O = 1:2 and a uniform size distribution with a diameter of 15 nm and a length up to hundreds micrometers.

In general, a high temperature and a vacuum are required in the growth of nanowires by the VLS method. An alternative method called the solution–liquid–solid (SLS) growth method was developed by Buhro's research group [58, 59] and first applied for the synthesis of InP, InAs, and GaAs nanowires with solution-phase reactions at relatively lower temperatures ($\leq$203 °C). The SLS method is very similar to VLS theory [58]. Nanowires were found to be polycrystalline or near single crystal with diameters of 10–150 nm and lengths up to several micrometers. Let us take the growth of InP nanowires as an example to illustrate the SLS growth process. Precursors used were typical organometallic compounds: $In(t-Bu)_3$ and PH_3, which were dissolved into hydrocarbon solvent with protic catalyst such as MeOH, PhSH, Et_2NH_2, or $PhCO_2H$. In the solution, precursors reacted to form In and P species for the growth of InP nanowires with the following organometallic reaction, which is commonly used in chemical vapor deposition [60]

$$In(t - Bu)_3 + PH_3 \rightarrow InP + 3(t - Bu)H \qquad (11)$$

Indium metal functions as the liquid phase or catalyst for the growth of InP nanowires. Indium melts at 157 °C and forms liquid drops. It is postulated that both P and In dissolve into the In droplets and precipitate to form nanowires of InP. The growth direction of InP nanowires was found to be predominated by $\langle 111 \rangle$, similar to that with the VLS method.

2.3. Stress-Induced Recrystallization

It is worth noting that nanowires can be synthesized by stress-induced recrystallization, though it has attracted little attention in the nanotechnology community. Application of pressure on solids at elevated temperatures is known to result in the growth of whiskers or nanowires with diameters as small as 50 nm [61]. It was demonstrated that the growth rate of tin whiskers increased proportionally with the applied pressure [61] and could be four orders of magnitude when a pressure of 7500 psi was applied [62]. The growth of such nanowires or whiskers is based on a dislocation at the base of the whisker [63, 64] and the growth proceeds from the base and not from the tip [65]. The formation of metallic nanorods is likely due to the confined growth at the surface between the metallic film and the grown nanowires, whereas no growth is possible in other directions (side faces of nanowires). It should be noted that this technique is not widely explored in the recent studies on the growth of nanorods and nanowires (see Table 1).

3. TEMPLATE-BASED SYNTHESIS

Template-based synthesis of nanostructured materials is a very general method and can be used in fabrication of nanorods, nanowires, and nanotubules of polymers, metals, semiconductors, and oxides. Various templates with nano-size channels have been explored for the template growth of nanorods and nanotubules. The most commonly used and commercially available templates are anodized alumina membrane [66] and radiation track-etched polymer membranes [67]. Other membranes have also been used as templates such as nanochannel array glass [68], radiation track-etched mica [69], mesoporous materials [70], porous silicon by electrochemical etching of silicon wafer [71], zeolites [72], and carbon nanotubes [73, 74]. Alumina membranes with uniform and parallel porous structure are made by anodic oxidation of aluminum sheets in solutions of sulfuric, oxalic, or phosphoric acids [66, 75]. The pores are arranged in a regular hexagonal array, and densities as high as 10^{11} pores/cm^2 can be achieved [76]. Pore size ranging from 10 nm to 100 μm can be achieved [76, 77]. The polycarbonate membranes are made by bombarding a nonporous polycarbonate sheet, with typical thickness ranging from 6 to 20 μm, with nuclear fission fragments to create damage tracks, and then chemically etching these tracks into pores [67]. In radiation track-etched membranes, pores have a uniform size as small as 10 nm, though randomly distributed. Pore densities can be as high as 10^9 pores/cm^2.

In addition to the desired pore or channel size, morphology, size distribution, and density of pores, template materials must meet certain requirements. First, the template materials must be compatible with the processing conditions. For example, an electrical insulator is required for a template to be used in electrochemical deposition. Except for the template directed synthesis, template materials should be chemically and thermally inert during the synthesis and following processing steps. Second, depositing materials or solution must wet the internal pore walls. Third, for the synthesis of nanorods or nanowires, the deposition should start from the bottom or one end of the template channels and proceed from one side to another. However, for the growth of nanotubules, the deposition should start from the pore wall and proceed inwardly. Inward growth may result in pore blockage, so that should be avoided in the growth of "solid" nanorods or nanowires. Kinetically, enough surface relaxation permits maximal packing density, so a diffusion-limited process is preferred. Other considerations include the easiness of release of nanowires or nanorods from the templates and of handling during the experiments.

Table 1. A summary of the oxide nanorods mentioned in this chapter.

Material	Form	Method	Diameter (or width for beltlike structures)	Length	Ref.
ZnO, SnO$_2$, ln$_2$O$_3$, CdO, Ga$_2$O$_3$	Nanobelts	Evaporation–condensation	30–300 nm	Up to a few mm	[12, 13]
SnO$_2$	Nanorods	Evaporation–condensation	70–90 nm	5–10 μm	[15]
Mn$_3$O$_4$	Nanowires	Dissolution–condensation (molten salt flux)	40–80 nm	Up to 150 μm	[23]
ZnO	Nanorods	Dissolution–condensation	~200–300 nm	~3 μm	[25]
CdWO$_4$	Nanorods	Dissolution–condensation (hydrothermal)	20–40 nm	80–280 nm	[26]
H$_2$Ti$_3$O$_7$	Nanotubes	Dissolution–condensation (hydrothermal)	9 nm	100 to several hundred nanometers	[27]
ZnO	Nanowires	VLS	20–150 nm	2–10 μm	[51, 54]
β-Ga$_2$O$_3$	Nanowires	VLS	33 nm	Up to 100 μm	[55]
GeO$_2$	Nanowires	VLS or VS	15–80 nm	Up to a few tens of μm	[56]
Amorphous SiO$_2$	Nanowires	VLS	~15 nm	Up to hundreds of μm	[57]
TiO$_2$, amorphous SiO$_2$, BaTiO$_3$, Pb(Ti,Zr)O$_3$, Sr$_2$Nb$_2$O$_7$	Nanorods	Template electrophoretic deposition	40–200 nm	Up to 10 μm	[102, 103]
ZnO	Nanowires and nanotubes	Template electrophoretic deposition	~200 nm	~25–55 μm	[104]
TiO$_2$	Nanowires	Template electrophoretic deposition (electrochemically induced sol–gel)	10–40 nm	2–10 μm	[105]
TiO$_2$, MnO$_2$, V$_2$O$_5$, Co$_3$O$_4$, ZnO, WO$_3$, SiO$_2$	Nanotubes and nanorods	Template filling with colloidal dispersion	22–600 nm	Tens of μm	[107, 109]
Bi$_2$O$_3$	Nanowires	Oxidation of metal nanowires (melt filling)	~10–100 nm	Up to tens of μm	[112]
ZnO	Nanowires	Oxidation of metal nanowires (electrodeposited)	15–90 nm	Up to 50 μm	[129]

3.1. Electrochemical Deposition

Electrochemical deposition can be understood as a special electrolysis resulting in the deposition of solid material on an electrode. This process involves (1) oriented diffusion of charged growth species (typically positively charged cations) through a solution when an external electric field is applied, and (2) reduction of the charged growth species at the growth or deposition surface, which also serves as an electrode. In general, electrochemical deposition is only applicable to electrically conductive materials such as metals, alloys, semiconductors, and electrical conductive polymers, since after the initial deposition, the electrode is separated from the depositing solution by the deposit and the electrical current must go through the deposit to allow the deposition process to continue. Electrochemical deposition is widely used in making metallic coatings; the process is also known as electroplating [78]. When deposition is confined inside the pores of template membranes, nanocomposites are produced. If the template membrane is removed, nanorods or nanowires are prepared.

Electrochemical deposition has been explored in the fabrication of nanowires of metals, semiconductors, and conductive polymers and the growth of nanowires of conductive materials is a self-propagating process [79]. Once a little fluctuation yields the formation of small rods, the growth of rods or wires will continue, since the electric field and the density of current lines between the tips of nanowires and the opposing electrode are greater, due to a shorter distance, than that between two electrodes. The growth species will more likely deposit onto the tip of nanowires, resulting in continued growth. However, this method is hardly used in practice for the synthesis of nanowires, since it is very difficult, if not impossible, to control the growth. Possin [69] prepared various metallic nanowires by electrochemical deposition inside pores of radiation track-etched mica. Williams and Giordano [80] grew silver nanowires with diameters below 10 nm. The potentiostatic electrochemical template synthesis yielded different metal nanowires, including Ni, Co, Cu, and Au with nominal pore diameters between 10 and 200 nm, and the nanowires were found to be true replicas of the pores [81]. Whitney et al. [82] fabricated the arrays of nickel and cobalt nanowires by electrochemical deposition of the metals into track-etched templates. Single crystal antimony nanowires have been grown by Zhang et al. in anodic alumina membranes using a pulsed electrodeposition [83]. Semiconductor nanorods by electrodeposition include CdSe and CdTe synthesized by Klein et al. in anodic alumina templates [84], and Schönenberger et al. [85] have made conducting polypyrrole electrochemically in porous polycarbonate.

Hollow metal tubules can also be prepared using electrochemical deposition [86, 87]. For growth of metal tubules, the pore walls of the template need to be chemically derivatized

first so that the metal will preferentially deposit onto the pore walls instead of the bottom electrode. Such surface chemistry of the pore walls is achieved by anchoring silane molecules. For example, the pore surface of an anodic alumina template was covered with cyanosilanes; subsequent electrochemical deposition resulted in the growth of gold tubules [88].

An electroless electrolysis process has also been applied in the fabrication of nanowires or nanorods [86, 89–91]. Electroless deposition is actually a chemical deposition and involves the use of a chemical agent to plate a material from the surrounding phase onto a template surface [92]. The significant difference between electrochemical deposition and electroless deposition is that in the former, the deposition begins at the bottom electrode and the deposited materials must be electrically conductive, whereas the latter method does not require the deposited materials to be electrically conductive and the deposition starts from the pore wall and proceeds inwardly. Therefore, in general, electrochemical deposition results in the formation of "solid" nanorods or nanowires of conductive materials, whereas the electroless deposition often grows hollow fibrils or nanotubules. For electrochemical deposition, the length of nanowires or nanorods can be controlled by the deposition time, whereas the length of the nanotubules is solely dependent on the length of the deposition channels or pores, which often equal to the thickness of membranes. Variation of deposition time would result in a different wall thickness of nanotubules. An increase in deposition time leads to a thick wall and a prolonged deposition may form solid nanorods. However, a prolonged deposition time does not guarantee the formation of solid nanorods. For example, the polyaniline tubules never closed up, even with prolonged polymerization time [93].

3.2. Electrophoretic Deposition

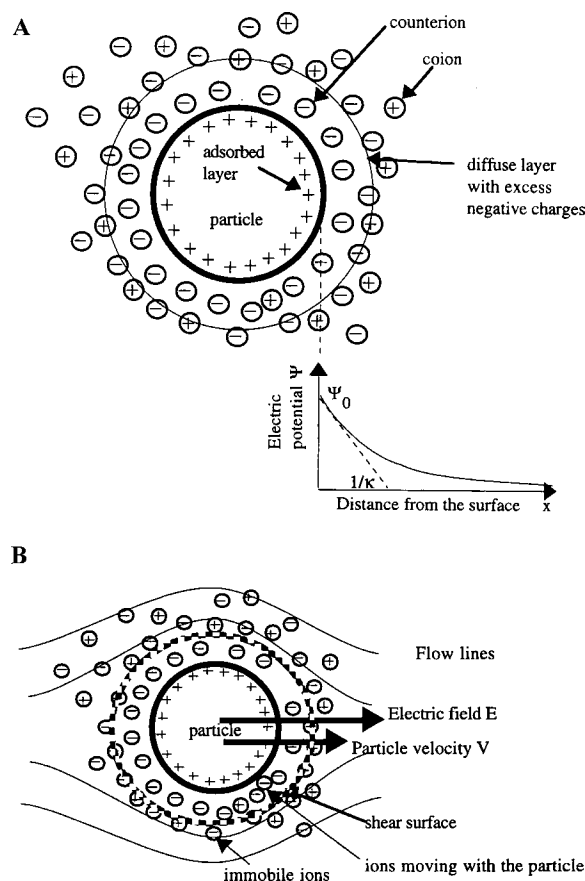
The electrophoretic deposition technique has been widely explored, particularly in film deposition of ceramic and organoceramic materials on cathode from colloidal dispersions [94]. Electrophoretic deposition differs from electrochemical deposition in several aspects. First, the deposit by the electrophoretic deposition method need not be electrically conductive. Therefore, this method is particularly useful for oxide systems. Second, nanosized particles in colloidal dispersions are typically stabilized by electrostatic or electrosteric mechanisms. When dispersed in a polar solvent or an electrolyte solution, the surface of nanoparticles develops an electrical charge via one or more of the following mechanisms: (1) preferential dissolution or (2) deposition of charges or charged species, (3) preferential reduction or (4) oxidation, and (5) adsorption of charged species such as polymers. Charged surfaces will electrostatically attract oppositely charged species (typically called counterions) in the solvent or solution. A combination of electrostatic forces, Brownian motion and osmotic forces would result in the formation of a so-called double layer structure, as schematically illustrated in Figure 8A. The figure depicts a positively charged particle surface, the concentration profiles of negative ions (counterions), and positive ions (surface-charge-determining ions), and the electric potential profile. The concentration of counterions gradually decreases with


Figure 8. (A) A schematic of the electrical double layer surrounding a particle in a colloidal suspension. (B) Diagram of the features of electrophoretic motion. Reprinted with permission from [98], A. C. Pierre, "Introduction to Sol–Gel Processing." Kluwer Academic, Boston, 1998. © 1998, Kluwer Academic Publishers.

distance from the particle surface, whereas that of charge-determining ions increases. As a result, the electric potential decreases with distance. Near to the particle surface, the electric potential decreases linearly, in the region known as the Stern layer. Outside of the Stern layer, the decrease follows an exponential relationship, and the region between Stern layer and the point where the electric potential equals zero is called the diffusion layer. Together, the Stern layer and diffusion layer are called the double layer structure in the classic theory of electrostatic stabilization.

Upon application of an external electric field to a colloidal system or a sol, the constituent charged particles are set in motion in response to the electric field, as schematically illustrated in Figure 8B. This type of motion is referred to as electrophoresis. When a charged particle is in motion, some of the solvent or solution surrounding the particle will move with it, since part of the solvent or solution is tightly bound to the particle. The plane that separates the tightly bound liquid layer from the rest of the liquid is called the slip plane. The electric potential at the slip plane is known as the zeta potential. The zeta potential is an important parameter in determining the stability of a colloidal dispersion or a sol; a zeta potential larger than about 25 mV is typically required to stabilize a system [95]. The zeta potential is determined

by a number of factors, such as the particle surface charge density, the concentration of counterions in the solution, solvent polarity, and temperature. The zeta potential around a spherical particle can be described as [96]

$$\zeta = \frac{Q}{4\pi\varepsilon_r a(1 + \kappa a)} \tag{12}$$

with

$$\kappa = \left(\frac{e^2 \sum n_i z_i^2}{\varepsilon_r \varepsilon_0 kT} \right)^{1/2}$$

where Q is the charge on the particle, a is the radius of the particle out to the shear plane, ε_r is the relative dielectric constant of the medium, and n_i and z_i are the bulk concentration and valence of the ith ion in the system, respectively. It is worthwhile to note that a positively charged surface results in a positive zeta potential in a dilute system. A high concentration of counterions, however, can result in a zeta potential of the opposite sign.

The mobility of a nanoparticle in a colloidal dispersion or a sol is dependent on the dielectric constant of the liquid medium, the zeta potential of the nanoparticle, and the viscosity of the fluid. Several forms for this relationship have been proposed, such as the Hückel equation [96]

$$\mu = \frac{2\varepsilon_r \varepsilon_0 \zeta}{3\pi\eta} \tag{13}$$

Double layer stabilization and electrophoresis are extensively studied subjects. Readers may find additional detailed information in books on sol–gel processing [97–99] and colloidal dispersions [96, 100].

Electrophoretic deposition simply uses such an oriented motion of charged particles to grow films or monoliths by enriching the solid particles from a colloidal dispersion or a sol onto the surface of an electrode. If particles are positively charged (more precisely speaking, having a positive zeta potential), then the deposition of solid particles will occur at the cathode. Otherwise, deposition will be at the anode. At the electrodes, surface electrochemical reactions proceed to generate or receive electrons. The electrostatic double layers collapse upon deposition on the growth surface, and the particles coagulate. There is not much information on the deposition behavior of particles at the growth surface. Some surface diffusion and relaxation is expected. Relatively strong attractive forces, including the formation of chemical bonds between two particles, develop once the particles coagulate. The films or monoliths grown by electrophoretic deposition from colloidal dispersions or sols are essentially a compaction of nanosized particles. Such films or monoliths are porous (i.e., there are voids inside). Typical packing densities, defined as the fraction of solid (also called green density), are less than 74%, which is the highest packing density for uniformly sized spherical particles [101]. The green density of films or monoliths by electrophoretic deposition is strongly dependent on the concentration of particles in sols or colloidal dispersions, zeta potential, externally applied electric field, and reaction kinetics between particle surfaces. Slow reaction and slow arrival of nanoparticles onto the surface would allow sufficient particle relaxation

on the deposition surface, so that a high packing density is expected.

Many theories have been proposed to explain the processes at the deposition surface during electrophoretic deposition. The electrochemical process at the deposition surface or electrodes is complex and varies from system to system. However, in general, a current exists during electrophoretic deposition, indicating reduction and oxidation reactions occur at electrodes and/or deposition surface. In many cases, films or monoliths grown by electrophoretic deposition are electric insulators. However, the films or monoliths are porous and the surface of the pores would be electrically charged just like the nanoparticle surfaces, since surface charge is dependent on the solid material and the solution. Furthermore, the pores are filled with solvent or solution that contains counterions and charge-determining ions. The electrical conduction between the growth surface and the bottom electrode could proceed via either surface conduction or solution conduction.

Limmer et al. [102, 103] combined sol–gel preparation and electrophoretic deposition in the growth of nanorods of various oxides, including complex oxides such as lead zirconate titanate and barium titanate. In their approach, conventional sol–gel processing was applied for the synthesis of various sols. By appropriate control of the sol preparation, nanometer particles with desired stoichiometric composition were formed, electrostatically stabilized by adjusting to an appropriate pH and uniformly dispersed in the solvent. When an external electric field is applied, these electrostatically stabilized nanoparticles will respond and move toward and deposit on either a cathode or an anode, depending on the surface charge (more precisely speaking, the zeta potential) of the nanoparticles. Using radiation-tracked etched polycarbonate membranes with an electric field of ~1.5 V/cm, they have grown nanowires with diameters ranging from 40 to 200 nm and a length of 10 μm corresponding to the thickness of the membrane. The materials include anatase TiO_2, amorphous SiO_2, perovskite structured $BaTiO_3$ and $Pb(Ti,Zr)O_3$, and layered structured perovskite $Sr_2Nb_2O_7$. Nanorods grown by sol electrophoretic deposition are polycrystalline or amorphous. One of the advantages of this technique is the ability of synthesis of complex oxides and organic–inorganic hybrids with desired stoichiometric composition; Figure 9 shows the nanorods and X-ray diffraction spectra of $Pb(Zr,Ti)O_3$ nanorods. Another advantage is the applicability for a variety of materials; Figure 10 shows the nanorods of SiO_2, TiO_2, $Sr_2Nb_2O_7$, and $BaTiO_3$.

Wang et al. used electrophoretic deposition to form nanorods of ZnO from colloidal sols [104]. ZnO colloidal sol was prepared by hydrolyzing an alcoholic solution of zinc acetate with NaOH, with a small amount of zinc nitrate added to act as a binder. This solution was then deposited into the pores of anodic alumina membranes at voltages in the range of 10–400 V. It was found that lower voltages led to dense, solid nanorods, while higher voltages caused the formation of hollow tubules. The suggested mechanism is that the higher voltages cause dielectric breakdown of the anodic alumina, causing it to become charged similarly to the cathode. Electrostatic attraction between the ZnO nanoparticles and the pore walls then leads to tubule formation.

Miao et al. [105] prepared single crystalline TiO$_2$ nanowires by template-based electrochemically induced sol–gel deposition. Titania electrolyte solution was prepared using a method developed by Natarajan and Nogami [106], in which Ti powder was dissolved into a H$_2$O$_2$ and NH$_4$OH aqueous solution, forming TiO^{2+} ionic clusters. When an external electric field was applied, TiO^{2+} ionic clusters diffused to cathode and underwent hydrolysis and condensation reactions, resulting in deposition of nanorods of amorphous TiO$_2$ gel. After heat treatment at 240 °C for 24 hr in air, nanowires of single crystal TiO$_2$ with anatase structure and with diameters of 10, 20, and 40 nm and lengths ranging from 2 to 10 μm were synthesized. However, no axis crystal orientation was identified. The formation of single crystal TiO$_2$ nanorods here is different from that reported by Martin's group [107]. Here the formation of single crystal TiO$_2$ is via crystallization of amorphous phase at an elevated temperature, whereas nanoscale crystalline TiO$_2$ particles are believed to assemble epitaxially to form single crystal nanorods. Epitaxial agglomeration of two nanoscale crystalline particles has been reported [108], though no large single crystals have been produced by assembly of nanocrystalline particles. Figure 11 shows such single crystal nanorods grown by electrophoretic deposition.

3.3. Template Filling

Direct template filling is the most straightforward and versatile method in preparation of nanorods and nanotubules. Most commonly, a liquid precursor or precursor mixture is used to fill the pores. There are several concerns in the template filling. First, the wettability of the pore wall should be good enough to permit the penetration and complete filling of the liquid precursor or precursor mixture. For filling at low temperatures, the surface of pore walls can be easily modified to be either hydrophilic or hydrophobic by introducing a monolayer of organic molecules. Second, the template materials should be chemically inert. Third, control of shrinkage during solidification is required. If adhesion between the pore walls and the filling material is weak or solidification starts at the center, or from one end of the pore, or uniformly, solid nanorods are most likely to form.
Figure 11. Single crystal TiO$_2$ nanorods growth by electrochemically induced sol–gel processing. Reprinted with permission from [105], Z. Miao et al., *Nano Lett.* 2, 717 (2002). © 2002, American Chemical Society.

However, if the adhesion is very strong, or the solidification starts at the interfaces and proceeds inwardly, it is most likely to form hollow nanotubules.

3.3.1. Colloidal Dispersion Filling

Martin and co-workers [107, 109] have studied the formation of various oxide nanorods and nanotubules by simply filling the templates with colloidal dispersions. Colloidal dispersions were prepared using appropriate sol–gel processing. The filling of the template was to place a template in a stable sol for a various period of time. The capillary force is believed to drive the sol into the pores, when the surface chemistry of the template pores was appropriately modified to have a good wettability for the sol. After the pores were filled with sol, the template was withdrawn from the sol and dried prior to firing at elevated temperatures. The firing at elevated temperatures served two purposes: removal of template so that freestanding nanorods can be obtained and densification of the sol–gel-derived green nanorods. Figure 12 shows some typical examples of oxide nanorods made by filling the templates.

In previous work, we discussed sol–gel processing and knew that the typical sol consists of a large volume fraction of solvent up to 90% or higher [97]. Although the capillary force may ensure the complete filling of colloidal dispersion inside pores of the template, the amount of the solid filled inside the pores can be very small. Upon drying and subsequent firing processes, a significant amount of shrinkage would be expected. However, the results showed that
most nanorods shrank only a little as compared with the size of the template pores. For example, Lakshmi et al. found that TiO_2 nanorods synthesized in this manner had the same diameter as the template pores, even after heating to 400 °C [107]. The results indicated that there are some unknown mechanisms which enrich the concentration of solid inside pores. One possible mechanism could be the diffusion of solvent through the membrane, leading to the enrichment of solid along the internal surface of template pores, a process used in ceramic slip casting [110]. The observation of formation of nanotubules (as shown in Fig. 13) by such a sol filling process may imply such a process is indeed present. However, considering the fact that the templates typically were emerged into sol for just a few minutes, the diffusion through membrane and enrichment of solid inside the pores must be a rather rapid process. It is also possible that electrostatic attraction between the positive particles and negative pore walls is responsible for this enrichment. This is a very versatile method and can be applied for any material, which can be made by sol–gel processing. However, the drawback is that it is difficult to ensure the complete filling of the template pores. It is also noticed that the nanorods made by template filling are commonly polycrystalline or amorphous. An exception was found: when the diameter of nanorods is smaller than 20 nm, single crystal TiO_2 nanorods were made [107].

3.3.2. Melt and Solution Filling

Metallic nanowires can also be synthesized by filling a template with molten metals [111]. One example is the preparation of bismuth nanowires by pressure injection of molten bismuth into the nanochannels of an anodic alumina template [112]. The anodic alumina template was degassed and immersed in the liquid bismuth at 325 °C ($T_m = 271.5$ °C for Bi), and then high pressure Ar gas of ~4500 psi was applied to inject liquid Bi into the nanochannels of the template for 5 hours. Bi nanowires with diameters of 13–110 nm and large aspect ratios of several hundred have been obtained. Individual nanowires are believed to be single crystal. When exposed to air, bismuth nanowires are readily oxidized. An amorphous oxide layer of ~4 nm in thickness was observed after 48 hours. After 4 weeks, bismuth nanowires of 65 nm in

diameter were found to be completely oxidized. Nanowires of other metals, In, Sn, and Al, and semiconductors, Se, Te, GaSb, and Bi_2Te_3, were prepared by injection of melt liquid into anodic alumina templates [111].

Polymeric fibrils have been made by filling a monomer solution, which contains the desired monomer and a polymerization reagent, into the template pores and then polymerizing the monomer solution [113–116]. The polymer preferentially nucleates and grows on the pore walls, resulting in tubules at short deposition times, as discussed previously in the growth of conductive polymer nanowires or nanotubules by electrochemical deposition and fibers at long times. Cai et al. [117] synthesized polymeric fibrils using this technique.

Similarly, metal and semiconductor nanowires have been synthesized through solution techniques. For example, Han et al. [118] have synthesized Au, Ag, and Pt nanowires in mesoporous silica templates. The mesoporous templates were filled with aqueous solutions of the appropriate metal salts (such as $HAuCl_4$), and after drying and treatment with CH_2Cl_2 the samples were reduced under H_2 flow to convert the salts to pure metal. Chen et al. filled the pores of a mesoporous silica template with an aqueous solution of Cd and Mn salts, dried the sample, and reacted it with H_2S gas to convert to (Cd,Mn)S [119]. $Ni(OH)_2$ nanorods have been grown in carbon-coated anodic alumina membranes by Matsui et al. [120], by filling the template with ethanolic $Ni(NO_3)_2$ solutions, drying, and hydrothermally treating the sample in NaOH solution at 150 °C.

3.3.3. Chemical Vapor Deposition

Some researchers have used chemical vapor deposition as a means to form nanowires. Ge nanowires were grown by Leon et al. by diffusing Ge_2H_6 gas into mesoporous silica and heating [121]. They believed that the precursor reacted with residual surface hydroxyl groups in the template, forming Ge and H_2. Lee et al. have used a platinum organometallic compound to fill the pores of mesoporous silica templates, followed by pyrolysis under H_2/N_2 flow to yield Pt nanowires [122].

3.3.4. Converting through Chemical Reactions

Nanorods or nanowires can also be synthesized using consumable templates [123]. Nanowires of compounds can be synthesized or prepared using a template-directed reaction. First nanowires or nanorods of a constituent element are prepared and then reacted with chemicals containing the desired element to form final products. Gates et al. [124] converted single crystalline trigonal selenium nanowires into single crystalline nanowires of Ag_2Se by reacting with aqueous $AgNO_3$ solutions at room temperature. The trigonal selenium nanowires were prepared first also using a solution synthesis method [17]. Selenium nanowires were either dispersed in water or supported on TEM grids during reaction with aqueous $AgNO_3$. The following chemical reaction was suggested:

$$3Se_{(s)} + 6Ag^+_{(aq)} + 3H_2O$$
$$\rightarrow 2Ag_2Se_{(s)} + Ag_2SeO_{3(aq)} + 6H^+_{(aq)} \qquad (14)$$
Nanorods can also be synthesized by reacting volatile metal halide or oxide species with formerly obtained carbon nanotubes to form solid carbide nanorods with diameters between 2 and 30 nm and lengths up 20 μm [125, 126]. Carbon nanotubes were used as removable templates in the synthesis of silicon and boron nitride nanorods [127]. Silicon nitride nanorods of 4–40 nm in diameter were also prepared by reacting carbon nanotubes with a mixture of silicon monoxide vapor and flowing nitrogen at 1500 °C [128]:

$$3SiO_{(g)} + 3C_{(s)} + 2N_{2(g)} \rightarrow Si_3N_{4(s)} + 3CO_{(g)} \qquad (15)$$
Silicon monoxide is generated by heating a solid mixture of silicon and silica in an alumina crucible at 1500 °C. The total transformation of carbon nanotubes into silicon nitride nanorods was observed.

ZnO nanowires were prepared by oxidizing metallic zinc nanowires [129]. In the first step, polycrystalline zinc nanowires without preferential crystal orientation were prepared by electrodeposition using anodic alumina membrane as a template, and in the second step, grown zinc nanowires were oxidized at 300 °C for up to 35 hr in air, yielding polycrystalline ZnO nanowires with diameters ranging from 15 to 90 nm and lengths of ∼50 μm. Although ZnO nanowires are embedded in the anodic alumina membranes, freestanding nanowires may be obtained by selectively dissolving alumina templates.

Hollow nanotubules of MoS_2 of ∼30 μm long and 50 nm in external diameter with wall thickness of 10 nm were prepared by filling a solution mixture of molecular precursors, $(NH_4)_2MoS_4$ and $(NH_4)_2Mo_3S_{13}$, into the pores of alumina membrane templates. Then template filled with the molecular precursors was heated to an elevated temperature and the molecular precursors thermally decomposed into MoS_2 [130].

Certain polymers and proteins were also reported to have been used to direct the growth of nanowires of metals or semiconductors. For example, Braun et al. [131] reported a two-step procedure to use DNA as a template for the vectorial growth of silver nanorods of 12 μm in length and 100 nm in diameter. CdS nanowires were prepared by polymer-controlled growth [132]. For the synthesis of CdS nanowires, cadmium ions were well distributed in a polyacrylamide matrix. The Cd^{2+} containing polymer was treated with thiourea (NH_2CSNH_2) solvothermally in ethylenediamine at 170 °C, resulting in degradation of polyacrylamide. Single crystal CdS nanowires of 40 nm in diameter and up to 100 μm in length with a preferential orientation of [001] were then simply filtered from the solvent.

4. LITHOGRAPHY

Lithography represents another route to the synthesis of nanowires. Various techniques have been explored in the fabrication of nanowires, such as electron beam lithography [133, 134], ion beam lithography, scanning tunnelling microscope lithography, X-ray lithography, proximal-probe lithography, and near-field photolithography [135]. Nanowires with diameters less than 10 nm and an aspect ratio of 100 can be readily prepared. Here we just take the fabrication of single crystal silicon nanowires

reported by Yin et al. [136] as an example to illustrate the general approach and the products obtained. Figure 14 outlines the schematic procedures used for the preparation of single crystal silicon nanowires. The nanoscale features were defined in a thin film of photoresist by exposing it to an ultraviolet light source through a phase shift mask made of a transparent elastomer, such as poly(dimethysiloxane) (PDMS). The light passing through this phase mask was modulated in the near field such that an array of nulls in the intensity was formed at the edges of the relief structures patterned on the PDMS mask. Therefore, nanoscale features were generated in a thin film of photoresist and the patterns were transferred into the underlying substrate using a reactive ion etching or wet etching process. Silicon nanostructures were separated from the underlying substrate by slight overetching. Figure 15 shows SEM images of silicon nanostructures fabricated using such near-field optical lithography, followed by pattern transfer into silicon with reactive ion etching, oxidation of silicon at 850 °C in air for ~1 hr, and finally lift-off in HF solution.

5. SUMMARY

This chapter summarizes the fundamentals and general approaches for the preparation of one-dimensional nanostructures, with emphasis on the synthesis and fabrication of oxide nanorods and nanowires. For a given fundamental concept, many different approaches can be taken and indeed have been developed. However, not all the synthesis methods have been included in this chapter. The coverage is limited so that the important fundamentals and concepts are included. It is certain that many new synthesis techniques will be developed soon.

GLOSSARY

Electrophoretic deposition The motion of charged particles in a sol or suspension under an applied electric field.

Electrostatic stabilization The surface of particles in a suspension becomes charged and counterions in the solvent will distribute in such a way that an electrical double layer at the vicinity of each particle will be formed. This layer is due to a combination of electrostatic force, entropic force, and Brownian motion. Such an electrical double layer will keep the nanoclusters from agglomerating, and thus a stable suspension is obtained.

Sol–gel processing A solution chemical route for forming oxide materials. Metal-organic (or inorganic) precursors undergo hydrolysis and condensation reactions, forming a stable suspension of nanoparticles (sol) or a continuous oxide network (gel).

Template growth The use of a physical template (such as a porous filtration membrane) to direct the formation of nanorods.

VLS growth Growth in which a catalyst is purposely introduced to direct and confine the crystal growth on a specific orientation and within a confined area. The catalyst forms a liquid droplet by itself or by alloying with growth material, trapping growth species. An enriched growth species in the catalyst droplets subsequently precipitates at the growth surface resulting in the one-directional growth.

Industrial Technology Research Institute, Hsin-Chu, Taiwan, R.O.C.

CONTENTS

1. INTRODUCTION

Mono- and bimetallic nanoparticles are of great interest due to their prominent chemical and physical properties. These nanoparticles, which are usually defined as isolable particles between 1 and 50 nm in size, could be newly categorized as mesoscopic materials [1]. This new category of materials, different from bulk material or atoms, can be defined as an "atom assembly" or "molecule" rather than the classical term "colloid." If the nanoparticles are well controlled in structure, the term "cluster" is often used [2]. In this chapter, we focus on the nanocluster of palladium and its alloy, which shows outstanding performance in a catalyst [3]. Various potential applications are also being explored owing to its extremely high surface area and different electronic structure.

Palladium and its bimetallic nanoparticles can be prepared from reduction of the corresponding metal salt encapsulated in various stabilizers, such as reversed micelle [4–7], dendrimer [8–9], and biomolecules [10–11]. In the early stage of nucleation, the metal salt is reduced to a zero-valent metallic state. Then, the metal atoms further collide with other atoms or clusters to form irreversible nuclei in the solution [1]. These stable nuclei provide (usually well below 1 nm, depending on the metal–metal bonds and the redox potential) seeds for the subsequent growth of particles. To prevent further agglomeration, the addition of protective agents is essential to control the particle in nanosize. These protective agents can be grouped as electrostatic and steric effects on the basis of different modes of stabilization [12]. Electrostatic stabilization is based on the coulumbic repulsion force between individual nanoparticles, where ligands (e.g., sodium citrate) are adsorbed on the surface of clusters, while steric stabilization is accomplished by the coordination of organic molecules, including polymers, surfactants, thiol derivatives, and long-chain alcohols, on the particle surfaces.

Now, those electronic, surface-to-volume, and optical properties are all size dependent for metal colloidal particles. The technology for the mass production of nanoparticles with enough uniformity becomes important and essential. With proper choices of precursor concentration, reductants, and stabilizers, highly monodispersed nanoparticles can be achieved, and much effort is being directed to this area.

2. SYNTHESIS OF PALLADIUM AND ITS ALLOY NANOPARTICLES

Colloidal Pd nanoparticles are, in general, prepared by the reduction of metal salt in a chemical, sonochemical, or electrochemical system. The system can be confined space or free space surrounded by appropriate templates, including surfactants, soluble polymers, and mesoporous materials.

2.1. Confined-Space Reduction Method

2.1.1. Reverse Micelle

Reverse micelle is an isotropic and thermodynamically stable system consisting of water nanodroplets surrounded by proper organic surfactants. These well-established nanostructures make microemulsion an ideal vehicle to synthesize metal nanoparticles by exchanging materials within hydrophilic nanodroplets. Furthermore, manipulation of the particle sizes can be achieved by simply altering the micellar radius. This is of great importance to control the particle dimension since nanomaterials reveal a "size-dependent" property.

In a reverse micelle system, exchanging reactants occur within water droplets by collisions to form dimers, and subsequently to form two separate nanodroplets again. The material exchange process is governed by: (1) the dimers formed by contacting micelles, and (2) the exchange process between two water pool droplets [13]. The first factor is related to the attractive interaction and collision of two micelles. The latter is due to the interface rigidity arising from the dynamic property of the interface. Controlling these parameters could affect the reaction rate, and thus change the particle size [4].

Palladium nanoclusters have been prepared in a water/ sodium bis(2–ethylhexyl) sulfosuccinate (AOT)/n–heptane microemulsion system [7]. In addition, a systematic study of the synthesis of Pd nanoparticles, including the kinetics of particle formation, was reported by Chen et al. [6]. The palladium particle size is mainly affected by the molar ratio of water to AOT (ω_0) and the concentration of palladium salt. Other factors, such as the AOT concentration, temperature, and pH of the aqueous phase, are less influential under the experimental conditions. During the particle formation, nucleation occurs without the formation of particles in the fast few minutes. In the following tens of minutes, the particles form, and gradually reach their final sizes. In addition to a systematic kinetic study, Chen et al. compare the diameter differences between reverse micelle and the formed metallic nanoparticles. The hydrodynamic diameters of reverse micelles, which are characterized by dynamic light scattering, are smaller than those of palladium nanoparticles. This phenomenon suggests that micelles might be enlarged by the growth of particles, although the reverse micelles limit the growth of particles.

In addition to palladium ultrafine particles, other Pd-based bimetallic nanoparticles prepared in a water/oil (w/o) microemulsion system have also been studied [5, 14]. In a Pd/Pt bimetallic system, the nanoclusters reveal a homogeneous alloy structure, and the composition is roughly identical to that of the feeding solution, while the Pd/Au alloy appears Pd-rich in the outer part of the nanoparticles. Thus, the reverse micelle technique, which provides versatile choices of materials, is shown to be a powerful method to prepare colloidal metal particles.

2.1.2. Dendrimer

Dendrimers are monodisperse, well-structured, and hyper-branched polymers with a high concentration of functional groups. They are extensively used as templates for the synthesis of palladium nanoparticles [8–9]. The advantages of dendrimers can be described as follows. (1) The monodisperse nanoparticles can be accomplished due to the highly uniform and well-defined porosity of the dendrimer template. (2) The hyperbranched dendrimers prevent particles from agglomeration stemming from the steric effect. (3) The surfaces of nanoparticles are only partially encapsulated by dendrimers, and therefore leave a substantial portion of the surface atoms for the following catalytic reactions, whereas some stabilizers will strongly absorb on the surface, and thus block the active sites for subsequent catalytic reactions. (4) By adjusting generations of dendrimers, different solvents, and functional groups, a dendrimer could act

as a "nanofilter" to control the access of small molecules (substrates) to the catalytic nanoparticles. (5) The terminal groups on the dendrimers can be linked to other functional groups, and therefore change the solubility of the nanocomposite between the hydrophilic and hydrophobic phases [15].

Two dendrimers, poly(amidoamine) (PAMAM) and poly(propylene imine) (PPI), were widely used to synthesize colloidal palladium particles [7–8, 15]. The dendrimers retain a guest molecule by covalent bonding, complex, electrostatic, or van der Waals force, and so on. Besides the formation of uniform palladium nanoparticles, the dendrimer-encapsulated Pd particles undergo phase transfer by adjusting the pH value, as illustrated in Figure 1 [8]. This reversible approach, which is driven on the basis of acid base and ion pairing, can shuttle the guests encapsulated in dendrimers between the hydrophobic and hydrophilic phases. This is of great importance, especially in homogeneous and colloidal catalytic reactions, because the catalyst is difficult to separate from the organic reaction mixture. So the recycling of a colloidal catalyst, an important "green chemistry" approach, can be accomplished by extracting the catalyst from the organic reaction mixture to the water phase through adjustment of the pH values.

In addition to Pd nanoparticles, bimetallic ultrafine particles can also be prepared in a dendrimer. Bimetallic nanomaterial can be prepared by the partial displacement reaction, cocomplexation, and sequential loading methods, as shown in Figure 2. Based on these procedures, a trimetallic or core/shell nanostructure might also be achieved with the aid of the encapsulation of dendrimers [15].

2.1.3. Hard Template

Many mesoporous materials, such as polycarbonate, aluminum oxide, carbon tube, and silica, can be used as hard templates for the synthesis of nanomaterials in different shapes, including nanowire, nanoball, and dendritic nanostructures [16–19]. Metal salts or organometallic precursors are reduced to their corresponding zero-valent state

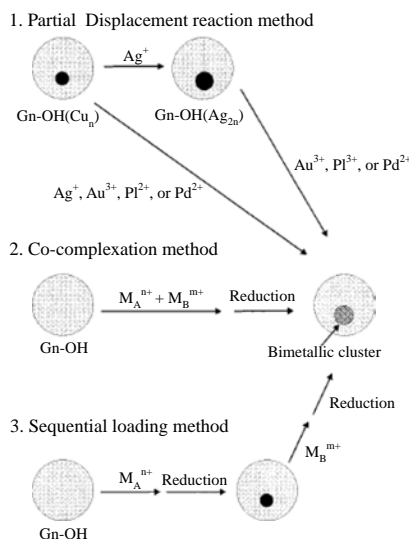

Figure 2. Three possible routes for the synthesis of bimetallic nanoparticles encapsulated in dendrimer. Reprinted with permission from [15], R. M. Crooks et al., *Acc. Chem. Res.* 34, 181 (2001). © 2001, American Chemical Society.

in the well-defined mesoporous templates. The skeleton of nanomaterials is therefore identical to the nanosized porous architecture. Among these hard templates, mesoporous silica is the most frequently used for preparing Pd nanomaterial. In order to fabricate a mesoscopically well-defined silica template, surfactants and silicate species are used for the self-assembly process under hydrothermal treatment. On the basis of the nanostructure, the M41S mesoporous silica can be categorized into hexagonal (MCM-41), cubic (MCM-48), and unstable lamellar (MCM-50). Furthermore, the architecture of mesoporous silica can be manipulated by adjusting the temperature and the addition of alcohol [20–21]. Therefore, the resulting structure of the nanomaterial can be significantly varied in shape by changing the template structure.

Porous palladium nanoballs and nanowires, as illustrated in Figures 3 and 4, can be prepared with the aid of mesoporous silica [16–17]. In this work, palladium nanostructures were produced in a silica matrix via chemical vapor infiltration (CVI), by which the organometallic precursor is decomposed under a mild thermal condition without deterioration of the silica template. Characterization by X-ray diffraction (XRD) reveals that the crystal structure is identical to that of bulk palladium. Moreover, the melting point of Pd nanowires is observed around 300 °C, which is significantly lower than that of the bulk material (1552 °C). This phenomenon is due to the high surface-to-volume ratio of the nanomaterials.

In addition to mesoporous silica, carbon material can serve as a template for the production of nanomaterials. Figure 5 shows the growth of hexagonal quasi-2-D palladium nanoparticles with the assistance of a carbon template [22]. The graphite sheet is used for the monolayer intercalation of the palladium precursor. The palladium ion is reduced to a hexagonal quasi-2-D structure, follow by H_2 reduction at a high temperature. Furthermore, the formation of the hexagonal crystal structure of Pd atoms results

from their interaction and induction with a hexagonal host lattice. The carbon sheet template controls the formation of the nanostructure in not only the lateral direction, but also in a vertical orientation, resulting in hexagonal quasi-2-D palladium nanoparticles.

Besides lamellar graphite, carbon nanotubes can also be applied for nanoparticle fabrication. Carbon nanotubes, which are different in structure from graphite and diamond, are rolled up cylindrically with a diameter in the nanoscale. The structure and morphology of the carbon nanotube justify its use as a template for synthesizing nanoparticles. Figure 6 shows the transmission electron microscopy (TEM) images of Pd nanoparticles grown on carbon nanotubes [23]. Most palladium nanoparticles developed on the outer surface of the carbon nanotubes and XRD characterization reveal well-crystallized Pd with lattice contraction.

Recently, another novel method for the preparation of palladium dendritic nanostructures was proposed, as shown in Figure 7 [18]. Raney nickel, which is derived from an Ni–Al alloy, is composed of a porous pattern, which is suit-

Figure 7. (a) TEM images of palladium dendrites. (b) The corresponding SAED pattern using Raney nickel as a template with the assistance of ultrasonic waves. Reprinted with permission from [18], J. Xiao et al., *Adv. Mater.* 13, 1887 (2001). © 2001, Wiley-VCH Verlag GmbH.

able to be a host material. In addition to the well-established nanostructure, Raney nickel can be easily removed with dilute HCl without damage to the dendritic Pd structure. Figure 8 illustrates a typical process for the fabrication of palladium dendrites. First, Pd^{2+} diffuses into the pores of Raney nickel with the aid of ultrasonic waves. Then, an interspace in the skeleton of the template is formed, and Pd^{2+} is reduced by Raney nickel. This process continues until the complete reduction of Pd^{2+}. In this case, Raney nickel works not only as a template, but also as a reductant, while other templates, such as mesoporous silica and a carbon nanotube, only play the role of a template. Moreover, a presumable mechanism of a diffusion-limited aggregation (DLA) model is also proposed to account for the dendritic growth.

2.2. Free-Space Reduction Method

2.2.1. Quasione-Dimensional DNA Template

In a biological system, a metal cluster can be used as an additional tool for the investigation of micromanipulation. Among these biological molecules, deoxyribonucleic acid (DNA) is particularly important since it is 2 nm in diameter and several micrometers in length with well-ordered sequent bases. The quasione-dimensional Pd nanostructure can be accomplished by metallization of DNA, as shown in Figure 9 [10]. The surface of the DNA was first activated with a Pd ion, and then immersed in a reduction solution consisting of sodium citrate, lactic acid, and dimethyl amine borane (DMAB). The separated metal clusters, which were formed in the beginning, gradually aggregated into a quasi-1-D metallic structure with a 3–5 nm diameter. In addition to formation of metallic DNA in solution, they could be immobilized with alignment on the substrate by controlling the evaporation of the solution. Accordingly, metallic DNA can be fixed between electrical contacts for further investigation.

2.2.2. Sonochemical Reduction

Sonochemistry relates to chemical reactin under the influence of acoustic cavitations, which generate extremely high temperature (thousands of degrees), pressure (megapascal), as well as a high cooling rate ($\approx 10^{10}$ K/s). It can be applied for manufacturing Pd nanoparticles [24–25]. The radicals arising from pyrolysis of the solvent and/or stabilizer can reduce Pd^{2+} to Pd^0, resulting in the formation of metallic particles. To prevent agglomeration, the addition of a biotemplate or solid template is essential [24–27]. In the sonochemical process, there are two different regions where the reaction might occur, that is, (1) the gas phase within the cavity, where extremely high temperature and pressure are generated, and (2) the liquid layer surrounding the collapsing cavity, where the chemical environment is still capable of conducting the sonochemical reaction even though the temperature is lower than that of the gas phase. In general, the liquid phase plays the major part in the sonochemical decomposition of the precursor since the low vapor pressure of the precursor in the gas phase eliminates the possibility of reaction within this zone.

A novel palladium nanostructure, an amorphous and carbon-activated porous nanoparticle, has been prepared with the assistance of ultrasound irradiation [26]. The organometallic precursor, tris–μ–[dibenzylideneacetone]di-palladium [$Pd_2(DBA)_3$], is decomposed, and therefore reduced to nanosize palladium particles with DBA ligands absorbing on the metal surface. These carbon-rich ligands may further crack into atomic carbon atoms or other volatile fragments due to the vigorous chemical environment, which cannot be obtained by conventional synthetic techniques. The carbon species so obtained form a protecting shell, and prevent Pd particles from coalescence, as demonstrated in Figure 10. Furthermore, the result of differential scanning calorimetry reveals that carbon-activated Pd particles have a broad peak with a long tail, while typical amorphous metal particles exhibit a sharp exothermic characterization. This interesting phenomenon might result from the presence of atomic carbons, which inhibit the crystallization process and influence the surface free energy of Pd particles.

2.2.3. Electrochemical Preparation

An electrochemical technique is commonly employed to reduce the metal ion to a metallic state on an electrode. Naturally, it has also been used widely for the size-selective
Figure 10. Transmission electron micrographs of initial carbon-activated Pd; scale bar: 50 nm. Reprinted with permission from [26], N. A. Dhas et al., *J. Phys. Chem. B* 101, 6834 (1997). © 1997, American Chemical Society.

preparation of Pd and its alloy nanomaterial [28–31]. A sacrificial anode usually serves as the meal source, while the surfactants (e.g., $R_4N^+X^-$) act as an electrolyte and stabilizer in organic solvent, as illustrated in Figure 11. The metal ions arising from the oxidation of the anode migrate to the cathode, and are reduced to ad atoms. These metal clusters
Figure 11. Schematic representation of electrochemical formation of $R_4N^+X^-$-stabilized transition metal colloids. Reprinted with permission from [29], M. T. Reetz et al., *Chem. Eur. J.* 7, 1084 (2001). © 2001, Wiley-VCH Verlag GmbH.

are then trapped by stabilizers, and form colloidal nanoparticles rather than metallic powders.

A systematic investigation of the electrochemical parameters on particle size has been carried out by Reetz and co-workers [29]. The first factor is the solvent effect. With increasing polarity of the medium (e.g., the addition of acetonitrile), the particle size also increases due to the reduced electrostatic interaction between the colloids in a polar solution. The second parameter is the charge flow. The particle sizes increase with increasing charge flow, and the effect is especially pronounced in the early stage of electrolysis. This phenomenon suggests that the diameter of the particle is largely influenced by the growth mechanism. The third effect is the current density. A fast nucleation rate, which results from the high current density, accounts for the formation of smaller particle sizes. The fourth is the temperature effect. The particle size increases with elevating temperature. This consequence arises from the higher diffusion, migration, and dissociation rate of the palladate intermediate, as well as the decreasing viscosity of the medium.

A combination of scanning tunneling microscopy (STM) and transmission electron microscopy is used to examine the actual structure of surfactant-protected nanomaterials [11]. The TEM study reveals the diameter of the metal core, while the STM can probe the outer dimensions of the nanostructure. The difference between these two diameters is directly related to the thickness of the stabilizer. On the basis of these studies, a model of a monolayer-coated palladium nanoparticle is proposed.

In addition to colloidal palladium, the electrochemical system has been extended to prepare a bimetallic colloid [30–31]. Reetz has shown that the colloidal alloy structure can be synthesized simultaneously by using two sacrificial anodes. Alternatively, one can start with the first colloidal metal, and subsequently reduce the second metal onto the formed particles electrochemically. Thus, electrochemical preparation provides various choices in materials, and the control of sizes could be easily accomplished by adjustment of the experimental conditions.

2.2.4. Metal Salt Reduction via Wet Chemical Method

The basic principle for the wet chemical preparation of colloidal nanoparticles is the reduction of the metal precursor with reductants under the protection of stabilizers. The choices of stabilizers can be versatile, including ligands [32–36] and soluble polymers [37–39]. These stabilizers, which play an important role in synthesis, can affect the particle size and the stability of the colloid. Owing to its reasonable cost and convenience, this approach has become one of the most common and powerful methods for the preparation of colloidal particles.

Protection by Ligands A palladium colloid can be protected by nitrogen-containing ligands such as phenanthroline, sodium sulfanilate [32], and water-soluble isocyanide [33]. A systematic study concerning the control of particles size has been reported by Quiros et al. [35]. In general, a long chain of ligands, increasing the amount of the stabilizer, and lengthening the reaction time all favor the diminution of colloidal particles. It seems that the formation of

self-assembly by a long-chained stabilizer occurs faster than that of the shorter one, due to the increase in hydrophobic interaction. This trend is also consistent with isocyanide-protected Pd nanoparticles [33].

These common synthetic methods, unfortunately, usually limit the diameter of palladium particles ($<$45 nm). In order to synthesize larger Pd particles (25–100 nm), a seeding growth method, protected by citric acid, has been proposed [36]. 12 nm diameter Au nanoparticles, used as "heterogeneous seeds" for the subsequent procedure, were prepared by the reduction of citric acid. The larger Pd particles were formed, following the reduction of Pd^{2+} onto the surface of preformed Au particles. The mean size of the particles increases from 25 to 100 nm by decreasing the gold seed concentration. Furthermore, the approach could be scaled up to produce larger and monodispersed palladium nanoparticles.

Stabilized by Polymer A solvent soluble polymer, poly(N–vinyl–2–pyrrolidone) (PVP), is widely chosen as a protective agent for the preparation of Pd ultrafine particles. PVP prevents the preformed particles from coalescence by the steric effect stemming from tail or loop segments of the polymer dispersing in the solvent. The higher the molecular weight of PVP is, the larger is the particle size [37]. This phenomenon is attributed to the larger fraction of high molecular weight adsorbing on the particle surface compared to that of low molecular weight. In addition, the thickness of the adsorbed layer on palladium increases by increasing the molecular weight on the basis of sedimentation with an ultracentrifugation study.

Besides the effect of PVP, there are other factors affecting the particle size [38]. The pH value, reaction temperature, and the types of reductants all play important roles in controlling the nucleation and crystal growth rate, and therefore affect the diameter of the size. A series of alcohols, including methanol, ethanol, propan–1–ol, propan–2–ol, butan–1–ol, and ethylene glycol, served as reducing agents. In general, the particle size is inversely proportional to the reducing power provided by the alcohol. In addition, a higher pH value and lower reaction temperature both result in the formation of smaller particle.

Different particle sizes of palladium nanoclusters can be accomplished by a stepwise procedure without changing other experimental conditions [39]. The preformed Pd nanoparticles are used as "homogeneous seeds" for the subsequent growth of palladium. Furthermore, the XRD patterns reveal that different sizes of Pd nanoparticles have a face-center cubic (fcc) structure in spite of the dilation of the lattice constant with decreasing particle sizes.

2.2.5. Metal Salt Reduction via Reactive Micelle as Template

When metal nanoparticles are prepared by chemical methods, the metal ions are often reduced by a reducing agent that is externally added. A protective agent is also added to stabilize the nanoparticles produced. Typical reducing agents are N_2H_4 [40], $NaBH_4$ [41], H_2 [42], and alcohol [38–39]. The choice of reductant and its concentration can drastically affect the nucleation rate and particle size: this highlights the complexity and delicacy of this reaction.

Recently, a method to chemically prepare noble metal nanoparticles without externally added reductant was developed [43]. The reductant is *in-situ* generated through the gradual decomposition of the surfactant contained in the solution as a protective agent. The surfactant chosen is an alcohol-type surfactant, sodium alkyl sulfate, which simultaneously acts as both the reductant and protective agent. In this method, sodium alkyl sulfate can gradually release the nonpolar alcohol of a long carbon chain in the system during refluxing [Eq. (1)]. Then, metal ions that had diffused into the core of the micelle are reduced by the alcohol [Eq. (2)].

$$R-O-\overset{\overset{O}{\|}}{\underset{\underset{O}{\|}}{S}}-O + H_2O \xrightarrow{Reflux} ROH + SO_4^{2-} + H^+ \quad (1)$$

$$R_nOH + M^{2+} + H_2O \rightarrow R_{n-1}COOH + M^0 + 2H^+. \quad (2)$$
The typical transmission electron microscopy (TEM) images of Pd nanoparticles reduced by sodium dodecyl sulfate (SDS) are shown in Figure 12. One remarkable finding is that the size of the nanoparticles can be controlled by varying the length of the carbon chain of the sodium alkyl sulfate (Table 1). Obviously, the time needed for the solution to turn dark brown, which signals the completion of the reaction, is a function of the length of the carbon chain. The reaction time increases with an increasing carbon chain length. The reducing power follows the trend $C_8 \geq C_{10} \succ C_{12} \succ C_{14}$, and the diameter of the particles decreases as the carbon chain lengthens. This trend is closely related to the nucleation and growth rate of the nanoparticles. As the rate increases, the nanoparticles grow in size accordingly. The alcohol reduces the metal ions to metal particles in the core of the micelles. The steric effect between the carbon chains of a micelle and the alcohol becomes more critical when the chain length of the hydrophobic group is sufficiently long, for example, $SC_{14}S$ and $SC_{12}S$ (SDS), and results in a slowing down of the growth rate of the Pd nanoparticles. In contrast, the effect is less pronounced in the case of SC_8S and $SC_{10}S$ systems.

Auvray et al. [45] reported that a transformation of the liquid crystal phase of the surfactant could occur under an elevated temperature and a high surfactant concentration. Consequently, the following intermediate phases have been
Figure 12. TEM images of Pd nanoparticles formed via reduction by sodium octyl sulfate (SC_8S) (mean diameter of the particles: 9.41 nm). Scale bar = 20 nm. Reprinted with permission from [43], C. L. Lee et al., *Adv. Funct. Mater.* 11, 344 (2001). © 2001, Wiley-VCH Verlag GmbH.

identified: disordered micellar phase $I\alpha$ → two-dimensional hexagonal $H\alpha$ → bicontinuous cubic phase $Q\alpha$ → lamellar phase $L\alpha$. The synthesis of various mesoporous silica–based nanostructures can be achieved by controlling the pH, the amount of alcohol, and the concentration of the surfactant. The micellar phases of the surfactant could be altered due to various experimental conditions. Consequently, different nanostructures could be obtained by adding inorganic silica compounds to link onto those soft cages, for example, MCM-41 (2-D hexagonal phase, P6m), MCM-48 (cubic phase, Ia3d), or MCM-50 (lamellar phase) [45]. Moreover, Hendrikx and Pansu [47] also found that, in H_2O, the liquid crystal phase of the $SC_{10}S$ surfactant could transform into a ternary structure that contained 2–octanol. In this case, 1–dodecanol was detected by ^{13}C NMR (see Fig. 13), which demonstrates how the alkyl sulfate surfactant could exhibit reducing power. Similarly, the Pd nanoparticle/$SC_{10}S$ system can produce 1–octanol, which then reduces the Pd ions to Pd, and affects the transformation of the liquid-crystal phase of the surfactant. This mild reaction of the alkyl sulfate compounds to generate an alcohol provides a self-regulated, stable supply of reductant to the metal ion, thereby eliminating the need for any other reducing agent.

Another remarkable finding regarding hydrophilic and hydrophobic colloids can be obtained by simple adjustment of the reaction time [48]. This dual hydrophilic–hydrophobic property involves the production of hydrophobic lipid acid

Table 1. Average particle size, reaction time, and reaction conditions for the various Pd/S_nS nanoparticles.

Surfactant	Average diameter of the particles (nm)	Reaction time: time taken for the solution to turn dark brown (h)	Conditions	
			Concentration of surfactant (M)	Reflux temperature (°C)
Sodium *n*–octyl sulphate (SC_8S)	9.41 ± 1.44	0.5	0.1	70
Sodium decyl sulfate ($SC_{10}S$)	2.12 ± 0.4	0.5	0.1	70
	7.81 ± 1.8			
Sodium dedecyl sulfate (SDS)	3.36 ± 0.71	4	0.1	110
Sodium *n*–teredecyl sulphate ($SC_{14}S$)	3.25 ± 0.6	5	0.1	110

from the oxidation of the self-generated alcohol from the long carbon chain within the lyophobic micellar core throughout the reaction. The surface modification can render the particle from hydrophilic to hydrophobic by lengthening the synthesis time.

Figure 14 shows pictures of hydrophilic (hy–Pd$_{nm}$) and hydrophobic Pd nanoclusters (hp–Pd$_{nm}$) templated within two micelle systems, sodium n–dodecyl sulfate (SDS) and sodium n–tetradecyl sulfate (SC$_{14}$S). Figure 14(A) and (B) are, respectively, hydrophilic and hydrophobic Pd nanoparticles, which are prepared from the aqueous solution of SDS micelles, and then well dispersed in H$_2$O and CHCl$_3$, whereas Figure 14(C) and (D) are hy–Pd$_{nm}$ and hp–Pd$_{nm}$, prepared from the aqueous solution of SC$_{14}$S micelles, and then dispersed in H$_2$O and CHCl$_3$, respectively. It is interesting to find that, no matter within which micellar system, hy–Pd$_{nm}$ is stably dispersed in H$_2$O indefinitely, and hp–Pd$_{nm}$ is also well dispersed in CHCl$_3$ for at least several months. In addition to Pd nanoparticles, this novel method can be extended to prepare other materials, including Pt, Ru, Ag [46] as well as an Ag/Pd colloid [49]. Figure 15 illustrates the typical images of these nanoparticles. A further study of the synthesis and characterization of an Ag/Pd bimetallic colloid will be done in due course.

3. SPECTROSCOPIC CHARACTERIZATIONS

3.1. TEM Observation

3.1.1. Transmission Electron Microscopy

Transmission electron microscopy can be best applied to characterize the shape and sizes of nanoparticles; although there are still other methods, such as dynamic light scattering (DSL) and small-angle X-ray scattering (SAXS) [50], which can be used to measure the particle size, TEM exclusively provides the real images and shapes of nanostructures.

Owing to the improvement of the high-voltage electron beam, the high-resolution TEM (HRTEM) is designed to produce the images of nanoparticles at an angstrom level. Thus, some defects, like distortion and dislocation, and the interatomic length of the nanomaterial, can be observed from HRTEM images [39]. The sample preparation of a colloidal solution for TEM is rather simple, involving the evaporation of the colloidal solution on carbon-coated metal grids. However, there may be some additives, including stabilizers and unreacted reactants, which can dissolve the colloid as well. These organic compounds, which may react under the influence of a high-voltage electron beam, will affect the resolution of TEM images. In order to obtain clear images, dilution or filtration may be necessary in some cases [2]. Besides, some studies [51] also reveal the possibility of coalescence during TEM observation.

An electron energy loss spectrometer (EELS) and an energy dispersive spectrometer (EDX), which are usually coupled with TEM, can provide an elemental analysis of the nanoparticles being examined. In addition, selected area diffraction patterns also characterize the crystal structure for single-crystalline or randomly oriented polycrystalline nanomaterial.

3.2. Ultraviolet–Visible Absorption Spectrum

Metal colloids usually exhibit absorption bands in the ultraviolet–visible (UV–vis) range due to excitation of the plasma resonance or interband transition. Therefore, the UV–vis spectrum is a convenient method of characterization for colloidal nanoparticles as long as they are synthesized. Some colloidal materials, which are different from bulk materials, show distinct absorption peaks in the visible region, and thus can be used for colorants. Bulk silver is gray, for example, while silver sol shows yellow in color. Copper, silver, and gold are the typical materials that show prominent absorption peaks, and thus are frequently used in colored glasses or decorative glazes. On the other hand, other colloidal metals, such as palladium and platinum, exhibit only broad absorption throughout the region of the UV–vis spectrum, and these colloids are brown or gray in appearance.

Creighton and Eadon [52] systematically computed 52 metallic elements in 10 nm diameters of spherical particles on the basis of the Mie theory. For the majority of the colloidal metallic elements, there is only a continuous absorption in the visible range. In addition, the size dependence is more pronounced with decreasing diameter due to the approximation between the particle diameter and the mean-free path of the conduction electrons.

Although many studies associated with the optical property of nanoparticles have been reported, there are still some discrepancies in metal sols owing to their complicated double-layer, metal–water interface. Mulvaney [53] found that the surface plasmon absorption was directly related to the electrochemical processes involved, which include polarization, chemisorption, metal ad atom deposition, and alloying. When the electrical charge is accumulated on the particle surface, a blue-shifted absorption peak is usually observed. Furthermore, dramatic optical shifts are correlated to the electrodeposition of metal atoms onto the preformed metal clusters to form bilayer colloids. In a core–shell bimetallic mesostructure, underpotential deposition (UPD) can be amenable to the blue-shifted spectrum.

In addition to optical properties, the colloidal particles of certain metals are extensively studied for surface-enhanced Raman scattering (SERS). There are two mechanisms to account for this effect [52]. First, the metal surface can enhance the nearby electromagnetic field when the incident radiation lies within the absorption band of the nanoparticles. Second, the scattering close to the metal–adsorbate charge-transfer transitions can improve the tensor of Raman scattering. The wavelength of colloidal metals corresponding to the most efficient excitation wavelengths for SERS has also been verified experimentally.

3.3. Fourier Transform Infrared Absorption Spectrometry

Infrared spectroscopy has been widely used to investigate the surface structure by adsorption of a small molecule on the metal surface. Carbon monoxide, which is frequently used for a surface probe molecule, has distinguishable IR characteristic absorption due to its strong adsorption ability to a metal's surface. In addition, the wavenumber of CO changes drastically with different surface structures, and thus is suitable to characterize the surface sites.

Bradley and co-workers studied a series of Pd and its alloy nanoparticles using CO as the surface probe molecule [54–56]. A size-dependence effect was observed in the Pd colloidal solution [54]. The smallest particles show the highest ratio of terminal to bridged CO, while the smallest particles possess only bridged CO. Terminal CO is more stable on the low coordination number atoms at edges and vertices. On the contrary, the bridged CO is preferred on atoms with a higher coordination number at the face terrace. With decreasing particle size, the relative portion of low coordination atoms increases, and therefore increases the ratio of the terminal to bridged CO peaks.

IR spectroscopy of CO adsorption can also provide information on the surface structure of bimetallic nanoparticles. One can evaluate the surface structure by a comparison of the CO adsorption at various compositions of bimetallic clusters. After subtraction of the adsorptions due to the colloid solution prior to CO addition, a clean spectrum of adsorbed CO is obtained to interpret the surface structure. The segregation of palladium on the surface of Pd/Cu clusters was investigated with an IR spectrum [55]. The formation of a palladium-rich surface was observed, and may result from the dissolution of surface copper atoms into the interior palladium. It is clear that, even under a mild deposition condition, copper atoms could readily diffuse into the palladium in order to form a maximal CuPd bond, which would decrease the energy of alloy formation.

3.4. X-Ray Methods

3.4.1. X-Ray Diffraction

X-ray diffraction is a powerful method to determine the palladium crystalline structure. From the characteristic peaks of diffraction patterns, we can characterize palladium nanoparticles with an fcc crystal structure, which is the same as bulk material. In addition, the primary particle size can be calculated from the calculation of the half width of the corresponding peaks, as illustrated in Eq. (3):

$$d = \frac{\alpha\lambda}{\beta\cos\theta} \tag{3}$$

where d is the particle's diameter, α is a geometric factor, λ is the X-ray wavelength, and β is the half width of the corresponding diffraction peak at angle 2θ. According to Eq. (3), a broader peak yields a smaller primary particle diameter. Therefore, nanoparticles usually show broader peaks than bulk material.

XRD can also be used to characterize the lattice constant from the diffraction patterns. When the substance is down to nanoscale, the interatomic length of nanoparticles may change with the particle size. Most materials, such as copper and platinum [57], show lattice contraction properties due to surface stress. In general, the interatomic length will decrease with decreasing particle size. However, most studies [51, 58–61] clearly illustrate that palladium nanoparticles possess lattice expansion rather than lattice contraction. This unique property can be explained by structure

change [51, 58], pseudomorphism [59], and the diffusion of impurities [60–61].

When the palladium nanoclusters are deposited on the solid supports, the lattice dilation phenomenon might be explained in terms of two reasons: structure change and pseudomorphism. Giorgio et al. [51] reported that, when the nanoparticles were deposited on an MgO substrate, an isotropic lattice expansion increased from 2 to 8%, while the particle sizes decreased from 6 to 2 nm. The truncated octahedral could be observed at the top and at the interface with the aid of HRTEM, and the structure change could account for the lattice dilation. Another mechanism, pseudomorphism [59], has frequently been mentioned to explain this special property. Pseudomorphism, which causes lattice strain due to the mismatch between palladium nanoclusters and the substrate, is the possible cause for the lattice expansion of palladium nanoparticles. However, for amorphous substrates such as carbon or SiO_2, pseudomorphism does not exist since the substrate is not single crystal.

It has also been found that the lattice dilation was correlated with the diffusion of hydrogen. Bulk palladium, which interacts with hydrogen easily, forms metal hydride and exhibits lattice dilation up to about 3%. Kuhrt and Anton [60] demonstrated the hydrogen diffusion into palladium nanoclusters by secondary-ion mass spectroscopy (SIMS) and X-ray photoelectron spectroscopy (XPS). The incorporation of hydrogen in the palladium lattice at an interstitial position leads to an isotropic expansion of the lattice parameter. The origin of hydrogen could result from dissociation of the hydrogen-containing molecules such as H_2, H_2O, or C_xH_y. In addition to Pd nanoparticles, Pd–Au alloy clusters also possess a nonlinear dependence of lattice expansion due to the different hydrogen diffusion coefficients in various alloy compositions.

Although the expansion of the lattice parameter is usually explained by hydrogen diffusion, an expansion as large as 6% for Pd [59] cannot be similarly explained since the maximum of the dilation for Pd–H formation is only 3.6%. Therefore, Jacobs and Schryvers [61] discussed the palladium lattice parameter dilation in terms of oxygen diffusion. They suggested that the distorted fcc structure, which was observed by TEM, represented Pd–O alloys. The dissolution of oxygen in the Pd nanoparticles might be responsible for the expansion of the interatomic length.

Most studies so far have focused on the expansion of the lattice constant for palladium clusters, and there are still a few works observing the lattice contraction phenomenon [62–63], which is the same as other materials. The presence of methyl and vinyl groups, followed by the activated diffusion of carbon atoms through the metal lattice, can lead to the formation of a Pd–C phase and the subsequent expansion of the lattice parameter.

3.4.2. X-Ray Photoelectron Spectroscopy

In contrast to other electron spectroscopies, X-ray photoelectron spectroscopy provides information regarding not only the atomic composition, but also the structure and oxidation state of the samples. Before XPS measurement, the colloidal particles must be precipitated by ultrahigh-speed centrifuge, and dried in the vacuum. Figure 16 [48] shows a
Figure 16. XPS spectra of the hy–Pd_{nm} and hp–Pd_{nm}.

typical XPS spectrum of hy–Pd_{nm} and hp–Pd_{nm} powders protected by sodium dodecyl sulfate. The detailed preparation method was discussed in Section 2.5.5. For the hy–Pd_{nm}, the resulting spectrum of the Pd element (Fig. 16) clearly reveals four bands, 335.6, 337.6, 341, and 343.2 eV, respectively. Two bands at 335.6 and 341 eV correspond to the $3d_{5/2}$ and $3d_{3/2}$ of zero-valence palladium, while the other two peaks represent the precursors (palladium acetate). It clearly indicates that Pd nanoparticles and precursors ($Pd(OAc)_2$) coexist in the core of the hydrophilic micelle mesostructure. In contrast to the XPS result of the hy–Pd_{nm}, the XPS spectrum of the hp–Pd_{nm} (Fig. 16) only shows Pd^0 (335.6 and 340.8 eV). It seems that, during the transformation from hy–Pd_{nm} to hp–Pd_{nm}, the particle growth reaches an end, so there is no longer a detectable palladium ion inside the hp–Pd_{nm} structure.

XPS can also be used to investigate the surface composition of palladium and its alloy nanoparticles. If the nanoclusters are synthesized by a chemical method, the surface of nanoparticles is coated with a thick layer of organic protecting agents, which influence the detection of XPS. To overcome this problem, a coordination capture method is usually employed to remove the protective agents [2]. The surface composition of nanoclusters can then be quantitatively determined.

Wu et al. [5] also used the thiophenol-capped Pd–Au bimetallic nanoparticles to investigate the composition on the outer surface of the particles. The Pd atoms were found to concentrate in the outer part of nanoclusters, which suggests an incomplete Au-core/Pd-shell mesostructure. Although XPS provides an indispensable method to investigate the surface composition of nanoparticles, a problem may arise because the structure might change

during the coordination capture process, resulting in experimental deviation.

Further, for the determination of the surface composition of nanoparticles, the concept of coordination capture can also be employed to immobilize two-dimensional nanoclusters onto a solid substrate [64–66]. The achievement of well-ordered metal clusters on the substrate makes the fabrication of a nanodevice possible.

4. CATALYTIC PROPERTIES

The high material cost of palladium naturally restricts the application of palladium nanoparticles. Catalysis is the most important application for palladium or its alloy clusters, and has been extensively investigated. Transition metal nanoparticles are known to be effective catalysts owing to their large surface area arising from the drastic reduction of size [12]. For the past decades, palladium nanoparticles have played an important role in organic catalysis. In general, the catalysis of organic reactions can be grouped as structure-sensitive, such as Suzuki coupling reactions [67] and Heck coupling reactions [68], or structure-insensitive, including hydrogenation reactions [69]. Pd nanoparticles show outstanding performance in reactivity and selectivity for catalyzing these organic reactions.

Besides catalyzing these organic reactions, pure palladium clusters can work as activators for electroless copper deposition [70]. Electroless deposition is an important technology to prepare circuits for industries, including printed-circuit boards (PCBs) and semiconductors. It was found that copper could be successfully deposited and filled in 0.25 μm vias and trenches on a TaN/ SiO_2/Si wafer surface [70]. The effects of particle size and carbon-chain length of surfactants (sodium akly sulfate) on the deposition kinetics were studied by electrochemical quartz crystal microgravimetry (EQCM).

4.1. Catalysis for Organic Coupling Reaction

4.1.1. Suzuki Coupling Reaction

The coupling reactions of aryl halides with arylboronic acids, namely Suzuki coupling reactions [Eq. (4)], provide a versatile route for synthesizing biaryls, which are important precursors for pharmaceutical, nucleoside analogs, polymers, and liquid crystals [67].

$$\text{\textcircled{}}-B(OH)2 \ + \ I-\text{\textcircled{}} \xrightarrow[\text{NaOAc, 80 °C}]{\text{PVP-Pd nanoparticles}} \text{\textcircled{}}-\text{\textcircled{}} \qquad (4)$$
Traditionally, these reactions are catalyzed by the phosphine–ligand palladium complex. In general, homogeneous catalysis is preferred because it is often highly selective toward the formation of a desired product. These homogeneous catalysts, however, involved problems such as separation from the reaction mixture and recovery of the catalyst. Recently, colloidal palladium has shown high reactivity, and the separation of the Pd catalyst can be easily carried out by using water as the reaction medium [71]. Accordingly, colloidal palladium has become a promising candidate as a commercial catalyst for the Suzuki coupling reaction for environmental and economical reasons.

The effects of size on the catalytic activity in Suzuki reactions have been systematically studied by El-Sayed's group [67]. They used a stepwise procedure to synthesize PVP-protected palladium nanoparticles with different particle sizes of 3.0, 3.9, 5.2, and 6.6 nm, respectively. The Suzuki reaction between phenylboronic acid and iodobenzene has been studied to probe the reactivity of Pd clusters. The activity of Pd nanoparticles is expressed in terms of the initial turnover frequency (TOF; moles of the product per mole of total surface Pd atoms per minute). They found the reactivity of the reaction in the order of Pd (3.9 nm) > Pd (3.0 nm) ≈ Pd (5.2 nm) > Pd (6.6 nm). The TOF changes significantly with different particles sizes, indicating that the activity is not the same for all surface atoms, since if all of the surface atoms were equally active, there would be no particle size dependence of TOF. In addition, the structure of the cuboctahedron model, as shown in Figure 17, suggests the different types of surface atoms and coordination numbers. The relative proportion of edge and vertex sites increases as the particle decreases. Accordingly, the general trend that the reactivity increases as the particle size decreases suggests that the Suzuki reaction is "structure-sensitive," that is, the low-coordination number of vertex and edge atoms on the particle surface is active for this coupling reaction. However, the lower catalytic activity for the smallest Pd (3.0 nm) nanoparticles might be due to stronger adsorption of the reaction intermediates on the surface, which retard the reaction rate and act as poison to the reaction by Piccolo and Henry [73]. They also found that the intrinsic activity depends not only on particle size, but also on particle shape.

The effect of the stabilizer on the activity and stability of a palladium colloid has also been studied El-Sayed and his co-workers [71]. A series of different stabilizers, hyroxyl-terminated poly(amido–amine) (PAMAM) dendrimers (*Gn*–OH, where *Gn* represents the *n*th generation), block copolymer polystyrene–*b*–poly (sodium acrylate), and poly (N–vinyl–2–pyrrolidone) (PVP), were used to investigate the activity and stability in Suzuki coupling reactions between phenylboronic acid and iodobenzene in an aqueous medium. The Suzuki reaction being refluxed at about 100 °C for 24 h is a good "acid test" for examining the stability of the colloid. It is found that the Pd clusters protected by PVP,
Figure 17. Structure of a three-shell cuboctahedron showing the different types of surface atoms and their coordination numbers. Reprinted with permission from [67], Y. Li et al., *Langmuir* 18, 4921 (2002). © 2002, American Chemical Society.

a block copolymer, and the G3 dendrimer are effective catalysts for the Suzuki reaction, while the palladium colloid encapsulated by the G4 dendrimer shows good stability, but results in the loss of activity. We may expect, that the activity and stability are found to be anticorrelated, that is, the most stable is the least catalytically active [71].

Recently, the fabrication of hollow palladium spheres and its application to Suzuki coupling reaction have been reported [74]. First, uniform silica spheres were synthesized, and the surfaces of silica spheres were modified with a thiol group. Then palladium acetylacetonate (Pd(acac)$_2$) was introduced, and Pd^{2+} ions were adsorbed onto the thoil-functionalized surfaces of these silica spheres. The Pd^{2+} solution was heated at 250 °C for 3 h to form Pd^0 metal-coated silica spheres, as illustrated in Figure 18. The reductant probably came from the CO generated *in-situ* from the thermal decomposition of acetylacetonate. Finally, 10 M HF was used to removal the silica template, and the hollow Pd spheres were then produced. Their TEM images, shown in Figure 19, illustrate that nearly monodispersed 300 nm hollow spheres with a uniform shell of 15 nm were obtained. The BET surface area of the palladium hollow spheres was measured to be 64 m$^2\cdot$g^{-1}, which is much larger than the surface of dense spheres. Iodothiophene and phenylboronic acid were used as test substrates for the Suzuki reaction. The palladium hollow spheres are shown to be extremely active for this reaction, and by simply filtrating the reaction mixture, this catalyst can be easily retrieved without losing its activity, even after seven recycles.

Besides Pd monometallic catalyst, mixed nanocluster colloids, including other metals like copper and platinum, were used for Suzuki coupling reaction [75]. An experimental design method was applied to investigate the monometallic and the combined catalysts, including palladium, ruthenium, platinum, and copper. A wide range of aromatic compounds were used for test substrates in Suzuki reactions. The designed mixed nanocluster can effectively catalyze these organic reactions, and provides an inexpensive and economic alternative to replacing the noble metal catalyst.

4.1.2. Heck Coupling Reaction

The Heck reaction, including coupling reactions between aryl halides and olefins [Eq. (5)], provides an important synthetic method for the production of intermediates of pharmaceuticals and fine chemicals. In general, coupling reactions, which occur on the surface defects rather than terrace sites in a heterogeneous catalyst, can be regarded as "structure-sensitive," which is significantly influenced by the particle size of the catalyst [76]. A conventional heterogeneous catalyst differing only in particle size, however, is technically very difficult to prepare, since different supports or preparation conditions produce catalysts intrinsically different from one another. Recently, colloidal methods [77], which can synthesize nanoparticles with constant properties except varying in particle sizes, provide a possible way to investigate the structure-sensitive reactions.

$$\text{(5)}$$
A series of well-defined PVP-stabilized palladium nanoparticles reduced by H$_2$ has been used for the Heck coupling reaction [68]. This systematic study confirms that these defect sites are responsible for the C–C bond coupling reaction other than terrace sites in Heck reaction. Furthermore, the activity of colloidal palladium is comparable to that of the most efficient homogeneous Pd catalyst in a similar reaction.

Although Pd nanoparticles show high activity toward the organic coupling reaction, the stability of colloid, which is especially important for pharmaceutical applications, has much room for improvement. A well-stabilized palladium colloid can be accomplished by being prepared in block copolymer micelles of polystyrene–*b*–poly–4–vinylpyridine [78]. The activity of the block-copo1ymer-stablized Pd colloid ranks about equal to that of conventional palladium complexes, but the former has higher stability. In addition, adjustment of the outer block to the environment allows the Heck reaction to proceed in many "simple" solvents, such as toluene, instead of amidic solvent.

Figure 18. Experimental procedure for production of hollow palladium spheres. Reprinted with permission from [74], S. W. Kim et al., *J. Am. Chem. Soc.* 124, 7642 (2002). © 2002, American Chemical Society.

In recent years, some homogeneous catalyst systems, such as $Pd(OAc)_2$ in the presence of $nBu_4N^+Cl^-$ or $Pd(OAc)_2$ in an aqueous medium, have been extensively used in the Heck reaction and Suzuki reaction. Although the phosphane was regarded as an activity agent before, the role of phosphane-free catalysts in a coupling reaction is uncertain. A mechanistic study, supported by TEM analysis, indicates the involvement of Pd nanoparticles as intermediate in the reaction [79]. The palladium salt undergoes thermolytic decomposition or RCO^{2-}-induced electron transfer to form a Pd colloid simultaneously in the Heck reaction. The resulting Pd colloid acts as a catalyst for the C–C bond-forming process. Thus, the phosphane-free palladium complex, which is traditionally regarded as a homogeneous catalyst in the Heck reaction, actually belongs to the area of a heterogeneous colloidal heterogeneous catalyst system.

4.2. Catalysis for Hydrogenation of Olefins

Polymer-stabilized Pd, Pt, Rh, and Ir nanoparticles have been used as catalysts for the hydrogenation of many unsaturated olefins [2]. In particular, palladium colloid was used as an effective catalyst for the partial hydrogenation of dienes to alkenes due to their high activity and selectivity.

A palladium cluster utilizing water-in-supercritical CO_2 has been tried as a catalyst for hydrogenation [80]. The palladium salt dissoved in the water core was reduced by the hydrogen gas. Hydrogen gas is a suitable reductant in supercritical CO_2 due to its miscibility and simplicity. Furthermore, the hydrogen gas can also serve as a starting material for the subsequent hydrogenation process. Besides the simplicity of the process, the water-in-CO_2 microemulsion system can dissolve hydrophobic organic compounds in the supercritical fluid and hydrophilic organic compounds in the water core. This unique property allows the hydrogenation of hydrophobic organic compounds, such as 4–methoxy–cinnamic acid to 4–methoxyhydrocinnamic acid [Eq. (6)], or the hydrogenation of water-soluble compounds in CO_2 [Eq. (7)]. Moreover, Pd nanoparticles in water-in-CO_2 microemulation can also catalyze other hydrogenation reactions, including the conversion of the nitro group (NO_2) to amine (NH_2).

$$\text{(6)}$$

$$\text{(7)}$$
Another novel method for catalyzing the hydrogenation of olefins is to utilize dendrimers as stabilizers. Dendrimers have been proven to be effective for the separation of chemical species due to their crowding structures. Traditionally, dendrimers can be used as stationary phases in various liquid separation techniques. These separation processes involve physical interactions between small molecules and dendrimers, such as size, shape, and electronic interaction, including surface charge and polarity. With the progress of nanotechnology, dendrimers have been used for capping metal nanoparticles [8, 9].

Crooks and co-workers systematically studied the hydrogenation of olefins by dendrimer-encapsulated palladium nanoparticles, and they showed that the selectivity can be adjusted by the surrounding dendrimer [81–82]. Nearly monodisperse (1.7 ± 0.2 nm) Pd nanoparticles were prepared within the interior of three different generations of hydroxyl-terminated poly(amidoamine) (PAMAM) dendrimers. Importantly, the Pd encapsulated in PAMAM dendrimers can act as an adjustable-mesh "nanofilter" by changing the generation of dendrimers; that is, a higher generation of dendrimer-encapsulated catalysts or larger substrates resulted in a lower hydrogenation reaction rate, as shown in Figure 20. In addition, the dendrimer-encapsulated Pd composite shows higher activity and good stability for months, even after several cycles of hydrogenation reactions.

Dendrimer-encapsulated Pd nanoparticles can also be synthesized as a fluorous phase-soluble catalyst [9]. This

catalyst is selectively soluble in the fluorous phase, while the reactants are preferentially soluble in the organic solvent. Stirring or sonicating the mixture leads to the formation of fine emulsion and partial homogenization, and the catalytic reaction proceeds at the interface between the two liquids, as shown in Figure 21. When the reaction is over, the liquid phases are separated, the product is isolated from the organic phase, and the catalyst-containing phase layer is recycled. Such easy separation and recycling are preferred owing to the economic and environmental concerns.

In addition to dendrimer-protected colloids, qualitative work concerning polyacid-stabilized palladium nanoclusters has been conducted to investigate the hydrogenation of cyclohexene [83]. This type of polymer can significantly influence the particle sizes, which affect the catalytic property, and the stability as well. The introduction of functional groups of the polymer, such as hydrogen transfer units, can create a certain surrounding environment, which subsequently allows or hinders the pathway of the reactions. Moreover, additional ions could be used to tune the catalytic reaction rate due to interaction with the surrounding polymer matrix.

4.3. Activation for Electroless Metal Deposition

4.3.1. Introduction to Electroless Metal Deposition

Electroless deposition has been widely used for the metallization of a nonconductive substrate. The best known application is the plating-through-hole (PTH) for a printed-circuit board and copper interconnection of ultralarge-scale integration in a semiconductor [84]. So the most common metal to be plated is copper, although nickel and cobalt are both electrolessly plated to prepare a device with special mechanical or magnetic properties [85].

Electroless metal deposition in theory should cover all chemical processes for metal deposition, except conventional electrodeposition. In practice, it only refers to the process of autocatalytic electroless deposition which involves metal reduction on a catalytic surface. Two electrochemical reactions, the reduction of metal ions and the oxidation of a

Figure 21. Illustration of the approach used to carry out fluorous biphasic catalysis using dendrimer-encapsulated metal nanoparticles modified on their exterior with perfluoroether "ponytails." Res.* 34, 181 (2001). © 2001, American Chemical Society.

reducing agent, occur at the same place at the electrode–electrolyte interface. The overall reaction is shown as follows:

$$M^{Z+}_{\text{solution}} + \text{Red}_{\text{solution}} \xrightarrow{\overset{\text{catalytic}}{\text{surface}}} M_{\text{lattice}} + Ox_{\text{solution}} \qquad (8)$$
where M^{Z+} is a metal salt, $\text{Red}_{\text{solution}}$ is a reducing agent in the electrolyte, M_{lattice} is solid-state metal, and Ox is the oxidized product of the reducing agent. The catalytic surface can be the substrate itself or a surface coated with catalytic colloids. A reducing agent, Red, binds to the catalytic colloids on the surface, and is oxidized, providing electrons to reduce metal ions so that metal is deposited on the substrate. As the reduction continues, the hydrogen generated due to the reduction provides new catalytic sites promoting the deposition. Hence, the process is called autocatalytic electroless deposition.

A similar process is called direct metallization. The process also needs to activate the surface with a catalyst, yet the catalyzed surface needs no electroless deposition to make it conductive, and can accept metal deposition directly [87]. The catalyst used is also similar to that for electroless deposition.

4.3.2. Conventional Pd/Sn Colloidal Activator

The Pd/Sn colloid is the most common catalyst for electroless metal deposition. In related industries, the catalyst is specially called an activator, and the process to render the surface catalytic is called activation. In a common commercial process [88], PdCl$_2$ and SnCl$_2$ were mixed and heated up to 80 °C for 8 h. The Pd^{2+} was then reduced by Sn^{2+} to form Pd/Sn colloids with stannic ions adsorbed as a stabilizer [Eq. (9)]:

$$\text{Sn}^{2+} + \text{Pd}^{2+} \rightarrow \text{Pd}^0 + \text{Sn}^{4+}. \qquad (9)$$
However, this colloidal solution has limited stability due to the oxidation of the stannic ion by the air, and usually can last for at most only a few months; obviously, this is a costly drawback to users. Recently, a novel method for the synthesis of noble metal nanoparticles was developed [43], and the Pd colloid so produced was studied as a possible new activator for electroless copper deposition.

4.3.3. Evaluation of Pd Colloidal Activator

Nanotechnology has gained increasing importance in many fields; however, there are a few studies concerning the possibility of using Pd nanoparticles as a catalyst for activating electroless copper deposition.

Recently, the kinetics of electroless copper deposition catalyzed by palladium nanoclusters and the effect of the surrounding functional group were investigated [53]. Pd nanoparticles were synthesized via reactive micelles with sulfate-type surfactants with different chain lengths (the detailed experimental procedure was previously discussed in Section 2.2.5). In order to test the catalytic activity of Pd nanoparticles for electroless copper deposition, a 0.25 μm TaN/SiO$_2$/Si wafer pattern was activated by Pd nanoparticles/SC$_{12}$S (sodium dodecyl sulfate) (Fig. 22). Then copper was deposited and filled in the microtrench by immersing the pattern in an electroless copper bath.

Figure 22. FE–SEM image of 0.25 μm TaN substrate of ULSI after activation with Pd nanparticles/SC$_{12}$S (top view; the white spots represent the Pd nanoparticles). Reprinted with permission from [70], C. L. Lee et al., *J. Electrochem. Soc.* (Mar. 2003). © 2003, Electrochemical Society.

Figure 23 shows that electroless copper can be deposited with this kind of Pd nanoparticle as the activator. A quantitative evaluation of the process was carried out with the aid of quartz crystal microgravimetry (QCM).

The results are summarized in Table 2. A comparison of the rate of the electroless copper deposition between systems with Pd nanoparticles/sodium alkyl sulfate and systems with a conventional Pd/Sn activator indicates that the newly developed Pd/alkyl nanoclusters can be effectively used as an activator for electroless copper deposition. In fact, Pd nanoparticles protected with SC$_8$S micelles are more catalytically active than the Pd/Sn colloids. Another surprising finding is that, not only the diameter of Pd nanoparticles, but also the carbon chain length of the surfactant influences the electroless rate. Based purely on the surface–volume area and available site of the catalyst, the rate of electroless deposition should theoretically increase with decreasing diameter of the catalytic particle without a protection agent. However, in our case, the Pd nanoparticle/SC$_8$S

system, which has a larger particle diameter than the Pd nanoparticles/SC$_{10}$S system, turns out to be more active. Similarly, the Pd nanoparticle/SC$_{12}$S is also more active than the Pd nanoparticle/SC$_{14}$S since SC$_{12}$S has a shorter carbon chain than SC$_{14}$S. Other evidence can be found from the FTIR spectra (2800–3000 cm^{-1}), as shown in Figure 24. This means that the alkyl groups of sodium alkyl sulfate strongly adsorb on the surface of Pd nanoparticles, which may result in a barrier for adsorption of formaldehyde during the incubation period. However, a faster deposition rate could also be attributed to smaller particles when comparing C$_{12}$ with C$_{10}$ system, even if lengthening the carbon chain has an influence. Overall, the activity of these four types of Pd nanoparticles is in the following order: C$_8$ >C$_{12}$ >C$_{10}$ >C$_{14}$, which shows that both the carbon chain length of the protection agent and the
Figure 24. The FT–IR spectra of Pd nanoparticles attached with sodium alkyl sulfate with various carbon chains: (a) C$_8$, (b) C$_{10}$, (c) C$_{12}$, (d) C$_{14}$. Reprinted with permission from [70], C. L. Lee et al., *J. Electrochem. Soc.* (Mar. 2003). © 2003, Electrochemical Society.

size of Pd nanoparticles are essential factors in controlling the catalytic activity.

Thus, electroless copper can be successfully deposited and filled in microtrenches of a 0.25 μm TaN/SiO$_2$/Si pattern wafer by using a newly developed Pd nanoparticle protected by sodium alkyl sulfate. In addition to Pd monometallic nanoparticles, Ag/Pd bimetallic nanoparticles can also be synthesized via reactive micelles. The bimetallic colloids are of great interest due to their tailed structures, resulting in the improvement of the catalytic properties [49]. Accordingly, the Ag/Pd bimetallic colloid is a promising candidate as a catalyst since it is significantly less expensive than Pd nanoparticles based on the material cost.

4.4. Other Catalytic Aspects

In recent years, a nanosized particle has been utilized for the synthesis of various transition metals in a hydrazine-reduced water/sodium bis(2–ethylhexyl) sulfosuccinate (AOT)/n–heptane microemulsion system [90]. However, only a few reports correlate the kinetic and mechanical study in a catalytic reaction. Spiro and co-workers [91–92] presented a qualitatively kinetic study on the reaction between p–Me$_2$NC$_6$H$_4$NH$_2$(DMPPD) and Co(NH$_3$)5Cl^{2+} catalyzed by reversed-micelle Pd nanoparticles [Eq. (10)]. The activation energy and rotating Pd electrode were also used to investigate the catalytic mechanism. However, one should bear in mind that the hydrodynamics are quite different between the actual surface of the nanoparticles and that of the rotating disk electrode.

$$DMPPD + Co(NH_3)_5Cl^{2+} \rightarrow S^+ + Co^{2+} + 5NH_3 + Cl^-. \quad (10)$$
Acetoxylation is a powerful method to functionalize various kinds of C–H bonds in hydrocarbons [Eq. (11)]. Recently, acetoxylation of toluene in the presence of oxygen was systematically studied by Kaneda and co-workers [93].

$$(11)$$
They used a novel method to prepare different palladium particle sizes containing Pd^0, Pd^{2+}, and Pd$^+$ species on the particle surface by simply adjusting the concentration of palladium nitrate. On the basis of this mechanism, they found that mixed-valence states, which is similar to supported metal particles, lead to a powerful colloidal catalyst, and this finding gives us a clue in understanding the roles of heterogeneous catalysts on the solid supports.

4.5. Hydrogen Storage

Metals in the form of hydride can exhibit useful properties, such as hydrogen storage [94] and conductivity [95]. Owing to the promotion of clean energy, bulk palladium has been extensively studied in the field of hydrogen storage due to its extremely high hydrogen storage ability at room temperature [96]. A cuboctahedral Pd$_{13}$/H model has been proposed to interpret the mechanism of phase transition.

With the advance of naonotechnology, the palladium cluster has been studied for its properties as a metal hydride [94]. Ligand-stabilized Pd nanoparticles of different sizes, Pd^2, Pd^5, as well as Pd^7, were synthesized to investigate the size effect on the capacity and kinetics. These clusters show prominent improvement in the discharge kinetics compared to the bulk. Pd nanoparticles with a diameter of 1.2 nm show a reversible hydrogen uptake, which is not observed in bulk material. Furthermore, X-ray diffraction data reveal that the crystalline structure of the nanoparticles is not influenced by adsorption/ adsorption cycles.

GLOSSARY

Colloid Colloid is a substance typically larger than 10 nm in diameter, with broader dispersion ($\gg$15% size dispersion), and poorly defined in composition. It is a classical and traditional term to describe these tiny substances suspended in the solutions.

Micelle When the concentration of surfactants is above critical concentration, surfactants will aggregate with their hydrophobic or hydrophilic groups to form micelles. The shapes of micelles could be spherical, rod-like, or lamellar. Micelles are extremely tiny, usually below 10 nm, and transparent to light. They can be used as soft templates to control the size and shape of nanoparticles.

Nanocluster Nanoclusters are substances about 1–10 nm in diameter, near monodisperse ($\leq$15% size dispersion), and well defined in composition.

Nanotechnology Nanotechnology concerns methods to produce useful materials, devices, and systems through the control of matter on the nanometer scale (1–100 nm), and the study of novel properties and phenomena developed at this scale.

Template Templates are host materials where the nanoparticles can nucleate and grow. The geometry and dimensions of the templates can manipulate the shape and size of the nanoparticles.

CONTENTS

1. INTRODUCTION

Patterned magnetic nanostructures and related magnetic quantum effects have been studied extensively, not only from a basic view point of understanding spin-electron quantum phenomena but also for various applications of ultra-high density magnetic recording [1–18] and new magnetic devices such as read heads, memory cells, magnetic sensors, magnetic logic elements, magnetic cellular automata, and so forth [19–32]. However, fabrication of patterned magnetic nanostructures is still a major challenge. To date, a lot of top-down methods have been used for producing patterned magnetic nanostructures with magnetic elements down to the nanometer scale [33–60]. Of all the top-down approaches, some of them can produce patterned magnetic nanostructures by one step, while others do this by a multistep process of resist coating, energy-beam exposure, etching, magnetic material deposition and liftoff, and so on. Some bottom-up methods of producing patterned magnetic nanostructures, including template growth [61–65] and mononanoparticle self-assembly [66–80], also have been developed. In this review, we will briefly describe traditional multistep lithography methods, and the single-step methods will be introduced in detail. Finally, the potential applications of patterned magnetic nanostructures for ultra-high density magnetic recording, new magnetic devices, and strong permanent magnets are briefly addressed.

2. MAGNETIC NANOPATTERNING— FABRICATION OF PATTERNED MAGNETIC NANOSTRUCTURES

Magnetic nanopatterning with the feature size down to deep submicron is beyond the reach of conventional optical lithography. Instead, a few multistep nanolithography techniques, which are combined with magnetic materials deposition and pattern transfer processes, have been used to pattern magnetic nanostructures. These methods include electron-beam lithography, X-ray lithography, nanoimprint lithography, and laser interference lithography, etc. Several single-step magnetic nanopatterning approaches also have been newly developed to simplify the patterning process and also for time and cost saving. Besides these lithography methods, bottom-up self-assembly methods also have been demonstrated by which magnetic particles are synthesized chemically or by ion-beam bombardment and are assembled as close-packed structures on a surface. Since magnetic nanopatterning technology and its application are not mature, a lot of efforts are still put on how to make patterned magnetic nanostructures efficiently with the smallest features and long-range order.

2.1. Multistep Magnetic Nanopatterning Approaches

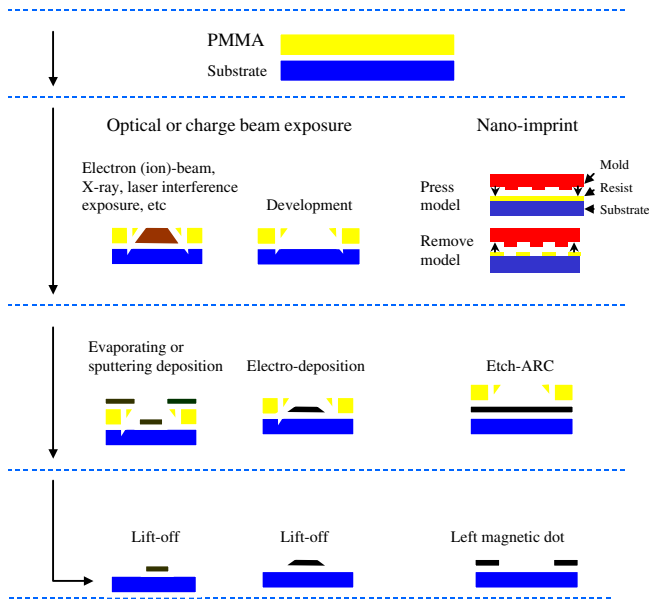
A typical multistep magnetic nanopatterning process consists of four successive steps: (i) coating a substrate with an irradiation-sensitive polymer layer (resist); (ii) generating a desired pattern by exposing the resist layer to a charge beam (electron or ion) and optical light (laser or X-ray), followed by developing the resist image with a proper chemical solution, or by nanoimprint; (iii) depositing a magnetic layer into the template by evaporating, sputtering, or electrodepositing; and (iv) using the liftoff process to remove the resist from the substrate or by reactive ion etching to leave the magnetic dot on the substrate. The whole process is schematically illustrated in Figure 1.


Figure 1. Schematic fabrication step for making patterned magnetic nanostructures. The first step is the resist coating on substrate. The second step is the pattern generation by optical or charge beam exposure or by nanoimprint. The third step is the evaporating or sputtering a magnetic layer on the template. Alternatively, the magnetic layer also can be electrodeposited into template. The last step is liftoff process to remove the resist from the substrate or by etching to leave the magnetic dot on the substrate.

During the process, the pattern generation can be fulfilled by a few methods, including ion- or electron-beam lithography [19–22], X-ray or optical lithography [23–24], nanoimprint lithography [25–26], proximal probe lithography assisted by scanning probe microscopes, such as the scanning tunnel microscope and the atomic force microscope (AFM), or by the scanning near-field optical microscope [81–90]. Magnetic nanopatterning then can be accomplished by additive or subtractive processes [19–26]. In an additive process, magnetic material is deposited after patterning, for instance, by sputtering or evaporating a magnetic film over the pattern or by electrodepositing through holes in a lithographically prepared template, followed by the liftoff process to remove the resist on the substrate (Fig. 1). In a subtractive process, a magnetic layer is deposited firstly and then is etched. Based on the mask generated by the lithography process, various desired patterns can be formed after etching.

Electron-beam or ion-beam lithography has been the most widely used nanopatterning method for fabricating small magnetic structures with dimensions of 10 nm and above. Because the electron-beam writing process is a serial method, it is unsuitable for making large-area samples but has been used to pattern relatively small (submillimeter) areas with fine enough features. Triangle, rectangle, pentagon, ellipsoidal, and circular dot arrays, wires, rings, and other shapes of nanomagnetic elements have been made by evaporation or sputtering and liftoff [91, 92]. Ion-beam or electron-beam lithography is very convenient for making patterns of arbitrary geometry, but its throughput is very low so far, and, also, because of the stitching errors between the different written fields, the long-range coherence of the pattern can be distorted when one wants to make a large-area pattern. However, recently developed projection electron-beam or ion-beam lithography may solve the low-throughput and long-range miscoherence problem.

X-ray lithography, laser interference lithography, and nanoimprint lithography are the other techniques that can pattern large-area samples. In X-ray lithography, a thin-membrane mask is placed in close proximity to a resist-coated substrate and is illuminated with soft X-rays of 0.5–4 nm wavelength. A typical mask consists of 2-micron-thick membrane of silicon carbide and absorber features of heavy metals such as Au, W, or Ta. In nanoimprint lithography, a rigid mold is used to physically deform a heated resist layer coated on a substrate. The mold can be made of metal or thermal silicon dioxide produced on a silicon substrate. The imprint can be carried out by applying a typical pressure of about 50 bar in the temperature of 100–200 °C depending on the resist used. This process has developed rapidly in the past few years. Features as small as 10-nm dots on a 40-nm period have been made by using evaporation and liftoff. The mold can be reused many times without damage. In both X-ray lithography and nanoimprint lithography, a mask or master mold must first be produced by using traditional lithography methods, but the large number of replications made from each mask or mold would justify this time-consuming step.

Interference lithography is a maskless method. In interference lithography, a resist layer is exposed by an interference pattern generated by two obliquely incident laser beams. After the development of the resist, lines are formed. The period of the pattern is given by $\lambda/2\sin\theta$, where θ is the half angle of intersection of the two laser beams, and λ is the laser wavelength exposure. Dot or hole array can simply be fabricated by a second exposure after rotating the substrate in the plane over ±90 degrees. The minimum period of the pattern is just over $\lambda/2$, typically 180–200 nm, by using an Ar-ion laser. Interference lithography has been used to make a variety of dot or ellipse arrays from evaporated Ni, Co, or Co/Pt multilayers, pillar arrays from electroplated Ni or Co, and dots or ellipses etched from single-layer or multilayer sputtered films.

A probe tip direct writing also can fulfill magnetic nanopatterning. For example, material can be evaporated from a fine tip under pulsed voltage to form sub-100-nm-diameter pillars. Cobalt and iron particles of heights up to 200 nm and diameters of 10 nm and greater were made by the decomposition of cobalt and iron pentacarbonyl under a probe tip in a chemical vapor deposition process. Although these methods are relatively slow, they allow tall structures to be made in precise locations on a substrate.

2.2. Single-Step Magnetic Nanopatterning Approaches

Besides the multistep nanopatterning methods, a few single-step magnetic nanopatterning approaches, which include electron-beam radiation induced nanoscale magnetic phase change [93–97] and direct interferometric laser annealing [98–104], anisotropy patterning [105–115], magnetization patterning [116–117], laser-assisted direct imprint

[118, 119], ion-beam-induced chemical vapor deposition (IBICVD) [120–125], and ion projection direct patterning [126] also have been newly developed to simplify the patterning process.

2.2.1. Electron-Beam-Radiation-Induced Nanoscale Magnetic Phase Change

Zhou et al. [93–97] proposed and demonstrated a novel method of direct magnetically nanopatterning a non- or weak-magnetic thin film by electron-beam radiation-induced nanoscale magnetic phase change. This is a simple single-step magnetic nanopatterning method. Firstly, a non- or weak-magnetic film (amorphous CoC or CoZr alloy films), which can be converted into a magnetic state upon annealing, is deposited. Then, the film is subjected to a focused electron-beam radiation to locally heat the irradiated region. The temperature of the irradiated region will rise. Under the proper condition, the region will undergo magnetic phase change to a magnetic state, as the whole film does after annealing. All kinds of nanostructured patterns can be produced easily by this method. So far, nanoscale dot and line array have been fabricated by using this method. Examples of the magnetic dot array and line array are shown in Figure 2.

With this method, the magnetic dots or lines are produced through a magnetic phase change. This phase change from nonmagnetic status to magnetic status is a kinetic process, which occurs under certain conditions and also takes time. This is the reason why the shorter dwell time per dot (0.95 and 1.9 sec) could not induce a magnetic phase change in the irradiated area.

When the as-deposited nonmagnetic films were subjected to electron-beam radiation, primary electrons penetrate the films and undergo scattering, and produce secondary electrons. As the primary electrons slow down continuously, some of their energy transfers into the film. The transferred energy is absorbed partly by the film. Once the film absorbs some energy, thermal diffusion occurs within the film. Because of the thermal diffusion, the phase change occurs not only in the irradiated area. One can expect that the phase change takes place within the scale of thermal diffusion length L_{ex}, which is described by:

$$L_{ex} \propto \sqrt{kt},$$

where t is the beam dwell time per dot and k is the thermal conductivity of the film [127–128]. This means that the thermal diffusion length rather than the electron beam size determines the magnetic dot size produced by such method. This is the reason why we observed that the magnetic dot diameter increases linearly with the square root of dwell time per dot (Fig. 3). By fitting the experimental data, the slope of magnetic dot size divided by the square root of dwell time can be obtained, and the thermal conductivity of the film can be calculated out.

Presently, the magnetic properties of such fabricated patterns are somewhat poor. The H_c is only about 75 Oe, indicating that the dots are magnetically soft. When using a magnetized MFM (MFM) tip to measure the MFM images, the field produced by the MFM tip can magnetize regions

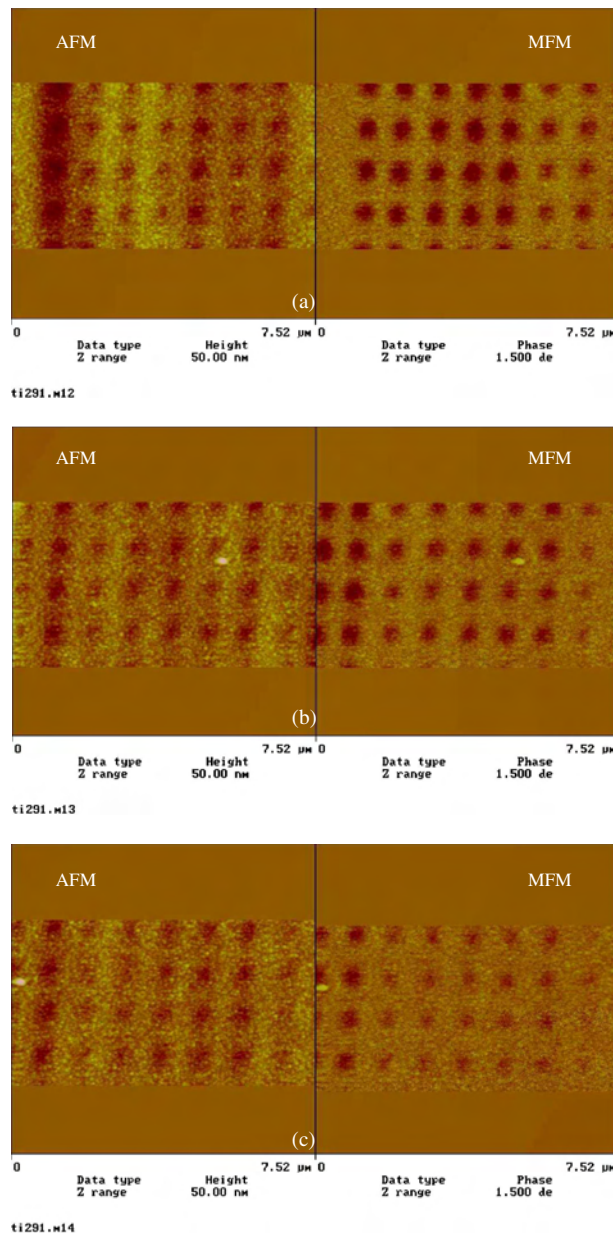
that have undergone a phase change, since they are magnetically soft, whereas the MFM tip did not interact with regions that did not undergo a phase change. These give rise to the MFM contrast, consisting of dark regions (due to


Figure 2. Examples of the magnetic dot (a–c) and line (d–e) array and line arrays. (a) AFM and MFM images of the fabricated dot array with dwell time of 15.2 and 7.6 sec per dot for the first five and last two columns, respectively; (b) AFM and MFM images of the fabricated dot array with dwell time of 15.2, 7.6, and 3.8 sec per dot for the first two, second five, and last one columns, respectively; (c) AFM and MFM images of the fabricated dot array with dwell time of 7.6, 3.8, and 1.9 sec per dot for the first two, second five, and last one columns, respectively; (d) AFM and MFM images of the fabricated line array with dwell time of 1.9 and 0.95 sec per pixel for the first three and last seven columns, respectively; and (e) AFM and MFM images of the fabricated line array with dwell time of 4 and 2 sec per pixel for the first six and last five columns, respectively.
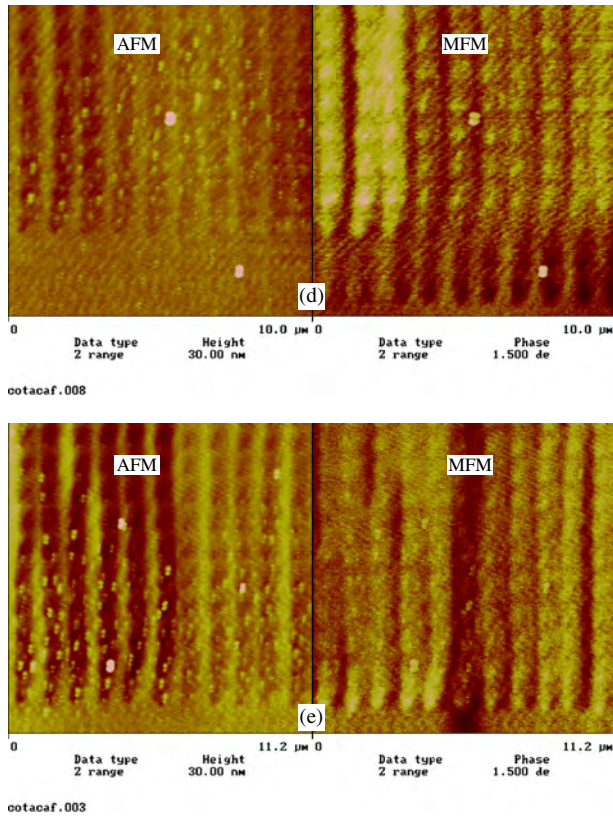

Figure 2. Continued.

the attractive magnetic force) embedded in a bright matrix (nonmagnetic).

The present single-step nanolithography eliminates the cumbersome traditional processes and is potentially a new and flexible alternative for fabricating patterned magnetic nanostructures for ultrahigh density magnetic recording and various magnetic devices.

2.2.2. Direct Interferometric Laser Annealing

Zheng et al. reported an approach to magnetic nanopatterning by direct laser interference annealing, which can produce 2-dimensional (2D) hexagonal dot arrays with a dot size around 250 nm [98–102]. This also is a single-step magnetic nanopatterning method. Firstly, nonmagnetic CoC films with a thickness of 40 nm were deposited onto a water-cooled glass substrate. Then the sputtered films were exposed to a 10-ns-pulsed excimer laser having a wavelength of 308 nm and a flux of 0.17 J/cm^2. The laser beam was split into two beams of an approximately equal intensity, and then were recombined, generating an interference pattern and a periodic modulation of the light intensity. The interference of the four beams leads to the formation of 2D arrays of modified regions, having a minimum lattice periodicity equal to half of the radiation wavelength. The size and shape of the regions depend on the incident angles of the beam, on the pulse duration, and on the flux. Examples of the magnetic dot array are shown in Figure 4.

With this method, the magnetic nanopatterning is attributed to the phase separation or precipitation of Co under local heating at the laser intensity maxima (also magnetic phase change) [129–131]. The as-deposited Co–C film actually contains some Co-rich nanoclusters that are superparamagnetic at room temperature. After laser local annealing, local atomic rearrangements will occur, and more strongly interacting magnetic Co or Co-rich clusters are formed or Co clusters grow bigger, to become a magnetic state in room temperature and yield the observed magnetic phase at room temperature. This method holds the promise to make a big-area pattern quickly and economically but has the drawback of low resolution and low flexibility, and also is limited only to patterns with a linear alignment.
Figure 4. Examples of the magnetic dot array. (a) TEM image of periodic arrays of patterned Co–C films, (b) and (c) AFM and (d) and (e) MFM images of a periodic array of patterned Co–C films after exposing the film to interference laser and a perpendicular field of 1700 Oe was applied parallel (d) and antiparallel (e) to the film-plane normal during scan. (f) MFM image of the patterned Co–C film under higher laser power. Reprinted with permission from [99 and 100], M. Zheng et al., *IEEE Trans. Magn.* 37, 2070 (2001) and M. Zheng et al., *Appl. Phys. Lett.* 79, 2606 (2001). © 2001, IEEE and AIP respectively.

2.2.3. Anisotropy Engineering

Ion-beam irradiation has been shown to be an effective way to alter the magnetic properties of thin multilayer films by roughening the interface or by mixing. Chappert et al. [105, 107–115] reported an alternative of planar patterning a magnetic media by ion-beam-radiation-induced change of magnetic anisotropy of (Co/Pt) multilayer film, and this was further developed by Terris et al. [106] by using a stencil masks. Figure 5 illustrates the schematic of an ion-beam patterning on a Co/Pt multiplayer film through a silicon stencil mask.

To pattern the film, a mask is placed on it and then the mask-covered films are bombarded with an ion beam. Because of the mask-effect, only those portions through which the ions pass will undergo anisotropy change (from out-of-plane to in-plane) by ion-beam induced mixing of interfaces, but this does not affect the parts of the film that are hidden from the radiation by the mask shadow. Thus an array of magnetic elements with a much smaller coercive force and in-plane anisotropy in a magnetic matrix with perpendicular anisotropy is produced. The size of each soft magnetic element is dependent on the resolution of the mask. Examples of the magnetic dot array are shown in Figure 6.

With this method, the magnetic media is patterned into areas with vastly different magnetic characteristics by ion-beam mixing, but the required dose is quite high, and the mask lifetime also is a concern. Additionally, since the coercive field of irradiated area is very low and are inappropriate for magnetic recording purposes. The magnetic contrast between irradiated and nonirradiated areas needs to be maximized, while the topographic variations caused by the ions need to be minimized by the judicious choice of substrate, ions species, and ion energy. However, this technique holds promise for ultra-high-density magnetic recording applications if magnetic properties of the irradiated areas can be improved.

Anisotropy also can be engineered to be out-of-plane and in-plane alternatively by using selective epitaxial growth. Li et al. [132, 133] reported an approach to anisotropy patterning by using selective epitaxial growth. In this method, a modulated single/polycrystalline substrate surface to modify locally the magnetic anisotropy in subsequently deposited magnetic films, which induces the desired artificial magnetic
Figure 6. Examples of the magnetic dot array produced by ion-beam mixing. (a) is SEM image of an area of a mask with 1-μm-dia. holes at 2-mm pitch. (b) is MFM image showing the magnetic contrast that arises from the ion-beam patterning. (c), (d), and (e) are MFM images of Co/Pt multilayers (14 periods of 4 Å Co and 10 Å Pt deposited on fused silica) of irradiated with 10^{15}, 5×10^{15}, and 10^{16} ions/cm^2 of 700 keV N$^+$ ions, respectively, and the circular regions were formed by irradiating the sample through a silicon stencil mask with 1-mm-dia. holes on a 2-mm pitch. Reprinted with permission from [106], B. D. Terris et al., *Appl. Phys. Lett.* 75, 403 (1999). © 1999, American Institute of Physics.

structure. Selective epitaxial growth introduces an alternation between single-crystal and polycrystalline structures in the film, according to the substrate patterning (Fig. 7a). Ni/Cu(001) films with appropriate thickness show perpendicular magnetization, which is due to the magneto-elastic interaction induced by the Ni/Cu(001) interface [134]. In contrast, the magnetization of polycrystalline nickel lies in the film plane because of the dominant demagnetizing field. This magnetic anisotropy patterning opens up new avenues for controlling the spin structure of magnetic materials within the nanometer scale. The simulation results show that the patterned bit resolution can be smaller than 30 nm. Such modulated structures can be used as patterned magnetic media either perpendicularly or longitudinally. Figure 7 shows the pattern produced by using this method.

2.2.4. Magnetization Patterning

Terris et al. reported that magnetic nanopatterning also could be fulfilled by magnetization patterning in one step [116–117]. It is found that magnetic properties of CoCrPt

Arrow indicates a switch of the perpendicular Ni induced by the external stray field of the MFM tip. (c) Polar magneto-optic Kerr-effect hysteresis loops for the unpatterned reference sample (left panel) and the wire sample (right panel). Solid and dotted arrows indicate the magnetization orientation in the epitaxial and polycrystalline regions, respectively, of the Ni film. Reprinted with permission from [132], S. P. Li et al., *Nature* 415, 601 (2002). © 2002, Macmillan Magazines Ltd.

films with perpendicular anisotropy can be changed by ion-beam irradiation. Figure 8 shows the hysteresis loops of CoCrPt measured by Kerr rotation as a function of an irradiated Ga$^+$ dose. It is clear that the coercivity drops with the dose, as does the remanent magnetization. Under the proper dose, the coercivity and remanence will vanish. With this method, a focused ion beam (FIB) is used to machine a grid pattern into thin-film CoCrPt media to leave isolated magnetic islands. The cuts were made by moving the beam in 5 nm steps to cover the desired grid. To ensure a regular period, the patterns were cut by repeated sweeps, rather than by making a single pass. Examples of such a produced dot array are shown in Figure 8.

Writing and reading on such produced media also were done with much better recording performance compared with unpatterned media [135–137].

The chemically ordered CrPt$_3$ with L1$_2$ (Cu$_3$Au) phase (the Cr atoms site at the corners and Pt atoms at the faces of a unit cell) also can be magnetically patterned by using magnetization patterning [138–142]. Neutron diffraction studies of magnetic measurements have shown that chemically ordered CrPt$_3$ is ferrimagnetic, with localized moments of 2.33 and -0.27 m for Cr and Pt, respectively. The chemically disordered CrPt$_3$, which is nonmagnetic, is structurally face-centered cubic (fcc) and the sites are randomly substituted. Hellwig et al. found that ion irradiation can locally
Figure 8. AFM and MFM images of a 2 μm×2 μm patterned region are shown in (a) and (b), respectively, along with higher magnification images of small regions in (c) and (d), respectively. The pattern period is ~100 nm. This pattern was made with a 60 sec exposure to a 1 pA 30 keV beam. Reprinted with permission from [116], C. T. Rettner et al. *IEEE Trans. Magn.* 37, 1649 (2001). © 2001, IEEE.

transform chemically ordered CrPt$_3$ into the chemically disordered fcc phase. This suppresses the ferrimagnetism and thus provides a mechanism for patterning magnetic and non-magnetic regions within a magnetic film.

2.2.5. Laser-Assisted Direct Imprint

Chou et al. [118] reported one ultrafast approach to nanopatterning by direct imprint of nanostructures. With this method, a single XeCl excimer laser pulse (308 nm wavelength and 20 ns pulse duration) passes through a quartz mold (which does not absorb the laser energy because it has a bandgap larger than the photon energy) and melts a thin surface layer of the silicon substrate within picoseconds [118, 119]. The molten silicon layer (which can be about 300 nm deep and remain molten for hundreds of nanoseconds) is then embossed by the quartz mold. After the liquid silicon solidifies, the mold is separated from the imprinted silicon for the next imprint. Figure 9 shows the process schematically. Chou et al. created features of 140-nm dimension (the limit of their mask). But detail at the level of 10 nm on these features also was replicated, indicating the extraordinary resolution of the process. This technique also can be used for patterning polycrystalline films of silicon, one of the most critical steps in patterning silicon chips. Because there is no need for expensive focusing optics, the printing equipment is much simpler than a stepper. And the absence of a resist eliminates the cost. The nanostructures fabricated by using this method, as an example, are shown in Figure 10. After direct imprinting, magnetic films can be deposited into the template to form patterned magnetic nanostructures.
Figure 9. Schematic of the process. (a) A quartz mold is brought into contact with the silicon substrate. A force presses the mold against the substrate. (b) A single XeCl (308 nm wavelength) excimer laser pulse (20 nm pulse width) melts a thin surface layer of Si. (c) The molten silicon is embossed, while the silicon is in the liquid phase. (d) The silicon rapidly solidifies. (e) The mold and silicon substrate are separated, leaving a negative profile of the mold patterned in the silicon. Reprinted with permission from [118], S. Y. Chou et al. *Nature*, 417, 802 (2002). © 2002, Macmillan Magazines Ltd.

2.2.6. Ion-Beam-Induced Chemical Vapor Deposition

Fabrication of magnetic dot arrays by IBICVD was proposed and demonstrated by Lapicki et al. [120, 121, 123]. The principle of the method is illustrated in Figure 11 [120]. It is dependent on the energy and momentum exchange between incident ions and molecules of a precursor suitable for the metal of interest (Fe, Co, Ni, etc.). Collisionally induced decomposition of the precursor occurs near the substrate surface, and it is followed by dynamic deposition of the metal into top layers of the substrate. Dot arrays of alloys and compounds, such as FeNi, FeCo, FePt, CoPt, $SmCo_5$, which have potential applications in data storage and information processing, can be produced by introducing two or
Figure 10. SEM image of the cross section of samples patterned by using LADI. (a) A quartz mold. (b) Imprinted patterns in silicon. The imprinted silicon grating is 140 nm wide, 110 nm deep, and has a 300-nm period, an inverse of the mold. Reprinted with permission from [118], S. Y. more precursors. Figure 12 shows the cobalt dot arrays fabricated by IBICVD on a glassy carbon substrate, and this is an *in-situ* imaging by secondary electron microscopy of the FIB system.

Such fabricated dots are rather flat and are partially embedded in the substrate layer, and post annealing usually is needed to obtain better magnetic properties. Although this method is best suitable for the laboratory scale, it has its analog among projection schemes, which can produce a large enough area for practical usage.

2.2.7. Ion Projection Direct Patterning of Magnetic Nanostructures

Ion-beam irradiation has been demonstrated to be an effective way to modify the magnetic properties of Co–Pt multilayers with strong perpendicular magnetic anisotropy, and patterning of magnetic nanostructures can be fulfilled by local ion-beam exposure-induced mixing. However, focused
Figure 12. Cobalt dots fabricated by IBICVD on glassy carbon. *In-situ* imaging by secondary electron microscopy of the FIB system. Reprinted with permission from [120], A. Lapicki et al., *IEEE Trans. Magn.* 38, 2589 (2002). © 2002, IEEE.

ion-beam direct writing is too slow to be of practical usage. Ion-projection direct structuring (IPDS), as sketched in Figure 13, was proposed and demonstrated by Deitzel et al. [126]. This method facilitates a large-area patterning process, which potentially is of commercial use for manufacturing future magnetic storage media. The structures required for reading and writing on spinning disks in hard-disk drives (HDD), including bit cells in a circular arrangement and servo (head positioning) structures, can be integrated in a single stencil mask. By IPDS, the stencil mask patterns can be transferred into the magnetic medium at a given demagnification factor, which relaxes the resolution requirements for the stencil mask process.

By IPDS, at $8.7\times$ demagnification, the smallest mask openings currently available in the mask test structures could be successfully transferred into a magnetic pattern, as shown in Figure 14. The nominal feature size can be deduced from the dimensions of square mask openings and the projector demagnification factor as 57 nm $\times$ 57 nm. Figure 14(a) confirms dot diameters of less than 100 nm. Potential reasons for the observed widening and rounding in the MFM images are the following: blur in the ion optics, magnetic-coupling phenomena, and, to some degree, MFM resolution. A second type of deviation from the geometrically projected array of mask openings is that some of the islands, especially in the denser pattern, are slightly shifted from their regular position. This can be attributed to local charging effects in the masks as presently used for the experiments. The unmodified surface roughness observed after exposure by means of AFM (Fig. 14b) confirms that IPDS is compliant with requirements regarding the surface quality of magnetic storage media.

Ion projection facilitates a direct structuring, which is an attractive potential manufacturing process for patterned storage media. In contrast to conventional resist processes or direct-contact printing techniques, this is a noncontact process, and the surface quality of the as-grown storage media is preserved. Nevertheless, further work, including improvements in mask technology, material development, and adaption of the ion projector to the some specific requirements,

Figure 14. (a) MFM analysis of a Co–Pt ML sample exposed through a stencil mask with 3×10 Xe/cm. The upper right part corresponds to a Cartesian configuration of 0.5-μm-wide square mask openings. The image was taken after fully magnetizing the sample with an external field of 1.4×10^6 A/m and subsequently countermagnetizing the irradiated islands by applying a field of 0.4×10^6 A/m in opposite direction. (B) AFM analysis of the same area. From this scan, a surface roughness (rms value) of 1.1 nm is determined. Reprinted with permission from [126], A. Dietzel et al., *IEEE Trans. Magn.* 38, 1952 (2002). © 2002, IEEE.

have to be carried out to demonstrate the application of IPDS for patterned magnetic media with areal densities well beyond 15 Gbit/cm^2 (100 Gbit/in^2).

2.3. Template Growth Approach

There are two main methods that have been developed for making arrays of magnetic particles with using self-organized templates. One is the use of anodized alumina films with ordered and variable-sized holes as templates for electrode-position [61–65]. The anodized alumina films or foils have an oxide layer that contains a close-packed arrangement of fine holes, with the hole spacing and size controlled by anodization conditions such as voltage, current density, or pH value, and a subsequent pore-widening process. The magnetic materials, such as cobalt, nickel, iron, alloys, can be deposited electrically into the holes to form patterned magnetic nanostructures. This method is well suited to the fabrication of arrays of longer nanowires with lengths of microns or more.

The other is self-assembled block copolymers with various geometries as a template to grow patterned magnetic nanostructures [143–158]. A block copolymer consists of chains of two chemically distinct, immiscible monomers, A and B, joined together to form a polymer An–Bm. Self-organized copolymers are spun onto a substrate to form copolymer films followed by selectively removing one domain to form a template. The template can be used to grow patterned magnetic nanostructures as anodized aluminum films do.

The drawback of these template methods is that the structures typically are lacking long-range order, even though the short-range order is good. By combination with traditional lithography, the long-range order could be improved. Alternatively, by growth in a field, to align the self-assembled structure over large distances, the long-range ordering also can be improved. These combined processes are still in the early stages of exploration.

Figure 13. Sketch of the IPDS technique. Ions are generated in a gas-ion source and a broad ion-beam illuminates the stencil mask. A demagnified image of the stencil mask is projected onto the ion-sensitive magnetic medium. The ion energy at the stencil mask is lower than the ion energy at the magnetic medium and the medium surface is at significant distance from the stencil mask. A pattern lock system can compensate for a drift of the image parameters such as linear drift, rotational drift, and magnification shift. Reprinted with permission from [126], A. Dietzel et al., *IEEE Trans. Magn.* 38, 1952 (2002). © 2002, IEEE.

2.4. Self-Assembly Approach

There are various approaches to self-assemble magnetic nanostructures. The first, which is widely used, is the wet self-assembly (chemical route) [66–80]. The other, which is far from mature, is the dry self-assembly by ion-beam bombardment [159, 160], cluster deposition [161–169], and thermal deposition [170–174].

2.4.1. Wet Self-Assembly

For wet self-assembly (chemical route), monodispersed magnetic nanoparticles are needed. The monodispersed nanoparticles can be synthesized by a few chemical ways, such as sol–gel or coprecipitation, and then are assembled on a surface to form a regular array without the need for lithography. This has the potential for making very-fine-scale structures over large areas in a rapid process and thus has attracted considerable attention. Structures with a period of less than 10 nm and a particle size around 3 nm can be made, and so tiny a feature is beyond that of traditional lithography techniques. An example of such a produced FePt dot array is shown in Figure 15.

The challenge for this method is that it is not easy to control the size distribution of the particles to obtain uniform properties. The second problem is that the long-range ordering is poor, although the short-range ordering is quite good. For this method, the ordering is very good at keeping within several microns, and in combination with lithography, this could be a way to overcome the short-range ordering.

Many other methods to grow nanoparticles besides chemical synthesis, have been developed including vapor phase growth by sputtering, laser ablation, arc discharge, and so forth. These methods typically produce a distribution of sizes from which highly monodisperse samples can be made by size-selective precipitation.

2.4.2. Dry Self-Assembly

Chen et al. [159] demonstrated that patterned magnetic nanostructures can be fabricated by depositing perpendicular magnetic films on self-assembled surfaces by ion-beam

Figure 15. FePt dot array produced by wet self-assembly. Reprinted with permission from [67], S. H. Sun et al., *Science* 287, 1989 (2000). © 2002, American Association for the Advancement of Science.

bombardment. By this method, the magnetic nanopatterning is realized by two steps. Firstly, by ion-beam bombardment, a self-assembled surface is formed, and then by depositing magnetic films on the patterned surface to form patterned magnetic nanostructures.

Chen et al. used a commercial broad ion-beam source with good uniformity (beam-current density better than ±5% within the bombarded area) to bombard epiready GaSb(100) substrate surfaces. Ion-beam bombardment was carried out with Ar^+ (420 eV) ions under normal incidence at a beam current density of ~ 0.4 mA/cm^2 (i.e., a flux of $\sim 2.5 \times 10^{15}$ ions/cm^2 s) and a dosage of $\sim 6 \times 10^{18}$ ions/cm^2. Then perpendicular magnetic Co/Pd multilayer films with a ~ 2.5 nm NiP seedlayer are deposited on the bombarded substrate surfaces to form patterned magnetic nanostructures. The mechanism of forming a patterned surface is due to the interplay between roughening due to the sputtering and smoothing because of a surface diffusion–viscous flow. Examples of such a patterned surface and magnetic nanopatterning are shown in Figure 16.

Further processing steps, such as etching or polishing, are needed to isolate the magnetic elements from each other to make ultrahigh-density magnetic storage media.

Two-dimensional superlattice of molecularly linked metal clusters is another approach to magnetic nanopatterning via dry self-assembly [161]. Andres et al. reported on a process that uses molecular self-assembly to fabricate a 2D superlattice of uniform metal nanocrystals linked by organic interconnects [161–169, 175, 176].

There are four steps involved in the synthesis of a linked cluster network (LCN): (i) synthesis of ultrafine metal crystals with uniform diameters in the nanometer range, (ii) adsorption of a self-assembled monolayer of organic surfactant on the surface of these particles to produce stable macromolecular entities that can be manipulated, (iii) formation of a close-packed monolayer film of these coated particles on a solid substrate, and (iv) displacement of the organic surfactant with a molecular interconnect that covalently bonds adjacent particles to each other without destroying the order in the monolayer film. This method is quite general with respect to the choice of metal, surfactant, and interconnect. If conductive and nonmagnetic metals (Au, Cu, etc.) are selected, the fabricated LCN can be used for nanoscale electronic devices, such as single-electron transistor. If magnetic metals or alloys are chosen, the produced LCN can be used for magnetic data storage and information processing. For the magnetic nanopatterning, the fourth step may not be needed as it is not necessary to bond the adjacent particles to each other covalently.

Figure 17 shows a schematic of the gas-phase cluster source that was used by Andres et al. in their study (Au was used in the study as an example). Au clusters with a controlled mean diameter in the range from 1 to 20 nm and a size distribution characterized by a full-width at half-maximum of 0.5 nm at the low end of this range and 5 nm at the high end have been synthesized in this source at total production rates of 100 mg per h. In order to assure that all of the clusters are single crystals, a dilute aerosol stream of clusters suspended in inert gas is passed through a meter-long tube in which the clusters are first heated to be crystallized and then cooled to room temperature. Then the

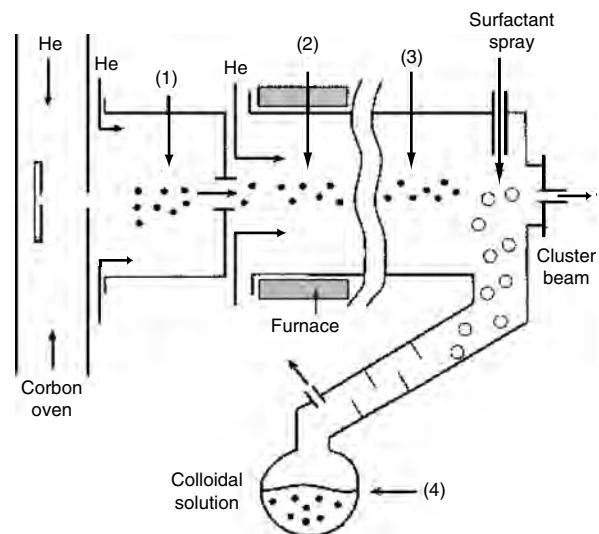
aerosol-containing Au clusters were passed through a spray chamber in which the clusters are captured by contact with a fine spray of organic solvent and surfactant. The spray droplets subsequently are removed from the gas stream and collected in a liquid receiver. The key for successful operation of this collection technique is a surfactant that rapidly adsorbs onto the surface of the clusters and prevents aggregation. With the proper surfactant, it is possible to capture nanometer-diameter metal clusters in various organic solvents without altering the cluster-size distribution [176]. Figure 18 is a schematic representation of the self-assembly process involved in the formation of these close-packed arrays, and Figure 19 is a TEM micrograph of such an unlinked array. The mean diameter of the clusters in


Figure 17. Schematic of process for synthesizing a stable colloidal suspension of crystalline gold clusters. Gold atoms evaporated from a carbon crucible in a resistively heated carbon tube are entrained in He and induced to condense into nanoclusters by mixing the hot flow from the oven with a room temperature stream of He. Controlling conditions in the oven and the flow downstream from the oven (see 1) controls the mean cluster size. The clusters are melted (see 2) and recrystallized (see 3) while still in the gas phase. They are scrubbed from the gas phase by contact with a mist of organic solvent containing 1-dodecanethiol and collected as a stable colloidal suspension (see 4). Before each run, a sample of the cluster aerosol is expanded as a cluster beam into a vacuum chamber and deposited on a TEM substrate for subsequent analysis. Reprinted with permission from [161], R. P. Andres et al., *Science* 272, 1323 (1996). © 1996, American Association for the Advancement of Science.

Figure 19 is 3.7 nm, and the average center-to-center distance between adjacent clusters is 5.0 nm.

By using Co, Fe, Ni, CoPt, FePt, and so forth, as precursors, magnetic nanostructures can be easily fabricated by this approach. The drawback of this method is that the long-range ordering is poor.

Self-assembly of nanoscale magnetic dots with narrow size distributions on an insulating substrate also is a way of magnetic nanopatterning via dry self-assembly. It has been realized that the strain energy associated with the lattice mismatch between the dot and the substrate materials can be exploited to induce a self-assembled formation of quantum dots with narrow size distributions [177–182]. Gai et al. introduced a growth method of magnetic dot array by strain-mediated dry self-assembly [170, 174]. They found that the iron dots could be self-assembled on insulating NaCl substrate by thermal deposition. It is shown that, by properly choosing the growth conditions, nanometer-scale magnetic iron dots with remarkably narrow size distributions can be achieved in the absence of a wetting layer. Furthermore, by changing the dosage of iron, both the vertical and lateral sizes of the dots can be tuned without introducing apparent size broadening, even though the clustering is already in the strong coarsening regime, signified by the decrease in dot density as a function of the iron dosage. The self-assembly is mediated by the strain between the iron dots and substrate. Figure 20 give an example of the fabricated iron dot array.
Figure 18. Self-assembly of a LCN. (A) A drop of organic solvent containing dodecanethiol-encapsulated gold clusters is cast on a smooth substrate. On evaporation of the solvent the long-range dispersion forces between clusters cause them to coalesce into a close-packed monolayer. A TEM micrograph of such an unlinked array is shown in Figure 19A. (B) The substrate with its unlinked cluster array is immersed in an acetonitrile solution containing aryl dithiol or di-isonitrile molecules. The molecular interconnects displace the dodecanethiol molecules from the clusters and form rigid molecular linkages between adjacent clusters. A TEM micrograph of such a linked network is shown in Figure 19B. Reprinted with permission from [161], R. P. Andres et al., *Science* 272, 1323 (1996). © 1996, American Association for the Advancement of Science.

3. APPLICATIONS OF PATTERNED MAGNETIC NANOSTRUCTURES

The applications of patterned magnetic nanostructures are quite broad (biology, drug delivery, spintronics, data storage, information processing, magnetic sensors, etc.) and this review cannot cover all these aspects. Instead, this review will briefly describe their important applications for ultrahigh-density magnetic recording as a medium, with information processing, with magnetic sensors, and with strong permanent magnets.

3.1. Ultrahigh-Density Magnetic Recording Medium

The increase in areal density of magnetic storage devices of >100% annually has been accomplished over the past few years by reducing the physical dimensions while maintaining the principle of storing information on a continuous, granular magnetic medium with in-plane magnetization. However, increases of areal density of hard-disk drives will be limited
Figure 19. Bright-field TEM micrographs of monolayer films of 3.7-nm gold clusters supported on a thin flake of MoS_2. (A) Unlinked array encapsulated by dodecanethiol. (B) Cluster network linked by 20 ADT. Reprinted with permission from [161], R. P. Andres et al., *Science* 272, 1323 (1996). © 1996, American Association for the Advancement of Science.

by thermal instability of the thin-film medium because of the superparamagnetism effect. Perpendicular recording was suggested to push the recording density higher, but it still is ultimately limited by the same effect. Patterned media, in which data are stored in an array of single-domain magnetic particles, have been proposed as an approach to overcome the limitation of superparamagnetism and to enable recording densities of over 1 Tbit/in^2 to be achievable.

A patterned recording medium, shown schematically in Figure 21, consists of an array of magnetic nanoelements, each of which has uniaxial magnetic anisotropy. The easy axis can be oriented parallel or perpendicular to the substrate. Each element stores one bit, depending on its magnetization direction; for instance, magnetization up could represent 1, and down could represent 0. Each element is a single crystalline particle or consists of some grains that are strongly coupled so that the entire element behaves as a single magnetic domain. The medium is incorporated into a system capable of reading and writing data, for example, a spinning-disk system with an ultra-narrow recording head or a system with an array of scanning probes that address the elements.

For a patterned media recording system, it must offer significantly higher data densities than can be achieved in a conventional hard drive. There is confidence that hard drives
Figure 20. Nanometer-scale iron dots grown on NaCl(001) with a nominal Fe dose of 1.7 ML. (a) A typical NC–AFM image. Scan area 500 nm × 500 nm. (b) Close-up and line profile (150 nm long) of the dots. Scan area 200 nm × 200 nm. The unit in the line profile is nm. (c) (d) Diameter and height distributions of the dots shown in (a) and the corresponding Gaussian fits. The center and dispersion for the diameter distribution are 13.5 and 1.1 nm, respectively; and for the height distribution they are 3.76 and 0.36 nm, respectively. that use longitudinal media will be able to reach 300 Gbit/in^2 or higher, so, patterned media designs must be capable of reaching densities of 500 Gbit/in^2 and beyond. This implies a periodicity of less than 40 nm, for instance, 20-nm elements with 15-nm separation. A 35-nm period corresponds to a density of 522 Gbit/in^2. However, fabrication of sub-20-nm features over large areas is somewhat beyond the traditional lithography techniques. The combination of lithography with self-assembly is a possible way to fabricate such required tiny features over large area. This combination is schematically shown in Figure 22. Firstly, using the lithography method, micron-sized features over a large area are fabricated and then self-assemble the nanoparticles onto the micron-sized features to solve the problem of long-range ordering. Nowadays, monodisperse particles with a size of 3 nm can be synthesized. The ultimate patterned medium may consist of an array of magnetic particles with a size down to a few nanometers, self-assembled on a substrate with the aid of lithography to produce an array with long-range ordering.
Figure 21. Schematic of longitudinal (a) and perpendicular patterned media (b).
Figure 22. Schematic of combination of traditional lithography with nanoparticle self-assembly.

Recently, circumferential magnetic patterned media were prepared on a 2.5-inch-diameter glass plate and on a 3-in-diameter silicon plate by combination of traditional lithography with self-assembly [183]. Figure 23 shows a schematic explanation of the preparation method by Naito et al. A Ni master disk with spiral patterns with 60-, 100-, 150-, 200-, and 250-nm-width lands and a 400-nm-width groove (110-nm depth) was purchased from the Nikon Corporation. The master disk was pressed onto a resist-covered magnetic film of either a CoPt or CoCrPt at room temperature and a pressure of 1000 bar. The magnetic film was prepared by sputtering CoPt or CoCrPt onto the disk substrate with a 40-nm Ti underlayer. A diblock copolymer solution [polymethylmethacrylate (PMMA) (Mw41500)–polystyrene (Mw172 000)] was cast into the obtained grooves, and then annealed to prepare self-assembling dot structures aligned along the grooves. The PMMA dots were selectively removed by the oxygen plasma treatment [184]. The resulting holes were filled by spin-on-glass (SOG). The underlying magnetic films were patterned by ion milling by using the SOG dots as a mask. As an example, Figure 24 shows the dot structures of the diblock copolymer in the grooves with different widths. One to four dot lines could be obtained by changing the groove width [185]. Another example, Figure 25(a) shows the SEM image of the patterned magnetic dots with about a 40 nm diameter. The image of the whole patterned media disk prepared on a

2.5-inch-diameter HDD glass plate is shown in Figure 25b. This is the first report on disk-level magnetic nanopatterning for patterned magnetic recording.

3.2. Magnetic Sensors

Cowburn et al. [27] has proposed a new approach to high-sensitivity magnetic field sensing, based on an array of dots that are superparamagnetic. A particle that shows superparamagnetic behavior is because its anisotropy energy $K_u V$ becomes smaller than or comparable to the thermal fluctuation energy $k_B T$. The M~H loops of superparamagnetic particles lose all hysteresis and have a shape that is determined by the Langevin function. The lack of hysteresis makes superparamagnetic particles interesting candidates for field sensors.

For magnetically hard materials, as their K_u is high, the superparamagnetic behavior normally is observed in particles with size of ~10 nm, in which case, the thermal fluctuation field, $k_B T/m$ (m is the moment carried by the particle), is large due to the small value of m. Consequently, the sensitivity of such sensors would be very low because the saturation field of the particles is typically thousands of Oe. Cowburn et al. found that the offset in the linear dependence of configurational anisotropy on size results in thin planar permalloy nanomagnets losing all anisotropy at relatively large sizes, typically 100 nm. This means that magnetically soft permalloy magnets become superparamagnetic
Figure 25. (a) SEM image of the patterned magnetic medium (Co Cr Pt) with a 40 nm diameter. The scale bar indicates 100 nm. (b) Whole image of the patterned media disk prepared on a 2.5-inch HDD glass plate. Reprinted with permission from [183], K. Naito et al., *IEEE Trans. Magn.* 38, 1949 (2002). © 2002, IEEE.

at a large size with large moment on the particles. Consequently, the fluctuation field (and hence saturation field) is very low. The magnetic response is, therefore, guaranteed to be ahysteretic while retaining high sensitivity. Figure 26 shows a hysteresis loop of such dot array. One observes a completely hysteresis-free response combined with very high sensitivity.

3.3. Information Processing—Magnetic Logical Elements

Devices for information processing have been dominated by electronics. However, the emerging of spintronic technologies, which are based on electron spin, as well as charge, may offer new types of devices that outstrip the performance of traditional electronic devices. Spintronic devices use magnetic moment to carry information. To date, two classes of spintronics device have been proposed: semiconductor and metallic. Semiconductor devices will use spin-population imbalances between electrons or nuclei. Metallic devices, including magnetic read heads in hard drive and MRAM (MRAM), represent the information by magnetization direction in a ferromagnetic metal. However, the extent to which information can be manipulated in the magnetic form has, to date, been very limited; MRAM cells, for instance, can only store information. The scope of spintronics could be greatly expanded if, in addition to data storage, magnetic data bits could interact to perform some computation between being written and detected. In the future, one can dream of programmable magnetic logic elements configured to form magnetic central processor units, the brain of the computer. So far, a few magnetic logic elements, such as magnetic quantum molecular automata [30] and magnetic NOT (NOT) gate and shift register [28, 29] have been proposed and demonstrated.

Cowburn et al. proposed magnetic quantum molecular automata. In their proposal, the networks of interacting submicrometer magnetic dots are used to perform logic operations and propagate information at room temperature. The
Figure 26. A hysteresis loops measured from 3-nm-thick square nanostructures of lateral size 150 nm. The magnetization of the entire structure can be reversed with ~2Oe of applied field and has zero hysteresis. Reprinted with permission from [27], R. P. Cowburn, *J. Magn. Magn. Mater.* 242–245, 505 (2002). © 2002, JMMM.

logic states are signaled by the magnetization direction of the single-domain magnetic dots; the dots couple to their nearest neighbors through magnetostatic interactions. Magnetic solitons carry information through the networks, and an applied oscillating magnetic field feeds energy into the system and serves as a clock. Figure 27 shows the networks of quantum molecular automata.

Figure 28 shows the calculated evolution of a soliton propagating along a chain of coupled nanomagnets under the action of a 30 Oe field applied from left to right (*x* direction). The propagation speed of the soliton is dependent on the applied field. These networks offer a several-thousands-fold increase in integration density and a hundredfold reduction in power dissipation over current microelectronic technology.

Cowburn et al. also proposed magnetic NOT gate and shift register. They use a trick of geometry to manipulate magnetization as conventional devices manipulate an electric charge. The NOT gate consists of a simple track of naturally magnetic nickel–iron wire, shaped like an upside-down Y (shown in Fig. 29). The magnetism of the alloy naturally runs parallel to the track, but it can be made to flip direction within a short length of the wire. In that case, the two opposing magnetizations meet at a region called a "domain wall." There they either both point toward the domain wall (head to head) or both point away from it (toe to toe). Those two magnetic configurations can be used to encode 0 and 1 values for bits of information. Up to 11 of these junctions are then directly linked together to create a magnetic shift register as shown in Figure 30.

This tiny device that answers "no" when it is told "yes" and vice versa could mark the first step toward microchips that calculate magnetically.

3.4. Strong Permanent Magnets

Exchange-spring magnets are nanocomposites that consist of magnetically hard and soft phases that interact through magnetic exchange coupling [186–191]. Such systems are

Figure 30. (A) FIB image of a magnetic ring, including 11 NOT junctions, with the asterisk indicating the position of subsequent MOKE analysis. The directions of elliptical magnetic field components, Hx and Hy, are also indicated. (B) MOKE analysis of an identical structure within a clockwise-rotating magnetic field (Hx = 15 Oe and Hy = 50 Oe). Reprinted with permission from [28], D. A. Allwood et al., *Science* 296, 2003 (2002). © 2002, American Association for the Advancement of Science.

promising for advanced permanent magnetic applications, as they have a large energy product—the combination of large coercivity field of permanent magnet and high magnetization of soft magnet—compared to traditional, single-phase materials [192–194]. Conventional techniques, including sputtering [195–197], mechanical milling [198–200], and melt-spinning [201–203], have been used to produce exchange-coupled magnets. However, it is still a big challenge to structurally control the hard and soft phases at the nanometer scale to fulfill exchange coupling efficiently. The recent and timely introduction of a fabrication method of exchange-coupled nanocomposites by using nanoparticle self-assembly by Zeng et al. [204] has opened a new window to structurally control the hard and soft phases at the nanometer scale. In their approach, both FePt and Fe_3O_4 particles are incorporated as nanometer-scale building blocks into binary assemblies. Subsequent annealing converts the assembly into FePt–Fe_3Pt nanocomposites, where FePt is a magnetically hard phase and Fe_3Pt, a soft phase. An optimum exchange coupling and, therefore, an optimum energy product, can be obtained by independently tuning the size and composition of the individual building blocks. They have produced exchange-coupled isotropic FePt–Fe_3Pt nanocomposites with an energy product of 20.1 MGOe, which exceeds the theoretical limit of 13 MGOe for nonexchange-coupled isotropic FePt by over 50 per cent. Figure 31 exemplifies the TEM images of Fe_3O_4:$Fe_{58}Pt_{42}$ binary assemblies with different sizes and a fixed mass ratio of 1:10. Figure 32 shows a typical high-resolution TEM image of a sintered sample obtained from a 4 nm:4 nm assembly.
Figure 31. TEM images showing binary nanoparticle assemblies. (a) Fe_3O_4 (4 nm):$Fe_{58}Pt_{42}$ (4 nm) assembly; (b) Fe_3O_4 (8 nm):$Fe_{58}Pt_{42}$ (4 nm) assembly; and (c) Fe_3O_4 (12 nm):$Fe_{58}Pt_{42}$ (4 nm) assembly. The assembly contained Fe_3O_4 and FePt binary nanoparticles with a mass ratio of Fe_3O_4:FePt = 1/10 and was formed by solvent vaporation of the mixed nanoparticle dispersions on amorphous carbon-coated TEM grids. All images were acquired using a Philips CM12 microscope at 120 kV. Reprinted with permission from [204], H. Zeng et al., *Nature* 420, 395 (2002). © 2002, Macmillan Magazines Ltd.
Figure 32. Structural analyses of the FePt–Fe_3Pt nanocomposite obtained from the annealed Fe_3O_4 (4 nm):$Fe_{58}Pt_{42}$ (4 nm) assembly. (a) A typical HRTEM image for a sintered FePt–Fe_3Pt particle. The FePt and Fe_3Pt phases are in coexistence as different domains within the particle, with each domain having a dimension of about 5 nm, showing a modulated FePt–Fe_3Pt spatial distribution. Here, the FePt (ordered f.c.t structure) and Fe_3Pt (ordered fcc structure) phases were identified by their different [001] projected potential, owing to their different composition modulation periodicities. The image was acquired by using a Jeol 4000EX HRTEM at 400 kV. To prepare the TEM samples, the composite was deposited on a solid NaCl substrate. The substrate was then removed in water, and the composite was thinned by using ion milling for TEM observation. (b) A typical SAD pattern of the FePt–Fe_3Pt nanocomposite. The f.c.t.-structured FePt was indexed in the ring pattern. The diffraction rings of the fcc-structured Fe_3Pt cannot be resolved from those of the FePt phase. The ring pattern of the diffraction demonstrates that the nanocrystallites in the nanocomposite are three-dimensionally randomly oriented. Reprinted with permission from [204], H. Zeng et al., *Nature* 420, 395 (2002). © 2002, Macmillan Magazines Ltd.

Although progress has been made by using a self-assembled composite of nanoparticles, there are still many practical challenges to be faced if energy products approaching the magic number of 144 MGOe are to be achieved. For instance, ways of compressing the two-phase material into a high-density compact must be explored, as well as improved alignment of the axes of the hard grains to exploit the full magnetic potential of the nanocomposite system.

4. CONCLUSION

We have attempted to review some of the current topics for magnetic nanopatterning methods and their applications. The starting point was the magnetic nanopatterning technology, including the most expensive and traditional approaches and some newly developed nontraditional methods. It is appears that all lithography methods presented are useful in enabling certain applications. As the feature size scales down further to sub 10 nm, which is aiming for, but not only limited to, advanced information technologies such as molecular electronics (moletronic), data storage (nanoBIT), and quantum information processing, it is necessary to develop new nanofabrication technologies with the help of molecular self-assembling and self-organization to produce tiny enough feature size with long-range ordering and large area.

Data storage, magnetic memory and sensors, magnetic information processing, and even biological microsystems are the well-identified application areas of patterned magnetic nanostructures. Due to the too many aspects of magnetic nanopatterning and too rapid development of their

applications today, it was not possible to cover the topic in an exhaustive manner, and a selection of the most important issues was thus chosen by the authors. However, we hope that the stimulating conjunctures in this chapter will encourage new exploration of this exciting area.

GLOSSARY

Anisotropy patterning A method to pattern magnetic film by engineering the anisotropy of the magnetic film to be out-of-plane and in-plane alternatively via ion beam radiation or selective epitaxial growth.

Anodized alumina template A film or foil having alumina layer which contains a close packed arrangement of fine holes, with the hole spacing and size controlled by anodization conditions such as voltage, current density, or pH value.

Block copolymers A polymer mixture consisting of chains of two chemically distinct, immiscible monomers A and B.

Electron beam lithography A lithography approach with which an electron beam is used to write pattern into resist layer.

Exchange-spring magnet Magnetic nanocomposites consisting of magnetically hard and soft phases that interact through magnetic exchange coup.

Ferromagnetism A term used to characterize strongly magnetic behavior with spontaneous magnetization.

Laser-assisted direct imprint (LADI) An ultrafast approach to nanopatterning by direct imprint of nanostructures on laser-melted surface.

Laser interference lithography A lithography approach using laser interference to write pattern into resist layer.

Lithography The art or process of putting writings or designs on stone with a greasy material and producing printed impressions therefrom; also, any process based on the same principle, as one using zinc, aluminium, or some other substance instead of tone.

Longitudinal medium A recording medium with which the magnetization of the recorded bit lies in the plane of the disk.

Magnetic NOT gate A magnetic logical element consisting of a simple track of naturally magnetic nickel-iron wire, shaped like an upside-down Y, which answers "no" when it's told "yes" and vice versa.

Magnetic quantum molecular automata (MQCA) A magnetic logical element using the networks of interacting submicrometer magnetic dots to perform logic operations and propagate information.

Magnetic random access memory (MRAM) Information is carried by magnetic moment.

Magnetization patterning A method to pattern magnetic film by selectively altering the magnetization of magnetic films via laser and ion beam radiation.

Paramagnetism A term describing a feeble magnetism, which exhibits positive susceptibility of the order of 10^{-5} to 10^{-2}.

Patterned magnetic nanostructure A 1- or 2-dimensional magnetic nanoelement array or 3 dimensional superlattice.

Patterned medium A recording medium consisting of an array of magnetic nanoelements with uniaxial magnetic anisotropy.

Perpendicular medium A recording medium with which the magnetization of the recorded bit is perpendicular to the plane of the disk.

Resist A polymer or polymer mixture used as a thin coating over some base and subsequently exposed in an image-wise fashion for micron or nano patterning.

Superparamagnetism A magnetic particle or particle assembly which exhibits paramagnetic behavior due to its anisotropy energy $K_u V$ becoming smaller than or comparable to the thermal fluctuation energy $k_B T$.

Thermal diffusion length A length, described by $L_{ex} \propto \sqrt{kt}$, referring to the thermal conducting distance in a material with thermal conductivity k within time t.

Pb-Based Ferroelectric Nanomaterials

Ki Hyun Yoon

Yonsei University, Seoul, Korea

Dong Heon Kang

University of Suwon, Suwon, Korea

CONTENTS

1. INTRODUCTION

There has been significant interest in the ferroelectric and antiferroelectric perovskite thin films such as $Pb(Mg_{1/3} \cdot Nb_{2/3})O_3$ (PMN), $Pb(Zr,Ti)O_3$ (PZT), $(Ba,Sr)\,TiO_3$ (BST), and $Pb(Zr,Sn,Ti,Nb)O_3$ (PZSTN) because of their potential advantages for electro-optic and microelectronic applications including capacitors, pyroelectric detectors, ultra-high-density data storage systems, nonvolatile semiconductor memories, piezoelectric sensors and devices [1–9]. Recently, with miniaturization and integration of electronic circuits, the electronic devices with high performance in their small size up to nano scale are increasingly required. Current microelectromechanical systems (MEMS) technology, which is typically constructed on the micrometer scale, is being pushed into the nanometer range as well, leading to the nanoelectrochemical system (NEMS) [10–13]. It is well known that such a regime will be attainable by not only nanomachining technique such as lithography and printing but also proper thin-film techniques with homogeneous and fine grains under 100 nm in size. However, in the early stage, the interest in this nanotechnology has been mainly focused on the ceramic powders, which increased enormously with the availability and the possibility of consolidation into dense nanostructured ceramics. The most important factors limiting this goal are powder agglomeration, contamination during processing, and the residual pores on various length scales in the bodies [14–16]. Nowadays, the nanocrystalline structure has been obtained more frequently and actually through the thin-film process rather than through the powder process. For such submicron-scale applications very fine-grained thin films with highly uniform and highly textured microstructures are preferable. Thus intensive and extensive studies have been attempted to prepare the applicable thin films with nanocrystalline structures by using various fabrication methods, such as wet-chemical processes, physical and chemical vapor depositions [17–31]. In the case of solution-based (wet)-chemical method, it has been known to offer numerous advantages, including excellent compositional control, uniform homogeneity, ease of fabrication over large area, and especially low cost. And so several wet-chemical methods utilizing metallorganic compounds and sol–gel processing have been extensively employed to prepare thin films of the lead-based ferroelectric materials [32, 33]. The methoxyethanol route in which 2-methoxyethanol was conventionally used as a solvent has been applied to the alkoxide-based sol–gel process for the film preparation because 2-methoxyethanol can act as a bridging ligand and has a sufficient solubility for alkoxides and salts [34, 35]. However, lead-based thin films deposited on the Pt or oxide electrode by conventional methoxyethanol sol–gel process suffer from the presence of irregular microstructures which are detrimental to submicron device performance. Modified processes using different solvents and/or chelating agents are often applied to overcome some problems of solution and film such as the instability against moisture and difficulty of multicomponent synthesis [36–38].

In this study we introduced the solution-derived lead-based perovskite thin films with different chemical compositions and electric phases such as ferroelectric $Pb(Mg_{1/3}Nb_{2/3})O_3$ (PMN), ferroelectric $PbTiO_3$ (PT), antiferroelectric $PbZrO_3$ (PZ), ferroelectric/antiferroelectric $Pb(Zr_{1-x}Ti_x)O_3$ (PZT), and ferroelectric/antiferroelectric

$Pb_{0.99}[(Zr_{0.6}Sn_{0.4})_{1-X}Ti_X]_{0.98}Nb_{0.02}O_3$ (PZSTN) by using the modified and conventional methoxyethanol routes [39–41]. Their microstructures could be controlled in the respect of solution chemistry, phase transformation kinetics, and composition control, respectively. The solution processing, film heat-treatment condition, film composition, and deposition sequence are widely discussed in terms of the nanocrystallization of the thin film. Considering the fact that in case of chemical solution-derived thin films, most of fabrication processes were limited to the hydrothermal and spray pyrolysis methods [19–27], this study seems to be meaningful. Furthermore, the recent approaches have been to acquire a long-term reliability of the ferroelectric thin films including resistance to electric fatigue, imprint, and leakage. It has been suggested that the fatigue in the antiferroelectric ceramics and thin films is much less severe than that in the ferroelectric counterparts [42, 43]. Also, the modification of nanocrystalline size is thought to be related closely with electrical fatigue. So the novel method has been introduced to modify nanocrystalline microstructure and to study its effect on electrical fatigue in PZT and PZSTN with the Pt electrode system. Therefore, the main topics of this chapter are to explain and analyze the effects of the modified solution chemistry, crystallization, and compositional variation on the nano-scale microstructure and related characteristics of the ferroelectric and antiferroelectric lead-based thin films.

2. SYNTHESIS OF LEAD-BASED FERROELECTRIC THIN FILMS

2.1. Solution Preparation

The Pb-based complex perovskite films were prepared by a conventional methoxyethanol chemical solution deposition [44] and a modified version of the route described by Yi et al. [35] and Park et al. [39, 45]. The starting materials were lead acetate ($Pb(CH_3COO)_2 3H_2O$), zirconium n-propoxide ($Zr(O-nC_3H_7)_4$), magnesium ethoxide ($Mg(OC_2H_5)_2$), tin acetate ($Sn(CH_3COO)_4$), titanium isopropoxide ($Ti(O-iC_3H_7)_4$), and niobium ethoxide ($Nb(OC_2H_5)_2$). Propylenglycol, deionized water, and 2-methoxyethanol ($CH_3OC_2H_4OH$) were used as a solvent. For the PMN and PZT precursors prepared by modified process, triethanolamine (TEA) and acetylacetone (AcAc) were used as a complexing agent to control hydrolysis reaction with metal alkoxides, respectively. In the case of PMN solution, the A-site and B-site precursors of ABO_3 perovskite structure were prepared separately. The appropriate amounts of the B-site precursors, such as magnesium ethoxide and niobium ethoxide, were mixed in 2-methoxyethanol and heated to ~110 °C for 24 h in a dry atmosphere. The solutions were then cooled to room temperature and then TEA (R = 1; where R = mole of TEA/mole of metal alkoxides) was added to create the B-site complex compound. In a separate vessel, to make the A-site precursor, lead acetate trihydrate was mixed with propyleneglycol and water in a 1:12:44 molar ratio. The solution was then heated to ~70 °C for dissolution of lead acetate trihydrate. This method was used to prepare all of Pb precursors. Finally, the A-site and

B-site precursors were mixed and allowed to react at room temperature for 3 h to form the PMN solution.

For the preparation of PT and PZ solutions, titanium isopropoxide and AcAc (R = 1; where R = mole of AcAc/mole of metal alkoxides) were added in 2-methoxyethanol. The refluxing and distillation of this mixture resulted in gold-colored solutions with a concentration of about 0.5 M. After refluxing for 3 h in air, the solution was cooled to room temperature. Finally, the PT chemical solution was prepared by mixing of the Pb and Ti solutions and diluting with 2-methoxyethanol. Similarly, PZ solution was prepared by the same solution processing method mentioned above. $Pb(Zr_{0.5}Ti_{0.5})O_3$ (PZT) solution was obtained by mixing and reacting equal amounts of PT and PZ precursors. For (x)PMN-$(1-x)$PZT and (x)PMN-$(1-x)$PT solutions, the corresponding amounts of PZT, PT, and PMN precursors were mixed and allowed to react for 3 h to obtain a desired composition.

In the conventional process, all starting sources of lead for A-site cation and others such as Zr, Nb, Sn, Ti for B-site cation were refluxed and distilled in 2-methoxyethanol as described elsewhere [42, 43]. Then each solution was admixed to the corresponding $Pb_{0.99}[(Zr_{0.6}Sn_{0.4})_{1-X}Ti_X]_{0.98}Nb_{0.02}O_3$ (PZSTN), PZ, and PZT compositions. Various PZSTN compositions with different electric phases were obtained by changing x; as $x = 0.03$ for antiferroelectrics (40/3/2) and $x = 0.15$ for ferroelectrics (40/15/2). All mixed-precursor solutions prepared by the modified and conventional processes were partially hydrolyzed to give a 0.3 M stable sol by diluting them with 2-methoxyethanol. After refluxing at room temperature for 24 h in air, they were aged for 24 h for the film coating process.

2.2. Thin-Film Fabrication

Film deposition was carried out on the Pt (111)-coated {100} silicon substrates (Si/10,000Å-SiO₂/200Å-Ti/1500Å-Pt) by spin-coating at 2800 rpm for 30 s. Following pyrolysis at 350–380 °C for 3 min, additional layers were spin-coated to build up the desired thickness. The films were crystallized by the rapid insertion heating process at 700–750 °C for 10 min. The final film thicknesses were about 330–350 nm. In order to investigate the effect of heat-treatment procedure on microstructure and related characteristics, three different conditions (F I, F II, F III) for the ferroelectric PMN-PT thin-film series and two different conditions (AF I, AF II) for the antiferroelectric/ferroelectric PZSTN thin-film series were selected, respectively. For the F I process, the film was singly crystallized at 730 °C for 5 min after deposition of multilayer amorphous film. For the F II, the film was crystallized at 730 °C for 5 min after heating the first layer at the same condition, while layer-by-layer heating at 730 °C for 5 min was done in sequence for the F III process [39].

The antiferroelectric/ferroelectric PZSTN thin films were formed by crystallizing at 700 °C for 10 min after heating each layer at 350 °C (AF I) and after crystallizing each layer at 700 °C for 5 min without pyrolysis at 350 °C (AF II), respectively. In case of the thin films having the buffered structure, a total of seven layers was deposited with varying stacking sequences such as AFE layer/FE layer/AFE layer

(AFE buffered FE), and FE layer/AFE layer/FE layer (FE buffered AFE), where PZT(50/50) and PZNST (40/15/2) thin films, and PZ and PZNST (40/3/2) thin films were applied as ferroelectric and antiferroelectric layers, respectively. The total thickness of the annealed films was about 330 nm.

2.3. Measurements and Characterization

2.3.1. Spectroscopic Characterization

The structure and crystallinity of the films were characterized by an X-ray diffraction (XRD; Rigaku Co., Japan) using CuKα radiation. Typically step scans from 20° to 60°, at 0.04 increments and 4 s count time, were used. A differential thermal analysis (DTA) and thermogravimetry (TG) were performed on dried gel powders which were prepared by heating to 150 °C for 24 h. DTA diagrams were obtained at a heating rate of 10 °C/min and an airflow rate of 40 cm³/min. Also organic residue of the film after coating each layer was analyzed by using FT-IR (1600, Perkin Elmer, USA), where the film was deposited on MgO(100) single crystal. The film morphology was observed by a scanning electron microscope (SEM; S4200, Hitachi, Japan).

2.3.2. Electrical Measurements

Electrical measurements were made through the film thickness using Pt top electrode 0.5 mm in diameter prepared by sputtering through a shadow mask. Electrical contact was made to the bottom electrode with a probe wire, whereas the top contact was made with a microprobe tip. Low field dielectric properties were determined by an impedance/gain phase analyzer (4194A, Hewlett-Packard, USA) with an oscillation of 10 mV and frequencies of 0.1 kHz to 100 kHz. The hysteresis loop of polarization (P) versus electric field (E) and the fatigue characteristics of each film were obtained with a modified computer-controlled Sawyer–Tower circuit using an RT66A ferroelectric tester (Radiant Tech., USA) in conjunction with an external function generator (19, Wavetek, USA) and digitizing oscilloscope (VC6025, Hitachi, Japan).

3. PHYSICAL PROPERTIES OF PMN AND PZT THIN FILMS

3.1. Solution Chemistry

Since Budd et al. [34] first demonstrated the methoxyethanol route, the modification of this route has been done in many ways. Especially to control the hydrolysis and condensation reaction of parent alkoxides during solution preparation, a number of related sol–gel methods using several alkoxides stabilized by chelating agents, or using other alcohol solvent, have been proposed. Alkoxides of some metals, such as Zr, Ti, and Nb, react with β-dikonates, diethanolamine, or triethanolamine to form chelate complexes [35, 39, 46]. These chelated complexes are less sensitive to moisture and result in stability to hydrolysis and precipitation during the solution preparation. Generally, thin films prepared by using solution stabilized by chelating agent show relatively high crystallization temperature and small grain size but little porous

microstructure because they contain more carboxyl ligand and require high thermodynamic driving force to decompose the organic compound. A good understanding of organic decomposition behavior of solution precursor and/or gel in chemical solution processing is essential to obtain more dense microstructure in chemical solution-derived thin films.

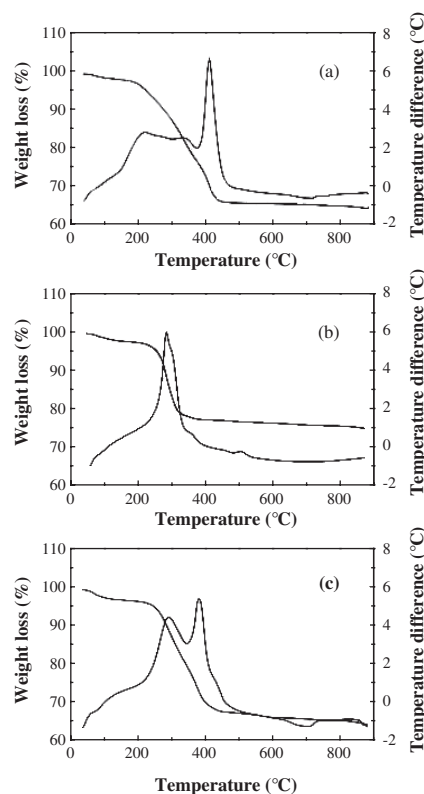
DTA/TG diagrams of PMN, PZT, and 0.5PMN-0.5PZT are represented in Figure 1a, b, and c. The main exothermic peaks at 300–400 °C are due to the combustion of the carboxylate compounds bound to the alkoxy groups in the precursors. This is also confirmed by a distinct weight loss in the TG data of Figure 1 [47]. It is noted that the temperature at which organic pyrolysis occurred is slightly different for the different compositions. In case of PMN gel powder, a large exothermic peak due to organic combustion appears at around 400 °C, while for the PZT and 0.5PMN-0.5PZT gel powders, it appeared at about 288 °C and 360 °C, respectively. The difference of organic pyrolysis temperature is mainly attributed to different chelating agents used in the preparation of each chemical solution as explained in the previous experimental section. This suggests that the pyrolysis behavior is related to the character of carboxylate groups in the PMN and PZT solution because different complexing agent was used to stabilize each solution. Tahan et al. [48] reported that DTA diagrams of dried gels were dependent on the mixed ratio of acetic acid to ethyleneglycol in (Ba, Sr)TiO$_3$ solution processing. Thus, this difference is


Figure 1. (a) DTA/TG curves of PMN solution-derived gel powder, (b) PZT solution-derived gel powder, and (c) 0.5PMN-0.5PZT solution-derived gel powder. Reprinted with permission from [47], J. H. Park et al., *Ferroelectrics* 260, 75 (2001). © 2001, Gordon and Breach.

also explained by comparison of physical properties of the constituents used in this study. Table 1 represents the physical constants of typical solvent and various chelating agents [49]. As shown in Table 1, TEA has higher molecular weight and boiling point than those of acetylacetone or acetic acid. This reason is why organic pyrolysis temperature of the PMN solution is higher than that of the PZT solution. Two exothermic peaks of the Figure 1c solution also indicate the behavior of different chelating agents in 0.5PMN-0.5PZT solution, where peak temperatures were slightly different. In case of the modified chemical solution process, it may be more worthwhile to consider appropriate heat-treatment condition to eliminate organic content in the amorphous films and minimize the film cracking during the crystallization. Organic pyrolysis behavior was also investigated by FT-IR spectroscopy analysis. The typical FT-IR transmittance spectra shown in Figure 2 ascertain that in case of 0.5PMN-0.5PZT thin films, most organic groups were burned out in the temperature ranges of 350–380 °C. Therefore, an intermediate pyrolysis at 380 °C was performed in case of PMN-containing thin films, while PZSTN thin films prepared by the conventional process based on 2-methoxyethanol were pyrolyzed at 350 °C as explained in the experimental section. Figure 3 shows XRD patterns of the PMN, PZT, and 0.5PMN-0.5PZT thin films crystallized at optimum temperature that was experimentally determined in the range of 700–750 °C. It can be found that all the films prepared by chemical solution have a single-phase perovskite structure within X-ray detection limit. In analyzing the lattice spacing of the materials, the thin-film spacings were slightly larger than in the bulk material. It may be due to the mechanical stress present in thin films caused by lattice or thermal expansion mismatch between the film and substrate, resulting in differences in lattice constant of bulk and corresponding thin-film materials. SEM photographs of the thin films corresponding to above compositions are shown in Figure 4. The PMN and PZT films showed uniform grain structures with an average grain size of about 400 nm and 150 nm, respectively. The 0.5PMN-0.5PZT films also showed uniform and dense microstructure with an average grain size

Figure 2. FT-IR transmittance spectra collected from thin layers by heating at different temperatures, (a) as deposited, (b) 200 °C for 3 min, (c) 300 °C for 3 min, (d) 350 °C for 3 min, and (e) 380 °C for 3 min.

around 200 nm. For the precursor modified with complexing agent or specific catalyst, it requires relatively higher temperature to decompose the organic compound and resulted in smaller grain size distribution or higher crystallization temperature. Similarly, Francis and Payne [50] reported that more uniform and small-grain-sized PMNT thin films were developed by adding benzoic acid as a catalyst.

Figure 5 shows the frequency dependency of the dielectric constant and loss for various films by chemical solution. The room-temperature dielectric constants, measured at 1 kHz, of the PMN, PZT, 0.5PMN-0.5PZT, 0.9PMN-0.1PZT, and 0.9PMN-0.1PT films, are summarized in Table 2

Table 1. Physical properties of typical solvents and chelating agents.

Chemical name Formula	M_w	b_p	ρ	n_D
2-methoxyethanol $C_3H_8O_2$	76.10	124.43	0.9663	1.4028
Propylenglycol $C_3H_8O_2$	76.10	188.2	1.036	1.4324
Acetic acid $C_2H_4O_2$	60.05	118	1.053	1.049

[47, 51, 52]. The dielectric properties of the Pb-based thin films were comparable or superior to those of the films with same composition prepared by conventional sol–gel process as reported previously [50, 53, 54]. This confirms that the chemical solution method modified by the chelating agent used in this study can be applied to prepare a reliable ferroelectric thin film with a variety of lead-based compositions.

3.2. Nucleation and Grain Growth

Figure 6 shows typical XRD patterns for 0.5PMN-0.5PT(50PMNT) thin films prepared according to the multilayer film formation and heating process as explained in experimental part. These diffraction patterns showed that they were developed highly (100)-oriented ones (F I film) (Fig. 3a) while the highly (111)-oriented films were obtained for F I and F II films (Fig. 3b and c). In regard to both (111)- and (100)-oriented thin films, Liu and Phule [55] reported that the (111) nuclei grew and a strong (111) texture developed in sol–gel-derived PZT film, when the film that had a perovskite seed layer formed *in-situ* was subjected to a higher-temperature heat treatment. Tani et al. [56] suggested that (100) PLZT texture was developed, when the film was deposited onto platinized Si substrate which was free of any intermetallic phase between Pt and Ti. Further, they also concluded that this (100) texture represented minimum surface energy. Figure 7 shows the SEM photographs of the 50PMNT films with different multilayer film formation conditions. The thin film deposited by F I process consisted of small and large grains with grain size distribution of
Figure 6. XRD patterns of solution-derived 0.5PMN-0.5PT thin films deposited on Pt-passivated Si by (a) F I, (b) F II, and (c) F III processes. Reprinted with permission from [41], J. H. Park et al., *J. Am. Ceram. Soc.* 82, 2116 (1999). © 1999, American Ceramic Society.

about 50 to 200 nm. On the other hand, the grain size of the film by F II process became smaller. For the film by the F III process shown in Figure 4c, its grain size reduced effectively up to average grain size under 20 nm. It means that introduction of a perovskite seed layer before a crystallization of amorphous thin film could facilitate the microstructural change of the films into more small and uniform grain size distribution. It is possibly ascribed to the presence of more nucleation sites between Pt substrate and the film or in the film, resulting in smaller grain size distribution [40, 57, 58]. The dielectric and ferroelectric properties of the films with different multilayer film formation conditions are summarized in Table 3. The dielectric constant of the F I film was slightly larger compared to that of F II or F III films heat-treated at 730 °C. These results imply that the degree of orientation and microstructure with different grain sizes have effects on the weak-field dielectric properties. A similar correlation between the orientation and grain size distribution has been also noticed by Aoki et al. [59] on sol–gel-derived PZT films, even when no pure perovskite phase was observed. Figure 8 indicates that the microstructure of PZT thin film effectively changed through the addition of relaxor compound and an increase of zirconium to titanium ratio, confirming that nanocrystallization of thin film can be controlled by compositional modification as well as crystallization condition.

Table 3. Comparison of dielectric properties of the 0.5PMN-0.5PT thin films deposited with various annealing conditions.

Annealing condition	Dielectric constant (at 1 kHz)	tan δ (at 1 kHz)	Preferential orientation
F I	1690	0.02	$\langle 100 \rangle$
F II	1378	0.03	$\langle 111 \rangle$
F III	1413	0.03	$\langle 111 \rangle$

4. ELECTRICAL FATIGUE OF PZSTN THIN FILMS

4.1. Grain Size Effect

PZSTN compositions are also known to be attractive material for actuator and transducer applications due to relatively easier introduction of antiferroelectric and ferroelectric phase, leading to large displacement [60–63].

The antiferroelectric (40/3/2) and ferroelectric (40/15/2) PZSTN thin films were prepared by different heat treatments (AF I, AF II, AF III) and their SEM photographs are shown in Figure 9. The films prepared by the AF I process consisted of the large grains for both films (Fig. 9a, b), while, in the films prepared by the AF II, the nanocrystalline microstructure of very fine grains under 100 nm was obtained, where the 40/15/2 film showed a little larger grains than 40/15/2 possibly due to the higher content of ferroelectric (PZT) phase.

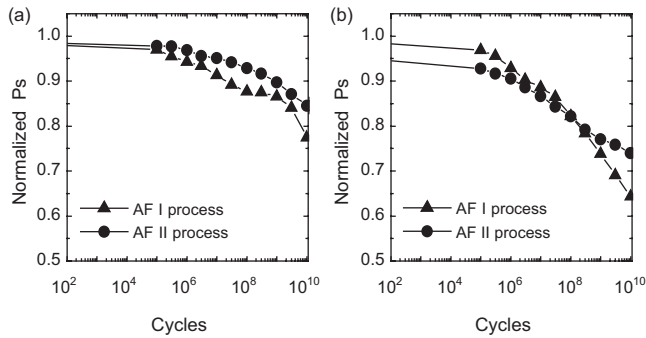
The antiferroelectric film (40/3/2) has small values of switchable polarization compared to those of the ferroelectric film (40/15/2). The saturated polarization (Ps), corresponding to the difference between switched polarization (P*) and the half value of switchable polarization ((P*r-P^r)/2), has been introduced [32, 40]. The change of normalized Ps in the PZSTN thin films is shown in Figure 10. The degradation of polarization in the ferroelectric composition (40/15/2) was steeper than that in the
Figure 9. SEM photographs of the PZSTN thin films with antiferroelectric (40/3/2) composition (a) by the AF I and (c) by the AF II process; and ferroelectric (40/15/2) composition (b) by the AF I process and (d) by the AF II process.


Figure 10. Comparison of the fatigue curves between the films prepared by the AF I process and the AF II process for (a) antiferroelectric (40/3/2) and (b) antiferroelectric (40/15/2) compositions.

Figure 11. Phase images of electrostatic charge of the PZSTN thin films with (a) antiferroelectric (40/3/2) and (b) ferroelectric (40/15/2) compositions after applying -10 V. antiferroelectric composition (40/3/2). It was considered that the antiferroelectrics contained mainly 180° domains which had smaller internal stress during switching cycles compared to 90° domains as reported elsewhere [64].

The following things seem to be more interesting. The PZSTN thin films prepared by the AF I process (the large and irregular grain size) showed more degradation of polarization than the films prepared by the AF II process showing nanocrystalline structure with regular grain size for both compositions. The steeper degradation of polarization in the films prepared by the AF I process could be mainly attributed to the larger grains and irregular microstructure. The different distributions of the applied electric field and internal stress between the large perovskite grains and the grain boundaries (or the different phases between grains) during repetitive switching should generate the electrical and mechanical defects especially at the interfaces of the two different phases. The uniformly distributed nanocrystalline structure could release the stress coming from the above reason more than the microstructure consisting of the large grains. Similar phenomena will be found in the results shown in the next section.

The phase images of electrostatic charge were taken using a commercial scanning force microscope. Initially, a dc voltage of -10 V was applied while a conductive tip scanned over the desired area. Subsequently, the phase images were obtained under applying an ac voltage of 1 V and a frequency of 17 kHz. Details of instrumentation and mechanisms for the imaging have already been published [65]. Figure 11 shows phase images of electrostatic charge of the 40/3/2 and 40/15/2 compositions. After being scanned with a conductive tip held under an applied dc voltage of -10 V, the thin film having 40/3/2 composition showed a quite different phase image compared with the film having 40/15/2 composition. In the 40/3/2 film [Fig. 11a], the bright regions of the phase image result from the polarization directions toward the bottom electrode while the dark regions result from the polarization directions toward the top electrode. The bright and dark regions seemed to consist of several nanocrystalline grains. This behavior implies that the very small nano-sized domains have their antiferroelectric properties. It was confirmed that the antiferroelectric 40/3/2 composition was switched by 180°. On the other hand, the phase image of the 40/15/2 film [Fig. 11b] showed no contrast in the whole area. This configuration also means that the full
nano domains of the 40/15/2 have switched to the unipolar direction and switched by 90°.

4.2. Buffer-Layer Effect

In addition to the effect of the overall grain size of the PZSTN thin films on the electrical properties, we have modified the grain size of very thin buffer layers existing on the interface between the electrode and the main body. The buffer layers have the PZT and PZSTN system but utilized different compositions to the main dielectric films. The PZ buffer layer on PZT body has grain size less than 20 nm as shown in Figure 12a. The PZT buffer layer on PZ body has two different grain sizes of about 20 nm, same as PZ buffer, and 60–70 nm as shown in Figure 12b.

The change of P^*r-$P^\wedge r$ as a function of switching cycles of PZT, PZ buffered PZT, and PZT buffered PZ is shown in Figure 13 [64]. P^*r is the switched remanent polarization between two opposite polarity pulses, and $P^\wedge r$ is the nonswitched remanent polarization between two same polarity pulses. The difference between P^*r and $P^\wedge r$ denotes the switchable remanent polarization, an important variable for nonvolatile memory application. The PZT films showed a significant drop in polarization after 10^5 cycles. The PZ buffered PZT did not show any drop of polarization up to 10^9 cycles with sufficient remanent polarization of about 5 $\mu C/cm^2$. The virgin state of the PZ buffered PZT has smaller remanent polarization than that of the PZT. However, the relative values were reversed after 2×10^6 cycles. This implies that the nanocrystalline antiferroelectric
Figure 12. SEM photographs of (a) AFE-PZ buffer on FE-PZT and (b) FE-PZT buffer on AFE-PZ thin films.
Figure 13. Switchable polarization (P*r-P^r) based on ferroelectric PZT(FE) and antiferroelectric PZ(AFE) thin films. Reprinted with permission from [64], J. H. Jang and K. H. Yoon, *Appl. Phys. Lett.* 75, 130 (1999). © 1999, American Institute of Physics.

layer should act as a barrier to degradation of polarization. Reduced stress related to 180° domains during switching would suppress the formation of electrical and mechanical defects, which cause the generation of the oxygen vacancies [42, 43]. The near zero fatigue in the PZ buffered PZT compared with that of the PZT films was attributed to the relatively low stress and the resulting low number of oxygen vacancies induced at the ferroelectric or antiferroelectric-Pt electrode interface [66, 67]. With the antiferroelectric phase, the nanocrystalline microstructure played an important role to reduce the internal stress. It was confirmed by the fact that PZT buffered PZ also showed very good fatigue endurance as shown in Figure 13, although it had an insufficient remanent polarization value for FRAM application. The saturated polarization (Ps) of AF, AF buffered FE, FE buffered AF, and FE is shown in Figure 14 [67]. All films except FE showed near zero fatigue after 10^9 cycles.
Figure 14. Switchable polarization based on ferroelectric PZSTN(FE) and antiferroelectric PZSTN(AFE) thin films. Reprinted with permission from [67], J. H. Jang and K. H. Yoon, *Thin Solid Films* 401, 67 (2001). © 2001, Elsevier Science.

The FE and AF buffered FE showed sufficient remanent polarization, while FE buffered AF and AF showed insufficient remanent polarization. The AF buffered FE showed excellent fatigue properties maintaining more than 90% of initial polarization values after 10^9 cycles. FE showed the stiffest degradation of polarization. FE buffered AF showed better fatigue endurance than FE. The near zero fatigue in the AF buffered FE was attributed to the fact that the nanocrystalline microstructure having antiferroelectric phase should act as a barrier to degradation of polarization. The relatively lower stress and the resulting smaller number of oxygen vacancies should be induced at the nanocrystalline buffer-Pt electrode interface than at the large grains-Pt electrode interface.

Figure 15 shows the hysteresis loops and the leakage current component of the PZ buffered PZT film with different switching cycles [64, 67]. The hysteresis loops and leakage current component of the corresponding hysteresis loop were measured using the same sample, using "Analysis" software in RT66A ferroelectric tester. During the voltage step, the change in charge (dQ) due to the leakage current can be estimated from the measured resistance by the following equation:

$$dQ = (V \times A \times \Delta T)/R \qquad (1)$$

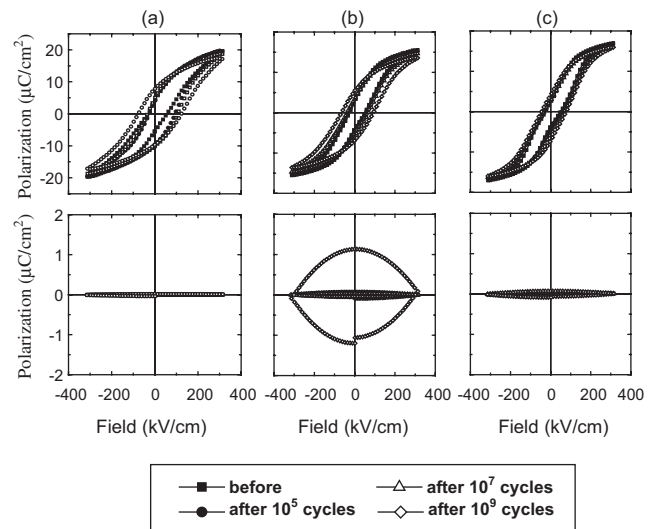
where V is the voltage applied across the film, A is the capacitor area, ΔT is the time increment, and R is the resistance for polarity of the applied voltage. In the hysteresis loop after 10^5 cycles, the remanent polarization increased compared with the initial state, and such behavior agreed with the P*r-P^r data in Figure 13. The increase of remanent polarization near 10^5 cycles should be related to the release of the suppressed polarization originating from the difference in lattice parameters between PZT and PZ. The


Figure 15. The change of P-E hysteresis loops and leakage current component of (a) the PZ buffered PZT thin film, (b) the FE, and (c) the AF buffered FE during fatigue. Reprinted with permission from [64], J. H. Jang and K. H. Yoon, *Appl. Phys. Lett.* 75, 130 (1999). © 1999, American Institute of Physics; and from [67], J. H. Jang and K. H. Yoon, *Thin Solid Films* 401, 67 (2001). © 2001, Elsevier Science.

release of polarization occurred asymmetrically. This behavior was attributed to the different natures of crystallization between the two PZ layers, because one PZ layer was crystallized on the Pt bottom electrode and the other PZ layer was crystallized on PZT layers during the deposition process of the films. As well as near 10^5 cycles, the leakage current component of the corresponding hysteresis loop (Fig. 15a) increased negligibly after 10^9 cycles. This result supports the release of the suppressed polarization. The resistivity measurement also indicated that the resistivity of the PZ1/PZT5/PZ1 film did not change after 10^9 cycles. In the hysteresis loop of FE (Fig. 15b), the increase of remanent polarization in hysteresis loop of FE was found after 10^7 cycles. The increase in FE should come from the leakage current component of the corresponding hysteresis loop increased after 10^7 cycles. The reason for leakage in fatigued FE could be explained by the large displacement of the grains under the applied field and the large stress during the 90° domain switching. The AF buffered FE showed nearly no increase of remanent polarization and leakage current component after 10^9 cycles as shown in Figure 15c. There should be a small amount of defect dipoles due to nanocrystalline antiferroelectric buffer. The negligible leakage current component could be explained by the reason that the antiferroelectric buffer has very small grain size and internal stress during 180° switching acts as a barrier to fatigue between the electrode and the ferroelectric layers. Therefore, the antiferroelectric buffer could be resistant to mechanical stress and resulting microcracking or production of electrical defects. The AF buffered FE showed somewhat different fatigue properties from the PZ buffered PZT. In the PZ buffered PZT, there was the release of the suppressed polarization originating from the mismatches in lattice parameters and microstructures between PZT and PZ, while there was no significant change in AF buffered FE during 10^9 cycles of ±10 V due to the similar lattice parameters and microstructures [64].

5. CONCLUSIONS

We have outlined the chemical synthesis of Pb-based nanocrystalline perovskite thin films and their effects on the electrical properties such as dielectric constant, hysteresis loop, and especially fatigue character. For Pb-based perovskites, the modification of metal alkoxide by a chemical solution processing gave rise to the formation of a stable complex against hydrolysis, and eventually enhanced reliability and uniformity of the films. Surface microstructural characteristics resulting from the crystallization of as-prepared thin films were found to depend strongly on the various multilayer film formations as well as solution chemistry. Moreover, with proper control of multilayer thin-film formation procedure, it may be possible to control its related dielectric properties as well as preferred orientation of the ferroelectric thin films.

For antiferroelectric and ferroelectric PZSTN thin films, nanocrystalline microstructure was obtained with various heat treatments and compositional change, and the modified multilayer processes improved the electric fatigue

endurance. From the scanning force microscopy, it was confirmed that the very small nano domains have their ferroelectric and antiferroelectric properties.

The nanocrystalline antiferroelectric buffer has improved the electric fatigue endurance of the PZT-based ferroelectric thin films prominently. The P*r-P^r of the PZ buffered PZT films and AF buffered FE (PZSTN) showed near zero degradation of polarization after 10^9 cycles on the Pt electrode. The nanocrystalline antiferroelectric PZ and AF buffers acted as barriers to fatigue due to their 180° domain switching and stress release in the nanocrystalline microstructure. It is expected to be applied to other popular thin-film processes for nonvolatile memory applications and other fields, such as the actuator which needs long-term reliability.

GLOSSARY

Antiferroelectric (AFE) There is no net polarization of a cell in the absence of an electric field, but the cell is polarized when a field is applied. An antiferroelectric material will be strongly repelled by an electric field. The dipole moments in an antiferroelectric are arranged with an equal number pointing in each direction.

Electric fatigue The loss in switchable polarization at a fixed drive voltage as a function of the continuous switching of a ferroelectric capacitor.

Ferroelectric (FE) A kind of electric phase in crystal where the centers of the positive and negative charges do not coincide even without the application of external electric field. In this case, spontaneous polarization exists in the crystal. And the polarization of the dielectric can be reversed by an electric field.

Microelectromechanical system (MEMS) Devices that have a characteristic length of less than 1 mm but more than 1 μm, that combine electrical and mechanical components that are fabricated using integrated circuit batch-processing technologies.

Nanoelectromechanical system (NEMS) The NEMS devices that have the dimension of nanometer range.

Sol–gel process Colloidal route used to synthesize chemicals with an intermediate stage including a sol/or a gel state. (Sol–gel is restricted to the gels synthesized from alkoxides).

monomers can design chemical properties of inner and outer walls of peptide nanotubes respectively. Of course, peptide monomers have to be functionalized through appropriate chemical structures to be assembled as the nanotube form. For example, cyclic D,L,-peptide nanotubes were designed to have hydrophobic outer walls and hydrophilic inner walls, which were suitable to fabricate artificial ion channels [16].

For some peptide nanotubes, the nanotube structures and the sizes are not consistent with the ones expected from the peptide monomer structures. It seems that the assembled structure of peptide nanotubes should be predictable from the monomer structure since charge distribution and strength of intermolecular hydrogen bonding of peptide monomers at various pHs are well understood. However, the peptide monomer could undergo conformation changes via pH change and the structure of peptide nanotubes is very sensitive to the peptide monomer conformation. As a result, it is not always straightforward to predict the structure and the size of peptide nanotube from the chemical structure of the peptide monomer.

It should be noted that the use of peptide nanotubes is not limited to biological applications. Biological recognitions of peptide nanotubes can be used to guide the nanotubes to desired locations in solution for nonbiological devices such as electronics and sensors. In this concept, device designs can be developed by biological interactions between the nanotubes and biological surfaces instead of patterning the designs with photolithography. This method may simplify nanometer-scale device fabrication procedures and reduce fabrication costs because synthesis of most of peptides described here is fairly inexpensive.

This chapter consists of three major sections; "Development of Peptide Nanotubes," "Characterization of Peptide Nanotubes," and "Peptide Nanotube Applications." Since this field is extremely young, there are more reports about peptide nanotube synthesis than their applications. However, recently several promising reports about their applications began to appear and they are summarized in Section 4.

2. DEVELOPMENT OF PEPTIDE NANOTUBES

2.1. From Linear Peptides to Nanotubes

Self-assemblies of linear amphiphiles (i.e., molecules with charged head groups and nonpolar tail groups) have been studied to mimic biological membrane structures for decades. Those simple linear amphiphiles were self-assembled by hydrophilic/hydrophobic interactions between the amphiphiles and surfactants. Phase diagrams of those assemblies have been well established as functions of temperature and pressure [17]. Then it was natural to evolve from the simple amphiphile self-assembly to peptide-derivatized amphiphile assembly to introduce a new parameter to control self-assemblies, hydrogen bonding [18–20]. Self-assembled peptide amphiphile structures are sensitive to pH that changes the strength of intermolecular hydrogen bonding between amide and carboxylic acid groups. When the peptide nanotube are self-assembled in aqueous solution, the hydrophobicity of peptide monomers also becomes

an important factor to determine the dimension of peptide nanotubes [21].

Figure 1 is an example illustrating how linear peptide monomers self-assemble into nanotubes [22]. The peptide amphiphile monomers in Figure 1a are assembled to orient the hydrophobic alkyl chain to the core and the amide group to the outer surface. While this assembled structure seems to have the same structure as micelles, protonation states of amides still play an important role to organize this structure, which is supported by the observation that the appearance of nanotube depended on pH of solution [23]. Since the nanotube structure from this type of linear peptide monomer is well defined (i.e., tail group inside and polar head group outside), functionalization of peptide nanotubes can be obtained by introducing the functional groups into the peptide monomer via chemical synthesis. If some functional groups are incorporated into the head groups, those groups appear on the outer surfaces of nanotubes, which determines the surface properties of nanotubes. For example, a certain peptide sequence for cell adhesion was incorporated into the head group of peptide to anchor cells onto the peptide nanotubes [22]. Figure 2 shows that nanotube structures are sensitive to chemical structures of peptide

monomers. The transmission electron microscope (TEM) image in Figure 2a shows that the peptide nanotubes, formed from peptide amphiphiles with 10 hydrocarbons in the hydrophobic chain, aligned in parallel, while the peptide nanotubes from peptide amphiphiles with 16 hydrocarbons in the hydrophobic chain were grown shorter and aggregated in random orientation as seen in Figure 2b [23]. The comparison of those TEM images indicates that the chemical structure of peptide monomers is very sensitive to the nanotube structure.

There is another type of linear peptide monomer with two amide head groups connected by a hydrocarbon tail group (called bolaamphiphile), which showed pH dependence in the assembled structures. This peptide bolaamphiphile monomer assembled into the helical form at pH 8 (Fig. 3a) and the nanotube form at pH 5 (Fig. 3b) [24]. This peptide monomer is assembled into the nanotube and the helical form via three-dimensional hydrogen between amide and carboxylic acid groups (Fig. 4a, c). X-ray diffraction and Raman microscopy indicate that lower pH induces stronger protonation to amide and carboxylic acid groups that results in stronger intermolecular hydrogen bonds [24–26]. This change increases the tilting angle of the peptide monomer alignment and more surface curvature of the
Figure 3. Visible microscopic images of self-assembled structures from the peptide bolaamphiphiles. (a) In a pH = 8 solution, the peptide bolaamphiphile assembled into helical ribbons. The width of the helices is about 2 μm and the length varies from 10 to 40 μm. The helical structures appeared after one week. (b) In a pH = 5 solution, the peptide bolaamphiphile monomers assembled into nanotube structures. The diameter of the nanotube is 10–1000 nm. The peptide nanotubes appeared after two weeks [24].
Figure 4. (a) Chemical structure of peptide bolaamphiphile monomer. (b) Chemical structure of peptide nanotube from the peptide monomer. The nanotube surface has free amide groups (shown by arrows and yellow squares) to immobilize biological molecules and ions to functionalize the peptide nanotubes [28–30, 62].

peptide assembly results in the nanotube formation as if a sheet of paper is rolled up to a cigar [24]. The observation of stripes in zigzags on the nanotubes in Figure 4b supports this nanotube-assembly mechanism. The monomer conformation of the peptide bolaamphiphile also shows a significant effect on the self-assembled form. The helix-to-nanotube transformation was observed in the peptide bolaamphiphile with the seven-hydrocarbon chain (Fig. 4a). However, the same peptide monomer with a six-hydrocarbon chain only forms nanotubes in pH 5 and the helical form did not appear at higher pH in solution. Spectroscopic studies indicate that the peptide nanotubes from the six-hydrocarbon chain peptide monomer are assembled via stronger hydrogen bonding than the peptide monomer with the seven-hydrocarbon chain [27]. It seems that the stronger intermolecular hydrogen bonding between peptide monomers with the six-hydrocarbon chain prevents the structural transformation between the helix and the nanotube. For this type of peptide nanotube, functionalization can be obtained by anchoring molecules onto the nanotube surfaces. While the peptide nanotube is assembled via intermolecular hydrogen bonds between amide groups and carboxylic acid groups, an interesting characteristic of the peptide nanotubes is that their free amide groups can capture and incorporate biological molecules such as DNAs, proteins, and porphyrins via hydrogen bonding (Fig. 4c) [28, 29]. This free amide group also captures metal ions such as Pt, Pd, Cu, Co, and Ni to form square planar complexes and the further electroless plating results in stable metallic coatings [30]. Therefore, instead of chemically modifying peptide monomer structure, this type of peptide nanotube can be used as an efficient template to produce various exotic nanotubes.

Another scheme to produce peptide nanotubes is to fold linear peptide monomers to the helical structure (i.e., a shape like a rattled snake). Oligophenylacetylenes were folded into helical forms as shown in Figure 5 [31]. This structural transformation is induced by solvophobical interaction between backbone phenyl rings. The peptide nanotube from the oligophenylacetylenes preserves a hollow coil structure because the turning angle of the helical conformation is wide enough to prevent a close-packed
Figure 5. Oligophenylacetylene folding equilibrium between the open state and the helical folded structure [31]. Reprinted with permission from [39], D. T. Bong et al., *Angew Chem. Int. Ed. Engl.* 40, 988 (2001). © 2001, Wiley–VCH.

core. The folded peptide monomers produce nanotubes of 4 Å in diameter. The ease to add additional derivatives into oligophenylacetylenes is advantageous for this type of folding peptide nanotubes [32]; however, the dimensions of the nanotubes in both diameter and length may be limited by the size of the monomer unless these nanotubes are integrated by noncovalent interactions to form longer tubes [33].

Peptide nanotubes have been produced from various linear peptide monomers [34]. Whereas the peptide nanotube dimension via changes of peptide chain length, functional groups in the chain, and pH of solution has been studied systematically [14, 35, 36], the complexity is that those factors cannot be treated separately. For example, the pH change will alter charge distributions and intermolecular hydrogen bonds between peptide monomers. However, it will also change the peptide monomer conformation via intramolecular charge interactions and/or intramolecular hydrogen bonds [23]. Since self-assembled nanotube dimension is also very sensitive to the peptide monomer conformation, sometimes it is difficult to predict the formation of peptide nanotubes from peptide monomer conformations. However, it is advantageous that the formation of peptide nanotubes via molecular self-assembly is very reproducible and the size of peptide nanotubes is quite monodisperse under the proper nanotube growth conditions. This feature is strength for the use of self-assembly in the nanotube formation [37]. In fact, the sensitivity of the assembled structure changes with experimental conditions may turn to an advantage when the exotic combined structures are aimed to be fabricated by controlling the growth conditions. For example, the monomer in Figure 6, which self-assembled into a microsphere at pH 8 and a nanotube at pH 7, can be formed as the combined structure between the microsphere and the nanotube (i.e., dumbbell) by switching pHs between the spherical growth and the tubular growth conditions [38]. The monomers in Figure 6 were first assembled into microspheres in a pH 8 solution. Once the microspheres were grown in diameter of 1 μm, the self-assembly condition was switched to the nanotube formation by tuning pH to 7. After 12 hours, the nanotubes (50 nm in
Figure 6. Strategy to produce nanotube-bridge geometry by controlling the molecular self-assembly mechanisms between microspheres and nanotubes. (a) First, the monomers are self-assembled in a pH 8 solution. (b) Then the nanotubes are assembled on the microspheres by changing pH to 7. The nanotubes grow to connect with other microspheres. (c) TEM image of the nanotube bridge between the microspheres [38].

diameter) were observed between the microspheres. Therefore, the adjustment of experimental conditions during self-assembling peptide monomers alters the growth processes in the intermediate time and it will produce exotic nanotube-based structures such as bridges, dumbbells, and multibranches.

2.2. From Cyclic Peptides to Nanotubes

Peptide nanotubes can also be self-assembled by stacking cyclic peptide monomers [39–41]. A typical assembling mechanism of a cyclic D,L-peptide monomer is shown in Figure 7 [42]. Those peptide rings were stacked through the backbone–backbone hydrogen bonding between neighboring amide groups. The sequence of octapeptide *cyclo*[-(L-Gln-D-Ala-L-Glu-L-Ala)$_2$-] was used to prevent subunit association through Columbic repulsion in basic aqueous solution. A cyclic D,L-octapeptide containing bis-aspartic acid was also self-assembled into nanotubes via pH control of solution [43]. One of the simplest cyclic monomers, benzene, can also be stacked to grow as nanotubes if benzene is derivatized with right functional groups at the right positions. When benzene rings were derivatized with secondary
Figure 7. Schematic diagram of peptide nanotube assembly from cyclic D,L-α-peptides. Reprinted with permission from [39], D. T. Bong et al., *Angew Chem. Int. Ed. Engl.* 40, 988 (2001). © 2001, Wiley–VCH.

amides at the 1,3,5-positions, those monomers stack with amide–amide intermolecular hydrogen bonding and π overlap (Fig. 8) [44]. At higher concentration of the peptide monomer, these stacks self-organized into spherical arrays [45]. This two-dimensional hexagonal array (Fig. 8c) can be directed with external electric fields because the stacked column has a macroscopic dipole moment parallel to the stacking direction. The stacked column can be self-organized into hexagonally arranged fibers or liquid crystalline phases by controlling chirality of the peptide monomer via chemical synthesis. Those types of cyclic peptide nanotubes may have limitations in the nanotube dimensional control over wide ranges. For example, the cyclic D,L-peptide monomer was sequenced between 9 and 13 Å in diameter and nanotubes needed to be bundled as arrays to obtain larger nanotube diameters [39].

To produce a larger diameter of peptide nanotubes from cyclic peptide monomers, the ring diameter of the cyclic peptide monomers needs to be larger. Whereas peptide sequencing may have limitations in the ring size of peptide monomers, combination of peptide molecules into an integrated cyclic structure via hydrogen bonding is possible. These integrated rings can be stacked in the length direction to form nanotubes. For example, a heteroaromatic bicyclic base $G \wedge C$, possessing the Watson–Crick donor–donor–acceptor of guanine and acceptor–acceptor–donor of cytosine, was self-assembled into nanotubes (Fig. 9a) [46]. This monomer formed a six-membered supermacrocycle held by 18 hydrogen bonds. Then this substantially more hydrophobic supermarcocycle self-assembled as a stack to produce nanotubes. The diameter of the nanotubes is 4 nm and the hydrodynamic radius is between 10 and 100 nm, depending on the monomer concentration. The inner space of the nanotube is determined by the distance separating the hydrogen bonding arrays within $G \wedge C$. The peripheral diameter and its chemistry depend on the choice of functional groups conjugated to this motif. Crown ether (Fig. 9a) was conjugated with the motif because of its broad
Figure 9. Hierarchical self-assembly of heteroaromatic bicyclic base $G \wedge C$ into a six-membered supermacrocycle and resulting nanotube. Each crown ether site within the assembled structure provides 328 Å³ of open space for binding of a molecular guest. Reprinted with permission from [49], H. Fenniri et al., *J. Am. Chem. Soc.* 124, 11064 (2002). © 2002, American Chemical Society.

solvent compatibility, synthetic accessibility, and functionality as versatile receptors [47]. The crown ether plays an important role in controling chiroptical properties by using chiral-promoting molecules, which induce a rapid transition from racemic to chiral nanotubes via electrostatic interactions between the crown ether moiety and the promoter [48]. The promoter molecules could even induce self-assembly of the monomer in the low concentration that the nanotubes were not assembled spontaneously [49]. The degree of chiral induction was sensitive to the chemical structure of the promoter. Similar cyclic peptide nanotube assemblies from noncyclic peptide monomers were reported with series of small dipeptides, L-Leu-L-Leu, L-Leu-L-Phe, L-Phe-L-Leu, and L-Phe-L-Phe [50].

One of characteristic features of the cyclic peptide nanotubes is the precise diameter control of the nanotubes, determined by the chain length, the size of side chains, and the bond angles of the peptide monomer. Proper side chain functionalization also enables those peptide nanotubes to possess distinct surface properties on the inner surfaces and the outer surfaces respectively. As pointed out in Section 1, hydrogen bond-driven self-assemblies are very naive against the environment. However, the peptide nanotubes from cyclic peptide monomers may be less sensitive to the external conditions such as pH and solvent because hydrogen bonds in only one direction need to stack the peptide monomers to produce the nanotubes. Therefore, the optimization of experimental conditions to grow nanotubes from the cyclic peptide monomers may be much more straightforward than the one from linear peptide monomers.

Figure 8. (a) Chemical structure of the monomer. (b) The intermolecular hydrogen bond conformation between monomers in the stacking direction. (c) The hexagonal arrays. (d) Model of a tetramer showing three helices of hydrogen bonds surrounding the exterior of the column. Reprinted with permission from [45], M. L. Bushey et al., *Angew Chem. Int. Ed. Engl.* 41, 2828 (2002). © 2002, Wiley–VCH.

The cyclic peptide nanotubes from linear peptide monomers may require more delicate experimental optimization than sequenced cyclic peptide monomers because this system must first form peptide rings from hydrogen-bonding linear peptide monomers and then stack them into tubular structures.

3. CHARACTERIZATION OF PEPTIDE NANOTUBES

Since chemical structures of peptide monomers are well defined, it is relatively straightforward to probe peptide nanotube structures if we have additional spectroscopic information. Conventional X-ray diffraction is a powerful spectroscopy to identify the nanotube structures [41, 50]. However, peptide nanotubes are necessary to grow as a perfectly aligned single crystal in the scale of mm^3 to resolve fine structures of peptide nanotubes in the X-ray diffraction. Recently, synchrotron X-ray diffraction has been applied to peptide nanotubes. For example, the synchrotron X-ray diffractogram of **1a** in Figure 8a resolved a single sharp peak at low angle that indicates their columnar assemblies and the hexagonal lattice structure was indexed by the diffraction peaks up to fifth order (Fig. 10) [44]. The fluidic packing of the side chain was also probed by the diffuse reflection at 4.5 Å [51]. The lateral core-to-core separation was 21 Å, which is consistent with the column separation with extended side chains, 27 Å [44].

Another technique to resolve peptide nanotube structures is vibrational spectroscopy. The most common vibrational spectroscopies to study chemical structures of peptide nanotubes are Fourier transform infrared spectroscopy and Raman spectroscopy [14, 16, 24, 35, 36, 52]. An advantage for these spectroscopies is that no sample preparation is required. Recently, Raman microscopy has been applied to study single carbon nanotubes [53] and peptide nanotubes [24, 54]. For peptide nanotubes, vibrational frequencies of amide groups are very important to monitor because the frequency shifts reflect the strength of hydrogen bonding with the amides. This information helps one to build the structural model: how the hydrogen bonding assembles peptide
monomers into peptide nanotubes. For example, the structure of the peptide nanotube from the monomer (Fig. 4a) was investigated with a Raman microscope. When the structural transformation between the helical form (Fig. 3a) and the nanotube (Fig. 3b) was monitored, the helical phase (Fig. 11a) has a peak for the C=O stretch at 1644 cm^{-1} while the nanotube (Fig. 11b) and the crystalline form (Fig. 11c) have two C=O peaks at 1637 and 1660 cm^{-1}. The C=O stretch with the highest frequency is assigned as the free C=O of the amide group. The C=O frequencies at 1637 and 1644 cm^{-1} are redshifted from the free C=O stretch since these C=O stretches bind the amide NH group via intermolecular hydrogen bonds (Fig. 4c). These assignments suggest that the C=O group in the nanotube and the crystal phase binds to NH stronger than the C=O group in the helical form due to a redshift of the vibrational frequency. This is consistent with the structural transformation model for the peptide bolaamphiphile that shortening amide–amide and acid–acid hydrogen bonds induces further tilt of the peptide monomer arrangement and makes the assembly surface more convex. This greater molecular tilting leads the assembled structure to the nanotubes by scrolling the sheetlike helical form into the tubular form (Fig. 4b). Nuclear magnetic resonance spectroscopy is an alternative way to study hydrogen bonding schemes of peptides in nanotubes [55].

Helicity of the peptide nanotube structure can be analyzed by CD spectroscopy [31, 45, 46]. The monomer concentration dependence of the structural change for the nanotubes stacked from monomer **1b** in Figure 8a was probed by CD spectroscopy, as shown in Figure 12 [45]. When the solution of **1b** in hexane was diluted with ca. 15% CH_2Cl_2, the helical order of nanotubes was observed

via an exciton coupling between degenerate chromophores. As the concentration of CH_2Cl_2 increased, the helical complex dissociated and the transition dipoles were not observed to couple. The series of CD spectra show that the monomers self-assembles through hydrogen bonds with their side chains close enough to interact with each other only when the solvent is hydrocarbonlike [45].

4. PEPTIDE NANOTUBE APPLICATIONS

4.1. Tissue Engineering

In nature, self-assembled fibrils and their biomineralization routinely produce various composite materials. Bone tissue is one of those examples. The collagen fibrils are formed by self-assembled collagen triple helices and the hydroxyapatite crystals grow in these fibrils with the hierarchical organization of their c axes along the long axes of the fibrils [56]. The peptide nanotube was applied as an artificial fibril to serve as crystal nucleation and growth of the inorganic hydroxyapatite crystals [22]. This peptide nanotube was self-assembled from the peptide amphiphile monomer shown in Figure 1a. This synthetic peptide monomer incorporates four important functions. The tail group (region 1 in Fig. 1a) and amide group (region 3 in Figure 1a) stabilize the nanotube structure via hydrophobic interactions and hydrogen bonds. The amide group also plays an important role in promoting the hydroxyapatite crystal growth because their negative charges established the local ion supersaturation [57]. The sulfide group (region 2 in Fig. 1a) provides extra stability to the nanotubes via disulfide bonds with adjacent peptide monomers. The phosphorylated group (region 4 in Fig. 1a) was introduced to nucleate calcium phosphate minerals. As this peptide monomer forms the peptide nanotube, the phosphoserine residue locates at the outer wall of the nanotube. This peptide nanotube with a highly phophorylated nanotube surface resembles the collagen fibrils. To proceed with the biomineralization efficiently, the fibrils should promote the adhesion growth of cells on their surfaces. The peptide sequence Arg–Gly–Asp (RGD), contained in collagen-associated fibronectin, is important for integrin-mediated cell adhesion [22] and this peptide sequence was also incorporated in the peptide monomer shown as region 5 in Figure 1a. When the assembled peptide nanotubes are treated with $CaCl_2$ and Na_2HPO_4 solution,

the crystalline minerals were observed on the nanotubes after 20 minutes [22]. The hydroxyapatite crystallographic c axis was aligned with the peptide nanotube long axis, which mimics the natural bone growth with collagen fibrils. The ability of the peptide nanotube to orient crystalline nuclei and subsequent crystal growth in the specific direction can be applied to other mineralized tissue repairs.

4.2. Electronics

While various nanocomponents have been applied as building blocks to construct nanodevices [9–14], more reproducible methods to assemble them onto precise positions are desirable. The improved fabrication method will be extremely significant to interconnect electronic components with nanotubes. The configurations of nanotubes on those components depend on the type of devices to develop. For example, when two nanowires are crossed perpendicularly at the centers of the nanowires, this configuration acts as an electric switch [58]. More complex nanowire configurations of logic gates such as OR, AND, and NOR have been fabricated [2, 59]. One of the simpler ways to align nanotubes for complex device configurations is to use freestanding nanotubes in solution. This strategy will allow nanotubes to freely move and attach at the target locations in solution via noncovalent interactions, charge interactions, or molecular recognitions. However, it remains highly challenging to fabricate freestanding nanotubes in solution. Biologically compatible peptide nanotubes are soluble in aqueous solution and therefore their aggregations are not a concern. Therefore, the use of peptide nanotubes as building blocks for electronics and sensor devices may be appropriate in the solution-based fabrications. Our strategy has been to use those functionalized peptide nanotubes, which can recognize and selectively bind a well-defined region on patterned substrates, as building blocks to assemble three-dimensional nanoscale architectures at uniquely defined positions [8, 38, 60] and then decorate the nanotubes with various materials such as metals [30, 61], quantum dots [62], and metalloporphyrins [29] for electronics and sensor applications. Complex device configurations may be achieved by using peptide nanotubes incorporating multiple recognition functions such as antibodies and antigens in solution [28]. When a large number of the monodisperse peptide nanotubes are required for practical applications, the peptide nanotubes can be grown in microporous membranes [63]. In this case, the peptide nanotube diameter is controlled by a porous size of polycarbonate membranes. After the nanotubes are grown inside the membrane pores, the membranes are dissolved by CH_2Cl_2 to extract the size-controlled nanotubes. When the peptide nanotubes are necessary to have higher mechanical strength for harsher environmental applications, the peptide nanotubes can be bundled via the ligand-ion bridge formations [54].

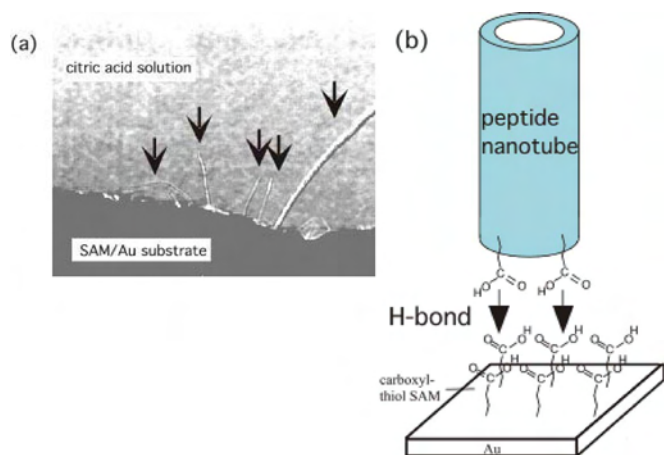
Patterning of peptide nanotubes in the desired device configurations is achieved before the functionalization of peptide nanotubes. We have demonstrated that the peptide nanotubes can be assembled as an array on Au surfaces via a 4-mercaptobenzoic acid self-assembled monolayer (SAM) [60]. The nanotube array was grown when peptide monomers were assembled to nanotubes with the SAM/Au substrates, as shown in Figure 13a. The SAM, with thiol


Figure 13. (a) Visible micrograph of the nanotubes grown on the 4-mercaptobenzoic acid monolayer/Au substrate in a citric acid/sodiumcitrate solution (black arrows shows the positions of nanotubes). (b) Proposed mechanism of the nanotube attachment on a mercaptobenzoic acid SAM/Au substrate [60].

groups at one end and carboxylic acid groups at the other end, serves as a junction between Au and the nanotubes because the thiol groups are attached firmly onto the Au surface while the carboxylic acid groups bind the carboxylic acid groups of the nanotubes via hydrogen bonds (Fig. 13b).

To demonstrate the surface-specific immobilization of nanotubes for the nanotube-cross-linking configuration, we connected carboxylic acid groups of SAM/Au surfaces with carboxylic acid groups of the peptide nanotubes via hydrogen bonds (Fig. 14) [60]. All peptide nanotubes were placed on the SAMs parallel to the substrates when we processed the tube immobilization in two steps; first the peptide nanotubes were grown in suspension and then placed in solution containing the 4-mercaptobenzoic acid SAM/Au substrates. The carboxylic acid groups of peptide nanotubes recognized the carboxylic acid groups on the SAM via the
Figure 14. Visible micrograph of the peptide nanotubes immobilized onto two separated 4-mercaptobenzoic acid SAM/Au substrates. Two bright squares of the Au layers ($10\ \mu m \times 10\ \mu m \times 0.2\ \mu m$), patterned on a glass substrate by photolithography, were deposited by the 4-mercaptobenzoic acid SAM. The peptide nanotubes, assembled in suspension, were placed on the carboxylic acid SAM/Au substrate and then complete the immobilization in a pH 6 citric acid/sodium citrate solution [60].

acid–acid hydrogen bonds to interconnect two substrates. After the site-specific immobilization of peptide nanotubes on the SAM surfaces, the nanotubes were coated with Ag by an electroless coating process (Fig. 14a). The surface of the nanotube was quite rough due to the nonuniform Ag coating on the nanotube and the concentrations of Ag ions and reducing agents need to be optimized to obtain smooth metallic coatings on the peptide nanotubes.

Whereas the peptide nanotubes have been patterned into simple device configurations in solution, those nanotubes must be conductive for use in electronics and sensors. Using the characteristic of the peptide nanotubes that their free amide groups can intercalate metal ions (Fig. 4c) [30], sidewalls of the peptide nanotubes can be coated with metals via electroless plating to form metallic nanowires [24, 30]. The difficulty in organic nanotube metallization is the creation of organic–inorganic junctions on the nanotube surfaces. But the peptide nanotubes can overcome this difficulty through the intercalating of free amide sites. For example, Figure 15 shows an X-ray photoelectron spectroscopy (XPS) microscopic image of the Ni $2p$ peak on the single peptide nanotube [64]. In Figure 15, brighter colors correspond to higher concentration of Ni. This image indicates that a uniform Ni coating is possible on the peptide nanotubes via a simple electroless coating. Au nanocrystals can also be coated on the peptide nanotube surfaces and they behave as metallic or semiconductor depending on the size and the density of Au nanocrystals [65]. The strategy is to use carboxylic acid-thiol capped Au nanocrystals that can be intercalated by the free amide group on the peptide nanotubes [62]. Figure 16 shows the Au nanocrystal-capped nanotube developed by coating carboxylic acid-thiol capped Au nanocrystals on the peptide nanotube templates. The magnified TEM image in Figure 16c shows multilayer coatings of Au nanocrystals as dots on the peptide nanotubes seen as a dark continuous background. The coated Au nanocrystals have preferred crystal orientations as (111), (200), (220), and (311). Hydrogen bonding between the amide groups of the peptide nanotube and the carboxylic acid groups of the Au nanocrystals was used as a driving force for this fabrication process.

While the peptide nanotubes can be conductive by coating metals on the nanotubes, recent computational studies

showed that some of peptide nanotubes may be conductive without any metallic coatings. For example, cyclic D,L-octapeptide nanotubes may be conductive due to delocalizations of electrons and holes through the hydrogen bonds between the peptide rings [66]. Because theory suggests that strengths of the intermolecular hydrogen bonds via the nanotube axis affect the electronic band-edge states sensitively [67], proper structures of peptide nanotubes may possess adequate electronic transport properties to build electronics. For example, the highest occupied molecular orbital/lowest unoccupied molecular orbital gap of the cyclic D,L-octapeptide nanotube was computed approximately as 5 eV [68].

4.3. Ion Channels and Biosensors

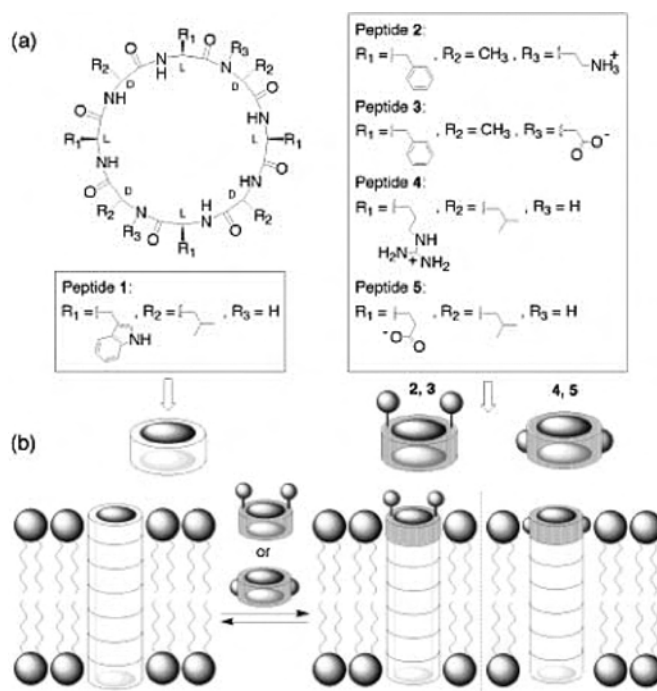
When functionalized peptide nanotubes were incorporated into membranes, Sanchez-Quesada and co-workers demonstrated that this system mimics transmembrane channels [69]. Transmembrane channels involved in electrical signaling in cells display ion selectivity and rectification, gated by their potentials [70]. While monomeric peptide nanotubes incorporated in membranes were used for size selective transmembrane transport of small molecules [52], membranes with heteromeric peptide nanotube channels showed altered conductance and rectification properties. In this demonstration, peptide nanotubes from the cyclic D,L-α-peptide monomers (Fig. 7) were used as templates to incorporate into membranes. The template nanotubes were capped with two different subunits and these heteromeric peptide nanotubes were assembled in membranes with locating designed functional groups of the nanotubes at the channel ends (Fig. 17). The ion conductivity and conductance of the nanotube channels were modulated via local electrostatic perturbation from the cap subunits bearing ionizable functionalities. When L-α-phophatidyl-choline (L-α-lecithin) planar bilayers were applied as membranes and transferred into symmetric KCL solution, the conductance of the peptide nanotubes decreased after capping the nanotubes with a positively charged functional group (cap peptides 2 and


Figure 17. Chemical structures of the cyclic D,L-α-peptides and schematic representation of the mode of interaction of the tube cap informing heteromeric transmembrane channels. The cyclic peptide monomer self-assembles in lipid membranes to form the core transmembrane channel structure, while the peptides 2–5 serve as the cap subunits creating the heteromeric channel assembles with altered ion conductance properties. 4 in Fig. 17), while the conductance increased after the nanotubes were capped with a negatively charged functional group (cap peptides 3 and 5 in Fig. 17).

If biological recognition functions are incorporated into the capping groups of peptide nanotubes, the membrane–nanotube complex will be applied to biosensors [39]. In this configuration, coupling of target antigen with antibody on the peptide nanotubes modulates the conductance, and the conductivity change will be analyzed to identify the target antigen. Thus, the introduction of the molecular recognition function to the membrane–nanotube complex will dramatically improve the signal-to-noise ratio and sensitivity [71, 72].

4.4. Antibacterial Agents

The technique to incorporate peptide nanotubes into membranes as described in the previous section can also be applied to kill bacteria. When cyclic D,L-α-peptides were functionalized to selectively target bacterial membranes, they were self-assembled in the bacterial membranes and exert antibacterial activity by increasing the membrane permeability [73]. From the library of antibacterial peptides, a series of six- and eight-residue amphiphilic cyclic D,L-α-peptides were designed to bear at least one basic residue to enhance their target specificity toward negatively charged

bacterial membranes [74, 75]. In order to determine the efficacy of the peptide nanotubes with respect to *in vivo* protection of mice from bacterial infection, groups of mice were infected with lethal doses of methicillin-resistant *S. aureus* (MRSA) and then each group was treated intraperitoneally with a given bolus dose of the peptide nanotubes at 45–60 min after initial infection [73]. In this study, the amino acid sequences of cyclic peptides to target MRSA were **KKKWLWLW**, **RRKWLWLW**, and **KKLWLW**, where bold letters indicate D-amino-acid residues. After seven days, single appropriate doses of the peptide nanotubes were sufficient to completely protect various groups of mice from MRSA infections. This result will be very useful in developing new therapeutic treatments of existing and emerging infectious diseases by designing peptides rationally via combinatorial peptide libraries.

5. SUMMARY

The field of device fabrication based on peptide nanotubes is still very young. At this stage, material development and fundamental mechanistic study of self-assemblies in peptide nanotubes have been very active and there is some progress in organizing peptide nanotubes in device configurations. These two areas are necessary to be coupled to develop real-world devices from peptide nanotubes, which have just started appearing in literature very recently. The biocompatibility of peptide nanotubes makes them valuable to build biotechnology-related devices such as biosensors and biomolecular filters, and their potential to position them into device configurations via biological recognitions may help build improved electronics. Physical properties of peptide nanotubes may not be suitable for certain applications; however, functionalization of peptide nanotubes will give them flexibility in physical properties to overcome it. As explained, functionalization can be achieved via peptide monomer modification or coating on the peptide nanotubes with functional groups.

GLOSSARY

Amphiphile A molecule with a functional group as a head and alkyl chain as a tail.

Bolaamphiphile A molecule with two functional groups as heads connected by an alkyl chain.

Functional group Systematic chemical structures with specific chemical/physical properties.

Functionalization Addition of specific chemical/physical properties onto self-assembled structures.

Intermolecular hydrogen bond Hydrogen bonding among multiple molecules.

Intramolecular hydrogen bond Hydrogen bonding within single molecule.

Peptide nanotube A nanometer-sized tubular structure self-assembled from monomers containing amino acids or amino acid-like molecules linked with peptide bonds.

Self-assembly Spontaneous organization of molecules into stable, larger-scaled structures.

CONTENTS

1. INTRODUCTION

Introduction of femtosecond (fs) laser pulse, which is characterized as an ultrashort time domain with good coherence over the whole pulse duration, significantly influences trends in various laser application fields. Specifically, when the fs pulse is applied to material processing, it provides additional advantages to conventional laser processing, including the capability of processing in transparent materials, nanosized patterning, and clean processing nearly free from thermal effects. Those features originate from the inherent nature of the pulse. First, fs laser pulses have extremely short time durations, leading to very high peak powers due mostly to the temporal compression of the laser energy. Such high peak powers can process almost all kinds of materials, typically by laser ablation [1–3]. When the energy is a little smaller than the ablation threshold, it can still induce structural changes, which are inevitably accompanied by refractive index modulation [4–8]. As the laser energy can be absorbed efficiently through a multiphoton process in such a high-power pulse, materials to be processed are not necessarily opaque against the laser wavelength. In other words, the fs laser processing is particularly suited to transparent materials, which are difficult to process by conventional lasers such as CO_2 and $YAG:Nd^{3+}$ lasers. Second, with the aid of nonlinear effects such as multiphoton absorption and selffocusing, we can concentrate the laser energy onto a very small spot. In addition, materials suffered ablation or structural changes only in a limited area where the accumulated energy exceeded a certain threshold value. Nanoscale structures may be formed in this way. Finally, the pulse terminates before the completion of energy transfer from photoexcited electrons or electron-hole plasma to the lattice, which minimizes thermal effects during the machining process and makes the process clean [1, 2, 6–9], specifically when only a single pulse is involved. By using these features, a large number of excellent works have been performed recently in fabricating various kinds of fine-scale structures on the surface and inside of transparent dielectrics, semiconductors, polymers, and metals.

Further, if we combine another distinct feature of the fs pulse, which is good coherence [10], with the above mentioned features, we can encode holograms, having a very fine internal structure in various materials, by splitting a single pulse into multiple beams and allowing interference. In this chapter, we will focus on an emerging technology of the formation of periodic microstructures with interfering fs laser pulses.

2. PROGRESS IN ENCODING TECHNOLOGY

Phillips et al. [11] at Rice University, performed an initial work, where they used a fs KrF eximer laser to record holographic gratings in polyimide with the intention to realize

fine patterning resulting from the thermal diffusion-free process. Also, an observation of a periodical fringe in diamond has been reported, which was accidentally encoded, presumably due to interference of the incident fs laser beam with a reflected beam [12]. In spite of these reports, material processing with the interfering fs pulses had not attracted much attention before Hosono's group succeeded in encoding holographic gratings in versatile materials, including transparent dielectrics, semiconductors, polymers, and metals with an interfering Ti:Sapphire laser pulse [13–18]. Since then, several groups have reported the formation of the periodic structures in polymers and glasses with the interfering fs pulse. Misawa's group, at Tokushima University, recorded three-dimensional structures in photoresist material with the interference of five beams split from a single fs pulse with the intention to form a photonic crystal [19]. Hirao's group at Kyoto University [20], and Ito's group at Osaka University [21], have succeeded in encoding embedded gratings in polymers and glass materials. The number of research groups involved in this technique is increasing, with an expectation that the interfering fs pulses will open a new frontier in laser processing.

3. FEATURES OF ENCODING

Features of the encoding technique that uses interference fs laser pulses are summarized. As is fs laser processing, almost all kinds of materials can be processed with the interfering fs pulses, and the structures are formed in a designated position in materials. Especially, embedded structures can be formed in transparent materials. The process can be completed in a single shot, thus, throughput of the process is potentially very high. Overall size of gratings is as small as $\sim$100 μm, where the fringe spacing is in the range of 0.1–5 μm, depending on the colliding angle of the beams and laser wavelength. As the spacing is proportional to the laser wavelength for a fixed crossing angle of the beams, use of fs pulse with a shorter wavelength is effective in narrowing the fringe spacing. On the other hand, as is common to the fs laser processing, minimum structure sizes for line width or dot diameter in the periodic structures can be reduced to the nanometer scale, which seems to be almost insensitive to the irradiated laser wavelength [22]. An additional novel feature of the technique is that two- and three-dimensional periodic structures can be fabricated by a double exposure and multiple-beam interfering methods.

4. ENCODING MECHANISM

As fs laser pulses exhibit good coherency over the entire pulse duration, interference takes place when multiple fs pulse beams split from a single pulse and overlap with each other both spatially and temporally. The interference pattern resulting from this overlapping can immediately lead to the modulation of the electron-hole plasma density in the irradiated materials through multiphoton absorption or avalanche ionization processes, where the plasma is excited more densely in an enhanced region of the interference than in a depressed region. The density modulation of the plasma causes the refractive index modulation. That is, a transient

grating is immediately formed in the material just after the irradiation of the interfering fs pulse. The transient grating, which likely lasts for several picoseconds (ps), may induce reconstructed beams that could interfere with the incident beams to form additional gratings. The plasma energy in the material is likely relaxed to the lattice within $\sim$1 ps to accumulate locally in the lattice.

With the relaxation proceeding, the transient grating is converted into a permanent grating when the local energy in the lattice exceeds a threshold for laser ablation or structural changes of the material. That is, the permanent gratings can be formed when the laser energy in the enhanced region of the interference is over a threshold value.

5. ENCODING SYSTEM

5.1. General Feature

A hologram encoding system by fs laser pulses does not differ significantly from conventional laser hologram exposure systems. A major difference between the two systems is that an fs laser pulse is used instead of a continuous wave light, typically from a gas laser having a long coherent length. A fs KrF excimer laser (248 nm, $\sim$400 fs) [11], Ti:sapphire laser (800 nm, $\sim$100 fs) [13–18, 20–25], second harmonics of Ti:sapphire (380 nm, $\sim$80 fs) [19], and third harmonics of Ti:sapphire (290 nm, $\sim$100 fs) [26,27] have been used so far as a fs pulse source. Because of a very short coherent length of the fs pulse, which is restricted by the spatial extent of the pulse, an optical delay line and a mechanism for detecting the time coincidence of the two beams, with a spatial accuracy of $\sim\mu$m, is, in general, required to ensure a spatial and temporal overlap. It also is desirable for the time-coincidence measurement to be independent of the angle between interference beams. By varying this angle, we can control over-fringe intervals in gratings and over shapes of unit elements in two-dimensional periodic structures. The sum of the frequency generation of the pulses due to optical nonlinear crystals (colliding angle dependent) [20] or third harmonic generation in air (colliding angle independent) [23] is effectively used for most of the systems, but alternative time-coincidence detecting system, without using the up-frequency conversion process, is necessary when a shorter wavelength fs pulse is used. A distributed feedback dye laser technique was used for the fs KrF laser [11], and for the pump and prove techniques, based on the optical Kerr effect and transient absorption, have been developed for the THG of the Ti:sapphire laser [26, 27]. On the other hand, use of a diffractive beam splitter in a multiple beam interfering system allows for the temporal coincidence without installing any adjusting mechanism [19].

When comparing the encoding systems developed so far, optical configurations are basically the same, and differences exist in the types of fs lasers and the detecting mechanisms for the temporal coincidence of the split beams, which are shown in Table 1.

5.2. Experimental Setup

Figure 1 shows, as a representative example, a schematic diagram of an experimental setup for grating encoding that uses near infrared (IR) fs laser pulses developed by

Table 1. Type of lasers and detection mechanisms for temporal coincidence used in encoding systems developed so far, together with encoded structures and materials in each encoding system.

	Type of laser	Detection for temporal coincidence	Encoded structure	Materials	Ref.
I	KrF excimer 274 nm ~400 fs	Distributed feedback dye laser	Surface grating	Polyimide	[11]
II-1	Ti: sapphire 800 nm ~100 fs	THG in air	Surface grating Embedded grating Two-dimensional periodic structure	SiO_2 glass, SiO_2 thin film $LiNbO_3$, ZnO, ZrO_2, MgO, TiO_2, diamond, carbon, SiC, ZnSe, Si, WC, Pt, Au	[13, 14, 15, 16, 17, 18, 22, 23]
II-2	Ti: sapphire 800 nm 100 fs~5 ps (chirped)	THG in air before chirping	Embedded grating Embedded two-dimensional periodic structure	SiO_2 glass	[24, 25]
III	Ti: sapphire 380 nm (SHG) ~80 fs	none	Multidimensional periodic structures	Negative photoresist (SU-8)	[19]
IV	Ti: sapphire 290 nm (SHG) ~100 fs	Transient optical absorption and optical Kerr gate	Surface grating	SiO_2 glass ZnO	[26, 27]
V	Ti: sapphire 800 nm ~150 fs	SFC in nonlinear optical crystal	Embedded grating	Azodye-doped PMMA	[20]
VI	Ti: sapphire 800 nm ~130 fs	Transilluminated optical microscope	Embedded grating	Soda-lime glass	[21]

Kawamura et al. [13]. A Ti:sapphire laser system, consisting of a Ti:sapphire oscillator, a stretcher, a regenerative amplifier pumped by the second harmonic of an Nd:YAG laser, and a compressor, is used as a light source. It generated 800-nm light pulses with a repetition rate of 10 Hz, a pulse duration of ~100 fs (an effective coherence length of ~30 μm), and a maximum energy of 3 mJ/pulse. A fs laser pulse from the laser system was divided into two beams by a half-silvered mirror. The separated beams propagated along different optical paths, with one having a variable path length (optical delay line). The two beams were focused onto a single spot of 50–100 μm in diameter by lenses with a focal length of 5–10 cm. The angle of intersection (θ) between these two beams was varied from 10° to 160°. The spatial

length of each optical path was equalized with a precise movement of mirrors in the optical delay line, while monitoring the time coincidence signal. Third harmonic generation (THG) from air was used for the signal [23], as will be described.

Once the time coincidence of the two beams was realized, samples were placed at the beam-focus position. Encoding of the gratings was confirmed *in-situ* by detecting diffracted light from an incident He–Ne laser. Figure 2

Figure 2. Images showing that spatial and temporal coincidence of two fs laser beams are required for encoding gratings. (a) No gratings are recorded when two fs beams are not in spatial coincidence. (b) No gratings are recoded when two fs beams are in coincidence spatially, but not temporally. (c) Gratings are encoded when two fs beams are in coincidence both spatially and temporally. Figure 1. Experimental setup for hologram encoding system using IR fs laser pulses. Reprinted with permission from [24], M. Hirano et al., *Proc. SPIE* 506, 89 (2003). © 2003, SPIE.

shows that both spatial and temporal coincidences were simultaneously required for encoding gratings.

As will be described, chirping of the fs pulse, which results in the stretching of the pulse width from ∼100 fs to ∼10 ps, keeping the total pulse energy unchanged, is very effective in encoding embedded gratings due mostly to the reduction of the surface damage [24, 25]. In using the stretched pulse for the encoding, the fs pulse is chirped by controlling the degree of the compression in the compressor, while keeping other optical configurations unchanged.

5.3. Detecting Mechanism

Representative examples of the detecting mechanism for the temporal coincidence of the beams are introduced in this session.

5.3.1. Third Harmonic Generation in Air

It has been reported that THG is induced when an intense fs laser pulse is focused in various gases such as air [28] or argon [29]; the mechanism has been discussed theoretically [30]. This phenomenon has been applied to monitoring the time coincidence of the two fs pulses [23].

When pulse energy of the first fs laser beam exceeds 1.5 mJ/pulse, a blue spot is observed at the beam center of the far field pattern, which is confirmed as the third harmonic of the laser fundamental (800 nm) at 266 nm. The THG was not observed when the pulse was focused in a vacuum, indicating that air was responsible for the THG. Then, a second focused beam, having an energy of 50 μJ/pulse, which was too small to induce the THG light by itself, was directed at the focal point so as to overlap spatially with the first beam. The far field pattern of the second beam on the luminescence screen yielded only weak white continuum light without the blue spot, likely due to the self-phase modulation in air when the relative time delay of the two pulses was large. While tuning the optical path length, the blue THG spot suddenly appeared at the center of the white continuum spot. Figure 3 shows the THG intensity in the second beam as a function of the delay time calculated from the change in the optical path length.
The intensity increases abruptly as the delay time approaches zero from below. The rise time for the THG enhancement estimated from the inset figure was ∼200 fs, which is in reasonable agreement with a pulse width of ∼100 fs. With a further increase in the delay time, the intensity, at first, decreases sharply. The decrease then becomes gradual and is still observed at delay times above 50 ps. Despite the gradual decay on the long delay time side, the peak in Figure 3 is sharp enough to determine the exact time coincidence of the two fs pulses. The trend in Figure 3 was independent of the angle of intersection of the two beams, as expected from the inherent nature of THG in the gas phase. The use of THG in air makes it possible to arrange the time coincidence of two fs pulses over a wide range of angles of intersection.

5.3.2. Pump and Prove Technique

The techniques using up-frequency conversion processes are not applicable for monitoring the time coincidence of ultraviolet fs pulses, because the resultant sum frequency light in the process has a too short wavelength to propagate in nonlinear crystals or even in air. To overcome this problem, alternative methods using a distributed feedback dye laser technique and two kinds of pump-probe techniques based on optical Kerr and transient absorption effects have been developed.

In the pump and prove techniques, the two beams to be interfered are used, respectively, as pump and probe pulses under the low intensity condition below the threshold for the ablation [26, 27]. In the optical Kerr gating method, the pump pulse is polarized perpendicular to the probe pulse by using a $\lambda/2$ plate, which is inserted in the pump beam path before a quartz plate (Fig. 4). On the other hand, the probe pulse goes into another $\lambda/2$ plate after passing through the quartz plate and then into polarized beam splitter (PBS) placed at the front of a photodiode detector (PD) equipped with a phase-sensitive detection system.

Silica has third-order susceptibility, with a very fast time response, and thus the pump pulse induces a birefringence through the electronic Kerr effect, also known as the nonlinear refractive index change. When the $\lambda/2$ plates are rotated by 45 degree with each other, the probe pulse can go through PBS only when the silica plate is irradiated simultaneously with the pump pulse (Fig. 5). That is, this geometry yields an autocorrelation measurement of the pulse. Although the observed pulse width stretches from that of the fundamental wavelength (870 nm) and the exact reason for that has not been clarified, the time zero is determined at the center position of the band.

In the transient absorption method, the probe pulse is directly collected at the PD without both the $\lambda/2$ plates and the PBS device. The absorbance change of the probe pulse perturbed by the pump-pulse irradiation is detected by the same procedure as the Kerr measurement. Because the laser energy (4.3 eV) is below the bandgap energy of silica, the absorption occurs through two photon processes. The electron hole plasma is momentary created and decays to a self-trapped exciton or transient defect centers with a fast relaxation time. Figure 6 shows the experimental result of the transient absorption measurement. The pulse width (FWHM) is obtained as 300 fs, which is a little larger compared to that obtained by the optical Kerr measurement. However, it is accurate enough to determine the time zero between the two pulses from the absorption band profile. Spectra for different colliding angles of two pulses also were demonstrated in Figure 6, indicating that the peak width has hardly changed with the angle, although dip structures become prominent in a longer delay time region with increasing the angle. These results indicate that the transient absorption measurement is a useful method to obtain the time zero, not restricted by the colliding angle between two pulses.

5.3.3. Distributed Feedback Dye Laser Technique

When the beams overlap with each other spatially and temporally in a dye cell placed at the focal point of colliding fs KrF laser beams, a grating is induced in the cell, which in turn acts as a Bragg mirror, thereby forming a distributed feedback dye laser [11]. In this way, monitoring the output of the dye cell while tuning an optical delay line makes it possible to achieve the temporal coincidence of the two KrF laser beams.

6. ENCODED HOLOGRAM

Several types of holographic structures have been encoded by the above mentioned exposure techniques in various materials, including dielectrics (SiO_2 glass, SiO_2 thin films, $LiNbO_3$, ZnO, ZrO_2, MgO, TiO_2, diamond, carbon), semiconductors (SiC, ZnSe, Si), metals (WC, Pt, Au, Al) and polymers (polyimide, PMMA, negative photoresist SU-8). Table 1 also summarizes types of periodic structures and encoded materials. Representative examples among them are shown in detail in this section.

6.1. Surface Relief Hologram

6.1.1. Silica Glass by IR fs Laser

When the intersecting beams were focused onto the surface, surface-reliefs type gratings were encoded because of material ablation.

Figure 7 shows surface-relief gratings encoded in silica glass for several θ values, with a total fluence of 0.3 mJ/pulse. Each grating forms a circle with a diameter of $\sim$100 μm and

Figure 5. Optical Kerr gate signal in silica plate as a function of delay time between pump and prove pulses. The crossing angle between the two beams is 30°. Reprinted with permission from [26], H. Kamioka et al., *Proc. SPIE* 4760, 994 (2002). © 2002, SPIE.
Figure 7. Optical microscope images of gratings recorded in silica glasses for various beam intersecting angles (θ). Fringe interval d varies with θ according to the equation $d = \lambda/[2\sin(\theta/2)]$. Reprinted with permission from [18], M. Hirano et al., *Appl. Surf. Sci.* 197–198, 688 (2002). © 2002, Elsevier Science.

is composed of parallel fringes with a constant spacing equal to $\lambda/[2\sin(\theta/2)]$, where λ is the laser wavelength (800 nm). This observation constitutes clear evidence that the gratings were encoded as the result of interference between the two fs pulses of the fundamental wavelength (800 nm). The formation of a periodic valley structure at the surface is revealed by (AFM) images. The deposition of debris or molten materials onto the surface indicates that the grating structure results from laser ablation at this fluence level.

Infrared spectra suggested O–Si–O bond angles in the laser-irradiated area suffered photo-induced changes, leading to the densification of the silica glass. Such structural changes have been observed in silica glasses during high-energy ion implantation or neutron bombardment; densification typically saturates at ~3% [31]. As this compaction is accompanied by a refraction index increase of ~0.7%, a refraction index modulation type grating can be simultaneously formed beneath the surface relief type grating.

High-resolution images of the grating acquired with a field emission scanning electron microscope (SEM) (Fig. 8) show periodic valleys in the internal structure of the grating. These valleys are very narrow, down to 15 nm. The compaction of silica glass in very localized areas due to intense laser irradiation generates tensile forces directed parallel to the surface, which likely play an important role in the formation of such narrow valleys.

6.1.2. Silica Glass by Ultraviolet fs Laser

When the interference UV fs pulse (290 nm), with a total energy of 20 μJ, was irradiated at bulk silica glass, the micrograting structure was encoded at the surface through an ablation, as shown in Figure 9. A colliding angle was set to be 30°. The fringe spacing is in good agreement with the calculated value of 560 nm for $\lambda = 290$ nm. The net fluence of the two laser pulses at the sample surface was 0.25 J/cm^2, which is similar to that of the 800 nm fs laser that encoded the surface grating on silicon surface. The slight dependence of the threshold power on the laser wavelength implies that the multiphoton absorption is not a major process, but the avalanche ionization is responsible for the excitation of electron-hole pairs in silica glass. The

smaller spacing between grooves is expected when increasing the colliding angle of the two pulses. The SEM picture of the grating is shown in Figure 10 for the colliding angle of 60°. The spacing agrees with the predicted value of 290 nm, which will be further narrowed down to ~150 nm with increasing of the angle.

6.1.3. Polyimide by fs KrF Laser

Surface-relief-type gratings with a spacing of 167 nm were produced at polyimide surface by a single shot of a 400 fs KrF excimer laser with an average energy of 83 mJ/cm^2. The colliding angle was 45 degree.

6.1.4. Silica Thin Film

Surface-relief-type gratings with a valley depth as shallow as 3.5 nm were recorded in thin-film silica on a silicon wafer by reducing the total fluence to 0.015 mJ. The surface profile of the fabricated grating was smooth and neither small deposits nor macroscopic laser damage or cracking was observed at this fluence, suggesting that the formed grating resulted from the densification of the films, not from laser ablation. The valley depth of the grating (3.5 nm) relative to the film thickness (114 nm) supported this suggestion, as it coincides with the saturation level ($\sim$3%) of radiation-induced densification in amorphous SiO$_2$. A difference in the properties of undensified and densified amorphous SiO$_2$ is manifested in the etching rates during stress-enhanced corrosion [32]. An AFM image and a cross section of grating structures formed by etching with 1% HF solution (Fig. 11) show that etching increases the depth of the valley by a factor of 5–6 relative to that before etching. In other words, chemical etching converted the refractive index modulation-type grating into a surface-relief-type grating.

6.2. Embedded Hologram

6.2.1. Full Compressed Pulse

When the focal point of the interfering fs laser pulses is positioned inside the target materials, an embedded grating is recorded through a refractive index modulation, either due to structural alternations such as densification in silica glass, crystallographic phase changes from crystalline to amorphous states, or the formation of micropores due to the evaporation of a small amount of the materials.

Such an embedded grating was recorded inside a diamond crystal [14]. Confocal microscopic images reveal the grating

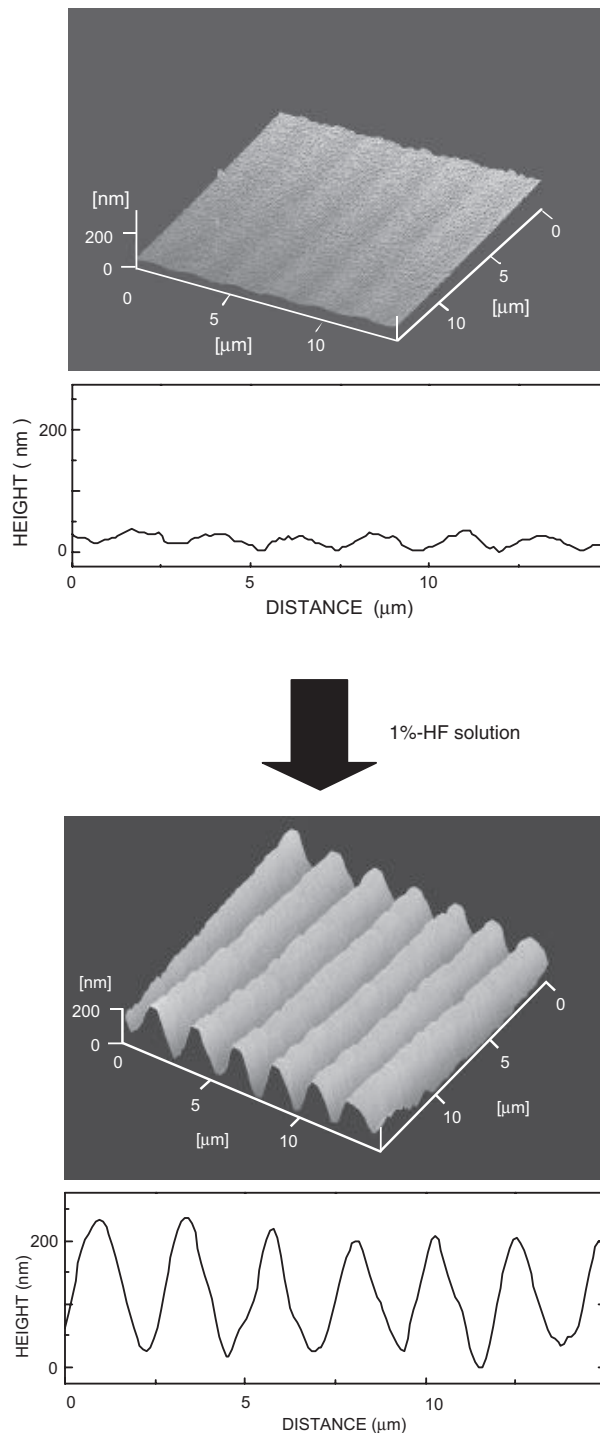
lies 0.45–1.05 μm beneath the surface. Raman spectra for the grating encoded area suggest that the refractive index modulation was caused by a structural change from diamond to diamond-like carbon or amorphous carbon [33]. Similar embedded gratings in a multicomponent glass plate [21] and


Figure 11. AFM images of surface-relief-type gratings encoded in silica thin films before and after etching by 1% HF solution. The valley depth was deepened due to preferential etching in the densified areas. Reprinted with permission from [18], M. Hirano et al., *Appl. Surf. Sci.* 197–198, 688 (2002). © 2002, Elsevier Science.

polymer [20] have been reported by using fully compressed fs laser pulse.

6.2.2. Chirped Pulse

In spite of the successes in encoding the embedded gratings by fully compressed fs pulse (∼100 fs), it is still difficult to encode embedded gratings deep inside versatile materials. The major reason for such a shallow processing depth is likely attributed to the fact that absorption coefficient is larger at the surface than the inside of materials, thereby, most of the pulse energy being lost around surface and the penetrating pulse is not intense enough for the encoding. The deterioration of the coherency of the pulse due to the interaction between the intense pulse and materials during the propagation may be an additional cause for the difficulty in encoding the gating inside of materials.

One possible approach to overcome the difficulty is to use focal lenses with a large numerical aperture, which makes it possible to reduce the laser-power density at the surface much lower than that at the focal area inside the material, thereby keeping accumulated energy at the surface below the threshold, while enhancing the energy at the focal point above the threshold. This approach is successfully used to encode embedded gratings for specific materials such as diamond [14], multicomponent glass [21], and polymers [20], as mentioned before. But, this approach alone unlikely provides enough controllability and flexibility to the encoding process of the embedded gratings.

An essential solution to overcome the difficulty is to reduce the peak energy of the pulse keeping the total energy of the pulse unchanged by expanding the pulse width. A chirped pulse, which is a partially compressed fs pulse, may meet the requirements. Before encoding embedded gratings with the chirped pulses, surface-relief-type gratings were encoded to confirm their effectiveness [24, 25]. The diameters of the surface-relief-type gratings at the surface slightly decrease with an increase in the pulse width from 100 to 5000 fs, each pulse having a constant total energy. As the energy density at the periphery of the recorded area corresponds to the threshold for the encoding, this observation implies that the threshold is more dominantly governed by the total energy than by the peak energy of the pulse in this pulse width range.

Figure 12 shows (FE)–SEM images of a cross section of the surface-relief-type gratings recorded by 100 fs and 400 fs pulses with the total energy of 50 μJ/pulse. The 100 fs pulse encodes the grating with very shallow grooves of ∼1 μm located at the surface. On the other hand, the groove depth becomes deeper for the 400 fs pulse irradiation, indicating the pulse energy penetrates deeper with an increase in the pulse width or a decrease in the peak power. The shallow processing depth by 100 fs pulse may be explained as follows. When the 100 fs pulse with an energy of ∼5 TW/cm^3 is irradiated at the silica glass, it generates the electron-hole pairs with a density of ∼10^{21}/cm^3 around the surface within the pulse duration via multiphoton absorption and avalanche ionization processes as predicated by Stuart et al. [34]. The resultant dense plasma strongly absorbs IR light through one photon process, thereby dramatically enhancing the plasma density and thus preventing the penetration of the pulse into
Figure 12. FE-SEM images of cross section of the surface-relief-type gratings recorded by 100 fs (a) and 400 fs (a) pulses in silica glass. Reprinted with permission from [24], M. Hirano et al., *Proc. SPIE* 506, 89 (2003). © 2003, SPIE.

the silica more than ∼1 μm. On the other hand, the front part of the stretched pulse may penetrate into materials before the electron-hole pair density at the surface becomes greater than ∼10^{21}/cm^3. These observations encourage the use of a stretched pulse for the formation of embedded gratings.

Then, the cross area of the two stretched pulse beams was shifted to the inside of the material to encode the embedded grating, as demonstrated in Figure 13, where the beam colliding angle of 45°, cross area of 30 μm below the surface, laser pulse width of 500 fs, and total pulse energy of 50 μJ/pulse were used. No gratings are observed in the crossing area in the as-cut sample, but faint gratings are seen in the beam entrance areas on the surface. After chemical etching, an embedded grating appears at the crossing area due to the stress-enhanced etching, as described previously. An expanded SEM image for the cross area shown in Figure 14, clearly demonstrates that the grating is encoded inside the silica glass at a depth of ∼30 μm. Periodic line grooves with a constant spacing (d) of ∼1 μm is visible in the grating. The spacing agrees with that given by the equation of $d = \lambda/[2 \sin(\theta/2)]$, where λ is the wavelength of the laser (800 nm), and θ is the colliding angle between two incident pulses (45°). Those gratings are observed directly without the chemical etching by a confocal microscope as shown in Figure 15b. The faint gratings in the beam entrance

areas on the surface, whose line spacing is ~ 1 μm, equaling to that of the embedded grating, are most likely created as results of the interference between an incident beam and a conjugated beam reconstructed from the transient grating, formed by the periodic density distribution of the laser-induced excited state or by electron-hole plasma.

Figure 16 shows a cross-sectional FE–SEM image of multiple gratings vertically located inside the silica glass. Each grating was recorded by a single shot. These gratings, which were encoded in four layers separated by 300 μm, show long tails downward to the beam propagation direction. When an array of gratings is encoded in each layer, it can be visualized by illuminating white light, as shown in Figure 15a.

No noticeable difference is observed between the gratings encoded by down- and up-chirped pulses, suggesting the nonlinear optical interaction, which may degrade the coherence of the pulse, does not play a significant role, at least in the stretched pulse.

These results clearly indicate that use of chirped pulses instead of a fully compressed fs pulse, which results in stretching of the pulse width from ~ 100 to ~ 5000 fs, provides controllability and flexibility to the encoding system, particularly giving rise to the capability in encoding embedded gratings in versatile materials. The optimized pulse width, which may be of material dependent, is ~ 500 fs for silica glass.

6.3. Multidimensional Periodic Structure

6.3.1. Double Exposure Technique

Two-dimensional periodic structures can be formed by a double-exposure technique [22]. A series of optical microscope images of the gratings in Figure 17 demonstrate the double-exposure procedure. Photos (a) and (b) in this figure show gratings with diameters of ~ 15 μm and ~ 50 μm encoded by laser pulse energies of 40 μJ and 100 μJ, respectively. After the first grating was encoding, the samples were rotated by 90° and a second grating was recorded superposed on the first grating. The resultant structure is not always a simple superposition of two kinds of gratings, but a complicated structure results from interactions between the two encoding processes. Figure 18 is an SEM image of a crossed grating encoded when energy in the second pulse (80 mJ) was larger than in the first one (40 mJ) with a 45° angle between the beams for both exposures. The periodic vertical lines represent fringes of the grating encoded by the first exposure, since the periodicity of 1.0 μm equals $\lambda/[2\sin(\theta/2)]$. It is noted that an array of round dots with a diameter of ~ 140 nm is observed in the center part of the crossed grating. The dots become ellipsoidal as one moves toward the edge of the grating and connect with each other to form periodic horizontal lines. Since the first grating was not encoded in the outer area and the spacing is consistent with the second exposure, the horizontal lines here are fringes of the second grating. The formation of the dot array in the central part results from the interaction between the first grating and the incident beams in the second exposure.

When the first pulse energy (80 μJ/pulse) is larger than that of the second pulse (40 μJ/pulse), a resultant structure is composed of periodic narrow valleys recorded by the first exposure and a two-dimensional dot array with exfoliations and cracks around the dot (Fig. 19). Diameters of the dots are ~100 nm and each dot seems to have a smaller dot

inside, whose diameter becomes smaller with a decrease in the pulse energy. The dot array results from the interaction between the periodic valleys and the incident beams in the second exposure, most likely due to the interference among two incident beams and reconstructed beams from the first grating. If this were the case, encoded structures would be equivalent with those by the interference among four beams divided from a pulse. By increasing θ from 45° to 90°, an array of trapezoid structures could be produced; this array looks like a simple superposition of two orthogonal gratings (Fig. 20).

These results indicate that the double-exposure technique of using fs laser pulses offers a new tool for the formation of two-dimensional nanostructures in various kinds of materials.

6.3.2. Multibeam Interference Technique

Results of the double-exposure process suggest that multibeam interference provides a novel technique in encoding multidimensional periodic structures. Especially, when we use the interference among five beams, we can fabricate three-dimensional periodic structures in transparent materials. Such three-dimensional structures have been encoded in polymers by using a Q-switched YAG:Nd^{3+} laser [35]. Three-dimensional periodic structures were encoded in negative photoresist SU-8 with interfering five beams split from a SHG of Ti:sapphire laser pulse [19], where the pulse was split into five beams by a diffractive beam splitter, making it possible to achieve the temporal coincidence without the detecting mechanism.

6.4. Application to Optical Device

Because sizes of the recorded gratings ($\sim 50~\mu m$) are slightly smaller than that of optical devices, gratings could be used as building blocks of the optical devices. For example, two gratings capable of coupling and decoupling of light to waveguide were encoded on a waveguide fabricated on a $LiNbO_3$ substrate. Figure 21 demonstrates that He–Ne laser light is coupled and decoupled to the waveguide through these gratings.

GLOSSARY

Chirped femto second laser pulse Not fully compressed pulse with a pulse width of $100\sim3{,}000$ fs from regenerated amplified fs pulse laser system.

Double exposure technique An interference fs pulse are irradiated exactly on as encoded grating which was rotated by 90 degree.

Embedded grating Refractive index type grating encoded inside transparent materials.

Interference fs laser pulse When two fs laser pulses split from a single pulse collided with spatial and temporal coincidences, interference of fs laser pulse occurs due to good coherency of the pulse.

Multi-dimensional periodic structure Two or three dimensional periodic structures are encoded by the interference among four of five fs laser pulses. Two dimensional structures are also fabricated by a double exposure technique.

Structural alternation Structural changes induced by the irradiation of fs laser pulse including densification of silica glass, crystallographic phase change from crystal to amorphous states in diamond, which accompany with the refractive index modulation.

Surface grating Surface relief type grating encoded by material ablation.

CONTENTS

1. INTRODUCTION

The dream of delivering a pharmaceutically active molecule to a specific site in the body has been a long-held aspiration with beginnings that may be traced back to Paul Erhlich, who in the early 20th century coined the phrase "magic bullet" to describe such an entity [1]. Today, extensive pharmaceutical research has led to the development of drug delivery systems and strategies, which go some way to fulfilling this idea, but few which could be described as "magic bullets." Side-effects and toxicities still afflict these approaches and, hence, Erhlich's visionary thinking has not yet been fully realized. This is especially relevant in tumor chemotherapy, where selective delivery to neoplastic cells in comparison to surrounding normal cells is an important principle [2]. As can be seen in Figure 1a, the challenge faced in site-specific delivery of drugs is immense due to the numerous obstacles barricading the drug along its desired route. Cellular structures and indeed the very components of the cell itself will either prevent or act in some selective manner to hinder to the migration of drug from its point of administration to the intended destination site.

On moving forward into the 21st century, it is apparent that modern medicine still faces many challenges. Nanotechnology is indeed one area that may offer scientific advances in the coming years, which could lead to significant progress in the improvement of therapeutic outcomes. In particular, the development of nanoparticulate drug delivery systems may enhance the probability of getting a drug to its target site [3]. Instead of relying on the physicochemical properties of the drug to dictate its biodistribution, the drug is incorporated as a payload into a particle resulting in a different transit mechanism for the drug after administration [4]. This can be enhanced further by virtue of the flexible nature of the nanoparticle scaffold, on to which subsections may be chemically bolted, producing a tailor-made and multifaceted device. This can be represented in Figure 1b, which gives the blueprint of an idealized nanoparticulate delivery system that must make its way to the target cell.

The particle in Figure 1b has several properties which are incorporated onto the particle, mostly by covalent bonding to surface groups. A targeting system, such as a monoclonal antibody, will recognize binding sites that are unique to the target cell and allow the particle to dock onto the exposed surface [5]. This has been the focus of much current research into developing strategies for targeting nanoparticles to the site of drug action [6–8]. A fusion protein will instigate the process of merging with the target cell, thereby bringing the particle into the cytoplasm [9]. As polymeric nanoparticles are recognized as foreign by the body's immune system, they are removed quite effectively by phagocytosis on exposure to the endoreticular system [10]. This will prevent the particle from reaching the target site and must be prevented. Steps toward this goal have already been taken with the production of so-called "stealth" nanoparticles. These are nanoparticles which incorporate a biomimetic polymer, usually polyethylene glycol, into their structure to avoid elicitation of an immune response [11–13]. Presently, such an idealized nanoparticle with these three important properties has yet to be realized, but attempts have been made to attach some of the subsystems described.

The construction of an idealized particle must start with the formation of a solid polymeric sphere with a diameter

intestinal wall   connective tissue   vascular endothelium   target cell

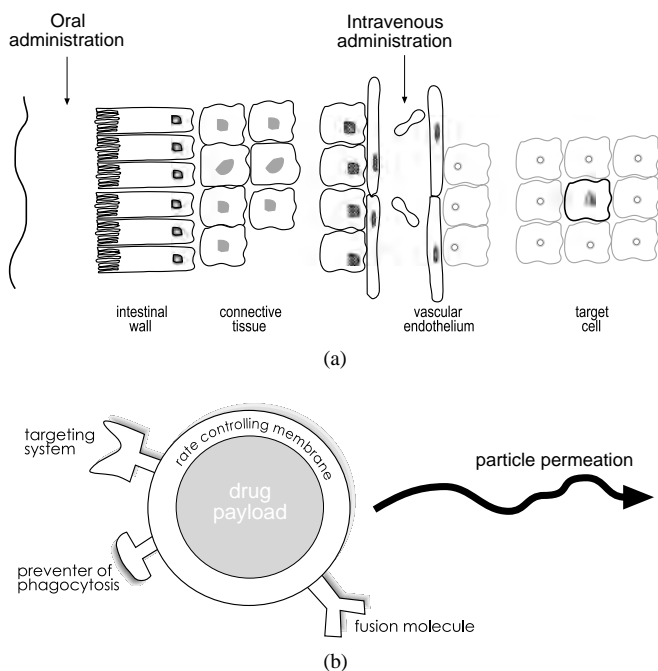

Figure 1. (a) A simplified overview depicting the barriers to drug localization at a target cell after oral administration into the gut or intravenous administration to the systemic circulation. For example, the path from a capillary to a target cell may involve crossing the vascular endothelium and various connective tissue structures. (b) An idealized draft of a multifaceted nanoparticulate system containing a drug payload that must also permeate in some way to the target cell. Pendent molecules, such as a targeting ligand, add to the functionality of the device.

of approximately 200 nm. This is followed closely by loading the drug into the naked particle. This is dependent on the physicochemical properties of the drug molecule, which may often present problems in terms of efficient loading, especially if the drug has appreciable water solubility. This scenario may not be uncommon given that the majority of candidate molecules for inclusion in nanoparticulate systems will possess some degree of aqueous solubility. This chapter discusses the construction of nanoparticles and describes their characterization. In particular, the process of incorporating a water-soluble payload is discussed and the problems associated with this are used to illustrate the complexities encountered during the proposed construction of a device, as typified in Figure 1b.

2. DEFINITION OF NANOPARTICLES

Nanoparticles have been studied extensively as carriers for drugs employed in a wide variety of routes of administration, including parenteral [14], ocular [15], and peroral [16] pathways. The term nanoparticle is a collective name for any colloidal carrier of submicrometer dimension and includes nanospheres, nanocapsules, and liposomes. They can all be defined as solid carriers, approximately spherical and ranging in size from 10 to 1000 nm. They are generally polymeric in nature (synthetic or natural) and can be biodegradable

or nonbiodegradable in character. Biodegradable polymers used include poly(alkylcyanoacrylates) [17, 18], poly(lactide-co-glycolide) [19, 20], chitosan [21, 22], and gelatin [23], while nonbiodegradable polymers include poly(styrene) [24], poly(acrylamide) [25], and poly(methylmethacrylate) [26]. Nanospheres represent the simplest carrier and are solid, monolithic systems in which the drug is dissolved or entrapped throughout the particle matrix. Alternatively, it may be adsorbed onto the surface. No continuous membrane surrounds the particle, as illustrated in Figure 2a.

Nanocapsules are reservoir type systems comprising an oily liquid core surrounded by a polymeric shell [27]. The drug is usually dissolved in this liquid core but may be more closely associated with the shell polymer and the exposed surface, as illustrated in Figure 2b.

Liposomes are closely related to nanocapsules in structural layout but consist of an aqueous core surrounded by a bilayer membrane composed of lipid molecules, such as phospholipids [28], as illustrated in Figure 2c. The drug can be located in the aqueous core or in the bilayer membrane.

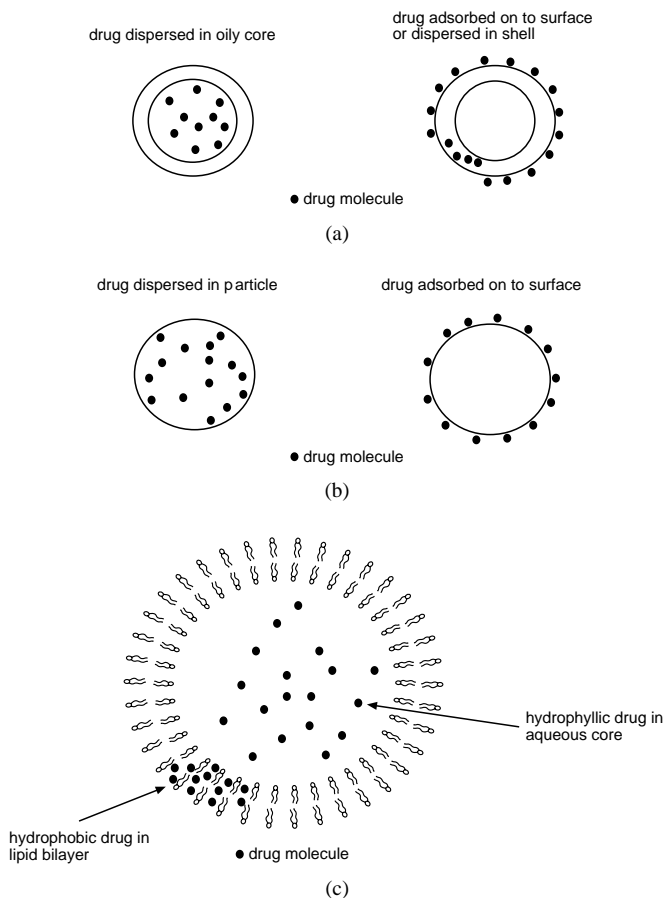

Figure 2. (a) The morphology of nanospheres, where drug can be either dispersed throughout the polymeric matrix of the particle or adsorbed onto the surface. (b) The morphology of nanocapsules, where drug is dispersed mostly in a liquid core. Drug can also be associated with the polymeric shell, either by dispersal through the polymer or adsorption to it. (c) The morphology of a small single lamellar liposome of submicrometer dimensions showing the possible location of a drug payload.

From a historical prospective, liposomes have been the most extensively studied nanoparticulate carrier [29–32]. However, their full development leading to extensive clinical use has been restricted by pharmaceutical problems entailing drug leakage, stability, and problems with scale-up procedures. These all arise due to their liquid and semisolid nature leading to a lack of rigidity and subsequent fragility. However, the important early work by Couvreur and co-workers [33] introduced nanoparticles prepared from biodegradable poly(alkylcyanoacrylates). This has prompted much research into nanoparticles made from polymeric materials and, furthermore, into finding polymers that are pharmaceutically acceptable, biodegradable, and nontoxic [34]. A wide variety of preparation methods for nanoparticles have now evolved, which encapsulate many different types of drug compounds [35, 36].

3. PREPARATION

Both nanospheres and nanocapsules are prepared from either a polymerization reaction of dispersed monomers or from a solvent dispersion procedure using preformed polymers. In many instances, the latter procedure using preformed polymer is desirable, as potential reactions between drug and monomer are avoided and the potential toxicity of residual monomers, surfactant, and initiator is reduced [37]. The final properties of nanoparticles, such as their size, morphology, drug loading, release characteristics, and biodistribution, are all influenced by the method of preparation [38].

3.1. Nanoparticles Prepared from Polymerization Reactions

Most examples of polymerization used to create nanoparticles occur by a free radical mechanism involving distinct initiation, propagation, and termination processes [39]. Polymerization occurs within a continuous liquid medium, which also comprises the monomer, initiator, and a surfactant. Four different polymerization techniques are described to polymerize vinyl type monomers, namely:

- emulsion polymerization, resulting in 0.05–0.2 μm particles
- dispersion polymerization, resulting in 0.3–10 μm particles
- precipitation polymerization, resulting in nonspherical 0.1–10 μm particles
- suspension polymerization, resulting in 20–2000 μm particles

3.1.1. Emulsion Polymerization in a Continuous Aqueous Phase

Continuous aqueous phase emulsion polymerization is one of the most widely used procedures to make nanoparticles for drug delivery purposes, especially those prepared from the alkylcyanoacrylate monomers. An oil-in-water emulsion system is employed where the monomer is emulsified in a continuous aqueous phase containing soluble initiator and surfactant [39, 40]. Under these conditions, the monomer is partly solubilized in micelles (5–10 nm), emulsified as large

monomer droplets (1–10 μm), and partly dissolved in the continuous aqueous phase. The polymerization takes place in the outer continuous phase and not in the micelle interior [41]. Initiation of polymerization occurs in the aqueous phase when a monomer molecule collides with an initiator molecule, which may be an ion or a free radical [42]. Alternatively, the monomer can be struck by a high-energy photon, such as gamma radiation and ultraviolet or intense visible light. Propagation occurs when nascent monomeric radicals interact with other monomer molecules forming primary particles [39]. The polymerization is maintained by the continuous supply of monomer from the monomer reservoirs, such as droplets and micelles, and is illustrated in Figure 3.

The surfactant is an important component of this process and acts to stabilize the growing polymeric particles by surface adsorption. Phase separation and the formation of solid particles occur before or after termination of the polymerization process [42]. Polymerization can occur in some systems without the presence of surfactants [40]. Various particulate systems have been prepared by this method, including poly(styrene) [43], poly(vinylpyridine) [44, 45], poly(acrolein) [46, 47], and poly(glutaraldehyde) [48–50].

Considerable work has been done using poly(alkylcyanoacrylate) (PACA) nanospheres due to their biodegradability, bioelimination, ease of preparation, low toxicity, and stability [18, 51, 52]. Although initially used as hemostatic aids in surgery [53, 54], their preparation was first recorded by Couvreur et al. [33]. Monomer was emulsified in a stirred, acidic, aqueous medium containing a nonionic surfactant, as illustrated in Figure 4. The suspension obtained displays a blue coloration due to the scattering of light by the particles known as the Tyndall effect. Glucose, Tween, Dextran 70, and Pluronic F68 have been used to stabilize and protect the particles from agglomeration [52]. Various monomers are available, such as methyl, ethyl, butyl, and isohexyl monomers, to prepare PACA nanoparticles, which differ in the length of their alkyl side chains.

The polymerization is an anionic mechanism initiated by hydroxide ions or any bases present [42]. The reaction scheme can be seen in Figure 5. The polymerization rate is regulated by hydroxyl ion concentration and hence is carried out at pH values below 3.5. Above this pH, the reaction rate is too rapid to allow discrete particle formation [55, 56].
Figure 3. Presentation of the emulsion–polymerization mechanism in an aqueous phase.
Figure 4. Preparation conditions used in the preparation of poly(alkyl-cyanoacrylate) nanoparticles.

The main advantage of this polymerization is that it can be carried out at room temperature without an energy input. PACA nanoparticles have been prepared reproducibly at a semi-industrial level and can be made aseptically [57].

Spherical particles of around 200 nm in diameter are prepared by this technique as demonstrated by scanning electron microscopy [58, 59]. Particles as small as 10 nm were obtained by altering the concentration of surfactant and by increasing amounts of sulphur dioxide [60, 61]. Freeze fracture studies confirmed that PACA nanospheres have a dense solid spherical core with no distinguishable surrounding membrane [27]. The contents of the polymerization medium, such as pH, concentration, type of surfactant, and monomer type have been shown to influence the particle size [55, 62–64]. A large variety of drugs, such as cytostatics and antibiotics, have been encapsulated in PACA nanospheres successfully, in part due to their porosity and high specific surface area [35, 65–68]. Drugs are incorporated into these nanospheres during polymerization or adsorbed onto the surface of preformed particles [52]. The loading of lipophilic drugs is limited by their solubility in the aqueous acidic continuous phase. Acid labile drugs can be incorporated using poly(dialkylmethylidenemalonate) esters as they polymerize at neutral pH [69, 70]. This is due to the presence of the less electrophilic alkoxycarbonyl group compared to the cyano
Figure 5. Anionic polymerization mechanism for alkylcyanoacrylate monomers (R = n-butyl).

group of the alkylcyanoacrylates. Their use, however, has been limited due to slow biodegradability [71].

3.1.2. Emulsion Polymerization in a Continuous Organic Phase

This procedure involves emulsifying a water-soluble monomer in a continuous organic phase containing a soluble initiator and surfactant. This constitutes a water-in-oil emulsion, as the different phases are reversed from the more common continuous aqueous phase based methods. The first process reported for nanoparticle formation by Birrenbach and Speiser is an example of this procedure [72]. Poly(acrylic) nanoparticles were prepared by dissolving acrylamide and N,N'-methylene bizacrylamide in an outer hexane phase containing anionic surfactants. The polymerization was initiated by gamma, ultraviolet, or visible radiation. Biologically active, antigenic materials were encapsulated and showed intact biological activity and high antibody production after encapsulation [72]. Spherical particles of 80 nm were produced based on electron microscopic studies. Kreuter [59] reported that transmission electron microscopy (TEM) revealed these particles to have a solid dense interior, forming matrix type nanopellets. Ekman and Sjoholm [73] investigated the polymerization of these monomers by radical initiation in a toluene/chloroform mixture, but higher particle sizes were obtained.

The main disadvantage in using poly(acrylamide) systems is that they are not biodegradable and the monomers are toxic. Extensive purification is also required to remove the organic solvents, anionic surfactants, and residual monomers. Edman et al. [74] produced biodegradable poly(acryldextran) particles by incorporating dextran into the poly(acrylamide) chain. These particulate systems were metabolized and eliminated faster, both *in vivo* and *in vitro*, than poly(acrylamide) particles.

3.1.3. Dispersion Polymerization

In dispersion polymerization, the monomer and initiator are dissolved in the continuous phase, which acts as a nonsolvent for the developing polymer. The continuous phase can be organic, aqueous, or a mixture of miscible phases. Two methods of initiation have been employed, including gamma radiation [75] and chemical initiation by potassium peroxodisulphate [76]. As the polymer is formed, it precipitates as nanoparticles. These particles are not polymeric precipitates as in precipitation polymerization. Rather, they are swollen by a mixture of the monomer and the continuous phase [39].

Kreuter and Speiser [77] developed a dispersion polymerization producing adjuvant nanospheres of poly(methylmethacrylate) (PMMA). The monomer is dissolved in phosphate buffered saline and initiated by gamma radiation in the presence and absence of influenza virions. These systems showed enhanced adjuvant effect over aluminum hydroxide and prolonged antibody response. PMMA particles could be distinguished by TEM studies and the particle size was reported elsewhere to be 130 nm by photon correlation spectroscopy [75]. The particle size could be reduced, producing monodisperse particles by inclusion of protective colloids, such as proteins or casein [40]. Poly(methylmethacrylate) nanoparticles are also prepared

by chemical means using potassium peroxodisulphate as initiator combined with heating at 65 or 85 °C [76]. Increasing monomer concentration and temperature resulted in an increase in particle size.

Copolymerization of PMMA has been carried out for the purpose of producing more hydrophilic particles [45, 78, 79]. Methylmethacrylate has been copolymerized with methacrylic acid, ethylene glycol dimethacrylate, hydroxypropyl dimethacrylate, or 2-hydroxyethylmethacrylate, by emulsion polymerization. Particle sizes from 30 to 340 nm in diameter can be produced by chemical initiation and 0.3–3.0 μm particles produced using gamma radiation [45, 80]. Antibodies, amino acids, and fluorescent molecules can be covalently bound to the active surface groups on these particles by cyanogen bromide, carbodiimide, and glutaraldehyde methods [78, 80]. The polymerization of PMMA and its copolymers avoids the use of organic solvents and anionic surfactants. However, PMMA is not biodegradable and, thus, persists in the body [18, 81]. The hydrolysis of these polymers requires an acid environment not generally found in body fluids.

3.2. Nanospheres Prepared from Preformed Polymers

Synthetic and natural polymers have been investigated which are biodegradable and biocompatible. The nanospheres are formed by precipitation of synthetic polymers or by denaturation/solidification of polymers of natural origin. Four techniques have been reported for preparing nanoparticles from synthetic preformed polymers. These include:

- emulsion–evaporation,
- salting out technique,
- emulsion–diffusion,
- coacervation/phase separation technique.

3.2.1. Emulsion–Evaporation

This method was first reported by Vanderhoff [82] for the preparation of artificial latexes. The polymer and drug are dissolved or dispersed in a volatile water-immiscible organic solvent, such as dichloromethane, chloroform, or ethyl acetate. This is emulsified in an aqueous continuous phase containing a surfactant, such as poly(vinylalcohol), to form nanodroplets. The organic solvent diffuses out of the nanodroplets into the aqueous phase and evaporates at the air/water interface, as illustrated in Figure 6. The solvent is removed under reduced pressure. The nanodroplets solidify and can be separated, washed, and dried to form a free-flowing powder.

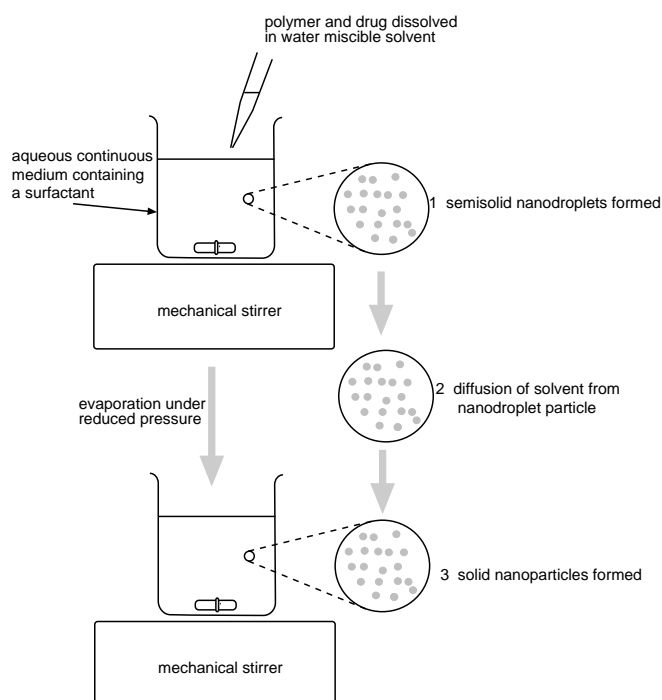
Poly(D,L-lactic acid) (PLA) nanospheres containing testosterone, with a particle size of 450 nm, were first produced by Vanderhoff et al. [83]. Microfluidization produced spherical particles of less than 200 nm with a narrow size distribution [84]. Krause et al. [85] produced PLA nanoparticles of 500 nm using sonication. The polymer and drug, triamcinolone acetonide, were dissolved in chloroform and emulsified, with sonication, for 45 minutes at 15 °C in a gelatin solution. The solvent was evaporated by heating to 40 °C for 45 minutes under continuous stirring. TEM


Figure 6. Preparation scheme for the emulsion–evaporation method.

showed these particles to have a highly porous interior structure. Scholes et al. [86] and Julienne et al. [87] optimized the particle size of poly(lactide-co-glycolide) (PLGA) nanospheres by altering preparation conditions in the emulsion–evaporation method. These conditions included the phase volume ratio of the emulsion formed, concentration and molecular weight of the polymer and surfactant, as well as homogenization time and pressure. Tice and Gilley [88] reported that size of the particles formed depended on the initial size of the emulsion droplets.

It is desirable to use good film forming polymers for the emulsion–evaporation process [88]. For example, Eudragit® RL, Eudragit® RS, ethyl cellulose, PMMA, and cellulose acetate butyrate polymers formed nanoparticles by this method [89]. Biodegradable poly(β-hydroxybutyrate) has been used to prepare nanospheres by this process [90, 91]. Particle sizes from 170 to 220 nm were obtained using high pressure emulsification with Brij® surfactants [90].

The successful entrapment of drugs by this preparation procedure involves minimizing the loss of drug to the aqueous continuous phase. Various strategies employed include the use of drugs with low water solubility in the continuous aqueous phase, a high concentration of polymer in the organic phase, and a fast precipitation rate of the polymer in the continuous aqueous phase [92, 93]. By pH adjustment of the continuous aqueous phase, the loss of ionizable drugs, such as quinidine, can be reduced [94]. The emulsion–evaporation method is most suited to the encapsulation of lipophilic drugs, such as hydrocortisone, progesterone, diazepam, and indomethacin [84, 94].

Adding water miscible solvents to the organic phase enhanced the encapsulation of water-soluble drugs due to rapid polymer precipitation in the aqueous phase [93, 95]. Bodmeier and McGinity [93] investigated using co-solvents

such as acetone, ethyl acetate, methanol, and dimethyl-sulphoxide (DMSO) with PLA to increase quinidine loadings. Niwa et al. [95] produced nanospheres of PLA and PLGA enhancing peptide encapsulation by incorporating acetone with DCM. Organic phases have been employed to improve the encapsulation of water-soluble drugs by the emulsion–evaporation method. Tsai et al. [96] first reported using light mineral oil as the continuous phase with Span 65 as the surfactant, but microspheres were produced. This was also reported by other authors [38, 97, 98].

3.2.2. Salting Out Technique

The salting out technique was first proposed by Bindschaedler et al. [99] This preparation method involves adding a water-soluble polymer, such as poly(vinylalcohol) (PVA), to a concentrated solution of an electrolyte or non-electrolyte forming a viscous gel. This is emulsified in a water-miscible solvent, such as acetone containing the polymer and drug. The saturated aqueous phase prevented acetone from mixing with the water by a salting out process. On further addition of the gel to the organic phase, an oil-in-water emulsion is formed. Sufficient water is then added to allow complete diffusion of the acetone into the aqueous continuous phase, thereby forming nanospheres [100, 101]. Typically, magnesium chloride and magnesium stearate are used as salting out agents. This method avoids the use of surfactants and chlorinated solvents, which offers distinct advantages over the emulsion–evaporation method. However, the hydrocolloidal PVA is employed as a viscosity increasing agent and stabilizing agent. The PVA, electrolyte, and acetone were removed from the nanospheres by cross flow filtration, as described by Allémann et al. [101].

The preparation conditions of the salting out technique could be altered to produce nanospheres of monomodal distributions with particle sizes in the range 170 to 900 nm using Eudragit® S as polymer [102]. The conditions investigated include homogenization, stirring rate, internal/external phase ratio, viscosity of the external phase, concentration of polymer in the organic phase, type of salting out agent, and concentration and type of stabilizing agent in the aqueous phase. The size of the droplets in the emulsion determined the size of the final particles [102]. Leroux et al. [103] prepared PLA particles of 70 nm using benzyl alcohol and high PVA concentrations.

Different polymers have been used to produce nanoparticles by the salting out process, such as Eudragit® S, Eudragit® E, poly(DL-lactic acid), polycaprolactone, ethyl cellulose, cellulose acetate and cellulose acetate butyrate [99, 100, 102, 103]. Other salting out agents, such as sucrose, and solvents, such as THF, ethyl acetate, and isopropyl alcohol, also produced nanoparticles [102]. The salting out technique was found to entrap lipophilic drugs successfully, such as savoxepine and chlorambucil, due to the continuous aqueous phase used [35, 103, 104]. Leroux et al. [103] commented on the pharmaceutical acceptability of the salting out process as the use of acetone and large amounts of salt may pose problems concerning salt recycling and compatibility with some drug substances. These authors used benzyl alcohol as the organic solvent and low amounts of salt and gelatin as the stabilizing hydrocolloid to improve the pharmaceutical acceptability.

3.2.3. Emulsion–Diffusion

This procedure is also referred to as the precipitation method and was first reported by Fessi et al. [105]. In this type of preparation, as shown in Figure 7, the polymer is dissolved in a water-miscible solvent and then poured under stirring into a nonsolvent, which is usually water. This leads to the polymer precipitating as nanospheres. Prior emulsification and inclusion of surfactants are not necessary.

The proposed mechanism for formation of nanospheres by this technique is by a diffusion and stranding mechanism, as illustrated in Figure 10 (Section 4.2) [106]. Polymer globules are formed as the polymer solution is added to the aqueous phase. As the solvent diffuses into the water from the polymer globule, the polymer precipitates out of solution and is stranded in the water in the form of fine emulsion droplets or "protonanoparticles." Complete diffusion of solvent from these protonanoparticles will provoke polymer solidification in the form of nanospheres of about 200 nm in diameter. Turbidity measurements are consistent with this mechanism [106]. In summary, the diffusion of the solvent causes regions of supersaturation from which nanoparticles are formed, due to phase transformation in these regions. The size of the resulting particles is dependent on this process.

This precipitation procedure has been successfully applied to a wide variety of polymers such as poly(lactide), poly-(lactide-co-glycolide), poly-(ε-caprolactone), ethylcellulose, poly(alkylcyanoacrylate), and poly(styrene) [107]. More recent biodegradable polyesters, called poly(β-malic acid-co-benzyl malate) copolymers, have formed nanospheres of 200 nm in diameter by the precipitation method [108, 109]. Solvent/nonsolvent mixtures that have been used include ethanol/water, acetone/water, and propylene carbonate/water [110]. Murakawi et al. [19] employed solvent mixtures, such as ethanol/acetone and methanol/acetone, providing high yields of PLGA nanometer sized particles with less aggregation. This preparation method is best suited to the encapsulation of lipophilic drugs as an aqueous continuous phase is used [111]. The lipophilic drugs are usually dissolved in with the polymer-rich phase. High encapsulation was reported for peptides, such as TRH and elcatonin, with this method [112].
Figure 7. Preparation procedure for precipitating technique. Shown also is the schematic illustration of the diffusion stranding mechanism for nanosphere formation that occurs during the precipitation method.

A major advantage of this procedure is that a surfactant is not required. This avoids its removal by purification procedures. However, poly(vinyl alcohol) has been used as a stabilizer in some instances and was found to adsorb strongly, resisting washing procedures [19, 106]. Without surfactant, nanoparticle formation and stability are dependent on the initial polymer concentration, the volume ratio of the solvent to nonsolvent, and the dielectric constant of the final mixture [111]. Ternary phase diagrams have been constructed to find the optimal region of nanoparticle formation [110, 111]. Another advantage of this procedure from an industrial point of view is that high-pressure homogenizers and ultrasonication are not required as spontaneous emulsification occurs [106].

3.2.4. Coacervation

Coacervation is a phase separation technique. It was first introduced by Bungenberg de Jong and Kruyt [113] who described a process in which aqueous colloidal solutions are separated into two liquid phases, a colloid-rich phase or coacervate and a colloid-poor phase. Many synthetic polymers are water-insoluble and consequently, nonaqueous coacervation systems have been employed. Coacervation usually consists of binary and ternary systems [114, 115]. Binary systems consist of one polymer dissolved in a solvent and ternary systems of either a single polymer in a binary solvent mixture or two polymers in a single solvent. For binary systems, phase separation can occur by changing the temperature or pH or by the addition of electrolytes, such as sodium sulphate, to gelatin [116]. For ternary systems, phase separation can be induced by adding a nonsolvent for a single polymer system or by adding a polymer incompatible with the second polymer for a two polymer system [117]. Solidification of the particles produced by coacervation can be effected by temperature, chemical cross-linking, adjustment of pH, or rinsing with a nonsolvent for the polymer.

The coacervation process is controlled by the interactions between polymer/solvent/nonsolvent. The formation of stable coacervates is influenced by the polymer type, molecular weight, and hydrophobicity and by the amount and viscosity of the added coacervating agent [118, 119]. By careful adjustment of these parameters, optimum coacervation conditions can be achieved by the use of phase diagrams. The classical coacervation method for nonaqueous systems has been modified to produce nanoparticles by using an emulsion-phase separation method in an oil system [120]. An aqueous solution of the drug, a peptide in this instance, was emulsified in a DCM–acetone mixture containing the dissolved PLGA using homogenization [112, 120]. Triester oil (caprylate and caprate triglyceride) was added gradually, inducing phase separation of the PLGA at the interface between the aqueous and oily phase. The aqueous droplets are covered with the coacervate droplets of PLGA and the evaporation of the organic solvent reduces the solubility of the PLGA and deposits it around the aqueous droplets containing the drug. This mechanism is illustrated in Figure 8.

Nanoparticles encapsulating 5-flurouracil were prepared by coacervation using cellulose derivatives [121]. An ethanolic solution of ethyl cellulose was desolvated by stirring in distilled water producing particles with an average diameter of 472 nm, as determined using scanning electron
Figure 8. Preparation mechanisms of PLGA nanospheres by the emulsion-phase separation method in an oil system.

microscopy (SEM). Nanospheres of methyl cellulose were prepared by desolvating an aqueous solution of the polymer with sodium sulphate solution [121]. An average particle size of 540 nm was obtained.

The main drawback to coacervation is the toxicological implication of residual solvents, coacervating agents, and hardening agents left in the particles. More biocompatible coacervating and hardening agents are being investigated along with approaches to minimize solvent residues [114]. The triester oil used in the coacervation of PLGA by Niwa et al. [120] is nontoxic and biocompatible and an alternative to silicone oil usually used in the coacervation of PLGA. Biocompatible hardening agents suggested include fatty acid esters, such as isopropyl myristate for PLGA [114]. For low molecular weight polymers, drying near the glass transition temperature of the polymer was found to be effective in lowering DCM content [114].

3.3. Nanoparticle Production Using Supercritical Fluids

Supercritical fluids are defined as those substances whose temperature and pressure have been raised above the point where the densities of the liquid and gaseous states are the same. When substances exist in a supercritical state, they can be used as solvents or antisolvents and, hence, used in the production of particulates in a similar manner to other solvent systems. The use supercritical fluids has increased significantly over the last few years, with many drugs either being encapsulated within, or being formed into, nanoparticles using this technique [122–125]. However, there are a number of advantages to using supercritical fluids over conventional solvent systems. Production is usually a one-step process, with little polydispersity in particle size and, perhaps, most importantly, much less organic solvent is used, with carbon dioxide being the most frequently used supercritical fluid. This is obviously of significance environmentally, especially if production is on the commercial scale.

A number of techniques are based on supercritical fluid technology. Three are of particular pharmaceutical interest, namely the supercritical antisolvent (SAS) system, the rapid expansion of supercritical solution (RESS) method, and the gas antisolvent (GAS) technique [126].

The SAS method involves the introduction of the supercritical fluid into a solution of solute in an organic solvent.

At high pressures, the fluid acts as an antisolvent, becoming soluble enough in the organic solvent to precipitate out the solute. At the final operating pressure, the supercritical fluid flows through the precipitation vessel stripping away any residual organic solvent. Finally, the vessel is depressurized and the solid product is collected. The GAS technique is a modified version of this method, with the organic solution being rapidly introduced into the supercritical fluid through a fine nozzle [127, 128]. The solution is quickly extracted into the fluid, resulting in instantaneous precipitation of the solute as fine particles.

In the RESS method, the solute of interest is solubilized in a supercritical fluid, which is then rapidly expanded through a nozzle. As the fluid expands, it loses its solvent capabilities and the solute precipitates out. While this technique has the advantage of not using any organic solvent, it is restricted by the generally poor solubility of most polymers in supercritical fluids. Indeed, polymers generally have to be below 10,000 MW in order to be eligible for this method of particle production [126].

4. CHARACTERIZATION

The physicochemical characterization of a colloidal carrier is necessary because important characteristics, such as particle size, hydrophobicity, and surface charge, determine the biodistribution after administration [129–132]. Preparation conditions, such as the pH of the polymerization medium, monomer concentration, and surfactant concentration, can influence the physicochemical characteristics of the particles [60, 62, 64]. It is, therefore, essential to perform a comprehensive physicochemical characterization of nanoparticles, which has been reviewed by Magenheim and Benita [133].

4.1. Particle Size

Clearly, the definitive characteristic of any nanoparticulate drug delivery system will be its submicrometer diameter. Sizing such particles in the suboptical region can be difficult as the measuring technique itself may alter size and properties by either hydrating or aggregating the particles. This will have a profound influence on the size of the particle [59]. Haskell [134] has discussed the various optical techniques available to measure the size of nanoparticles.

Photon correlation spectroscopy (PCS) has been used extensively for the sizing of submicrometer particles and is now the accepted technique in most sizing determinations. PCS is based on the Brownian motion that colloidal particles undergo, where they are in constant, random motion due to the bombardment of solvent (or gas) molecules surrounding them. The time dependence of the fluctuations in intensity of scattered light from particles undergoing Brownian motion is a function of the size of the particles. Smaller particles move more rapidly than larger ones and the amount of movement is defined by the diffusion coefficient or translational diffusion coefficient, which can be related to size by the Stokes–Einstein equation, as described by

$$d(H) = \frac{kT}{3\pi\eta D} \qquad (1)$$

where D is the diffusion coefficient, k is the Boltzmann's constant, T is the absolute temperature, η is the viscosity, and $d(H)$ is the hydrodynamic diameter. The hydrodynamic diameter, or Stokes diameter, measures how a particle moves within a fluid. To obtain mass or volume diameters, the full Mie theory should be used, which requires knowledge of the refractive indices of the particulate material and sizing medium. The upper limit of size for PCS is determined by the density of the particle and, most importantly, its onset of sedimentation, rather than limitations on the technique itself.

PCS is a rapid, nondestructive technique which enables the measurement of many types of spherically shaped entities, including discrete living cells, without causing alteration or damage [133]. However, the use of PCS is not possible when the size distribution of the sample is broad, the sample material is nonspherical, and multimodal distributions are present. PCS is also susceptible to errors from the presence of larger particles, such as dust, microbial contamination, crystallization of ingredients, or secondary particle agglomerates. Larger particles scatter more light than smaller particles, as shown by the Rayleigh ratio, and thus will swamp the scattered light from smaller particles. Samples for PCS measurements must be clean and filtered to ensure removal of contaminating dust particles. Another disadvantage of this method is that the particle size is influenced by the surrounding medium, such as adsorbed surfactants or hydration layers.

PCS has been applied in nanoparticulate characterization to investigate the effect of altering preparation parameters on the particle size of various nanoparticulate carriers, such as poly(alkylcyanoacrylates) [55, 60, 61, 135]. The effect of the incorporation of drugs on nanoparticle size has also been investigated [136, 137]. PCS has been used to examine the degradation of PACA nanoparticles [138]. This technique has been useful in determining the influence on size of using different surfactants in the preparation process and also the thickness of the surfactant coating layer on the surface of the nanoparticle [139, 140].

Electron microscopy techniques, such as SEM and TEM, have been used to measure the particle size of nanoparticles. TEM has the additional advantage in that interior particle morphology can be determined by freeze fracturing [133]. TEM has been used to size poly(acrylic) acid and cellulose nanoparticles and it was shown that the sizes obtained were comparable to PCS [59, 121]. TEM has been used to optimize the preparation conditions of poly(methylmethacrylate) nanoparticles to obtain small particle sizes [141]. SEM requires the particles to be coated with gold to make them conductive. This coating varies in thickness from 30 to 60 nm and has to be subtracted in order to determine the size of the uncoated particles. On comparison to other sizing techniques, the particle sizes of poly(acrylic) acid nanoparticles by SEM were in good agreement [59]. Although electron microscopy allows the measurement of individual particles, this may be unrepresentative of the whole sample. The low vacuum used, gold coating, and any surfactants present may alter the particle size [59].

4.2. Surface Charge

Particles in a suspending medium carry a thin layer of ions and solvent around them, which will cause the particle to drift when placed in an electric field. The surface separating the stationary medium from the moving particle and its bound ions and solvent is called the surface of hydrodynamic shear [142]. The potential at this surface is called the zeta potential, as illustrated in Figure 9. This surface potential can originate from the dissociation of surface polymeric groups or preferential adsorption of ions or other ionic molecules from the aqueous suspending medium. The zeta potential of the particle is dependent on electrolyte concentration and pH of the suspending particle medium [142, 143].

The zeta potential can be measured by electrophoresis, which determines the velocity of particles in an electric field of known strength [144]. This particle velocity, v, can then be related to the electrical field strength, E, as the electrophoretic mobility, μ. This is shown by

$$\mu = \frac{v}{E} \qquad (2)$$

The electrophoretic mobility, μ, can be converted to a zeta potential by using the Smoluchowski equation,

$$Z_p = \frac{\mu 4 \pi \eta}{\varepsilon} \qquad (3)$$

where Z_p is the zeta potential (mV), μ is the electrophoretic mobility [(cm/s)/(Volt/cm)], η is the dynamic viscosity of the dispersion medium (poise), and ε is the dielectric constant.

Electrophoretic mobility measurements can be performed by laser Doppler anemometry (LDA). LDA is fast and capable of high resolution of particle velocities [144]. It measures particle velocity, which is measured in the stationary layer, where the particles are moving solely with a velocity due to their charge [142]. This stationary layer is defined by the crossing of two laser beams, as illustrated in Figure 10. Interference fringes are produced by the crossing of the two beams. Particles inside the scattering volume interact with these fringes to produce scattered light, which is detected by the photomultiplier tube. The frequency of the scattered light by the particles differs from the frequency of the incident laser beam. This shift in frequency is caused by the Doppler effect and is a function of the particle velocity [142].
Zeta potential measurements have been used to determine the stability of particle suspensions. Particles with large negative or positive zeta potentials (+30 and −30 mV) will form stable colloidal suspensions as they tend to repel each other and reduce aggregation [143, 145]. Zeta potential measurements have been used to estimate particle opsonization, a process whereby specific proteins in blood plasma adsorb to the particle surface. It is relevant to this discussion as such proteins make the particle more susceptible to phagocytosis and subsequent unwanted removal by the body. High negative zeta potential values in the presence of serum are indicative of particles that have become highly opsonized [10] and may indicate a poor formulation. Zeta potential measurements have also been applied to investigate drug/polymer association. Alonso et al. [67] found the negative charge of poly(alkylcyanoacrylate) nanoparticles was neutralized by the adsorption of the polar drug, amikacin sulphate, indicating an electrostatic association.

An alternative technique to LDA for zeta potential measurement using Bragg cells is amplitude weighted phase structuration (AWPS). It is a laser light scattering technique allowing the simultaneous determination of particle size and zeta potential [142]. The major difference between AWPS and LDA is in the theoretical treatment and signal processing. A major advantage of this technique over LDA is the ability to measure at low field strengths, which can be important for sensitive biological samples [144].

4.3. Surface Hydrophobicity

Surface hydrophobicity can be evaluated using several techniques. One method involves determining the contact angle of a polymer film that is representative of the surface of the particle. This is performed by removing all the water from nanoparticulate suspension, dissolving in a suitable solvent, and casting as a film on a microscope slide [59]. The contact angles can then be determined by a goniometer. The contact angles increase with increasing hydrophobicity.

Figure 9. Formation of Stern plane and diffuse layer on particle surface (Ψ_O = surface or Nernst potential, Ψ_i = potential of inner Helmholtz plane, Ψ_δ = Stern potential, ζ = thickness of Stern plane, ZP = zeta potential at surface of shear, d = distance from particle surface).
Figure 10. Optical setup for LDA, consisting of a laser beam being split and focused by a lens through a suspension of particles in a sample cell. Scattered light is focused through a pinhole and detected by a photomultiplier tube.

This method has been used to determine the hydrophobicity of poly(methylmethacrylate) nanoparticles and acrylic acid copolymer nanoparticles [146–148].

An alternative procedure is the adsorption of the hydrophobic dye Rose Bengal [144]. This particular dye shows different degrees of affinity for the particle surface depending on the surface hydrophobicity. After incubating the particles in Rose Bengal, the dye undergoes partitioning between the surface of the particles and the dispersion medium and is determined by spectroscopic measurements at 542.7 nm [142]. This enables the partition quotient of Rose Bengal for the particles to be calculated and plotted against the surface area of the particles. The slope of this plot is a measure of hydrophobicity, with a steep gradient indicating high hydrophobicity. This approach was used by Lukowski et al. [147] to investigate the decrease in hydrophobicity on increasing the acrylic acid content of acrylic acid copolymer nanoparticles.

Hydrophobic interaction chromatography (HIC) is a column chromatography technique which can determine particle hydrophobicity by interaction with a hydrophobic gel matrix [142, 149, 150]. Hydrophilic particles pass through the column without interaction, whereas particles with increased hydrophobicity show a retarded elution and are retained by the column. Hydrophobicity measurements are used to determine the hydrophobicity of nanoparticulate carriers and correlate this to their *in vivo* biodistribution [10, 149].

The components of the HIC apparatus are essentially similar to those found on basic high performance liquid chromatographic systems and consist of a column, pump, and ultraviolet spectrophotometer. Particles are detected by a reduction in optical density at 400 nm. A miniaturized version of HIC with a 1 ml bed volume has been developed to establish a rapid and less costly screening method [151]. Alkyl agarose gels are used as the column packing and their hydrophobicity increases with alkyl-chain length. Phosphate buffered saline is usually used as the elution medium. The chromatograms obtained are analyzed with regard to the elution volume and the area under the elution peak, which enables quantitation.

HIC enables the particles to be determined in their original suspending medium preserving their true surface properties. Contact angle and Rose Bengal partitioning require removal of the particles from their dispersion medium, which could result in a modification of the surface properties. These two methods only determine an average value for hydrophobicity and are unable to detect subpopulations differing in surface hydrophobicity. The detection of subpopulations is possible with HIC, which also allows the polydispersity in surface properties to be determined.

4.4. Molecular Weight Characterization

The determination of the molecular weight of nanoparticles is performed by gel permeation chromatography (GPC). The experimental setup consists of a high performance liquid chromatography system with a size exclusion column and a refractive index detector. The nanoparticles are usually freeze-dried and dissolved in tetrahydrofuran for analysis on the system. Poly(styrene) or poly(methylmethacrylate) standards are used to calibrate the column, to enable the determination of number average molecular weight (M_n), as in

Eq. (4), and the weight average molecular weight (M_w), as in Eq. (5),

$$\bar{M}_n = \frac{\sum Q_i}{\sum (Q_i/M_i)} \tag{4}$$

$$\bar{M}_w = \frac{\sum ((Q_i \cdot M_i))}{\sum Q_i} \tag{5}$$

where Q_i represents the amount of polymer having a molecular weight M_i. The polymer molecular weight distribution can be estimated by calculating $\bar{M}_w/\bar{M}_n$.

Molecular weight determinations have been used to elucidate the polymerization mechanism of polymers [152, 153]. Poly(butylcyanoacrylate) (PBCA) polymers were reported to be made up of numerous oligomeric subunits rather than one or a few polymer chains due to rapid termination at the low pH values required for preparation [153]. The pH and monomer and surfactant concentrations were found to influence the resulting molecular weight of the PBCA nanoparticles produced [153, 154]. Interaction between the drug and polymer could be detected by molecular weight measurements [60, 137, 155]. The biodegradation of nanoparticles can be monitored by molecular weight measurements and the mechanism of degradation can also be elucidated [156–158].

It is not possible to determine the molecular weight of highly cross-linked polymers and natural polymers by GPC as they do not dissolve in tetrahydrafuran. Accurate results for molecular weight can only be obtained if the polymer standards used have similar properties to the polymer employed to prepare the nanoparticles. In most cases, this similarity is absent.

4.5. Microscopic Characterization

The two main techniques used to characterize nanoparticles by microscopy are scanning electron microscopy and transmission electron microscopy. SEM has been used to determine particle size, morphology, surface roughness, and porosity of nanoparticles made from various materials [27, 33, 159, 160]. SEM can also provide information on the behavior of adsorbed drugs [161]. Aprahamian et al. [162] characterized lipiodol nanocapsules by the X-ray emission of iodine using SEM fitted with an energy-dispersive X-ray spectrometer. The preparation of samples for SEM involves drying a portion of the particle suspension at room temperature and then coating it with a thin metallic film, such as gold, which is usually 30–60 nm in thickness [59]. A 10 nm layer was obtained by spraying the nanoparticle suspension onto an aluminum foil with the aid of an atomizer [85]. Samples for SEM analysis must be capable of withstanding a vacuum environment. This technique is limited for sizing due to the interference from surfactants in the nanoparticles, but their presence is necessary to prevent the particles from agglomerating [59].

TEM has been used to determine the shape and particle size of nanoparticles [27, 33]. Samples are prepared by placing a drop of preparation on copper grids, followed by negative staining with an aqueous solution of sodium phosphotungstate, phosphotungstic acid, or uranyl acetate [27, 163, 164]. Freeze fracturing with TEM has been

used to investigate the internal structure of nanoparticles and applied to samples which are not suitable for staining or which melt or sinter when irradiated by the electron beam. Nanospheres were shown to have a dense, solid internal matrix and nanocapsules a hollow internal structure [27]. The interior morphology and surface roughness have been characterized for various nanoparticulate carriers [33, 59, 165]. TEM has been used to establish the wall thickness of nanocapsules, which was found to be 3 nm for PBCA nanocapsules [135]. TEM is not useful for routine measurements as the sample preparation is time-consuming and laborious.

Other more advanced microscopic techniques have been developed, including near-field scanning optical microscopy [166] and scanning probe microscopy techniques, such as atomic force microscopy and scanning tunnelling microscopy [166, 167].

5. DRUG LOADING

Drugs may be incorporated into nanoparticles by addition to the polymerization medium or by adsorption to preformed particles [168]. Depending on the drug, polymer, and preparation method used, the drug can exist as:

- a solid solution of the drug in the particle,
- a solid dispersion of the drug in the polymer,
- surface adsorption of the drug,
- chemical binding of the drug to the polymer [169].

Determination of drug content in nanoparticles is mainly concerned with the effective separation of the free drug from the bound drug. Various techniques have been employed including:

- ultracentrifugation,
- ultrafiltration,
- gel filtration,
- dialysis.

The separation must be as rapid as possible to prevent desorption of drug from the particle [170].

Ultracentrifugation is the most extensively used separation technique, where the particle suspension is spun at high speeds, usually at 100,000 g for one hour [171–173]. The supernatant is carefully removed and analyzed for the amount of free drug present. This is subtracted from the total drug added to the system, to determine the amount of drug bound to the particles. However, the pellet itself can be analyzed directly to measure the amount of drug bound to the particles [174, 175]. Usually, both the supernatant and pellet are analyzed together [176–178]. The main disadvantage of this technique is that drug desorption and caking of the pellet can occur due to the long centrifugation times and large centrifugal forces required. Undissolved free drug in the form of nanocrystals may spin down with the sedimented pellet, leading to inaccurate determination of loading [133].

Reszka et al. [168] used ultrafiltration to separate free mitoxantrone from PBCA nanoparticles. The particle suspension was passed through a cellulose nitrate membrane with a pore size of 20 nm with magnetic stirring and pressurized nitrogen. The filtrate obtained was analyzed for free drug content. Recovery of the particles is not possible with this method and the particles themselves can clog the filter. Undissolved drug may be removed with the particulate carrier and it must be ensured that drug adsorption to the filter membrane does not occur.

Gel filtration employs a column containing a packing material, such as Sephadex® media, to separate free drug from the particles. The particles elute first in the void volume followed by the drug, which is retained on the column, thus enabling its separation. The eluted fractions are collected from the column and analyzed by ultraviolet/visible spectrophotometry. Beck et al. [170] used gel filtration with Sephadex® G50 packing to separate five model drugs from PBCA nanoparticles. This media was also used to separate free mitoxantrone and ampicillin from liposomes [168, 173]. This technique is rapid and does not alter the particle size, but desorption of the bound drug can occur. It can be scaled up and equipment costs are low [179].

Dialysis has been used by Labhasetwar and Dorle [180] to determine free drug concentration in particle suspensions. The suspension is placed in a dialysis bag and then positioned in an aqueous continuous phase until there is no change in drug concentration. The main disadvantages of dialysis are that the equilibration times are long, causing drug desorption. Large volumes of continuous phase are required and particle aggregation can occur [170, 181].

A potentially new separation method called field flow fractionation has been introduced only on a preliminary basis for the determination of adsorbed substances to particles [182]. A novel method was developed by Illum et al. [68] to determine both free and bound drug on PBCA nanoparticles without prior separation. For example, a bathochromic shift was observed in the ultraviolet/visible (UV/vis) spectrum of Rose Bengal after binding to PBCA nanoparticles. The amount of free drug was determined at 540 nm and bound drug at 548 nm. This type of analysis is very specific to the drug under investigation.

The end result of the separation techniques described is to calculate the particle drug loading. The drug loading usually expresses the bound drug as a percentage of the total drug content used in the preparation or as a percentage of the weight of the dried nanoparticles. The total drug content is usually taken as the amount of drug added to the preparation medium initially [66, 136], but errors may result if drug degradation occurs [183]. Alternatively, total drug content can be expressed by dissolving the whole nanoparticle suspension in a suitable solvent and analyzing both the free and bound drug contents [171, 184]. Total drug content used can also be calculated from the bound and free drug contents analyzed separately in the supernatant and pellet [137, 185]. The drug loading efficiency is a measure of the total amount of drug recovered on analyzing the particles compared to the total amount of drug added initially at the preparation stage.

Various analytical techniques have been employed to determine the drug content in nanoparticles after the separation procedures. High performance liquid chromatography and UV/vis spectroscopy are two of the most extensively used techniques [133]. Other techniques used include scintillation counting [186], spectrofluorodensitometry [176], microbiological assays [136], spectrofluorimetry [187], and polarization fluoroimmunanalysis [67].

6. INCORPORATION OF WATER-SOLUBLE DRUGS

When introducing a water-soluble drug into a nanoparticulate system, a number of factors must be considered. Different preparation methods will give rise to particles with a wide range of surface properties, sizes, and drug incorporations. Some methods may appear to offer the solution to a particular loading problem, but the efficiency of particle formation may be preclusive to their use. In our experience, there are a number of factors that can be optimized in terms of loading and particle manufacture, but unfortunately the level of optimization may not reach that which is deemed acceptable in a therapeutic context. Many of the problems encountered by those attempting to encapsulate a water-soluble drug have been experienced in our own work studying the incorporation of 5-fluorouracil. As such, it represents a good model drug for testing the incorporation efficiency of nanoparticle production methods.

Much information exists in the literature about the various payloads introduced into nanoparticles. The choice of pharmaceutically active compound that is incorporated is dictated by many considerations but is driven primarily by the potency of the drug, its route of administration, and the need to give the compound some protection against enzymatic degradation. It must be remembered that nanoparticles have a low capacity for carrying drugs and large doses cannot be administered by this means. As can be seen from Table 1, the range of drugs that have been incorporated is wide, with many of high potency and some requiring protection from proteolytic attack. Other applications exploit the unique properties of nanoparticles in enhancing drug delivery to the eye, with many examples to be found in the literature. This list is by no means absolute, with further work produced regularly using new drug payloads for novel applications.

7. INCORPORATION OF 5-FLUOROURACIL INTO NANOPARTICLES

5-Fluorouracil (5FU) is 5-fluoropyridrimidine-2,4(1*H*, 3*H*)-dione. Its structure is illustrated in Figure 11. The hydrogen in the naturally occurring pyrimidine, uracil, is substituted by fluorine in the 5 position. The presence of the heteroatoms in the structure imparts hydrophilicity to the compound as they are capable of hydrogen bonding.

The incorporation of 5FU into particulate carriers made from both natural and synthetic polymers has been reported extensively. The natural carriers investigated have included albumin [188], chitosan [189], casein [190], liposomes [191], and fibrinogen [192]. The drug-loaded particles are usually prepared by an emulsion-cross-linking procedure, which can be performed chemically or by heat. The loading of 5FU in albumin and chitosan particles by this procedure has been reported to be low [193, 194]. Nanospheres of chitosan loaded with 5FU derivatives were coated with anionic poly(saccharides) for targeting studies involving cell-specific recognition [189]. Methyl and ethyl cellulose nanospheres containing 5FU have been prepared by a desolvation technique with drug loading efficiencies of 45% for ethyl

Table 1. The diverse range of pharmaceutically active compounds that have been incorporated into nanoparticles or nanocapsules.

Active compound	Ref.
Peptides and proteins	
insulin	[207–219]
muramyl dipeptide	[220–222]
salmon calcitonin	[223–227]
chymotrypsin	[228–230]
Steroids	[231]
triamcinolone	[232]
hydrocortisone	[233, 234]
dexamethasone	[235, 236]
prednisolone	[237, 238]
progesterone	[233, 239, 240]
Nonsteroidal anti-inflammatory drugs	
indomethacin	[241–248]
diclofenac	[249–254]
Polysaccharides	[255–268]
Antibiotic drugs	[269–278]
Antisense	[24, 279–284]
Beta receptor blocking drugs	[285, 286]
timolol	[287]
carteolol	[288]
Anticonvulsant drugs	[289–293]
primidone	[294]
Cytotoxic drugs	
fluorouracil	[295–298]
cisplatin	[299–301]
doxorubicin	[302–310]
paclitaxel	[311–316]
methotrexate	[317, 318]
vinblastine	[319, 320]
Antiarrhythmic drugs	[321]
Miscellaneous	
chlorhexidine	[322, 323]
diazapam	[324–326]
cyclosporin	[327–334]
pilocarpine	[335–337]
primaquine	[338–340]

cellulose and 11.6% for methyl cellulose [121]. Synthetic carriers have also been used to incorporate 5FU, including PMMA [195], PLGA [196], PLA [197], PBCA [198], and poly(glutaraldehyde) (PGL) [50]. The most widely used carriers for 5FU are the PLA and PLGA polymers. An emulsion–evaporation preparation technique is frequently used to prepare the drug-loaded particles [196, 199]. Such a method loaded 5FU up to 30% w/w in PLGA particles with a diameter of 20–540 μm, which were implicated for the treatment of cerebral tumors by implantation [200].

$C_4H_3FN_2O_2$

Molecular Weight = 130.1

CAS- 51-21-8
Figure 11. Chemical structure of 5FU.

Nanospheres of PLGA were prepared by emulsion–evaporation by employing homogenization and a solvent system consisting of acetone in which both the drug and polymer were dissolved [95]. The encapsulation of 5FU in these nanospheres was low compared to the more hydrophobic drug, indomethacin. It was reported that the hydrophilic 5FU leaked to the aqueous phase. PGL nanoparticles were prepared by aldol condensation loading 5FU with an efficiency of 14.32% [50].

The process of loading 5FU into a nanoparticulate system proves to be far from simple and is representative of other water-soluble drugs. The methods used to encapsulate drugs tend toward low drug loading encapsulation efficiency by the nature of the solvent systems used. Our work focused on the use of the emulsion–polymerization scheme with a continuous aqueous phase. In order to assess the most suitable parameters for particle formation, response surface methodology was used. Three variables were analyzed—surfactant concentration, pH of the polymerization medium, and monomer concentration. By varying these parameters and then analyzing the resultant particles produced, it was possible to predict the set of conditions which would lead to the formation of an optimized nanoparticulate system. Using this methodology enabled the production of particles that could be tailored to meet specific requirements, such as a certain diameter with a low polydispersity, and so on. When the optimum conditions were known, work involving the encapsulation of 5FU could proceed.

Preliminary results using the optimized system from the response surface model proved disappointing. Particle loadings were below 1% and this value was even lower when a washing step was introduced. In fact, around 90% of the drug which was "encapsulated" was removed upon the washing of the particles, indicating a large surface bound fraction, which was freely soluble in the wash. A number of strategies were used in order to raise the loading efficiency of the system. Various surfactants were tried to assess whether there was an advantage in the use of one over another with respect to drug loading. Indeed, there is evidence that the type of surfactant used can influence drug loadings of nanoparticles [62]. Sodium lauryl sulphate was found to be effective in increasing the loading of the polar drug, amikacin sulphate, in PBCA nanoparticles [67], with the percentage drug loading efficiency increasing from 4.76% to 60.47%. It was reported that this surfactant reduced the aqueous solubility of the drug, thereby improving its incorporation into nanoparticles. These authors also reported that poloxamer 188 (Pluronic F68) appeared to hinder the drug–polymer interaction for the sorption of amikacin sulphate onto freeze-dried PBCA nanoparticles. Similar results were also obtained by Harmia et al. [201]. The most appropriate surfactant depends on the drug under investigation. Surfactants can further affect the molecular weight and size of the drug-loaded particles obtained as well as the drug release [62, 202]. However, in our work, despite definite advantages being seen in the use of particular surfactants, the loading could not be increased significantly solely by their careful selection.

Alterations to the concentration of 5FU, surfactant concentration, pH, and monomer concentration were also made to effect an increase in the loading. However, in each case the changing of the preparatory conditions made little impact upon the loading of the particles. It was found that changes could lead to various particle size differences and zeta potential changes, but any variation in loading was in the manner of 1–2%. It was clear that the absence of any dynamic for the water-soluble drug to move into the monomer-rich micelles during particle formation was fundamental to the lack of success in the incorporation of 5FU. Hence, other methods of particle formation were employed, including an oil-in-oil emulsion/solvent diffusion method. It was reasoned that if all sources of water could be eliminated from the manufacturing process, there was a much greater likelihood of achieving significant incorporation into the nanoparticles.

8. DRUG RELEASE

Drug release can be defined as the fraction of drug released from the nanoparticulate system as a function of time after the system has been administered [203]. The release of drug from nanoparticles depends on the location and physical state of the drug loaded into the colloidal carrier [133]. The drug can be released by:

- desorption of surface-bound drug,
- diffusion through the nanoparticulate matrix,
- diffusion through the polymer wall of nanocapsules,
- nanoparticle matrix erosion,
- a combined erosion diffusion process [169].

Measurement of true release profiles requires good sink or infinite dilution conditions so that the drug has the greatest opportunity to be released [204]. Therefore, the release must occur into a large volume of sink or continuous phase. However, as the sink volume is increased the concentration of drug being measured decreases. As a compromise, it is recommended that the drug concentration in the continuous phase be kept below 10% of saturation [203]. Good sink conditions are required to avoid errors from the readsorption of the drug to the carrier and saturating the sink with drug, especially if it is poorly water-soluble. Two techniques have been employed to determine drug release from nanoparticulate carriers, which include membrane diffusion techniques and the sample and separate techniques. Drug release from submicrometer carriers has been reviewed by Washington [203] and Magenheim and Benita [133].

8.1. Membrane Diffusion Techniques

A volume of the particle suspension is placed in a dialysis bag, which is sealed and placed into the continuous sink phase, which is usually phosphate buffered saline. The entire system is kept at 37 °C with continuous magnetic stirring of the sink [203]. The drug in the particles diffuses into the aqueous phase in the dialysis bag with a rate constant, k_i. This drug concentration in the dialysis bag diffuses through the dialysis membrane to the sink phase with rate constant k_m. The drug concentration in the sink is periodically assayed to determine the amount of drug released. The main disadvantage of this method is that the release of drug from particles in the dialysis bag is driven by the partitioning of the drug between the particle and its continuous phase in

the dialysis bag [204]. The release is determined by K_p, the partition coefficient, and is independent of k_i. This reduces the amount of drug available for release through the dialysis membrane and k_m becomes the rate-limiting step in the release. In contrast, the diffusion of free drug across the membrane is rapid, as the release is driven by the drug's concentration gradient as all the drug is available for release [204]. The rate constant, k_m, is fast in this instance. Another disadvantage is that the membrane diffusion experiment is not performed under sink conditions. This is because the particulate sample itself is never diluted in the sink, since it is separated from it by the dialysis membrane. Therefore, the membrane diffusion technique is not a measure of the true release rate and has been found limited for the prediction of release from nanoparticles *in vivo* [205]. The technique is less prone to error where dissolution or disintegration of the carrier occurs [203]. However, the technique has been extensively used to determine release from nanoparticulate carriers *in vitro* for many different carriers, including liposomes and emulsions [159, 160, 206].

9. CONCLUSIONS

Nanoparticles represent a unique drug delivery system due to their small size, which allows them to pass through the narrowest components of the circulatory system. They also represent a generic system that has the potential for adaptation so that they can be tailor-made to specific applications. Because of this, more sophisticated drug delivery is possible, based on active targeting methods, allowing localization to sites that can be accessed from the circulation. An attached monoclonal antibody can be used to recognize an exposed antigen and so effect attachment. Consequent drug release will be concentrated around the target cells and will increase the probability that drug will diffuse into the cell of choice and not into those that do not require drug administration.

Incorporating water-soluble drugs has proved to be problematic. However, much work is underway to develop methods to achieve loadings in the particle that can be used in clinical problems. Development of particles with targeting capabilities has been less successful and more investigations are awaited, although one potential opportunity remains to be exploited and involves the integration of technology, more commonly seen in solid state-based electronic technology, with the design of particles described herein. Whether a particle can be controlled by onboard processing capabilities remains a debatable possibility, but an exciting one with no shortage of potential clinical applications.

GLOSSARY

Coacervation The separation of two liquid phases in colloidal systems.

Liposome A spherical capsule consisting of a liquid core surrounded by a lipid bilayer.

Nanocapsule A spherical particle of submicrometer diameter consisting of an outer polymeric wall which encapsulates an inner core.

Nanoparticle Any solid particle ranging in size from 10 to 1000 nm.

Nanosphere A spherical particle of submicrometer diameter consisting of a solid monolithic polymer matrix with no discernable core.

Photon correlation spectroscopy A technique for measuring the size of submicrometer particles by analyzing their size-dependent scattering of laser light.

Supercritical fluid A substance whose temperature and pressure has been raised beyond the point where its gaseous and liquid states have equal density.

Tyndall effect The scattering of light as it passes through colloidal suspensions.

Ultracentrifugation The centrifugation of samples at very high speeds.

Zeta potential The potential existing between the suspending medium and the effective electrical surface of a particle.

CONTENTS

1. INTRODUCTION

The mechanical properties of bulk materials are known to change with grain refinement. Extreme changes are expected when the average grain size is of the order of 100 nm or less. At the time when nanostructured materials (often defined as polycrystals with the average grain size of less than 100 nm) are becoming a major focus of materials research, the attention of researchers is turning more and more to their mechanical performance. Mechanical properties of nanostructured materials were recently reviewed by D. G. Morris [1]. His report provided an analysis of experimental literature and a comprehensive overview of the relevant deformation mechanisms. Still, the mechanical behavior of nanocrystalline materials remains a controversial issue and the roles of the different deformation mechanisms, such as dislocation glide and grain boundary processes, are not fully understood. Most recent molecular dynamics simulations [2] suggest that mechanical twinning may also play an important part in the plasticity of nanocrystalline materials, thus adding to the complexity of the emerging picture of the operating deformation mechanisms.

Grain boundary sliding is often considered a deformation mechanism in nanostructured materials that permits a high level of strain before failure and may be responsible for superplastic forming (see [1] and references therein). Yamakov et al. [3] observed grain boundary sliding in their molecular dynamic simulations. As this mechanism would require grain boundary diffusion as an accommodation mechanism, it is claimed that grain boundary diffusion and grain boundary sliding "are closely connected and, perhaps, represent one and the same deformation mechanism"—a view the present authors subscribe to.

In this chapter, we give an account of the mechanical properties of ultra-fine grained materials from our current viewpoint. It is based on recent modeling that appears to provide a conclusive description of the phenomenology and mechanisms underlying the mechanical properties of nanostructured materials. Common to the proposed models is the concept of a "phase mixture" in which the grain boundaries are treated as a separate phase. The volume fraction of this "phase" may be quite appreciable in a nanostructured material. The issues covered include strength, ductility, and the elastic properties of single-phase materials as well as the elastic properties of nanocomposites.

Experimental data on the mechanical properties of nanocrystalline metallic materials are appearing in literature at an ever-increasing rate. However, the range of data is still somewhat limited, except in the case of copper, where an extensive experimental database already exists. The various published mechanical properties of nanocrystalline Cu are summarized in Table 1. The table highlights a fundamental difficulty associated with the interpretation of experimental measurements made on nanomaterials. Residual porosity is an omnipresent feature of specimens manufactured using common production techniques. Porosity influences the observed bulk mechanical properties and, in fact, may dominate the behavior. Care must therefore be taken when drawing conclusions based on the bulk behavior. However, as will be seen later, porosity may be included in the phase mixture model to permit the effects of pores to be isolated from the grain size effects.

2. PHASE MIXTURE MODEL FOR PLASTICITY OF NANOCRYSTALLINE MATERIALS

It is generally believed that grain refinement leads to enhancement of strength of metallic materials. Indeed, the classical Hall–Petch relation predicts an inverse square root dependence of the yield strength on the average grain size. However, it is clear that there must be a limit to an increase of strength with decreasing grain size. Grain refinement will reduce the characteristic length for vacancy diffusion. Mass transport by diffusion across the grains and along grain boundaries therefore becomes more significant and may eventually prevail over dislocation glide-controlled plastic flow. In addition, the very mechanism of dislocation glide may become inoperative when the grain size drops below a certain critical level, perhaps around 10 nm [4], when dislocation sources in the grain interior or in grain boundaries cannot be activated. The rate of plastic flow will then be controlled by vacancy diffusion through the bulk (the Nabarro–Herring mechanism) or along grain boundaries (the Coble

mechanism). In both cases, the plastic strain rate is proportional to stress and inversely proportional to the average grain size, d, raised to the power n, where $n = 2$ for the Nabarro–Herring mechanism and $n = 3$ for the Coble mechanism [5]. Hence, for a fixed strain rate, the stress turns out to increase with the average grain size as d^2 or d^3, respectively. There is evidence in literature [6–7] that a pronounced departure from, or even inversion of the Hall–Petch behavior, is observed for nanostructured materials. Unfortunately, the picture is clouded by the inevitable presence of porosity, as fully dense specimens of very fine-grained materials are difficult to prepare. In such cases, mathematical modelling offers a unique opportunity to provide further insight into the behavior of such materials.

Ductility usually decreases with increase of strength, but expectations have been expressed in literature [8] that for the grain size in the submicrometer range, enhancement of strength without loss, or even with an increase, of ductility can be achieved. Such expectations were raised [9], particularly with regard to materials that have undergone severe plastic deformation, for example, by equal-channel angular pressing.

The challenge in modelling the effects of ultra-fine grained structures is not only to capture the relevant physical phenomena, including dislocation glide and diffusion mechanisms, but also to correctly represent their relative contributions to the mechanical behavior of the material. In modelling the behavior of actual test specimens, porosity or other embedded flaws may represent an important component of the model.

A constitutive model has been proposed that provides an adequate description of the grain size dependence of strain hardening in a broad range of grain sizes, down to the nanometer scale [10–12]. A distinctive feature of the model is that grain boundaries are treated as a distinct separate phase [4, 13], which is assumed to deform by a diffusion mechanism [12]. The grain interiors are considered to represent another phase. This phase is assumed to deform by a combination of two mechanisms: dislocation glide and diffusion transport. A transition between the regimes where the different mechanisms prevail can therefore be incorporated.

Table 1. The mechanical properties of nanocrystalline copper.

Property	(Grain size, property value, density)	Ref.
Young's modulus E	(10 nm, 108 GPa, 97.6%), (16 nm, 113 GPa, 98.6%), (22 nm, 116 GPa, 98.9%), (100 μm, 131 GPa, 100%)	[21]
Ultimate tensile strength	(16 nm, 340 MPa, 98.6%), (26 nm, 425 MPa, 99%), (49 nm, 460 MPa, 99.1%), (110 nm, 415 MPa, 99.4%), (22 nm, 480 MPa, 98.8%), (20 μm, 290 MPa, 100%)	[21]
Tensile elongation	(16 nm, 2.4%, 98.6%), (26 nm, 1.8%, 99%), (49 nm, 1.6%, 99.1%), (110 nm, >8%, 99.4%), (22 nm, 1.6%, 98.8%), (20 μm, >8%, 100%)	[21]
	(15 nm, 1.52%), (20 nm, 0.79%), (25 nm, 6.3%), (50 nm, 2.2%), (61 nm, 2.2%)	[26]
	(209 nm, 10%), (206 nm, 17%)	[28]
	(29 nm, 0%), (32 nm, 2%), (31 nm, 7%), (41 nm, 5%), (58 nm, 5%), (175 nm, 5%)	[27]
	(26 nm, 0.7%), (39 nm, 0.3%), (49 nm, 1.2%), (110 nm, 10%), (20000 nm, 15%)	[18]
	(210 nm, 5%)	[29]
Micro-hardness	(34 nm, 797 MPa), (26 nm, 802 MPa), (25 nm, 779 MPa), (24 nm, 767 MPa), (22 nm, 752 MPa), (22 nm, 773 MPa), (18 nm, 696 MPa), (18 nm, 748 MPa), (18 nm, 769 MPa), (19 nm, 801 MPa), (21 nm, 822 MPa), (21 nm, 884 MPa), (18 nm, 889 MPa), (16 nm, 877 MPa), (16 nm, 854 MPa), (16 nm, 810 MPa), (16 nm, 812 MPa), (12 nm, 849 MPa), (11 nm, 773 MPa), (10 nm, 793 MPa), (10 nm, 828 MPa), (7 nm, 806 MPa)	[21]
	(7.8 nm, 144 MPa), (8.4 nm, 173 MPa), (14 nm, 207 MPa), (15 nm, 223 MPa)	[51]

Combined with a rule of mixtures, the constitutive equations for the mechanisms considered provide a simple description of the deformation behavior [10–12]. This model is illustrated by application to ultra-fine grained Cu—the material for which a most extensive experimental database is available.

The grain boundary phase is considered to deform by a vacancy diffusion mechanism [12]. The corresponding plastic strain rate is given by

$$\dot{\varepsilon}_{GB} = A \frac{\Omega \sigma_{GB}}{kT} \frac{D_{GB}}{d^2} \tag{1}$$

Here σ_{GB} is the stress acting in the grain boundary (GB) phase, Ω the atomic volume, T the absolute temperature, k the Boltzmann constant, D_{GB} the self-diffusion coefficient for grain boundary diffusion, and A is a numerical constant. This formula represents an interesting "hybrid" of the Nabarro–Herring and the Coble equations in that the grain size dependence is that of Nabarro–Herring, while the (grain boundary) diffusivity is that of the Coble mechanism. A similar relation was recently obtained through molecular dynamics simulations [3].

Plastic flow of the crystalline grain interiors is considered to be carried by two mechanisms that operate in parallel: the dislocation glide mechanism (contributing the plastic strain rate $\dot{\varepsilon}_{disl}$) and the diffusion-controlled mechanism. In principle, both bulk and grain boundary diffusion need to be considered. However, for most cases of interest in connection with ultra-fine grained materials, the bulk diffusion contribution can be neglected [10]. Accordingly, the plastic strain rate for the grain interior (GI) phase can be written as

$$\dot{\varepsilon}_{GI} = \dot{\varepsilon}_{disl}(\sigma_{GI}) + \dot{\varepsilon}_{Coble} \tag{2}$$

where

$$\dot{\varepsilon}_{Coble} = 14\pi \frac{\Omega \sigma_{GI}}{kT} \cdot \frac{w}{d} \cdot \frac{D_{GB}}{d^2} \tag{3}$$

Here σ_{GI} is the stress acting in the grain interior and w is the grain boundary width. We note that the latter contribution to the strain rate is similar to the expression for the plastic strain rate of the grain boundary phase, Eq. (1)—apart from the exponent in the grain size dependence.

The dislocation glide contribution to the plastic strain rate of the grain interior phase is described in terms of a model [14] based on the dislocation density evolution. The total dislocation density is considered to be an internal variable. The evolution of dislocation density is affected by the grain size through its influence on the dislocation mean free path. The relation between the plastic strain rate $\dot{\varepsilon}_{disl}$ and stress is given by

$$\dot{\varepsilon}_{disl} = \dot{\varepsilon}_o \left(\frac{\sigma_{GI}}{\sigma_o} \right)^{m_i} Z^{-m_i/2} \Theta(d - d_c) \tag{4}$$

where Z denotes the dislocation density normalized with respect to its initial value, and the parameters $\dot{\varepsilon}_o$, σ_o, and m_i can be considered constant for a given temperature. The values of these parameters for Cu are known [15]. The Heviside step-function $\Theta(d - d_c)$ expresses the fact that for d below some critical value, d_c, the dislocation mechanism becomes

inoperative and its contribution to plastic strain rate, $\dot{\varepsilon}_{disl}$, drops to zero. Following Wang et al. [4], the value of d_c for Cu was taken to be 8 nm.

The evolution equation for the dislocation density is

$$\frac{dZ}{dt} = \dot{\varepsilon}_{disl} \left[C + C_1 \sqrt{Z} - C_2 \left(\frac{\dot{\varepsilon}_{disl}}{\dot{\varepsilon}_o} \right)^{-1/n} Z \right] \tag{5}$$

Here t denotes the time, C, C_1, C_2, and $\dot{\varepsilon}_o$ are constants, while n is constant if the temperature is fixed. Grain size effects, which are of main concern here, enter through the term C, which is inversely proportional to d [14].

It is further assumed that the strain in both phases is the same (and equal to the macroscopic strain). Henceforth, the subscripts "GI" and "GB" in the respective strain rates will be dropped. The stress is determined using a rule of mixtures,

$$\sigma = f\sigma_{GB} + (1 - f)\sigma_{GI} \tag{6}$$

where f is the volume fraction of the grain boundary phase given by

$$1 - f = \left(1 - \frac{w}{d} \right)^3 \tag{7}$$

Equation (7) reflects the assumption of cube-shaped grains. A schematic illustrating the phase mixture model is shown in Figure 1.

The set of Eqs. (1–7) furnish a full constitutive description for a "single-phase" material, which, in fact, is treated at the microscopic level as consisting of two subphases. It has been applied to the case of Cu [10–12] for which the parameters pertaining to the dislocation mechanism and the grain boundary diffusion mechanism are known from previous work [5, 15–16]. As an example, the stress versus strain curves for tensile deformation with constant strain rate are presented in Figure 2. The curves show a good agreement with reported experimental data [17–18].

The dependence of the offset yield stress, $\sigma_{0.2}$, on the calculated grain size using this model is plotted in the "Hall–Petch" diagram of Figure 3. It is seen that a Hall–Petch-like behavior in the range of large grain sizes breaks down for d below about 50 nm, and an "inverse" Hall–Petch behavior
Figure 1. Schematic of two-phase model of grain deformation. The contribution of the Nabarro–Herring (N–H) creep mechanism in the grain interior becomes insignificant for very small grain size, d. is predicted for small values of d and $\dot{\varepsilon}$. The numerical correspondence between the calculated curves and the experimental results is rather poor, but the main trends predicted seem to be confirmed by experiments. It should be noted, however, that the experimental data were obtained for specimens manufactured by different methods [17–21], but in all cases, residual porosity and other imperfections may be responsible for the over-prediction of strength by the model considered.

The model can also be used to study the grain size dependence of the tensile ductility. Koch and Malow [22], in their compilation of ductility data, demonstrated that ultra-fine grained single-phase materials exhibit little room-temperature ductility in tension. For elemental metals that are ductile when coarse grained, the data show a clear trend for decreasing tensile ductility with decreasing grain size (Fig. 4). A similar behavior was recently observed in Al alloys [23]. The effect of grain size on ductility was
Figure 3. Average grain size dependence of $\sigma_{0.2}$ for fine grain Cu at strain rates of 10^{-2}, 10^{-3}, 10^{-4}, and 10^{-5} s^{-1} calculated using the phase mixture model with a log-normal distribution of the grain volume. Also shown are the experimental data points (see Fig. 2). Reprinted with permission from [12], H. S. Kim et al., *Mater. Sci. Eng.* 316A, 195 (2001). © 2001, Elsevier Science.
Figure 4. Strain to necking (calculated) and experimental tensile room temperature ductility as a function of the average grain size d. Symbols: □ Ref. [26], ○ Ref. [27], △ Ref. [28], ▽ Ref. [18], ◇ Ref. [29]. Reprinted with permission from [24], H. S. Kim and Y. Estrin, *Appl. Phys. Lett.* 79, 4115 (2001). © 2001, American Institute of Physics.

considered [24] using Hart's condition for the onset of necking [25]:

$$\theta \leq \sigma(1 - 1/m) \qquad (8)$$

Here the strain hardening coefficient and the effective strain rate sensitivity parameter are defined as $\theta = (\partial\sigma/\partial\varepsilon)_{\dot{\varepsilon}}$ and $1/m = (\partial\log\sigma/\partial\log\dot{\varepsilon})_{\varepsilon}$, respectively. It can easily be seen from this criterion that for extremely fine-grained materials, when plasticity is carried chiefly by the diffusion mechanisms and m tends to unity, tensile deformation will always be stable, strain-to-necking tending to infinity, as long as strain hardening is nonzero. That is to say, the material will never fail by necking, its ductility being limited by other failure mechanisms. In a real case, however, even for a very small grain size, the fulfillment of the necking condition, indicated by the equality in Eq. (8), will depend on the interplay of m, σ, and θ. For d in the range, where diffusion mechanisms of plasticity prevail over the dislocation glide mechanism, $1/m$ tends to unity and the strain-hardening coefficient tends to zero. Indeed, diffusion-controlled mechanisms do not exhibit any strain hardening. It is apparent that the loss of strain hardening as grain size is decreased cannot be compensated for by the stabilizing effect of the growing strain rate sensitivity, as it is not close enough to unity to outstrip the destabilizing effect.

Numerical simulations of a strain rate jump test can be used to determine the dependence of the instantaneous strain rate sensitivity $1/m$ on the grain size. These numerical experiments show that the strain dependence of the rate sensitivity parameter $1/m$ is fairly weak. Substituting the values of σ, θ, and $1/m$ (calculated for strain of 0.2%) into Hart's condition, the grain size dependence of strain-to-necking was determined. This dependence is shown as a solid line in Figure 4.

The results presented in Figure 4 demonstrate that the experimentally observed reduction of tensile room temperature ductility with grain refinement is in close quantitative agreement with the model. The loss of ductility with grain refinement found for room temperature deformation of copper does not necessarily represent a generic trend with all

materials at all temperatures. In fact, a simple linear stability analysis shows that the characteristic strain required for an incipient neck to grow to a sizable defect, ε_{growth}, is of the order of $(1 - \theta/\sigma) \cdot 1/m$. That is, it scales with $1/m$. As seen in Figure 5, which shows the grain size and temperature dependence of $1/m$ for small grain sizes (below 50 nm, for instance), ε_{growth} increases with temperature quite significantly and rapidly becomes more important than the strain to the onset of necking. In other words, a tensile specimen can sustain a significant strain as the pace of neck development is slow. The effect becomes more pronounced with decrease of the grain size. It can be stated that while nanostructured materials do not possess good room temperature ductility, their ductility at elevated temperatures is much better than for their coarse-grained counterparts. Thus, a common expectation that the temperature and strain rate range for superplastic forming may be moved to lower temperatures and higher strain rates by grain refinement down to the submicrometer range is qualitatively supported by these calculations.

3. PHASE MIXTURE MODEL FOR ELASTIC MODULUS

There are some conflicting results in the literature regarding the variation of elastic modulus E with grain size in nanostructured materials [20–21, 30–34]. Most of the experimental results indicate a reduction in E when the grain size is reduced to nanoscale [20–21, 30–31], although some reports suggest there is only little, if any, grain size effect [32–34]. Many authors [20–21, 31–32, 35] attribute the decrement of E to porosity and assume the intrinsic elastic modulus of the material itself is independent of the grain size. For example, Sanders et al. [21] relate the decrement of E for nanocrystalline Cu to the degree of porosity by analogy with the porosity dependence of E for coarse-grained Cu. By contrast, several investigators [30, 36] assumed an intrinsic grain size dependence of E. Weller et al. [30] attributed a reduction in the shear modulus G for nanocrystalline Pd to increased atomic interaction distance in the interface region. Similarly, Chen [36] explained a reduction
in E for nanocrystalline Fe in terms of increased spacing between atoms in the grain boundary. Since the elastic modulus is a measure of the bonding between atoms, an overall decrease in E is expected in nanostructured materials as a result of the increased volume fraction of the less stiff grain boundary phase. Porosity can be taken into account by including pores as a *third phase* with bulk modulus K and shear modulus G set to zero. The phase mixture model is combined with Budiansky's self-consistent method [37] for a random mixture of isotropic constituents. Since the bulk modulus and shear modulus of the pore are both zero, the bulk modulus K and the shear modulus G of the composite are related, in Budiansky's self-consistent approach, to the moduli K_i and G_i of the ith constituents by the following equations:

$$\frac{f_{GI}}{1 - a + a\frac{K_{GI}}{K}} + \frac{f_{GB}}{1 - a + a\frac{K_{GB}}{K}} + \frac{f_{PORE}}{1 - a} = 1 \quad (9)$$

and

$$\frac{f_{GI}}{1 - b + b\frac{G_{FI}}{G}} + \frac{f_{GB}}{1 - b + b\frac{G_{GB}}{G}} + \frac{f_{PORE}}{1 - b} = 1 \quad (10)$$

where

$$a = \frac{1}{3}\left(\frac{1 + \nu}{1 - \nu}\right) \quad (11)$$

$$b = \frac{2}{15}\left(\frac{4 - 5\nu}{1 - \nu}\right) \quad (12)$$

and ν, Poisson's ratio of the phase mixture, is, in turn, given by

$$\nu = \frac{3K - 2G}{6K + 2G} \quad (13)$$

Here, the pore volume fraction, f_{PORE}, was introduced, in addition to the volume fractions of the GIs and the GBs. In this formulation, the volume fractions of the grain boundaries proper, the triple lines, and the quaternary nodes were lumped together in the quantity f_{GB}. An alternative approach was adopted in [38], where these regions were treated separately. The Newton–Raphson method was used to obtain the solution of the set of coupled Eqs. (9–13). The model was applied to three metallic systems (Cu, Fe, and Pd), as data for these materials in the nanocrystalline range are available in literature.

The local elastic constants for the grain boundary region were calculated by atomistic simulation to be around 70% of the values for the crystalline phase [39]. Thus, the elastic modulus of the grain boundary was taken to be 70% of that for the corresponding coarse-grained polycrystal.

Figure 6 shows the calculated elastic modulus as a function of grain size for Fe, Pd, and Cu for various levels of porosity [21, 31]. It can be seen that the elastic modulus decreases very slowly with decreasing grain size as long as d remains in the range of relatively coarse grain size (>20 nm), but this decrease becomes very rapid when the grain size is below about 20 nm. It was also found that for a given level of porosity, the shape of the E versus d curve follows the grain size dependence of the volume fraction of the crystallite phase f_{CR}. The effect of porosity is clearly much

more significant than that of the grain size. Since nanostructured materials usually contain some porosity (whose level depends on the processing route and conditions), the effect of the grain size on the elastic modulus will, in many cases, be insignificant. The calculated values of E for the Cu and Pd specimens correlate reasonably well with the experimental data. In the case of Fe, the theoretical results show a good agreement with experimental data, both for relatively coarse grained ($d = 100$ nm, 90 nm, and 44 nm) and ultra-fine-grained ($d = 4 \sim 20$ nm) material.

4. YOUNG'S MODULUS OF A NANOCOMPOSITE

Using the same concept of a phase mixture, Young's modulus of a nanocomposite—a particle reinforced metal matrix composite with an ultra-fine grain size—can be evaluated [40]. The composite is now treated as a mixture of a metallic matrix phase, a reinforcing ceramic particle phase, and a boundary phase. Porosity—an inevitable companion of nanostructured materials—can be treated as a separate phase, but it can also be considered to reside in the boundary phase [40]. Indeed, residual pores are usually found at the interfaces between reinforcement particles and the matrix, as well as at the boundaries between matrix grains themselves. For example, Kizuka et al. [41] reported the evidence of voids residing on grain boundaries rather than in the grain interiors: an observation valid for many compacted MMCs.

Figure 7 shows a schematic representation of the phase mixture model identifying a unit cell [40]. The material is considered to be constructed by a periodic reproduction of this unit cell in three dimensions. The unit cell consists of a reinforcing particle and the matrix material separated from each other by the boundary phase. It should be noted that the matrix is not considered to be a contiguous phase, but is rather taken to consist of compacted matrix material "particulate." The model has been applied to a composite containing ceramic inclusions with an average diameter of 200 nm, a grain size of 247 to 126 nm, and an interparticle spacing of 330 to 137 nm [40].
Figure 7. Phase mixture model for a particle reinforced composite with ultra-fine microstructure. Reprinted with permission from [11], H. S. Kim et al., *Mater. Sci. Eng.* 276A, 175 (2000). © 2000, Elsevier Science.

The model of Figure 7 has the provision for distinguishing between the properties of the boundaries between matrix particles and matrix/inclusion interfaces; however, the same properties were assumed for both kinds of interface. A cylindrical geometry was assumed for the ceramic particles. The overall effective relative density, R_{eff}, of the composite can be represented in terms of the volume V and density ρ of each phase as [11]:

$$R_{eff} = \frac{V_p\rho_p + V_m\rho_m + V_b\rho_b}{V_p\rho_p + V_m\rho_m + V_b\rho_m} \qquad (14)$$

Here the subscripts m, p, and b refer, respectively, to the matrix, particles, and boundaries. From Eq. (14), the density of the boundary phase ρ_b can be obtained when the volume and density of the other two phases and the overall density are known.

The unit cell dimensions used in the calculations are based on experimental data [42]. Three kinds of ball-milled, compacted, and sintered composites with reinforcement volume fractions of 0, 10, 20, and 30% (referred to as C-00, C-10, C-20, and C-30) were prepared. A fully dense bulk Al material (referred to as "Al standard") was used as a reference material. The details (volume fraction, hardness, grain size, and density) of these materials are summarized in Table 2. Although these materials are not fine scaled enough to be referred to as genuinely nanocrystalline, the general trends observed can be translated to nanocomposites. The particle radius was taken to be 100 nm. The unit cell size (radius) was considered to be 247 nm, 215 nm, 171 nm, and 149 nm, which corresponds to the particle volume fraction of 0, 10, 20, and 30%, respectively.

The notion of a "generalized" boundary phase in the current model includes various imperfections, such as voids and cracks in the interface region. Hence, its properties need not be identical with those of the grain boundary proper. The effective width of the grain boundary was selected by taking into account the following considerations [16]. Using Auger electron spectroscopy of the surface products on atomized stainless steel powder particles, as well as on the particle boundaries that existed prior to compaction [43], the average oxide thickness was estimated to be 6 nm. This is much larger than a typical grain boundary thickness in elemental

metals usually taken to be of the order of 1 nm. The inhomogeneous surface region, as indicated by the variations of the chemical composition, reached an even larger depth of up to 10 nm. This value may be taken as representative of the effective boundary thickness scale for the case considered. Fortunately, the sensitivity of the mechanical properties of interest here to the boundary thickness is fairly weak: both the magnitude of the strength and the effective Young's modulus of the composite vary with the boundary width only slightly, the general trends remaining unchanged. The calculations that follow were done for a constant thickness of the boundary phase (assumed to be amorphous and porous) set at 1, 6, and 10 nm.

The dependence of mechanical properties on porosity can be represented by various empirical equations [44]. Spriggs' empirical relation [45] for Young's modulus, E, was adopted for the grain boundary phase where porosity was assumed to be concentrated [40]:

$$E_{GB} = E_0 e^{-s(1-R)} \qquad (15)$$

Here, E_0 is zero-porosity Young's modulus of the grain boundary material, R is the relative density (the ratio of the actual and the theoretical density), and s is a material constant that was found to range between 3 and 4.5 [45]. Young's modulus and Poisson's ratio of the particle material (Al_2O_3, in the particular case of an Al-Al_2O_3 composite considered) were taken to be 380 GPa and 0.22 [42], respectively. Fracture of particles and debonding between a particle and the matrix were not included.

The modulus of elasticity of the grain boundary phase in the absence of porosity cannot be calculated from the available experimental data. The boundary phase was considered to be amorphous in character. Indeed, glass-like behavior in nanocrystalline alloys has been reported in the literature [46]. This provides certain albeit indirect support for the above assumption. It is generally accepted that the modulus of elasticity of an amorphous material E_{am} amounts to $60\sim75\%$ of that of the corresponding equilibrium crystalline alloy [47]. This value is further reduced by the effect of porosity, in accordance with Eq. (15). Thus, the modulus of elasticity of the Al matrix, the Al_2O_3 reinforcement, and the boundary phase used in the calculations were 70, 380, and 47.3 GPa, respectively.

The classical models of Voigt and Reuss determine, respectively, the upper and the lower bounds of Young's modulus of the composite in the form

$$\begin{aligned} E_{upper} &= \Sigma f_i E_i, \\ E_{lower} &= (\Sigma f_i/E_i)^{-1} \end{aligned} \qquad (16)$$

where f_i and E_i are the volume fraction and Young's modulus of the component i. In a nontextured polycrystalline material, the effective modulus often lies between these two bounds, as determined by Hashin and Shtrikman [48]. Results very similar to those by Hashin and Shtrikman may be obtained by making use of Hill's approach [49], in which an effective Young's modulus is determined simply as the average of the upper and the lower bounds:

$$E_{eff} = (E_{upper} + E_{low})/2 \qquad (17)$$

Table 2. Microstructure and measured properties of the composite materials investigated.

	Al Standard	C-00	C-10	C-20	C-30
Volume fraction of reinforcement, %	0	0	10	20	30

Local relative density of boundary phase, %, as obtained using Eq. (2)	100	29.4	11.1	58.4	77.1

The volume fractions of the reinforcing particle, matrix, and boundary phases as a function of the unit cell size are shown in Figure 8 for the boundary width of 10 nm and the particle radius of 100 nm. As the radius of the unit cell r_u increases, the volume fraction of the matrix increases as well, while those of the particles and the boundary decrease. The trends seen in Figure 8 are consistent with the results presented in Table 2. It should also be noted that as the volume fraction of reinforcing particles increases, the grain size of the matrix decreases, and the volume fraction of the boundary phase increases.

While the density of the grain boundary phase taken in isolation is hardly accessible to experimental determination, it can be deduced from the overall density of the composite and the volume fraction of reinforcement particles. Figure 9 represents the contour plot for the relative density of the *boundary phase* as a function of the volume fraction of the particles and the relative density. As the overall relative density increases at a constant volume fraction of reinforcement particles, the local relative density of the boundary phase increases as well. When the volume fraction of the reinforcement particles is low, the relative density of the boundary phase is also low for a constant overall relative density. It should be noted that the effect of the overall relative density on the relative density of the boundary phase is much more significant than the effect of the volume fraction of the reinforcement particles. That is, the relative density of the boundary phase is inversely proportional to its volume fraction, since the volume occupied by pores, given by the product of the local porosity and the boundary volume, is constant. As shown in Table 2, the overall densities of the C-00, C-10, C-20, and C-30 specimens are 95.8, 92.4, 95.2, and 96.9% and the local relative densities in the boundary phase are 29.4, 11.1, 58.4, and 77.1%, respectively. The substantial variation in the derived density of the boundary phase may come as a surprise. However, it must be remembered that the model assumes that all the porosity resides in the grain boundary phase and the relative density of the grain interior is 100%. When the volume fraction of the grain boundary phase is small (For instance, <10%), the resulting calculation of relative density of the grain boundary will be very sensitive to the level of porosity. It follows

Figure 9. Contours of relative density of the boundary phase on a particle volume fraction versus overall relative density map. Reprinted with permission from [40], H. S. Kim et al., *Z. Metallkd.* 90, 863 (1999). © 1999, Carl Hanser Verlag.

that this calculation will also be very sensitive to the accuracy with which measurements of overall relative density are made, and caution must therefore be exercised in interpreting the results.

The effect of the volume fraction of the reinforcing particles is therefore not limited to a hardening role due to the particles themselves, but it also has an influence through the change in the volume fraction and the local density of the boundary phase. Small variations in the global density can be a result of large variations in the local density, such as in the grain boundaries.

In order to assess the relative importance of the overall relative density, the volume fraction of the reinforcement particles and the width of the boundary phase, we can view the overall (effective) Young's modulus E_{eff} in Figure 10. The calculation is based on Hill's rule of mixtures, Eq. (17).

In all cases, the effective elastic modulus increases with the volume fraction of the reinforcement particles. When

Figure 10. Effective Young's modulus of the composite consisting of three phases (reinforcement, matrix, and boundary) as a function of volume fraction of the reinforcement particles calculated using Hill's modification to the rule of mixtures (Eq. (5)). The cases when the width of the boundary phase is 5 and 10 nm, and the overall relative density is 1 and 0.95 are compared. Reprinted with permission from [40], H. S. Kim et al., *Z. Metallkd.* 90, 863 (1999). © 1999, Carl Hanser Verlag.

the specimen has no porosity, the material with less boundary phase ($w = 5$ nm) shows a higher overall Young's modulus than the material with more boundary phase, thereby reflecting the lower modulus exhibited by the boundary phase. However, in the presence of porosity, a composite with a fixed overall density will possess a higher elastic modulus, if it has a larger volume fraction of boundary material. Indeed, for a fixed overall density R, the local density within the boundary phase increases with its volume fraction.

Figure 11 shows the calculated and experimental values of Young's modulus of the Al-Al$_2$O$_3$ composites as well as the measured overall relative density. The agreement between experimental data and the results obtained using the rule of mixtures is satisfactory. As can be seen in the figure, the experimental data are better represented by the calculations that include local porosity than by the calculations for a material with zero porosity. The relatively large difference between the calculated results for a porous and a nonporous material for the C-10 specimen can be attributed to the relatively high level of porosity in the test samples.

The relation between the volume fraction of particles, the overall relative density, and the effective Young's modulus of the composite is shown in Figure 12. As expected for a fixed overall relative density, the effective Young's modulus increases nearly linearly with the volume fraction of reinforcement particles. Its dependence on the overall relative density R_{eff} for a fixed volume fraction of particles is much stronger: it follows an exponential law. The circled numbers represent the experimental values of Young's modulus. The calculated and experimental data are in good agreement. The diagrams in Figure 12 provide a useful tool for predicting the value of Young's modulus as a function of the volume fraction of reinforcement particles and the relative density that can be controlled by the degree of compaction.

5. CONCLUSIONS

In this overview, it was demonstrated that the phase mixture modelling concept, based on the notion that the grain boundaries can be treated as a separate phase, is very productive in accounting for mechanical behavior of nanostructured materials. Various aspects of this behavior, particularly plastic and elastic properties, were considered using different variants of the phase mixture modelling. Such salient features of plastic behavior as the breakdown of the Hall–Petch behavior and a drop in room temperature ductility of single-phase nanostructured metals with decreasing grain size were recovered adequately. Similarly successful is the description of the grain size dependence of the elastic modulus. The approach taken was also shown to be suitable for dealing with the elastic properties of ultra-fine grained metal-matrix composites. Plasticity of such materials (not considered here) can also be successfully modelled using similar approaches [10]. To summarize, mechanical properties of nanostructured single-phase and composite materials can be rationalized from a unifying viewpoint based on the phase mixture approach. A critical proof of the models presented will come from experiments done on porosity-free nanocrystalline materials on one side and molecular dynamic simulations [2, 3, 50] on the other. The latter are needed for checking the assumptions made in the above models regarding the role of grain boundaries as impenetrable obstacles to dislocations and their elastic and plastic properties.

GLOSSARY

Coble mechanism   A mechanism of plastic flow in a polycrystalline material controlled by matter transfer along grain boundaries.

Constitutive model   A set of equations establishing relations between macroscopic mechanical quantities and describing the mechanical behavior of a material, usually in terms of the evolution of internal variables.

Figure 11. The overall density and elastic modulus of the nanocomposites. The open circles correspond to the model predictions, while the triangles represent the experimental data. Dislocation glide A mechanism of plastic deformation of crystalline materials controlled by the movement of dislocations on crystallographic slip systems.

Hall–Petch relation An inverse square root dependence of strength or hardness of a polycrystalline material on the average grain size.

Metal matrix composite (MMC) A composite material consisting of particles or fibers of reinforcing material (usually ceramic) embedded in a metal matrix.

Nabarro–Herring mechanism A mechanism of plastic flow in a polycrystalline material controlled by matter transfer across crystallites by bulk diffusion.

CONTENTS

1. INTRODUCTION

There is considerable current interest in the physics of nanostructured materials in view of their numerous technological applications [1, 2] in a variety of areas such as catalysis [3], magnetic data storage [4], ferrofluids [5], soft magnets [6], machinable ceramics and metallurgy [7], nonlinear optical and optoelectronic devices [8], and sensors [9]. In addition, obtaining an understanding of the properties of nanostructured materials is of interest from a fundamental point of view. Only a proper understanding of the dependence of a given property on the grain/particle size can lead to design/tailoring of the nanostructured material for the related application. It is also important to understand when a material could be considered as nanostructured. Although one can in principle classify materials with grain size less than 1000 nm as nanostructured, several properties such as optical [10] and vibrational [11] properties do not differ much from the corresponding bulk value unless the grain/particle size is less than typically 20 nm. In view of this it is reasonable to treat a material with a grain size smaller than a certain value as nanostructured only if the property of interest differs from the bulk value at least by a few percent. It is also possible that a material with nanometer grain size may behave as nanostructured for a specific property while it could act like bulk for other properties. In addition to the grain size, the properties of the nanostructured materials may sometimes depend on the method of their synthesis. Generally nanostructured materials are synthesized in

one of the three forms: (a) as isolated or loosely connected nanoparticles in the form of powder [12], (b) as composites of nanoparticles dispersed in another host [13], or (c) as compact collection of nanograins as pellets [14] or thin films [15]. The last form is also called nanophase material. This chapter reviews the vibrational properties of the various forms of nanostructured materials.

Phonons are quanta of atomic vibrations in crystalline solids. In a simple monoatomic solid with only one atom per primitive cell (for example, α-iron, copper), one can have only three acoustic phonon branches corresponding to the three degrees of freedom of atomic motion. On the other hand, for monoatomic solids with two atoms per primitive cell such as diamond, magnesium, or diatomic compounds such as GaAs, one also has three optic phonon branches in addition to the three acoustic phonons [16]. In compounds with a greater number of atoms and complex crystal structures, the number of optic phonons is more than three. If the crystal unit cell contains N atoms, then 3N degrees of freedom result in 3 acoustic phonons and $3N - 3$ optical phonons. These phonons can propagate in the lattice of a single crystal as a wave and exhibit dispersion depending on their wavelength or equivalently their wavevector in the Brillouin zone [17]. Phonon propagation is interrupted when a grain boundary is encountered in a polycrystalline material. In an isolated grain the phonon can get reflected from the boundaries and remain confined within the grain. However, from the point of view of phonons, a well-crystallized polycrystalline sample with several micrometer grain size can be treated as a bulk/infinite crystal for all practical purposes. The consequences of phonon confinement are noticeable in the vibrational spectra only when the grain size is smaller than typically 20 lattice parameters.

The atomic vibrational frequencies in crystalline solids range from zero to about 100 THz. A more common unit to describe the vibrational frequencies is wavenumber (cm^{-1}) obtained by dividing the actual frequency by the velocity of light or by inverting the wavelength. Acoustic phonons have frequencies from zero to about a few hundred

wavenumbers while the optic phonons have higher frequencies. Hence the vibrational spectra could be probed using infrared absorption/reflectivity or using Raman spectroscopy [18]. The wavevector of the IR photon for these energies is of the order of 10^2–10^3 cm^{-1}. On the other hand, in a Raman scattering experiment the magnitude of scattering vector is $2k_0 \sin(\theta/2)$, where k_0 is the wavevector of the incident light and θ is the scattering angle. Thus the maximum value of the scattering vector could at best be $2k_0$ (corresponding to the backscattering geometry), which has a value $\sim 5 \times 10^4$ cm^{-1} for visible light. Hence the wavevector probed by either of these two techniques is much smaller than the wavevector q of the full phonon dispersion curve, which extends up to the boundary of the Brillouin zone ($\pi/a \sim 10^8$ cm^{-1}, where a is the lattice parameter). Thus these techniques sample only the optical phonons close to the zone center ($q \sim 0$). This $q \sim 0$ selection rule is essentially a consequence of the infinite periodicity of the crystal lattice [19]. However, if the periodicity of the crystal lattice is interrupted, as in the case of nanocrystalline materials, this rule is relaxed and phonons away from the Brillouin zone center also contribute to the phonon lineshape observed in spectroscopic measurements. This can be qualitatively explained in the following manner. Consider the phonon dispersion curve of a typical diatomic solid as shown in Figure 1. For a particle/grain of size d, the phonon wavefunction must decay to a very small value close to the boundary. This restriction on the spatial extent of the wavefunction, via a relationship of the uncertainty principle type, results in an uncertainty $\Delta q \sim \pi/d$ in the wavevector of the zone-center optical phonon and a corresponding uncertainty $2\delta\omega$ in its frequency [20]. Now the light scattering can take place from quasi-zone-center optical phonons with wavevectors Δq up to π/d. This results in asymmetric broadening of the phonon lineshape. In addition to the changes in the optical phonon lineshape, confinement of acoustic phonons also leads to other interesting changes in the spectra. A quantitative formalism of phonon confinement will be discussed in subsequent sections.

1.1. Dimensionality of Confinement

It is important to distinguish between the dimensionality of the system and the dimensionality/degree of confinement. A bulk material is a 3D system and is unconfined; that is, dimensionality/degree of confinement is zero. The first
level of confinement occurs in single- and multilayer thin films grown using layered deposition on substrates. Semiconductor superlattices, single-quantum well structures, and multiple-quantum well structures [21] are well-known examples of 2D systems because the phonons and charge carriers are confined within a plane, say, the x-y plane; however, the degree of confinement is 1D because phonons and charge carriers are restricted along the z direction. Similarly, 2D confinement occurs in nanowires [22] and in carbon nanotubes [23], whereas the dimensionality of the system reduces to 1D. The highest degree of confinement (3D) occurs in quantum dots [24] and nanoparticles [25, 26] where the propagation is restricted in all three directions. Here the dimensionality of the system is zero.

2. OPTICAL PHONONS

As mentioned in the Introduction, only zone-center optical phonons can be observed in ideal single crystals using optical techniques such as Raman spectroscopy. However, this $q = 0$ selection rule is relaxed due to interruption of lattice periodicity in a nanocrystalline material. In this section we present a phenomenological model of phonon confinement in an isolated nanoparticle. The case of spherical nanoparticle is considered first.

2.1. Phenomenological Confinement Model

A quantitative formalism for the confined-phonon lineshape [27] involves taking into account the contributions of the phonons over the complete Brillouin zone with appropriate weight factors. Consider a spherical nanoparticle of diameter d as shown in Figure 2. A plane-wave-like phonon wavefunction cannot exist within the particle because the phonon cannot propagate beyond the crystal surface. In view of this, one must multiply the phonon wavefunction with a confinement function or envelope function $W(r)$, which decays to a very small value close to the boundary.

The wavefunction of a confined phonon of wavevector q_0 can be written as

$$\Psi(q_0, r) = W(r)u(q_0, r)\exp(-iq_0 \cdot r) \qquad (1)$$

$$\Psi(q_0, r) = \Psi'(q_0, r)u(q_0, r) \qquad (2)$$

Figure 1. Schematic representation of the optical phonon dispersion curve and the range Δq of the wavevectors probed in Raman scattering from a nanoparticle of diameter d. $2\delta\omega$ is the corresponding range of phonon frequencies that contribute to the first-order Raman scattering.
Figure 2. The Gaussian confinement function $W(r)$ for a spherical nanocrystal of diameter d.

where $u(q_0, r)$ has the periodicity of the lattice. In order to calculate the effect on the Raman spectrum, we expand $\Psi'(q_0, r)$ in Fourier series:

$$\Psi'(q_0, r) = \int C(q_0, q) \exp(iq \cdot r) d^3q \qquad (3)$$

where the Fourier coefficients $C(q_0, q)$ are given by

$$C(q_0, q) = (2\pi)^{-3} \int \Psi'(q_0, r) \exp(-iq \cdot r) d^3r \qquad (4)$$

The particle (nanocrystal) phonon wavefunction is a superposition of plane waves with q vectors centered at q_0. Gaussian confinement functions have been extensively used as the confinement function [27–29]. One can write $W(r)$ as

$$W(r) = \exp(-\alpha r^2/d^2) \qquad (5)$$

where the value of α decides how rapidly the wavefunction decays as one approaches the boundary. This gives $C(q_0, q)$ as

$$C(q_0, q) = \exp\{-d^2(q - q_0)^2/4\alpha\} \qquad (6)$$

Richter et al. (RWL model) [27] used the boundary condition that the phonon amplitude $|\Psi|^2 \propto W^2(r)$ reduced to 1/e at the boundary $r = d/2$ of the particle. This corresponds to $\alpha = 2$. Other values of α such as $8\pi^2$ used by Campbell and Fauchet (CF model) [28] and 9.67 (bond polarizability model) [29] have also been proposed. Thus Ψ' are the eigenfunctions of the phonons with wavevectors q in an interval $|q - q_0| < \pi/d$ centered at q_0 and the weight factors $C(q_0, q)$ also have a Gaussian distribution. As one-phonon Raman scattering probes zone-center phonons, one can set $q_0 = 0$. This yields

$$|C(0, q)|^2 = \exp(-q^2 d^2/2\alpha) \qquad (7)$$

The first-order Raman spectrum is then given as

$$I(\omega) = \int \frac{|C(0, q)|^2 d^3q}{[\omega - \omega(q)]^2 + (\Gamma_0/2)^2} \qquad (8)$$

where $\omega(q)$ is the phonon dispersion curve and Γ_0 is the natural linewidth of the zone-center optical phonon in the bulk. In order to simplify the calculations, one can assume a spherical Brillouin zone and consider the phonon dispersion curve to be isotropic. These assumptions are valid when only a small region of the Brillouin zone, centered at Γ point, contributes to the scattering. The optical phonon dispersion curve could then be approximated to an analytical function of the type

$$\omega(q) = \omega_0 - \Delta\omega \sin^2(qa/4) \qquad (9)$$

where a is the lattice parameter, ω_0 is the zone-center optical phonon frequency, and $\Delta\omega$ is the width of the phonon dispersion curve.

The calculated Raman lineshapes of 4- and 8-nm GaAs nanoparticles are compared in Figure 3 with that of the bulk. One can see that as the particle size reduces, the
Figure 3. Calculated Raman spectra of confined LO phonon in GaAs nanoparticles. The bulk spectrum is also shown for comparison. Note the asymmetric broadening of the lineshape and also the shift of the peak towards the low-frequency side.

Raman spectra develop marked asymmetry towards the low-frequency side and exhibit marginal shift in the peak position also towards the same side. As the optical phonon dispersion curves in most solids have negative dispersion, that is, phonon frequency decreases as a function of wavenumber, the increased intensity in the wing of the Raman spectra on the low-frequency side basically arises from the contribution from the phonon branch away from the zone center. The dependence of the peak shift and the line broadening on the particle size is shown in Figure 4 for the longitudinal optic phonon in GaAs. Note that both peak shift and the linewidth increase as the particle size reduces. However, the changes are marginal if the particle size is larger than 10 nm.

It is sometimes useful to combine the results of Figure 4 into a single curve of peak shift versus line broadening. This is particularly useful while analyzing data on nanocrystalline systems where information about the particle size is not available. For ion-implanted GaAs, Tiong et al. [30] argued that crystallite size reduced due to irradiation-induced damage in the lattice; however, spatial correlation (size of crystalline region) persisted over a small length. In view of this the changes in the peak shift and line broadening as a function of fluence were ascribed to the residual spatial correlation over the nanocrystalline grains in the implanted sample. Figure 5 shows peak shift as a function of line broadening for GaAs nanoparticles.

In addition to the Gaussian function, other analytic functions such as sinc and exponential have also been considered as confinement functions. In analogy with the ground-state wavefunction of an electron in a spherical potential well, a sinc $(\sin(x)/x)$ function was considered [28]:

$$\begin{aligned} W_S(r) &= \sin(2\pi r/d)/(2\pi r/d) \qquad &\text{if } r < d/2 \\ &= 0 \qquad &\text{otherwise} \end{aligned} \qquad (10)$$

Here the wavefunction becomes zero at the boundary of the particle. The Fourier coefficient in this case becomes [29]

$$C_S(0, q) \cong \frac{\sin(qd/2)}{q(4\pi^2 - q^2 d^2)} \qquad (11)$$

Similarly, in analogy with the propagation of a wave in a lossy medium, an exponential decay of phonon amplitude
Figure 4. The dependence of linewidth (a) and peak shift (b) of the longitudinal optic phonon on the particle size for GaAs nanoparticles. Dashed line is the linewidth of the bulk phonon.
Figure 5. The relationship between peak shift $\delta\omega$ and line broadening Γ for the three different confinement functions. Adapted with permission from [28], I. H. Campbell and P. M. Fauchet, *Solid State Commun.* 58, 739 (1986). © 1986, Elsevier Science.

has also been considered [28]. The confinement function used in this case was

$$W_E(r) = \exp(-4\pi^2 r/d) \tag{12}$$

The Fourier coefficient is then given by [28]

$$C_E(0, q) \cong \frac{1}{(16\pi^4 - q^2 d^2)^2} \tag{13}$$

These confinement functions yield different dependence of peak shift on the line broadening. Figure 5 also compares the dependencies for the sinc and exponential confinement functions with that of Gaussian. Note that each confinement function has a different shape of $\delta\omega$ versus Γ curve. From the analysis of their data and other reported results [27, 31], Campbell and Fauchet [28] have shown that a Gaussian confinement with $\alpha = 8\pi^2$ fits best to the data. This corresponds to a strong/rigid confinement of phonons within the nanoparticle with zero amplitude near the boundary.

We now consider other confinement geometries. As mentioned earlier, rodlike shape corresponds to 2D confinement and platelike (thin-film) shape gives 1D confinement. A rodlike particle is characterized by two length scales, its diameter d_1 being much smaller than its length d_2. Again using $\alpha = 8\pi^2$ in Gaussian confinement, the expressions for the Fourier coefficients $C(0, q_1 q_2)$ have been obtained [28]:

$$|C(0, q_1, q_2)|^2 \cong \exp(-q_1^2 d_1^2/16\pi^2) \exp(-q_2^2 d_2^2/16\pi^2)$$
$$\times \left| 1 - erf\left(\frac{iq_2 d_2}{\sqrt{32\pi}}\right) \right|^2 \tag{14}$$

On the other hand, a thin film has only its thickness d as the confining dimension. For a thin film, the Fourier coefficient is given by [28]

$$|C(0, q)|^2 \cong \exp(-q^2 d^2/16\pi^2) \left| 1 - erf\left(\frac{iqd}{\sqrt{32\pi}}\right) \right|^2 \tag{15}$$

The changes in the Raman lineshape, quantified in terms of line broadening and peak shift, are compared in Figure 6 for 1-, 2-, and 3D confined systems within the framework of Gaussian confinement. Note that as the dimensionality of confinement reduces, the magnitude of peak shift and line broadening reduce dramatically. The departure from bulk is maximum for a particle while it is least for a thin film of the same dimension.

2.2. Bond Polarizability Model

In addition to the phenomenological models of phonon confinement, there have been some attempts to theoretically obtain [29] the Raman spectrum of nanocrystals using bond polarizability model [32] within the framework of partial density approximation [33]. In this method eigenvalues and eigenvectors are obtained by diagonalizing the dynamical matrix, while the force constants are obtained by using partial density approach. The eigenvectors thus obtained are analyzed to give vibrational amplitude as a function of distance from the center of the particle. The phonon amplitude in a Si nanosphere was shown to closely
Figure 6. The relationship between peak shift $\delta\omega$ and line broadening Γ for three different shapes of the nanoparticles. In all the three curves the open circles correspond to a size of 4 nm. Adapted with permission from [28], I. H. Campbell and P. M. Fauchet, *Solid State Commun.* 58, 739 (1986). © 1986, Elsevier Science.

Figure 7. Squares of the Gaussian confinement functions $W(r)$ (a) and the corresponding Fourier transform $C(q)$ (b) for different values of α. Curve (1) $\alpha = 2.0$ (RWL model), (2) $\alpha = 9.67$ (bond-polarizability model), and (3) $\alpha = 8\pi^2$ (CF model). The phonon amplitude W^2 is plotted up to the boundary of the particle ($r = d/2$) and C^2 up to the Brillouin zone boundary $q = \pi/a$.

resemble a sinc function or a Gaussian with $\alpha = 9.67$ [29]. Amplitude at the boundary was calculated to be around 3.6%. This is much smaller than $1/e$ used by Richter et al. [27] and much larger than $\exp(-4\pi^2)$ used by Campbell and Fauchet (CF) [28]. The Gaussian confinement functions and the corresponding Fourier coefficients corresponding to three different α (2, 9.67, and $8\pi^2$) are compared in Figure 7. Note that weight factor $|C(q)|^2$ for the Raman intensity drops too rapidly for $\alpha = 2$ and too slowly for $\alpha = 8\pi^2$ as one moves away from the Brillouin zone center. Consequently the RWL model predicts only a marginal change in the Raman spectra while that of CF model causes maximum departure from the bulk for the same particle size. On the other hand, the calculations of Zi et al. suggest an effect intermediate between the two limiting cases. It is important to point out that a large number of results have been satisfactorily explained on the basis of Gaussian confinement model using $\alpha = 8\pi^2$ [20, 34–38].

3. RESULTS

In this section we discuss various results reported on phonon confinement in 1-, 2-, and 3D confined systems.

3.1. 1D Confined Systems

Superlattices consisting of alternate thin layers of a pair of semiconducting materials such as GaAs and AlAs, grown on a substrate using molecular beam epitaxy, have been extensively studied [21] in view of their applications in light-emitting diodes and diode lasers [39]. In these superlattices GaAs layer constitutes the quantum well while the AlAs layer forms the barrier layer. It is important to point out that the range of optical phonon frequencies of GaAs does not overlap with that of AlAs. Hence the phonons of GaAs layer cannot propagate into the neighboring AlAs layers and vice versa. Thus phonons in each of the GaAs and AlAs
layers are confined within those layers. The confined optical phonons in such superlattices can be described as modes of a thin slab, arising from the standing wave pattern formed within each slab. A set of modes at discrete wavevectors $q_j = \pi j/d_1$, where d_1 is the thickness of the GaAs layer, are allowed. The confined phonon frequencies ω_j then correspond to the discrete q_j points on the dispersion curve of GaAs [40]. Similarly the confined optical phonons of AlAs layer of thickness d_2 correspond to the $q_j = \pi j/d_2$ discrete points on the AlAs dispersion curve. In GaAs/AlAs superlattices the confined optical phonons in the GaAs layers have been observed only under resonant conditions, that is, when the incident photon energy is close to that of an electronic excitation of the GaAs quantum well [40]. Under nonresonant conditions the intensities of these modes are weak.

In many cases one of the layers is an alloy $Al_xGa_{1-x}As$ [21]. This mixed crystal system exhibits a "two-mode" behavior [41]; that is, it exhibits both GaAs-like and AlAs-like modes. Hence AlAs-like phonons remain confined in the barrier layer ($Al_xGa_{1-x}As$) in a $GaAs/Al_xGa_{1-x}As$ superlattice. On the other hand, the GaAs-like modes of the quantum-well layer (GaAs) can propagate in the barrier layer and vice versa. In view of this one expects "zone folding" to take place with new periodicity of $(d_1 + d_2)$ at $q_j = \pi j/(d_1 + d_2)$; however, this effect has not been observed for propagating optical phonons in $GaAs/Al_xGa_{1-x}As$ superlattices because of the highly dispersive character of the optical

modes [42]. It may be mentioned that the acoustic phonons, whose dispersion curves overlap over a wide range of frequencies, propagate through both the layers exhibiting zone-folding effects due to new periodicity [43].

Confined optical phonons have been found also in single GaAs quantum wells under resonant conditions [44]. Resonance was achieved at a fixed photon energy by exploiting the temperature dependence of electronic excitations in the quantum well. Recently, IR absorption measurements have been used for studying confined optical phonons in $(PbTe)_m/(EuTe)_n$ superlattices [45]. The confined phonons manifest themselves as minima in the transmission spectrum. In the normal incidence only transverse optic (TO) phonons are observed, while in oblique incidence both TO and longitudinal optic (LO) phonons are seen. From the frequencies of these confined phonons the dispersion curve along the $\langle 111 \rangle$ direction could be deduced. In contrast to $GaAs/Al_xGa_{1-x}As$ superlattices, zone-folding effects have been observed in $GaN/Al_xGa_{1-x}N$ superlattices [46]. As this mixed crystal system exhibits "one-mode behaviour," it is argued that the overlap between the density of states in the two layers is significant. In superlattices and in quantum-well structures, interface optical phonons have also been observed [47, 48]. Phenomenological models [49] predict that these modes have frequencies between TO and LO phonons of the constituent layers. If the interfaces are sharp, the interface phonons are found to be weak [46].

3.2. 2D Confined Systems

Recently, several tens of micrometers long nanowires of a variety of materials such as Si [22, 50], Ge [51], GaAs [52], SiC [53–55], and TiC [56] have been synthesized using laser ablation [57] and other methods. The diameter of these nanowires ranges from 5 to 50 nm. Their optical properties are strongly influenced by the confinement of electrons and holes in these 1D systems. In view of their unique properties, they find applications in several devices [56]. In analogy with electron confinement, phonon confinement has also been found to give rise to interesting changes in the vibrational spectra.

Raman spectra of the F_{2g} optical phonon in Si nanowires show broadening and peak shifts [50] similar to those predicted by Gaussian confinement model. For a 10-nm-diameter nanowire the peak is found to shift to 505 cm^{-1} from 519 cm^{-1} and also broaden to 13 cm^{-1} from 3.5 cm^{-1}. Additional peaks at 302 and 964 cm^{-1} have also been reported. These were assigned to overtones of the zone-boundary phonons [50]. Appearance of zone-boundary phonons in crystals with large density of defects [58] or in mixed crystals [59] has often been reported. This arises due to the relaxation of the $q = 0$ selection rule due to the presence of disorder in the crystal. Similarly, overtones and combinations constitute the second-order spectra and these also are enhanced in the presence of disorder. On the other hand, Wang et al. [50] apply the phonon confinement model also to the overtones of zone-boundary phonon and try to interpret their shifts and broadening. In fact, the changes in the Raman spectra of overtones, etc., as a consequence of reducing the nanowire diameter should only be ascribed to higher defect density resulting in the appearance of peaks

corresponding to one- and two-phonon density of states. Quite interestingly, Wang et al. also introduce a new term "phonon confinement length" (in analogy with exciton confinement length). By this they imply a size of nanostructure below which the phonon confinement effects are noticeable in the Raman spectra. In this context it is important to point out that for a given material the confinement effects may be different for phonons of different symmetries [37], making such terms lose their physical significance. This will be discussed further in a subsequent section.

Germanium nanowires with an oxide layer coating have been synthesized using laser ablation technique [51]. As expected, larger core diameters in the range 20–51 nm do not exhibit any noticeable change in the Raman spectra. On the other hand, nanowires with 6–17 nm core show asymmetric broadening; however, no quantitative analysis has been carried out. Gallium arsenide nanowires with a GeO_x sheath have exhibited broad TO and LO phonon modes [52]; however, the broadening was found to be nearly symmetric. Surprisingly, the red shift of the LO phonon was very large, ~ 40 cm^{-1} for nanowires with diameters in the range 10–120 nm with an average diameter of 60 nm. Such a large shift cannot be accounted for based on phonon confinement effect alone. Other factors such as defects and residual stresses have been argued to contribute to the decrease of LO phonon frequency. Silicon carbide nanowires of average diameter 80 nm with a coating of 17 nm SiO_x [53] have also shown very broad Raman spectra that resemble those arising from phonon density of states rather than from phonon confinement effects. The red shifts of 12 to 34 cm^{-1} for the TO and LO phonons were attributed to confinement effects and internal stresses [53]. CdSe nanofilaments incorporated in fibrous magnesium silicate (chrysotile asbestos) have shown polarized Raman spectrum [60].

Carbon nanotubes are unique one-dimensional systems [61, 62], whose diameters are typically 1–2 nm and whose lengths are up to several tens of micrometers. Vibrational properties of these hollow tubes are quite different from those of solid nanorods discussed earlier. A single-wall carbon nanotube (SWNT) can be described as a single atomic layer of graphite rolled up into a seamless cylinder. A SWNT is specified by a pair of indices (m, n) that represent the number of unit vectors $n\mathbf{a}_1$ and $m\mathbf{a}_2$ on the 2D hexagonal honeycomb lattice contained in the chiral vector. Folding of the graphite sheet is done such that the chiral vector is perpendicular to the axis of the nanotube (see, e.g., Fig. 1 of [63]). The magnitude of the chiral vector gives its circumference. The diameter of the nanotube is related to the (m, n) indices as

$$d = 3^{1/2}(m^2 + mn + n^2)^{1/2}a_{c-c}/\pi$$

where a_{c-c} is the nearest-neighbor C-C distance (1.421 Å in graphite). The phonon dispersion relations in a carbon nanotube are obtained from those of an isolated 2D graphite layer (graphene sheet) by using the zone-folding approach [64]. Zone folding of acoustic branches leads to several low-frequency modes, whose frequencies depend strongly on the diameter of the nanotube. Notable among these are the E_{2g} mode, the E_{1g}, mode, and the A_{1g} radial breathing mode. For a (10, 10) nanotube of diameter 1.36 nm, these modes

have frequencies of 17, 118, and 165 cm^{-1} [63]. For tube diameters ranging between 0.6 and 1.4 nm, a power law dependence of the mode frequencies has been found [65]. The exponent for the E_{1g} and A_{1g} modes is close to -1 while that for the lowest energy E_{2g} mode is close to -2. Figure 8 shows the dependence of the frequencies of several Raman active modes on the index n for (n, n) armchair nanotubes [66]. The inverse dependence of the radial breathing mode frequency on the tube diameter serves as a secondary characterization to estimate the mean diameter of SWNTs. In addition to these features, the internal modes associated with the hexagonal ring stretching vibration of the graphite sheet around 1581 cm^{-1} exhibits splitting into $A_{1g} + E_g$. This splitting arises due to the curvature of the nanotube graphene sheet. A novel feature of the Raman spectra of SWNTs is the diameter selective scattering at different excitation energies, arising from the 2D quantum confinement of electrons. Resonance Raman spectroscopic studies in the energy range 1–4.8 eV have proved to be a powerful probe of these quasi-1D materials [67–69]. Depending on its chirality (i.e., n and m), an individual SWNT could be semiconducting or metallic. Any sample of SWNTs is a mixture of $\sim$1/3 metallic and $\sim$2/3 semiconducting tubes. Raman excitations at different energies could selectively probe either of these sets of tubes.

Specific-heat measurements at low temperature have shown evidence of quantized phonon spectrum of SWNT [70]. The data show the expected linear T dependence and were found to be significantly different from that of 3D graphite and 2D graphene. The analysis also yielded an energy of 4.3 meV for the lowest quantized phonon subband. The nanotubes that are produced in either an electric arc or pulsed laser vaporization are mostly in the form of bundles, where nanotubes are aligned in a close-packed triangular lattice. Intertube interactions that arise in the lattice are usually weak and are approximated by van der Waals interaction. This is similar to coupling between adjacent graphene layers in 3D crystalline graphite. This coupling causes a slight increase ($\sim$7%) in the frequency of radial breathing mode, independent of the tube diameter. This arises from additional restoring force due to the nearest-neighbor tube-tube interaction [71].

3.3. 3D Confined Systems

Isolated or loosely connected nanoparticles as self-supporting powders and nanoparticles dispersed in other hosts have been the most extensively studied nanostructured systems. In many investigations quantitative fitting of phonon lineshape has also been carried out [20, 38, 72]. The extent of peak shift and line broadening is expected to depend on the shape of the dispersion curve. For phonon branches with less dispersion the effects are expected to be small. On the other hand, the phonons that exhibit large dispersion would get modified significantly. This was demonstrated for the first time [37] in the case of zinc oxide nanoparticles by examining the phonons of different symmetries (irreducible representations). Zinc oxide has wurtzite structure and consequently has phonons of symmetries A_1, E_1, and E_2 at 393, 591, and 465 cm^{-1}, respectively. For a 4-nm particle size, E_1-LO mode exhibited a change in linewidth from 18 to 38 cm^{-1} whereas E_2 mode showed an increase of only 2 cm^{-1}. Figure 9 shows the fitted lineshape for 4-nm particles along with the data. Because of insufficient intensity, A_1 mode was not analyzed in detail. The widely different behavior of E_1 and E_2 phonons could be understood when the widths of the corresponding dispersion curves $\Delta\omega$ were taken into account. Table 1 shows the peak shift and line broadening data for these modes in 4-nm particles.

There are a number of Raman spectroscopic studies on nanocrystalline powders which exhibit broadening and peak shifts similar to those expected for phonon confinement [73–75]; however, quantitative analyses have not been carried out. In the case of composites synthesized either as thin films using co-sputtering [15] or by doping melt-quenched oxide glasses [76], nanocrystalline precipitates form during annealing at elevated temperatures [77, 78]. A departure of LO phonon frequency from the expected behavior for

Figure 8. Dependence of the vibrational frequencies of (n, n) armchair single-walled carbon nanotubes on the index n. The diameter of the nanotube is $d_n = 1.357n$ Å. The frequencies of the A_{1g} radial breathing mode and other low-frequency modes depend strongly on the diameter. Adapted with permission from [66], P. C. Table 1. Peak shift $\delta\omega$ and line broadening Γ data for optical phonons of different symmetries for 4-nm zinc oxide nanoparticles.

Phonon	$\Delta\omega$ (cm^{-1})	Γ_0 (cm^{-1})	Γ (cm^{-1})	$\delta\omega$ (cm^{-1})
E_2	12	12	14	1
E_1-LO	60	18	38	7

Note: $\Delta\omega$ is the width of the dispersion curve and Γ_0 is the natural linewidth of the phonon.

CdS nanoparticles smaller than 5 nm dispersed in GeO$_2$ matrix has been attributed to defects [79]. Evidence of the presence of CdO surface capping layer on pulsed laser deposited CdS nanoparticles in SiO$_2$ matrix has been found from the presence of its characteristic peak in the Raman spectrum [80]. A comparison of the Raman spectra of Si doped SiO$_2$ films with those of theoretically calculated vibrational density of states of Si$_{33}$ and Si$_{45}$ clusters suggested the presence of such clusters in SiO$_2$ [81]. Semiconductor mixed crystals such as CdS$_x$Se$_{1-x}$ [82] and Cd$_{1-x}$Zn$_x$S [77] dispersed in oxide glasses as nanocrystalline precipitates have been extensively studied in view of their interesting optical properties and applications as long-pass optical filters. The system CdS$_x$Se$_{1-x}$ exhibits two-mode behavior and both CdSe-like and CdS-like confined LO phonons are observed [20]. On the other hand, Cd$_{1-x}$Zn$_x$S system exhibits single-mode behavior. The shift of the LO phonon frequency during late stage of annealing of Cd$_{1-x}$Zn$_x$S nanoparticles dispersed in oxide glass host containing 20% ZnO suggested a change in the stoichiometry (x) in the nanoparticle [77]. A few monolayers of AlSb deposited on GaAs substrate using molecular beam epitaxy are found to self-assemble in the form of platelike quantum dots during annealing at 500 °C [83]. In addition to phonon confinement effects, sometimes compressive stresses also play a role in determining Raman lineshapes [84]. Nanopores of zeolites have also been used to capture nanoparticles of Se and Te [85]. Raman spectra showed evidence of trapping of either a molecular Se$_8$ or Te$_8$ or formation of an irregular array of chains and clusters depending on the size and connectivity of pores. The lifetime of phonons in nanocrystalline Si has also been measured and found to be more than that in amorphous Si [86].

As pointed out earlier, in most of the systems the optical phonon frequency decreases as one moves away from the Brillouin zone center; that is, the optical phonon branch exhibits negative dispersion. In this context, thorium oxide is a unique system, whose optical phonon branch splits into two components; one exhibits a negative dispersion with $\Delta\omega = -50$ cm^{-1}, while the other undergoes a positive dispersion of $\Delta\omega = +160$ cm^{-1} [87]. For nanocrystalline thorium oxide both the branches are expected to contribute to the Raman lineshape. Recently, Raman spectra of nanocrystalline ThO$_2$ have been reported, which are found to be less asymmetric as compared to other crystals [88]. This is attributed to the broadening arising on the left and the right side of the peak from the contributions from branches of the dispersion curve with negative and positive dispersions, respectively.

In addition to the confined optic phonons, the presence of surface phonons in the Raman spectra of nanostructured materials has been reported in a number of systems [72, 89–91]. Surface phonons are expected to have frequencies between TO and LO phonons [72]. As the fraction of surface atoms increases as the grain size of a nanostructured material reduces, the surface phonons are observed with noticeable intensity for small size particles. The dependence of surface phonon frequency on the dielectric constant of the surrounding medium has also been examined [90]. In the nanoparticles of mixed crystals such as CdS$_x$Se$_{1-x}$, two surface phonons, one each of CdSe-like and CdS-like, have been reported [89].

Porous-silicon (p-Si), obtained from electrochemical etching of Si [92], has been a subject of considerable interest in view of its efficient photo- and electroluminescence at ambient temperature [93]. The pore diameter and consequently the size of interconnected Si-nanostructure depends on the electrochemical conditions [94]. Raman spectrum of p-Si consists of an asymmetrically broadened F$_{2g}$ phonon line characteristic of nanocrystalline Si and an overlapping broad peak at 480 cm^{-1} associated with amorphous Si [95, 96]. Fitting of the Raman spectrum to a confined phonon lineshape has frequently been carried out to estimate the average particle size [97]. Confined phonons of p-Si have been found to be responsible for the photoluminescence arising from radiative recombination of carriers across the indirect transition [98] similar to that found in crystalline Si.

As mentioned earlier, if the phonon spectrum of the particle overlaps significantly with that of the surrounding medium, phonons of the particles can propagate into the surrounding medium. In such cases a strong confinement model of the Gaussian type is not expected to be satisfactory. This was indeed found to be true [99] in the case of nanocrystalline diamond particles surrounded by amorphous-carbon region. Figure 10 shows the Raman spectrum of nanocrystalline diamond embedded in amorphous-carbon matrix. The observed linewidth was found to be much more than expected for a Gaussian confinement model. In order to understand these results, an alternate confinement model was proposed, which took into account the reflection of the phonon from the dielectric/elastic boundary of the particle. This leads to the existence of a
Figure 10. Raman spectrum of 26-nm diamond particles embedded in amorphous-carbon host. The continuous curve is the calculated spectrum based on the discrete model of phonon confinement. standing wave pattern in the particle with phonon wavevector sampling the Brillouin zone at discrete points $q_n = nQ_B/N$ $(1 \leq n \leq N)$, where Na is the size of the particle. The intensities I_n from the discrete phonons $\omega(q_n)$ were taken to vary according to a power law $I_n \sim b^n$ $(b < 1)$. The discrete model of the phonon confinement yielded a satisfactory fit to the experimental phonon lineshape.

In order to probe the changes in the electron-phonon interaction, resonance Raman scattering from confined optical phonons has been investigated in a number of systems. Effect of valence band mixing, arising from the degeneracy at Γ point in the Brillouin zone of zinc-blende semiconductors, on the electron phonon coupling has been studied [100] in GaP nanoparticles. Surface phonons with angular momentum $l = 2$ were found to participate in the resonance Raman scattering, while in another study [101] only the transitions with $l = 0, 2$ have been argued to contribute to the resonance Raman scattering. In addition to the LO phonons, zone-boundary TO phonons and their overtones have also been observed [102] in the nanoparticles of indirect gap semiconductor AgBr under resonant conditions. Using a phenomenological model, the ratio of intensities of the overtone and the fundamental Raman spectra have been analyzed [103] and the results suggested that electron-phonon coupling decreased as the particle size reduced. Interference effects in the resonance Raman efficiency profile [104] of 1- and 2-LO confined phonons in $Cd_{1-x}Zn_xS$ mixed crystal nanoparticles, arising from a nonresonant contribution to the polarizability, have also been reported. A detailed theory [105] of the one-phonon resonance Raman scattering from spherical nanoparticles has shown that in the dipole approximation, only $l = 0$ phonon modes couple to the photon. On the other hand, in the electric quadrupole approximation $l = 1$ phonon modes can be excited and their polarizability amplitude is proportional to the wavevector of the photon.

In most of the analyses of the phonon lineshapes, the bulk phonon dispersion curves have been assumed to be still applicable. However, this is not guaranteed for very small particles. Recent studies have shown that use of bulk phonon dispersion in Gaussian confinement model gives a good agreement for 6-nm CdS particle; on the other hand, for 1.6-nm particles the predicted lineshape is more asymmetric (Fig. 11) than that observed [106]. This disagreement has been attributed to the inapplicability of the bulk phonon dispersion curves. It may be pointed out that the phonon density of states (DOS) of nanocrystalline iron [107] measured using neutron scattering exhibits smearing of sharp features and broadening on both low- and high-frequency side as compared to the bulk. Molecular dynamics simulations show that the increased density of states at low energies arises from the vibrations of atoms at surface/grain boundaries [108], whereas the increase in the DOS at high frequencies has been attributed to shortening of bond length [109] and lifetime broadening [110] due to anharmonic effects.

4. ACOUSTIC PHONONS

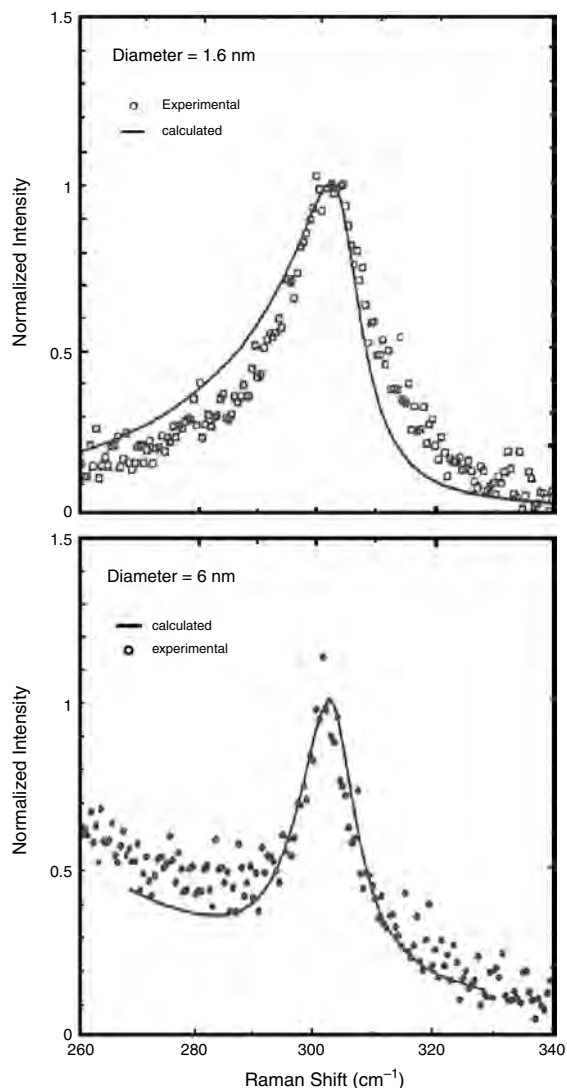
Similar to the optical phonons, the acoustic phonons also get confined within the particles. In the elastic continuum limit, the confinement of long-wavelength acoustic phonons


Figure 11. Raman spectra of CdS nanoparticles of diameter 1.6 and 6 nm. The disagreement of the calculated lineshape and the data for the 1.6-nm particles suggests inapplicability of bulk phonon dispersion curves. Reprinted with permission from [106], P. Nandakumar et al., *Physica E* 11, 377 (2001). © 2001, Elsevier Science.

(sound waves) leads to the emergence of discrete modes of particle which depend on the elastic properties through the longitudinal and transverse sound velocities [111]. These are spheroidal and torsional modes of the particle and their frequencies depend on the angular momentum associated with the vibration. We now briefly describe the procedure to obtain the frequencies of these modes.

4.1. Vibrational Modes of a Small Particle

By considering a spherical particle to be a homogeneous elastic body, its free vibrations can be obtained by solving the equation of motion [111–113],

$$\rho \partial^2 D/\partial t^2 = (\lambda + \mu)\nabla(\nabla \cdot D) + \mu\nabla^2 D \qquad (16)$$

where D is the displacement, ρ is the density, and λ and μ are Lame's constants. The solutions are obtained by introducing scalar and vector potentials and by using appropriate boundary conditions for spheroidal and torsional modes. The eigenvalue equation for the spheroidal modes is [111]

$$2[\eta^2 + (l-1)(l+2)\{\eta j_{l+1}(\eta)/j_l(\eta) - (l+1)\}]$$
$$\times \xi j_{l+1}(\xi)/j_l(\xi) - \tfrac{1}{2}\eta^4 + (l-1)(2l+1)\eta^2$$
$$+ \{\eta^2 - 2l(l-1)(l+2)\}\eta j_{l+1}(\eta)/j_l(\eta) = 0 \quad (17)$$

where l is the angular momentum, $\eta = \omega R/c_t$ and $\xi = \eta c_t/c_l$ are dimensionless variables, ω is the spheroidal mode frequency, R is the radius of the particle, and c_t and c_l are the transverse and longitudinal sound velocities, respectively. $j_l(\eta)$ is the spherical Bessel function of the first kind. The angular momentum quantum number l can take values $0, 1, 2, \ldots$. The eigenvalue equation for torsional modes is [114]

$$j_{l+1}(\eta) - \frac{(l-1)}{\eta} j_l(\eta) = 0 \quad \text{for } l \geq 1 \quad (18)$$

Solving these equations for discrete values of l results in a set of eigenvalues for each l, labeled as $\eta^S_{(l,n)}$ and $\eta^T_{(l,n)}$ for spheroidal and torsional modes, respectively. The index n represents the branch number. It may be mentioned that $l = 0$ torsional mode has null displacement. In addition, the eigenvalues of the torsional modes do not depend on the material, whereas those of spheroidal modes are completely determined by the ratio c_l/c_t. The eigenvalues of these modes have been reported for many materials with widely different values of the velocity ratio, such as 1.54 ($MgAl_2O_4$) [115], 2.00 (Se) [38], 2.28 (CdS) [116, 114], 2.32 (CdSe) [117], 2.51 (Pb) [111], and 2.77 (In) [111]. The lowest eigenvalues for $n = 0$ for both spheroidal and torsional modes correspond to the surface modes. These modes have large amplitude near the surface. The subsequent eigenvalues ($n \geq 1$) correspond to the inner modes. These discrete modes for different values of l are essentially similar to the acoustic phonons at discrete q-points in the Brillouin zone given by $\pi(l+\tfrac{1}{2})/R$ up to a maximum value π/a at the zone boundary [111]. These modes modify the density of states of the bulk [118] and have been argued to be responsible for excess specific heat of small particles at low temperatures [119, 120].

The symmetries of the particle vibrations correspond to the irreducible representations of the rotation inversion group O(3) of the sphere. The spheroidal modes transform according to the irreducible representations $D_1^g, D_2^u, D_3^g, \ldots$ [121]. The subscripts represent the angular momentum, and the superscripts g and u imply symmetry and antisymmetry with respect to inversion. In addition, the components of electric dipole moment transform according to D_1^u. On the other hand, the components of the symmetric polarizability tensor for Raman scattering will transform according to the irreducible representations resulting from the symmetric product $[D_1^u \times D_1^u]_{\text{sym}} = D_0^g + D_2^g$. Therefore the only allowed Raman active modes are the spherical mode D_0^g and the quadrupolar mode D_2^g. The torsional modes are not Raman active [121]. This is different from the assignment by other researchers [114, 122] based only on the parity of the wavefunctions, where all spheroidal modes with even l and all torsional modes of odd l were argued to be Raman active.

In addition to the elastic continuum model, a microscopic lattice dynamical calculation of confined acoustic phonons in nanocrystalline Si has been carried out [123]. For this the bond polarizability model within the partial density approximation has been used, similar to the confined optical phonon calculation [29]. The disagreement of the calculated confined acoustic phonon frequencies with the experimental data [124] was attributed to the fact that the calculations were carried out for free Si particles while the data was for Si nanoparticles dispersed in SiO_2 matrix. On the other hand, studies of the effect of host matrix on the spheroidal mode frequencies [111, 125] suggest only marginal changes. In a recent formalism the linewidth of the confined acoustic phonon has also been taken into account by making the eigenvalue complex [126].

4.2. Low-Frequency Raman Scattering

The frequencies of the spheroidal and torsional modes can be calculated from the eigenvalues $\eta^S_{(l,n)}$ and $\eta^T_{(l,n)}$, respectively, as

$$\omega^S_{(l,n)} = \eta^S_{(l,n)} c_t/R \quad (19a)$$

and

$$\omega^T_{(l,n)} = \eta^T_{(l,n)} c_t/R. \quad (19b)$$

In order to express the vibrational frequencies in cm^{-1}, one can divide Eqs. (19) by the velocity of light in vacuum c. In most materials, for particles of diameter less than 10 nm, these frequencies lie in the range of 5 to 50 cm^{-1}. Hence it is possible to observe the modes, allowed by the selection rules, in the low-frequency Raman scattering. It is noteworthy that Brillouin spectroscopy is extensively used for probing the acoustic phonon branch close to the zone center in crystalline solids. The Brillouin shifts of the order of 1 cm^{-1} are conveniently measured by interferometric techniques using Fabry–Perot etalon. However, the range of confined acoustic phonon frequencies makes Brillouin spectroscopy unsuitable for this purpose. On the other hand, the particle modes were observed for the first time by Duval et al. [115] in the spinal ($MgAl_2O_4$) particles dispersed in oxide glass in the low-frequency Raman scattering. The inverse dependence of the mode frequencies on the particle size was also established experimentally. Subsequently, confined acoustic phonons have been reported in metal [127–129] and semiconductor [124, 130, 131] nanoparticles.

Often the assignment of the peaks observed in the low-frequency Raman spectrum in terms of angular momentum quantum number l and branch number n may be tricky and nonunique. In order to obtain unambiguous assignment, it is useful to know the size of the particle from independent measurements such as high-resolution transmission electron microscopy (HRTEM) [122], X-ray diffraction (XRD) [132], or small-angle X-ray scattering (SAXS) [117] and plot the observed mode frequencies as a function of inverse diameter along with the theoretically expected linear dependencies

[72, 114]. In addition, making a polarized measurement is useful in the assignment, as the spheroidal mode appears only in the polarized geometry while the quadrupolar mode occurs in both polarized and depolarized geometry.

Silver nanoparticles dispersed in different hosts such as alkali halides [128], soda-lime glass [129], SiO_2 [122, 127], and ZrO_2 [132] have been studied in great detail. Fuji et al. found the frequencies of Ag particles of sizes between 2 and 5 nm close to those expected for $l = 0$ and $l = 2$ spheroidal modes [122]. The strong Raman signal was attributed to resonance associated with localized surface plasmons. The growth of Ag nanoparticles in SiO_2 during isochronal annealing has been recently examined [127]. In view of its depolarized characteristics, the Raman peak was assigned to the $l=2$ quadrupolar mode. The average size thus estimated was found to be consistent with that obtained from the width of the surface plasmon absorption. Quadrupolar mode has been observed also for Ag nanoparticles dispersed in soda-lime glass [129]. Silver nanoparticles synthesized in ZrO_2 by annealing a polycrystalline pellet coated with Ag, at 1073 K exhibited as many as four peaks in the Raman spectra [132] which were assigned to the quadrupolar mode. These were interpreted as arising from a multimodal distribution of particle sizes ranging between 3.5 and 7 nm. However, the average particle diameters obtained from the width of the XRD peak and TEM were of the order of 23 nm. The quadrupolar mode frequency corresponding to such a large average size is much smaller and not expected to be observed in the low-frequency Raman spectrum. This makes their assignment to quadrupolar modes doubtful. The average size of gold clusters found in SiO_2 due to ion beam mixing and subsequent annealing has been estimated to be around 4 nm from low-frequency Raman scattering [133].

Semiconductor nanoparticles dispersed in oxide glass [77, 116, 134], SiO_2 [135], and GeO_2 [114] have been extensively studied. Many of these composites are synthesized by doping the glass by the semiconductor up to about 2% in the melt and rapidly cooling to room temperature. The solid solution thus formed is supersaturated and semiconductor nanoparticles nucleate and grow upon annealing the "semiconductor doped glass" above 500 °C [136]. Synthesis of composites in the form of thin films is carried out using the technique of co-sputtering. There have been several studies on commercial long-pass optical filters such as GG495, GG475, and RG630 from SCHOTT, which contain CdS_xSe_{1-x} mixed crystals dispersed in oxide glass [137]. In the early studies the lowest energy surface mode and the lowest energy breathing mode were identified in the Raman spectra [116]. The frequencies of these modes were found to decrease during annealing, suggesting growth of particles [117]. Figure 12 shows the dependence of spheroidal mode frequency and the estimated particle size on the annealing temperature in $Cd_{1-x}Zn_xS_{0.95}Se_{0.05}$ nanoparticles dispersed in oxide glass. During annealing the zinc concentration x in the nanoparticle was reported to increase, if the host glass contained ZnO as one of the constituents [77]. Some studies have revealed very large width of the confined acoustic phonon $\omega_{(2,2)}$ in semiconductor doped glass GG495 [134]. This has been attributed to the existence of a log-normal particle size distribution. In addition, resonance enhancement of the quadrupolar
Figure 12. Dependence of confined acoustic phonon frequencies (a) and average particle size (b) of $CdS_{1-x}Se_x$ nanoparticles dispersed in borosilicate glass (GG475) on annealing temperature. Symbols '•' and 'Δ' represent the corresponding values for the unannealed filter. Reprinted with permission from [77], M. Rajalakshmi et al., *J. Phys.: Condens. Matter* 9, 9745 (1997). © 1997, IOP Publishing.

mode was found for excitation with green wavelength but not with blue line. For CdS nanoparticles dispersed in GeO_2 glass, a linear dependence of confined phonon frequencies on inverse diameter has been reported [114]. From this analysis the mode was identified as the $l = 0$ spheroidal mode. In addition to the confined acoustic phonons, another broad peak called "boson peak" arising from the glassy host has been observed in the low-frequency Raman spectra of semiconductor doped glasses [72]. Confined acoustic phonons have also been reported in selenium nanoparticles dispersed in a polymer host [38].

5. SUMMARY

In this chapter we have examined the consequences of confinement of the optical and acoustic phonons within a grain of nanostructured materials on the vibrational spectra. These are the shift and asymmetric broadening of the optical phonon lineshape and the appearance of spheroidal and quadrupolar modes of the nanoparticle in the low-frequency Raman spectra. Among the confined acoustic phonons, only the spherical mode with angular momentum $l = 0$ and quadrupolar mode with $l = 2$ are Raman active. The inverse dependence of the particle mode frequencies on its diameter is useful as a secondary method for the estimation of particle size. Changes in the optical phonon Raman lineshape arise from the contribution of phonon with finite wavevector whose magnitude is of the order of inverse diameter of the

grain. Noticeable differences in the spectra are found only when the particle/grain size is smaller than about 20 lattice parameters. Furthermore, the effect of confinement is least for 1D confinement and maximum for 3D confinement. For very small grain size the phenomenological models that use the bulk phonon dispersion curves as inputs fail because for these sizes, phonon density of states differs significantly from that of the bulk. Detailed theoretical studies are required to obtain a full understanding of the vibrational spectra of very small size particles.

GLOSSARY

Acoustic phonons   Phonons created by atoms vibrating in phase with each other.

Anharmonic effects   Effects such as thermal expansion, arising from non-parabolic nature of interaction potential between atoms. Parabolic atomic potential leads to harmonic atomic vibrations.

Brillouin scattering   Inelastic scattering of photons by acoustic phonons in a solid.

Brillouin zone   Unit cell formed in the reciprocal space by reciprocal lattice vectors.

Carbon nanotube   A graphene layer rolled up into a tube of diameter of the order of a few nanometers and length several micrometer.

Chiral vector   A vector formed from the superposition of integral multiples of unit vectors of a 2D-hexagonal plane of graphite. This vector is perpendicular to the axis of the carbon nano-tube, and its magnitude determines the circumference of the tube.

Dispersion curve   Plot of phonon frequency versus wavevector for a phonon of specific symmetry.

Long-pass filter   An optical filter that allows light longer than a given wavelength to pass through.

Nanowire   Wire/rod of a few nanometers diameter and several micrometer length.

Optical phonon   Phonons in the high frequency region created by atoms in a crystal vibrating out-of-phase with each other.

Phonon   Quantum of atomic vibrations in crystalline solids.

Quantum dot   A small particle surrounded by vacuum or a material of larger band gap, capable of exhibiting effects of quantum mechanical confinement of charge carriers.

Quantum well   A thin layer of a material of smaller band gap sandwiched between adjacent layers of another material with larger band gap, capable of exhibiting effects of quantum mechanical confinement of charge carriers.

Raman scattering   Inelastic scattering of photons by atomic vibrations or other elementary excitations in solids/molecules.

Resonance Raman scattering   Enhancement of efficiency of Raman scattering when the incident photon energy is close to one of the electronic transitions in a solid/molecule.

Scattering vector   Wavevector transferred in the scattering of light by elementary excitations.

Superlattice   A periodic arrangement formed by depositing thin alternate layers of two materials on a substrate.

Wavevector   A vector in the direction of propagation of phonon with a magnitude that is inverse of wavelength of the phonon.

Phonons in GaN-AlN Nanostructures

J. Frandon, J. Gleize, M. A. Renucci

Université Paul Sabatier, Toulouse, France

CONTENTS

1. INTRODUCTION

The scope of this chapter is the review of recent experimental studies of phonons in nanostructures made of nitride semiconductors with an hexagonal structure. First let us recall some basic definitions. A quantum well (QW) is described as a thin layer exhibiting semiconducting properties, located between a couple of layers made of another semiconductor and playing the role of barriers. Indeed, the electronic bandgap energy in the latter is higher than its counterpart in the former, thus favoring carrier confinement and electrical transport inside the well. Single or multiple QW structures can be fabricated as well as superlattices (SL) which are periodic arrays of QWs. A quantum dot (QD) is an island made of a given semiconductor embedded in another semiconductor acting as barrier. It is usually characterized by a pyramidal shape and a small height (typically 5 nm). The samples are periodic stackings of planes containing the QDs, which can be self-assembled by the effect of vertical correlation.

The purpose of the extensive work recently devoted to GaN-AlN or GaN-AlGaN nanostructures is the development of new devices, particularly laser diodes emitting in the ultraviolet range. Their light emission is expected to be much stronger than from heterostructures made of GaN and AlN (or AlGaN) thick layers grown in the nineties, due to the low-dimensional geometry of nanostructures. In addition, the crystallographic structure of nitride semiconductors is responsible for their piezoelectric properties, generating very strong electric fields in strained nanostructures; as a result, the emission is significantly red-shifted with respect to the absorption edge by the so-called confined quantum Stark effect, and the luminescence can be tuned within a wide interval from the visible range up to the near ultraviolet.

Such high-performance devices, grown using techniques recently developed, are currently fabricated and are already on the market. However, the knowledge of the structural and optical properties involved in the light emission process must be improved. So numerous experimental studies have been recently devoted to such nanostructures. Among the various techniques used for this purpose, Raman spectroscopy is known to be a powerful probe of vibrational modes (or phonons) in semiconductor materials. Measurements of phonon frequencies in nanostructures give the opportunity of determining the strain state inside their constituent layers; these results are key data, directly related to the light emission of the device. This kind of experiment is rather simple, nondestructive, and usually needs no special sample preparation. The size of the optical probe can be very small (as low as 1 μm). In addition, this technique is accurate and very reproducible, allowing measurements of the phonon energy within an uncertainty lower than 1 cm^{-1} (about 0.1 meV).

This chapter is organized as follows: basic concepts concerning phonons in bulk nitride semiconductors and GaN-based nanostructures, as well as Raman scattering, are given in Section 1. Section 2 is devoted to the Raman studies on GaN-AlN (or GaN-GaAlN) QW structures and SLs, in nonresonant and resonant conditions. Section 3 of this chapter deals mostly with phonons in QDs stackings.

2. RAMAN SCATTERING IN HEXAGONAL CRYSTALS AND NANOSTRUCTURES

2.1. Phonons in "Bulk" GaN-Like Semiconductors

Only GaN, AlN, or AlGaN semiconductors with wurtzite structure will be considered in the present article. Before dealing with nanostructures, we must recall briefly the vibrational properties of bulk crystals, which were recently

reviewed by Frandon et al. [1]. In fact, almost all the samples studied up until now are layers grown on a substrate and on a buffer layer, but they behave usually as "bulk" materials due to their large thickness. Hexagonal nitride crystals belong to the space group C_{6v}^4. The unit cell contains two nitrogen atoms and two Ga or Al atoms [2]. The lattice constants a and c of GaN [3] and AlN [4] are given in Table 1. In the following, the c axis of the hexagonal structure will be chosen as the z axis. Let us recall briefly how the symmetry of Raman active modes are derived in this structure. Here we are only interested in the zone center phonons, that is, characterized by a vanishing $\mathbf{q}$ wavevector. The 12-dimensional representation of the atomic motions in the unit cell can be reduced into irreducible representations of the C_{6v} group. Besides the acoustic modes and the "silent" (inactive) B_1 optic phonons, one obtains four optical modes, two nonpolar (infrared inactive), and two polar (both Raman and infrared active) phonons [5]. The nonpolar phonons exhibit the E_2 symmetry, corresponding to atomic motions perpendicular to the z axis. One of them may be observed at low frequency. The other, denoted by E_2 (high), shows up at a higher frequency with a high intensity in Raman spectra recorded far from resonant conditions. In addition, it cannot couple to plasmons and does not display any angular dispersion, on account of its nonpolar character. Therefore, it is frequently used as a probe of structural properties in the Raman characterization of nitride semiconductors.

Polar optic phonons are characterized by their A_1 or E_1 symmetries, related to atomic motions, parallel or normal to the z axis, respectively. They may be either longitudinal or transverse (LO or TO). In these ionic crystals, the long-range forces associated with the strong macroscopic electric field of longitudinal phonons are responsible for an important LO-TO splitting (202 cm^{-1} for GaN). Moreover, due to the uniaxial properties of these crystals, the LO and one of the TO phonons are extraordinary modes, thus exhibiting an angular dispersion; their frequency varies with the angle θ between the phonon wavevector $\mathbf{q}$ and the z axis [6]. This variation range corresponds to the A_1-E_1 splitting governed by short-range interatomic forces. However, it should be noted that this variation (27 cm^{-1} for TO phonons of GaN) is much lower than the LO-TO splitting. The symmetry of the $\mathbf{q} = 0$ extraordinary modes depends on the value of θ; for a vanishing angle, the LO and TO phonons exhibit the A_1 and E_1 symmetry, respectively, and the reverse is found for $\theta = 90°$. For intermediate $\mathbf{q}$ values, the extraordinary modes called quasi-LO and TO (QLO and QTO), have a mixed symmetry. Finally, the ordinary TO phonon is nondispersive and keeps the E_1 symmetry when varying the angle θ. Table 2 gives the frequencies of the $\mathbf{q} = 0$ phonons for relaxed "bulk" GaN and AlN [7, 8].

Note: The notation of phonons is that used in [5].

Note that $\mathbf{q} \neq 0$ phonons, usually not involved in first-order Raman scattering, must be invoked in some cases, for example, when the translational symmetry is lost in the sample under study. For hexagonal GaN, the phonon dispersion $\omega(\mathbf{q})$, which is quite distinct from the angular dispersion previously discussed, has been calculated in the high-symmetry directions of the Brillouin zone [9, 10] and have been recently determined by X-ray inelastic scattering [11]. A scatter of results is observed, but the dispersion of published data is always found much lower for the branch starting from the E_2 (high) phonon than for its LO counterpart, for example. We must keep in mind this difference when effects of phonon confinement in the nanostructures will be considered later.

For bulk-disordered AlGaN solid solutions, the evolution of phonon frequencies versus their aluminum content is characterized either by a "two-mode" or a "one-mode" behavior, depending on the symmetry of the vibrational mode. In the first case, corresponding to the E_2 (high) optic phonon for example, the GaN- and AlN-like oscillators exhibit strengths of comparable orders of magnitude in most parts of the composition range. In the second case, observed for A_1 (LO) and E_1 (LO) phonons, the oscillator strength is strongly transferred from one to the other type of oscillators, thus allowing the observation of one mode only in the whole composition range of the alloy [12–16]. Evidence for two-mode behavior of the E_1 (TO) mode has been given from infrared measurements [17]. In contrast, the case of the A_1 (TO) phonon seems to be more complicated [16].

As previously mentioned, most samples are thick layers grown on a substrate (sapphire, SiC, or Si) and on a buffer layer (GaN or AlN). Due to the lattice mismatch and to the different expansion coefficients of materials constituting the nanostructure, the layers are usually submitted to a strong biaxial stress acting in the plane normal to the z axis of the hexagonal crystal. The induced strains ε_{zz} and ε_{xx}, respectively parallel and perpendicular to the z axis, modify the phonon frequencies in the layers. For the mode λ, the corresponding frequency shift with respect to its value in the relaxed material is given by the following linear equation

$$\delta\omega_\lambda = 2\, a_\lambda \varepsilon_{xx} + b_\lambda \varepsilon_{zz} \qquad (1)$$

where a_λ and b_λ are the deformation potentials of the phonon λ. The knowledge of these parameters is of crucial importance for evaluating the strains in the thick layers as well as in the nanostructures. For GaN, the phonon deformation potentials were measured [18–19] and calculated [20–21], but they are more controversial for AlN [22–25]. Some of the calculated and experimental values of phonon

deformation potentials are given for wurtzite GaN and AlN in Table 3.

When the material is under biaxial stress σ^B ($\sigma^B > 0$ for compressive stress), one can also use the Raman stress coefficient, defined by

$$K^B = \frac{d\omega}{d\sigma^B} \tag{2}$$

If Hooke's law is obeyed, K^B can be expressed using the deformation potentials and the elastic constants only. As a rule, the observed frequency shift of phonons is positive (resp., negative) if the material is under compressive (resp., tensile) biaxial stress.

2.2. Phonons in GaN-Based Nanostructures

Let us consider nanostructures made of alternate layers exhibiting the wurtzite structure, grown along the z axis. Their structural and optical properties have been extensively studied during recent years. Under adequate growth conditions, the Stranski–Krastanov mechanism of strain relaxation of GaN on AlN leads to the growth of strained GaN islands on very thin (two monolayers thick) GaN wetting layers, embedded in the AlN barriers, leading to QD structures [26]. Different experimental conditions allow a two-dimensional growth, thus leading to strained QW structures or to SLs; the internal strain of the layers depends on numerous factors, including the nature of the underlying buffer layer and the thicknesses of the layers in the structure. Obviously, as a result of internal strains, the phonons from the wells and barriers will be shifted in the Raman spectra according to Eq. (1). The same equation may also be tentatively applied to QDs, assuming a nearly biaxial stress, in consideration of their pyramidal shape and their lateral size usually about 10 times larger than their height.

But new vibration modes must be considered in nanostructures. Some phonons can be confined inside one type of layer. Their properties have been extensively studied in the SLs made of III–V cubic semiconductors, such as GaAs and AlAs [27]. Confined vibrational modes are oscillations located in one type of layer and characterized by an effective wavevector q_z. The latter is quantized, due to boundary conditions at the interfaces with the adjacent layers

$$q_z = n \cdot \frac{\pi}{d_1} \tag{3}$$

where n is an integer and d_1 is the layer thickness. The frequencies of confined modes can be deduced from the LO phonon dispersion $\omega(\mathbf{q})$ of the bulk material along the z direction; they correspond to the discrete q_z values calculated using Eq. (3). If the top of the branch of the LO branch is at the zone center Γ, as for the LO phonon of GaN, frequency shifts towards lower frequencies are expected and can be measured, specially for very thin (a few nanometers thick) layers. On the other hand, confinement effects should be negligible for the E_2 (high) phonon, due to the weak dispersion of the corresponding branch in the Brillouin zone.

Other phonons specific to the SLs are the "folded" acoustic phonons. Indeed, if the dispersion of acoustic branches is similar in both materials, that is, when their sound velocities are not too different, acoustic waves can propagate through the whole nanostructure. Folding of the acoustic phonon branches of the constituent layers into the reduced Brillouin zone of the SL generate new vibrational modes, which are characteristic of the periodicity $d = d_1 + d_2$ of the SL (d_1 and d_2 stand for the thicknesses of wells and barriers, respectively). They may show up as doublets located in the low-frequency range of the Raman spectra. The average frequencies of these doublets are given by [27]

$$\omega_n = n \cdot \frac{2\pi \cdot v}{d} \tag{4}$$

where n is an integer and v is an average sound velocity in the nanostructure calculated from the sound velocities v_1

and v_2 in the wells and barriers of the SL according to

$$v = \frac{v_1 \cdot v_2}{(1 - \alpha)v_2 + \alpha v_1} \tag{5}$$

where $\alpha = d_2/(d_1 + d_2)$. The frequency difference between the components of each doublet depends on the phonon wavevector q_z

$$\Delta\omega = 2 \, q_z \cdot v \tag{6}$$

The value of q_z is determined by the experimental geometry of Raman scattering, as it will shown in the following section.

2.3. Experiments

In the following, the incident (resp., scattered) light is defined by its wavevector $\mathbf{k_i}$, its frequency ω_i, and its linear polarization $\mathbf{e_i}$ (resp., $\mathbf{k_S}$, ω_S and $\mathbf{e_S}$). The experimental configuration will be indicated by the usual Porto's notation $\mathbf{k_i}(\mathbf{e_i} \ \mathbf{e_S})\mathbf{k_S}$. For bulk crystals, conservation law between the initial and final states is obeyed both by the wavevector and the energy. In first-order Raman scattering, the wavevector $\mathbf{q}$ and the frequency ω of the phonon involved in the scattering process are given by

$$\mathbf{q} = \mathbf{k_i} - \mathbf{k_S} \tag{7}$$

and

$$\omega = \omega_i - \omega_S \tag{8}$$

According to Eqs. (7) and (8), $\mathbf{q}$ is completely defined by the experimental geometry and the laser energy. In the particular case of backscattering ($\mathbf{k_S} = -\mathbf{k_i}$), Eq. (7) can be written as

$$|\mathbf{q}| = 2|\mathbf{k_i}| = \frac{4\pi \cdot n}{\lambda_i} \tag{9}$$

where n is the refractive index of the material at the frequency ω_i, and λ_i is the wavelength of the incident light.

Most Raman spectra of GaN-AlN or GaN-AlGaN nanostructures reported in the literature have been recorded at room temperature. The simplest experiment is performed in a backscattering geometry along the growth axis z of the nanostructure, with polarizations of incident and scattered light either perpendicular or parallel, corresponding to the configurations $z(xy)\underline{z}$ or $z(xx)\underline{z}$, respectively. In the latter case, both E_2 and A_1 (LO) phonons are allowed. Moreover, a micro-Raman spectrometer, using a small laser spot whose diameter is lower than 1 μm, allows the achievement of other scattering conditions, particularly backscattering on the edge of the sample under study. In this configuration, the phonon wavevector $\mathbf{q}$ is perpendicular to the z axis and additional phonons can be evidenced. The selection rules for all the Raman active phonons in wurtzite materials are recalled in Table 4.

The excitation of Raman scattering is usually made using the monochromatic lines of an argon or krypton laser, either in the visible or ultraviolet range (from 3.41 eV to 3.80 eV). The experimental results strongly depend on the excitation energy. If the latter corresponds to the visible range, that is,

Table 4. Selection rules for phonons in wurtzite crystals.

Configuration	Allowed phonons
$z(xx)\underline{z}$	E_2, A_1 (LO)
$z(xy)\underline{z}$	E_2
$x(zz)\underline{x}$	A_1 (TO)
$x(yy)\underline{x}$	E_2, A_1 (TO)
$y(zy)\underline{x}$	E_1 (LO)

Note: The notation of phonons is that used in [5].

far from any electronic resonance, the dominant electron-phonon interaction is the "deformation potential" process and the nonpolar E_2 (high) optic phonon exhibits a scattering cross section much stronger than the other phonons, specially the A_1 (LO) mode also allowed in the $z(xx)\underline{z}$ configuration. Note that the Raman spectra usually contain features from the GaN QDs or QWs and from the barriers of the nanostructure, but also from the underlying thick buffer layer (usually GaN or AlN), due to the negligible optical absorption of the constituent layers in the visible range; thus an unambiguous assignment of phonons may prove difficult. However, the signature of the nanostructure itself can be obtained using a confocal set-up with a low depth of focus, as illustrated later.

On the other hand, a strong enhancement of Raman scattering by the polar LO phonon is observed under near resonant conditions, that is, if the energy of incident or/and scattered photons is close to an electronic transition energy, when the "forbidden" scattering process associated with the intraband Fröhlich electron-phonon interaction becomes dominant [28]. With the present materials, resonant conditions can be achieved in the ultraviolet range only; indeed the room temperature bandgap energy is about 3.4 eV and 6.1 eV for bulk GaN and AlN, respectively. The scattering cross section of the A_1 (LO) phonon can be enhanced by several orders of magnitude [29], thus allowing the signature of very small volumes inside the sample. However, it should be noted that the penetration depth of the incident light in the sample is strongly reduced under ultraviolet excitation, due to high optical absorption. In addition, an intense photoluminescence (PL) band may show up in the spectra, making an observation of faint Raman features superimposed on the PL signal very difficult.

3. PHONONS IN QUANTUM WELLS AND SUPERLATTICES

3.1. Nonresonant Raman Scattering: Signature of Wells and Barriers in Superlattices

When Raman experiments are performed far from resonant conditions, the signal coming from the nanostructure itself is rather weak; it can be easily measured only if the sample is thick enough (about 0.5 μm), due to the low-scattering cross section of GaN, and specially of AlN. Actually, this kind of research study is still scarce; the main motivation is to determine the nature of the vibrational modes in the SLs and to derive the built-in strain of the constituent layers.

The first Raman study of an SL with a wurtzite structure was published by Gleize et al. [30]. This structure was made of a hundred periods of undoped GaN wells and AlN barriers, with nominal thicknesses of 6.3 nm and 5.1 nm respectively, deposited by MBE on a thick AlN buffer layer and a sapphire substrate. The layer thicknesses were large enough for neglecting the frequency shift of phonons induced by confinement, specially for the E_2 mode. Micro-Raman spectra were recorded in backscattering geometry under various polarization configurations, under a 2.54 eV excitation, far from resonant conditions. Thanks to selection rules, most observed features could be unambiguously assigned to all optical phonons but the E_1 (LO), either from the underlying AlN buffer layer or from each type of SLs layers. Due to internal strains, phonons from wells and barriers were found significantly shifted with respect to their frequency in relaxed materials. Using the phonon deformation potentials of GaN, a biaxial stress of 6.3 GPa and an in-plane strain $\varepsilon_{xx} = -1.3\%$ were derived for the GaN layers of the SL from the measured shift of the E_2 (high) phonon. This strain is close to the value expected for a "free-standing" state of the present nanostructure. On the other hand, the measured frequency shifts of AlN phonons, actually larger than those of GaN phonons, could not be used to determine the internal strain in the barriers of the SL, because the corresponding deformation potentials were not known at this time. Note that a feature observed at 560 cm^{-1} in $x(yy)\bar{x}$ Raman spectra could not be associated to an A_1 (TO) phonon from strained GaN layers, although it obeyed the regular selection rules; it was thus tentatively assigned to an interface mode. Finally, micro-Raman spectra were also recorded from place to place on a bevel made by mechanical polishing of the nanostructure; the angle between the beveled surface and the (0001) plane was about 1°. The strain-induced shift of the E_2 (GaN) phonon was found higher in the deeper part of the SL than near the surface, giving evidence for a partial strain relaxation in the first layers of the structure.

Schubert et al. [31–32] performed other investigations combining Raman scattering and infrared ellipsometry experiments. The latter is an indirect technique for investigating the polar phonons, specially the E_1 (TO) phonon when a near normal incidence is used for the measurements. A standard calculation allows the reproduction of the experimental infrared spectrum; this model needs several fitting parameters, including the TO and LO phonon frequencies of the constituent materials, together with the concentration and mobilities (parallel and perpendicular to the z axis of the SL) of free carriers. The latter data must be introduced when the sample under study is doped, intentionally or not. Indeed, the free-carrier plasmon and the LO phonon, which are both longitudinal excitations, can couple together if their energies are close to each other, thus shifting in frequency the high frequency component of the coupled mode with respect to the uncoupled phonon [33]. In [32], eight GaN-AlGaN SLs, grown by MOVPE or by MBE on thick GaN layer and on sapphire, exhibiting typical layer thicknesses of 25 nm and various aluminum contents in the barriers ($0.08 < x < 1$), were compared. As expected, the strain-induced frequency shifts of the nonpolar E_2 phonon for each constituent layer, derived from Raman measurements, proved that GaN (resp., AlGaN) layers were

submitted to an internal compressive (resp., tensile) stress. A detailed discussion of the Raman data suggested that these SLs were in a free-standing state: both kinds of layers adopted a common in-plane lattice parameter, different from the one of the underlying thick GaN layer. The analysis of infrared ellipsometry measurements led to the determination of an electron concentration higher than 10^{18} cm^{-3} in the GaN layers of the SLs; these free carriers could originate from dislocation-activated donors or from the AlGaN layers. Moreover, the in-plane mobility introduced for fitting the infrared spectra was found higher than its out-of-plane counterpart: this result indicated a confinement of free carriers inside the wells along the z axis, the AlGaN layers of the SL acting as barriers for the free electrons as expected.

Another more recent article combining Raman and X-ray diffraction measurements [34] deals with a GaN-AlN SL grown on an AlN buffer layer and on a 6H-SiC substrate; the GaN wells were specially thin (1.5 nm) in this sample, compared to the AlN barriers (10 nm). The map of the reciprocal lattice, which was deduced from X-ray diffraction experiments, gave the average value of both lattice constants a and c of the whole SL. Figure 1 shows three micro-Raman spectra recorded in the $z(xx)\bar{z}$ configuration, when the laser spot was focused slightly higher and higher upon the surface of the sample. The variation of relative intensities of the experimental features made their assignment easy either to the SLs layers or to the underlying buffer layer, allowing the measurement of the strain-induced frequency shift of the E_2 (high) phonons from the SL. Combining all these data and taking into account the measured in-plane strain of GaN layers ($\varepsilon_{xx} = -2.35\%$) derived from *in-situ* RHEED experiments, both components of the biaxial strain of AlN and GaN layers could be determined. The out-of-plane strain ε_{zz} was found almost negligible for both types of layers, giving for the ratio $\varepsilon_{zz}/\varepsilon_{xx}$ a value quite different from that predicted from the simple elastic theory ($-2C_{13}/C_{33} = -0.51$). This difference is likely due to the large spontaneous and piezo-electric polarization effects which can significantly decrease this strain ratio in the hexagonal SL, as demonstrated in a calculation by Gleize et al. [35].

3.2. Resonant Raman Scattering: Signature of Single or Multiple QWs

The first resonant Raman study of single GaN QWs was published by Behr et al. [36]. In these samples grown by MOCVD directly on a sapphire substrate without any buffer layer, the wells lying between thick Ga$_{0.85}$Al$_{0.15}$N layers were 2 nm, 3 nm, or 4 nm thick. As expected, only the phonons from the alloy were evidenced when the excitation was achieved in the visible range, due to the negligible volume of the QW. However, when the 3.54 eV laser line was used for the excitation, that is, for an energy close to the estimated fundamental electronic transitions in the wider QWs, the resonance conditions were nearly fulfilled and Fröhlich-induced scattering by the GaN A_1 (LO) mode was favored. As can be shown in Figure 2, a Raman feature was observed at 732 cm^{-1} for the structures containing the 3nm- and 4nm-wide QWs. The origin of this feature could be unambiguously assigned to the single well; its measured frequency shift was negligible, because both confinement and strain
Figure 1. Micro-Raman spectra recorded in backscattering along the z axis, on a GaN (1.5 nm)-AlN (10 nm) SL grown on an AlN BL and a SiC substrate. The excitation was made at 2.33 eV. Spectra 1 to 3 were obtained by focusing farther and farther away from the surface of the sample. Modes from the SL and the BL are indicated by arrows. Asterisks mark phonons from the substrate. effects were probably weak in the well. In contrast, the LO feature was broadened and shifted towards higher frequencies for the 2 nm thick QW. This observation was explained by cation intermixing at the GaN-AlGaN interface, which could not be neglected in that case. Smoothing of interfaces likely due to poor growth conditions prevents the signature of confinement effects, which would induce an opposite frequency shift.
Figure 2. Resonant Raman spectra of GaN single QW with different widths embedded in $Al_{0.15}Ga_{0.85}N$ barriers, recorded under the 3.54 eV excitation. Reprinted with permission from [36], D. Behr et al., *Appl. Phys. Lett.* 70, 363 (1997). © 1997, American Institute of Physics.

Further resonant scattering experiments on single or multiple GaN-AlGaN QW structures will be reported in the following. Later Ten GaN QWs of 1.5 nm width, embedded in 5 nm wide $Ga_{0.89}Al_{0.11}N$ barriers and grown on a GaN buffer layer, have been investigated under various ultraviolet excitations [37]. In the present structure, the QWs were nearly relaxed, whereas the barriers were submitted to an internal compressive stress, due to the presence of the underlying buffer layer. As expected, first-order scattering by the A_1 (LO) phonons from GaN wells, favored by the Fröhlich interaction, was found strongly enhanced by electronic resonance in the incoming channel when excitation is achieved using the 3.54 eV laser line. Indeed, the energy of the incident photon was very close to the QWs' fundamental transition, as estimated using the simple model of independent square potential wells of finite height. In these experimental conditions, the second-order scattering by the LO phonons from the thick buffer layer was dominant. Under a 3.70 eV excitation, LO phonons from GaN wells were clearly evidenced in the second-order scattering signal, due to electronic resonance in the outgoing channel; weak contributions from the barriers were also evidenced. Similar features were also observed in third-order scattering under 3.80 eV excitation.

Another study performed in resonant conditions has been devoted to a collection of four different single GaN QWs separated by 10 nm thick $Ga_{0.83}Al_{0.17}N$ barriers and grown on a thick GaN buffer layer [38]; their thicknesses were 1 nm, 2 nm, 3 nm, and 4 nm (corresponding, respectively, to 4, 8, 12, 16 monolayers). The fundamental excitonic transitions in these wells were already determined from previous PL measurements performed at a low temperature. In this work, thick GaN and $Ga_{0.83}Al_{0.17}N$ layers were also investigated in the same experimental conditions for comparison with the structure under study. The Raman spectra recorded at room temperature in backscattering geometry are shown in Figure 3. The PL signature of the various wells was clearly observed in the spectra, thus accurately giving the energy of the fundamental transitions in the wells at room temperature. Under excitation at 3.53 eV, first-order scattering by GaN A_1 (LO) phonons confined in one of the wider QWs (3 nm) showed up in the spectra, enhanced by electronic resonance in the outgoing channel; no similar observation could be achieved on the thick GaN layer used as reference, since the excitation was too far from resonance in the bulk material. The measured frequency was close to 734 cm^{-1}, corresponding to relaxed GaN, because the well involved was almost unstrained in the nanostructure. In this case, the Raman signature of the 3 nm-thick well, whose PL signal was located at 3.43 eV, close to the observed Raman feature, could be obtained. On the other hand, when the 3.70 eV excitation was used, a first-order Raman feature peaking at higher frequency (775 cm^{-1}) and a weak contribution at lower frequency was observed. They are clearly related to phonons of the $Ga_{0.83}Al_{0.17}N$ barriers and of the GaN wells, respectively. Scattering by vibrational modes of both layers requires an extended intermediate electronic state of the QW with a significant penetration into the barriers. This delocalization implies high-lying states whose energy is close to the bandgap of the alloy. Resonance most likely
Figure 3. Resonant Raman spectra of four single GaN QW in $Al_{0.17}Ga_{0.83}N$ barriers, recorded using 3.53 eV and 3.70 eV excitations. The thicknesses of these QWs were 4, 8, 12, and 16 monolayers. Arrows mark the PL signal from the QWs. Reprinted with permission from [38], F. Demangeot, *Phys. Stat. Sol.(B)* 216, 799 (1999). © 1999, Wiley-VCH.

occurred in the incoming channel, as the incident photon energy was almost tuned on the bandgap of the alloy. Moreover, the Raman signal was found just superimposed on the PL signal from the thinner (1 nm) QW, centered at 3.60 eV; no similar Raman features could be observed with thick GaN or $Ga_{0.83}Al_{0.17}N$ thick layers. The signal was thus likely enhanced by a double resonance effect, as the second intermediate state involved in the Raman process was a bound electronic state localized in the 1 nm-thick QW.

3.3. Calculations of Lattice-Dynamical Properties of Wurtzite Nanostructures

Komirenko et al. [39] first investigated the extraordinary polar phonons of wurtzite single QWs in the framework of a dielectric continuum model. The anisotropy of the materials was taken into account by introducing both components $\varepsilon_\perp(\omega)$ and $\varepsilon_z(\omega)$ of the frequency-dependant dielectric tensor of the constituent materials; the latter involve the frequencies of A_1 and E_1 (LO and TO) phonons, polarized along the z axis and in the (xOy) plane, respectively. The electrostatic boundary conditions on the interfaces, together with the assumption of a scalar potential vanishing far from the wells, were used. For a long wavelength phonon characterized by the in-plane $q_\perp$ wavevector, the angular dispersion can be deduced from the following equation:

$$\varepsilon_\perp(\omega) \cdot q_\perp^2 + \varepsilon_z(\omega) \cdot q_z^2 = 0 \qquad (10)$$

where q_z is the z component of an effective wavevector. Depending on the sign of the product $\varepsilon_\perp \cdot \varepsilon_z$ in each medium, q_z is found either real or imaginary, leading to linear superposition of oscillating or decaying solutions, respectively. Therefore, phonons could be classified according to their localization. Confined modes are mainly located inside

the well but can penetrate significantly into the surrounding layers, interface modes decay exponentially from the interfaces in both types of layers, and propagating modes oscillate in the whole structure. Their frequency variation versus the product $q_\perp \cdot d$ was given for a GaN well of width d embedded in infinite barriers made of AlN or of $Ga_{0.85}Al_{0.15}N$. Note that in another article, the same authors extended their study to the calculation of scattering rates by the Fröhlich electron-phonon interaction in QW structures [40].

Very few investigations of lattice dynamics in hexagonal superlattices by *ab initio* calculations have been published up until now. Wagner et al. [41] computed the structural, dielectric, and lattice-dynamical properties of short-period hexagonal GaN-AlN SLs, which were compared to their cubic counterparts. In this calculation, the widths of barriers as well as of QWs were as low as two monolayers. Both types of layers were assumed to be pseudomorphically strained on the same in-plane lattice constant; the latter could be either that of relaxed constituent materials (AlN or GaN) or an average value corresponding to an elastically relaxed SL. The goal of this work was to study the angular dispersion of phonons in the structures. The frequency ω of the zone center phonons was calculated as a function of θ, the tilt angle of the phonon wavevector with respect to the z axis, within the framework of the density-functional perturbation theory. Most calculated modes were assigned either to confined phonons or to interface phonons. The atoms involved in each vibration mode, together with the strength of the associated dynamical polarization, were also given. The angular dispersion of these modes is shown in Figure 4 for a GaN-AlN wurtzite SL in several strain states. Actually, only a few differences were evidenced in the angular dispersions of cubic and hexagonal SLs. In both cases, for an increasing in-plane lattice constant, all modes decrease in frequency, except the folded TA modes; the downward shift was found more pronounced for LO phonons than for the TO phonons. The only remarkable difference affects the TO modes confined in the GaN layers of the hexagonal SL, spreading in a narrower range than their counterparts in the cubic nanostructure.

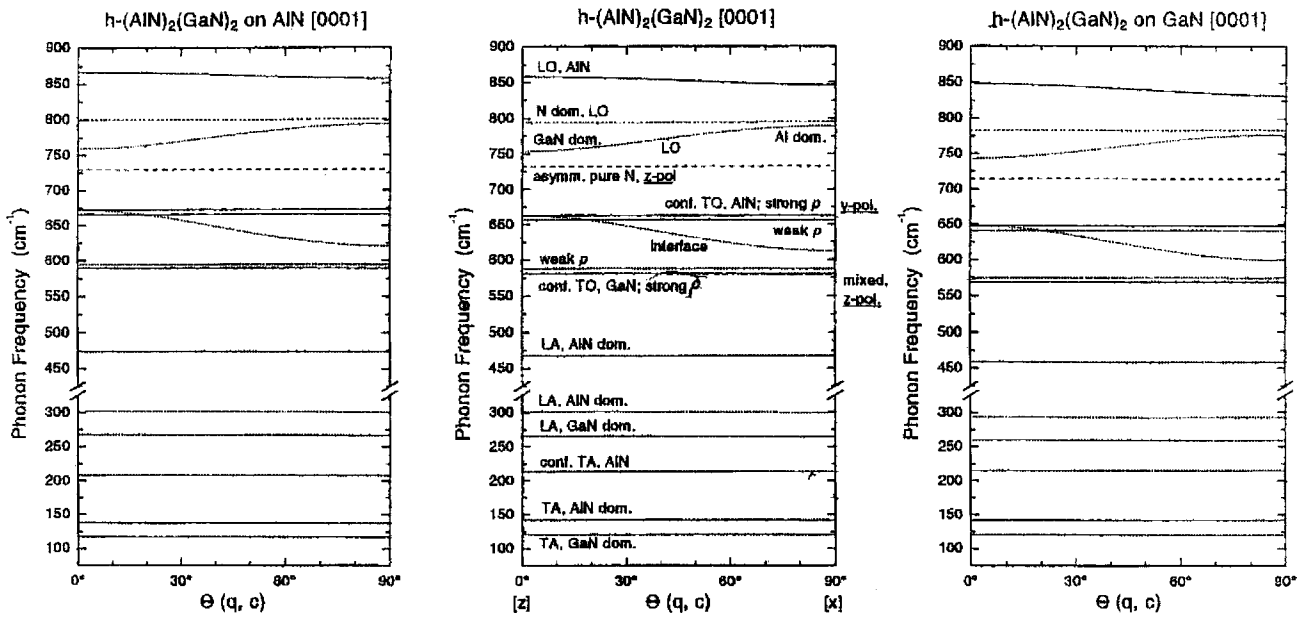
However, the latter results cannot be easily checked. Indeed, experimental studies are usually performed on nanostructures with much larger periods. An alternative calculation based on the dielectric continuum model, first developed in [39] for the GaN QWs, was applied to wurtzite SLs with more realistic periods [42–44]. Within this framework, the vibrational modes were described by the dynamical polarization associated with the atomic motions in each type of layer. The Maxwell equations, the electric boundary conditions at each interface, and the Bloch's theorem, taking into account the SLs periodicity, were used together with the $\mathbf{q} = 0$ phonon frequencies of the two types of layers in the strain state actually achieved in the SL. Note that the phonon dispersion $\omega(\mathbf{q})$ of the bulk constituents was ignored in this model. For GaN-AlN SLs, this calculation predicted two types of polar phonons characterized by an angular dispersion $\omega(\theta)$. The first ones were the interface modes which have been already found for SLs of cubic structure; the corresponding amplitude of atomic motions decreases from the interface in both types of layers. Their


Figure 4. Angular dispersion of zone-center phonons of an ultra-thin hexagonal GaN (0.5 nm)-AlN (0.5 nm) SL calculated in different strain situations. From (l)–(r), the results are given for SLs pseudomorphic on AlN, elastically relaxed on an average in-plane lattice constant, and pseudomorphic on GaN. Reprinted with permission from [41], J. M. Wagner et al., *IPAP Conference Series* 1, 669 (2000). © 2000, Institute of Pure and Applied Physics.

dispersion is related to the anisotropy of the nanostructure. In contrast, another type of phonon, the quasi-confined modes, exhibit an angular dispersion originating from the anisotropy of the constituent materials. Indeed, the frequencies of the A_1 and E_1 phonons of GaN and AlN, in the TO as well in the LO range, are the limits of their spectral regions; the corresponding intervals are finite for wurtzite crystals, but vanish for isotropic materials. Quasi-confined modes correspond to oscillations in one type of SLs layers but, in contrast with confined modes in cubic SLs, the associated electric field penetrates into the adjacent layer with a decay length much larger than the lattice constant: that is why they are called "quasi-confined." Note that modes delocalized throughout the whole nanostructure, characterized by an oscillatory behavior in both types of layers, were found only in GaN-GaAlN SLs with barriers made of Ga-rich alloys within this dielectric approach.

Very recently, Romanov et al. [45–46] calculated the polar phonons of a single GaN QD, within the framework of a macroscopic continuum dielectric model. They obtained formal analytical solutions for the surface vibrations of a GaN QD exhibiting an oblate spheroidal form, embedded in AlN. These modes are not discrete, in contrast with their counterparts in cubic GaAs-AlAs QDs, and they are found inside a continuous, allowed frequency range, due to the crystal anisotropy. In addition, two other types of phonons were found: runaway modes that freely leave the QD surface and quasi-stationary leaky modes.

The influence of strong electric fields present in GaN-AlN nanostructures has been discussed by Coffey and Bock [47]. These authors calculated the wavefunctions associated with electron and holes confined in strained GaN-AlN QWs. The influence of the electric fields (up to 1 MV/cm) induced by internal strains on these states was shown in the particular case of a 2.6 nm-thick QW: holes and electrons are spatially separated in the QW by the confined quantum Stark effect. Strong effects on the Raman cross section by A_1 (LO) phonons confined in the GaN layer were proven to proceed from the breaking of symmetry with respect to the center plane of the well. In the calculated cross section, both contributions to the electron-phonon interaction associated with deformation potentials and Fröhlich processes were taken into account. For vanishing electric fields, only confined phonons characterized by a quantum number of even parity are allowed. In contrast, it was found that confined phonons with an odd parity dominate the calculated Raman spectrum when strong fields are present in the involved layer. Therefore, it was suggested that this breakdown of parity selection rules could be used for measuring the electric field in wurtzite nanostructures. Unfortunately, the frequencies given for confined modes is questionable, considering the dispersion $\omega(\mathbf{q})$ calculated by the authors for the LO phonon of bulk GaN, which is in agreement neither with measurements nor with calculations already published [9–11].

3.4. Experimental Investigations of Phonons in Nitride-Based Superlattices

As previously shown for superlattices made of cubic III–V semiconductors, the Raman signatures of disordered solid solutions and ordered nanostructures with the same mean composition are quite different, except for SLs containing ultra-thin (thinner than three monolayers) layers. Evidence for SL ordering can thus be achieved by Raman spectroscopy, which is a nondestructive technique in contrast to transmission electron microscopy (TEM) needing cross sections of the samples. However, Raman spectra of GaN-AlN SLs and AlGaN alloys can at first sight exhibit some similarities, specially concerning the frequencies of E_2 (high)

phonons, due to the "two-mode behavior" of the latter modes in the alloy (see Section 2.2). Gleize et al. [30] have observed that the ambiguity could be lifted by considering the A_1 (LO) phonon which is, on the contrary, characterized in alloys by its "one-mode behavior." Indeed, the phonon frequency expected for the A_1 (LO) mode of the $Ga_{1-x}Al_xN$ alloy with the mean Al content of the SL under study ($x = 0.45$) would be 821 cm^{-1} [13]. Actually, the only feature obeying the appropriate selection rules, found at a much lower frequency (738 cm^{-1}) in Raman spectra, was assigned to A_1 (LO) phonons confined in the wells, slightly shifted from the corresponding frequency in relaxed GaN by the opposite effects of confinement and strain. It should be noted that the A_1 (LO) phonon confined in the barriers could not be observed, likely due to the low-scattering cross section of AlN. Finally, it was concluded that the SLs modes could be unambiguously probed by nonresonant Raman scattering.

At this point of the discussion, one can wonder if Raman experiments can determine the nature of the SL phonons, delocalized or confined in one type of layer. A simple criterion has been suggested by Davydov et al. in several articles [48–50]; if two distinct phonons of the same symmetry can be evidenced in Raman spectra from short period SLs, the corresponding modes are claimed to be confined in one type of layer. In the opposite case, the modes can be considered as delocalized. However, it should be noted that the weakness of the Raman signal coming from one type of layer can make a convenient use of this criterion difficult. The same approach has been used by Gleize et al. [30], who implicitly considered phonons confined in each type of layer, with the exception of a phonon exhibiting the A_1 (TO) symmetry, assigned to an interface mode.

Chen et al. [51] claimed to obtain the first evidence for a confinement effect of the A_1 (LO) phonon in GaN layers of an hexagonal superlattice. In this study, three GaN-$Ga_{0.8}Al_{0.2}N$ SLs were investigated; the thickness of the GaN layers was 1.2 nm, 2.4 nm, and 3.6 nm, respectively. The authors concentrated on the A_1 (LO) mode observed in $z(xx)\underline{z}$ micro-Raman spectra. The corresponding broad feature was slightly red shifted in frequency, compared to the relaxed material; this shift was found increasing for shrinking GaN wells. An approximate fit of the measured frequencies was obtained, using $\omega(q_z) \approx \sin^2(q_z \cdot c/4)$ for the dispersion of the LO branch of GaN. However, it should be noted that the SLs contained only 30 periods and that the total thickness of GaN in the SL was as low as 36 nm for the thinner layers; one can thus wonder if a clear signature of the wells could be really obtained in nonresonant scattering conditions, considering the presence of an underlying thick GaN buffer layer.

Davydov et al. [48–50] investigated by nonresonant Raman scattering a set of GaN-$Ga_{1-x}Al_xN$ superlattices, grown by MOCVD on buffer layers and sapphire substrates. The SL period was varied between 2.5 nm and 320 nm. For the sake of simplicity, the thicknesses of wells and barriers in the various nanostructures were the same in all the nanostructures investigated. The aluminum content x in the alloy of the barriers was lower than 50%. The total thickness of the SLs under study was sufficient for achieving Raman experiments in nonresonant scattering, with an excitation at 2.54 eV. In the recorded spectra, E_2 (high) and E_1 (TO)

phonons from GaN were observed and assigned to confined modes in the wells, whereas their counterparts could not be evidenced for the AlGaN layers of the SL. The lack of signal from the barriers has been tentatively attributed to the low-scattering cross section by phonons of the AlGaN alloy. On the other hand, the E_2 (low) phonon confined in the barriers of the SL was also found in the low-frequency range of the spectra, together with that from GaN layers [50]. Due to its high sensitivity to the Al content (but not to the built-in strain), the E_2 (low) phonon from the alloy could be used as a probe of the composition in the barriers of the SL. The same authors also gave evidence for confinement of the A_1 (LO) phonon either in GaN or in GaAlN layers. In Figure 5, two modes are clearly observed in $z(yy)\underline{z}$ spectra from various SLs where the alloy content of the barriers was kept constant (28%). Note that the range of investigated periods was very wide, between 5 nm and 3 μm.

In contrast, the behavior of E_1 (LO) and A_1 (TO) phonons was found quite different. Actually, each of them is always observed as a single line; its location in Raman spectra is similar to that in a $Ga_{1-x}Al_xN$ disordered alloy, whose composition corresponds to the mean Al content in the SL

$$\langle x \rangle = x \frac{d_2}{d_1 + d_2} \tag{11}$$

where d_1 and d_2 are the width of wells and barriers, respectively. Accordingly, these modes are considered as delocalized in the whole structure. The frequency variations of the
Figure 5. Raman spectra in the region of the A_1 (LO) phonons, recorded in backscattering along the z axis, on a set of GaN–$Al_{0.28}Ga_{0.72}N$ SL with different periods: (1) 3 μm, (2) 640 nm, (3) 320 nm, (4) 160 nm, (5) 80 nm, (6) 40 nm, (7) 20 nm, (8) 10 nm, (9) 5 nm. The thicknesses of wells and barriers in the SLs were the same (unpublished results). Reprinted with permission from V. Yu. Davydov.

A_1 (TO) phonons from the SLs under study and from the corresponding ternary alloy were found rather similar. The same observation was made on the E_1 (LO) phonons. This kind of evolution seems to be consistent with results of a calculation performed in the framework of a dielectric continuum model, where the nanostructure was treated as an homogeneous and anisotropic crystal, characterized by an average dielectric constant $\varepsilon_z(\omega)$.

Another possible evidence for the nature, localized or not, of SLs phonons could be found by measuring their angular dispersion $\omega(\theta)$ experimentally, if the latter is significantly different from that of the "bulk" material. This has been done by Gleize et al. [44] for polar phonons through an experimental study of a GaN-AlN SL, performed for checking the validity of the continuum dielectric model previously developed [42]. Micro-Raman spectra were recorded under 2.54 eV excitation, in backscattering geometry on the top surface ($\theta = 0$), on the edge ($\theta = 90°$), and also on a bevel at $45°$ fabricated on the edge of the nanostructure by ion etching. The variation of the angle θ around the above values was achieved by tilting the sample with respect to the incident light beam; in this experiment, the uncertainty on θ was lower than 5°. The measured frequencies of various polar modes from the SL could be compared with the predicted ones. As observed in Figure 6, the agreement was found rather satisfactory, particularly for the TO modes quasi-confined in GaN and AlN layers, which could not be confused with the dispersive extraordinary TO modes from the underlying thick AlN buffer layer.

3.5. Folded Acoustic Phonons in Hexagonal Superlattices

The work published by Davydov et al. [49] on GaN-AlGaN superlattices has evidenced for the first time zone-center-folded acoustic phonons in hexagonal SLs, characteristic of their periodicity. As shown in Figure 7, remarkable sharp Raman features were detected in the low-frequency range of the spectra recorded in the $z(yy)\underline{z}$ scattering configuration, from a few nanostructures made of GaN and $Al_{0.28}Ga_{0.72}N$ layers of same thicknesses, with SLs periods ranging between 6.1 nm and 23.8 nm. Actually, only the doublet expected from the first folding of acoustic branches was clearly observed in each case. As expected, the mean frequency of the doublet increases for decreasing SLs periods. The measured frequencies of both components of the doublet obeyed fairly well Eqs. (4) and (6) appearing in Section 1.2. An average sound velocity $v = 8140$ m/s in the nanostructure was derived from these measurements. Finally, different scattering configurations were achieved for changing the z component q_z of the wavevector of the phonon involved in Raman scattering. This experiment allows the probing of the frequency dispersion of the folded acoustic modes [27]. Indeed, the authors found that the spectral spacing of both lines in the doublet was decreasing with q_z.

4. PHONONS IN QUANTUM DOTS STRUCTURES

4.1. Nonresonant Raman Scattering

The first Raman signature of QD structures has been published by Gleize et al. [52]. The samples were stackings of GaN-AlN QDs grown along the (0001) direction on an AlN buffer layer and a sapphire substrate. As demonstrated by TEM studies [53], GaN islands exhibited a pyramidal shape with a broad basis (about 30 nm) and a typical height of 4 nm, as shown in Figure 8. Micro-Raman spectra were recorded under 2.54 eV excitation, in a backscattering geometry along the z axis. However, the whole sample was probed

Figure 6. Angular dispersion of polar phonons of a GaN (5 nm)- AlN (5 nm) superlattice. Full circles and full lines correspond to the experimental values and to the calculated variation, respectively. The angular dispersion of the relaxed thick buffer layer is indicated by dashed lines. under visible excitation and the distinction between signals originating from the stacking and the buffer layer was not straightforward. In order to overcome this difficulty, the confocal configuration was used and the laser spot was focused higher and higher above the surface, inducing a relative intensity variation of the E_2 phonons from the buffer layer and from the QDs, as already illustrated for SLs. It allowed the unambiguous signature of the GaN islands. A slight (tensile) strain of the AlN spacers was deduced from the measured (negative) frequency shift of the E_2 phonon. The effect of vertical correlation of QDs in these structures can be evidenced from small changes of the strain measured for the spacers.

Another study has been devoted to a set of GaN-AlN QD stackings characterized by various heights and densities of dots, deposited either on sapphire or on silicon [54]. Using various backscattering geometries, most Raman-active optic phonons from the structure could be observed. Except for the A_1 (LO) mode, the measured phonon frequencies were rather close to those found in the similar disordered AlGaN alloy. The observed frequency shifts were assigned to strain effects, as in the case of SLs. An in-plane strain in GaN dots of -2.4% or -2.6% was estimated from the frequency shift (as high as $+35$ cm^{-1} or $+38$ cm^{-1}) of the corresponding E_2 phonon, using the corresponding deformation potentials. The QDs were found completely strained on AlN in all the structures under study, as expected. Obviously, the mean strain in the AlN spacers, tentatively derived from the experimental data, was found much lower.

4.2. Resonant Raman Scattering

Room temperature micro-Raman experiments have been also performed on QD structures using ultraviolet laser lines, in order to enhance the scattering intensity by means of electronic resonance. In the paper by Gleize et al. [55] the sample under study was a stacking of 39 periods of GaN QDs embedded in 18 nm thick AlN spacers, grown on both GaN and AlN buffer layers and on a Si (111) substrate. A thick GaN unstrained layer was also available for comparison. Three laser lines at 3.41 eV, 3.70 eV, and 3.80 eV

were used. In fact, large internal electric fields take place in this kind of nanostructure, thus lowering the fundamental bandgap energies significantly. In the present structure, this quantum confined Stark effect was specially strong. The room temperature PL originating from GaN QDs was centered around 2.35 eV, much lower than the excitation energy, and thus did not merge the Raman signal. The more interesting result was obtained using the 3.80 eV laser line. A feature clearly showed up in the first-order scattering range at 744 cm^{-1} in Raman spectra from the nanostructure, in contrast to those recorded on the GaN layer used as a reference (see Fig. 9). The observed peak, which could not originate from the underlying GaN buffer layer of the sample, was assigned to the polar A_1 (LO) phonon from the QDs. A weaker Raman feature located at 602 cm^{-1} was associated with the nonpolar E_2 phonon from the strained dots. It should be noted that the latter mode could be observed under the 2.33 eV excitation, that is, at an energy close to the PL maximum, in contrast to the A_1 (LO) phonon from QDs. These results gave evidence for a strong resonant enhancement of the scattering by polar phonons in the incoming channel at 3.80 eV, implying probably an excited state of the dots.

Another original study was carried out by Kuball et al. [56] on a single plane of self-assembled GaN QDs grown on a $Al_{0.15}Ga_{0.85}N$ layer, using silicon as anti-surfactant. Two clearly distinct distributions of QD sizes were revealed by means of atomic force microscopy. The Raman spectra from the nanostructures are shown on the top of Figure 10. Under a 3.53 eV excitation, first-order scattering located at 736 cm^{-1}, superimposed onto a broad PL band, was assigned to the A_1 (LO) phonon from the "large" (about 40 nm high) dots, where confinement effects on the LO phonon frequency are almost negligible. In the same experimental conditions, a phonon was observed at the same frequency but with a lower intensity, on another sample grown in similar
Figure 9. Raman spectra of a thick GaN layer (a) and of a GaN–AlN quantum dot structure (b) grown on GaN and AlN buffer layers and on a Si substrate, recorded in backscattering along the z axis under 3.41 eV and 3.80 eV excitations. Reprinted with permission from [44], J. Gleize et al., *Phys. Stat. Sol.* (*A*), 95 (2003). © 2003, Wiley-VCH.
Figure 10. Raman spectra of self-assembled GaN QDs grown on $Al_{0.15}Ga_{0.85}N$ using Si as antisurfactant (A), and of a continuous GaN layer grown on $Al_{0.15}Ga_{0.85}N$ (B). The spectra have been recorded at 3.53 eV (top) and at 5.08 eV (bottom). In the latter case, a reference spectrum of an Al mirror shows the system response function. Asterisks and circles mark laser plasma lines and the Raman signal from the SiC substrate, respectively. Reprinted with permission from [56], M. Kuball et al., *Appl. Phys. Lett.* 78, 987 (2001). © 2001, American Institute of Physics.

conditions but without Si, made of a continuous 0.3 μm thick GaN layer on the alloy layer. The spectra recorded at 3.70 eV and 3.81 eV did not give any signature of the QDs. But under excitation in the far ultraviolet (5.08 eV), a significant shift (9 cm^{-1}) towards lower frequencies was observed for the A_1 (LO) phonon from the GaN dots, as shown on the bottom of Figure 9. In the same experimental conditions, no frequency shift could be evidenced with the continuous GaN layer. The feature found at 727 cm^{-1} was thus assigned to the A_1 (LO) phonon in "small" QDs; the shift should be due to confinement effects in dots exhibiting smaller heights of about 2–3 nm. The electronic transition favoring the resonant effect under the 5.08 eV excitation was not yet identified.

4.3. GaN Nanowires and Pillars

Several investigations of samples containing GaN nanowires have been recently published. For example, Jun-Zhang and Lide-Zhang [57] studied by Raman spectroscopy such as nanostructures, made of nanowires embedded in the nanochannels of an anodic alumina membrane. The hexagonal structure of the nanowires was checked by X-ray

diffraction. The shift towards lower frequencies observed in the Raman spectra for the E_2 (high), E_1 (TO), and A_1 (TO) phonons of GaN was associated with nanosize effects.

Demangeot et al. [58–59] studied structures made of nanometer-size GaN pillars designed for photonic crystals. The samples were obtained by reactive ion-etching using a mask technique on 300 nm thick GaN layers grown on a thick AlN buffer layer and on a sapphire substrate. Individual pillars of 300 nm in height, with diameters ranging between 5 μm and 100 nm, were fabricated in this way. The samples were investigated by micro-Raman spectroscopy under a 2.54 eV excitation. No one-dimensional effects were observed as expected, considering the pillar size. Spectra recorded in the $z(xx)\underline{z}$ configuration showed the allowed phonons from each pillar. Due to the compressive strain of the larger pillars, the E_2 (high) mode was slightly shifted from the frequency of relaxed material; in contrast, strain relaxation was evidenced in smaller pillars. Moreover, the upward shift of the LO phonon in the smaller pillars could be explained by angular dispersion (see Section 2.1). Indeed, the wavevector transferred to the phonon by the incident and scattered light entering and coming out, respectively, through the facets of the pillars was tilted with respect to the z axis, leading to the observation of a shifted quasi-LO mode. The measured frequency shift was found in good agreement with the value of the facet angle (25°).

5. SUMMARY

Hexagonal GaN-AlN or GaN-GaAlN QW and QD structures have been extensively studied in the last few years, on account of their important applications in opto-electronics. The lattice-dynamical properties of two-dimensional systems have been reviewed in this article. Only a few calculations of phonons in such nanostructures have been performed yet. Most articles published are actually devoted to experimental studies by Raman spectroscopy, or less often by infrared measurements. The signature of QW and QD structures has been obtained from nonpolar or polar phonons, by means of nonresonant or resonant Raman scattering, respectively. The results allowed the probing of internal strains and confinement effects in the constituent materials. Up until now, specific modes of GaN-AlN or GaN-GaAlN SLs have been the subject of a few investigations. However, phonon confinement in layers of the structures has been evidenced for SLs in a wide range of periods. Moreover, the angular dispersion of quasi-confined and interface modes has been predicted and checked experimentally for the former. Finally, GaN pillars recently investigated by Raman spectroscopy did not exhibit lattice dynamical properties characteristic of one-dimensional systems.

GLOSSARY

Quantum dot (QD) A small island made of a given semiconductor embedded in another semiconductor.

Quantum well (QW) A thin layer made of a given semiconductor located between two other semiconductors called barriers.

Superlattice (SL) A periodic array of wells and barriers.

Photochemical Molecular Devices

Alberto Credi

Università degli Studi di Bologna, Bologna, Italy

CONTENTS

1. INTRODUCTION

In everyday life we make extensive use of *macroscopic devices*, which are assemblies of components designed to achieve a specific function. Each component of the device performs a simple *act*, while the entire device performs a more complex *function*, characteristic of the assembly. For example, the function performed by a hair dryer (production of hot wind) is the result of acts performed by a switch, a heater, and a fan, suitably connected by electric wires and assembled in an appropriate framework (Fig. 1a).

The concept of a device can be extended to the molecular level [1–4]. A *molecular-level device* can be defined as an assembly of a discrete number of molecular components (i.e., a *supramolecular* structure) designed to achieve a specific function. Each molecular component performs a single act, while the entire assembly performs a more complex function, which results from the cooperation of the various molecular components (Fig. 1b).

The extension of the concept of a device to the molecular level is of interest for the growth of nanoscience and the development of nanotechnology. Indeed, the miniaturization of components for the construction of useful

devices, which is an essential feature of modern technology, is currently pursued by the large-downward (top-down) approach [5]. This approach, however, which leads physicists and engineers to manipulate progressively smaller pieces of matter, has intrinsic limitations [6]. An alternative and promising strategy is offered by the small-upward (bottom-up) approach [7]. Chemists, by the nature of their discipline, are already at the bottom, since they are able to manipulate molecules (i.e., the smallest entities with distinct shapes and properties) and are therefore in the ideal position to develop bottom-up strategies for the construction of nanoscale devices.

1.1. Role of Light in Molecular-Level Devices

Light is made of photons, and photons are at the same time *quanta of energy* and *bits of information* [8]. This is evident in nature, where light constitutes an energy source and is consumed (converted) in massive amounts in photosynthesis, while it functions as a signal in vision-related processes, the energy used to run the operation being biologic in nature. Therefore, taking one of these two extreme views, one can think of molecular-level devices that use light as an energy supply to perform energy-expensive functions, for example, conversion into chemical energy. On the other hand, light could be used by a molecular device as an input/output signal to be processed and eventually stored and retrieved.

In general, molecular-level devices that perform light-induced functions, that is, in which photons act as an energy supply and/or input/output signals, can be termed *photochemical molecular devices* (PMDs) [2, 4, 9]. The role of light in reference to the relevant features of molecular-level devices will be discussed in more detail in the following section.

1.2. Characteristics of Molecular-Level Devices

Molecular-level devices operate via electronic and/or nuclear rearrangements, that is, through some kind of chemical reaction. Like their macroscopic counterpart, they are
Figure 1. Schematic representation of the assembly of (a) a macroscopic device and (b) a supramolecular system capable of performing as a molecular-level device.

characterized by (a) the kind of energy input supplied to make them work, (b) the way in which their operation can be monitored, (c) the possibility of repeating the operation at will (cyclic process), (d) the time scale needed to complete a cycle, and (e) the performed function.

As far as point (a) is concerned, the most obvious way to supply energy to a chemical system is through an exergonic chemical reaction. In his address to the American Physical Society, R. P. Feynman observed [10]: "An internal combustion engine of molecular size is impossible. Other chemical reactions, liberating energy when cold, can be used instead." This is exactly what happens in our body, where the chemical energy supplied by food is used in long series of slightly exergonic reactions to power the biological machines that sustain life.

If a molecular-level device has to work by inputs of chemical energy, it will need addition of fresh reactants ("fuel") at any step of its working cycle, with the concomitant formation of waste products [11]. Accumulation of such waste products, however, will compromise the cyclic operation of the device unless they are removed from the system, as it happens in our body as well as in macroscopic internal combustion engines. The need to remove waste products introduces noticeable limitations in the design and construction of artificial molecular-level devices based on "chemical fuel" inputs. In any case, since a molecular device has to work by repeating cycles [point (c)], a fundamental requirement is that any chemical process taking place in the system has to be reversible.

Chemical fuel, however, is not the only means by which energy can be supplied to operate molecular-level devices. As recalled in the previous section, nature shows that in green plants the energy needed to sustain the machinery of life is supplied by sunlight. Photochemical energy inputs can indeed cause the occurrence of *endergonic* chemical reactions, which can make a device work without formation of waste products. Currently there is an increasing interest in

the development of photon-powered molecular-level devices, taking advantage of the recent, outstanding progress made by supramolecular photochemistry [2, 4]. Photochemical inputs offer other advantages compared to chemical inputs. For example, they can be switched on and off easily and rapidly. It should also be noted that lasers provide the opportunity of working in very small spaces and very short time domains.

To control and monitor the device operation [point (b)], the electronic and/or nuclear rearrangements of the component parts should cause readable changes in some chemical or physical property of the system. In this regard, photochemical and electrochemical methods are very useful since both photons [2, 4] and electrons (or holes) [12, 13] can play the dual role of "writing" (i.e., causing a change in the system) and "reading" (i.e., reporting the state of the system). Luminescence spectroscopy [14], in particular, is a valuable technique since it is easily accessible and offers good sensitivity and selectivity, along with the possibility of time-resolved studies.

The operation time scale of molecular-level devices [point (d)] can range from less than picoseconds to seconds, depending on the type of rearrangement (electronic or nuclear) and the nature of the components involved.

Finally, as far as point (e) is concerned, the functions performed by molecular-level devices can be various and, to a large extent, still unpredictable; some specific examples will be discussed in this chapter.

In the past 10 years, a noticeable number of photochemical molecular devices based on threaded and interlocked supramolecular architectures, such as pseudorotaxanes, rotaxanes, and catenanes, have been developed. From the viewpoint of the functions performed [point (e)], PMDs of this kind can be subdivided into three categories, namely, artificial photosynthetic systems, molecular-level mechanical machines, and devices for information processing. It is worth noting that, although the energy-carrying and information-carrying aspects of light cannot be separated sharply, artificial photosynthetic devices and molecular-level mechanical machines can be regarded as "light-powered" PMDs, while the third kind of system represents "light-processing" devices. Before illustrating specific examples belonging to these categories, it is useful to recall some important features of pseudorotaxanes, rotaxanes, and catenanes.

2. PSEUDOROTAXANES, ROTAXANES, AND CATENANES

Research on pseudorotaxanes, rotaxanes, and catenanes has grown exponentially during the past few years [15–27]. Figure 2 shows schematically the structure of pseudorotaxanes, rotaxanes, and catenanes. The names of these compounds derive from the Latin words *rota* and *axis* for wheel and axle and *catena* for chain. In general, these species are referred to as [*n*]name, where *n* is the number of molecular components; therefore, the diagrams in Figure 2 represent [2]pseudorotaxane, [2]rotaxane, and [2]catenane.

[2]pseudorotaxane

Figure 3. Two examples of self-assembling of pseudorotaxanes based on π-electron donor/acceptor interactions: (a) from [28] and (b) from [29].

2.1. Pseudorotaxanes

Pseudorotaxanes are a particularly interesting family of host–guest systems. As in the case of any host–guest complex, formation of a pseudorotaxane occurs via a molecular recognition process between two "instructed" components [1]. It is a thermodynamically controlled self-assembly process that may occur as a result of a variety of interactions deriving from the size, shape, and electronic properties of the partners. The most important types of interactions are those involving electron donor/acceptor ability, hydrogen bonding, hydrophobic/hydrophylic character, π–π stacking, coulombic forces, and, on the side of the strong interaction limit, metal–ligand bonding. Usually, it is not difficult to understand which is the predominant interaction in a given system. It should be noted, however, that in some cases the strongest interaction as far as association is concerned is not that causing the most relevant changes in the properties of the system [e.g., ultraviolet–visible (UV–vis) absorption, fluorescence and NMR spectra, electrochemical behavior] on going from the separated components to the pseudorotaxane structure.

A number of pseudorotaxanes have been obtained by threading a wire-type molecule containing π-electron acceptor units into a macrocycle comprising π-electron donor units or, vice versa, a wire-type component containing electron donor units into a macrocycle that comprises electron acceptor units. Two examples are shown in Figure 3: (a) the 1,1'-dibenzyl-4,4'-bipyridinium electron acceptor dication $\mathbf{1}^{2+}$ threaded into the 1,5-dinaphtho-38-crown-10 (1/5DN38C10) electron donor macrocycle **2** [28] and (b) the acyclic polyether **3** containing a tetrathiafulvalene electron donor unit threaded into the electron acceptor cyclophane $\mathbf{4}^{4+}$ [29]. Species composed of a macrocycle covalently connected to a wirelike moiety, giving rise to self-threaded pseudorotaxane structures, are also
known [30]. Although in these cases a large contribution to the association driving force comes from the electron donor/acceptor interaction, other kinds of interactions, particularly hydrogen bonding, can play an important role, as clearly shown in the cases of [2]pseudorotaxanes composed of 4,4'-bipyridinium [31] or 1,2-bis(pyridinium)ethane [32] threads and crown ethers.

Several pseudorotaxanes have been obtained by threading wire-type and macrocyclic components carrying complementary hydrogen-bonding functions. Figure 4a shows, as an example, the threading of a wire-type component containing a secondary ammonium function, such as the N,N-dibenzylammonium ion $\mathbf{5H}^+$, into a suitable crown ether like dibenzo-24-crown-8 (DB24C8), **6** (Fig. 4a) [33]. Besides hydrogen bonding, other types of interactions (e.g., ion–dipole, π-stacking) can contribute to stabilize the pseudorotaxane structure.

Pseudorotaxanes can also be obtained as a consequence of simple hydrophobic/hydrophilic interactions. This is the case for the since long-known species in which a wire-type component ($\mathbf{7}^{2+}$) threads the cavity of α-cyclodextrin **8** (Fig. 4b) [34].

A different approach is the metal-based template method [15, 23], for example, starting from a wire (**9**) and a macrocycle (**10**), both containing a phenanthroline unit, and using Cu$^+$ as a template (Fig. 4c) [15]. Species of this kind are essentially metal complexes and may have very large formation constants.

The examples reported above refer to pseudorotaxane species with a 1:1 thread/macrocycle ratio ([2]pseudorotaxanes). It is also possible to obtain species exhibiting different stoichiometric ratios, as illustrated by the fascinating [5]pseudorotaxane formed from four cyclophane $\mathbf{4}^{4+}$ components and a Zn(II)-phthalocyanine with appended four polyether substituents carrying π-electron-rich hydroquinone units [35]. Examples of pseudorotaxanes are known in which a macrocycle is threaded by two linear components [36] and a linear component threads two macrocycles [37]. Long linear arrays can be obtained by using homoditopic threads and macrocycles [38]; homogeneous or
Figure 4. Examples of self-assembling of pseudorotaxanes based on (a) [N⁺—H···O] hydrogen bonding [33], (b) hydrophobic/hydrophilic interactions [34], and (c) coordination around a metal ion [15].

heterogeneous pseudopolyrotaxanes [16] have also been prepared, as well as dendritic ones [39].

Pseudorotaxane species whose components incorporate units capable of exhibiting specific photochemical and/or redox properties are of particular interest for the purpose of constructing photochemical molecular devices. Some examples are reported in Figure 5, namely, a thread (**11H⁺**) with an ammonium function and a photoactive anthracene as a
Figure 5. Some pseudorotaxane components containing units capable of exhibiting specific properties. The wirelike molecule **11H⁺**, with an ammonium center and a photoactive anthracene unit as a stopper [40]; the bipyridinium-containing wire **12⁴⁺**, with a photo- and redox-active [Ru(bpy)₃]²⁺ moiety [41]; crown ether **13**, incorporating a binaphthyl unit [42]; cyclophane **14⁶⁺**, which contains a [Ru(bpy)₃]²⁺ complex and two bipyridinium units [43].

stopper [40], a bipyridinium-type wire (**12⁴⁺**) with a photo- and redox-active [Ru(bpy)₃]²⁺ (bpy = 2,2′-bipyridine) moiety [41], a crown ether (**13**) incorporating a binaphthyl unit [42], and a cyclophane (**14⁶⁺**) containing a Ru complex and two bipyridinium units [43].

2.2. Rotaxanes and Catenanes

Rotaxanes and catenanes are supramolecular (multicomponent) species [1, 15] strictly related to, but also very different from, pseudorotaxanes (Fig. 2). Whereas pseudorotaxanes can undergo dissociation into their wirelike and macrocyclic components, rotaxanes and catenanes are interlocked species, whose dissociation requires breaking of a covalent bond. The general strategy to prepare rotaxanes and catenanes with high yields is based on the template effect [44], which relies on the presence of molecular recognition sites in the components to be assembled.

Figure 6 shows the routes by which components bearing suitable recognition sites lead to the formation of rotaxanes: (i) *threading* of a molecule through a preformed ring, followed by capping the end(s) of the thread; (ii) *slipping* of a preformed ring over the stoppers of a preformed dumbbell-shaped component into a thermodynamically favorable site on the rod part of the dumbbell; and (iii) *clipping* of a preformed dumbbell with a suitable U-type component that is subsequently cyclized. Figure 7 shows the synthesis of a rotaxane based on donor/acceptor interaction by the threading or the clipping approach [45]. In the first case (Fig. 7a), threading of the electron acceptor tetracationic cyclophane by a thread containing a dioxybenzene electron donor unit yields a pseudorotaxane; then, reaction of the terminal hydroxy groups of the thread with triisopropylsilyl triflate leads to the rotaxane. In the clipping approach (Fig. 7b), the rotaxane is obtained by constructing the electron acceptor cyclophane around the preformed dumbbell-shaped component.

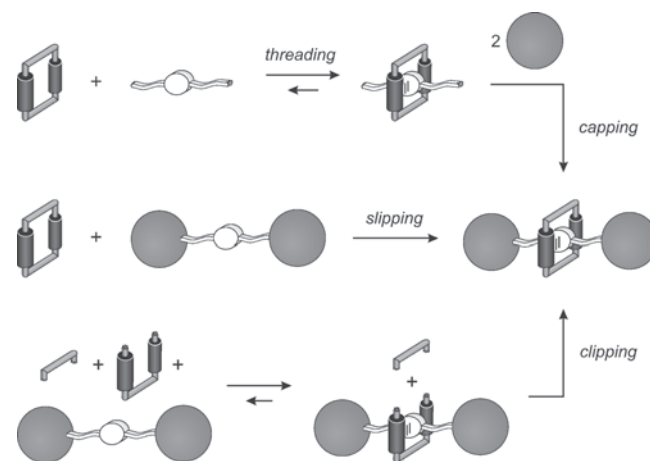
In the case of catenanes, the most rationale synthetic strategy is the clipping of a macrocycle onto a preformed one (Fig. 8). A double-clipping procedure can also be used [46]. Figure 9 shows the synthesis of a catenane templated by electron donor/acceptor interactions [45]. Reaction of a


Figure 6. Routes for the synthesis of [2]rotaxanes.

dication with a dibromide gives a tricationic intermediate, which interacts with bis-*p*-phenylene-34-crown-10 to afford a pseudorotaxane-like, or precatenane, structure. The subsequent cyclization, as a result of nucleophilic displacement of a bromide ion, gives the corresponding catenane.

In some cases, catenanes are formed from relatively small molecules by one-pot synthesis in a more or less serendipitous manner [47–49]. Figure 10 shows the one-pot synthesis of an amide-based [2]catenane from very simple compounds [48]. This synthesis is thought to involve the perpendicular preorganization of the components caused by three templating effects: (i) steric complementarity, (ii) hydrogen bonding between carbonyl oxygen atoms and amide protons, and (iii) π–π interactions between the benzene rings of host and guest units. Several related amide-based rotaxanes have also been prepared [18, 21, 27].

Besides simple rotaxanes and catenanes, a great variety of more complex systems have been synthesized, including branched [*n*]rotaxanes [50], rotaxanes bearing dendritic stoppers [51], catenanes composed of three, five, and seven interlocked macrocycles [52], polyrotaxanes and polycatenanes [16–18, 24], catenanes with very special shapes [53], rotacatenanes [54], pretzelanes [55], and knots [15, 23, 27]. Some of these compounds are shown in Figure 11.
Figure 10. One-pot synthesis of an amide-based [2]catenane [48].

3. ARTIFICIAL PHOTOSYNTHETIC DEVICES

An intelligent approach toward the design of artificial systems for solar energy conversion (artificial photosynthetic devices) is to take the natural energy conversion sequence as a model and see whether some of the processes involved can be replaced by more convenient routes and/or the natural components can be replaced by artificial ones. In nature, a large number of light-absorbing species (pigments) deliver the excitation energy to a small number of energy-converting centers where the collected electronic energy is used to obtain charge separation [56]. This choice, made by nature, is very suitable and should therefore also be adopted in artificial systems.

Generally speaking, an artificial photosynthetic device should be made of a light-harvesting molecular array (i.e., an antenna system), a charge separation supramolecular species (a reaction center), and some kind of device capable of making use of the separated charges to produce stable, high-energy chemical species (fuels) or electricity [57–60]. Production of electricity by artificial photoelectrochromic devices has already been achieved [61], whereas photogeneration of fuels by artificial systems is a much more difficult task [62].

3.1. Antenna Systems

Generally speaking, an antenna for light harvesting is an organized multicomponent system in which several chromophoric molecular species absorb the incident light and channel the excitation energy to a common acceptor component. Artificial antenna systems based on porphyrin arrays [63], multichromophoric cyclodextrins [64], polynuclear metal complexes [65, 66], dendrimers [66–68], and polymers [69, 70] have been reported. In all these systems, the chromophoric units are connected by means of covalent
Figure 11. Examples of peculiar rotaxane and catenane structures: (a) a branched [4]rotaxane [50], (b) a [5]catenane named "olympiadane" [52], (c) a rotacatenane [54], and (d) a [2]catenane composed of three macrocyclic rings [53].

bonds, in contrast with natural photosynthetic systems where the molecular components are held together by noncovalent interactions.

Artificial antenna systems in which several chromophoric units are mechanically linked together in a polyrotaxane structure have recently been reported [71, 72]. Such species are composed of many α-cyclodextrin units, each bearing one or more naphthyl chromophoric groups, threaded by a poly(ethyleneglycol) chain and stoppered by bulky groups. The polyrotaxane **15**, schematized in Figure 12 [71], contains about 15 α-cyclodextrins, each bearing two naphthalenesulfonate units and an axle composed of an average of 45 [OCH$_2$CH$_2$] units, stoppered by two adamantane groups. When the dansyl-modified β-cyclodextrin **16** is added to **15** in aqueous solution at 298 K, a photoinduced energy transfer process takes place from the naphthyl chromophoric groups of **15** to the dansyl unit of **16**, which binds to the adamantane stoppers by virtue of hydrophobic interactions (Fig. 12). Such a process, evidenced by the quenching of naphthalene fluorescence and sensitization of the dansyl fluorescence, can be switched off by adding 1-adamantanol to the solution, which competes with the adamantane extremities of **15** for the cavity of **16**.

In a successive related work [72], anthracene units have been employed as stoppers for a series of polyrotaxanes; indeed, an efficient energy transfer process from the naphthalene units of the α-cyclodextrin rings to the anthracene stoppers takes place within the polyrotaxanes. Fluorescence anisotropy measurements also indicate excitation energy migration between naphthalene chromophoric units. The rotaxane architecture, in conjunction with the threading procedure (Fig. 6) employed for the synthesis of this series of compounds, gives the interesting opportunity of adjusting the number of chromophores simply by changing the ratio between naphthalene-decorated and plain α-cyclodextrin units during the preparation of the polyrotaxanes.

3.2. Charge Separation Devices

The simplest supramolecular species capable of performing a charge separation process are those containing two components (diads) [73]. A possible scheme for a diad is represented in Figure 13. Light excitation of the electron donor (D) (process 1) leads to an electron transfer (process 2), which produces a charge separation and is in competition with the deactivation of the excited state of D (process 3). However, the recombination of the charges in such systems (process 4) is usually very fast. To increase the lifetime of charge separation, which is of fundamental importance for utilizing the energy transiently stored in the charge separation process, more complex systems have to be considered. In particular, an additional charge stabilization step may be introduced, in which the charges are moved far apart from each other. Supramolecular species of this type are called triads [73]. Two possible schemes for charge-separating triads are shown in Figure 14. Although the scheme in Figure 14b is reminiscent of the natural photosynthetic reaction center, that of Figure 14a seems to be more popular in the field of artificial triads. In both cases, excitation of a chromophoric component (process 1) is followed by a primary photoinduced electron transfer to a primary acceptor (process 2). This is followed by a secondary thermal electron transfer (process 3) from a donor component to the oxidized chromophore (Fig. 14a) or from the primary acceptor to a secondary acceptor component (Fig. 14b). The primary process competes with excited-state deactivation (process 4), while the secondary one competes with primary charge recombination (process 5). Finally, charge recombination between remote molecular components (process 6) leads the triad back to its initial state.

Porphyrins, owing to their outstanding photophysical and redox properties [74], are extensively used for the construction of photochemical molecular devices to achieve charge separation over nanometric distance [75]. Porphyrin units have been successfully incorporated into rotaxane structures [76, 77], first playing the role of stoppers. In CH$_3$CN solution at room temperature, [2]rotaxane **17**$^{2+}$ (Fig. 15) [78, 79] undergoes a very fast (ca. 2 ps) electron transfer process from the Zn(II) to the Au(III) porphyrin upon excitation of the Zn(II) porphyrin moiety (process 1 in Fig. 15). Although direct back electron transfer from the Au(II) to the Zn(III) porphyrin indeed occurs (530 ps), the initial state is restored mainly via oxidation/reduction of the central copper unit, that is, through an electron transfer from
Figure 12. The light-harvesting polyrotaxane **15** [71] is composed of a poly(ethyleneglycol) axle encircled by an average of 15 α-cyclodextrin units, each bearing approximately two naphthalenesulfonate groups; therefore, **15** contains about 30 naphthyl chromophoric groups held together mechanically. In aqueous solution, the dansyl-modified β-cyclodextrin **16** is able to bind to the adamantane stoppers of **15**; under such conditions, a photoinduced energy transfer process from the excited naphthalenesulfonate moieties of **15** to the dansyl group of **16** is observed.
Figure 13. Cartoon illustration and working scheme, based on an orbital representation, of a supramolecular diad for photoinduced charge separation.

the Cu(I) unit to the oxidized Zn porphyrin (process 2; 20 ps) followed by another electron transfer from the oxidized copper site to the Au porphyrin (process 3; 2.5 ns). Interestingly, if the copper ion is removed, the so-obtained demetallated [2]rotaxane exhibits electron transfer properties similar to those of the free bis-porphyrin dumbbell components [80]. However, the very short lifetime of the primary charge-separated state and the complexity of the deactivation pattern constitute major limitations to the performance of 17^{2+} as a charge separation system. Rotaxane 18^{2+} (Fig. 16) [81] is composed of an axle bearing one Cu(I)-bis(phenanthroline) complex and two Zn(II) porphyrins as stoppers and a macrocyclic component that incorporates one Au(III) porphyrin. In such a compound, excitation of the Zn(II) porphyrin units (CH_3CN; room temperature) leads to energy transfer to the central copper unit (process 1), which, in turn, transfers an electron to the Au(III) porphyrin (process 2). Since the oxidized Cu(II) moiety can be reduced by the Zn(II) porphyrin, a charge shift occurs (process 3), leading to the final charge-separated state, which lasts for 5 ns before back electron transfer from the Au(II) to the Zn(III) units (process 4) takes place [81]. Therefore, this assembly operates according to the scheme depicted in Figure 14a, except for the fact that light is absorbed by porphyrins and not by the central copper unit; however, an efficient energy transfer process takes place from the zinc porphyrin to the copper complex.

17^{2+}
Figure 15. Photoinduced electron transfer processes that take place in [2]rotaxane 17^{2+} [78, 79].

Among the systems proposed as models for the photosynthetic reaction center, supramolecular assemblies in which Ru(II)-polypyridine complexes and 4,4′-bipyridinium units are held together noncovalently in threaded and interlocked structures have been extensively studied [43, 82–88]. In such assemblies, connections between the molecular components rely on charge transfer interactions between the electron acceptor bipyridinium units and aromatic electron donor groups (Fig. 3). For instance, in the various pseudorotaxanes formed in acetonitrile solution at 298 K by the threading of cyclophane 4^{4+} by the dioxybenzene-containing tethers of 19^{2+} (Fig. 17) [84], an efficient photoinduced electron

18^{2+}
Figure 16. Photoinduced energy and electron transfer processes occurring in [2]rotaxane 18^{2+} [81], which behaves as a triad for photoinduced charge separation according to the scheme illustrated in Figure 14a. For more details, see text.
Figure 17. Branched compound 19^{2+} [84], which contains a $[Ru(bpy)_3]^{2+}$ core and six pendant threadlike substituents, forms pseudorotaxanes with macrocycle 4^{4+}. In such pseudorotaxane species, efficient photoinduced electron transfer takes place from the excited state of the ruthenium complex of 19^{2+} to the bipyridinium units of 4^{4+}.

transfer process takes place from the excited state of the $[Ru(bpy)_3]^{2+}$ moiety of 19^{2+} to a 4,4′-bipyridinium unit of 4^{4+}. The back electron transfer occurs on a time scale (ca. 1 μs) considerably longer than that found for covalently linked $[Ru(bpy)_3]^{2+}$/bipyridinium assemblies (nanosecond time domain), a behavior that has been attributed to increased spatial separation of the photogenerated redox pair due to repulsive electrostatic interactions between the positively charged macrocycle and Ru(II) complex [84]. It has also been found that recombination takes place within the threaded supramolecular assemblies, indicating that the pseudorotaxanes do not break apart upon light irradiation. However, in the light of the large variety of threaded species that can be formed, as well as of the relatively small stability constants of the resulting pseudorotaxanes, well-defined interlocked (catenane or rotaxane) structures might be preferred [85–88].

One intriguing aspect of the bacterial photosynthetic reaction center is the redox asymmetry of the cofactors; electron transfer proceeds exclusively along one branch of an almost symmetrical pair of reagents [89, 90]. The catenane structure can be exploited to reproduce such an asymmetry with artificial systems; in catenane 20^{6+} (Fig. 18) [86], the two bipyridinium electron acceptors, linked to a $[Ru(bpy)_3]^{2+}$-type primary electron donor, possess different reduction potentials because one of them is encircled by an electron donor crown ether that both attenuates its electron acceptor affinity via charge transfer interactions and hinders access to solvent molecules. Indeed, in CH_3CN solution at 293 K, a very fast ($k = 5.9 \times 10^{10}$ s^{-1}) electron transfer takes place from the photoexcited $[Ru(bpy)_3]^{2+}$ moiety to a bipyridinium unit. Although it can be anticipated with thermodynamic arguments that the redox asymmetry of the two acceptor branches in 20^{6+} should result in a fivefold difference in rate constants [86], there is no means to distinguish between the two electron transfer paths by time-resolved

20^{6+}
Figure 18. In [2]catenane 20^{6+} [86], upon excitation of its $[Ru(bpy)_3]^{2+}$ moiety, a very fast electron transfer process to a bipyridinium unit occurs. Owing to the catenane structure, the two bipyridinium units do not possess the same reduction potential (half-wave potential values versus SCE for the "inside" and "outside" units are indicated); such a redox asymmetry could mimic that of the cofactors in the bacterial photosynthetic reaction center.

spectroscopic techniques. In such a system, back electron transfer is also extremely rapid ($k = 2.4 \times 10^{10}$ s^{-1}), owing to the close proximity of the reactants, despite the fact that it should fall in the Marcus "inverted" region.

The photoinduced processes taking place in triad 21^{6+} (Fig. 19), made of a Zn(II) porphyrin linked to a $[Ru(bpy)_3]^{2+}$-crown ether component catenated with one 4^{4+} macrocycle have been studied recently (H_2O, phosphate buffer, 293 K) [88]. Upon excitation of the Zn(II) porphyrin moiety, direct electron transfer occurs from the photoexcited porphyrin to the tetracationic macrocycle. The same charge-separated state can be reached upon excitation of the Ru(II) complex followed by two electron transfer steps (Fig. 19), according to the scheme reported in Figure 14a. Two semisynthetic systems, obtained by incorporation of 21^{6+} into two different proteins, namely, cyctochrome b$_{562}$ and myoglobin, were also studied [88]. Interestingly, the lifetime values for the photoinduced charge-separated state increase substantially when the heme moiety of the triad is embedded in the protein matrix: from 300 ns found for free 21^{6+} to 600–900 ns of cytochrome-b$_{562}$-(21^{6+}) and 1.1–18 μs of myoglobin-(21^{6+}). This study not only demonstrates that protein matrix effects play a crucial role in electron transfer processes of biological importance, but also that hybrid

natural/artificial supramolecular assemblies are promising candidates for the realization of molecular devices to be used in artificial photosynthetic systems.

4. MOLECULAR-LEVEL MACHINES

A molecular-level machine can be defined [91–93] as an assembly of a distinct number of molecular components that are designed to perform mechanical movements as a result of an appropriate external stimulation. Although there are many chemical compounds whose structure and/or shape can be modified by an external stimulus (see, e.g., photoisomerizable species), the term molecular machine is used only for systems showing large-amplitude movements of the molecular components. Chemical, photochemical, or electrochemical stimuli can be used to feed molecular-level machines [91–93]; however, for the reasons discussed in the Introduction, light is the most convenient form of energy to make molecular machines work [11]. Two kinds of light-induced processes have been used so far for this purpose: photoisomerization reactions [94] and photoinduced electron transfer processes [95]. It is very important that such molecular-level motions are accompanied by changes of some chemical or physical property of the system, resulting in a readout signal that can be used to monitor the operation of the machine. The reversibility of the movement, that is, the possibility to restore the initial situation by means of an opposite stimulus, is an essential feature of a molecular machine. Since the induced motions usually correspond to transitions between two stable structures (states), systems of this kind behave according to a binary logic and could also prove useful for information processing [3].

Threaded and interlocked compounds, owing to their peculiar structure [15–27], are attractive candidates for the construction of molecular-level machines; therefore, it is not surprising that most of the recently designed molecular-level machines are based on pseudorotaxanes, rotaxanes, and catenanes. Figure 20 shows pictorially some of the movements that can be imagined for these systems, namely, threading/dethreading of the wire and ring components of pseudorotaxanes (Fig. 20a), shuttling of the macrocyclic component along the axle in rotaxanes (Fig. 20b), and rotation of one molecular ring with respect to the other in catenanes (Fig. 20c).
4.1. Piston/Cylinder Systems

Dethreading/rethreading of the wire and ring components of a pseudorotaxane resembles the movement of a piston in a cylinder (Fig. 20a) [91]. The first attempts at designing a photochemically driven molecular machine of this type were carried out on pseudorotaxanes stabilized by electron donor/acceptor interactions (Fig. 3). In such systems, the donor/acceptor interactions introduce low-energy charge transfer (CT) excited states responsible for absorption bands in the visible region. Light excitation in these CT absorption bands leads formally to the transfer of an electron from the donor to the acceptor component, as illustrated in Figure 21 for the pseudorotaxane formed in H_2O or CH_3CN solution by the electron donor thread **22** and the electron acceptor macrocycle $\mathbf{4}^{4+}$. As a consequence, particularly when this process leads to formation of charges of the same sign in the two components, one can expect destabilization of the pseudorotaxane structure followed by dethreading. In practice, however, this simple approach does not work because the back electron transfer process is much faster than the separation of the molecular components, a process that requires extended nuclear motions and solvent rearrangement. In some particular cases [96, 97], laser flash photolysis experiments have suggested that a small fraction of the irradiated pseudorotaxane may undergo dissociation.

To really achieve photoinduced dethreading, a different approach has been devised [98, 99], based on the use of an external electron transfer photosensitizer (P) and a sacrificial reductant (Red), as illustrated in Figure 22. The photosensitizer must be able to (i) absorb light efficiently and (ii) have a sufficiently long-lived and reductant excited state, so that its excitation (process 1) in the presence of the pseudorotaxane will lead (process 2) to the transfer of an electron to a bipyridinium unit of the cyclophane. The relatively fast back electron transfer from the reduced cyclophane component to the oxidized photosensitizer is prevented by the sacrificial reductant, which, if

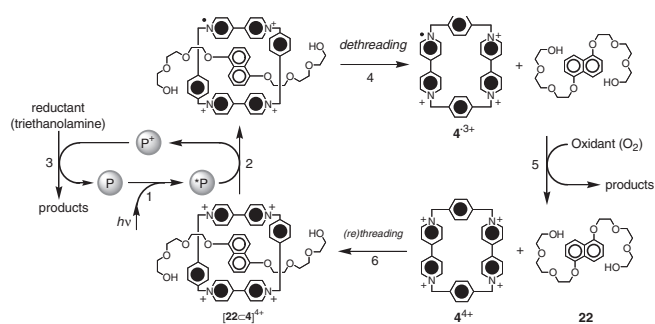
Figure 20. Pictorial representation of machine-like movements that can be obtained with pseudorotaxanes, rotaxanes, and catenanes: (a) dethreading/rethreading of the molecular components in a [2]pseudorotaxane, (b) shuttling of the macrocyclic component along the axle in a [2]rotaxane, and (c) ring rotation in a [2]catenane.
Figure 21. Photochemical processes associated with [2]pseudorotaxane $[\mathbf{22}{\subset}\mathbf{4}]^{4+}$ upon excitation in its charge transfer absorption band [98, 99]. The processes indicated by dashed arrows are unlikely to occur.


Figure 22. Photochemically induced dethreading of [2]pseudorotaxane [**22**⊂**4**]$^{4+}$, based on the use of an external photosensitizer (P) and a reductant scavenger. Rethreading occurs upon oxygenation of the previously deaerated solution [98, 99].

present in a sufficient amount, intercepts the oxidized photosensitizer and regenerates (process 3) its original redox state. Good candidates for the role of photosensitizer are 9-anthracenecarboxylic acid [100] and metal complexes such as [Ru(bpy)$_3$]$^{2+}$ [101], while efficient reductant scavengers are triethanolamine and polycarboxylate (e.g., oxalate) anions [102]. Under these conditions, the persistent reduction of a bipyridinium unit of **4**$^{4+}$ is achieved and the pseudorotaxane dethreads (process 4), as evidenced by absorption spectral changes and, more important, by the increase in the intensity of the dioxynaphthalene fluorescence, which can only originate from free **22**. Oxygenation of the solution, from which O$_2$ was initially removed, reoxidizes the macro-

cycle back to the tetracationic form (process 5), thereby promoting rethreading with **22** (process 6), as also shown by the absorption and luminescence spectra. Very recently, it has been shown that this same system can be operated in unconventional environments such as the interior pores of a sol–gel silica framework [103]. The possibility of mounting such a molecular-level machine on a solid support, by trapping the wirelike molecule onto the surface of a sol–gel film, has also been demonstrated [103].

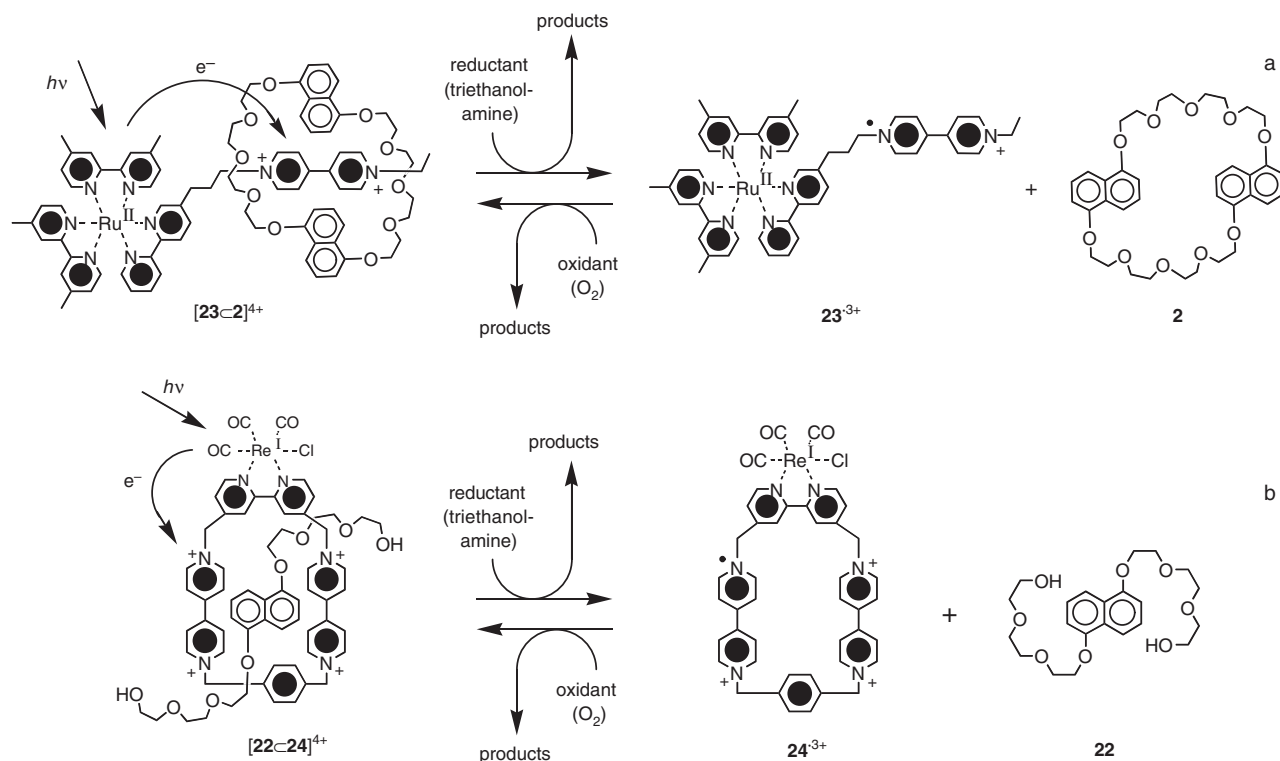
This strategy has been extended recently to second-generation pseudorotaxanes [**23**⊂**2**]$^{4+}$ and [**22**⊂**24**]$^{4+}$ in which the metal-complex photosensitizer (the "light-fueled" motor [104]) has been incorporated either into the thread (Fig. 23a) [41] or into the ring (Fig. 23b) [105] component. The successful operation of these pseudorotaxanes as molecular machines is the result of (i) the appropriate choice of the functional units and (ii) their covalent linking into the thread and ring components in order to achieve the correct integration of the needed functions (e.g., receptor ability, redox features, photophysical properties, etc.), the right sequence of processes, and the lack of interference between the active units. As in the case of the molecular machine shown in Figure 22, the dethreading and rethreading motions of the pseudorotaxanes represented in Figure 23 can be triggered by visible-light irradiation and oxygenation of the solution, respectively. The motions can also be easily monitored by means of UV–vis absorption and luminescence spectroscopy. The most important readout signal is the intensity of the dioxynaphthalene fluorescence associated with the free ring **2** (Fig. 23a) or free thread **22** (Fig. 23b)


Figure 23. Photocontrollable molecular machines based on [2]pseudorotaxanes. In these second-generation systems, the "light-fueled" motor (i.e., the photosensitizer) is part of the threadlike and of the macrocyclic components of [**23**⊂**2**]$^{4+}$ and [**22**⊂**24**]$^{4+}$, respectively [41, 105]. As for the system described in Figure 22, a reductant scavenger is employed, and rethreading is performed by allowing oxygen to enter the irradiated solution.

components. It is worth noting that many [deoxygenation–irradiation (dethreading)/oxygenation (rethreading)] cycles can be performed on the same solution without any appreciable loss of signal until most of the reductant scavenger is consumed. It should also be stressed that systems that rely on this photosensitizer–scavenger strategy utilize, in addition to light energy, the irreversible decomposition of a reductant scavenger that produces "waste" species. In this regard, the search for efficient molecular machines exploiting "clean," reversible photochemical reactions (in other words, machines that use only light as an energy supply) is of fundamental importance.

Photoisomerization reactions, particularly the well-known [94] reversible *cis/trans* photoisomerization of the azobenzene group, have long been used to exert photochemical control on chemical systems [106]. Since the early 1980s, azobenzene-containing compounds have been employed both as photocontrollable hosts [107, 108] and guests [109]. The first example of a pseudorotaxane in which dethreading/rethreading is based on such a principle and is powered exclusively by light energy, without generation of any waste products, has been reported only recently (Fig. 24) [110]. The threadlike species *trans*-**25**, which contains an electron-rich azobiphenoxy unit, and the electron acceptor macrocycle **26**$^{4+}$ self-assemble very efficiently in acetonitrile solution to give a pseudorotaxane, stabilized by donor/acceptor interactions. In the pseudorotaxane structure, the intense fluorescence characteristic of free **26**$^{4+}$ is completely quenched by the donor/acceptor interaction. Irradiation with 365 nm light of a solution containing *trans*-**25** and **26**$^{4+}$, in which the majority of the species are assembled to give the pseudorotaxane, causes *trans* → *cis* photoisomerization of **25**. Since the affinity of the macrocycle for *cis*-**25** is much lower than that for *trans*-**25**, photoexcitation causes a dethreading process (Fig. 24), as indicated by a substantial increase in the fluorescence intensity of free **26**$^{4+}$. On irradiation at 436 nm or by warming the solution in the dark, the *trans* isomer of **25** can be reformed and, as a result, it rethreads inside the
macrocycle. Owing to the full reversibility of the photoisomerization process, the light-driven dethreading/rethreading cycle can be repeated at will (Fig. 24). Another relevant feature of this system is that it exhibits profound changes of a strong fluorescence signal.

4.2. Molecular Shuttles

In rotaxanes containing at least two (or more) different recognition sites ("stations") in the axle component, it is possible to switch the position of the macrocycle between the two stations by an external stimulus [91]. The [2]rotaxane *trans*-**27**$^{4+}$ (Fig. 25) [111] incorporates an α-cyclodextrin torus and a *trans*-azobiphenoxy-containing axle. Initially, the cyclodextrin ring resides exclusively around the *trans*-azobiphenoxy recognition site. Upon irradiation at 365 nm in H$_2$O at 278 K, the azobiphenoxy unit isomerizes [94] from *trans* to *cis*, "pushing" the α-cyclodextrin component away to encircle one of the [(CH$_2$)$_2$O] chains. Further irradiation at 430 nm causes back isomerization of the azobiphenoxy group from the *cis* to the *trans* form, leading to the shuttling of the cyclodextrin component back to the *trans*-azobiphenoxy recognition site (Fig. 25). The photoisomerization/shuttling processes are accompanied by changes in the circular dichroism signals induced by the chiral cavity of the cyclodextrin on the azobiphenoxy π–π* transitions.

The [2]rotaxane **28**$^+$ (Fig. 26) [112] has a phenanthroline and a terpyridine unit in its axle component, and it incorporates a Cu(I) ion coordinated tetrahedrally by the phenanthroline ligand of the axle together with the phenanthroline ligand of the macrocycle. Oxidation of the tetracoordinated Cu(I) center produces a tetracoordinated Cu(II) complex; in response to the preference of Cu(II) for a pentacoordination geometry, the macrocycle shuttles away from the bidentate phenanthroline ligand of the axle and places itself on the terdentate terpyridine site. Subsequent reduction of the Cu(II) center to Cu(I) causes an opposite shuttling process, affording a return to the original structure. These movements can of course, be, performed electrochemically [113], but can also be induced photochemically [114], as illustrated in Figure 26. Upon irradiation at 464 nm of an acetonitrile solution of the [2]rotaxane (process 1), the Cu(I)-based

Figure 24. Dethreading/rethreading of [2]pseudorotaxane [**25**⊂**26**]$^{4+}$ as a consequence of the *cis/trans* photoisomerization of the azobenzene-type unit contained in the threadlike component **25** [110].
Figure 25. Light-controlled reversible shuttling of the macrocyclic component of **27**$^{4+}$ along its axle, based on the *cis/trans* photoisomerization of the azobenzene unit [111].
Figure 26. Photoinduced shuttling, based on the use of an oxidant scavenger (*p*-nitrobenzylbromide), of the macrocyclic component in the copper-containing [2]rotaxane **28**[+] [114].

chromophoric unit is excited to a metal-to-ligand charge transfer (MLCT) state. In the presence of a suitable oxidant (*p*-nitrobenzylbromide), electron transfer from the photoexcited rotaxane to the oxidant follows (process 2), which generates a tetracoordinated Cu(II) center and products deriving from reduction of *p*-nitrobenzylbromide. Such a reaction competes with the intrinsic deactivation of the MLCT excited state, which includes luminescence; therefore, emission spectroscopy is a useful tool to evaluate whether photooxidation takes place. Indeed, light excitation of the rotaxane causes spectral changes indicating the disappearance of the Cu(I) chromophore and the concomitant formation of the tetracoordinated Cu(II) center [114]; spectroscopic measurements showed that subsequent transformation of tetracoordinated Cu(II) into the more stable pentacoordinated Cu(II) species, that is, shuttling of the macrocyclic component (process 3), was slowly occurring. The cycle can be completed upon addition of an excess of ascorbic acid, which reduces the Cu(II) center back to Cu(I) (process 4), affording the shuttling of the macrocyclic ring back to its initial position (process 5). It is worth noticing that in this case the back reduction step cannot be induced by light since in Cu(II) complexes the lowest excited state decays to the ground state very rapidly and therefore cannot be involved in a bimolecular reaction with a reductant.

The design principles that form the basis of the light-driven molecular machines shown in Figure 23 have been employed to obtain the [2]rotaxane **29**[6+] (Fig. 27) [115], specifically designed to achieve photoinduced ring shuttling. This compound is made of the electron donor macrocycle R and a dumbbell-shaped component that contains (i) [Ru(bpy)$_3$]$^{2+}$ (P) as one of its stoppers, (ii) a 4,4′-bipyridinium unit (A$_1$) and a 3,3′-dimethyl-4,4′-bipyridinium unit (A$_2$) as electron-accepting stations, (iii) a *p*-terphenyl-type ring system as a rigid spacer (S), and (iv) a tetraaryl-methane group as the second stopper (T). The stable translational isomer of rotaxane **29**[6+] is the one in which the R component encircles the A$_1$ unit, in keeping with the fact

that this station is a better electron acceptor than the other one. Two strategies have been devised in order to obtain the photoinduced abacus-like movement of the R macrocycle between the two stations A$_1$ and A$_2$: One is based on processes involving only the rotaxane components (intramolecular mechanism), while the other one requires the use of external reactants (sacrificial mechanism).

The intramolecular mechanism, illustrated in the left part of Figure 27, is based on the following four operations [115]:

(a) *Destabilization of the stable translational isomer*. Light excitation of the photoactive unit P (process 1) is followed by the transfer of an electron from the excited state to the A$_1$ station, which is encircled by the ring R (process 2), with the consequent "deactivation" of this station; such a photoinduced electron transfer process has to compete with the intrinsic decay of *P (process 3).

(b) *Ring displacement*. The ring moves from the reduced A$_1$ station to A$_2$ (process 4), a step that has to compete with the back electron transfer process from A$_1^-$ (still encircled by R) to the oxidized photoactive unit, P$^+$ (process 5). This is the most difficult requirement to meet in the intramolecular mechanism.

(c) *Electronic reset*. A back electron transfer process from the "free" A$_1^-$ station to P$^+$ (process 6) restores the electron acceptor power to the A$_1$ station.

(d) *Nuclear reset*. As a consequence of the electronic reset, back movement of the ring from A$_2$ to A$_1$ takes place (process 7).

The results obtained (CH$_3$CN solution, 298 K) [115] seem to indicate that the back electron transfer (process 5) is faster than the ring displacement (process 4). It is worthwhile noticing that in a system that behaves according to the intramolecular mechanism shown in Figure 27 (left) each light input causes the occurrence of a forward and back ring movement (i.e., a full cycle) without generation of any
Figure 27. [2]Rotaxane 29^{6+} and schematic representation of the intramolecular (left) and sacrificial (right) mechanisms for the photoinduced shuttling movement of macrocycle R between the two stations A_1 and A_2 located on the axle component.

waste product. In some way, it can be considered as a "four-stroke" cyclic linear motor powered by light.

The alternative, less demanding mechanism is based on the use of external sacrificial reactants (a reductant like triethanolamine and an oxidant like dioxygen) that operate as illustrated in the right part of Figure 27:

(a) *Destabilization of the stable translational isomer*, as in the previous mechanism.

(b′) *Ring displacement after scavenging of the oxidized photoactive unit*. Since the solution contains a suitable sacrificial reductant, a fast reaction of such species with P^+ (process 8) competes successfully with the back electron transfer reaction (process 5); therefore, the originally occupied A_1 station remains in its reduced state, A_1^-, and the displacement of the ring R to A_2 (process 4), even if it is slow, does take place.

(c′) *Electronic reset*. After an appropriate time, restoration of the electron acceptor power of the A_1 station is obtained by oxidizing A_1^- with a suitable oxidant, such as O_2 (process 9).

(d) *Nuclear reset*, as in the previous mechanism (process 7).

Such a sacrificial mechanism, although fully successful, is less appealing than the intramolecular one because it leads to the formation of waste products. However, instead of using a sacrificial reductant, that is, an electron donor molecule that undergoes a fast decomposition reaction after electron transfer has taken place, a "reversible" reductant, giving rise to a stable oxidized form, may be successfully employed, provided that the back electron transfer process can be slowed down by a wise choice of the partners.

A light-driven molecular shuttle that relies on this strategy has been reported [116]. The [2]rotaxane **30** (Fig. 28) consists of a benzylic amide macrocycle that surrounds an axle featuring two hydrogen-bonding stations, namely, a succinamide unit and a naphthalimide unit, separated by a long alkyl chain. Initially, the macrocycle resides on the succinamide station because the naphthalimide unit is a much poorer hydrogen-bonding recognition site. Light excitation at 355 nm (process 1) in acetonitrile at 298 K
Figure 28. Light-induced reversible shuttling of the macrocyclic component in the hydrogen-bonded [2]rotaxane **30** [117]. The operation of this system relies on the use of a reductant (DABCO). For more details, see the text.

generates the singlet excited state of the naphthalimide unit, which then undergoes high-yield intersystem crossing to the triplet excited state. Such a triplet state can be reduced in bimolecular encounters by an electron donor (1,4-diazabicyclo[2.2.2]octane; DABCO) added to the solution in a sufficiently large amount (process 2). Because the back electron transfer process (process 3) is spin forbidden and thus slow, the photogenerated ion pair can efficiently dissociate; as a matter of fact, the naphthalimide radical anion survives for hundreds of microseconds before it decays by bimolecular charge recombination with a DABCO radical cation. Since the naphthalimide anion is a much stronger hydrogen-bonding station compared to the succinamide, upon reduction of the naphthalimide unit the macrocycle is expected to shuttle from the latter to the former station (process 4); this has been demonstrated by cyclic voltammetric experiments. Laser flash photolysis studies have demonstrated that this is indeed the case; the time required for ring shuttling (ca. 1 μs) is much shorter than the lifetime of the naphthalimide radical anion (ca. 100 μs). After charge recombination (process 5), the macrocycle moves back to its original position (process 6). This [2]rotaxane constitutes an outstanding example of a linear molecular motor driven exclusively by light, although its operation still relies on the presence of external reactants, which, however, are not consumed. The device can be cycled at a frequency depending on the charge recombination rate of the rotaxane radical anion. It can be estimated that if the shuttle is pumped by a laser at the frequency of its "recovery stroke" (process 5), that is, 10^4 s^{-1}, this molecular-level machine generates approximately 10^{-15} W of mechanical power per molecule [116].

In a very recent work [117], the complex fluorescence behavior exhibited by a similar peptide-based [2]rotaxane bearing an anthracene unit as one of the stoppers has been interpreted in terms of a very fast (subnanosecond), short-amplitude translation of the macrocycle upon light excitation of the anthracene subunit. However, it seems that alternative explanations, such as the formation of intercomponent exciplexes [118], cannot be ruled out.

4.3. Ring Rotation in Catenanes

There are several examples of catenanes where ring movements can be induced by external stimulations like simple chemical reactions or homogeneous or heterogeneous electron transfer processes [91–93], but only very few cases are reported in which the stimulus employed is light. It has been shown that in azobenzene-containing [2]catenanes like **31**$^{4+}$ (Fig. 29) it is possible to control the rate of thermally activated rotation of the macrocyclic components by photoisomerization of the azobenzene moiety [119, 120]. Such systems can be viewed as molecular-level brakes operated by light.

To date, only one case has been reported in which the ring motions are induced photochemically, using the same strategy adopted to operate molecular shuttle **28**$^+$ (Fig. 26). Irradiation at 464 nm of the [2]catenane **32**$^+$ (Fig. 30) [121] in CH$_3$CN solution at room temperature in the presence of *p*-nitrobenzylbromide causes an electron transfer process from the photoexcited [2]catenane to *p*-nitrobenzylbromide, thus generating a Cu(II) center. Owing to the preference of the Cu(II) ion for a pentacoordination geometry, the terpyridine-containing macrocycle rotates through the cavity of the other, affording a pentacoordinated Cu(II) center. Upon addition of ascorbic acid, the Cu(II) ion is reduced to Cu(I); in response to the preference of Cu(I) for tetracoordination, the terpyridine-containing macrocycle rotates again through the cavity of the other, restoring the original structure (Fig. 30).

5. MOLECULAR DEVICES FOR INFORMATION PROCESSING

As mentioned in Section 1.1, photons represent not only quanta of energy, but also information bits, and can be used by a PMD as input/output signals, to be processed and eventually even stored and retrieved. Apart from futuristic applications related, for instance, to the construction of a chemical computer [122], the design and realization of a *molecular-level electronic set*—that is, a set of molecular-level systems capable of playing functions that mimic those performed by macroscopic components in electronic devices—is
Figure 29. Photocontrollable molecular-level brake. The thermally activated circumrotation of the macrocyclic polyether component of [2]catenane **31**$^{4+}$ can be modulated reversibly by *cis/trans* photoisomerization of the azobenzene unit incorporated into the tetracationic macrocycle [119, 120].
Figure 30. Photoinduced rotation, based on the use of an oxidant scavenger (*p*-nitrobenzylbromide), of the terpyridine-containing macrocycle in the copper-containing [2]catenane **32**[+] [121]. The system is brought back to the initial structure through another ring rotation, induced chemically by reduction with ascorbic acid.

of great scientific interest because it introduces new concepts into the field of chemistry and stimulates the ingenuity of researchers engaged in the bottom-up approach to nanotechnology. In the past few years, many systems that could prove useful for information processing at the molecular level [3, 4, 6–9, 123] (e.g., wires [6, 124–127], antennas [63–70], switches [127, 128], rectifiers [129, 130], plug/socket devices [42], memories [127, 128, 131], logic gates [3, 127, 128, 132–134]) have been constructed and studied. It has already been pointed out that suitably designed pseudorotaxanes, rotaxanes, and catenanes could prove useful for information processing because they can be interconverted at will between two (or more) stable states that can be used to represent information bits on the molecular scale. In some particular cases, the relationship between the input and output signals in such molecular devices corresponds to a logic operation, opening the way to the construction of molecular-level logic gates based on pseudorotaxanes, rotaxanes, and catenanes.

5.1. Molecular Wires

Very attractive candidates to play the role of wire-type compounds for the vectorial transfer of energy or electrons are linear oligo- or poly-*p*-phenylenes [135]. Such rigid rodlike conjugated molecules have been employed as spacers between chromophoric units in systems designed to achieve long-range photoinduced energy or electron transfer (photonic molecular wires) [136, 137]. It has been shown that the luminescence, stability, and processability of polymers of the poly-*p*-phenylene type can be enhanced by threading them through macrocycles to form conjugated polypseudorotaxanes and polyrotaxanes that could be viewed as "insulated molecular wires" [138, 139]. Hydrophobic binding holds the monomer inside the cavity of a macrocycle, for example, a cyclodextrin; such a [2]pseudorotaxane

is then polymerized to form a conjugated polypseudorotaxane, which can then be stoppered at both ends to give a polyrotaxane (Fig. 31) [139]. It remains to establish, though, whether the encirclement of the molecular wire with macrocyclic rings in the polyrotaxane will result in improvement of the performance of photonic molecular wires.

5.2. Plug/Socket and Extension Systems

A macroscopic plug/socket system is characterized by the following features: (i) the possibility to connect/disconnect the two components in a reversible way and (ii) the occurrence of energy flow from the socket to the plug when the two components are connected. Pseudorotaxane-type supramolecular systems have been designed that may be considered as molecular-level plug/socket devices. In the system illustrated in Figure 32 [42], the plug-in function is related to the threading, driven by the formation of strong N[+]—H···O hydrogen bonds in dichloromethane solution [33], of (±)binaphthocrown ether **33** by a (9-anthracenyl)benzylammonium ion, obtained by protonation of the corresponding amine (**34**). The association process can be reversed quantitatively (plug-out) by addition of a suitable base, like tributylamine, which deprotonates the ammonium ion. In the plug-in state, which corresponds to a pseudorotaxane structure, light excitation of the binaphthyl unit of the crown causes the sensitized fluorescence of the anthracenyl unit of the thread, showing that an efficient electronic energy transfer process has occurred between the two chromophoric groups. Addition of a stoichiometric amount of base to the pseudorotaxane structure causes the revival of the binaphthyl fluorescence and the disappearance of the anthracenyl fluorescence upon excitation in the binaphthyl bands, demonstrating that plug-out has happened. The plug/socket concept at the molecular level can
Figure 31. Synthesis, directed by hydrophobic binding, of an "insulated molecular wire" [139].
Figure 32. Acid/base-controlled plug-in/plug-out of (9-anthracenyl) benzylammonium ion **34**H$^+$, obtained by protonation of the corresponding amine **34**, with ($\pm$)-binaphthocrown ether **33** [42]. The occurrence of photoinduced energy transfer in the plug-in state is schematized.

be extended straightforwardly to the construction of systems where (i) light excitation induces an electron flow instead of an energy flow and (ii) the plug-in/plug-out function is stereoselective (the enantiomeric recognition of chiral ammonium ions by chiral crown ethers is well known).

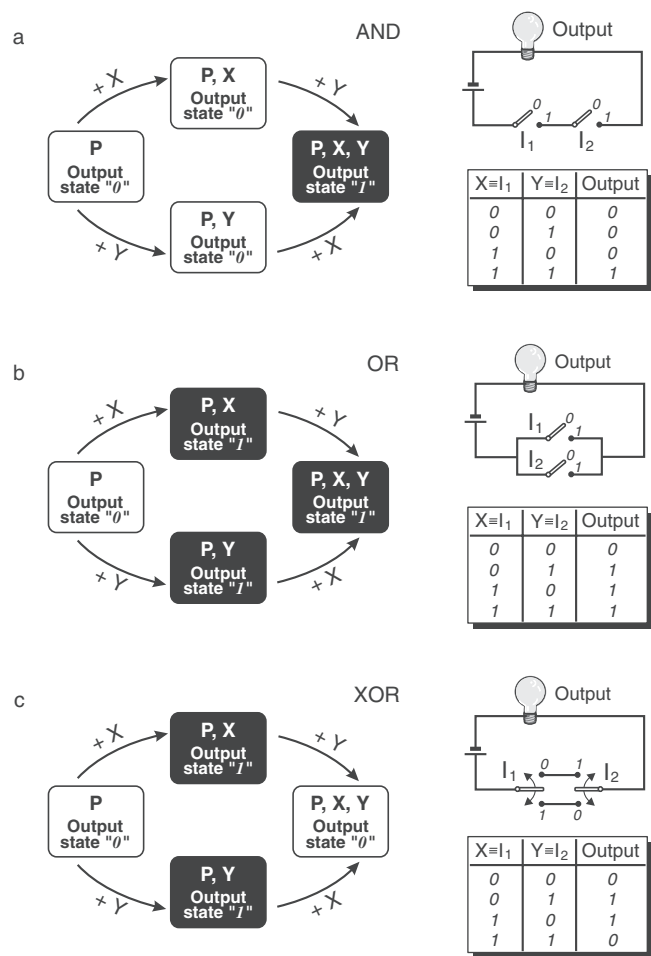
The plug/socket concept has recently been used to design and construct a self-assembling [3]pseudorotaxane that mimics at the molecular level the function played by a macroscopic extension. The system is made (Fig. 33) [140] of three components, **35**$^{2+}$, **36**H^{3+}, and **2**. Component **35**$^{2+}$ consists of two moieties—a [Ru(bpy)$_3$]$^{2+}$ unit, which plays the role of electron donor under light excitation, and a

DB24C8 crown ether, which plays the role of a socket. The wire-type component **36**H^{3+} is also made of two moieties: an ammonium unit, which, driven by hydrogen-bonding interactions, threads as a plug into the DB24C8 socket, and a bipyridinium unit, which, driven by donor/acceptor interaction, threads as a plug into the third component **2**, a 1/5DN38C10 crown-ether socket. In CH$_2$Cl$_2$/CH$_3$CN (98:2 v/v) solution, reversible connection/disconnection of the two plug/socket functions can be controlled independently by acid/base and red/ox stimulation, respectively. In the fully connected **35**$^{2+}$⊃**36**H^{3+}⊂**2** triad, light excitation of the [Ru(bpy)$_3$]$^{2+}$ unit of component **35**$^{2+}$ is followed by electron transfer to the remote bipyridinium unit of component **36**H^{3+}, which is plugged into component **2**. Possible schemes to improve the system have also been discussed.

5.3. Logic Gates

Computers are based on semiconductor logic gates that perform binary algebraic operations [141]. Logic gates are switches whose output state (*0* or *1*) depends on the input conditions (*0* or *1*). YES and NOT single-input gates are the simplest logic devices. A YES gate passes the input bits to the output without changes (input: *1*, output: *1*; input: *0*, output: *0*), while a NOT gate inverts any input data (input: *1*, output: *0*; input: *0*, output: *1*).

Molecular systems that can perform simple YES and NOT logic operations are very common, and luminescence
Figure 33. Supramolecular system that mimics the function played by a macroscopic extension [140]. The two pseudorotaxane-type connections between the three molecular components can be controlled independently by acid/base and red/ox stimulation, respectively. In the fully assembled [3]pseudorotaxane, a photoinduced electron transfer process occurs from the excited state of the [Ru(bpy)$_3$]$^{2+}$ moiety of **35**$^{2+}$ to the bipyridinium unit of **36**H^{3+}, which, in turn, is plugged into crown ether **2**.

is a particularly useful signal to monitor such operations [132, 142]. To perform more complex logic operations, however, carefully designed multicomponent chemical systems are needed. Figure 34 shows schematically the changes that have to occur in a chemical system in order to perform the AND, OR, and XOR fundamental logic operations under the action of two chemical inputs (X and Y). For illustration purposes, the equivalent (from a logic viewpoint) electric circuits are also shown. The equivalent circuit of the AND gate has switches connected in series (Fig. 34a), whereas that of the OR gate has switches connected in parallel (Fig. 34b). An XOR (eXclusive OR) gate is a much more complex device, as one can understand from the fact that its equivalent circuit contains two bipolar switches (Fig. 34c). The truth table of the XOR operation is the same as that of the OR operation except that the output is *0* if *both* the inputs are *1*. In today's processors, addition is performed with an AND gate, which gives the carry digit, and an XOR gate, which gives the sum digit. It is also important to notice that the XOR gate is actually a comparator because it can establish whether the two inputs have the same value. Interesting


examples of supramolecular systems capable of performing the AND, OR, and XOR logic operations, as well as more complex ones, and even integrating two such functions in a single supramolecular device, have been reported [132, 142–147]. In all these systems, binding of different chemical species (input) results in changes in luminescence intensity (output).

The first example of a chemical system capable of performing the XOR logic operation was based on the pseudorotaxane $[37 \subset 38]^{2+}$ illustrated in Figure 35 [148]. It results from self-assembly, in CH_2Cl_2/CH_3CN (90:10 v/v) solution, of the electron-accepting 2,7-dibenzyldiaza-pyrenium dication 37^{2+} with the crown ether 38, which contains two 2,3-dioxynaphthalene electron-donating units. In the pseudorotaxane structure, the electron-deficient diaza-pyrenium unit is sandwiched between the electron-rich 2,3-dioxynaphthalene units of 38. Because of the electron donor/acceptor interaction, a low-energy charge transfer excited state is formed that is responsible, *inter alia*, for the disappearance of the strong fluorescence exhibited by 38 ($\lambda_{max} = 343$ nm). Upon addition of tributylamine (**B**, Fig. 35), a 1:2 adduct, $[37 \cdot (\mathbf{B})_2]^{2+}$, is formed between the 2,7-dibenzyldiazapyrenium dication 37^{2+} and the amine, with the consequent dethreading of 38 (process 1 in Fig. 35). This process causes large spectral changes, including the recovery of the fluorescence of free crown ether 38. Subsequent addition of a stoichiometric amount (relative to the previously added amine) of trifluoromethanesulfonic acid unlocks 37^{2+} from the $[37 \cdot (\mathbf{B})_2]^{2+}$ adduct (process 2 in Fig. 35) and allows rethreading between dication 37^{2+} and macrocycle 38 to give back the original pseudorotaxane. This process is accompanied by spectral changes opposite to those observed upon addition of amine. Processes 1 and 2 can be repeated on the same solution by repeating the addition of amine and acid; of course, the ammonium ion originated from protonation of amine **B** is also produced at the end of each cycle. As shown in Figure 35, the dethreading/rethreading cycle can also be performed by reverting the order of the two inputs. Both processes 1 and 3 cause a strong increase in emission intensity at 343 nm, which is cancelled by processes 2 and 4, respectively. Therefore, we can conclude that the chemical system described above shows the input/output

Figure 34. Schematic representation of a chemical system (P) that performs the AND (a), OR (b), and XOR (c) logic operations under the action of two chemical inputs (X and Y). The truth tables of such operations are also shown, along with their representations based on electric circuit schemes.
Figure 35. Schematic representation of the threading/dethreading pattern of [2]pseudorotaxane $[37 \subset 38]^{2+}$, which corresponds to an XOR logic function.

relationships indicated by the truth table of the XOR logic gate (Fig. 34c): The strong fluorescent signal at 343 nm is present (output: *1*) only when either amine or H^+ (inputs X and Y in the truth table) are added (i.e., X: *1* and Y: *0* or vice versa); conversely, the fluorescent signal is absent (output: *0*) when none or both of the inputs are present (i.e., X = Y: *0* or X = Y: *1*).

6. CONCLUSION

The progress made in the fields of supramolecular chemistry and photochemistry, and in particular the investigations performed in the last few years on pseudorotaxanes, rotaxanes, and catenanes, has led to the design and construction of molecular-level devices capable of performing a variety of light-induced functions (photochemical molecular devices). Light stimulation is particularly convenient for operating molecular-level devices. For example, it can be switched on and off easily and rapidly and, by employing lasers, it provides the opportunity of working in small space regions and very short time domains. A further advantage offered by the use of photochemical techniques is that photons, besides supplying the energy needed to make a device work, can also be useful in reading the state of the system and thus controlling and monitoring its operation.

It should be noted, however, that the molecular-level devices described in this chapter operate in solution, that is, in an incoherent fashion. For most kinds of applications, they need to be interfaced with the macroscopic world by ordering them in some way, for example, at an interface or on a surface [103, 149], so that they can behave coherently, either in parallel or in series. Research on this topic is developing at a fast-growing rate [6, 7]. Furthermore, addressing a single molecular-scale device by instruments working at the nanometer level is no longer a dream [150, 151].

The extension of the concept of a device to the molecular level is of interest not only for the development of nanotechnology, but also for the growth of basic research. Looking at supramolecular chemistry from the viewpoint of functions with reference to devices of the macroscopic world is indeed a very interesting exercise that introduces novel concepts into chemistry as a scientific discipline.

GLOSSARY

Antenna for light harversing (molecular-level) A recognized array of molecular components (i.e., a supramolecular species) capable of absorbing light and delivering the resulting electronic energy to a predetermined component of the array; this function is often called antenna effect.

Catenane A supramolecular species consisting of two or more interlocked macrocyclic components.

Charge separation A chemical reaction, usually photoinduced, involving the transfer of an electron in a supramolecular species from a neutral component to another neutral component, leading to a species made of a positively and a negatively charged moieties.

Logic gate (molecular-level) A molecular or supramolecular species capable of performing a logic operation.

Molecular device An assembly of a discrete number of molecular components (i.e., a supramolecular species) designed to perform a specific function.

Molecular machine A particular type of molecular device in which the component parts display changes in their relative position as a result of some external stimulus.

Molecular wire A common name to indicate a long, highly conjugated molecule.

Pseudorotaxane An inclusion complex in which a molecular thread is encircled by a macrocyclic component; see also rotaxane.

Rotaxane A supramolecular species consisting of a dumbbell-shaped component and a macrocyclic component which surrounds the linear portion of the dumbbell and is trapped mechanically by bulky stoppers; when at least one of the stoppers is absent, the macrocyclic component can dethread and the supramolecular species is called pseudorotaxane.

Supramolecular chemistry Branch of chemistry bearing on organized entities of higher complexity that result from the association of two or more molecular components.

Photochemistry in Zeolite Nanocavities

Masanobu Kojima

Shinshu University, Kami-ina, Nagano, Japan

1. INTRODUCTION

The spectroscopic and chemical behavior of ion radicals generated through photo-induced electron transfer reaction has attracted much attention in the last several decades. The invention of flash photolysis techniques and the improvement of laser light pulse-width made it possible for us to directly observe ion radicals with nano- and pico-second order lifetimes and to make a significant contribution to our understanding of the reaction mechanisms involved in organic photochemistry. However, now that the behavior of ion radicals has been well elucidated, the interest of researchers in photochemistry is shifting from small molecules to supramolecules.

There has been much interest in the discovery that the spectroscopic and photochemical behavior of organic small molecules included in zeolite nanocavities (zeolite supramolecules) is very different from that in solution and also that short-lived species such as ion radicals and carbocations generated spontaneously in the cavities are surprisingly stable [1–13]. These findings suggest that zeolite nanocavities have considerable potential as novel reaction vessels which can regulate the photochemical reaction of organic guest molecules. The characteristics of zeolite nanocavities affecting spectroscopic and photochemical behavior are well understood, and as a result, it is to be expected that the cavities will be used increasingly as photoreaction vessels.

This article provides a brief summary of the spectroscopic and photochemical behavior of organic guest molecules in the cavities, mainly using aliphatic and aromatic alkenes:

1. direct (nonsensitized) photo-oxygenation by excitation of contact charge-transfer (CCT) complexes between alkenes and oxygen molecules,
2. oxygenation by singlet oxygen,
3. *cis-trans* photoisomerization,
4. photodimerization,
5. photorearrangement,
6. spectroscopy and photoreaction of short-lived species,
7. photochemical asymmetric induction.

Particular emphasis will be given to the differences between the reaction behavior in the zeolite nanocavities and that in solution. In addition, the factors influencing the excited states of guest molecules will be concisely summarized.

2. ZEOLITE NANOCAVITIES AS PHOTOCHEMICAL MICROREACTORS

Zeolites are crystalline aluminosilicates that have been widely utilized as molecular sieves and in thermal catalysis. They comprise corner-sharing SiO_4^{4-} and AlO_4^{5-} tetrahedral, and the framework contains a large number of pores, channels, and cages of various dimensions that can accommodate organic molecules of the right size. The supercage structure of X- and Y-type synthetic zeolites, and the cation location (I, II, and III) within the cages are illustrated in Figure 1 [1]. The two zeolites have the following typical unit cell compositions:

$$X \text{ type} \qquad M_{86}(AlO_2)_{86}(SiO_2)_{106} \cdot 264H_2O,$$
$$Y \text{ type} \qquad M_{56}(AlO_2)_{56}(SiO_2)_{136} \cdot 253H_2O,$$
where M is a monovalent cation. These zeolites can adsorb most small organic molecules including aromatic compounds in the cavities, which have supercages (diameter, ca. 13 Å) and pore windows (ca. 7.4 Å) of sufficient size; accordingly,
Figure 1. Supercage structure, cation location (I, II, III) within X and Y type zeolites. Bottom portion shows the reduction in available space (relative) within the supercage as the cation size increases. Reprinted with permission from [45], V. Ramamurthy and N. J. Turro, *J. Incl. Phenom. Mol. Recog. Chem.* 21, 239 (1995). © 1995, Kluwer Academic Publishers.

they have often been used in the photoreactions described in this article. The average number $\langle S \rangle$ of guest molecules adsorbed in a supercage per 1 g of dry NaY zeolite can be estimated as follows [14, 15]. Because the weight of a unit cell with eight supercages is $M_{56}(AlO_2)_{56}(SiO_2)_{136} = 12742$ g, the weight of a supercage is 12742 g$/8 = 1594$ g. Accordingly, the number of supercages per 1 g of dry NaY is estimated to be the Avogadro number $\times$ $(1\ /1594) =$ ca. 3.8×10^{20}. The supercage capacity per 1 g of dry NaY has been determined experimentally to be 0.378 cm^3 [16]. When this value is divided by the volume (827 Å^3) of a supercage for NaY, the number of supercages is calculated to be ca. 4.6×10^{20}. This is in close agreement with the above calculated value, ca. 3.8×10^{20}. Reference [1] should be referred to for other zeolites such as ZSM-5 and Mordenite. The physical parameters of M$^+$Y zeolite are summarized in Table 1. As zeolites are photo-inert, the confined environment of their framework can be successfully utilized to attain remarkable selectivity in photochemical reactions [1–13].

3. INFLUENCE OF BRØNSTED AND LEWIS ACID SITES IN ZEOLITE NANOCAVITIES

Brønsted and Lewis acid sites in zeolite nanocavities may spontaneously generate the carbocations and ion radicals of alkenes adsorbed in the cavities [17–23]. Thus, these acid sites sometimes impede the study of the photoreaction of the guest molecules. It is very common for the acidity of Brønsted acid sites on solid surfaces to be determined by using Hammett indicators. Recently, it was found that the fluorescence and phosphorescence characteristics of organic guest molecules, such as pyrene and acetophenone, were also useful in determining the acidity in the cavities [24–27]. Kojima et al. [28] studied the influence of Brønsted and Lewis acid sites on the fluorescence lifetime of 2-quinolone (**1**) in order to estimate the acidity. The lifetimes (τ) of **1**–Brønsted acid (1.2 ns) and **1**–Lewis acid complexes (1.6 ns) have been measured in dichloromethane [29]. It was found that the acidity of the sites in zeolite nanocavities significantly affected the lifetimes of the complexes, as can be seen in Table 2. On the basis of the lifetimes, the acidity can be estimated more precisely than by using Hammett indicators. Therefore, the data provided the criteria necessary to select zeolites suitable for use in studying the photochemistry of guest molecules.

Corrent et al. [30] found that the dye coumarin 6 (**2**) was extremely sensitive to the presence of Lewis and Brønsted sites and that it could be employed to determine acidity in NaY, which was usually considered to be nonacidic, as can be seen in Figure 2 and Scheme 1. Due to the large shifts seen for the dye molecule in its neutral **2**, monocation **3**, and dication forms, both the absorption and fluorescence spectra resulted in detection of the dye species in zeolites with intermediate acidity. The ability of **2** to sense small amounts of Lewis and Brønsted sites may prove useful in studying other systems.
Scheme 1

Table 1. Dependence of physical parameters of MY zeolites on the cation.

Cation (M$^+$)	Ionic radius of the cation (Å)	Electrostatic field (V/Å) within the case	Electrostatic potential (e/r) of the cation	spin-orbit coupling	Vacant space within the supercage (Å^3)	
					Y Zeolite	X Zeolite
Li	0.76	2.1	1.67		834	873
Na	1.02	1.3	1.05	27	827	852
K	1.38	1.0	0.75	87	807	800
Rb	1.52	0.8	0.67	360	796	770
Cs	1.67	0.6	0.59	840	781	732

Table 2. Fluorescence decay lifetimes of 2-quinolone (**1**) in solution and in zeolite.[a]

Condition	Lifetime (τ_i)/ns[b]			Preexponential factor (a_i)			Hamett acidity[c]
	τ_1	τ_2	τ_3	a_1	a_2	a_3	
CH_2Cl_2[d]	0.16 (0.18)[g]			1.0			
EtOH[d]	0.16	0.42		0.69	0.31		
HCl/CH_2Cl_2[e]	0.16	1.2		0.93	0.07		
BF_3/CH_2Cl_2[f]	0.16	1.6 (1.6)[g]		0.79	0.21		
NaY	0.30	1.0		0.88	0.12		$+3.3\sim+1.5$
KL	0.33	1.1		0.94	0.06		$+4.0\sim+3.3$
HY	0.33	1.8		0.88	0.12		$-3.0\sim-5.6$
H-mordenite	0.32	2.3		0.88	0.12		$-3.0\sim-5.6$
H-ZSM-5	0.63	2.6	7.8	0.82	0.17	0.01	$-5.6\sim-8.2$

[a] The fluorescence decay lifetimes were determined by using a single photon counting apparatus, as reported in [149], H. Satozono, S. Suzuki, N. Tokou, H. Takehara, and Y. Uno, *J. Chem. Soc. Jpn., Chem. Indus. Chem.* 115 (1994). The decay curves were analyzed by using the equation, $I(t) = \Sigma a_i \exp(-t/\tau_i)$; the excitation wavelengths were 320 nm for solution and 330 nm for zeolite; the emission wavelength was 373 nm.
[b] Measured under air.
[c] Determined by using Hammett indicators.
[d] Data for **1** = 1.0×10^{-4} M in the absence of HCl and BF_3.
[e] Data for **1** = 1.0×10^{-4} M in the presence of 2 equiv. of HCl-OEt_2.
[f] Data for **1** = 1.0×10^{-4} M in the presence of 2 equiv. of BF_3-OEt_2.
[g] Lifetime reported in [29], F. D. Lewis, G. D. Reddy, J. E. Elbert, B. E. Tillberg, J. A. Meltzer, and M. Kojima, *J. Org. Chem.* 56, 5311 (1991).

4. CHARACTERISTICS OF ZEOLITE NANOCAVITIES AFFECTING PHOTOCHEMICAL REACTIONS

4.1. Adsorption Sites

The distribution of guest molecules in zeolites is more complex than in homogeneous solution. The adsorption sites for guest molecules in zeolites significantly influence the photochemical behavior of the molecules. It is thought that there are two important adsorption sites in zeolites, one of which is a pore window and the other a metal cation in the cavities. Analysis of fluorescence decay from aromatic hydrocarbons such as pyrene, naphthalene, and phenanthrene provided an insight into distribution of the sites in zeolites [14]. It was quite clear, as can be seen in Figure 3, that the distribution of lifetime measured in NaY reflected the presence of two main adsorption sites, which are heterogeneous in contrast to the homogeneous environment in solution. The width of

distribution of lifetime was affected by the structure of the guest molecules and co-adsorbents in NaY. The effect of the co-adsorbents was demonstrated by the results obtained in the case of pyrene with water and other solvents, as shown in Figure 4.

4.2. Effect of Co-Adsorbed Water

Co-adsorbed water in zeolites can impede the interaction of guest molecules with adsorption sites. For example, the formation of dimers of cationic dyes such as methylene blue (**4**) and thionin (**5**) was accelerated in NaY containing co-adsorbed water, while in dry NaY the monomers exist as a main species as shown in Figure 5 and Scheme 2 [31, 32]. The decay rate constants for fluorescence [33] and triplet excited state [16] were also greatly affected, as was the distribution of fluorescence lifetimes of aromatic hydrocarbons by co-adsorbed water as described above. Therefore, careful attention should be paid to the influence of moisture under irradiation conditions [34].
Figure 2. Absorption (A, left scale) and fluorescence (F, right scale) spectra of 4×10^{-6} M coumarin 6 in CH_2Cl_2 for the neutral species (solid line) and for the monocation formed upon the small addition of acid (broken line). cations [35]. Measurements of the fluorescence and phosphorescence intensity of aromatic hydrocarbons like naphthalene (**6**) indicated that for light metal cations, such as Li^+ and Na^+, the intensity was relatively unaffected by the interaction. In contrast, for heavy metal cations such as Rb^+, Cs^+, and Tl^+, it was found that the rate of intersystem crossing increased remarkably to enhance the phosphorescence intensity, as can be seen in Figure 6. This indicates that metal cations can be used for controlling the excited state of guest molecules. On the other hand, it should be noted that the enlargement of the ion radius of a metal cation causes a decrease in the vacant space in zeolite cavities, as shown in
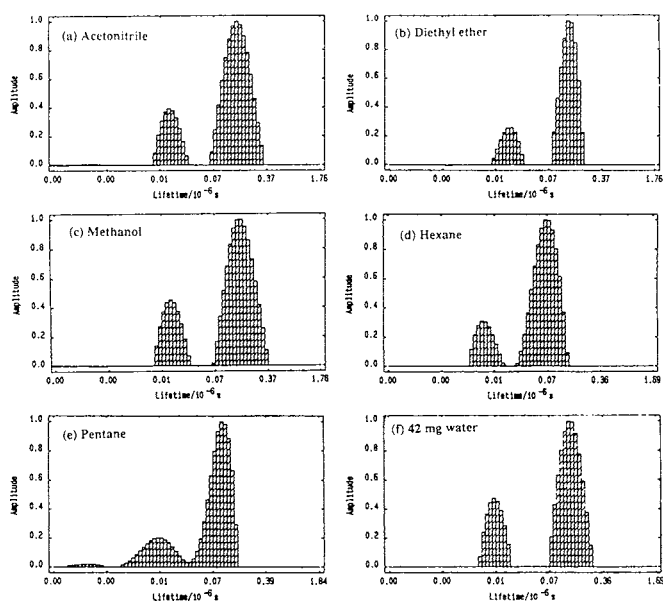

Figure 4. Distribution of lifetime of the excited monomer of pyrene within NaY co-included with organic solvent and water. Compare Figure 3a and note the change in distribution width. Figure 1; therefore, $\langle S \rangle$ decreases and also steric hindrance on bond formation increases. In addition, it is important to note that the strength of the electrostatic field depends on the metal cations, as shown in Table 1. These factors may affect the spectroscopic and photochemical behavior of guest molecules.

Sadeghpoor et al. [36] and Pitchumani et al. [37] found that photolysis of β,γ-unsaturated ketone **7** and **8** included in MY zeolites, as shown in Scheme 3, gave the oxa-di-π-methane products **9** and **10**, which were believed to originate from the triplet state caused by heavy atom cation present in the supercage. Warrier et al. [38] observed a difference in product selectivity between dibenzyl ketones **11** and naphthyl esters in zeolites and concluded that this was due to the difference in spin of the radical pairs formed from these precursors (Scheme 4). Heavy cations present in zeolites can enhance intersystem crossing between triplet and singlet
Scheme 3
Scheme 4

geminate radical pairs. Furthermore, *ab initio* molecular orbital calculations and product analysis have shown that the nature of the lowest triplet state of enones **12** is altered by the cations present in Y zeolites (Scheme 5). Excited state energy, estimated at the CIS(D)/6-31+G* level, indicated that the lowest triplet was n-π^* in character for the enones, but switched to π-π^* on coordination with alkali metal ions,

such as Li$^+$, due to interaction with the carbonyl unit of the enones. The observed product distribution in zeolite was consistent with this theoretical prediction [39].

4.4. Electrostatic Interaction of Metal Cations with Guest Molecules

Aromatic carbonyl compounds rarely undergo dark reaction due to the acid sites in zeolite cavities. Therefore, the differences between the spectroscopic and photochemical behavior in zeolite cavities and that in solution can be clearly distinguished. The data obtained from the carbonyl compounds are also useful for predicting the photochemical reaction of alkenes in zeolites. It was found for carbonyl compounds in the excited state that the selectivity of α-bond fission (Norrish type-I reaction) and γ-hydrogen abstraction, followed by β-bond fission from the 1,4-biradical intermediates generated (Norrish type-II reaction), was regulated by the electrostatic interaction of the carbonyl oxygen with metal cations in the zeolite nanocavities, as illustrated in Scheme 6 [40–45]. This interaction with metal cations also influences the photochemical behavior of alkenes as described below; thus, this is one of the most important factors for regulating the photoreaction of guest molecules.
Scheme 6

5. PHOTOCHEMICAL BEHAVIOR OF ALKENES IN ZEOLITE NANOCAVITIES

Although it seems likely that alkenes, which are more electron-donating compounds than ketones, are sensitive to Brønsted and Lewis acid sites in zeolite nanocavities [17–23], their photochemical behavior can be easily observed if the dark reaction is suppressed by choosing a combination of guest molecules and zeolites. For Na^+- and K^+-exchanged zeolites, in general, due to weak acidity in the cavities, the dark reaction of alkenes with the acid sites does not occur. However, alkenes with an electron-donating group like a methoxy group readily react with the acid sites [46–48]. Particularly, H^+-exchanged zeolites often generate the carbocations and cation radicals of the alkenes.

5.1. Direct Photo-oxygenation

In the 1950's, Evans [49] discovered the formation of CCT complexes between aromatic substrates and oxygen molecules (O_2). However, the quantity of literature related to the photochemical reaction of CCT complexes is relatively small [50]. Kojima and Onodera et al. [51–56] studied the photoreaction of the CCT complexes for 4-substituted styrenes, 1-arylcyclohexenes, and 1,1-diarylethenes and found that excitation of the CCT band caused photo-induced electron transfer reaction from the alkenes to O_2. For aliphatic alkenes, however, there is no report of photoreaction of the CCT complexes in solution.

Interestingly, Blatter and Sun et al. [57–68] found that hydrocarbons such as 2,3-dimethyl-2-butene (**13**), propane, cyclohexane, and toluene, formed CCT complexes with O_2 in zeolite NaY, the absorption band of which was observed up to the visible wavelength region, as can be seen in Figure 7. The stabilization of the CCT complexes was explained as being due to the strong electrostatic field in the zeolite nanocavities. When the CCT absorption band in the visible wavelength region was excited by using a laser light, it was suggested on the basis of infrared (IR) absorption spectra that the alkene cation radicals and superoxide anion radical ($O_2^{\bullet-}$) were generated through photo-induced electron transfer (Scheme 7). Myli, Xiang, Panov, and Larsen et al. [69–72] further studied the photo-oxygenation of hydrocarbons in zeolite nanocavities to find a close correlation
Figure 7. Alkene/O_2/NaY diffuse reflectance spectra ratioed against alkene/N_2/NaY reflectance spectra. Chem.* **98**, 13403 (1994). © 1994, American Chemical Society.
between the strength of the electrostatic field in the cavities and the distribution and yield of photo-oxygenation products.

Takeya, Kojima, and Matsubara et al. [73–76] investigated the photoreaction of CCT complexes comprising aromatic alkenes and O_2 formed in zeolites and compared the distribution and yield of products with those in solution. Although styrene (**14**), 1,1-diphenylethene (**15**), and *cis*- and *trans*-stilbenes (*t*-**16**), but not triphenylethene (**17**), formed their CCT complexes with O_2 in solutions, the CCT absorption band was observed in NaY only for **14** and **16**, as can be seen in Figure 8. Irradiation of alkenes **14–17** included in the zeolite nanocavities under O_2-produced benzaldehyde (**18**) and benzophenone (**19**) as the major oxygenation products. In particular, the photo-oxygenation for **14** proceeded at the expense of the dimer formation and that for **16** and **17** competed with a photoelectrocyclic reaction, which subsequently yielded phenanthrenes (**20**) as the

Scheme 7

exclusive photoproducts under O_2 in solution, as shown in Schemes 8 and 9, respectively. It is likely that the oxygenation products were produced through the alkene cation radicals and $O_2^{\cdot-}$ generated by excitation of the CCT complexes and/or photo-induced electron transfer from the excited alkenes to O_2. Kojima et al. [74] also reported that YAG laser (266 nm) excitation of **14** included in the zeolite cavities under vacuum produced the alkene cation radical and the trapped electron, Na_4^{3+}, both of which were quenched by O_2 (Figure 9). On the basis of semi-empirical molecular orbital calculations, it was suggested that the photooxygenation reaction was regulated by the electrostatic interaction between the guest molecules and alkali-metal cations in the nanocavities.
Scheme 8
Scheme 9

Itoh et al. [77] found that the mesoporous silica FSM-16 is a recyclable promoter for the photo-oxidative cleavage of double bonds conjugated with an aromatic nucleus, affording the corresponding carboxylic acid in the presence of catalytic iodine in aerobic isopropyl ether. When **14** was irradiated under the same conditions, 68% benzoic acid was produced. However, **15** and **16**, which possess di-substituted double bonds, behaved differently: the former gave **19** in low yield (12%), and in the case of the latter, the starting

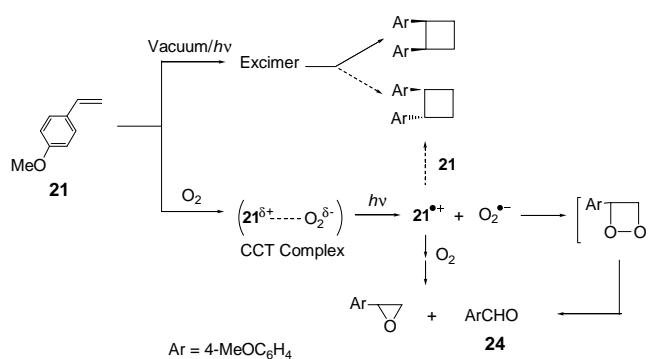
For 4-methoxystyrene (**21**), about 30% of the alkene was consumed by dark reaction with Brønsted acid sites in NaY to produce chain dimers **22** and alcohol **23** through the alkene carbocation (Scheme 11) [46–48]. The photoreaction of the **21**/NaY sample was compared to the dark reaction. As in the case of styrene (**14**) [74], the formation of dimers was a minor path in the zeolite, while the product selectivity that gave 4-methoxybenzaldehyde (**24**) increased significantly, as illustrated in Scheme 12 [75, 76]. This result was also understood in relation both to the formation of the CCT complex with O$_2$, as can be seen in Figure 10, and to the electrostatic interaction with Na$^+$ in the nanocavities (Figure 11). Lakshminarasimhan et al. also observed the formation of CCT complex in NaY between 1,1-bis-(4-methoxyphenyl)ethene (**25**) and O$_2$ [78]. The intensity of the CCT band was much weaker than that for **21** [76]. The product distribution for **15** and **25** in NaY as hexane slurries were significantly affected by excitation wavelength and changed in comparison with that under dry conditions, reported in [74].

5.2. Oxygenation by Singlet Oxygen

Ramamurthy and Shailaja et al. prepared the cationic dye-exchanged zeolites X and Y using methylene blue and thionin [31, 32] and studied oxygenation of trisubstituted

Ar = 4-MeOC$_6$H$_4$


Scheme 11

Scheme 12

chain alkenes and 1-alkylcycloalkenes by singlet oxygen (^{1}O$_2$) [32, 79, 80]. It was found that the minor product in solution became the major product in the zeolites. The following two reasons were adduced to explain the high regioselectivity observed in the products: (i) because a metal cation interacted with π orbital of the carbon-carbon double (C=C) bond, ^{1}O$_2$ reacted with the alkenes from a

sterically less-hindered site, where metal cation did not exist; (ii) because the electron density on the C=C bond decreased due to interaction of the C=C bond with a metal cation, electrophilic $^1O_2$ reacted selectively with a disubstituted carbon with relatively high electron density, as illustrated in Scheme 13.
Scheme 13

Clennan and Zhou et al. [81–84] and Stratakis and Froudakis [85] independently studied the high regioselective oxygenation by $^1O_2$ in zeolites. On the basis of the correlation between distribution of products and the bulkiness of the alkyl groups on the C=C bond, they first proposed another oxygenation mechanism by $^1O_2$, whereby the high regioselectivity found in the oxygenation of trisubstituted alkenes was caused by complexation of a metal cation to the pendant oxygen in the perepoxide intermediate [81, 82, 85], as depicted in Scheme 14. However, Clennan and Sram et al. [83, 84] later revised this mechanism and explained that the novel regiochemistry of the reactions can be rationalized by invoking both cation complexation with the alkenes and electrostatic interaction between the cation and the pedant oxygen. Although further study is required in order to confirm the mechanism, the high regioselectivity in the $^1O_2$
Scheme 14

reaction with alkenes that occurred in the nanocavities has led to an increased interest in zeolites.

As illustrated in Scheme 15, dye-sensitized photo-oxygenation of stilbenes (**16**) in solution produced endoperoxide **26**, while benzaldehyde was the sole product in zeolite nanocavities [86]. The oxygenation proceeded more efficiently in Li$^+$- and Na$^+$-exchanged zeolites which, compared to Rb$^+$- and Cs$^+$-exchanged zeolites, do not have the effect of accelerating the intersystem crossing process of the guest molecules. Therefore, it is likely that this sensitized oxygenation occurred through the singlet excited state of the dyes. The oxidation in zeolites was quenched by 1,4-diazabicyclo[2.2.2]octane and N,N-dimethylaniline, but not by aliphatic alkene **13** and β-carotene. This supported the conclusion that the oxidizing species generated in zeolites was not $^1O_2$ and that the oxygenation was initiated by photo-induced electron transfer between the dyes and the alkenes.
Scheme 15

5.3. *Cis-Trans* Photoisomerization

There have been many detailed studies of *cis-trans* photoisomerization in solution for C=C and nitrogen-nitrogen double (N=N) bond systems, which is one of the most important photoreactions so far discovered [87, 88]. Kuriyama et al. studied the direct (nonsensitized) photoisomerization of stilbene (**16**) adsorbed in NaY and KY zeolites [89]. Compared to the *cis-trans* isomer ratio in the photostationary state (PSS) obtained in solution using 254 nm light [(c/t)$_{PSS}$ = 76/24], the ratio of *trans* isomer in PSS in the zeolites was remarkably high [(c/t)$_{PSS}$ = 5/95].

On the basis of the optimized structure of Na⁺/*t*-**16** complexes calculated using semi-empirical molecular orbital calculations, it was suggested that the *trans* isomer was better stabilized than the *cis* isomer (*c*-**16**) due to the electrostatic interaction of π-electrons on the C=C bond with a metal cation, as depicted in Figure 12. Therefore, it was proposed that the interaction increased the activation energy from the excited singlet and triplet states to the ground states, as shown in Figure 13. Because of this, it was argued that deactivation from the excited states to the ground state would occur more efficiently in the zeolite cavities.

For 4-aminostilbene (**27**), on the other hand, $(c/t)_{PSS}$ obtained in NaY using 313 nm light was in close agreement with that in solution: $(c/t)_{PSS} = 85/15$ in solution and 75/25 in NaY [90]. The result of molecular orbital calculations suggested that the metal cation interacted electrostatically with a lone pair of the nitrogen atom, but not with the π-electrons on the C=C bond. Therefore, it was concluded that the activation energy from the excited state of the *trans* isomer to the twisted state was unaffected. Ramamurthy et al. [91] reported that the excited singlet state lifetime of *t*-**16** adsorbed in NaY was 200 ps, which was determined by a single photon counting apparatus. Compared to the lifetime in methylcyclohexane (110 ps), the lifetime measured in NaY seemed to indicate the stabilization of the excited state of *t*-**16** in the zeolite, as suggested by Kuriyama et al. [89]. However, Ellison and Thomas [92] also measured the fluorescence lifetime of *t*-**16** in NaY, which was 52 ps compared to 66 ps in hexane and 32 ps in methanol. Evidently, there is a need for further study of the relation between the photoisomerization and lifetime.

Recently, Kojima et al. [93] also investigated the photoisomerization of azobenzene (**28**) adsorbed in solution. On the basis of the observation that *trans*-to-*cis* photoisomerization was very inefficient in higher concentrations and that 4-methoxyazobenzene (**29**) gave unknown products, which may be dimers in higher concentration, a novel photoisomerization mechanism through excited complexes was proposed. In zeolites $(c/t)_{PSS}$ changed depending on the pore size as summarized in Table 3 [94]. In contrast to the photoisomerization in solution, regardless of the amount of **28** adsorbed, the *cis* isomer was produced efficiently in NaY (pore size, 7.4 Å) by irradiation using a high-pressure mercury lamp through a HOYA U-340 glass filter $[(c/t)_{PSS} = $ ca. 80/20]. However, $(c/t)_{PSS}$ in Na-mordenite (7.0×6.5 Å) was ca. 50/50 and no photoisomerization occurred in NaZSM-5 (5.3×5.4 and 5.1×5.5 Å). On the basis of molecular orbital calculations it was suggested that the metal cation interacts
Figure 13. Potential energy surface for photoisomerization of stilbene in zeolite cage. Reprinted with permission from [89], Y. Kuriyama et al., *Chem. Lett.* 843 (1998). © 1998, The Chemical Society of Japan.

with a lone pair of one of the two nitrogen atoms, as shown in Figure 14. These results indicate that photoisomerization can be regulated by both the cavity size and the adsorption sites in guest molecules.

Hoffmann and Marlow et al. [95–97] found that *cis-trans* photoisomerization of **28** in molecular sieve hosts such as ALPO₄-5 and ZSM-5 caused large and reversible changes in the refractive index of the composite systems. This process depended heavily on both the irradiation wavelength and the molecular sieve hosts.

Gessner et al. and Baldovi et al. achieved *cis*-to-*trans* [98] and *trans*-to-*cis* one-way photoisomerization of **16** [99], respectively, using cavity size and the shape of the zeolites. 3,4-Dimethylbenzophenone (**30**) used as a sensitizer and *c*-**16** have molecular structures larger than the cavity size of silicalite S-115. Because of this, only the *trans* isomer can be adsorbed in the cavities. Thus, when an isooctane solution containing *c*-**16** and **30** was irradiated with the silicalite, the *trans* isomer produced was selectively adsorbed in the nanocavities. Due to the constrained space in the cavities, the *trans*-to-*cis* photoisomerization did not occur in the cavities.

When solvent slurry containing the *trans* isomer and 4-aminoazobenzophenone adsorbed in ZSM-5 was irradiated, the *trans* isomer was sensitized by the ketone in the cavities and finally isomerized to the *cis* isomer in the solution, as illustrated in Scheme 16. The *cis* isomer was stable because the isomer did not encounter the sensitizer within the cavities due to the fact that its molecular size is larger than the cavity size. This method has considerable potential for the synthesis of *cis* isomers.

Lalitha et al. [100] described the influence of metal cations in Y zeolites in *cis-trans* isomerization of 4-bromophenyl styryl sulfone (**31**). The predominance of the *cis* isomer in zeolites with larger cations was attributed to the smaller cage size.

When anils (**32**) with a C=N bond was incorporated in NaY, Raman spectra analysis showed that **32** existed in the zeolite nanocavities predominantly in a zwitterionic form **33** [101] (Scheme 17). Steady state irradiation at 400 nm led to persistent changes in the diffuse reflectance UV-visible spectra with decrease of the reflectance of the band at 400 nm,

as well as the appearance of a new absorption band at longer wavelengths. No photochromism was observed and this was attributed to the isomerization of the zwitterionic form to other stereoisomers, possibly by rotation about C—C or C—N bonds with partial double bond character.

Photo-induced electron transfer isomerization of *c*-**16** in Y zeolite cavities using 2,4,6-triphenylpyrylium cation (**TP**⁺), an electron accepting sensitizer, was studied by Corma et al. [102]. Isomerization of the *cis*- to *trans*-isomer occurred
Figure 14. Optimized structure for *trans*-azobenzene (*t*-**28**)–Na⁺ complex calculated using the AM1 method. Reprinted with permission from [94], M. Kojima et al., *Mol. Cryst. Liq. Cryst.* 344, 179 (2000). © 2000, Taylor & Francis Ltd.
Scheme 17

via the corresponding cation radicals. The reaction was not affected by the presence of oxygen. This contrasted with the expensive photo-oxygenation by 2,4,6-triphenylpyrylium tetrafluoroborate under homogeneous conditions. A higher contribution of the in-cage isomerization, associated with retardation of back electron transfer in the ion radical pairs, appeared to be the most noticeable characteristic of the intrazeolite process (Scheme 18). When the novel aluminosilicate MCM-41 with 20 Å monodirectional channels hexagonally arranged was used as a host, the *cis*-to-*trans* photo-induced electron transfer isomerization of **16** occurred more efficiently than in Y zeolite [103].

Lakshminarasimhan et al. [104] also studied photo-induced electron transfer isomerization of **16** with N-methylacridinium as the sensitizer and found that iso-merization of *c*-**16** cation radical to *t*-**16** occurred. Their
Scheme 18

proposal that a recombination of ion radicals resulted in excited triplet state **16** was based on a *cis/trans* isomer ratio in the photostationary state similar to that obtained using 2-acetonaphtone as a triplet sensitizer. Diffuse reflectance flash photolysis studies showed that independent of the isomer being sensitized only *t*-**16** cation radical is formed. However, the T-T absorption spectrum for the triplet **16**, believed to have been generated, was not observed by this time resolved spectroscopy.

5.4. Photodimerization

On the basis of fluorescence spectra, it was estimated that the number of pyrene molecules per unit cell needed to form an excimer was 0.14–0.30 and 0.02–0.08 in X and Y zeolites, respectively [105, 106]. The excimer emission was observed at a value of 0.00034 in zeolite L, while only the monomer emission was seen at the same value in Mordenite [107]. It has been found that the diffusion rate of guest molecules between the cages slows considerably [108]; therefore, it seems likely that the excimer emission observed coincided with the formation of the ground state complexes. These results indicate that guest molecules do not exist homogeneously in the cavities even in the smallest quantity of adsorbed molecules.

The intermolecular interaction of guest molecules is probably enhanced in zeolite nanocavities as described above. But, although numerous investigations of the photodimerization of alkenes in solution have been reported, there are few studies of this process in zeolites. Ramamurthy et al. studied [2 + 2] photodimerization of acenaphthylene (**34**) in metal-cation exchanged Y zeolites (Scheme 19) [109]. It was found that the ratio of the *cis*- (**35**) and *trans*-cyclobutane dimers (**36**) changed depending on the intersystem crossing rate enhanced by the metal cations.
Scheme 19

Lem et al. [110] studied regioselectivity and stereoselectivity in [2 + 2] photodimerization of cyclopentenone (**37**) and cyclohexenone (**38**) in X and Y zeolites. Both enones formed a head-to-tail [2 + 2] dimer (HT) as the major product in solution, while the major dimer produced in zeolites was a head-to-head [2 + 2] dimer (HH), as shown in Scheme 20. The ratio of HT/HH was lowest in CsX, which also had the smallest supercage volume and the weakest electrostatic interaction of the ion. However, a similar result was obtained for **37** and **38** in NaX and CsX, the relative free volumes of which were quite different. Thus, it was suggested that the complexing effect of the charge-compensating cation and the size constriction factor

in the NaY supercage probably played a role in controlling regiochemistry.
Scheme 20

Lalitha et al. [111] investigated the photodimerization of *trans*-2-styrylpyridine (*t*-**39**) in various cation-exchanged Y zeolite. At a lower loading level, *trans-cis* isomerization was the only process observed. When the loading level was increased, in addition to isomerization, significant amounts of dimerization (**40**) and cyclization products (**41**) were also observed with the product distribution, depending on the free volume available inside the cages (Scheme 21). Acidic zeolites such as HY and MgY were found to catalyze the thermal reaction of *t*-**39**.
Scheme 21

Brancaleon et al. [112] studied photo-induced electron transfer reactions between excited singlet acceptors and arylalkenes included in NaX zeolites. Diffuse reflectance flash photolysis studies indicated that quenching of singlet cyanoaromatic sensitizers such as 2,3-dicyanonaphthalene and 1-cyanonaphthalene by *trans*-anethole (**42**) and **21** occurred through electron transfer and yielded relatively long-lived radical cations, which finally yielded the dimeric cyclobutane products as in solution (Scheme 22 and Figure 15). However, the dimer ratios were substantially different with the *cis*/syn cyclobutanes formed preferentially in the zeolite reactions, presumably as a result of the constraints imposed by the restricted space of the zeolite supercage.
Scheme 22
Figure 15. Transient spectra measured after 355-nm excitation of 2,3-dicyanonaphthalene (10 μmol/g) plus *trans*-anethole (**42**: 52 μmol/g) in NaX under nitrogen (●) and oxygen (◆). The insert shows the spectrum obtained by direct 266-nm excitation of an oxygen-saturated sample of 10 μmol **42** in NaX. Reprinted with permission from [112], L. Brancaleon et al., *J. Am. Chem. 5.5. Photo-Fries and Photo-Claisen Rearrangements

Pitchumani and Gu et al. demonstrated by investigating photo-Fries rearrangements of phenyl acetate (**35**), phenyl benzoate (**43**) [113], and 1-naphthyl esters (**44**) [114], in addition to photo-Claisen rearrangements of allyl phenyl ether (**45**) [113] and aryl benzyl ethers (**46**) [115], that sharp selectivity consisted in a subtle matching of size and shape of reactants and/or products with the size and shape of pores, cages, and pore volumes of the intracrystalline zeolite phase. In the photorearrangements, a nearly 1 : 1 mixture of *ortho* (**47** and **48**) and *para* isomers (**49** and **50**) was normally produced in solution (Scheme 23). However, the photoreactions in zeolites were controlled selectively toward either the *ortho* or the *para* products by conducting the reactions either in faujasites X and Y or pentasils ZSM-5 and ZSM-11, respectively. For the photo-Fries reactions of phenyl acetate and phenyl benzoate in X and Y zeolites, the formation of the *ortho* isomer was highly selective (76–98%). This selectivity was not the result of shape exclusion since both the *ortho* and *para* isomers fit well within the supercage. Therefore, it was suggested that the selectivity resulted from the restrictions imposed on the mobility of the phenoxy and the acyl
(benzoyl) fragments by the supercage framework and also by the interaction with the cations. Vasenkov and Frei monitored a transient at 2125 cm^{-1} assigned to acetyl radical generated in NaY by means of step-scan FT-infrared spectroscopy of 1-naphthyl acetate and gained a better mechanistic understanding of the photo-Fries reaction [116]. The kinetic result was interpreted in terms of a complete separation of the photogenerated pairs from the parent supercage, followed by random walks in the subspaces of the zeolite lattice imposed by the much less mobile precursor molecules. It is likely that these forced the geminate radicals to react and thereby contributed to the high selectivity of the photorearrangement.

For pentasils ZSM-5 and ZSM-11 only, the *para* isomers fit the shape and size of the zeolites. Indeed, when photolysis was conducted in water and 2,2,4-trimethylpentane, a clear preference for the *para* isomer was observed.

5.6. Spectroscopy and Photoreaction of Short-Lived Species

H$^+$-exchanged zeolites such as HY, H-mordenite, and H-ZSM-5 have strong Brønsted acid sites. Using the strong acid sites and an electrostatic field in the zeolites, it has been possible to generate very stable carbocations in the cavities [17–23, 46–48, 117]. Garcia et al. [118] investigated the photoisomerization of 1,3-diphenylpropenylium (**51**) and 1,5-diphenylpentadienylium (**52**) ion generated within acid ZSM-5 and Mordenite zeolites as a persistent species by adsorption of α,ω-disubstituted α,ω-diphenylalkanes (Scheme 24). Irradiation of these allylic cations produced in zeolites led to *cis-trans* isomerization as the only observable process.
Scheme 24

O'Neill et al. studied the reactivity of 4-methoxycumyl cation (**53**) [119] and 9-fluorenyl cation (**54**) [120] generated in nonacidic zeolites using nanosecond laser flash photolysis (Schemes 25 and 26, respectively). In dry zeolites, the absolute reactivity of **53** was found to be heavily dependent on the nature of the alkali counterion, the Si/Al ratio, and the framework morphology, with the lifetime of the carbocation in Naβ being almost 10,000-fold longer than in CsY. The observation of the highly reactive and highly unstable **54** under these conditions afforded a remarkable example of the extraordinary ability of nonproton exchanged zeolites to provide kinetic stabilization for electrophilic guests. The

Scheme 23

Scheme 25

Scheme 26

Figure 16. CW-EPR spectra (right) of radicals **1R**–**4R**@NaZSM-5 produced by photolysis of **56**@NaZSM-5 ($\lambda_{irr} > 280$ nm) and corresponding decay kinetics of the EPR signal (left) after short irradiation (10 s, $\lambda_{irr} > 280$ nm). reactivity of **54** was found to be highly influenced by the nature of the alkali metal counterion, as well as by the inclusion of cosolvents within the zeolite matrix.

Turro et al. [121] investigated supramolecular effects on the dynamics of radicals generated in zeolites. Isomeric pairs of p, p'-dialkyl-substituted phenyl benzyl ketones (**55**) adsorbed on MFI zeolites (silicalite and ZSM-5) were photolyzed and investigated by electron paramagnetic resonance (EPR) spectroscopy. The photolysis produced persistent "benzoyl-type" and "benzyl-type" radicals, which depended on the length and position of the p-alkyl chain. The photolysis of dibenzyl ketones (**56**) adsorbed on MZSM-5 (M = Li, Na, K, Rb, Cs) zeolites also produced persistent carbon-centered radicals that were easily observed by conventional steady-state EPR spectroscopy (Scheme 27) [122, 123]. The lifetimes of the radicals increased as the group X attached to the carbon atom at the radical center increased from X = H ($t_{1/2}$ ca. 2 min) to X = $(CH_2)_4CH_3$ ($t_{1/2} > 200$ min), as can be seen in Figure 16. In addition, it was shown that the radical lifetimes depended heavily on the size of the metal cation ($t_{1/2}$ ca. 10 min for Li and $t_{1/2} > 200$ min for Cs), as can be seen in Figure 17.

Cozens et al. directly observed a single "free" benzyl radical by means of a nanosecond diffuse reflectance laser photolysis of phenylacetic acid (**57**) incorporated into cation-exchanged Y zeolites [124] (Figure 18). The spectra showed a strong absorption band centered at 315 nm and a shoulder at 305 nm that coincided with the known

absorption spectrum for the benzyl radical in solution. The mechanism proposed for the generation of the benzyl radical is shown in Scheme 28. A second weaker absorption band at 350 nm was assigned to a benzyl anion on the basis of a quenching experiment using oxygen and product analysis. On laser photolysis of xanthene-9-carboxylate (**58**) incorporated in NaY in the absence of oxygen, prompt formation of the xanthyl radical and the xanthylium cation was observed [125]. The xanthyl radical

Scheme 27
Figure 18. Transient diffuse reflectance spectrum generated upon 266-nm laser photolysis of phenylacetic acid in evacuated (10^{-3} Torr) NaY under dry conditions. The inset shows the transient spectrum after the sample was exposed to the atmosphere for a period of 10 s and then reevacuated (10^{-3} Torr). Spectra were recorded at (▲) 0.20, (△) 0.74, (○) 1.76, and (●) 6.36 μs after the laser pulse. Reprinted with permission from [124], F. L. Cozens et al., *J. Am. Chem. Soc.* 120, 13543 (1998). © 1998, American Chemical Society.

was formed by photoionization of **58** to the corresponding acyloxy radical, which then rapidly decarboxylates, as illustrated in Scheme 29. The xanthylium cation was produced by photoionization of the xanthyl radical. In addition, in the presence of oxygen, the formation of the xanthylium cation was also heavily dependent on the zeolite counterion.
Scheme 29

5.7. Photochemical Asymmetric Induction

The chiral induction of chemical reactions has been one of the main concerns of chemists for the past few decades. While great advances have been made in thermal asymmetric synthesis [126, 127], asymmetric photochemical reactions have not enjoyed the same level of success [128, 129]. However, several photochemists are exploring the possibility of employing zeolites as media for conducting chiral induction during photoreactions [130–132].

5.7.1. With No Chiral Inductor

Noh et al. [133] studied the diastereoselectivity in the photocyclization of α-(o-ethylphenyl)acetophenone (**59**) to 1-methyl-2-phenyl-2-indanol (**60**) in X and Y zeolites (Scheme 30) and made comparisons with the diastereoselectivity in isotropic solvents. The E/Z ratios in the zeolites

were much higher than in isotropic solvents. The ratios for the X zeolites were found to decrease as the cation size increased from Li^+ to Cs^+, but this was not the case with the Y zeolites. The diastereoselectivity observed in the zeolites was interpreted using the conformational restriction imposed by the cavity size.
Scheme 30

Lalitha et al. [134] found that irradiation of 2-phenyl-propionic acid (**61**) in various cation-exchanged Y zeolites led to the predominant formation of *dl*-2,3-diphenylbutane (**62**) over the *meso*-isomer, in marked contrast to photolysis in isotropic solvents (Scheme 31). This zeolite-induced diastereoselectivity was attributed to steric and electronic factors.
Scheme 31

The ene reaction of $^1O_2$ with the chiral alkene 2-methyl-5-phenyl-2-hexene (**63**) in solution was not regioselective and exhibited very poor diasteroselectivity (~10% *de*), as shown in Scheme 32. In contrast, in thionin-supported NaY, significant enhancement of product regioselectivity (94%) and diastereoselectivity (44% *de*) was obtained [135].

5.7.2. With a Chiral Inductor

Irradiation of achiral tropolone methyl ether (**64**) [130, 136], tropolone ethyl phenyl ether (**65**) [130, 137], and (S)-tropolone 2-methyl butyl ether (**66**) [130, 138] in solution undergoes a four π-electron disrotatory ring closure to yield the chiral bicycle[3.2.0] product **67**. For **64** and **65**, a racemic

In Solution	53%	47% (de 10%)
In Zeolite	6%	94% (de 44%)
Scheme 32

mixture of **67** was produced as the result of an equal probability of "in" and "out" rotation, as illustrated in Scheme 33. However, irradiation of **64** with (−)-norphedrine, a chiral inductor, in NaY at −20 °C produced 50% *ee*. For **65**, it was found that the nature of the favored enantiomer was reversed between wet and dry zeolites and between NaY and NaX. The extent of *ee* depended on water content, the nature of the cation (Li$^+$, Na$^+$, K$^+$, Rb$^+$), and the number of cations (NaY versus NaX). For **66**, it was clearly shown that the cation controlled both the extent and the direction of diastereoselectivity.
Scheme 33

Wada et al. [139] reported that enantio-differentiating photoisomerization of (Z)-cyclooctene (**Z-68**), sensitized by (R)- or (S)-1-methylheptyl benzoate immobilized in zeolites, afforded the respective enantiomer pair, (−)- and (+)-(E)-isomer (**E-68**) in 5% *ee* (Scheme 34), while racemic **E-68** was obtained on photosensitization with the sensitizer pair in an isotropic solvent.
Scheme 34

5.7.3. With a Chiral Auxiliary

It was demonstrated by Chong and Sivaguru et al. [140, 141] that alkali metal cation-exchanged Y zeolites significantly enhanced asymmetric induction in the photoisomerization of a number of *cis*-1,2-diphenylcyclopropane derivatives (**69**) containing a chiral auxiliary (Scheme 35). The same chiral auxiliary failed to effect asymmetric induction during irradiation in solution. This fact suggested that the confined space of the zeolite was essential to force a chirally significant interaction between the auxiliary and the site of reaction on the three-membered ring. In addition, it was found that the cations present in the zeolite not only controlled the extent of diastereoselectivity but also the isomer that was being enhanced.

Jayaraman et al. further confirmed the enhancement of enatio- and diastereo-selectivities via confinement in zeolites by exploring both the photorearrangement
Scheme 35

of 2,2-dimethylnaphthalenone (**70**) [142] and 2,4-cyclohexadienones (**71**) [143], and the Norrish–Yang reaction of 2-benzoyladamantane-2-carboxylic acid derivative (**72**) [142] with covalent chiral auxiliaries (Schemes 36 and 37). They also investigated the photochemical conversion of α-oxoamides (**73**) into β-lactam derivatives (**74**) (Scheme 38) [144].

Scheme 38

A combination of a chiral inductor and a chiral auxiliary succeeded in boosting the photoproduct *de* for **66** [138, 145], but failed to do the same for 2*β*,3*β*-diphenylcyclopropane-1*α*-carboxylic acid (**75**) [146]. Although the uniqueness of zeolites as media-inducing enatio- and diastereo-selectivities has been established in the studies described above, the factors that control the high chiral induction in zeolite with respect to solution are yet to be established.

6. CONCLUDING REMARKS

Zeolite nanocavities continue to hold considerable attraction for photochemists because of the unique characteristics regulating the spectroscopic and photochemical behavior of included organic substrates. However, it should be noted that the acidity of Brønsted and Lewis acid sites in zeolites may change during the preparation and/or pretreatment for adsorption of organic guest molecules even if the same type of zeolite is used. This problem sometimes makes it difficult to reproduce the results obtained in another laboratory. In addition, co-adsorbents such as water and organic solvents might influence the reactivity of organic guest molecules in the ground and excited states. Therefore, experimental conditions must be carefully arranged. However, there is no doubt that zeolites have considerable potential to act as novel microreactors, which control the spectroscopic and photochemical behavior of organic guest molecules. It is also likely that the use both of transparent poly(dimethylsiloxane) or polyimide films of zeolites incorporating organic guests [147] and also zeolite-coated quartz fibers as media for photochemical and photophysical study [148] will lead to practical applications in industry and to further developments in nanotechnology.

GLOSSARY

Contact charge-transfer (CCT) Electronic interaction in which the highest occupied molecular orbital of an electron donor makes contact with the lowest unoccupied molecular orbital of an electron acceptor.

Excited singlet state Electronically excited state in which two electrons spin in opposed directions.

Excited triplet state Electronically excited state in which the spin of two electrons is parallel.

Fluorescence The emission of light by a molecule in the excited singlet state.

Intersystem crossing The process of crossing from the excited singlet state to the excited triplet state.

Laser photolysis Photochemical reaction caused by laser light in order to measure time-resolved absorption spectra for short-lived species.

Photophorescence The emission of light by a molecule in the excited triplet state.

Photostationary state (PSS) The state of equilibrium reached photochemically in which the ratio between starting materials and products remains unchanged on further irradiation.

Singlet oxygen A reactive oxygen molecule in the excited singlet state.

Zeolite supramolecule Molecules adsorbed in zeolite cavities.

CONTENTS

1. INTRODUCTION

Since the discovery of carbon nanotubes (CNTs) by Iijima in 1991 [1], they have attracted great attention as potential electronic materials because of the one-dimensional tubular network structure on a nanometer scale. The variety of band structures of the CNTs, being either semiconducting or metallic, depending on the chirality and diameter of the CNT, is also a novel feature. For this reason, it is expected that CNTs become model samples for an ideal one-dimensional metal and an ideal one-dimensional semiconductor. In addition, CNTs are also expected to be one of the greatest candidates for nanotechnology materials, such as nanometer scale wirings and nanometer scale devices [2–4].

A CNT can be described as a single graphite (graphene) sheet rolled into a cylindrical shape. A concentric tubular structure can be made of two or more nanotubes with different diameters. The former and the latter are called single-wall carbon nanotubes (SWCNTs) and multiwall carbon nanotubes (MWCNTs), respectively. The thinnest CNTs are found in a most inner CNT of MWCNTs and SWCNTs grown in zeolite $AlPO_4$-5 (AFI) single crystals; the diameter is about 0.4 nm [5, 6]. The diameter of thick CNTs is at most a few 10 nanometers. In most cases, CNTs with large diameters are MWCNTs; in the case of SWCNTs, a cross-section will not be able to maintain circular structure but it will be distorted. Moreover, in MWCNTs with large diameters, structure strongly depends on production conditions and can be not only concentric, but also the

structure in which a graphene is scrolled up—a polyhedral graphite tube with defects at the vertex and mixtures of them [7–10].

For the theoretical approach and the interpretation of experimental results, SWCNTs are suited, because interaction between layers and the effect of defects must be taken into consideration in the case of MWCNTs. Most of the experimental observation had been on MWCNTs in the beginning of research on CNTs. After the establishment of a synthesis method for high-quality SWCNTs [11–13], extensive research on SWCNTs, as well as MWCNTs, is performed. Since researches field of photoconductivity of CNTs reviewed in this article have a short history, only the research for two kinds of SWCNT samples are reported [14–19]. Photoconductivity has not been observed in MWCNT samples. Therefore, if there is no notice, there will be a discussion about the SWCNT in this article.

This chapter is organized as follows. The physical properties needed for discussion about the photoconductivity of CNTs are presented in Section 2. In Section 3, the photoconductive properties observed in two kinds of SWCNTs are shown. Here, experimental methods are also described, because introduction of this is important because it has been succeeded only with a few groups in spite of many trials. As related phenomena, two types of photo-induced current modulations are presented in Section 4. Section 5 summarizes the chapter.

2. PHYSICAL PROPERTIES OF CARBON NANOTUBES

A number of excellent books and review articles have summarized the physical and chemical properties of CNTs [2–4, 20, 21]. In this section, properties related to photoconductivity are briefly described.

2.1. Molecular Structure

A SWCNT can be made by rolling a graphene sheet into a cylindrical shape [2–4, 20–23]. Although the tubular structure with any diameter and direction can be made when

we make it from papers without a pattern on the surface, the network structure of carbon has to be take into account for CNTs. In a graphene sheet, carbon atoms form a two-dimensional network of a six-membered ring, namely, a hexagonal (or honeycomb) lattice by connecting their three sp^2 hybrid orbitals. There are two sites, A- and B-site, in the graphene: one carbon is bonded to three carbons of another site. When graphene is rolled into cylindrical shape and one carbon is put on any other carbon in the same site, a CNT can be formed in principle. Relation between these two overlapped carbon atoms on the graphene can be described by chiral vector $\boldsymbol{C}_h = n\boldsymbol{a}_1 + m\boldsymbol{a}_2$, where n, m are integers and $\boldsymbol{a}_1, \boldsymbol{a}_2$ are the unit vectors of the graphene. The direction of the chiral vector $\boldsymbol{C}_h$ is perpendicular to the CNT axis and its length, $L \equiv |\boldsymbol{C}_h| = a(n^2 + m^2 + nm)^{1/2}$ is equal to that of circumference of the CNT, where a is the length of $\boldsymbol{a}_1$ and $\boldsymbol{a}_2$. In actuality, because a sp^2 hybrid orbital cannot be maintained for small diameters and the tubular structure is distorted for large diameters, the diameter of SWCNTs is considered to be about 0.4–2.0 nm.

2.2. Electronic Structure

It is intelligible when the electronic structure of a SWCNT, as well as molecular structure, is considered on the basis of a graphene sheet [20–25]. It is necessary to consider the periodic boundary conditions along the circumference of the CNT to the electronic structure of the graphene. Since the graphene sheet has a hexagonal lattice, the first Brillouin zone becomes a right hexagon. In energy-dispersion relations, the π^* (conduction) band and the π (valence) band are degenerate only at the six corners of the hexagonal first Brillouin zone, K and K' points, which the Fermi energy passes. Since the density of states at the Fermi energy is zero, the graphene is a zero-gap semiconductor. Although all the points in the first Brillouin zone are allowed for the graphene sheet, in the case of CNTs, allowed points are only on the line prolonged in the direction of the CNT axis through the Γ point (the center of the first Brillouin zone) and the parallel lines that separated $2k\pi/L$ (k: integer) from this line. Therefore, when these straight lines pass through K (K') points, since energy dispersion will pass Fermi energy, CNTs become metallic. The distance between K (K') points and the allowed line through the Γ point is $2\pi (2n + m)/3L$. As a result, when $2n + m$, that is, $n - m$, is the multiple of 3, CNTs become metallic. In other cases, CNTs become semiconducting. In the energy dependence of density of states in CNTs, van Hove singularity (VHS) appears to be reflecting one-dimensional nature. Moreover, because π^* (conduction) and π (valence) bands are almost symmetrical, the density of state near the Fermi energy shows the symmetrical energy dependence in respect to the Fermi energy.

2.3. Optical Absorption

Theoretical prediction shows the optical transition takes place only between symmetrical bands, under the configuration that the polarization vector $\boldsymbol{E}$ is parallel to the nanotube axis by taking into account the depolarization effect [26]. Corresponding to high transition probability between the symmetric VHSs, three characteristic absorption bands in

an optical absorption spectrum are observed in the energy range from an infrared region to a visible region [13, 27]. Two absorption bands in the lower energy and one at the highest energy originate from semiconducting and metallic SWCNTs, respectively.

It is well known that the exciton binding energy becomes infinite in the limit of an ideal one-dimensional electron-hole system [28–30]. Therefore, the effect of exciton plays an important role in optical absorption for the one-dimensional system of SWCNTs. This effect is considered to mainly modify the lowest band of the optical absorption spectrum, which was predicted theoretically [31]. Experimental results of optical absorption are consistent with this prediction [13, 27].

2.4. Electronic Transport Properties

Although there are many findings of novel properties and functions, such as single electron transport [32, 33], spin transport [34], rectification [35, 36], switching function [37], tunable electronic structure by magnetic fields [38, 39], single molecule CNT transistors [40–42], and superconductivity [43, 44] in electron transport properties, we focus on the electron scattering—ballistic or diffusive. The ballistic conduction in CNTs even at room temperature (RT) was pointed out by observation of quantized conduction in MWCNTs at first [45]. Ballistic conduction of SWCNTs was proposed by the detailed analysis of the coulomb blockade behavior of SWCNTs which act as a quantum dot [32]. From the subsequent research for semiconducting SWCNTs, the mean-free path is estimated to be about 100 nm which is about one-tenth of the CNT length, and the result suggests diffusive conduction in semiconducting SWCNTs in spite of ballistic conduction in metallic SWCNTs [46]. This is considered to be due to the electron scattering at defects and the bending parts of CNTs.

3. PHOTOCONDUCTIVITY OF CARBON NANOTUBES

The research on photoconductivity for two kinds of SWCNTs has been reported. One is observed in the SWCNTs with a diameter of about 1.4 nm, being closed-packed into bundles and forming a two-dimensional triangular lattice [14–17]. Another is in the SWCNTs, with a diameter of about 0.4 nm grown in zeolite AlPO$_4$-5 (AFI) single crystals, which are one type of the thinnest SWCNTs [18, 19]. In MWCNTs, photoconductivity has not been observed thus far.

3.1. Single-Wall Carbon Nanotube Bundles

Photoconductivity of CNTs has been discovered in the film sample of SWCNT bundles, and the most detailed research has been performed for this sample [14–17]. In this section, detailed experimental methods for the observation, photoconductive properties, and possible mechanisms are presented.

3.1.1. Experimental Technique

The samples of SWCNT bundles were synthesized by evaporation of composite rods of nickel (Ni), yttrium (Y), and graphite in helium atmosphere by arc discharge [12, 13] or ablating a graphite target containing Ni and cobalt (Co) catalysts at 1250 °C in an argon atmosphere by using a pulsed Nd:YAG laser [11]. Observations by transmission electron microscopy (TEM) revealed that soot is mainly composed of SWCNTs and also amorphous carbons and metal particles. The diameter of the SWCNTs is determined to be about 1.4 ± 0.2 nm by the Raman frequency of a breathing mode and TEM observation. The typical length of SWCNT bundles estimated by scanning electron microscopy (SEM) is a few micrometers.

To prepare film samples, soot-containing SWCNTs were dispersed in methyl alcohol by an ultrasonic vibrator and suspension of SWCNTs was dropped on a glass substrate. The typical film sample size is about 100 μm × 100 μm and the thickness of the film is between 300 and 500 nm. The samples were annealed in vacuum at 10^{-6} Torr and 673 K for 2 hours to remove the absorbed gases and methyl alcohol from samples. A pair of gold electrodes separated by a 10-μm gap was evaporated in vacuum onto the surface of the film samples and connected to a DC regulated power supply (100 mV). In order to reduce the number of junctions between SWCNTs in the current pass, the narrow gap of 10 μm was chosen because the resistance of the junctions dominates the total resistance of the sample and obscures the intrinsic transport properties of SWCNTs.

The samples were mounted in a continuous-flow cryostat and cooled by flowing the vapor of liquid He and liquid N_2 in the temperature range from 10 K to RT and from 100 K to RT, respectively. As a light source, an optical parametric oscillator (OPO), excited by a pulsed Nd:YAG laser, was used. The photon energy was in the range of 0.5 to 2.8 eV and the pulse duration was 5 ns. The light intensity is from a few tens nJ/pulse to 1500 nJ/pulse. The temporal profiles of the laser pulse and the photocurrent were monitored with a digitizing oscilloscope. In order to avoid spurious ringing in the fast pulse detection, we were obliged to use the input impedance of the oscilloscope (50 Ω) as the reference resistor, despite the obvious disadvantage of lower sensitivity. The resistance of samples in the dark is ca. 100 Ω at RT and 800 Ω at around 10 K.

3.1.2. Observed Behaviors

The temporal evolution of photocurrent shows a Gaussian-like peak with a 5 ns width corresponding to the pulse duration of the laser. Photocurrent increases with increasing incident light intensity. When photocurrent is less than 10 μA, the photocurrent intensity responds linearly to incident light intensity. On the other hand, it shows a saturation behavior above 10 μA; this saturation is often observed under intense light intensity and might be due to the lack of replenishment of carriers [47]. In photoconductivity excitation spectra estimated from the slope of the linear part in light intensity dependence of photocurrent, two clear peaks in photoconductivity excitation spectra at RT are observed around 0.7 and 1.2 eV. These energies are very close to the energy difference of first and second symmetrical pairs

of VHSs of semiconducting SWCNTs with a diameter of 1.4 nm. In addition, these spectra are very similar to the optical absorption spectra of SWCNTs prepared by the same method [13, 27].

The photoconductive response at 13.2 K is much higher than that at RT, whereas the optical absorption is hardly enhanced even at a low temperature [48]. Moreover, the enhancement strongly depends on the photon energy; the intensities of the peak in photoconductivity excitation spectra at 0.7 and 1.2 eV were enhanced by about two and one orders of magnitude, respectively. The observed photoconductive response monotonically increases with a decrease in temperature between 10 K and RT, and shows the saturation around 10 K.

3.1.3. Mechanism

From the correspondence between the optical absorption spectra of semiconducting carbon nanotubes and photoconductivity spectra, it is clear that the photocurrent originates from photoexcitation of electrons in semiconducting SWCNTs. Temperature dependence of photoconductivity $\Delta\sigma(T)$ can be represented by $\Delta\sigma(T) = \Delta n(T) \times e\mu(T) = \Delta n(T)(e^2/m^*)\ \{l(T)/v(T)\}$, where $\Delta n(T)$, e, $\mu(T)$, m^*, $l(T)$, and $v(T)$ are carrier numbers increased by light irradiation, carrier charge, mobility of charge carrier, effective mass of charge carrier, mean-free path, and thermal velocity [47]. Therefore, the temperature dependence of $\Delta\sigma(T)$ should be attributed to that of $\Delta n(T)$ and/or $\mu(T) \propto l(T)/v(T)$. $T^{-3/2}$ dependence of $\mu(T)$ is expected in conventional semiconductors with the regime of the diffusive transport due to electron–phonon interactions, because $l(T)$ and $v(T)$, respectively, follow T^{-1} and $T^{1/2}$. On the other hand, by assuming the ballistic conduction, $l(T)$ is expected to be limited to the nanotube length and to become independent of temperature. In this case, $\mu(T)$ is expected to follow $T^{-1/2}$. Therefore, $\Delta\sigma(T)$ is expected to follow $T^{-3/2}$ or $T^{-1/2}$ for the interband transition, because $\Delta n(T)$ hardly depends on temperature. In this way, photoconductivity increases with a decrease in temperature for the interband transition, although temperature dependence of photoconductivity changes owing to the type of transport—ballistic or diffusive.

If exciton absorption is dominant in the semiconducting SWCNTs, as pointed out by the theoretical and experimental approach on optical absorption [13, 27, 31], free carriers contributing to the photoconductivity $\Delta n(T)$ are created through thermal dissociation of excitons. In this case, $\Delta n(T)$ will decrease with a decrease in temperature, and then, $\Delta\sigma(T)$ will decrease, which is contrary to the experiment result. Experimental results naively support the theory that the photocarriers originate from the usual interband transition. Very recently, photoconductivity was observed in SWCNTs with the diameter of 0.4 nm [18, 19] as described in the next subsection. Since these samples have a stronger one-dimensional structure, binding energy of exciton is expected to be much larger than our samples. It is expected that the comparison of the photoconductive properties between these samples gives valuable information to solve this contradiction.

3.2. Single-Wall Carbon Nanotubes in Zeolite Single Crystals

Another example of observation of photoconductivity is shown in this section [18, 19]. Novel features of this type of sample are the smallest diameter and the almost perfect alignment of SWCNTs in the zeolite single crystals. For these reasons, this sample is very suitable for estimation of the effect of the one dimensionality and the optical anisotropy.

3.2.1. Experimental Technique

The samples of SWCNTs in one-dimensional channels of zeolite AFI single crystals were synthesized by thermal treatment of paralyzed carbon encapsulated in the AFI crystal at 500–800 °C [6, 49]. Single-wall carbon nonotubes are grown in one-dimensional channels along the c-axis of AFI. Observations by TEM revealed that after dissolving the AFI framework residual materials are SWCNTs and raft-like graphite; the diameter of the SWCNTs is determined to be about 0.42 ± 0.2 nm. Three possible structures, $(n, m) = (5, 0), (3, 3), (4, 2)$, are proposed for this type of nanotube. Typical dimensions of an AFI single crystal containing SWCNTs are 75–160 μm in a cross-section diameter of a hexagonal face and ca. 300 μm in length along the c-axis of AFI.

The gold wires of 100–150 mm in diameter were attached to both hexagonal faces of the AFI single crystal. Bias voltage was applied between these two wires by a DC regulated power supply up to 1.5 V. Current flows along the c-axis of AFI, namely, the CNT axis. Linearly polarized light from a CW-Ar$^+$-ion laser or a CW-Ti/sapphire laser pumped by an Ar$^+$-ion laser was focused onto the central part of one surface of the AFI crystal. The direction of incident light is perpendicular to the CNT axis. The size of the illuminated spot was set about 100 μm in diameter. The resistance of samples in the dark is around 100 MΩ at RT.

3.2.2. Observed Behaviors

Conductance increases during the photo irradiation with the period of about 10 s. The response time is less than 50 ms. Photocurrent is proportional to the incident light intensity at low intensities. Although neither photon energy dependence (photoconductivity excitation spectra) nor temperature dependence have been investigated in detail, the information about optical anisotropy have been presented in this sample. By using this sample, it is confirmed that three absorption bands characteristic of CNTs are observed when a polarization vector is parallel to the c-axis of the AFI crystal ($E \parallel$ c), that is, the CNT axis, whereas optical absorption has hardly been detected for the case that the polarization vector is perpendicular to the nanotube axis ($E \perp$ c) [19, 50, 51], which is consistent with the theoretical prediction as described in Section 2–3 [26]. Corresponding to this, photoconductive response strongly depends on the angle between the polarization vector and the CNT axis; photocurrent for $E \parallel$ c is about twice as large as that for $E \perp$ c.

Intrinsic resistance of the SWCNT sample in the dark increases to more than twice the values by irradiating an intense light of about 10 mW. During the process of an increase in the resistance, the increases in photoconductive response and in optical anisotropy are also observed. This result suggests that the intense light irradiation results not in the collapse of CNTs but in the increase in an effective semiconductor SWCNT, namely, the rearrangement of the nanotube structure within zeolite—for example, the connection of a divided semiconductor nanotubes and the structure conversion from the metallic SWCNTs to semiconducting ones.

4. RELATED PHENOMENA

In this section, two related phenomena, photo-induced current modulation, are presented.

4.1. Conductance Modulation Due to the Molecular Photodesorption

Conductance of an individual semiconducting SWCNT decreases by 10% upon ultraviolet (UV) illumination in air, NO_2, and NH_3 atmosphere, contrary to the photoconductive response [52]. The conductance recovers after the light is turned off. This reaction occurs in reverse by repeating irradiation of light. This is caused by photodesorption of gases which acts as an electron donor or acceptor. Through photodesorption of molecules, SWCNTs becomes intrinsic semiconductors without any carrier doping and its conductance decreases. Therefore, when UV illumination is performed in a high vacuum, the conductance decreases drastically by a few orders of magnitude, and exhibit no appreciable recovery when the light was switched off.

4.2. Photo-Induced Tunneling Current in STM Measurements

It is expected that the local photocurrent can be measured by the scanning tunneling microscopy (STM) method [53]. A photo-induced tunneling current is observed for semiconducting and metallic SWCNTs, only when the photon energy exceeds energy difference of the first symmetrical pairs of VHS in the density of state. It is observed at both a positive and negative bias voltage of STM measurements, and increases linearly to the light intensity and is reversible. Although this behavior is preferred to observations of photoconductive response and electronic structure modulation through light irradiation in nanometer scale spatial resolution, it is necessary to clarify the extrinsic effects, such as the effect of thermal expansion of the CNT sample and the tip of STM to tunnel current, which is extremely sensitive to the distance between the sample and the tip.

5. SUMMARY

In this chapter, we have reviewed current states of photoconductivity of carbon nanotubes. Photoconductive properties for the bundles of SWCNTs with a diameter of 1.4 nm and the SWCNTs with a diameter of 0.4 nm in Zeolite single crystals are presented. Two types of photo-induced current modulation are also presented. The mechanism of photoconductivity is still unclear because of its short history. However, from the viewpoint both of nanoscale science and practical application for nano-scale devices, the

understanding of this phenomenon is very important. It is expected that the origin of photocarriers, the conduction characteristic of a semiconductor nanotube—ballistic or diffusive will be clarified from the detailed experiments on the temperature dependence of photoconductivity. In addition to this, the effect of the one dimensionality and the contribution of the exciton for the carrier generation will be clarified by comparing the photoconductive properties between these two types of SWCNTs with different diameters. This field is now ongoing and will develop further.

GLOSSARY

Carbon nanotube (CNT) A tubular molecule made of carbon with nanometer diameter.

Exciton A mobile, electrically neutral, excited condition of holes and electrons in a crystal. One example is a weakly bound electron-hole pair.

Multiwall carbon nanotube (MWCNT) A type of carbon nanotube with the structure that a concentric tubular structure can be made of two or more nanotubes with different diameters.

Optical parametric oscillator (OPO) A laser-pumped crystal with nonlinear optical properties that generates coherent light whose output can be tuned continuously over wide range of wavelengths.

Photoconductivity An electrical conductivity increase exhibited by some nonmetallic materials, resulting from the free carriers generated when photon energy is absorbed in electronic transitions.

Photocurrent A current produced by photoelectric or photovoltaic effects.

Scanning electron microscope (SEM) A type of electron microscope that uses a beam of electrons to scan the sample surface, ejecting secondary electrons that form the picture of the sample.

Scanning tunneling microscope (STM) A high-solution microscope that can detect and measure the positions and heights of individual atoms on the surface of the sample.

Single-wall carbon nanotube (SWCNT) A type of carbon nanotube with the structure that a single graphite (graphene) sheet rolled into a cylindrical shape.

Transmission electronic microscope (TEM) A type of electron microscope that uses magnetic lenses to transmit a beam of electrons through the sample; the electrons are then focused on a fluorescent screen to form an enlarged image or a diffraction image.

van Hove singularity (VHS) A singularity observed in energy spectrum of density of states for electrons and phonons, showing divergences of the slope.

1. INTRODUCTION

Cluster physics is by its very nature an interdisciplinary field with connections to well established domains such as chemistry, atomic physics, molecular physics, and solid state physics [1–4]. These various branches of science have found in clusters sort of a melting pot in which several concepts and techniques have merged. For a long time, light has been preferred tool of investigation of cluster properties. Incoherent light constitutes here the simplest, natural means of approach and allows one to address the linear response domain. This is the realm of the so-called optical response, with clusters responding in the visible part of the electromagnetic spectrum, in a way similar to the response of atoms in the sky, subject to solar radiations. This linear domain provides clues on both static and dynamic properties of clusters. In particular it is an especially powerful tool of investigation of structure properties, as we shall discuss. For a few years, though, in relation to the rapid progresses in laser technology, it has also become possible to investigate truly dynamic properties of clusters subject to lasers of various intensities. Beyond the linear domain accessible to low fluence lasers one can now routinely address problems in

the truly nonlinear domain with intense laser beams. In all these situations, both in the linear and nonlinear domains, it turns out that the basic electronic response of the cluster, the aforementioned optical response, plays a key role, both in metallic systems and in nonmetals. It is thus a key issue in this field, whatever dynamical regime one wants to address. We shall thus spend some time discussing its properties in some detail, before considering more "dynamical situations."

Large clusters at the nanometer scale contain hundreds or thousands of particles and modelling them thus constitutes a formidable task which requires simplifying assumptions. Small clusters have been attacked with a variety of detailed methods inherited mostly from chemistry and molecular physics (from the experimental as well as the theoretical points of view), and very large clusters can be studied with methods imported from solid state physics. Intermediate size clusters, typically in the nanometer range, constitute specific systems which are yet little explored in detail. They require dedicated approaches in between chemistry and bulk techniques. The building of simple and realistic models hence constitutes a key issue in the progress of the field, both to guide experiments and to understand the produced results. It is obvious that a detailed description, at the level of all electronic and ionic degrees of freedom (even when restricting the approach to the least bound electrons), is far beyond the possibilities of any practical calculation. One thus has to employ simple pictures, based on microscopic considerations, but dealing with more or less macroscopic or semi-macroscopic quantities.

Simplifications are even more crucial when one aims at describing cluster dynamics, which is a central issue for understanding photodynamics of nanoclusters. Most experiments on clusters indeed deal with light or electromagnetic

probes. The rapid development of laser technology in the last few decades has allowed the attainment of large electric fields (comparable to the ones binding clusters together) and on short time scales, typically of the order of electronic time scales [5, 6]. One is thus in a position of studying the response of clusters to short and strong electromagnetic signals which place the system far away from its ground state. In such dynamical situations, there is an urgent need for guidelines and the invention of simple tractable models is thus a key issue.

It is the aim of this chapter to discuss the response of clusters of various types to irradiations by light (in particular with various laser lights). A major goal will thus be to describe the many types of measurements performed in the various dynamical regimes attained as a function of the intensity of the excitation process. And we shall emphasize the key role played by the collective response of clusters to light, the so-called optical response. We will also discuss examples of simple models dedicated to the study of large clusters irradiated by lasers of various intensities. We shall see that "back of the envelope models," in particular the Mie model of plasmon response, provide a key ingredient for the understanding of the coupling between light and nanoclusters. The latter model particularly allows one to understand basic physical mechanisms at work. And yet a more detailed explanation, and at least a semiquantitative approach, requires more elaborate models, which can be built in a rigorous way on the basis of well defined microscopic approaches.

The chapter is organized as follows. We first discuss the historical case of the coupling of metal clusters with light (optical response). This corresponds to a regime of small perturbation of the electron cloud. Elementary models (Mie plasmon) allow one to understand the mechanism underlying the cluster's response, but not at a fully quantitative level. Similar plasmon behaviors are also observed in other types of clusters than in metal clusters, although with slightly different patterns, and we shall also discuss these situations. We next consider the case of more violent laser irradiations. We discuss in particular the very recent case of clusters subject to intense lasers and show that Mie plasmon again provides a key to understand the cluster behavior. However, once again details of the response go beyond simple arguments. The last part of the chapter is devoted to a discussion of how to make progress in the understanding of the cluster's response by means of microscopic methods. We illustrate the achievements of such simplified approaches and we sketch the next steps of development to reach an even more coherent description of these various phenomena.

2. OPTICAL RESPONSE IN NANOCLUSTERS

Because in metal clusters valence electrons move quasi freely, they respond particularly easily to an electromagnetic probe. This constitutes the so-called plasmon (or optical response) in metal clusters. Similar behavior can be observed in other not strictly metallic objects such as carbon systems. We shall discuss here these various aspects although

we shall particularly focus on the most important and most studied case of metals.

2.1. Metal Nanoclusters

2.1.1. The Shining Colors of the Optical Response

Clusters have been used for practical purposes for centuries. The tailoring of fine dispersed pieces of material (clusters!) inside bulk has been turned into an art by craftworkers, from the Romans to modern artists. At least from a practical point of view, how to tune the size of dispersed particles in a glass to produce various colors has been known for a long time. The understanding of colors of such small metal particles goes back to Mie [15]. He addressed the question of the response of small particles to light, and how this response might depend on the size of the considered particle. And Mie realized immediately the potential applications of such studies for our understanding of the properties of matter. Let us briefly quote him: "Because gold atoms surely differ in their optical properties from small gold spheres [it would] probably be very interesting to study the absorption of solutions with the smallest sub-microscopical particles; thus, in a way, one could investigate by optical means how gold particles are composed of atoms" [16]. Indeed the optical response of metal clusters to light is strongly dependent on their size. This is illustrated in Figure 1 where the peak response (to light) of clusters of various sizes is plotted precisely as a function of their size. As can be clearly seen, the position of the peak response is monotonously linked to cluster's size, which explains the reflections of various colors exhibited by glasses with metallic inclusions. In fact, what we are seeing here is just the response of a metallic sphere to an external electric field. It should thus be easy to understand the basic mechanism responsible for this effect. And we go back here to Mie's picture. Let us briefly see how such an approach works.
Figure 1. Optical response of silver and gold clusters embedded in a rare gas matrix. The peak value of the response is plotted as a function of inverse cluster radius. Reprinted with permission from [14], M. Gaudry et al., *Phys. Rev. B* 64, 085407 (2001). © 2001, American Physical Society.

2.1.2. A Simple Model of the Optical Response in Metals

Massive metal clusters, such as the ones included in glass matrices, constitute typical examples of metallic spheres. The valence electrons form there an almost uniform electron gas not too tightly bound to the ionic background. It is thus no big surprise that a moderate external electric field as delivered by natural visible light may easily affect such clusters and possibly provide a fingerprint of some cluster properties. This is the essence of Mie theory describing the response of metallic spheres to light.

Let us consider an extremely simple model of a spherical metal cluster X_N in which the ionic background is taken as an homogeneous positively charged sphere of radius R (density ρ). Electrons are modelled by a negatively charged sphere with the same density ρ. We thus assume that the cluster is a neutral system and that both electrons and ions occupy the same volume (which is an intuitive, although slightly excessive, approximation). In addition, we make the assumption that both electrons and ions will oscillate as rigid spheres against each other. This hypothesis may be realistic for ions. Electrons are probably not behaving that rigidly. But it fortunately turns out that the electronic response is primarily collective as long as the system is not too perturbed. Thus, the rigid sphere approximation makes sense in the regime of small excitations. If this system is put in a small uniform external electric field E_{ext} electrons will slightly separate from ions, each one going in opposite directions. Still, because ions are much heavier than electrons, they basically remain fixed and one can consider that only electrons are displaced with respect to ions. The displacement builds up a strong Coulomb field which provides a restoring force on the displaced electron cloud counterweighting the effect of the external field E_{ext}. In the limit of small values a of the electron–ion separation the net force acting on the electron cloud (along electric field E_{ext}) becomes proportional to a,

$$F = -N \frac{\rho e^2}{3\epsilon_0} a = Ne E_{ext}$$

where N is the number of electrons. Once the external perturbation is switched off, there remains only the attracting (restoring) force between electronic and ionic clouds, proportional to the actual separation between ions and electrons. Electrons will thus undergo harmonic oscillations around ions, with a frequency

$$\omega_{\text{Mie}}^2 = \frac{\rho e^2}{3\epsilon_0 m_e} = \frac{Ne^2}{4\pi\epsilon_0 m_e R^3} \tag{1}$$

where m_e is the electron mass. This oscillation frequency ω_{Mie} is known as the Mie frequency. When a cluster is irradiated by photons, its response will be particularly strong for light frequencies around ω_{Mie}. In simple alkaline metals the frequency ω_{Mie} takes values in the visible part of the electromagnetic spectrum, hence the term "optical response" to characterize this phenomenon.

The Mie model, as just outlined, does explain the gross features of the response of clusters to light, but it misses the crucial size dependence. As can be seen from Eq. (1), ω_{Mie} only depends on the density ρ and not on the cluster size N. The density ρ differs from one metal to the next. But metal clusters of a given material do all have the same average density. This is an effect of electron density saturation, much similar to the behavior observed for example in nuclei [17]. This saturation can be seen in terms of cluster radii R which follow a law of the form $R \sim r_s N^{1/3}$, where r_s is the Wigner–Seitz radius of the material. Any size dependence is obviously absent from the simple expression in Eq. (1) while experimental results do depend on cluster size. The Mie model thus provides an explanation for the basic mechanism of optical response in metal clusters but does not give access to the crucial size effects observed in this optical response. A more detailed approach is thus necessary, as we shall discuss.

2.1.3. Optical Response as a Function of Frequency

Our discussion has shown that the optical response of a cluster is characterized by one typical frequency for which the Mie model provides a good guess. Thus the response of the cluster will strongly depend on the color of the light used. In other words, the optical response is a resonant phenomenon. Depending on the excitation frequency, the response will be more or less strong, as in any resonant situation. This resonant behavior is illustrated in Figure 2 in the case of massive
Figure 2. Examples of optical response in massive Li and K clusters. Photoabsorption cross-sections are plotted as a function of photon energy. Reprinted with permission from [18], C. Bréchignac et al., *Phys. Rev. Lett.* 70, 2036 (1993). © 1993, American Physical Society.

Li and K clusters. Both spectra exhibit a marked resonant behavior around a well defined peak. As a consequence one may expect a high sensitivity of the response to the excitation frequency; the stronger the response, the closer the excitation frequency to peak frequency. Practically the optical response is explored by means of a low intensity laser irradiating the metal cluster. By scanning the laser frequencies one can explore the full frequency spectrum and attain an optical response spectrum as presented in Figure 2.

2.1.4. Size Dependence

Optical spectra do depend on cluster size. The average resonance frequency follows a trend $\omega_{\text{Mie}}(N) = \omega_{\text{Mie}}(\infty) + cN^{-1/3}$ typically down to $N \approx 100$ and levels off for smaller clusters. The slope c is generally small with different signs depending on the material. Negative c prevail for alkalines, positive c are found for most noble metals, and Hg is an example with zero slope [20], as can be seen in Figure 3. It is due to surface effects, in fact a combination of them. In a metal cluster electrons, mostly because of their quantal nature, do occupy a volume slightly larger than ionic cores. One usually calls this effect the spill out of the electron cloud. This spill out reduces the plasmon frequency [21] and small clusters have, relatively, more surface than volume which leads to a negative slope. The spill out effect dominates for example in alkaline clusters, hence the negative slope for these materials. But in noble metals, for example, the plasmon frequency is strongly influenced by the collective dipole oscillations of the d core electrons which redshifts the resonance. This effect is inactive at the surface which means that larger surfaces yield less redshift, which favors a positive slope. The core electron effect dominates in noble metals, hence the positive slope. The two effects, core electrons and spill out, seem just to compensate for Hg.

2.1.5. Temperature Effects

As can be seen from Figure 4 the thermal effect plays a crucial role for the observed linewidth in optical absorption. The spectrum at low temperature shows three narrow
Figure 3. Mie plasmon frequencies as a function of system size for a variety of metals. Reprinted with permission from [19], C. Bréchignac and Ph. Cahuzac, *Com. Atom. Mol. Phys.* 31, 215 (1995). © 1995, IOP Publishing.
Figure 4. Photoabsorption strength for Na_7^+ at three different temperatures as indicated.

and well separated peaks reflecting the deformation of the considered cluster (see insert). We see here the collective splitting of the strongly oblate Na_7^+ and the lower peak is furthermore Landau fragmented [26] by one close $1ph$ state [27]. The picture changes systematically for larger temperatures. The peaks grow broader and the lower double peak merges into one. It is the temperature which causes the large width. Thermal effects at the side of the electrons cannot induce such a width because 400 K is a small energy at an electronic scale. It is the thermal ionic motion which is responsible for that line broadening. The ionic excitation energies reach down to below 100 K for Na_7^+ [28]. A thermal excitation of 400 K is large on that scale. Many ionic eigenmodes are excited to rather large amplitudes. The cluster thus undergoes substantial thermal shape fluctuations. But deformation has a strong influence on the dipole spectrum; the more elongated the cluster in one direction, the lower the eigenfrequency along this direction. Thus, each member of the thermal ensemble, with its different deformation, contributes a different spectrum to the total optical response. These spectra all add up incoherently to rather broad peaks. This thermal line broadening mechanism has been discussed first in [29, 30] on the grounds of the jellium model with quadrupole shapes. The crucial impact of octupole deformations was pointed out in [31] and confirmed in the fully microscopic analysis of [32].

2.2. "Optical" Response in Covalent Clusters

Carbon clusters are halfway between metallic and covalent binding. The optical absorption spectra thus show pronounced resonance peaks together with a swamp of noncollective peaks. This is not so surprising. An interesting aspect of C is that its particular binding properties allow stable

chains over a broad range of sizes. The case of C chains is thus presented in Figure 5. In a given chain the strength is distributed over a broad range of frequencies. But there sticks out a pronounced peak at low frequency. It is sort of a plasmon peak due to the metallic behavior of the p electrons which can travel freely along the whole chain, in the spirit of the Mie picture. The s electrons are more localized but take part by their large dipole polarizability (in a way similar to the d electrons in noble metals). The linear geometry of the chain altogether leads to a strong size dependence of the plasmon frequency. The picture is here that a chain of electrons is oscillating relative to the chain of ions. This produces basically a dipole field whose energy is $\propto d^2/L$ where L is the length of the chain and d is the displacement of the cloud. The spring constant is thus $\propto 1/L$ and so is the plasmon frequency. Figure 5 shows the trend of the low-lying dominant peak with size N of the chain. Theoretical and experimental results are in agreement and the trends line up nicely with the predicted trend $\propto N^{-1/2}$ for the longitudinal mode.

3. NANOCLUSTERS IN INTENSE LASER BEAMS

3.1. From Low to High Laser Intensities

3.1.1. Similarity in Diversity

As we have seen, the interaction of low fluence lasers with clusters leads to different patterns from one cluster to another depending on the type of the cluster, metallic, covalent, rare gas, etc. Still, we have also seen that in many cases the electronic response exhibits a qualitatively similar, more or less collective, behavior, as exemplified by the Mie model in metal systems. With increasing laser intensity the differences between the various types of clusters tend to
be smoothed, while the Mie plasmon mechanism remains a valuable tool for understanding the qualitative behaviors of the systems. This evolution with laser intensity is not surprising. At low laser intensity the coupling to light mostly leads to electron oscillations with only occasional electron emission. In turn, for sufficiently high laser intensity the dominant primary mechanism of excitation is electron emission. But electron emission is soon slowed down by the net charge acquired by the cluster which tends to retain the electrons, otherwise ready to leave. This, at least, lasts as long as the system has not disappeared, for example by Coulomb explosion, when the net charge becomes too high. During this transient regime with quasi free electrons stripped from their parent atoms, but still bound to the cluster by its net charge, electrons more or less behave the same, whatever the type of cluster they do belong too. For example, the difference between metal and rare gas clusters (both of which under experimental investigation) thus essentially lies in the initial amount of free electrons, which turns out not to be a decisive factor for high laser intensities. In that sense, the differences between the various types of clusters tend to disappear for these large intensities. For intermediate intensities, the situation is of course a mixture, with traces of specific behaviors (to a given cluster type) and generic pattern.

3.1.2. Intense Laser Domain

The investigation of the (nonlinear) dynamical properties of atomic clusters has lived up with the advent of table-top devices that produce subpicosecond laser pulses with intensities easily exceeding 10^{17} W/cm^2 [39–45]. Due to the collective electron dynamics discussed, there may be a strong electromagnetic coupling to the Mie frequency that leads to nearly 100% absorption rates [46]. The clusters being isolated objects, no surrounding environment will absorb their excitation energy, in contrast to solids. The emission of high energy (keV) electrons [43], highly charged and very energetic ions [42] and fragments [44], as well as X-ray production [39, 47] are then the spectacular manifestations of this laser–cluster interaction.

3.1.3. Basic Mechanisms at Work

Several models have been developed to explain the experimental features observed in the regime of "high" laser intensities [89–94]. All these models emphasize the major role played by the electrons inside the cluster. The basic mechanisms at work in intense laser–cluster interactions can be summarized as follows. The laser very quickly strips a sizable number of electrons from their parent atoms. These electrons form a reservoir of quasi free electrons, which can strongly couple to the laser when the electron density matches a critical value characteristic of the dipole eigenfrequency of the system (Mie resonance). The global response of the cluster is characterized by a heating of the electron cloud and electronic emission, in addition to the possibly enhanced dipole oscillations. The net charge and the high excitation energy acquired by the cluster lead to its final explosion. It should be noted that this violent scenario is, to a large extent, independent of the nature of the irradiated clusters. The general scenario we have just outlined

Figure 5. Systematics of longitudinal plasmon resonance frequencies for $N = 2$–32. Results from various sources are compiled, experiments from [33, 34], CI calculations from [35, 36], TDLDA YB are TDLDA calculations from [37], and TDLDA BRS from [38].

does not precisely specify the relative importance and the time scales of the various mechanisms at work. As a consequence, although the global scheme is generally accepted, the debate on the relative importance of the competing processes (various ionization mechanisms inside the cluster, role of the plasma resonance, of electron temperature, of net charge, ...) remains largely open and various models are still investigated to explain experimental trends.

3.2. Rare Gas Clusters

3.2.1. High Energy Phenomena

Experimental studies of large rare gas clusters with high intensity lasers started in the early 1990s. Multiphoton induced X-ray emissions have been observed by McPherson et al. in Kr clusters as early as 1993 [39]. The emission of radiation in the keV energy range was clear evidence of the appearance of new phenomena specific to clusters. This was later confirmed by many other groups; see Figure 6a [47, 50]. Sustained experimental efforts were then devoted to laser–cluster interaction in the high intensity regime, mainly in the Lawrence Livermore National Laboratory, the Blacket Laboratory (Imperial College), and in the CEA-Saclay. Most of these studies dealt with rare gas clusters because of the possibility to produce such large clusters in supersonic beams. The most striking experimental results are the observation of emitted ions with charges larger than those expected for isolated atoms exposed to the same laser intensity, the appearance of extremely energetic ions, and the production of electrons with kinetic energies in the keV range. We show in Figure 6b typical results obtained for xenon clusters. Here, a cluster of 2500 xenon atoms was irradiated by a laser with a peak intensity of 2×10^{16} W/cm^2 [48]. Although most of the emitted ions have kinetic energies of a few keV, the mean kinetic energy is 45 ± 5 keV. Another remarkable aspect of this energy distribution is the presence of ions with energies up to 1 MeV. Figure 6c shows the energy distribution of electrons in conditions close to the previous ones (2100 xenon clusters irradiated by a laser with 1.5×10^{16} W/cm^2 maximum intensity) [49]. Two bands appear. The first one is centered around 0.8 keV and is expected to be due to warm electrons emitted before the plasmon resonance occurs and the second one around 2.4 keV corresponds to hot electrons released by the cluster during the occurrence of plasmon resonance when important heating of electrons has been realized through collisions.

3.2.2. Dependence on Cluster Size and Laser Intensity

Systematic studies of the response of rare gas clusters to intense laser fields have been performed by different groups. In Figure 7, we show the results of a systematic study of average electron and ion energies as a function of the cluster-jet backing pressure, which basically fixes cluster sizes in the case of rare gas clusters irradiated by long-pulse laser fields obtained by the CEA-Saclay group [51, 52]. The results from three different clusters, argon, krypton and xenon, are shown. We note that the mean size
Figure 6. Experimental results obtained after irradiation of clusters by intense laser beams. of clusters grows approximately quadratically with the stagnant pressure and goes from 3×10^4 to 5×10^6 atoms in the entire pressure range. It appears that the electron-to-ion energy ratio depends on the constituents of the clusters and the highest ion energies were observed for krypton clusters in combination with relatively low electron energies. The huge difference between the electron and ion energies also
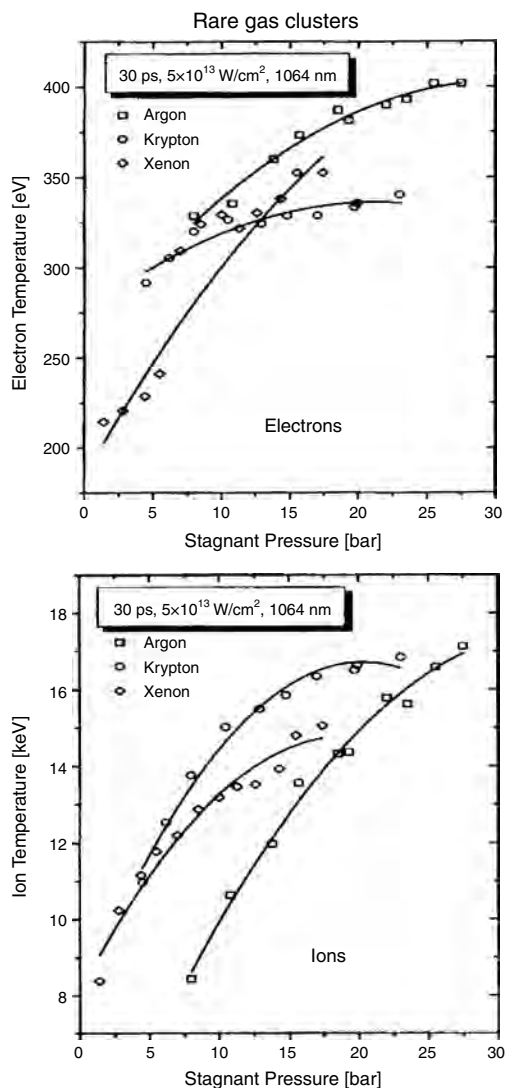

Figure 7. Average kinetic energies of electrons (upper panel) and ions (lower panel) for various backing pressures of the cluster gas. These results were obtained by irradiating rare gas clusters with a 30-ps, 1064-nm laser pulse with peak intensity 5×10^{13} W/cm². Reprinted with permission from [51], M. Lezius and M. Schmidt, in "Molecules and Clusters in Intense Laser Fields" (J. Posthumus, Ed.), p. 142. Cambridge Univ. Press, Cambridge, UK, 2001. © 2001, Cambridge University Press.

Figure 8. Maximum ion energies from xenon (filled circles) and krypton (open circles) clusters measured as a function of cluster size (upper panel) with a 170-fs, 780-nm laser pulse with peak intensity 1.3×10^{16} W/cm², and as a function of laser intensity (lower panel) with a 230-fs, 780-nm laser pulse and for 5300-atom Xe and 6200-atom Kr clusters. observed in the case of subpicosecond intense laser pulses (see Fig. 6) resists a simple interpretation but seems to lead, in this case, to the formation of a strongly heated, nonthermalized plasma.

A similar systematic investigation has been conducted by the Blackett Laboratory group at Imperial College [53–55]. Figure 8 shows the maximum ion energies obtained for krypton and xenon clusters irradiated by high-intensity laser pulses as a function of cluster size (upper panel) and as a function of laser intensity (lower panel). The maximum ion energies as a function of cluster size (upper panel) were obtained with a 170-fs laser pulse with a peak intensity of 1.3×10^{16} W cm⁻². The maximum ion energy of Xe clusters rises from 8 keV at a cluster size of about 1000 atoms to a peak of 150 keV for clusters of ~5000 atoms before falling to 100 keV as the cluster size is increased beyond 10,000 atoms. Kr clusters show a similar trend as Xe clusters, but the ion energies are lower. The experimental setup limits did not allow in this case an increase of the cluster size to the point where an optimum cluster size could be observed. The scaling of ion energies with laser intensity (lower panel) has been obtained with Xe clusters containing ~5300 atoms (corresponding to a 43 Å radius) and Kr clusters with ~6300 atoms (41 Å). Again, a similar behavior is observed for both rare gas species, with about 20% lower energies for Kr.

3.2.3. X-Ray Production

Another systematic study concerning X-ray generation has been conducted by the same CEA-Saclay group for rare gas clusters submitted to ultrashort and intense lasers [47]. Figure 9 shows the obtained mean photon number per pulse as a function of the laser intensity (upper panel) and as a

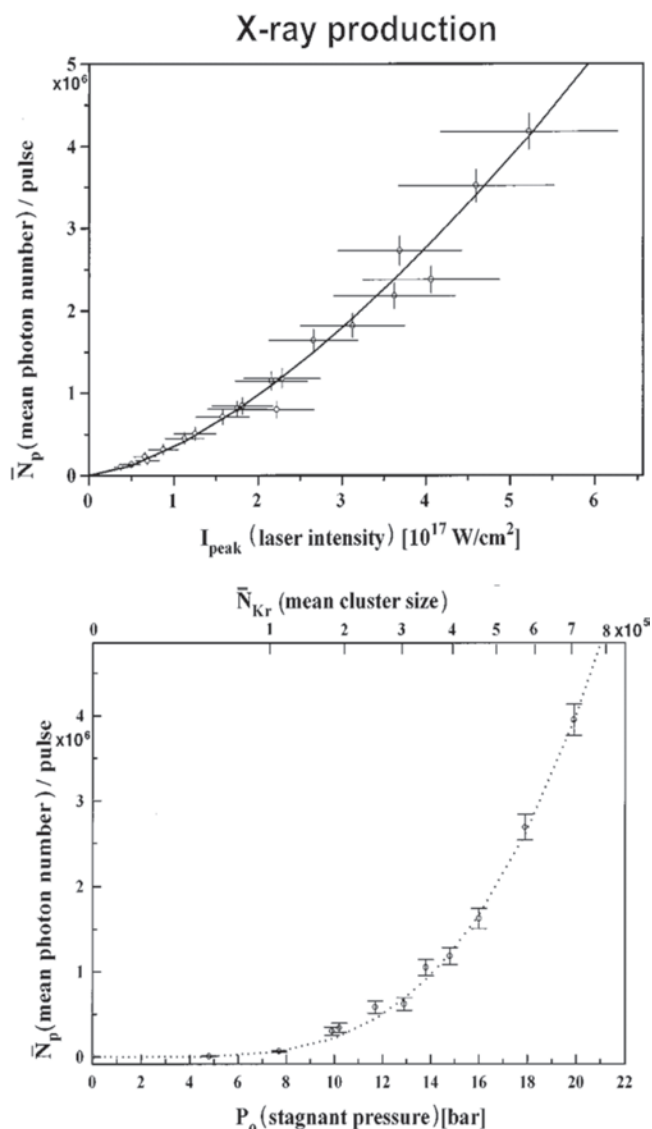
X-ray production


Figure 9. X-ray photon yield measured as a function of laser peak intensity (upper panel) for Kr clusters of estimated mean size 7×10^5, and as a function of backing pressure and the corresponding mean cluster size on the upper scale (lower panel) with a laser peak intensity of 4×10^{17} W/cm². Reprinted with permission from [47], S. Dobosz et al., *Phys. Rev. A* 56, R2526 (1997). © 1997, American Physical Society. The solid line in the upper panel and the dashed line in the lower one represent power law fits to the experimental results (see text).

function of stagnant pressure (or cluster size, lower panel) for krypton clusters. The mean photon number as a function of laser intensity (upper panel of the figure), obtained for clusters of estimated mean size 7×10^5 atoms corresponding to a backing pressure $P_0 = 19.5$ bar, has been fitted by a power law $\overline{N}_p \propto I_L^{3/2}$ (solid line). This scaling is typical for a saturated process in the focus of an intense laser field with a Gaussian intensity profile [47]. The dependence of the mean photon number on the stagnant pressure (lower panel), obtained with a laser intensity of 4×10^{17} W/cm², has also been fitted with $\overline{N}_p = (P_0 - P_c)^3$ with $P_c \approx 3$ bar. The mean cluster size scale $\overline{N}_{Kr}$ is also shown at the top of

the figure. Accordingly, the X-ray yield scales as $\overline{N}_{Kr}^{3/2}$. These results suggest that the onset of X-ray production occurs at a pressure offset of $P_c \approx 3$ bar, corresponding to a mean cluster size $\overline{N}_{Kr}$ close to 10^4 atoms. This value would then indicate the minimum cluster size for significant X-ray production in the present experimental conditions.

3.3. Metal Clusters

The first experiment on metal clusters in the nonperturbative regime was performed by Gerber and co-workers on mercury clusters [56, 57]. The mercury atom has a $5d^{10}\,6s^2$ closed electronic shell configuration. Diatomic and small mercury clusters are predominantly van der Waals bound systems. However, the electronic structure strongly changes with increasing cluster size and finally converges toward the bulk electronic structure where the $6s$ and $6p$ bands overlap, giving mercury its metallic properties. Hg_n ($n \leq 80$) clusters were produced in a cold supersonic beam and were ionized by femtosecond laser pulse of 50–120 fs duration in the wavelength range from 255 to 800 nm. The originality of these experiments arises from the study of the cluster behavior in the transition region, going from the low field regime (intensity $\sim 10^{11}$ W/cm²) to the strong field one (intensity $\sim 10^{13}$ W/cm²). Figure 10 represents the time of flight mass spectra of the mercury clusters obtained at 800 nm. For a laser intensity of 10^{11} W/cm² (Fig. 10a) a "normal" cluster size distribution is observed constituted by ionic fragments Hg_n^{q+} in the range $q = 1, 2$. At 10^{12} W/cm² (Fig. 10b), the Hg^+ signal increases while the signal of other fragments decreases. Moreover, the ratio between singly and doubly charged clusters of a given size does not change, which indicates that the small fragments come from the fragmentation of larger cluster ions. Increasing the intensity to 2×10^{12} W/cm² (Fig. 10c), highly charged mercury atoms (up to Hg^{5+}) appear. Note that the direct multiphoton ionization of Hg atom requires an intensity of about one order of magnitude higher. Finally, at the highest applied intensity of 10^{13} W/cm², the signal due to molecules and clusters disappears and only atomic ions, singly and multiply charged, are observed. In this case the whole cluster breaks into pieces by Coulomb explosion. These results clearly show that the energy absorption is strongly enhanced at relatively small laser intensity and the interaction process is beyond the classical multiphoton ionization.

Other investigations on metal clusters have been performed with the high intensity regime. Exhaustive studies were performed at the CEA-Saclay by Lebeault et al. [58] for lead clusters exposed to an intense laser field of 10^{15} W/cm² intensity, whereas platinum clusters (and lead clusters as well) excited by strong femtosecond laser pulses with intensities up to 10^{16} W/cm² were studied by Meiwes-Broer and co-workers [44, 59–61]. At such high intensities, it turns out that the metallic character of the clusters does not play an important role and the results can be interpreted in terms of plasmon resonance. In the Meiwes-Broer experiments, the cluster size distribution is estimated to be below about 100 atoms. The interaction with the laser pulse makes no clusters survive the excitation. The net result is the production of highly charged ions. Ion charges as high as Pt^{20+} were observed at 2×10^{15} W/cm² whereas only quadruple

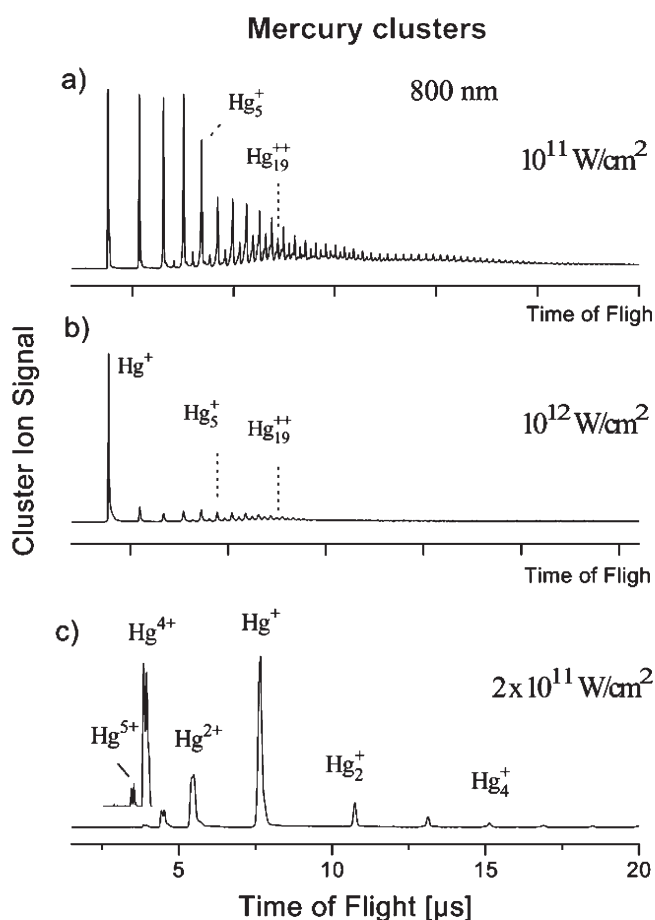
Mercury clusters


Figure 10. Time-of-flight mass spectra obtained by irradiating Hg_n clusters ($n \leq 80$) with femtosecond (50–100 fs) 800-nm laser pulses with peak intensities (a) 10^{11} W/cm², (b) 10^{12} W/cm², and (c) 2×10^{12} W/cm². ionization is obtained if isolated atoms were irradiated by the same laser intensity. The production of multiply charged platinum and lead cluster ions shows a significant increase of efficiency when increasing the laser pulse length. Figure 11 shows the abundance of platinum ions as a function of the pulse width for a given pulse energy of 5 mJ. The important feature is that the optimum pulse width of 600 fs that gives the largest abundances corresponds to neither the shortest pulse width for which the highest intensity is obtained nor the longest time duration for which the interaction time is longest.

In the Saclay experiments, small size lead clusters with a few hundred of atoms are irradiated with laser pulses with duration between 60 fs and 2.5 ps and a laser intensity of about 10^{15} W/cm². The kinetic energies and ionic charge of fragments were studied as a function of the laser intensity and pulse duration. Highly charged Pb^{n+} ions up to $n = 26$ have been detected with kinetic energies up to 15 keV. Moreover, the measure of the kinetic energy of ionic fragments versus the charge state exhibits a quadratic dependence for charge states lower than 10 and a linear dependence for higher charge states. These results were interpreted in the framework of the so-called nanoplasma

Platinum clusters
Figure 11. Abundances of platinum ions Pt^{z+} ($z = 1, \ldots, 11$) for different laser pulse widths ranging from 140 fs to 1 ps at a fixed pulse energy of 5 mJ. model (see Section 4.5). One can then conclude that the fragments with charges below 10+ are driven by Coulomb forces, whereas the higher charged fragments are accelerated by hydrodynamics forces.

3.4. Other Materials

Experiments with molecular (or mixed species) clusters irradiated by high-intensity ultrafast laser pulses have also been conducted by several groups [63–65]. Mixed species clusters offer the advantage to allow the use of elements which may hardly bind together to form "pure" clusters. For example, the formation of large hydrogen clusters in gas jets (or its isotopes for fusion experiments; see next section) requires very high backing pressures and cryogenic cooling. Hydrogen iodide (HI) gas, investigated by Tisch et al. [63], or deuterated methane (CD_4), investigated by Grillon et al. [65], forms large clusters very readily at low pressures even at room temperature.

Figure 12 shows the energy spectra of iodine ions (upper panel) and protons (lower panel) obtained by irradiating HI clusters of an estimated mean size of 60,000 molecules by 260-fs, 780-nm laser pulses at a peak intensity of 2×10^{16} W cm^{-2}. The maximum kinetic energy of iodine ions is ~92 keV, while the mean value is about 8.6 keV. The mean and maximum kinetic energies of protons are approximately 270 eV and 2.5 keV, respectively. A monotonous increase of both iodine and proton energies was also observed with increasing the size of HI clusters [63]. The observation of energetic protons and iodine ions indicates that molecular clusters can indeed be used to produce energetic ions from a range of much broader elements than could be expected otherwise. This was also the case for the experiment by Grillon et al. [65] using deuterated methane (CD_4) to produce energetic deuterium ions for fusion experiments.
Figure 12. Measured energy spectra of iodine ions (upper panel) and protons (lower panel) from explosions of 60,000-molecule HI clusters irradiated by 260-fs, 780-nm pulses at a peak intensity of 2×10^{16} W/cm^2. Figure 13. Mass spectra of ionized carbon, platinum, and lead clusters and atomic ions after irradiation of neutral clusters by femtosecond laser pulses of 3×10^{15} W/cm^2 at 800 nm. In contrast to carbon where only a small fraction of the ion intensity originates from the higher charged ions, the metal cluster spectra show that the main intensity emerges from the abundance of atomic Pt^{z+} and Pb^{z+}. Reprinted with permission from [60], T. Döppner et al., *Int. J. Mass Spectr.* 192, 387 (1999). © 1999, Elsevier Science.

Photoexcitation of other types of nanoclusters (covalent, molecular) has also been performed by several groups. Bescós et al. have studied the photoionization and photofragmentation of large neutral silicon clusters Si$_n$ with sizes up to $n \approx 6000$ irradiated by both nanosecond pulses with intensities 10^4–10^5 W cm^{-2} and femtosecond pulses with intensities ranging from 10^8 to 5×10^{11} W cm^{-2} [66]. Dobosz et al. have studied X-ray generation from carbon dioxide (CO$_2$) clusters with sizes of 80–100 nm irradiated by a 60-fs laser pulse with peak intensity of 10^{18} W cm^{-2} [64]. Schumacher et al. have investigated the photoionization of small covalent carbon clusters submitted to strong femtosecond laser pulses with up to 10^{16} W cm^{-2} [59]. Their results are shown in Figure 13 compared to the results obtained with platinum and lead clusters submitted to the same laser pulse.

Photoionization and photofragmentation experiments of carbon fullerenes C$_{60}$ have also been performed using subpicosend intense laser pulses by Campbell and co-workers [68–70]. Photoelectron as well as C$_{60}^{n+}$ spectra have been determined for different pulse durations and intensities. As an example, the C$_{60}^{n+}$ ion spectra are shown in Figure 14 for fullerenes submitted to a 35-fs, 795-nm laser pulse with a peak intensity of 10^{14} W/cm^2. The most striking feature of these mass spectra is the appearance of multiply charged species. Metastable fragments C$_{60-2n}^{+}$, C$_{60-2n}^{2+}$, and C$_{60-2n}^{3+}$ are also clearly observed indicating a strong coupling of electronic excitation energy to vibrational degrees of freedom leading to fragmentation.

3.5. Fusion

Large opportunities are opened by the studies of laser–cluster interactions. This can be illustrated by the experimental realization of nuclear fusion in deuterium by Ditmire et al. at LLNL [67]. In this experiment one irradiates a large cluster of deuterium D$_2$ by a laser with a peak intensity of 10^{16} W/cm^2. The explosion of clusters results in their fragmentation into D$^+$ ions with kinetic energies of a few keV. This is sufficient to realize nuclear fusion in the collisions D$^+$ + D$^+$ $\rightarrow$ He$_3$ + n that take place in the cluster beam. The detection of neutrons with 2.45 MeV kinetic energy clearly confirms the phenomenon. The experiment was later repeated by Grillon et al. using, instead of D$_2$ clusters, deuterated methane (CD$_4$) clusters leading to much higher D$^+$ energies of the order of 45 keV compared to the 2.5 keV obtained by Ditmire et al. [65] (see Fig. 15). In this experiment, the number of neutrons generated per shot at the maximum intensity of several 10^{17} W cm^{-2} was estimated as 7000 (over the whole solid angle). The pulse width of neutrons produced by intense laser irradiation of deuterium clusters was measured by Zweiback et al. and found to be under 100 picoseconds in duration near the source [71]. Such a short time-scale neutron pulse may represent a table-top source of neutrons that enables a new class of ultrafast neutron pump–probe experiments.

4. TOWARD QUANTITATIVE MODELS

4.1. General Strategy

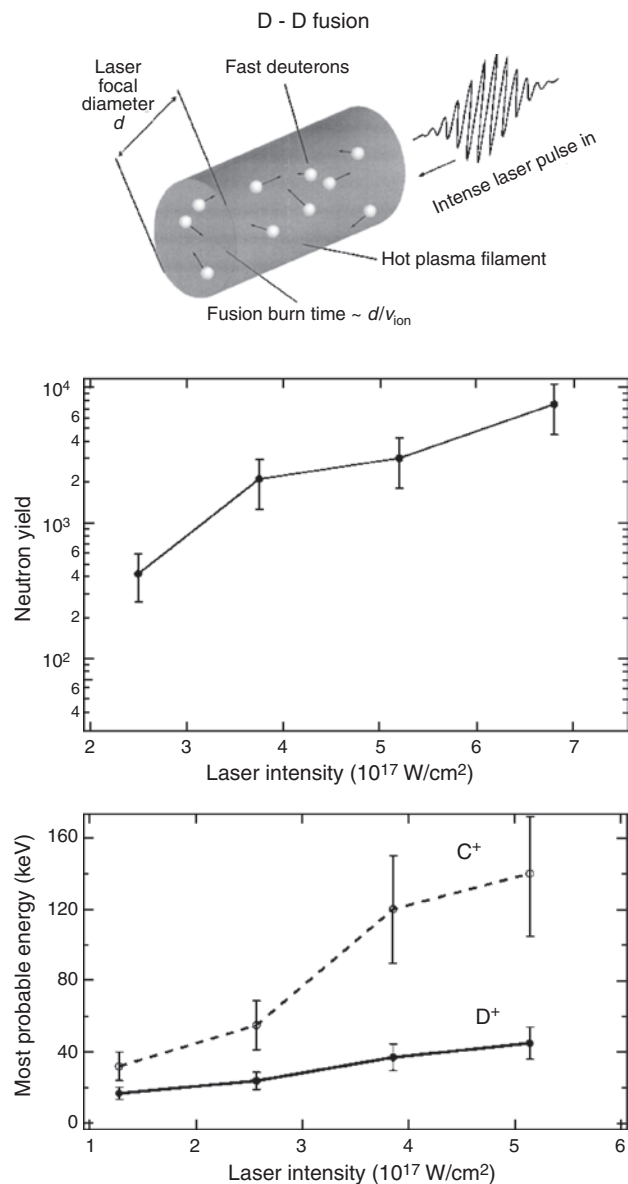
Our discussions have shown that while simple models allow one to understand basic mechanisms of interaction and qualitative behaviors of irradiated nanoclusters, they fail in providing quantitative access to experimental results. It is thus highly desirable to work out more elaborated approaches for such problems. The starting point of any quantum many body problem is, of course, the many body Schrödinger equation serving as basis for sequences of approximations. In nanometer scale systems far from equilibrium, a quantum description remains far beyond today's computers, even at an approximate level (e.g., mean field approaches). Mean field approaches, however, provide crucial guidelines for deducing simplified models [7]. It has to be remembered


Figure 15. Upper part: Experimental concept for an ultrafast neutron source. Reprinted with permission from [71], J. Zweiback et al., *Phys. Rev. Lett.* 85, 3640 (2000). © 2000, American Physical Society. Middle panel: Intensity dependence of the total neutron yield over the whole solid angle. Lower panel: Most probable energies of the measured distributions of C^+ and D^+. Reprinted with permission from [65], G. Grillon et al., *Phys. Rev. here that we want to consider situations in which electrons are deeply involved into the dynamics. Irradiating a cluster by a laser will primarily involve electrons, which will respond in various ways (collective oscillations, emission, ...) depending both on the laser characteristics and on the nature of the cluster (metallic, covalent, rare gas, ...). One thus needs to explicitly treat electronic dynamics and this eliminates the powerful approaches based on atomic molecular dynamics, which by construction cannot accommodate electronic excitations. The basic challenge is thus an efficient description of electronic dynamics. Of course, ions

will also couple to the laser field. But the ionic response takes place on a much longer time scale (typically 100–1000 fs) than the electronic one (typically 1–10 fs). A key constraint is hence to describe electronic dynamics both on the short and the long time scales and in a sufficiently simple approach to allow the study of sufficiently large systems.

Along the line of simplifying the original quantum many body problem, the step from the quantum to the semiclassical world is certainly an efficient, though reliable, step. Indeed, semiclassical methods have been developed and used in cluster physics for several years now, in particular in the case of metal clusters [8–10]. The term semiclassical deserves some explanation. By semiclassical we mean approaches in which electrons are treated as classical particles but augmented with a simplified Pauli exclusion principle (namely, a given maximal occupation in elementary phase space cells). The step from quantum to semiclassical worlds allows one to replace electronic wavefunctions by a phase space occupation function $f(\mathbf{r}, \mathbf{p})$ representing the ensemble of all electrons together. Still, basic quantum properties such as the Pauli principle are fulfilled by f, hence the label semiclassical. A great advantage of semiclassical approaches is that they allow the treatment of large clusters [10], but with a "maximum" of microscopic inputs. Furthermore, as is well known from basic quantum mechanics, the larger the involved energies, the less necessary the quantum details. Semiclassical models thus constitute an even more justified approximation in situations far from equilibrium. Finally, it should be noted that, from the more formal side, semiclassical methods open the door to the world of kinetic theory with its well established techniques for dealing with strongly interacting particles [11]. Indeed, semiclassical approximations to quantum mean-field calculations constitute a well established starting point for going beyond a mere mean-field description by including explicit electron–electron collisions, in the spirit of kinetic theory in electronic systems. This "beyond the mean-field" path has been attacked only very recently [12, 13] but provides a useful, and sometimes indispensable, tool for investigating the dynamics of clusters in the strongly out of equilibrium domain. We shall present some of these developments at the end of this chapter. Before reaching these latest developments we shall consider even more simplified approaches and show their interest and limitations for the problems we are interested in here.

4.2. Quantal Framework

The simplest semiclassical approximation can be derived directly from the quantal many body problem. Even in simple small systems, solving the quantal many body problem represents a formidable task, still on the edge of modern computers. At the nanometer scale it is hardly conceivable to consider a detailed microscopic approach containing all electronic correlations. One has in any case to recur to simplified descriptions. The major difficulty lies here at the side of electrons which do behave quantally in many situations, while ions can often be treated as classical particles. A most efficient and robust, and still quantal, scheme is provided here by density functional theory [7], which

allows one to reformulate the quantum many body electronic problem in terms of an effective mean field Hamiltonian $\hat{h}$ involving the local electronic density $\rho_e(\mathbf{r})$ only. The many body Schrödinger equation can then be recast into a set of coupled, one-electron equations following the famous prescription of Kohn and Sham [72]. When time dependent problems are considered the former strategy can be extended and the time dependent Schrödinger equation for the many electron system replaced by a set of time dependent one-electron equations (time dependent Kohn–Sham equations). Of course a key ingredient of this approximation scheme lies in the choice of the one-electron Hamiltonian $\hat{h}$. We shall not discuss here the many (interesting) researches on the topic, which actually go much beyond cluster physics. Rather we shall mention the simplest approximation, the so-called LDA (local density approximation) in which $\hat{h}$ is expressed as a function of the density $\rho_e(\mathbf{r})$, namely $\hat{h} = \hat{h}(\mathbf{r}) = \hat{h}(\rho_e(\mathbf{r}))$. This simple, although robust, approximation provides a starting point for many efficient applications, both in cluster and outside cluster physics, also in the case of time dependent problems [73].

4.3. Vlasov Equation

The semiclassical limit thus starts from the time dependent version of LDA, the so-called TDLDA (time dependent LDA). In terms of the one-body density operator $\hat{\rho}$, TDLDA takes a simple, compact form, well suited to apply semiclassical approximations [74]:

$$\dot{\hat{\rho}} = \frac{1}{i\hbar}[\hat{h}(\hat{\rho}), \hat{\rho}] \qquad (2)$$

It furthermore offers a form adapted for going "beyond" the mean field in the realm of kinetic equations. The semiclassical limit of Eq. (2) is the so-called Vlasov equation, well known in plasma physics [75]. But here it emerges as a semiclassical approximation of a truly quantal equation. Following the usual recipe, it can be formally obtained from Eq. (2) by replacing the density operator $\hat{\rho}$ by a one-body phase space distribution $f(\mathbf{r}, \mathbf{p}, t)$ and the commutator with Poisson brackets [74]. This then leads to

$$\frac{\partial f(\mathbf{r}, \mathbf{p}, t)}{\partial t} + \{f, h\} = 0 \qquad (3)$$

where the mean field Hamiltonian h is now classical but still a functional (or a function, in the case of LDA) of the (semiclassical) electron density $\varrho(\mathbf{r}, t)$. The latter is computed by integrating $f(\mathbf{r}, \mathbf{p}, t)$ over momentum space $\varrho(\mathbf{r}, t) = \int d^3 p\, f(\mathbf{r}, \mathbf{p}, t)$. It should, however, be noted that the semiclassical approximation leading from Eq. (2) to Eq. (3) has to be performed with due caution. The problem is here of a formal nature. Indeed a semiclassical approximation such as the one performed previously corresponds to the lowest order term of an expansion in terms of $\hbar$. And the convergence of this $\hbar$ expansion may raise some difficulties, in particular when the mean field Hamiltonian is self-consistent, namely itself depending on the actual density $\varrho(\mathbf{r}, t)$. A thorough discussion of this problem can be found in [76–78] and we shall not further elaborate on it here. Another difficulty with Eq. (3) concerns the capability of

numerical simulations to preserve Fermi statistics on long times [79]. Indeed, as already mentioned, the term semiclassical precisely requires that the theory does preserve some quantal features. This holds in particular for the fermionic nature of the involved particles which is not guaranteed in a purely classical Vlasov equation. This question, however, is highly technical and we refer the reader to appropriate references on the topic [80, 81].

4.4. Time-Dependent Thomas–Fermi Approximation

The Vlasov approach provides a phase-space description of electron dynamics. This allows one to treat a wide range of electronic excitations in systems of various sizes and in very different dynamical contexts. In particular it can accommodate reasonably nonlinear situations, as encountered, for example, in the interactions between clusters and intense laser beams. In particular the full phase space description provided by the phase space distribution $f(\mathbf{r}, \mathbf{p}, t)$ allows one to treat possibly large distortions of the local Fermi sphere, a feature typical of strongly out of equilibrium dynamics. But in the case of metal clusters two effects tend to suppress these local distortions. First, the dominating presence of the Mie plasmon mode, which carries little momentum space anisotropy, tends to soften effects linked to actual distortions of the Fermi sphere. In addition, electron–electron collisions (which go beyond the actual mean field picture; see Section 4.6) act on very short time scales of order a few fs, so that they tend to remove remaining momentum sphere anisotropies very quickly. To a very good approximation, the local momentum distribution of electrons thus deviates only a little from sphericity [82]. This provides a justification for going one step further down in terms of the semiclassical approximation: integration over momentum space then leads to the so-called time dependent Thomas–Fermi (TDTF) approximation. The TDTF approach is exactly a hydrodynamical reformulation of the original problem, assuming a Thomas–Fermi kinetic energy for the electrons. It is interesting to note here that the TDTF approximation can be formally derived either from the Vlasov equation by integration over momentum space, or directly from TDLDA by a proper choice of a model wavefunction [82]. In both cases one ends up with the same set of coupled equations for the local electron density $\varrho(\mathbf{r})$ and local velocity field $\mathbf{u}(\mathbf{r}) = \nabla \chi$ [82]. At this stage it should also be noted that TDTF represents a genuine density-functional method (see [83]), as it only involves the actual local density $\varrho(\mathbf{r})$ and its associated flow.

In cluster dynamics, the full three-dimensional (3D) electronic TDTF approximation has been explored in [82, 84]. It was shown in these publications that TDTF provides a fairly good approach to TDLDA, even for moderate excitations, as is illustrated in Figure 16. Furthermore, the simplicity of the picture allows one to treat systems of large sizes, contrarily to more detailed approaches. It is thus an ideal tool of investigation of nanocluster dynamics. It was also used in simpler versions of the theory (restricted to 1D geometry) in direct relation to irradiation by intense lasers [85–87]. Furthermore, an explicit account of the ionic background by means of pseudo-potentials allows one to accede the local
Figure 16. Time Dependent Thomas Fermi calculation of the optical response of a medium size metal cluster compared to experimental data. Cluster is Na_{93}^+; experimental data have been obtained at temperature $T = 105$ K, which explains part of the spreading of the optical peak. Reprinted with permission from [82], A. Domps et al., *Phys. Rev. Lett.* 80, 5520 (1998). © 1998, American Physical Society.

behavior of collective currents during Mie plasmon oscillations. The TDTF picture, with its underlying hydrodynamical structure, thus provides an ideal tool of investigation of the nature (collective or not) of the optical response [84]. Coupling to ion dynamics is also possible and has already been investigated at the Born–Oppenheimer level in [88]. Extensions to nonadiabatic electron dynamics are also in reach, although they have not yet been investigated.

4.5. Rate Equations and High Intensity Regime

Along the series of more and more simplified models, the next step beyond the hydrodynamical picture provided by TDTF is to consider rate equations for describing the dynamics. The relevant variables then reduce to a set of integral quantities (radius, ionization, . . .), the evolution of which being followed in time. Such an oversimplified picture may, however, make sense when only gross properties of the system may be attained. This is typically the case of high intensity irradiations of clusters. At sufficiently high laser intensities, the details of the excitation mechanism tend to be washed out to the benefit of a global plasmalike behavior of the set of quasi free electrons. It is then sufficient, at least for a first step, to remain at the level of a gross description of the system, in terms of a few global variables, the primary goal being to understand the key mechanisms at work. This is the spirit of the so-called nanoplasma model developed by Ditmire et al. at Lawrence Livermore National Laboratory [95]. This model offers, at the level of global cluster characteristics, a complete scenario of the interaction process, taking into account ionization, heating, electronic emission, and cluster expansion simultaneously. In contrast to other models, it treats the polarization field radiated by the charges explicitly. In this model, the cluster is treated as a spherical plasma—a nanoplasma—where the plasmon resonance takes place. Whether the cluster can be treated as a plasma

or not has given rise to a controversy, though. For example, classical dynamics simulations including the Coulomb field of the ions but neglecting the polarization field indicate that the electrons are quickly removed at the beginning of the interaction even from large clusters [96]. That makes the existence of a nanoplasma questionable. Until now there has not been any time-resolved measurement at the femtosecond scale to settle the question.

The nanoplasma model consists essentially of a few rate equations expressing the time variation of the number N_j of ions of a given charge state j due to ionization

$$\frac{dN_j}{dt} = \left(W_j^{\text{tun}} + W_j^{\text{coll}}\right)N_{j-1} - \left(W_{j+1}^{\text{tun}} + W_{j+1}^{\text{coll}}\right)N_j \qquad (4)$$

with j running from 0 to the maximum charge state considered. Here, W_j^{tun} and W_j^{coll} represent the rate of direct optical ionization and collisional ionization of ions with charge j, respectively. These rate equations are supplemented by an additional equation expressing charge conservation inside the cluster and two other equations expressing the cluster expansion and heating. For more details, we refer the reader to the original paper [95].

As an example, the computed temporal evolution of an exploding cluster of 5000 Xe atoms irradiated by a 100-fs, 780-nm laser pulse with a peak intensity of 10^{16} W/cm^2 is illustrated in Figure 17 [97]. Time $t = 0$ fs is the time at which the laser reaches its maximum intensity. We have represented in the upper part of the figure the time variation of the electron density inside the cluster normalized to the critical density n_c and in the lower part the electric field inside the cluster (solid line) together with the external one (dashed line).
At the rising edge of the pulse, quasi free electrons are produced inside the cluster from neutral atoms by tunnel ionization. The rapid increase of the number of quasi free electrons leads the system through a first modest resonance at $t \simeq -135$ fs when the density matches three times the critical density n_c. The electric field is then shielded due to the high electron densities reached. The tunnel ionization rate falls off, but electrons are still created through thermal collisions. From times $t \simeq -100$ fs onward, the electron temperatures are high enough for some electrons to leave the cluster leading to a fall of the density inside the cluster until time $t \simeq 10$ fs when the second, more important resonance takes place. The inner field is then amplified to 1.5 times the external field and electronic temperature reaches 1.2 keV. The rate of electron emission increases consequently giving a highly positively charged cluster which will explode due to the huge Coulomb repulsion between ions.

Even though the model provides a good description of the gross features of the interaction of intense lasers with clusters, it fails to give a good account of all the experimental results observed, especially those far from average values. For example, the model agrees with the average ion charges observed experimentally but fails in describing the far tails of ion charge distributions which are at the origin of X-ray generation.

4.6. Beyond Mean Field—The Vlasov–Uehling–Uhlenbeck Equation

As is well known, the Vlasov equation represents the basic level of the hierarchy of many body dynamical equations [98]. The TDTF approach of course does not go beyond Vlasov in that respect, as it only represents an average of the Vlasov dynamics over momentum space. Neither do, of course, rate equations, which provide an even grosser picture of the dynamics. Furthermore, as already discussed, both TDTF as well as Vlasov remain at the pure mean field level and are thus *a priori* only suited to situations where dissipative effects are not too large, actually just as the quantal cousin TDLDA. But dynamical correlations, not included in mean field, do play a key role in the dynamics of highly dissipative systems. Remembering the underlying kinetic theory picture, it is no surprise that these correlations show up at the level of two-body effects. They furthermore usually take place at a faster time scale than the mean field motion. This is the justification of treating them by instantaneous two body collisions, which formally leads to the inclusion of a Markovian collision term to complement the mean field theory. This yields the well known Vlasov–Boltzmann equation for classical systems. In the case of dense fermion systems, such as metal clusters, atomic nuclei, and liquid helium, Fermi statistics plays a central role in many situations. This then leads to the so-called Vlasov–Uehling–Uhlenbeck (VUU) scheme, as proposed in the late 1920s and early 1930s [99, 100]. This VUU scheme has furthermore been intensely studied during the last two

Figure 17. Temporal history of an exploding 5000-atom Xe cluster irradiated by a 100-fs, 780-nm laser pulse with peak intensity 10^{16} W/cm^2. Upper part: electron density normalized to critical density n_c; lower part: amplitudes of internal (solid line) and external (dashed line) electric fields.

decades in nuclear physics [101–103]. The resulting VUU equation reads

$$\frac{\partial f}{\partial t} + \{f, h\} = I_{\text{VUU}}[f(\mathbf{r}, \mathbf{p}, t)] \qquad (5)$$

with $I_{\text{VUU}} = \int d\mathbf{p}_2\, d\mathbf{p}_3\, d\mathbf{p}_4\, W(12, 34)(f_{12}^{\text{in}} f_{34}^{\text{out}} - f_{12}^{\text{out}} f_{34}^{\text{in}})$ where $W(12, 34)$ is the collision rate, proportional to the elementary cross section $d\sigma/d\omega$, which constitutes a key ingredient of the approach. In Eq. (5), "in" and "out" label the distribution of particles entering or exiting a two body collision ($12 \leftrightarrow 34$), such that $f_{ij}^{\text{in}} = f_i f_j$, $f_{kl}^{\text{out}} = (1 - f_k)(1 - f_l)$, with the short hand notation $f_i = f(\mathbf{r}, \mathbf{p}_i, t)$. The weights are in a way similar to a standard Boltzmann collision term but augmented by the Pauli blocking factors in the exit channel f_{kl}^{out}. The latter terms impose that no more than one particle, or two with opposite spins, can occupy an elementary phase space cell of volume $(2\pi\hbar)^3$. This blocking factor plays a dramatic role for electronic systems [104], in particular at zero temperature where it fully blocks electron–electron collisions, as expected. In dynamical situations, when the system is hot or sufficiently excited, phase space opens up and two body collisions start to play a (possibly dominating) role.

It is important to note here that the VUU scheme only represents a first exploratory step in the direction of accounting for dynamical correlations. Of course one should be cautious with the possible double counting of interactions between the effective interaction in the mean field term and the collision term, an effect which has not yet been truly explored in the case of clusters. However, results obtained in related fields of physics, in which a similar question has been addressed in full detail, show that with minimal precautions one can circumvent this problem. Relying on the experience gathered in nuclear dynamics [105] and in the physics of plasmas [106], or liquid helium [107], one can assume that there is no problem as long as collisions are treated in a Markovian approximation (i.e., as instantaneous) [105]. The rule is then to use together the LDA for the mean field and a screened Coulomb cross section for the collision integral. In the case of metal clusters an explicit reevaluation of the cross section [12] actually has lead to values in agreement with the bulk values of condensed matter calculations [104]. With such an established framework, one can now envision direct applications in realistic cases [13], even with coupling to ionic molecular dynamics [108].

5. CONCLUSIONS

We have seen that the interaction of light with clusters may lead to various scenarios depending on the intensity of the lasers used for probing the clusters. In the optical response regime clusters are only slightly perturbed and respond in a correlatively gentle manner. Optical response nevertheless provides a bunch of interesting information on clusters, in particular because of its marked size dependence. The case of irradiations by intense lasers opens the door to a bunch of new challenging phenomena such as the production of highly energetic species (photons, electrons, ions). In this domain of physics the interaction process between the cluster and the laser is so strong that it leads to a complete destruction of the cluster. At variance with the optical response regime it thus does not provide direct information on the clusters themselves, which constitute laboratories rather than true objects of studies. However, and this time in a similar way as in the low intensity regime, we have also seen that, again, the capability of the electron cloud to respond collectively to the external field remains a key issue. The dominant role of this plasmon is obvious for metallic systems, whatever the laser intensity. But is also indeed present in the case of rare gas clusters irradiated by sufficiently intense lasers. In this spirit irradiation of clusters by intense lasers leads us to plasma physics in the framework of the so-called nanoplasma model. The latter original model, similarly to the simple Mie model of the optical response, does provides interesting insights into the physical mechanisms at work. Both these simple models, however, only allow a qualitative description of the experiments. They miss many details, starting with the crucial finite size effects.

The step from basic simple models toward more elaborate approaches for describing these various dynamical situations is not an easy one. Indeed fully quantal calculations are much too involved to be applied to such huge systems in strongly out of equilibrium situations. One is thus bound to find appropriate approximations, keeping as much as possible of the microscopic world. Semiclassical methods offer here an appealing possibility. They have already been a little explored in the context of metal cluster dynamics, but one is still far away from having fully exploited the many opportunities they offer, in particular for large systems out of equilibrium. More developments of these methods are thus to be expected in the field of the dynamics of nanometer scale clusters irradiated by lasers of various intensities.

GLOSSARY

Density functional theory (DFT) A systematic way to develop a mean-field theory with purely local potentials. It proves the existence of a local representation for the nonlocal exchange as well as correlation terms and it set the framework for practical approximations (see LDA).

Landau damping or fragmentation A mechanism, first introduced by Landau, which describes the damping of collective degrees of freedom due to their coupling to single-particle degrees of freedom.

Local density approximation (LDA) The most widely used realization of DFT. It uses the exchange-correlation energy of the homogeneous electron and interprets it as a function of the now local density. By density variation, one thus derives a local single-particle potential depending on the local density. The kinetic energy remains approximated (in contrast to the Time dependent Thomas-Fermi approximation) and the single-particle wavefunctions remain the relevant degrees-of-freedom.

Mean field theory The description of a many-particle system in terms of independent particles moving each in a common effective single-particle potential. This mean-field potential, in turn, depends on the particle density summed up from the single-particle densities. A typical example is the Hartree-Fock theory where the mean-field potential becomes non-local in the exchange term.

Mie plasmon, Mie model Collective description of the dominant dipole mode as small oscillations of the frozen electron cloud against the ionic background. The original formulation was done for a metal sphere using dielectric theory.

Nanoplasma model A phenomenological model which describes the interaction of intense laser pulses with large atomic clusters in terms of macroscopic variables. The laser field ionizes individual atoms creating a plasma of quasi-free electrons and ions of the size of the nanocluster, the nanoplasma.

Time-dependent LDA (TDLDA) The time-dependent generalization of the LDA employing a time-dependent variational principle instead of the stationary Ritz variational principle.

Time dependent Thomas-Fermi approximation An approximation to TDLDA in which one also replaces the kinetic energy by a functional of the local density, called the Thomas-Fermi kinetic energy. The system is then described purely in terms of the local one-particle density.

Vlasov equation The semi-classical limit of time-dependent mean-field theory. It describes the propagation of the single-particle phase-space distribution under the influence of a mean-field potential.

Vlasov-Uehling-Uhlenbeck equation An extension of the Vlasov equation taking into account collisions among particles (here electrons) in a Boltzmann-like collision term including Pauli exclusion principle.

Photoexcitation Dynamics of Fullerenes

Mamoru Fujitsuka, Osamu Ito

Tohoku University, Sendai, Japan

CONTENTS

1. INTRODUCTION

Fullerene C_{60} (Fig. 1) was found in the laser vaporization of graphite in 1985 by Kroto et al. [1]. Since the first demonstration of large scale synthesis of fullerenes in 1990 [2], quite a large number of studies on fullerenes have been carried out for clarification of their basic properties and for their applications. Up to date, in addition to C_{60}, various kinds of fullerenes such as higher fullerenes and endohedral metallofullerenes have been isolated. Furthermore, various kinds of derivatives of fullerenes have been synthesized. Thus, many kinds of compounds are included in the fullerene group. Fullerenes show interesting properties in the field of materials science: Superconductivity, photoconductivity, ferromagnetism, and nonlinear optics are examples of characteristic properties of fullerenes [3–6]. Furthermore, it should be noted that fullerenes are also attractive materials in the field of biochemistry, since the excited fullerenes are effective in cleavage of DNA in the presence of molecular oxygen and electron donors [7, 8]. Furthermore, computer simulation made clear that C_{60} would be active to HIV protease [9].

Photoexcitation dynamics of fullerenes have been also widely investigated. Nowadays, the excitation–relaxation processes of C_{60} and C_{70} have been well established [10–15]. Singlet and triplet properties have been investigated by using pico- and nanosecond laser flash photolysis techniques. One of the important photophysical properties of C_{60} and C_{70} (Fig. 1) is almost quantitative triplet generation, which results in effective photochemical bimolecular reactions [10].

From the viewpoint of photochemistry, fullerenes are good electron acceptors and many photoinduced reactions have been reported by using these fullerenes as acceptors [16–20]. The excellent acceptor ability of fullerene is a key feature of photoconductivity for fullerene-doped polymer films such as poly(N-vinylcarbazole) and poly(p-phenylene vinylene) [4, 21]. Furthermore, many derivatives of the fullerenes have been synthesized due to high reactivities of fullerenes [22]. Fullerene oligomers and polymers are interesting materials as well as pristine fullerenes [23, 24].

Utilization of fullerenes to mimic photosynthesis systems has been investigated, resulting in enhanced efficiencies of the charge separations, which relates to application of the highly efficient photovoltaic cells [25–27].

In this chapter, we review the photoexcitation dynamics of fullerenes including C_{60}, C_{70}, higher fullerenes, endohedral metallofullerenes, and fullerene oligomers. Furthermore, photoinduced processes in the fullerene-donor linked molecules have been also reviewed, since they will serve as important molecular devices.

2. PHOTOEXCITATION AND RELAXATION PROCESSES OF FULLERENES

2.1. Excited Singlet State Properties of C_{60} and C_{70}

C_{60} and C_{70} show weak fluorescence at 700 and 660 nm (Fig. 2) [28, 29]. The quantum yield of the fluorescence of C_{60} is as low as 3.2×10^{-4} [30]. Small quantum yields of the fluorescence processes can be attributed to the forbidden transition due to closed shells with high symmetry (I_h-symmetry). When the symmetry of C_{60} is decreased by the introduction of a functional group, about a threefold
Figure 1. C_{60} and C_{70}.

increase of the fluorescence quantum yield is attained [31]. From the low symmetry, C_{70} shows a slightly larger fluorescence quantum yield (5.2×10^{-4}) than C_{60} [30]. The fluorescence lifetimes of pristine C_{60} and C_{70} are reported to be 1.2 ns and 660 ps, respectively [30].

Introduction of multiaddends to C_{60} changes fluorescence properties to a great extent. Schick et al. reported that the hexa-adduct of C_{60} (T_h-symmetry) shows a fluorescence peak at 550 nm, with high fluorescence quantum yield (0.024), which is 75 times larger than pristine C_{60} [32]. They also reported that the hexa-adduct shows apparent phosphorescence. These findings indicate that the optical devices are possible by using fullerene compounds with many addends.

By using ultrashort laser pulses, transient absorption bands due to the singlet excited states of C_{60} and C_{70} can be observed. In the case of C_{60}, the transient absorption bands due to the singlet excited state appeared around 900 nm upon ultrashort laser pulse irradiation [33]. As for the singlet excited state of C_{70}, the transient absorption spectrum shows a peak around 700 nm [34]. It has been reported that the decay rate constants of the absorption bands of the singlet excited states agreed well with the corresponding fluorescence decay rate constants. When the excitation wavelength is short enough to pump fullerenes to the higher excited states (S_n), the lowest excited state (S_1) should be generated after the internal conversion process (Fig. 3). In the case of C_{60}, it has been reported that the S_1 state is converted with a time constant of 250 fs from the higher excited state [35]. As for C_{70}, it was confirmed that the internal conversion process proceeds within 1 ps after the excitation with the laser pulse.

Figure 3. Schematic energy diagram of the excitation and relaxation processes of fullerenes.

2.2. Excited Triplet States of C_{60} and C_{70}

Photoexcitation of C_{60} and C_{70} generates the triplet excited states almost quantitatively from the singlet excited states; that is, the quantum yields for the intersystem crossing yields (Φ_{ISC}) are >0.95 for C_{60} and C_{70} [10, 36]. The quantitative triplet generations of the fullerenes are important in the various photochemical processes. For example, the triplet excited fullerenes are important reagents for the quantitative generation of singlet oxygen [10], which is one of the important species in the fields of photobiology. C_{60} and C_{70} in the glassy matrix of the brominated hydrocarbon at 77 K show phosphorescence at 794 and 810 nm [37], respectively, which correspond to 1.56 and 1.53 eV of the triplet energies.

Upon nanosecond laser irradiation, C_{60} shows a clear absorption band due to the triplet excited state at 750 nm (Fig. 4) [11–15], which is a good spectral probe for the photochemists who trace the photoinduced process via the triplet excited state of C_{60}, since the extinction coefficient of the transient absorption band is as large as 16,100 M^{-1} cm^{-1} at 750 nm [15]. The decay rate of the triplet excited state of C_{60} in solution is governed by the triplet–triplet annihilation and the self-quenching processes,

$$^3C_{60}^* + \,^3C_{60}^* \xrightarrow{k_{TT}} \,^1C_{60}^* + C_{60} \qquad (1)$$

$$^3C_{60}^* + C_{60} \xrightarrow{k_{sq}} 2C_{60} \qquad (2)$$

Figure 2. Absorption and fluorescence spectra of (a) C_{60} and (b) C_{70} in benzene. Reprinted with permission from [29], A. Masuhara et al., *Bull. Chem. Soc. Jpn.* 73, 2199 (2000). © 2000, Japan Chemical Society.
Figure 4. Transient absorption spectrum of C_{60} in toluene at 100 ns after laser light irradiation. Inset: Absorption-time profile at 750 nm.

Both processes were investigated by dependence of the decay rate of the triplet excited C_{60} on the excitation power or concentration (Fig. 5) [29, 38]. It has been reported that the bimolecular rate constants of both processes are on the order of 10^9 M^{-1} s^{-1}, indicating that both processes are effective quenching processes of the triplet excited states. Ausman and Weisman reported that the intrinsic lifetime of the triplet excited state of C_{60} is as long as 143 μs in toluene at room temperature [38].

In the case of C_{70}, the triplet absorption band shows peak at 980 nm, of which the extinction coefficient is 6500 M^{-1} cm^{-1} [14]. In the case of C_{70}, the intrinsic triplet lifetime is reported by Ausman and Weisman to be as long as 11.8 ms in toluene [38].

These long triplet lifetimes of C_{60} and C_{70} indicate that the wide varieties of the photoinduced reactions are expected via the triplet excited states of both fullerenes.

Triplet properties of the derivatives of C_{60} have been also reported [31]. In the case of 1,2-adducts of C_{60}, the triplet absorption band appeared around 700 nm. It has been reported that the Φ_{ISC} values are 0.8–0.9 for these 1,2-adducts [31]. Thus, the triplet excited states of the derivatives are also good precursors for the photoinduced reactions.

3. PHOTOINDUCED REACTIONS OF FULLERENES

3.1. Electron Acceptor Abilities of Fullerenes

The first reduction potential of C_{60} is reported to be -0.42 V vs saturated calomel electrode (SCE) in benzonitrile [39], which is similar to the reduction potential of p-benzoquinone (-0.51 V vs SCE) [40], a typical acceptor in the photosynthesis systems. The cyclic voltammogram of C_{60} shows multiple reduction waves up to sixth reduction steps [41]. From these results, C_{60} is a good electron acceptor. Its electron acceptor ability is enhanced in its excited state, since free-energy
Figure 5. Laser power dependence of absorption-time profiles of triplet excited C_{60} at 750 nm. Inset: Analysis of the triplet–triplet annihilation process according to the relation $-d[\ln \Delta A_0]/dt = \Delta k_{1st} = k_{1st}^0 + (2k_{2nd}/\varepsilon_T)\Delta A_0$, where ΔA_0, k_{1st}^0, k_{2nd}, and ε_T are T-T absorbance at $t = 0$, an intrinsic first-order decay rate, rate constant of the T-T annihilation, and an extinction coefficient of the T-T absorption band. Reprinted with permission from [29], A. Masuhara et al., *Bull. Chem. Soc. Jpn.* 73, 2199 (2000). © 2000, Japan Chemical Society.

change for the electron transfer (ΔG_{et}) in the excited state [Eq. (3)] is more negative than that in the ground state [Eq. (4)] [42],

$$\Delta G_{et} \text{ (excited state)} = E_{ox} - E_{red} - E_{00} - e^2/\varepsilon r \quad (3)$$

$$\Delta G_{et} \text{ (ground state)} = E_{ox} - E_{red} - e^2/\varepsilon r \quad (4)$$

where E_{ox}, E_{red}, E_{00}, and $e^2/\varepsilon r$ are oxidation potential of donor, reduction potential of acceptor, excitation energy, and Coulombic term, respectively. As for the oxidation, five oxidation waves were confirmed in the cyclic voltammogram, although reports on the oxidation processes of C_{60} are scarce compared to the reduction processes.

3.2. Electron Transfer via the Singlet Excited States of Fullerenes

Since the decay rate constants of the singlet excited states are 8.8×10^8 and 1.5×10^9 s^{-1} for C_{60} and C_{70}, respectively, electron transfer processes via the singlet excited states become evident when a charge-transfer complex is formed in the ground state or when the concentration of the donor is as high as $\sim$100 mM.

When C_{60} or C_{70} was excited in the presence of highly concentrated amines such as dimethyl aniline and triphenyl amines, C_{60} or C_{70} showed exciplex emission. For example, the C_{70}-dimethylaniline system showed exciplex emission in the 700–800 nm region with decrease of fluorescence intensity of C_{70} in the 600–700 nm region [43]. The exciplex formation is apparent in nonpolar solvents rather than polar solvents, since the polar solvents solvate the generated radical ions as free radical ions. When the concentration of the donor is high, one-to-one charge transfer complex formation can be observed as broadening of the ground state absorption band of C_{60}. Sension et al. observed electron transfer from the singlet excited state of C_{60} within 1–2 ps by observing the absorption band around 1000 nm upon excitation of the C_{60}-dimethylaniline complex with a femtosecond laser [44]. The recombination occurs on a time scale in the range from 20 to 55 ps.

Electron transfer via the singlet excited states of the fullerenes also became evident in the solid state materials such as conjugated polymer films. Sariciftci et al. reported that the femtosecond laser irradiation on the polythiophene–C_{60} composite film, in which the charge–transfer complex was formed, results in the radical ion pair formation within 1 ps [45, 46]. Thus, laser excitation on the charge transfer complex results in fast electron transfer. This kind of electron-transfer process is important in the photoconductive materials in which the substantial carriers are generated by photoirradiation. It has been reported that the photoconductivity of these composite films of fullerenes and conjugated polymer persisted about 10 ns after a short laser pulse, indicating that the charge-migration processes take place in these films.

A fast charge-separation process of the charge-transfer complex is also reported for the C_{60}-doped poly(N-vinylcarbazole) (PVCz) film, for which enhanced photoconductivity was also reported [4]. In the C_{60}-doped PVCz films, the electron transfer occurred immediately after the

picosecond laser pulse [47]. The decay of the initial charge-separated state with a time constant of 1.2 ns comprises three channels: the charge–recombination, the hole migration to the neighboring carbazolyl chromophores, and the formation of the local triplet excited state of C_{60} (Fig. 6).

It should be noted that under low concentrations of these photoconductive polymers (<10 mM) in solution, the electron-transfer process via the triplet excited states of fullerenes or triplet excited polymers is a major process as shown below.

3.3. Electron Transfer via the Triplet Excited States of Fullerenes

One of the important characteristics of C_{60} and C_{70} is the high quantum yield of the intersystem crossing from $^1C_{60}^*$ ($^1C_{70}^*$) to $^3C_{60}^*$ ($^3C_{70}^*$). Thus, the reaction systems including donors of lower concentrations (<10 mM) attain highly efficient electron transfer via $^3C_{60}^*$ and $^3C_{70}^*$.

For observations of the electron-transfer processes via the triplet excited states of fullerenes, a nanosecond laser flash photolysis method observing transient spectra in the near-infrared (IR) region is advantageous, since the transient species of the fullerenes appeared in the near-IR regions. For example, absorption bands of the triplet excited state and radical anion of C_{60} appeared at 750 and 1080 nm, respectively. As for C_{70}, they appeared at 980 and 1360 nm, respectively. The first paper on the electron-transfer process via the triplet excited C_{60} was reported by Arbogast et al. [48]. Their studies using transient absorption spectroscopy showed the generation of the radical anion in the near-IR region. Furthermore, they showed the dependence of the rate constants for the electron-transfer processes on the free-energy changes according to the tendency described by the Rehm–Weller equation, which are calculated by the oxidation potentials of aromatic amines used as donors.

In addition to the aromatic amines, many kinds of organic compounds are known to show sufficient donor abilities. For example, tetrathiafulvalene (TTF) or bis(ethylenedithio)tetrathiafulvalene (BEDT-TTF) is a donor which shows metallic conduction when it forms a charge-transfer complex with appropriate acceptors [49]. C_{60} is one of the acceptors which forms a charge-transfer complex with TTF [50]. In benzonitrile solution which contains C_{60} and TTF,
Figure 7. Transient absorption spectra of C_{60} (0.1 mM) in the presence of TTF (1.0 mM) in benzonitrile. Inset: Absorption-time profiles at 750 and 1070 nm. Reprinted with permission from [51], M. M. Alam et al., *J. Photochem. Photobiol. A: Chem.* 104, 59 (1997). © 1997, Elsevier Science.

the radical ions are generated upon nanosecond laser irradiation (Fig. 7) [51]. The electron transfer was confirmed to proceed via the triplet excited state of C_{60}. The bimolecular quenching rate constant (k_q) of the triplet excited C_{60} is 5.0×10^9 M^{-1} s^{-1}, indicating that the quenching process is a diffusion-limiting process (k_{diff} in benzonitrile is 5.3×10^9 M^{-1} s^{-1} at 298 K) because of sufficiently negative free-energy change for the electron-transfer process. On the other hand, the quantum yield for the electron transfer (Φ_{ET}) via the triplet excited state was evaluated to be 0.75, which was estimated as a ratio of the generated radical ions to the initial concentration of the triplet excited C_{60}; these values can be estimated from the transient absorption spectra by using extinction coefficients of the radical ions and the triplet excited states. Since the electron-transfer rate constant (k_{ET}) value can be estimated by using the relation $k_{ET} = \Phi_{ET} \times k_q$, the k_{ET} value for the C_{60} and TTF system was evaluated to be 3.8×10^9 M^{-1} s^{-1}. The Φ_{ET} value smaller than unity indicates that other bimolecular deactivation processes of the triplet excited C_{60}, such as an energy transfer and collisional quenching, are present (Scheme 1). In the present case, the latter quenching process seems to be plausible due to the higher triplet energy of TTF compared to that of C_{60}.
Scheme 1. Reaction scheme for $^3C_{60}^*$ in the presence of electron donor.

Figure 6. Charge-separation and charge-recombination processes of C_{60}-doped PVCz film. CR and ISC denote charge recombination and intersystem crossing, respectively.

As for BEDT-TTF, the k_{ET} value was somewhat smaller than that of the C_{60}-TTF system due to the smaller free-energy change for the electron-transfer system of C_{60} and

BEDT-TTF. When the polarity of the solvent decreases, the Φ_{ET} values decrease while the k_q values are still close to the corresponding k_{diff} values. This observation can be attributed to the difficulty of the radical ion pair dissociation in the nonpolar solvents because of poor salvation ability of the radical ion pair in these nonpolar solvents.

The electron-transfer process competitive with the energy-transfer process has been confirmed in the mixture systems of C_{60} with β-carotene or retinol, which is reported to be a good triplet energy acceptor [52, 53]. In nonpolar solvents, only the energy-transfer process was observed. On the other hand, the electron-transfer process also becomes evident with increasing solvent polarity. In the case of the photoinduced reaction of C_{60} with β-carotene in benzonitrile, the quantum yields for the electron transfer and energy transfer were estimated to be 0.84 and 0.16, respectively. As for the reaction system of C_{60} and all-*trans* retinol, the values were 0.45 and 0.55, respectively. The lower quantum yield for the electron transfer of C_{60}-retinol system can be attributed to less negative free-energy change for the electron transfer (-9.9 and -14.1 kcal mol^{-1} for C_{60}-retinol and C_{60}-carotene systems, respectively).

Porphyrins and phthalocyanines also act as donors for fullerenes under photoexcitation [54, 55]. It was confirmed that the electron transfer proceeded via both $^3C_{60}^*$ and triplet excited porphyrins. Zinc-including porphyrin compounds such as tetraphenylporphyrin and octaethyl-porphyrin showed higher donor ability to fullerenes in comparison with copper and H incorporated porphyrins. A similar tendency was also confirmed with phthalocyanine derivatives [55].

3.4. Electron Transfer with Polymers

Photoconductive polymers such as PVCz and polythiophene are reported to enhance their photoconductivities upon doping of the fullerenes [4, 45]. As mentioned above, electron transfer within the charge-transfer complex in the films is responsible for the photocarrier generation upon light illumination. When the concentrations of these polymers are sufficiently lower in solution, formation of the charge-transfer complex with fullerenes in the ground state can be ignored. Under these conditions, electron-transfer processes via the triplet excited states of the fullerenes or the conjugated polymers are important.

When C_{60} is photoexcited in the presence of PVCz, the electron-transfer process proceeds via two mechanisms depending on the excitation wavelength [56]. It was confirmed that electron transfer proceeds from the triplet excited state of C_{60}, when the reaction mixture is irradiated by visible light, that is, a 532-nm laser, which excites C_{60} only. The electron-transfer rate constant was estimated to be 5.1×10^6 M^{-1} s^{-1}, which is ca. 1/1000 of the k_{diff} value of benzonitrile solvent. The quite slow electron-transfer rate constant can be attributed to the somewhat positive free-energy change for electron transfer. On the other hand, electron transfer proceeds more rapidly when the reaction mixture is excited with the laser pulse in the ultraviolet region, that is, a 355-nm laser, which excites both C_{60} and PVCz. The radical anion of C_{60} is generated by capturing the electron which is ejected from PVCz by excitation with

the 355-nm laser in polar benzonitrile [Eq. (5)]. This mechanism was supported by the fact that the generation rate of the C_{60} radical anion depends on the concentration of C_{60} and that PVCz radical cation is generated by the 355-nm laser irradiation even in the absence of the C_{60} in benzonitrile. The rate constant indicates that the electron-capture process by C_{60} [Eq. (5)] is the diffusion-limiting process:

$$ PVCz \xrightarrow{h\nu} PVCz^{\cdot+} + e^- \xrightarrow{C_{60}} PVCz^{\cdot+} + C_{60}^{\cdot-} \qquad (5) $$
The electron-transfer rate constant of the C_{60}-PVCz system is larger than the system of C_{60} and N-ethylcarbazole (EtCz) when C_{60} is excited by the 532-nm laser, although EtCz corresponds to the unit structure of PVCz. The larger rate constant of PVCz can be attributed to the stable radical cation of PVCz due to the stacking of the carbazole moieties in the polymer chain as observed by the charge-resonance band in the near-IR region of the transient absorption spectra. The effect of the stacking of the carbazole moieties on the electron-transfer rate constants was discussed on the basis of the data on the electron-transfer processes between C_{60} and various carbazole dimer models (Fig. 8) [57]. It has been confirmed that electron transfer proceeds effectively with the fully stacked carbazole dimers which stabilize the radical cations effectively.

In the case of the conjugated polymers such as polythiophene in polar solution, photoinduced electron transfer between fullerenes and the polymers proceeds via the triplet excited states of fullerenes or polymers rather than the charge-transfer complex. It has been well known that the oxidation potentials and triplet energies of conjugated

PVCz $k_{et} = 5.1 \times 10^6$ M^{-1}s^{-1} m-DCzPe $k_{et} = 8.1 \times 10^7$ M^{-1}s^{-1}

DCzCBu $k_{et} = 2.5 \times 10^4$ M^{-1}s^{-1} DCzBu $k_{et} = 2.6 \times 10^4$ M^{-1}s^{-1}
Figure 8. Carbazole dimers and the rate constants for the electron-transfer process with $^3C_{60}^*$ in benzonitrile upon laser excitation at 532 nm.

polymers depend on their conjugation length to a great extent. The studies on the electron-transfer processes with the structure-defined oligomers give important information on improvement of efficiency of the electron-transfer processes. In the electron-transfer system of fullerenes and oligothiophene, it was confirmed that the electron-transfer rate constants become large with an increase in the number of repeating units until tetramer (Fig. 9) [58]. On the other hand, a decrease in the k_{ET} values due to the smaller Φ_{ET} values was observed for longer oligomers. This finding can be attributed to the large contribution of the energy-transfer process because of the lower triplet energies of the longer oligothiophene compared to those of fullerenes.

Electron-transfer processes with conjugated oligomers were also investigated in detail for the oligomers of poly(p-phenylenevinylenes) including the triphenyl amine moiety [59]. From the comparison with the monomer models of oligomers, it was revealed that the rate constants of the electron transfer with oligomers are larger due to the larger collision probability of the oligomers compared to the corresponding monomer models (Fig. 10).

3.5. Back Electron Transfer

When the radical cation and radical anion decay completely after laser pulse, the generated radical ion pair returns to the corresponding neutral ground state by the back electron-transfer process [60]. When the solvent is highly polar, the generated radical ions are solvated as free radical ions; thus, the back electron transfer obeys second-order kinetics [Eq. (6)]. On the other hand, in the less-polar solvents, the radical ions are present as geminate ion pairs; thus, the back electron transfer obeys first-order kinetics [Eq. (7)]:

$$(C_{60}^{\cdot-})_{solv} + (Donor^{\cdot+})_{solv} \xrightarrow{k_{BET}^{2nd}} C_{60} + Donor \qquad (6)$$

$$(C_{60}^{\cdot-},\ Donor^{\cdot+})_{solv} \xrightarrow{k_{BET}^{1st}} C_{60} + Donor \qquad (7)$$

In the electron-transfer system in the solvent mixtures with moderate polarities, the back electron-transfer process by the mixed-order kinetics has been observed, suggesting selective solvation of the radical ions, because of large fullerene molecules.

3.6. Formation of Fullerene Adducts via Electron Transfer

Fullerenes are such active compounds that they form derivatives easily. Radical anions and cations are also intermediates for the formation reaction of the fullerene derivatives. Some examples are shown below.

Akasaka et al. reported that the photoexcited C$_{60}$ generates [2 + 3] cycloadducts with the disiliranes, such as 1,1,2,2-tetramesityl-1,2-disilirane via the electron-transfer process (Scheme 2) [61]. It is interesting to note that the adduct formation was not observed by the thermal reactions in the dark. The photoadduct formation occurs in the nonpolar toluene, suggesting that the exciplex is a plausible intermediate. When the reaction proceeds in benzonitrile, the generated radical cation of the disilirane forms 1:1 or 1:2 adducts with benzonitrile; in this case, C$_{60}$ acts as a photocatalyst

of bissilylation of benzonitrile (Scheme 2) [62]. Photocatalytic reactions of C_{60} in bisslylation were also confirmed with other carbonyl compounds used as solvents.
Scheme 2. Reaction scheme for C_{60} in the presence of disiliranes.

The different reactivities depending on the solvents can be attributed to the solvation of the reaction intermediate: In toluene, adduct formation is considered to proceed in the triplet exciplex; on the other hand, in benzonitrile, the solvated radical ion pair can react with solvent molecules. In the case of the reaction with the $La@C_{82}$, Akasaka et al. observed adduct formation in both the photo- and thermal-reaction conditions [63]. Higher reactivity of $La@C_{82}$ can be attributed to the high electron acceptor ability of $La@C_{82}$. It has been reported in the electrochemical studies on metal encapsulated fullerenes that the reduction potential of $La@C_{82}$ shifts to the anodic direction by 0.7 V in comparison with C_{60}.

With the photoirradiation on the pristine C_{60} and disilane in benzene, 1,16-addition product was obtained via the silyl radical formation (Scheme 3) [64]. These bissilylated fullerenes show lower oxidation potential due to the electron-donating nature of silicon addends. Actually, laser flash photolysis study on the photophysical properties of these bissilylated fullerenes shows a substantial change of the photoexcited state properties, such as triplet absorption and fluorescence spectra (Fig. 11) [65]. Thus, bissilylation changes properties of the fullerenes to a great extent.
Scheme 3. Reaction scheme for C_{60} with siliy radical.

As for the C–C bond formation with fullerene, the photoinduced electron transfer with ketene silyl acetal (KSA) was reported. For example, KSA derived from ethyl acetates generated fullerene-acetates quantitatively upon photoirradiation in benzene (Scheme 4) [66]. Their reactivities to form C_{60}-adducts are studied on the basis of the oxidation potentials of the KSA, indicating adduct formation via electron transfer with triplet excited C_{60}. Furthermore, Danishefsky's diene, which is a vinylogue of KSA, formed [4 + 2] cycloadducts of C_{60} by the Diels–Alder reaction (Scheme 5)

[67]. In the case of this reaction, the radical anion of C_{60} was confirmed by the laser flash photolysis experiments.

Fukuzumi et al. reported that 4-*t*-butylated 1-benzyl-1,4-dihydronicotineamide (BNAH) generated the anion of *t*-butylated C_{60} upon photoirradiation via the electron transfer [68]. Generated *t*-butylated C_{60} anion was quenched in the presence of acid or benzylbromide to generate 1,2-*t*-BuC_{60} or 1,4-*t*-Bu(PhCH$_2$)C$_{60}$, respectively. In the present

case, electron transfer via the triplet excited state of C_{60} is responsible for the adduct formation (Scheme 6). After electron transfer, the radical cation of *t*-butylated BNAH generates the *t*-Bu radical which reacts with C_{60} to generate *t*-butylated C_{60}. Using 10-methyl-9,10-dihydroacridine,

generation of 1,2-dihydrofullerene was reported to be attained by a similar electron-transfer mechanism.

The radical cation of fullerene is also an active intermediate which generates fullerene adducts. Siedschlag et al. reported that the C_{60}-adduct generated via the radical cation of C_{60} which was formed by the cosensitizer under photoirradiation [69]. The C_{60} radical cation abstracts α-proton from the alcohol to generate $C_{60}H$ cation and alkyl radical, which forms alkylated C_{60} (Scheme 7).
Scheme 7. Reaction scheme for C_{60} with methanol via $C_{60}^{\bullet+}$.

3.7. Electron Transfer in the Ground State

Tetrakis(dimethylamino)ethylene (TDAE) has a strong donor ability to form strong charge-transfer complexes with electron acceptors. It has been reported that charge-transfer complex salts of fullerenes with TDAE show ferromagnetism at low temperature [5]. It was revealed that C_{60} in polar solvents can be reduced in the presence of TDAE without photoirradiation (Fig. 12) [70]. From the relation between the
Figure 12. Steady-state absorption spectra of C_{60} and various concentrations of TDAE in deaerated *o*-dichlorobenzene at room temperature. Numbers indicate the concentration of TDAE in mM. Inset: Plot according to the relation: $[TDAE]_0/Abs = [C_{60}]_0 [TDAE]_0/Abs^2 - 1/K\varepsilon$. Reprinted with permission from [70], M. Fujitsuka et al., *J. Phys. Chem. B* 103, 445 (1999). © 1999, American Chemical Society.

absorption intensity of the C_{60} radical anion and the amount of TDAE, it becomes clear that C_{60} and TDAE are in equilibrium with the corresponding radical ions [Eq. (8)]. From the analysis of thermal equilibria, the equilibrium constant was estimated to be 240 for C_{60} and TDAE in benzonitrile. On the other hand, in less-polar solvents (dielectric constant <7), the generated radical ions are solvated as radical ion pairs [Eq. (9)]:

$$C_{60} + TDAE \rightleftharpoons (C_{60}^{\bullet-})_{solv} + (TDAE^{\bullet+})_{solv} \qquad (8)$$

$$C_{60} + TDAE \rightleftharpoons (C_{60}^{\bullet-}, TDAE^{\bullet+})_{solv} \qquad (9)$$
By laser irradiation on C_{60} in the solution in which C_{60} and TDAE are in equilibrium with the corresponding radical ions, other amounts of radical ions are generated photochemically, although the reaction system returns to thermal equilibrium by the back electron-transfer process. On combination of the back electron-transfer rate and the thermal equilibrium constant, the electron-transfer rate at the ground state can be estimated. For example, the rate constant of the electron-transfer process between C_{60} and TDAE in the ground state was estimated to be 6.4×10^8 M^{-1} s^{-1} in o-dichlorobenzene, which is about 1/3 of the rate constant between the triplet excited C_{60} and TDAE. The smaller rate constant of the electron transfer in the ground state can be attributed to the smaller free-energy change for the electron transfer in the ground state.

Similar electron transfer in the ground state was also confirmed with C_{70} and adducts of C_{60} [71]. In the case of the adducts of C_{60}, it was revealed that electron-transfer rate constants in the ground and the triplet states are affected by the substituents. The substituent effects of the reaction rate constants were successfully analyzed on the basis of the linear free-energy relationship. It was revealed that electron transfer in the ground state needs considerable activation energy compared to that for the electron transfer via the excited triplet state in the reaction system with TDAE (Fig. 13).

3.8. Electron Mediating from C_{60} Radical Anion

When a donor decomposes to nonactive compounds after donating an electron to C_{60}, the radical anion of C_{60} shows a considerably long lifetime. For example, the generation rate of the superoxide anion $(O_2^{\bullet-})$ via the radical anion of C_{60} can be estimated by applying this method [72]. The radical anion of C_{60} generated using tetrabutylammonium tetraphenylborate $[^-BPh_4(^+NBu_4)]$ as electron donor was persistent, because $^\bullet BPh_4$ dissociates into less electron-accepting compounds such as BPh_3 and biphenyl promptly as described by

$$C_{60} + {}^-BPh_4 \longrightarrow C_{60}^{\bullet-} + BPh_3 + 1/2\ Ph\text{-}Ph \qquad (10)$$
The radical anion of C_{60} also acts as an electron mediator. In the presence of molecular oxygen, the persistent radical anion of C_{60} begins to decay according to the electron-mediating process (Fig. 14)

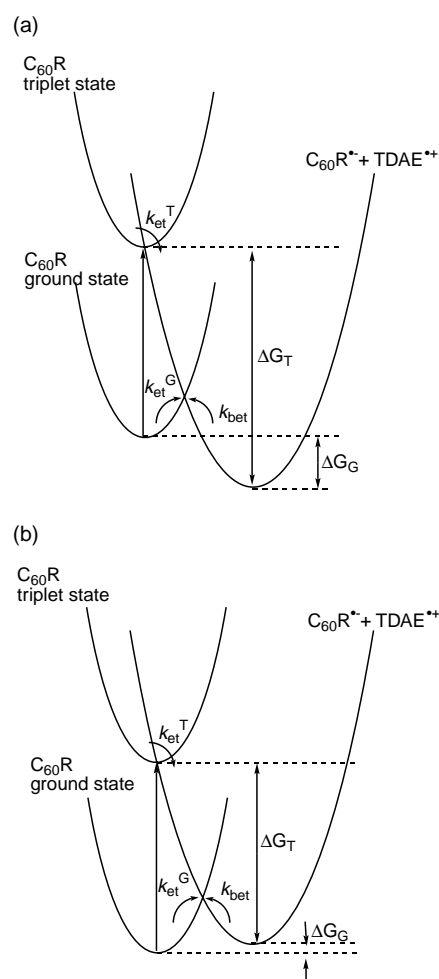
$$C_{60}^{\bullet-} + O_2 \longrightarrow C_{60} + O_2^{\bullet-} \qquad (11)$$


Figure 13. Energy diagram of electron transfer processes of 1,2-adducts of C_{60} ($C_{60}R$) and TDAE in (a) polar solvents and (b) nonpolar solvents. k_{et}^T, k_{et}^G, and k_{bet} denote the electron transfer rate constants from the triplet excited state, and from the ground state, and back-electron-transfer rate constant, respectively. ΔG_T and ΔG_G indicate the free-energy changes for the electron transfer from the triplet excited state and the ground state, respectively. Reprinted with permission from [71], C. Luo et al., *Phys. Chem. Chem. Phys.* 1, 2923 (1999). © 1999, The Royal Society of Chemistry on behalf of the PCCP Owner Societies.

From the dependence of the decay rate constant of $C_{60}^{\bullet-}$ on the concentration of O_2, the bimolecular rate constant for the generation of the superoxide anion was estimated to be 3.7×10^2 M^{-1} s^{-1} in benzonitrile. The small reaction rate constant for this electron-mediating process can be attributed to an endothermic process as estimated from the reduction potentials of C_{60} and O_2 (-0.92 and -1.2 V vs ferrocene/ferrocenium (Fc/Fc^+), respectively). It should be noted that the generated superoxide anion can act further as an electron mediator: In the presence of viologen dication, the superoxide anion donates an electron to generate the radical cation of viologen, although the quantum yield of the electron transfer from superoxide ion to viologen dication was somewhat small, 0.1–0.2 [73].

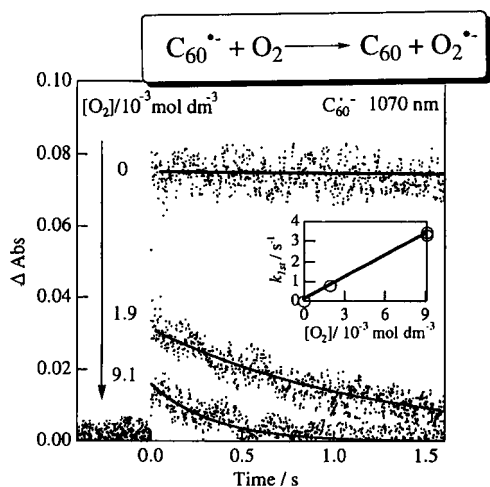
It becomes clear that triethylamine and triethanolamine also act as donors which generate the persistent radical anion of C_{60}, because the corresponding radical cations


Figure 14. Absorption-time profiles of $C_{60}^{\bullet-}$ in the presence of the molecular oxygen. Inset: Pseudo-first-order plot. Reprinted with permission from [72], T. Konishi et al., *Chem. Lett.* 202, (2000). © 2000, The Japan Chemical Society.

Figure 15. Time profiles at 1600 nm of the electron-transfer systems of (a) C_{60} and PTA-PV monomer and (b) PTA-PV oligomer in the presence and absence of OV^{2+}. Reprinted with permission from [59], H. Onodera et al., *J. Phys. Chem. A* 105, 7341 (2001). © 2001, American Chemical Society.

easily decompose into less electron-accepting compounds, which are not identified yet. It should be noted that these donors are soluble in water. Thus, they can be employed as sacrificial donors also in aqueous systems.

In the electron-transfer systems of the C_{60} and monomer/oligomer of poly(p-phenylenevinylene), C_{60} acts as a photosensitizer and electron mediator, since photoexcited C_{60} accepts an electron from the donor and mediates the electron to octylviologen dication (OV^{2+}), another electron acceptor, efficiently [59]. In the electron-transfer system of C_{60} and monomer of TPA-PV (Fig. 10) in the presence of OV^{2+}, the generation of the radical anion of C_{60} was confirmed in the transient absorption spectra. With decrease of $C_{60}^{\bullet-}$, generation of $OV^{\bullet+}$ was confirmed, indicating that electron transfer from $C_{60}^{\bullet-}$ to $OV^{\bullet+}$ occurs (Scheme 8). It should be noted that the radical cation of TPA-PV of the electron-mediating systems showed slow decays (Fig. 15), indicating that the back electron transfer between $OV^{\bullet+}$ and the radical cation of the TPA-PV monomer/oligomer is retarded due to the repulsion of the positive charges of both radical cations.

water-soluble compounds and introduction of water-soluble addends to fullerenes.

The water-soluble complexes with fullerenes have been achieved by using γ-cyclodextrin (γ-CD), water-soluble calixarene, miscelle, and water-soluble polymers.

Yoshida et al. reported that C_{60} forms the 1:2-complex with γ-CD (Fig. 16), which shows good solubility in water [74]. Andersson et al. reported that C_{70} also forms the complex with γ-CD [75]. Since the spectral shapes of the ground state and triplet excited state are not changed by the inclusion in γ-CD, the interaction between fullerenes and γ-CD is quite weak. It was revealed that the bimolecular excitation–relaxation and electron-transfer processes of the inclusion complex of fullerene in γ-CD are changed in comparison to the pristine fullerenes [29]. For example, the rate constants for the triplet–triplet annihilation processes of C_{60} and C_{70} in γ-CD are much smaller than

Scheme 8. Electron-mediating system of C_{60}.

3.9. Water-Soluble Fullerenes

Pristine fullerenes are not soluble in water, while advantageous properties are expected in the fields of biology. Thus, much effort has been devoted to prepare water-soluble fullerenes. Sufficient solubility in water was achieved by several manners: inclusion complex formation of fullerenes with

Figure 16. C_{60} encapsulated in γ-cyclodextrin.

the diffusion-limiting rate of the solvent. Furthermore, the rate constant for electron transfer of C_{60} in γ-CD with 1,4-diaza[2.2.2]bicyclooctane (DABCO) is 1/10–1/100 of the corresponding rate constants of the pristine fullerenes. Thus, the γ-CD is a retarder for the photoinduced processes of the fullerenes. Since γ-CD acts as retarder for the back electron-transfer process, the radical anions of fullerenes in γ-CD show long lifetimes compared to those of the pristine fullerenes. This aspect is favorable in the utilization of the radical anion of fullerenes as an electron mediator. Furthermore, the persistent radical anion formation was observed in the presence of triethanolamine as mentioned in Section 3.8. It was revealed that both the radical anion of C_{60} in γ-CD and the radical cation of methyl viologen are present at the same time as the equilibrium in water media.

Fullerenes are also known to form the inclusion complexes with calixarenes. In the case of the water-soluble inclusion complex of C_{60} and calixarene (cationic homooxacalix[3]arene), substantial interaction between fullerenes and the calixarene was observed in the ground state absorption spectrum [76]. Increase in the absorption intensity around 400–500 nm of C_{60} in calixarene can be attributed to the charge-transfer complex formation due to the π-electron system of calixarene. Strong interaction between the calixarene and fullerenes was also observed in the excited states. The triplet absorption peak of C_{60} in the calixarene appeared at 545 nm, which is largely blueshifted compared to that of pristine C_{60}. The triplet lifetime is as short as 50 ns. The substantial interaction between calixarene and included C_{60} was also observed in the singlet excited state as a large blueshift of the fluorescence peak.

Pristine fullerenes become soluble in water when they are incorporated in a micellar system. It was confirmed that a micellar system of poly(vinylpyrrolidone) and C_{60} showed bioactivity, such as mutagenicity, lipid peroxidation, and DNA-strand scission, upon visible-light irradiation in the presence of O_2, via generation of the active oxygen species [7].

By introduction of the hydrophilic groups such as COO^- to C_{60}, the C_{60} adducts are dissolved in water as clusters [77]. The cluster formation was excluded by using surfactants. Guldi reported that the excited singlet state properties of the clusters are not changed from the monomer state [77]. On the other hand, they showed acceleration of the decay of the triplet state of the adduct in the cluster due to triplet–triplet annihilation.

Water-soluble clusters of fullerenes were also achieved by introduction of addend with positive charge [78]. It is interesting to note that the positively charged fullerene clusters showed fast reduction of the fullerene core in a cluster due to electron-attracting force. Furthermore, it has been reported that the fullerene with cationic addend showed cleavage of double-strand DNA via generation of the active oxygen species [79].

3.10. Fullerodendrimers

Dendrimers have attracted wide attention because of their artificial three-dimensional nanostructures [80]. Fullerenes have been employed as a core, in branches, or as terminals of dendrimer molecules, that is, fullerodendrimers [81–87].

Introduction of dendritic branches to the fullerene core can improve solubility and processability. Furthermore, it also provides an additional functionality of the branches themselves [85].

For the fullerodendrimers, in which fullerene moieties are employed as focal points of dendrimers (Fig. 17), it has been reported that bimolecular processes of the dendrimers are varied to a great extent depending on the generation of the dendrimer moiety [86]. For example, photoinduced electron-transfer rate constants of fullerodendrimers with benzyl-ether type dendrons depend on dendrimer generation: the electron-transfer rate constants of the fourth generation were ca. 1/2–1/4 of the second generation. For the electron-transfer processes of the dendrimers, long-range electron-transfer processes were suggested from the comparison with the expectation by the semiempirical Rehm–Weller relation [42]. The findings indicate the shielding effect of the dendron groups. It should be pointed out that these shielding effects are also observed for other bimolecular processes such as triplet–triplet annihilation and energy-transfer processes and are effective for dendron groups larger than the third generation as reported for Fréchet-type dendrimers. The shielding effect of the dendrimer is important from the viewpoint of drag delivery, since it retains chemically active species for long time.

As for the monomolecular processes of the fullerene moiety of the dendrimers, such as singlet and triplet lifetimes,
Figure 17. Molecular structures of fullerodendrimers.

substantial dependence on the dendrimer generation was not observed, indicating that the effects of the dendron groups on the excited state properties of the fullerene moiety are small [86].

Introduction of the dendrimer moiety to the fullerene is also beneficial to attain water-soluble fullerenes. Takaguchi et al. reported that fullerodendrimer bearing dendritic poly(amidoamine) substitute shows substantial solubility in water [87]. It was confirmed that the singlet oxygen was generated by the energy transfer from triplet excited fullerene moiety of the dendrimers. Furthermore, since their dendrimer generates pristine C_{60} by reversible Diels–Alder reaction, their dendrimers are interesting from the biological point of view.

By introduction of functionality on the dendron groups, electronic interaction between the dendron groups and fullerene moiety becomes evident. Guldi et al. reported the photoinduced charge separation and energy-transfer processes in the fullerodendrimers having phenylene vinylene dendron groups [85]. The fast and highly efficiently intramolecule processes are interesting as summarized in the next section. Further interesting properties are expected for these fullerodendrimers by adding functions both to core and branch moieties.

4. PHOTOINDUCED PROCESSES OF FINE PARTICLES OF FULLERENES

4.1. Photochemistry of Fullerene Fine Particles

Fullerenes do not show sufficient solubility in the conventional organic solvents. Thus, it has been reported that fullerenes generate aggregates in poor solvents [88]. By utilizing this aspect of fullerenes, one can obtain fullerene fine particles easily.

The fine particles of the fullerenes are prepared by injection of fullerene in *o*-dichlorobenzene solution to continuously stirring ethanol [89, 90]. The fine particles of C_{60} have granular-type shape and the average diameter was estimated to be 270 nm (Fig. 18). The crystalline structure of the C_{60} fine particles was confirmed by X-ray scattering and
transmission electron microscope (TEM) observation. In the TEM picture, it was confirmed that the crystalline structure is retained throughout the fine particle. In the case of C_{70}, the generation of the fine particles was also confirmed. The average diameter of the C_{70} fine particles is estimated to be 140 nm. It was revealed that the fine fullerene particles several tens of nanometers in diameter can be obtained by using supercritical conditions.

The ground state absorption spectrum of the C_{60} fine particles is quite broad compared to the isolated C_{60} in toluene. The spectral features of the C_{60} fine particles are similar to those of the C_{60} bulk crystals. These findings indicate that substantial interactions are present between the C_{60} molecules in the fine particles. It is interesting to note that the absorption peak of the C_{60} fine particles shifts to the shorter wavelength side compared to that of the C_{60} bulk crystal. The shift of the absorption peak will indicate the size effect of the fine particles as observed with the fine crystals of perylene [91].

The fine particles of C_{60} showed weak fluorescence around 700–750 nm upon excitation with a picosecond laser. The fluorescence decay profile of the C_{60} fine particles shows the two-component-decay with 0.8 and 2.1 ns of the fluorescence lifetimes (Fig. 19). The two-component-decay can be attributed to the deactivation processes of the free exciton and self-trapped exciton levels as supposed for the organic crystalline materials.

The transient absorption bands of the triplet excited state of the C_{60} fine particles can be observed by the nanosecond laser irradiation (355 nm). Immediately after the laser irradiation, the C_{60} fine particles show a quite broad absorption band around 700 nm (Fig. 20). The quite broad transient absorption band decays within 50 ns, and a sharp absorption band remains at 500 ns after the laser irradiation. From the comparison with the transient absorption spectrum of C_{60} in toluene, the sharp absorption band at 750 nm can be attributed to the localized triplet excited state of C_{60} in the fine particles. The fast-decaying component can be attributed to the triplet–triplet annihilation process in the fine particles, since the fast-decaying component can

Figure 20. Transient absorption spectra of C_{60} fine particles at 50 ns (solid circle) and 500 ns (open circle) after 355-nm laser light irradiation. Inset: absorption-time profile at 740 nm. Scheme for the T-T annihilation in the C_{60} fine particles. Reprinted with permission from [90], M. Fujitsuka et al., *J. Photochem. Photobiol. A: Chem.* 133, 45 (2000). © 2000, Elsevier Science.

be attributed to the triplet excited state from the picosecond laser flash photolysis measurements, in which generation of the broad absorption band via the intersystem crossing process was observed.

From the laser power dependence of the absorption-time profiles of the C_{60} fine particles, it was confirmed that the fast-decaying part appears when the excitation laser power becomes high; only the slow-decaying part appears with lower laser power excitation. This finding indicates that the triplet–triplet annihilation process in the fine particles becomes apparent only when the density of the triplet excited states becomes sufficiently high by the higher laser power.

On the other hand, the localized triplet excited state was not confirmed with the C_{70} fine particles. Furthermore, the fine particles of C_{60} with diameter smaller than 100 nm also did not show such localized triplet states. These findings indicate that the triplet–triplet annihilation process in the fine particles largely depends on the crystalline structure and diameter of the fine particles.

When the dispersion of the C_{60} fine particles was saturated by oxygen, the absorption band of the localized triplet excited state was quenched. The quenching of the localized triplet excited state can be attributed to the energy-transfer reaction from the triplet excited state to the oxygen generating the singlet oxygen. This finding indicates that the localized triplet excited state of the C_{60} fine particles is reactive to the substrate in the dispersion. The energy-transfer process can be observed when the dispersion solution includes β-carotene, a triplet energy acceptor. The energy-transfer process can be confirmed by the generation of the triplet excited state of β-carotene with the concomitant decay of the localized triplet excited state of the C_{60} fine particles. The bimolecular quenching rate of the energy transfer between β-carotene and the C_{60} fine particles was estimated to be 1.5×10^9 M^{-1} s^{-1}, indicating that the efficient energy transfer process takes place on the surface of the C_{60} fine particles.

Photoinduced electron-transfer processes of the C_{60} fine particles were also confirmed in the transient absorption spectra. When the nanosecond laser light was irradiated to the solution containing the C_{60} fine particles and DABCO, an electron donor, generation of the radical anion of the C_{60} fine particles was confirmed with a decrease of the triplet excited state of C_{60} localized in the fine particles (Fig. 21). This finding indicates that the localized triplet excited state is also active to the photoinduced electron-transfer processes. The bimolecular rate constant for the present electron transfer was estimated to be 2×10^8 M^{-1} s^{-1}, which is smaller than the rate constant between C_{60} and DABCO in solution (4×10^9 M^{-1} s^{-1}). The smaller rate constant of the C_{60} fine particles can be attributed to the reaction process on the surface of the fine particles. The generated radical ions are finally recombined to form their neutral states. The photoinduced oxidation process of the C_{60} fine particles was also confirmed using the cosensitization reaction with the nanosecond laser flash photolysis.

These observations indicate that the localized triplet excited states of the fine particles are reactive species to the molecules in the solution both for the electron-transfer and for the energy-transfer processes, although the rate constants are somewhat smaller than those for the reaction systems, in which both donor and acceptor are isolated molecules in the solution.

5. FULLERENE OLIGOMERS, HIGHER FULLERENES, AND METALLOFULLERENES

5.1. Fullerene Dimers and Trimers

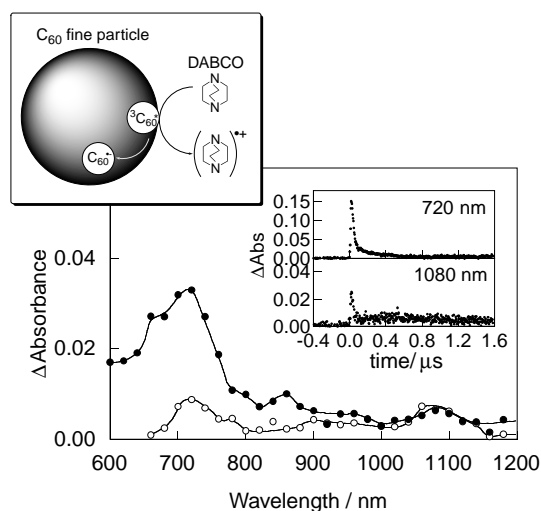
Fullerenes are also reactive to fullerene itself. Fullerene polymers have been synthesized by several methods [23, 92–94]. Investigations on properties of fullerene dimers


Figure 21. Transient absorption spectra of C_{60} fine particles in the presence of DABCO at 100 ns (solid circle) and 500 ns (open circle) after 355-nm laser light irradiation. Inset: absorption-time profiles. Scheme for the electron transfer process of the fine particles of C_{60}. Reprinted with permission from [90], M. Fujitsuka et al., *J. Photochem. Photobiol. A: Chem.* 133, 45 (2000). © 2000, Elsevier Science.

and trimers seem to be important to elucidate properties of one-dimensional and two-dimensional fullerene polymeric materials. From this viewpoint, several experimental and theoretical investigations have been reported on fullerene dimers and trimers. Fullerene dimer (C_{120}) and trimer (C_{180}) can be obtained by the high-speed vibration milling developed by Komatsu et al. (Fig. 22) [23, 95]. Ground state absorption spectra of C_{120} and C_{180} showed an absorption band around 700 nm which is characteristic of 1,2-adducts of C_{60} [96–98]. Furthermore, fluorescence spectra showed fluorescence bands similar to those of 1,2-adducts of C_{60}. fluorescence quantum yields were in the order: 1,2-adducts of C_{60} > dimer (C_{120}) > trimer (C_{180}) > C_{60} polymer (Table 1). In the triplet absorption spectrum of C_{180}, substantial broadening of the transient absorption band was observed (Fig. 23). This finding indicates that the interactions between the fullerene moieties are present in the excited triplet state. It was revealed that the extinction coefficient of $^3C_{180*}$ is about 1/5 that of C_{60}. Ma et al. [96] reported that the C_{60} polymer did not show a transient absorption band upon excitation. Thus, properties of C_{180} can be regarded as intermediate between C_{60} and C_{60} polymers.

In the case of $C_{120}O$, spectral features of ground state absorption and fluorescence are quite similar to those of 1,2-adducts of C_{60} [99]. Thus, the interactions between the fullerene moieties are also small in the ground and excited states. As for the triplet absorption band, on the other hand, transient absorption bands appear at 630 and 480 nm, which are blueshifted compared with those of C_{120} and 1,2-adducts. Furthermore, the triplet lifetime was estimated to be 160 ns, which is quite shorter than those of C_{120} and 1,2-adducts. These findings indicate a substantial interaction between the two C_{60}-moieties. Therefore, interaction between two C_{60}-moieties depends largely on distance and orientation of two C_{60}-moieties.

When $C_{118}N_2$, a dimer of azafullerene $C_{59}HN$, is excited with the nanosecond laser, transient absorption bands appeared at 1280, 1000, 880, and 680 nm which are quite
Figure 22. Molecular structures of C_{120}, $C_{120}O$, $C_{118}N_2$, and C_{180}.

different from azafullerene $C_{59}HN$: $C_{59}HN$ shows a transient absorption peak at 750 nm along with a shoulder at 1050 nm (Fig. 24) [100]. It has been reported that the laser irradiation of $C_{118}N_2$ generates $C_{59}N$ radical [101]. However, it becomes clear that these absorption bands include the triplet excited state of $C_{118}N_2$, because these transient absorption bands are quenched in the presence of oxygen due to the triplet energy transfer generating singlet oxygen, which was observed in the near-IR emission spectra. Thus the different spectral features of the triplet excited $C_{118}N_2$ and $C_{59}HN$ indicate the interactions between two azafullerenyl cages. The decay lifetime of the triplet excited $C_{118}N_2$ is 10 μs, while that of $C_{59}HN$ was 5 μs. The Φ_{ISC} values were estimated to be 0.48 for both $C_{118}N_2$ and $C_{59}HN$. It has been reported that the triplet excited $C_{118}N_2$ and $C_{59}HN$ work as sensitizers in the oxidation reactions of olefins; 2-methyl-2-butene and α-terpinene undergo ene and Diels–Alder photooxygenation reactions, respectively, to produce the corresponding peroxides in the presence of a minute amount of $C_{118}N_2$ or $C_{59}HN$ (Scheme 9) [102].
Scheme 9. Reaction scheme for oxidation reactions of olefins by $C_{118}N_2$ or $C_{59}HN$ sensitizer. Reprinted with permission from [102], N. Tagmatarchis and H. Shinohara, *Org. Lett.* 2, 3351 (2000). © 2000, American Chemical Society.

When the C_{120} is excited in the presence of N, N, N, N-tetramethyl-1, 4-phenylenediamine (TMPD), absorption bands of the C_{120} radical anion appear with the decay of the triplet state of C_{120}, indicating the electron transfer via the triplet excited state [97]. Spectral features of the C_{120} radical anion are similar to those of the 1,2-adducts of C_{60}, indicating that interaction among fullerene cages is also negligibly small in the radical ion state. This finding indicates that a minus charge of the C_{120} radical anion is localized on one fullerene cage of the dimer molecule as in the case of the excited states. It should be noted that the radical anion of C_{120} decayed by the back electron transfer to the ground state. On the other hand, the ground state reduction of C_{120} by TDAE resulted in decomposition of the C_{120} radical anion into C_{60} and C_{60} radical anion. Thus, the decomposition of the C_{120} radical anion is a slower reaction than the back electron-transfer process between the C_{120} radical anion and the TMPD radical cation. The rate for the decomposition should be slower than the order of 10^5 s^{-1}:

$$C_{120} \xrightarrow{\text{reduction}} C_{120}^{\bullet-} \xrightarrow{+\text{TMPD}^{\bullet+}} C_{120} + \text{TMPD}$$

$$\searrow \text{decomposition} \qquad (12)$$
$$C_{60}^{\bullet-} + C_{60}$$

Table 1. Photophysical properties of C_{60}, 1,2-adduct of C_{60} ($C_{60}R$), C_{120}, $C_{120}O$, and C_{180}.

Φ_{ISC}	1.0	0.88–0.95	0.7 ± 0.1	0.48	0.74 ± 0.1

In the case of $C_{120}O$, electron transfer was confirmed by the appearance of a new absorption band at 1000 nm in the presence of DABCO [99]. It became clear that the generated radical ions decayed predominantly by the back electron transfer at the diffusion-limiting rate.

In Table 1, estimated properties of fullerene dimers are summarized as well as those of C_{60}, 1,2-adducts of C_{60}, and C_{180}. It becomes clear that the interaction between the fullerene moieties in the fullerene oligomers largely depends on C_{60}–C_{60} distance and orientation.

5.2. Higher Fullerenes

Recently, photophysical and photochemical processes of C_{76}, C_{78}, C_{82}, and C_{84} (Fig. 25) have been investigated [103–107]. Compared with C_{60} and C_{70}, ground state absorption spectra of higher fullerenes are ranging to the near-IR region. Although absorption spectra of higher fullerenes depend on their size and symmetry, roughly saying, higher fullerenes are expected to have absorption edges at the longer wavelength side, suggesting the smaller highest occupied–lowest unoccupied molecular orbital (HOMO–LUMO) gaps. These small HOMO–LUMO gaps of the higher fullerenes also accord with the small differences between the first oxidation and reduction potentials of higher fullerenes (Table 2)

[108]. Therefore, facile oxidations of fullerenes are expected as well as easy reductions.

C_{76} showed transient absorption bands at >900, 625, and 550 nm upon subpicosecond laser light irradiation at 388 nm (150 fs fwhm) as shown in Figure 26. These absorption bands decayed quickly within 100 ps, and a broad absorption band remained around 550 nm. Since the 388-nm laser light pumps C_{76} into the higher singlet excited state (S_n), the fast-decaying component can be attributed to an internal conversion process generating the lowest singlet excited state (S_1) from the higher singlet excited state (Fig. 3). The slow decaying component corresponds to the deactivation process of the lowest singlet excited state to the ground and the triplet excited states. The rates for the fast- and slow-decaying components correspond to 83 ps and 2.6 ns of the lifetimes of S_n and S_1, respectively. A similar two-step decay process was also observed with C_{78}.

In the triplet excited state, higher fullerenes show the absorption bands in the visible and near-IR regions (Fig. 27). It should be noted that the intensities of the transient absorption bands of higher fullerenes are quite low compared with those of C_{60} and C_{70}. These low signal intensities

Figure 23. Transient absorption spectra of C_{60} (triangle), C_{120} (open circle), and C_{180} (closed circle) at 100 ns after the laser light irradiation. $C_{76}(D_2)$ $C_{78}(C_{2v}')$

$C_{82}(C_2)$ $C_{84}(D_2)$
Figure 25. Molecular structures of $C_{76}(D_2)$, $C_{78}(C_{2v}')$, $C_{82}(C_2)$, and $C_{84}(D_2)$.

can be explained on the basis of low Φ_{ISC} values. Quite low Φ_{ISC} values seem to be a common feature of the higher fullerenes, in which the nonradiative deactivation process from the singlet excited states to the ground states may be an efficient pathway. The transient absorption bands of higher fullerenes are governed by the self-quenching process rather than the triplet–triplet annihilation [Eqs. (1) and (2)]. The estimated intrinsic triplet lifetimes of the higher fullerenes (Table 3) are shorter than those of C_{60} and C_{70}. Therefore, shorter triplet lifetimes seem to be a common feature of higher fullerenes.

When the higher fullerenes are treated with TDAE, the radical anions of the higher fullerenes are generated: The generation of the radical anions of higher fullerenes was confirmed by the electron paramagnetic resonance (EPR) measurements. It should be noted that the radical anion

of C_{82} is also generated by TMPD or DABCO without photoirradiation. The generation of the radical anion of C_{82} by TMPD or DABCO can be attributed to the lower reduction potential of C_{82} compared with other fullerenes such as C_{60} and C_{70}, which do not generate the radical anions in the dark.

The photoinduced electron-transfer processes with TMPD were also confirmed with higher fullerenes. The reaction rate constants are $C_{60} \approx C_{70} > C_{82} > C_{76}$ (Table 3). Based on the Rehm–Weller equation, free-energy changes for electron transfer from TMPD to the triplet excited fullerenes to TMPD are calculated to be -22, -22, -15, and -18 kcal mol^{-1} for C_{60}, C_{70}, C_{76}, and C_{82}, respectively. Therefore, the order of reaction rate constants reflects the free-energy changes for the electron-transfer processes.

Oxidations of the higher fullerenes have been attempted by the two photoinduced processes: oxidation of excited higher fullerenes by the strong electron acceptor directly and oxidation by the sensitized reaction indirectly. For fullerenes, tetracyanoethylene (TCNE) can be utilized as an electron acceptor for direct photoinduced electron transfer. The generation of the radical cations of higher fullerenes was confirmed by their transient absorption spectra. In the case of C_{82}, oxidation of C_{82} in the ground state takes place with TCNE because of the lower oxidation potentials of C_{82}. Using N-methylacridinium hexafluorophosphate (NMA$^+$) and biphenyl (BP) as sensitizer and cosensitizer, respectively, the radical cations of fullerenes are generated by the following reaction schemes [109]:

$$\text{NMA}^+ \xrightarrow{h\nu} {}^1(\text{NMA}^+)^* \xrightarrow{+\text{BP}} \text{NMA}^\bullet + \text{BP}^{\bullet+} \quad (13)$$

$$\text{BP}^{\bullet+} + \text{C}_n \longrightarrow \text{BP} + \text{C}_n^{\bullet+}$$
$$(n = 60, 70, 76, \text{ and } 82) \quad (14)$$
The reaction rate constants for Eq. (14) are estimated to be $\sim 10^{10}$ M^{-1} s^{-1} for higher fullerenes, indicating that the radical cations of higher fullerenes are formed effectively as observed with other fullerenes (C_{60} and C_{70}).

5.3. Metallofullerenes

Several kinds of endohedral metallofullerenes have been reported. Especially lanthanum-containing C_{82}'s have been widely investigated. In the case of La@C_{82}, it was confirmed by the EPR study that three electrons of La transfer to the C_{82} cage, that is, La^{3+} and C_{82}^{3-}. Furthermore, fullerenes can also include two or three metal ions in one fullerene cage, such as La$_2$@C_{80}. In this section, photoexcitation and relaxation processes of La@C_{82} and La$_2$@C_{80} (Fig. 28) are summarized [110].

The steady-state absorption spectra of La@C_{82} show the absorption bands at 1412, 1002, and 636 nm, which are characteristic of the lanthanide metal-encapsulated C_{82}-fullerenes. Since it has been reported that the change of central metal does not affect the positions of absorption maxima, the electronic transitions take place within the C_{82}^{3-}. The absorption spectrum of La$_2$@C_{80} shows a broad band around 900 nm and a relatively sharp shoulder at 400–450 nm, which are characteristic bands of endohedral metallofullerenes.
La@C_{82} La$_2$@C_{80}

Figure 28. Molecular structures of La@C_{82} and La$_2$@C_{80}.

Immediately after the laser light irradiation, the transient absorption band appeared at 780 nm with broad bands around 1500 and 840 nm. The transient absorption band decays according to two components. The decay rate constants of the fast- and slow-decaying components were 1.2×10^7 and 3.4×10^5 s^{-1}, respectively. The fast- and slow-decaying components may be due to the doublet and quartet states, respectively.

In the case of La$_2$@C$_{80}$, the decay with two steps was also observed. The fast- and slow-decaying components can be attributed to the excited singlet and triplet states, respectively. On cooling the solution as low as $-30\,^\circ$C, the intensity and decay rate were not increased. Thus, the movement of internal La ions does not affect the excited state properties much.

6. CHARGE SEPARATION AND RECOMBINATION PROCESSES OF DONOR-FULLERENE LINKED MOLECULES

6.1. Donor-Fullerene Dyad Molecules

Photoinduced processes of the donor-fullerene dyad molecules have been investigated widely [25–27]. In 1995, Williams et al. reported the intramolecular photoinduced charge-separation (CS) and charge-recombination (CR) processes of N,N-dimethylaniline-C$_{60}$ dyad molecules, in which the length between C$_{60}$ and dimethylaniline was 3 or 11 σ-bonds (Fig. 29a) [111, 112]. They confirmed the CS process by observing a transient absorption band due to the radical cation of dimethylaniline. The CS proceeds from the singlet excited state of the C$_{60}$ moiety, since the fluorescence lifetime due to C$_{60}$ moiety becomes short. The CS rate constants were as fast as $>1.6 \times 10^{10}$ and 5.5×10^9 s^{-1} for the 3- and 11-bond system, respectively, indicating that the CS process of these dyads proceeds almost quantitatively. On the other hand, the lifetime of the CS state of the 11-bond system is 0.25 μs. Williams et al. attributed the fast CS and long lifetime of the CS state to very strong electronic coupling with the bridge by the special symmetry properties of the fullerene π-system.

As for the donor molecules, varieties of donors have been employed for the donor-fullerene linked molecules. Carotenoid, porphyrin, ferrocene, tetrathiafulvalene, oligothiophenes, aromatic amines, etc. have been employed for the dyad molecules [25–27, 113–124]. In these molecules, the quantum yields of the CS processes are close to unity. The lifetimes of the CS states are on the order of subnanosecond to microseconds. Imahori et al. reported that the reorganization energy of the dyad molecule including fullerene acceptor is small compared with that of reported electron acceptors such as benzoquinones due to the large π-electron system of fullerene. The small reorganization energy of the dyad molecules including fullerene is confirmed by analyses of the charge-transfer absorption and emission spectra of porphyrin-fullerene dyad molecules (Fig. 29b) in benzene [125]. The reorganization energy was estimated to be as small as 0.23 eV, which is comparable to the smallest values (0.22 eV) in the photosynthetic reaction
Figure 29. Molecular structures of dyads and triads including C$_{60}$.

center. This feature seems to be one of the advantages of the fullerene-containing dyad molecules which are aiming at a long-lived CS state with high quantum yield for application to energy-storage systems or other sensitized reactions.

Usually, the CS process proceeds from the singlet excited state of fullerene or donor moiety. The triplet excited state of fullerene moiety is also a precursor of the long-lived CS state of the porphyrin-C$_{60}$ dyad [126], in which the CS rate from the triplet state was estimated to be 5.5×10^8 s^{-1} (Fig. 30).

In the case of the oligothiophene-fullerene dyad molecules, it has been reported that the CS state of tetrathiophene-C$_{60}$ dyad (Fig. 29c) shows lifetimes as long as 6.3 μs in benzonitrile due to an equilibrium between the CS state and the excited triplet state of C$_{60}$ (Fig. 31a) [120]. The long-lived CS states were also observed for the aromatic amine-C$_{60}$ and retinyl-C$_{60}$ dyads (Fig. 29d, e) [120–122, 124]. In the latter case the lifetime of the CS state is 20 μs. The equilibrium between the CS state and the triplet state is supported by energetical consideration and some experimental facts, such as oxygen sensitivity and solvent polarity dependence of the CS state. The equilibrium is achieved when
Figure 30. Schematic energy diagram for CS processes of ZnP-C_{60} in benzonitrile.

both states have close energy levels. When the energy level of the CS state is shifted by changing solvent polarity, the equilibrium is not obtained and the lifetime of the CS state becomes quite short, <1 ns (Fig. 31b). It should be noted that the equilibrium processes and the CR to the ground state are competitive. Thus, the long lifetime components are one part of the generated CS state. For example, in the case of octathiophene-C_{60} dyad in benzonitrile, 85% of the CS state has lifetimes of 63 ps, while the long lifetime was 15% of the generated CS state.
Figure 31. Schematic energy diagrams for CS and CR processes of oligothiophene(nT)-C_{60} in (a) polar and (b) moderatory polar solvents.

6.2. Fullerene-Donors Triad and Tetrad Systems

The long lifetime of the CS state was also achieved by the introduction of the multistep-electron-transfer system. Liddell et al. reported that carotenoid-porphyrin-fullerene (C-H_2P-C_{60}) triad molecule (Fig. 29f) generates the final charge-separated state (C$^{\bullet+}$-H_2P-$C_{60}^{\bullet-}$) via the C-P$^{\bullet+}$-$C_{60}^{\bullet-}$ upon excitation of porphyrine moiety [127]. In 2-methyltetrahydrofuran, the lifetime and the quantum yield for the generation of the final CS state were 170 ns and 0.14, respectively.

The quantum yield and the lifetime become long and high in the ferrocene-zinc porphyrin-fullerene (Fc-ZnP-C_{60}, Fig. 29g). The lifetime and the quantum yield for the generation of the CS state (Fc$^{\bullet+}$-ZnP-$C_{60}^{\bullet-}$) were 7.5 μs and 0.65, respectively [128].

A further long lifetime is expected for the tetramer including fullerene. The Fc-ZnP-ZnP-C_{60} tetrad shows lifetimes as long as 19 μs in benzonitrile [129].

6.3. Supramolecular Dyad and Triad Systems

By means of metal–ligand coordinate bonds, hydrogen bonds, etc., noncovalently linked donor–acceptor molecules have been reported [130]. To date, several noncovalently linked dyads are reported for fullerene derivatives [131–135]. For example, zinc porphyrin was connected via a coordinate bond with pyridine moiety of fullerene derivatives. Intrasupramolecular charge separation processes have been confirmed by observing radical ion species in laser flash photolysis experiments. By utilization of metal coordinate bonding of zinc porphyrin, further functionalities can be donated to dyad molecules. For example, D'Souza et al. reported that supramolecular triad molecules could be obtained by forming a coordinate bond between zinc porphyrin and C_{60}-porphyrin dyad with pyridyl group (Fig. 32) [135]. Furthermore, control of distance between the chromophores of zinc porphyrin-fullerene dyad by an axial coordination is also an interesting example of supramolecular systems [134].

Supramolecular dyad molecules are also available by utilizing host–guest chemistry. Konishi et al. reported that improvement of electron-transfer efficiencies could be attained in the electron-transfer systems composed of donors and fullerenes connected with calixarene, in which calixarene could capture the electron donor [136]. It is interesting to note that back electron transfer in these systems obeyed second order kinetics, indicating that the generated radical ions are solvated separately after electron transfer by deforming the supramolecular.

6.4. Light-Energy Conversion Using Donor-Fullerene Linked Molecules

The long lifetime and high quantum yield of the CS state of these donor-fullerene linked molecules seem to be efficient charge-generation species in the photoactive devices. A photoelectrochemical cell has been developed using a gold electrode which is covered by self-assembled monolayers of porphyrin-C_{60} dyad with S–Au interaction [137].
Figure 32. Supramolecular triad of zinc porphyrin and fullerene-porphyrin dyad. Reprinted with permission from [135], F. D'Souza et al., *J. Phys. Chem. B* 106, 4952 (2002). © 2002, American Chemical Society.

Using methylviologen as a carrier in the electrochemical cell, 5 mW cm^{-2} of photocurrent was obtained. This kind of photocurrent generation was also reported for the cell using self-assembled monolayers of oligothiophene-C$_{60}$ dyads [138].

Furthermore, the generated radical ion pair can be utilized for the electron-mediating process. For example, C$_{60}^{\bullet-}$ moiety of ZnP$^+$-C$_{60}^{\bullet-}$ dyad or ZnP$^+$-H$_2$P-C$_{60}^{\bullet-}$ triad donates an electron to hexyl viologen to generate a radical cation. On the other hand, ZnP$^+$ moiety of the dyad or triad oxidizes NADH analogs. Thus, both ZnP-C$_{60}$ and ZnP-H$_2$P-C$_{60}$ act as efficient photocatalysts for the uphill oxidation of NADH by hexylviologen [139].

6.5. Photoinduced Charge Separation and Recombination Processes of Fine Particles of Donor-Fullerene Linked Molecules

Photoinduced processes of the donor–acceptor linked molecules in condensed condition are important, since these photoactive molecules are expected to be used in a condensed form such as fine particles and assembled membranes. Thus, the investigations on the fine particles of the donor–acceptor dyad molecules give fruitful discussion on the light-energy conversion systems.

Thomas et al. reported the photoinduced CS and CR processes of aniline-C$_{60}$ dyad molecule (Fig. 29h) [140]. They
Figure 33. Size distribution of the fine particles of octathiophene(8T)-C$_{60}$. Inset: SEM picture. Reprinted with permission from [141], M. Fujitsuka et al., *J. Phys. Chem. B* 105, 9930 (2001). © 2001, American Chemical Society.

found that the CS process occurs within a few nanoseconds and that CS state has a lifetime, as long as several microseconds, due to the hopping of the radical ions among the molecules in each fine particle.

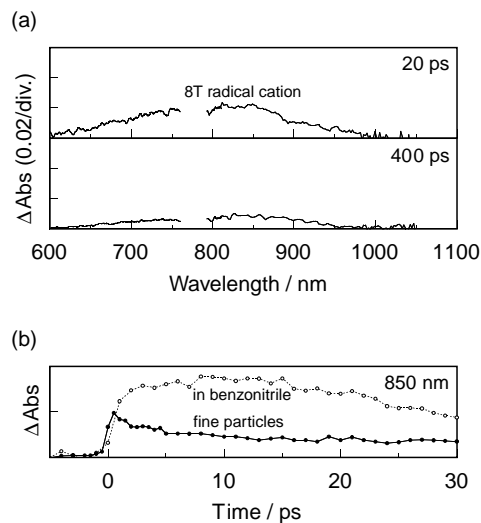
In the case of fine particles of octathiophene-C$_{60}$ (8T-C$_{60}$) dyad (Fig. 33), the CS occurs within 1 ps upon subpicosecond laser light irradiation, indicating that the rate constant for the charge separation is quite fast ($>1 \times 10^{12}$ s^{-1}), while CS in benzonitrile occurs at 1.1×10^{11} s^{-1} (Fig. 34) [141]. The fast CS process can be attributed to the intermolecular charge separation within each fine particle. On the other hand, the CR process occurs by a two-step process: Fast CR within a few picoseconds can be attributed to CR between the geminate radical ion pair, while the slow CR in the nanosecond regions can be attributed to the recombination after the hopping of the radical ions. The quite fast CS and CR processes of the oligothiophene-fullerene dyads can be attributed to the molecular arrangement in the fine particles.


Figure 34. (a) Transient absorption spectra of fine particles of octathiophene(8T)-C$_{60}$ upon subpicosecond laser light irradiation (388 nm, FWHM 150 fs). (b) Absorption-time profiles of fine particles of 8T-C$_{60}$ (solid line) and 8T-C$_{60}$ in benzonitrile (dot line). Reprinted with permission from [141], M. Fujitsuka et al., *J. Phys. Chem. B* 105, 9930 (2001). © 2001, American Chemical Society.

In the case of oligothiophene-fullerene dyads, oligothiophene and fullerene moieties seem to be located at the closest position since both oligothiophene and fullerene moieties are hydrophobic. On the other hand, aniline-fullerene dyad is considered to form a spontaneous self-assembly in such a way that the hydrophobic fullerene moieties come together, leaving the polar aniline moiety outside, in which the distance between aniline in a dyad and C_{60} in another dyad will be similar to that of the dyad molecule in solution. These findings indicate that the self-assembly of donor–acceptor linked molecules in the fine particles is an important factor governing the rates of the CS and CR processes.

7. CONCLUDING REMARKS

In the present chapter, we summarized photoexcitation dynamics of the fullerenes and related materials. In the case of the conventional fullerenes, C_{60} and C_{70}, their photophysical and photochemical properties were well established: A lot of photochemical reactions have been cleared and they have been employed for many applications such as photobiology and photoactive molecular devices. The fine particles of C_{60} show interesting photophysical and photochemical properties due to the migration of the singlet and triplet excited states in each fine particle. As for the higher fullerenes and metallofullerenes, although reports on their photophysical and photochemical properties were scarce, further interesting properties are expected after accumulation of the experimental data. The dyads and triads including fullerene showed a long-lived CS state with higher quantum yield than ever reported for dyads and triads. Thus, application of the donor–acceptor linked molecules to devices such as the light-energy conversion system seems to be interesting.

GLOSSARY

Back electron transfer Reverse reaction process of electron transfer. Original ground state is formed.

Energy transfer Process donating singlet or triplet excitation energy from an energy donor to an energy acceptor.

Fullerenes Molecules composed of carbon with football-like shapes. Carbon allotrope of diamond and graphite. Most famous C_{60} was found in 1985.

Laser flash photolysis Spectroscopic measurement of absorption spectral change in shorter time scale upon excitation with pulsed laser. Nowadays, time resolution from femto- to millisecond region is available.

Metallofullerenes Fullerenes including metal ions in fullerene cage.

Photoinduced electron transfer Process donating an electron from an electron donor to an electron acceptor upon photoexcitation of the donor or acceptor.

CONTENTS

1. INTRODUCTION

Photonic crystal lasers are lasers in which the resonant cavity is formed by a periodic dielectric constant. In this sense, they have much in common with distributed feedback lasers, which have long been an important optical source for fiber communication systems, and with vertical cavity surface emitting lasers. In this work, we take photonic crystal lasers to be lasers in which the dielectric constant is periodic in at least two dimensions. Photonic crystals came into existence as part of a program to modify spontaneous emission rates in optical microcavities by modifying the optical mode density [1]. Photonic crystals open up gaps in the optical spectrum through spatially and spectrally overlapping Bragg planes. These electromagnetic bandgaps can be, and have been, used to confine optical modes in laser cavities. These cavities can be very small. In fact, their mode volume can be made to be only a little larger than a cubic half-wavelength. In high contrast dielectric systems, only a few lattice periods may be necessary to confine an electromagnetic mode, and a lattice period has a length scale on the order of one half of the optical wavelength. More generally, photonic crystals take advantage of the nanofabrication processes which are available to pattern the dielectric function at the subwavelength scale. This patterning ability presents the possibility of designing the electromagnetic modes of photonic devices in microscopic detail. It is possible, in principle, to design laser cavities in which the optical mode's resonant frequency, spatial profile, radiation pattern, and polarization are engineered by engineering and patterning the dielectric function at the subwavelength scale. Actually, accomplishing all of this, however, is still very challenging. In addition, because of their small volume, photonic crystal lasers can be expected to operate at very low threshold pump powers. From this aspect, they benefit both from a small cavity volume that must be inverted as well as from microcavity effects [2, 3]. This article will review the basic properties of photonic crystal lasers and the progress that has been made in their development. The first section covers the basic electromagnetic principles involved and the relevant numerical models. This will be followed by an introduction to the fabrication of semiconductor photonic crystals and a description of the progress that has been made in laser development.

2. ELECTROMAGNETIC PROPERTIES OF PHOTONIC CRYSTALS

In this first section, we will begin with a discussion of the electromagnetic properties of photonic crystals. This discussion is not intended to be a complete review of the electromagnetic properties of photonic crystals, but instead an overview of their properties and the relevant calculation methods that are useful in understanding their application to lasers. The discussion will proceed from calculation methods to the properties of these lattices that are of interest for semiconductor lasers.

Photonic crystals are typically modeled as a patterned dielectric structure in which the dielectric material is a source-free region in which the dielectric constant is scalar.

$$\begin{cases} \nabla \times \vec{E} = -\dfrac{\partial \vec{B}}{\partial t} - \vec{M} \\[2mm] \nabla \times \vec{H} = \dfrac{\partial \vec{D}}{\partial t} + \vec{J} \\[2mm] \nabla \cdot \vec{D} = \rho \\[2mm] \nabla \cdot \vec{B} = 0 \end{cases}$$

This article will also take the dielectric constant to be a real number. This will later limit us to predicting, for example, the cold cavity behavior of photonic crystal resonant cavities. There have been analyses in which the nonlinear interactions have been considered [4], but in this article we focus on linear interactions. For simplicity, we also ignore any frequency dependence of the dielectric constants. Finally, we take the permeability to be unity.

$$\vec{B} = \mu_0 \vec{H}$$

Since Maxwell's equations are linear, we can expand the fields of interest into a set of time-harmonic fields

$$\begin{cases} \vec{E}(\vec{r}, t) = \vec{E}(\vec{r})e^{i\omega t} \\ \vec{H}(\vec{r}, t) = \vec{H}(\vec{r})e^{i\omega t} \end{cases}$$

The periodicity of $\varepsilon(\vec{r})$ implies

$$\varepsilon(\vec{r} + \vec{R}) = \varepsilon(\vec{r})$$

where $R = m_1 a_1 + m_2 a_2 + m_3 a_3$ is a lattice vector of the direct lattice with $\{m_i\}$ a set of arbitrary integers. The reciprocal lattice vector are given by

$$\vec{G} = l_1 \vec{b}_1 + l_2 \vec{b}_2 + l_3 \vec{b}_3$$

where

$$\vec{a}_i \cdot \vec{b}_j = 2\pi \delta_{ij}$$

and $\{l_j\}$ are arbitrary integers and δ_{ij} is the Kronecker delta. With these assumptions, Maxwell's equations are

$$\begin{cases} \nabla \times \vec{E}(r) = -i\omega\mu_0 \vec{H}(r) \\ \nabla \times \vec{H}(r) = i\omega\varepsilon(r)\vec{E}(r) \\ \nabla \cdot [\varepsilon(\vec{r})\vec{E}(r)] = 0 \\ \nabla \cdot \vec{H}(r) = 0 \end{cases}$$

Finally, we can use Bloch's theorem to write the fields as Bloch waves characterized by a wave vector $\vec{k}$ in the first Brillouin zone and a band index n as

$$\begin{cases} \vec{E}(\vec{r}) = \vec{E}_{n\vec{k}}(\vec{r}) = \vec{u}_{n\vec{k}}(\vec{r}) \exp(i\vec{k} \cdot \vec{r}) \\ \vec{H}(\vec{r}) = \vec{H}_{n\vec{k}}(\vec{r}) = \vec{v}_{n\vec{k}}(\vec{r}) \exp(i\vec{k} \cdot \vec{r}) \end{cases}$$

where $u_{n\vec{k}}(\vec{r})$ and $v_{n\vec{k}}(\vec{r})$ are periodic functions that satisfy

$$\begin{cases} \vec{u}_{n\vec{k}}(\vec{r} + \vec{R}) = \vec{u}_{n\vec{k}}(\vec{r}) \\ \vec{v}_{n\vec{k}}(\vec{r} + \vec{R}) = \vec{v}_{n\vec{k}}(\vec{r}) \end{cases}$$

Analytical solutions to these equations for the electromagnetic fields are not available, in general, and we are left to resort to various numerical methods to predict the electromagnetic properties of photonic crystals. Among the common numerical techniques that have been applied to these structures are the plane-wave expansion method (PWE), the finite-difference, time-domain method (FDTD), and the

finite element method (FEM). Both the plane-wave expansion and finite element methods solve the vector Helmholtz eigenvalue equation that is derived from the simplified Maxwell equations above.

$$\begin{cases} \dfrac{1}{\varepsilon(\vec{r})} \nabla \times \left[\nabla \times \vec{E}(\vec{r}) \right] = \dfrac{\omega^2}{c^2} \vec{E}(\vec{r}) \\ \nabla \times \left[\dfrac{1}{\varepsilon(\vec{r})} \nabla \times \vec{H}(\vec{r}) \right] = \dfrac{\omega^2}{c^2} \vec{H}(\vec{r}) \end{cases}$$

The finite element method has proved itself to be the fastest method in calculating photonic crystal band structure, so we will briefly describe this method. The variational procedure leads to the weak form of this equation

$$\int_\Omega \nabla \times \vec{W} \cdot \nabla \times \vec{E} \, d\Omega - k_0^2 \int_\Omega \varepsilon_r \vec{W} \cdot \vec{E} \, d\Omega$$

$$- \oint_{\partial\Omega} \vec{W} \cdot \nabla \times \vec{E} \, d\vec{S} = 0$$

where $\vec{W}$ is the weighting function. The surface integral term vanishes on boundaries that correspond to perfect electric conductors (PEC), perfect magnetic conductors (PMC), or periodic boundaries [5]. This term will be dropped hereafter because we will apply one of those three boundary conditions. To guarantee the one-to-one mapping of the approximated nonzero eigenvalues to the physical modes, edge elements are used. Using the same basis function as those of the weighting function to approximate the vector field (Galerkin method), the electric field in any tetrahedron is expressed as

$$\vec{E} = \sum_{i=1}^{6} E_i \vec{W}_i$$

Therefore, we arrive at the matrix equation

$$\int_\Omega \nabla \times \vec{W}_i \cdot \nabla \times \vec{W}_j \, d\Omega - k_0^2 \int_\Omega \varepsilon_r \vec{W}_i \cdot \vec{W}_j \, d\Omega = 0$$

which is a generalized eigenvalue equation of the form $Ax = \lambda Bx$. If the boundary is a PEC or a PMC, which is the case when field symmetry is used to simplify resonant cavity problems, the matrices are real and symmetric. For spatially periodic structures, the periodic boundary condition is imposed on each pair of the periodic surfaces using Bloch's theorem

$$\vec{W}_{i'} = \exp(-j\vec{\beta} \cdot \vec{\alpha})\vec{W}_i$$

where i' is the corresponding edge number of edge i [6]. The matrix elements that correspond to the edges on the periodic surfaces are complex and this leads to a complex hermitian matrix. The matrix equation can be solved using Arpack++ (C++ interface to Arpack and direct solvers such as SuperLU and UMFPack), which is in the public domain [7].

The plane-wave expansion method solves the eigenvalue equations by Fourier expanding the electromagnetic field and the dielectric function

$$\frac{1}{\varepsilon(\vec{r})} = \sum_{\vec{G}} \kappa(\vec{G}) \exp(i\vec{G} \cdot \vec{r})$$

$$\begin{cases} \vec{E}(\vec{r}) = \sum_{\vec{G}} E_{n\vec{k}}(\vec{G}) \exp(i\vec{G} \cdot \vec{r}) \exp(i\vec{k} \cdot \vec{r}) \\ \vec{H}(\vec{r}) = \sum_{\vec{G}} \vec{H}_{n\vec{k}}(\vec{r}) \exp(i\vec{G} \cdot \vec{r}) \exp(i\vec{k} \cdot \vec{r}) \end{cases}$$

By choosing a sufficiently large number of plane waves, the eigenvalues are obtained by diagonalizing the resultant coefficient matrix which has the dimension of the number of plane waves. The plane-wave expansion method is very straightforward to utilize and thus was the first numerical method successfully applied in photonic crystal band structure calculations. However, its convergence is dependent on the number of plane waves applied, which in turn increases the computing time since the diagonalization is usually proportional to the matrix size. This is especially important in three-dimensional structures where the matrix size grows as N^3. In addition, convergence can be very slow even with a large number of plane waves, as the spatial dielectric variation is large [8, 9]. The convergence of the plane-wave expansion method can be improved by using spherical waves instead of plane waves as a basis when the photonic crystal is composed of dielectric spheres or circular cylinders [10].

The finite-difference, time-domain method, introduced by Yee in 1966 [11] is a marching-in-time procedure that simulates the continuous electromagnetic waves by volumetric sampling of the unknown fields within and surrounding the structure of interest [12]. The finite-difference, time-domain method avoids the difficulties with the linear algebra used in both the finite element method and the plane-wave expansion method which limits the size of modeling structure. It is also highly scalable because the computing time is linearly proportional to the mesh density. The finite-difference, time-domain method, however, solves the eigenvalue problem indirectly. The simulation starts from a random initial condition with a particular wavevector, k, so as not to exclude any possible modes, and propagates the fields in time. The amount of time required for this propagation depends on the precision required in the eignemodes and eigenvalues. The eigenvalues for a given wave vector, k, are obtained by a Fourier transformation of the complex-valued field components in the time-domain recorded at various low-symmetry locations [13]. The peaks in the Fourier spectrum correspond to the eigenvalues. By applying a band-pass filter in time with its window aligned with each eigenvalues, the final steady-state eigenmode distributions are calculated by taking the time average of the time-domain solution at each mesh point.

To overcome the staircase approximation of Yee's original staggered leapfrog meshing, several alternative grids have been proposed, including hexagonal grids, tetradecahedron/dual-tetrahedron grids, and a local subcell model. Despite the significant accuracy advantage, the usage of the alternative meshings by the finite-difference, time-domain community has been quite limited, mainly due to the additional complexity in its mesh generation and field updating.

2.1. Two-Dimensional Photonic Crystals

Having discussed the basic numerical modeling techniques, we will now consider the properties of these structures that are of interest for laser applications. We will begin by introducing two-dimensional photonic crystals. This will be followed by a discussion of the modes of the dielectric slab into which two-dimensional photonic crystal lattices have been patterned. Both symmetrically clad and asymmetrically clad membranes will be included in this discussion. Finally, this section will conclude with a look at resonant modes created by including defects in the lattices. Both the modes of the two-dimensional photonic crystal slab and the resonant modes introduced by defects in the lattice are of interest in photonic crystal laser design.

A two-dimensional photonic crystal is characterized by having a dielectric structure that is uniform in the z direction, while preserving a set of discrete translational symmetries in the x-y plane. The electromagnetic field is characterized by an in-plane wave vector $k_\parallel$ and the wave vector in the homogeneous direction k_z

$$\vec{H}(\vec{r}) = e^{ik_z z} e^{i\vec{k}_\parallel \cdot \vec{r}_\parallel} u_{k_z, \vec{k}_\parallel}(\vec{r}_\parallel)$$

In the case where the light is strictly propagating in the x-y plane, that is, $k_z = 0$, solutions to Maxwell's equations can be written as solutions to two independent sets of equations. These solutions are classified conventionally as transverse electric (TE$_z$) modes and transverse magnetic (TM$_z$) modes. One field component for each of these sets, H_z for TE and E_z for TM, satisfies a scalar Helmholtz equation. The band structures for TE$_z$ and TM$_z$ modes can be completely different

$$\begin{cases} \dfrac{\partial H_z(\vec{r}_\parallel)}{\partial y} = i\omega\varepsilon(\vec{r}_\parallel)E_x(\vec{r}_\parallel) \\[2mm] \dfrac{\partial H_z(\vec{r}_\parallel)}{\partial x} = -i\omega\varepsilon(\vec{r}_\parallel)E_y(\vec{r}_\parallel) \\[2mm] \dfrac{\partial E_y(\vec{r}_\parallel)}{\partial x} - \dfrac{\partial E_x(\vec{r}_\parallel)}{\partial y} = -i\mu_0\omega H_z(\vec{r}_\parallel) \end{cases}$$

$$\begin{cases} \dfrac{\partial E_z(\vec{r}_\parallel)}{\partial y} = -i\mu_0\omega H_x(\vec{r}_\parallel) \\[2mm] \dfrac{\partial E_z(\vec{r}_\parallel)}{\partial x} = i\mu_0\omega H_y(\vec{r}_\parallel) \\[2mm] \dfrac{\partial H_y(\vec{r}_\parallel)}{\partial x} - \dfrac{\partial H_x(\vec{r}_\parallel)}{\partial y} = i\omega_0\varepsilon(\vec{r}_\parallel)E_z(\vec{r}_\parallel) \end{cases}$$

Most of the investigations of photonic crystals have focused on the triangular lattice and the square lattice. However, since these structures are lithographically defined, there is in principle no need to confine the investigation to naturally occurring Bravais lattices [14]. In any case, in

designing photonic devices formed in photonic crystals, care must be taken with choosing both the lattice and the dielectric distribution in the unit cell. A triangular lattice of air holes patterned into a high refractive index membrane creates a bandgap for both the guided TE and TM modes of the membrane for a range of hole radii. In general, a photonic lattice that consists of a connected high dielectric region is likely to exhibit a TE bandgap, while a lattice formed by disconnected high dielectric regions is more likely to exhibit a TM bandgap [15–18]. Both [18] and [19] have calculated the dispersion relations for several types of structures with a variety of lattices and unit cells.

Figure 1 shows the dispersion relation for the TE and TM modes of a two-dimensional square lattice consisting of dielectric rods. The TE dispersion relation is shown in dashed lines and the TM dispersion relation is in solid lines. Shown alongside is the conformal meshing of the unit cell that was used in this calculation. In this disconnected lattice, there is no TE bandgap, but a TM bandgap is formed. The inverse lattice consisting of low index holes in a high index matrix can be made to have both TE and TM bandgaps.

In the triangular lattice, the bandgaps for the two polarization types are formed between different bands. The first TE bandgap is formed between the first and second TE bands, while the first TM bandgap is formed between the second and third bands. Figure 2 shows the band structure for TE and TM modes of a dielectric lattice perforated by a triangular array of holes. In this figure, the dielectric constant of the background material is 13.6 and the dielectric constant of the holes is 1. The ratio of hole radius to lattice constant, r/a, is 0.47. This photonic crystal has a large TE bandgap. The frequency width of the gap is nearly 20% of the midgap frequency. The size of this gap can be changed by changing r/a. As r/a gets larger, the bottom band—called the dielectric band because at the bandedge the standing wave field is peaked in the high dielectric regions—moves up in frequency. This can be thought of as being due to the fact that this mode has a decreasing effective index as r/a increases. The second band—called the air band because the standing wave field at the bandedge is peaked in the low dielectric regions—also moves up in frequency. Since more of field of the air band is located in the low dielectric regions than the field of the dielectric band, the air band moves up in frequency with increasing r/a faster than the dielectric band and the bandgap therefore increases with increasing r/a.
Figure 2. The photonic band structure of a triangular lattice of air holes ($r/a = 0.47$) perforating a dielectric material ($n = 11.56$) using the plane-wave expansion method.

The photonic crystal structures that have been physically realized in the optical domain are not uniform in z direction, which is taken to be the epitaxial growth direction. Current etching technology often leads to lattices that are only a few microns deep. This forces the device designer to resort to membranes of photonic crystal slabs above low-index dielectric layers. The finite thickness of the photonic crystal structures complicates the electromagnetic analysis [20]. For lattices of a finite thickness, there are no longer strict TE or TM modes since the translational invariance in the z direction no longer exists. A fully three-dimensional numerical method with all six field components is required to accurately simulate a photonic crystal structure in a dielectric slab. Nevertheless, when mirror symmetry in the z direction exists, as in photonic crystals in suspended membranes, the field can be categorized as being an even or odd mode with respect to the midplane of the slab. This information can be used to help cut simulation time in half. This, of course, also requires that the layers which clad the suspended membrane be symmetric. However, in cases where the refractive index of the bottom cladding is not significantly different from air that serves as the top cladding layer at the desired working wavelength—such as sapphire and silicon dioxide at 1.55 micron—it is found that the even and odd modes describe the field reasonably accurately. To emphasize the approximation involved in the model, these modes are most often referred to in the literature as even-like or odd-like. It is worth noting that the photonic bandgap in a dielectric slab is not a three-dimensional electromagnetic bandgap [21, 22]. Since two-dimensional photonic crystals offer only lateral confinement, the lattice produces only a bandgap in the guided modes of the slab. Optical confinement depends on the index contrast in the third dimension to keep the field from radiating. The confinement of the slab is good only if the mode lies outside the light cone of the cladding. This effect is no different from what occurs in an ordinary dielectric slab waveguide [23]. In other words, a photonic bandgap exists only for those modes that are totally internally reflected at the photonic crystal membrane interfaces. Figure 3 shows the dispersion relation for a dielectric

Figure 1. The photonic band structure of a square lattice of dielectric rods ($n_{\mathrm{rods}} = 12$) of radius of $r/a = 0.2$ in an air background using the finite element method (left), and the conformal meshing used in the calculation (right).
Figure 3. Photonic band structure of the triangular lattice photonic crystal membrane. The light cone is mapped as a gray region.

slab in which a triangular lattice photonic crystal has been patterned. The radiation modes of the slab are shaded in the figure. The photonic crystal modes above the light line in the reduced Brillouin zone will be radiating vertically. This vertical radiation is an important element of microcavity photonic crystal laser design.

If the photonic crystal slab is placed on a low-index dielectric film instead of being symmetrically air clad, then complications are introduced into resonant cavity design. There are three major effects of breaking the symmetry about the midplane of the photonic crystal plane. These are a reduction in the effective bandgap width, an increase in the radius of the radiation cone, and the loss of a rigorous bandgap in the guided modes of the slab [24–26]. The first two of these effects are the most serious for device designers. The reduction in the bandgap occurs because the presence of a higher index substrate affects the frequency of the second band more than the lowest band. The radiation cone of the substrate is also larger than the radiation cone of the upper cladding material assuming that the substrate has a large refractive index. The third effect, the loss of the guided wave bandgap, results from the loss of strict even and odd symmetry. In a symmetrically clad membrane, the bandgap of the even guided modes and the odd guided modes are not identical. The even guided mode bandgap is usually at a lower frequency range than the bandgap for the odd guided modes. When this even and odd classification is lost, due to the asymmetric nature of the cladding, the bandgap is lost due to the spectral overlap of the dispersion relation of the modes that were formerly odd with the dispersion relation of the modes that were formerly even. The coupling between these two sets of modes is very small, however, so there is still an effective bandgap.

Most photonic devices designed to date work in the first bandgap, either in the bandgap as a result of a defect in the lattice or at one of the band edges. Band edges are useful because at the Brillouin zone boundary, the group velocity of the guided modes of the photonic crystal membrane are zero. As previously mentioned, the lower band edge mode is a standing wave with the peaks of its electric field located

in the high dielectric regions. This allows them to be used as laser modes in distributed feedback laser structures.

2.2. Localization of Light by Defects in the Lattice

Modes can be introduced into the electromagnetic bandgaps in photonic crystal membranes by introducing one or more defects into the lattice. The presence of defects in the lattice has the effect of pulling bandedge modes into the bandgap [27]. This phenomena is similar to formation of deep levels in an electronic bandgap of a solid due to impurities and identical to the formation of resonant modes in vertical cavity surface emitting lasers (VCSELs) by placing an active region of a precise thickness between two distributed Bragg reflectors. For example, if a high index perturbation is added to the lattice, such as by filling a hole with a high index material, then one or more modes is pulled from the upper band edge into the bandgap. This mode is sometimes referred to as a donor. Similarly, by including a low index perturbation, acceptor modes are pulled into the bandgap from the lower band edge. Thus by perturbing a single lattice site, a localized mode or group of modes is formed which have a frequency in the gap.

In analyzing these modes and designing them for laser cavities, one of the most important parameters is the Q of the resonance. The quality factor of the cavity is related to the material gain required to reach threshold through

$$\Gamma g = \frac{2\pi \bar{n}}{\lambda} \frac{1}{Q}$$

where Γ is the optical confinement factor and g is the threshold material gain. Three numerical methods can be used to calculate the quality factor of the cavity modes. The first method is to measure the slope of the exponential decay of the energy of a given cavity mode with time. This decay of energy from the cavity is described by $\exp(-t/t_{ph})$, where t_{ph} is the photon lifetime that is related to the quality factor Q, by $Q = \omega t_{ph}$. This method is most useful for relatively low Q modes where the slope of energy decay is visibly greater than zero.

Another method is to calculate the ratio of full width at the half magnitude of the cavity resonance in the frequency domain, $\Delta\omega$, to center frequency, ω_0. However, distortion to the spectrum is often introduced because the numerical simulation terminates before the impulse response is fully evolved. This is, in effect, viewing the true time-domain response through a rectangular window, which translates mathematically into the convolution of the true spectrum with a sinc function. The convolution widens the peaks in the spectrum among other effects. Distortion can be reduced by increasing the time-response window, but at a price of longer simulation time. A better approach in addressing the problem is to apply digital signal analysis techniques to extrapolate the electromagnetic field in time-domain by 10:1 or more beyond the actual simulation window. Several methods have been proposed including Prony's method [28], generalized pencil-of-function technique [29, 30], and Padé's approximation [31]. The first two techniques extrapolate the

field by representing it in the time-domain as a sum of complex exponentials, while the last one uses a Padé approximation in conjunction with the fast Fourier transform. The Padé approximation technique proves itself less sensitive to the field sampling condition and thereby are more suited for general purpose extrapolation.

A third method calculates the ratio of cycle-averaged power absorbed in the boundary to the total energy in the cavity mode. This method has the advantage of being able to separate the radiation losses into different directions. For example, the effective vertical quality factor $Q_\perp$ is given by the ratio of power lost to the absorber at the top and bottom $P_\perp$ with respect to the total cavity energy $U(t)$, times the resonant frequency and effective in-plane quality factor $Q_\parallel$ is similarly given by the ratio of in-plane power loss $P_\parallel$ to the product of the total cavity energy and the resonant frequency. It should be noted that all of the calculations of Q in photonic crystals to date are of the cold cavity Q value. It is possible, however, to include absorption and gain in these calculations.

The field profile, resonant frequency, and quality factor of the modes introduced by placing defects in the lattice can be engineered. Not only can we create a defect mode with a frequency in the bandgap; we can also design a range of defect frequencies that sweep continuously across the bandgap by varying adjacent defect hole size or lattice constants [26]. Tuning the defect frequency to any value within the bandgap is one of the most important features of photonic crystal resonant cavities. One of the most common methods of creating a resonant cavity in a two-dimensional photonic crystal lattice is to fill one hole in a triangular lattice. This has the effect of introducing a doubly degenerate dipole mode into the bandgap. The resonant frequency of this mode depends on the lattice constant, r/a, and the membrane thickness in cases where the cavity is formed in an undercut membrane. The dipole mode does not have a particularly high Q. It is on the order of a few hundred. So while this mode is very easy to form, it is probably not the most interesting cavity design for laser operation. The problem with the dipole mode is that it suffers from rather large, out-of-plane radiation losses.

Understanding the role played by the in-plane and vertical radiation loss in a particular cavity is very useful in device design. The in-plane quality factor increases rapidly as the number of lattice periods increase, but for the smallest defects, the limiting factor for the cavity quality factor is usually the vertical radiation. This phenomena is illustrated in Figure 4. This figure shows the quality factors corresponding to the radiation loss in the vertical and in-plane directions as well as the total quality factor of this cavity. In this particular calculation, the cavity modeled was a single defect in a two-dimensional photonic crystal membrane. As mentioned above, the triangular lattice is often used in photonic crystal resonant cavities. This lattice has a large TE bandgap that is useful because this is the polarization that is predominantly emitted by conduction band to heavy hole radiative transitions in III–V semiconductor gain media. In addition, the larger the bandgap, the stronger the localization of the resonant fields at midgap. Because of this strong, in-plane localization, quality factors of the smallest cavities in this lattice are often dominated by out-of-plane radiation.
Figure 4. In-plane Q, vertical Q, and total Q. Reprinted with permission from [26], C. Kim et.al., *J. Opt. Soc. Am. B* 19, 1777 (2002) © 2002, Optical Society of America.

This occurs because part of the mode overlaps the radiation cone of the slab. Since the mode is strongly localized in real space, it is spread out in wave vector space and overlaps the radiation modes of the slab. A Fourier transform of the dipole mode along with its real-space field profile is shown in Figure 5a. The figure shows the Brillouin zone boundary and the radiation cone as well. This loss can be reduced by reducing the resonant frequency of the mode. This moves the resonant mode farther away from the light cone. Equivalently, reducing the frequency of the resonant mode reduces the size of the radiation cone in k-space. This frequency reduction can be accomplished by reducing the r/a ratio of the lattice. This increases the effective index of the membrane and reduces the resonant frequencies. There is a trade-off in this, however, since reducing r/a reduces the size of the bandgap which can cause a reduction of in-plane confinement. This resonant frequency reduction can also be accomplished by increasing the thickness of the photonic crystal membrane. This also has the effect of increasing the effective index of the modes and reducing their frequencies. This strategy is effective as long as the slab does not become multimoded. Once the slab supports more than one waveguide mode, then the bandgap begins to close. This is due to the presence of the dispersion relations of the higher order slab modes. Another way in which the Q of the smallest cavities can be increased is by engineering the lattice near the missing hole. This method is the most general, but also the most open-ended. The strategy to achieve this increase in Q is most clearly illustrated by the Fourier transform of the dipole mode [32]. Again, this is shown for one of the degenerate dipole modes in the triangular lattice in Figure 5a. This figure shows that the greatest overlap of the mode with the radiation cone occurs along the Γ-M direction. Relaxing the in-plane confinement in this direction will allow the mode distribution in k-space to be more well localized and thereby reduce the overlap of the mode with the radiation cone. An illustration of the implementation of this design strategy is shown in Figure 5b. In this figure, the dielectric constant in the direct lattice has been modified to allow the resonant mode to expand along the y direction. This has the effect of increasing the Q by reducing the out-of-plane radiation loss. The strategy is fairly general,
Figure 5. The spatial profile and the Fourier transform of the dipole mode in an (a) unmodified and (b) modified, single-defect photonic crystal cavity. At right, the outer black line is the first Brillouin zone boundary and the inner black circle is the light cone in k-space.

but the particular lattice instantiation in which to achieve this increase is not unique.

Larger cavities have also been formed by removing several holes from the lattice. For these larger cavities, there are, of course, more resonant modes formed. It has not always been possible to identify the lasing modes in these larger cavities. For larger defect photonic crystal cavities, it is found that the loss of some of the defect modes is not dominated by vertical radiation loss. These modes benefit from being less tightly confined in real space and thereby spread less in reciprocal space. If the mode does not overlap the radiation cone in reciprocal space, it will not radiate out of plane. Of course, all confined modes overlap this radiation cone, but the extent of this overlap determines the out-of-plane radiation loss.

The square lattice has also been utilized in photonic crystal cavities. This lattice does not have a large TE bandgap. In fact, a complete bandgap may not even be necessary for the localization of a mode at a defect site. If the mode consists of wave vector components mainly from the region where a bandgap exists, then the mode can still be localized. In fact, quality factors from a single defect in the square lattice are thought to be higher than in a single defect in a triangular lattice [33]. This is attributed to the reduction of the in-plane confinement of the mode in the square lattice as compared to the triangular lattice. This relaxation of the in-plane confinement will then help to localize the mode in k-space, reducing the overlap of the mode with the radiation modes of the slab.

One of the more interesting features of photonic crystal lasers is that their resonant wavelength can be lithographically defined. Lithographic tuning of the wavelength can be achieved by varying the lattice constant and the hole radius. This scaling property of Maxwell's equation can be seen as follows. Assuming there is a resonant mode that satisfies the

equation,

$$\nabla \times \left(\frac{1}{\varepsilon_1(\vec{r})} \nabla \times \vec{H}_1(\vec{r}) \right) = \left(\frac{\omega_1}{c} \right)^2 \vec{H}_1(\vec{r})$$

then we can rescale the space by

$$\vec{r}' = \alpha \cdot \vec{r}$$
$$\varepsilon_2(\vec{r}) = \varepsilon_1(\alpha \vec{r})$$
$$\vec{H}_2(\vec{r}) = \vec{H}_1(\alpha \vec{r})$$

where obviously

$$\nabla' = \frac{1}{\alpha} \nabla$$

In the rescaled problem, then

$$\nabla' \times \left(\frac{1}{\varepsilon_1(\vec{r}')} \nabla' \times \vec{H}_1(\vec{r}') \right) = \left(\frac{\omega_1}{c} \right)^2 \vec{H}_1(\vec{r}')$$

Using the second and third of these equations, this last equation can be reduced to

$$\frac{1}{\alpha^2} \nabla \times \left(\frac{1}{\varepsilon_2(\vec{r})} \nabla \times \vec{H}_2(\vec{r}) \right) = \left(\frac{\omega_1}{c} \right)^2 \vec{H}_2(\vec{r})$$

then moving the denominator α^2 to the right side we have

$$\nabla \times \left(\frac{1}{\varepsilon_2(\vec{r})} \nabla \times \vec{H}_2(\vec{r}) \right) = \left(\frac{\omega_2}{c} \right)^2 \vec{H}_2(\vec{r})$$

where $\omega_2 = \alpha \omega_1$ and the eigenfrequencies have been scaled.

3. FABRICATION OF TWO-DIMENSIONAL PHOTONIC CRYSTALS

In this section, an overview of the fabrication procedures used in the formation of semiconductor photonic crystals will be presented. Most of the 2D photonic crystal lasers that have been demonstrated to date were fabricated in III–V compound semiconductors. There have been demonstrations in the AlGaAs/GaAs material system [34–36] as well as the InGaAsP/InP system [37–38]. The fabrication processes for these lasers is similar to each other even though the demonstrated lasers were designed for various types of optical modes with various physical structures. The typical semiconductor device fabrication processes include molecular beam epitaxy (MBE) or metal organic chemical vapor deposition (MOCVD) epitaxial growth of the active and waveguide materials, dielectric mask and/or metallic mask deposition for masking the pattern transfer, photolithography or electron beam lithography for defining the geometry of the laser devices, and plasma etching and/or wet chemical etching for defining the device geometry in semiconductor. Because of the similarity between the fabrication processes of all these laser devices, we are going to give the detailed description of the fabrication process of only one of the photonic crystal lasers in this article—the two-dimensional photonic crystal membrane laser in InGaAsP/InP [38]. This illustrates the basic nanofabrication process necessary to

pattern and transfer the photonic lattice into the semiconductor. The final structure consists of a 220-nm-thick, InGaAsP suspended membrane containing four quantum wells in which a triangular lattice of holes has been etched. The resonant cavity is formed in the center where there is one or more holes missing from the lattice.

To realize this structure, an epitaxial structure containing the active region, usually several quantum wells to provide TE gain, and any additional optical waveguiding layers, is deposited first. The epitaxy is capped with a thin, ~50 nm layer that will subsequently be removed. This layer protects the active region during the etching and its removal at the end of the process guarantees a smooth top surface. The masking layers are then deposited. A silicon nitride layer that is typically on the order of 100 nm thick is deposited on top of which 100-nm of 2% polymethylmethacrylate (PMMA) is spin-coated.

The photonic lattice is defined in the PMMA by electron beam lithography. After the electron beam exposure, the PMMA is developed. At this point, the pattern is transferred through the SiN mask layer in a reactive ion etch (RIE). This nitride layer is then used to mask the pattern transfer into the semiconductor. This last pattern transfer, dry-etching step can be done using a chemically assisted, ion beam etch (CAIBE), an inductively coupled plasma etch (ICP), or an electron cyclotron resonance etch (ECR). To pattern InGaAsP/InP material, an etch recipe based on a $CH_4/H_2/Ar$ plasma is often used, although Cl-based recipes [39–41] have also been demonstrated. For an AlGaAs/GaAs structure, a Cl-based plasma chemistry is most often used [41]. An SEM image-showing the cross-sectional view of the photonic crystal lattice after a typical $CH_4/H_2/Ar$ plasma ECR etch, is shown in Figure 6. After this step, one last plasma etch is used to remove any remaining mask materials.

At this point, the photonic lattice is transferred into the semiconductor. A wet chemical etch is used to form the suspended membrane. To remove the InP below an InGaAsP membrane, this etch is a HCl-based mixture. For example, a 4:1 $HCl:H_2O$ etch at 0 °C has been reported. This etch also removed the cap layer on the epitaxy. Care must be taken with this etch, however, because HCl is an anisotropic etch
in InP [42]. The resulting membranes are suspended over a V-shaped groove that runs along the $\langle 0, -1, -1 \rangle$ crystalline directions in the InP substrate. An electron micrograph image of a finished laser cavity is shown in Figure 7.

4. DEMONSTRATED RESONANT CAVITY TYPES

A large variety of photonic crystal lasers have been demonstrated. This variety exists in both the resonant cavity design as well as in the gain material. In this section, we will review the experimental demonstrations of photonic crystal lasers. These demonstrations will be classified as lasers with photonic crystal end mirrors, lasers operating along traditional distributed feedback principles, and lasers that depend on high Q modes localized to a defect in the lattice. Most of the discussion will focus on the latter cavity type.

The simplest use of photonic crystals in laser structures is as end mirrors in a Fabry–Perot cavity. The earliest experimental demonstrations of 2D photonic crystal lasers in semiconductors were accomplished in this geometry [43]. Later, researchers conducted more detailed studies of these structures [40, 44–46] and employed an intracavity photonic crystal mirror to achieve a stable, single-mode, coupled-cavity laser. These laser structures can be straightforwardly made to be electrically pumped. The disadvantage of this geometry, however, is that the lattice must be etched deeply enough so that the lattice overlaps the entire mode profile in order to obtain the highest reflectivity [25]. There is much in common between these lasers and short-cavity, distributed Bragg reflector (DBR) lasers. Two-dimensional periodicity has the potential to offer greater mode stability, however. Quality factors in these cavities can be made very large due to a potentially long path length and therefore a potentially long photon lifetime.

Two-dimensional photonic crystal lasers have also been used in what are essentially DFB lasers as well. In these devices, the lasing occurs at the band edge of the photonic bandgap. Lasing has been observed in 2D and even in 3D periodical structures of polymers [47–49]. Many reports have observed lasing phenomenon in various types of naturally

Figure 6. Cross-section SEM of a triangular photonic crystal lattice in InGaAsP/InP after ECR etching.
Figure 7. SEM micrograph showing a tilted view of a finished, photonic crystal membrane laser cavity.

formed periodic structures in polymers. In 1998, Berggren et al. [50] and Meier et al. [51, 52] demonstrated a 2D photonic crystal DFB laser by etching a square lattice into SiO$_2$ and then spin-coating the patterns PBD doped with laser dyes.

Photonic crystal DFB lasers in semiconductor materials were demonstrated later in both triangular lattice and square lattice photonic crystals [53–56]. As reported in [53], electrically pumped DFB lasers were fabricated by directly wafer-bonding a p-InP layer containing multiple InGaAsP quantum wells, onto an n-InP substrate on which had been etched a shallow 2D photonic crystal structure. Coherent and incoherent lasing at three equivalent Γ-X directions was observed with different electrical pumping conditions. A more sophisticated study of mode polarization control by deforming the symmetry properties of the photonic crystal unit cell was later reported by the same group of researchers [54]. Optical pump thresholds as low as 35 μW have been demonstrated at 80 Kelvin [55]. This demonstration utilized pulsed pumping of a 200-nm, air-clad, InGaAsP slab containing a triangular lattice photonic crystal.

Lasing in larger cavities is not strictly confined to DBR and DFB-type photonic crystal cavities. There have been other demonstrations of photonic crystal semiconductor lasers. A bent-ridge, waveguide laser cavity with two-dimensional photonic crystals as the lateral confinement has also been demonstrated [57]. The radiation loss of the waveguide bend is reduced using this method. A coupled cavity waveguide structure, formed by 40 coupled hexagonal cavities with 91 defects surrounded by two-dimensional triangular lattice photonic crystals, has also been reported [58]. Minibands inside the photonic bandgap form and single-mode lasing is observed at the first miniband edge.

The preceding photonic crystal lasers do not make use of defects in the lattice. There have been several demonstrations, however, of microcavity lasers in which the mode is formed by defects in 2D photonic crystals. These microcavities have resonant modes that exist within the electromagnetic bandgap of the photonic crystal and are localized to the immediate vicinity of a defect in the lattice. Two-dimensional photonic crystals are used to provide the in-plane localization of the mode, while the vertical confinement is provided by total internal reflection at a dielectric interface. Maximum confinement can be achieved using air as the cladding layers on both sides of a semiconductor membrane. The InP/InGaAsP material system is most often used for these demonstrations because it provides two advantages. One advantage is the relatively lower surface recombination rate, and the other is the long emission wavelength around 1.55 μm. Surface recombination in semiconductor photonic crystals has been studied in [59]. Most of these demonstrations have been of pulsed, optically pumped lasing. Here we will first consider the smallest of these cavities, those in which the defect consists of a single missing hole in the lattice. The first two-dimensional, photonic crystal defect laser demonstration was reported by Painter et al. in June 1999 [60]. This demonstration occurred in a suspended membrane in which a triangular lattice was patterned. This device was optically pumped at 143 K. The resonant mode was formed at a single defect in the lattice. The threshold pump power and pump conditions in

this demonstration were 6.75 mW and 10 ns pulses with 250 ns period. The reported Q of this cavity was 250. This lasing mode had one of the smallest mode volumes ever reported in any laser. The cavity quality factor of this cavity was subsequently improved by a factor of approximately two or more by reducing the hole size which led to a room-temperature demonstration [61]. The highest Q mode in these single-defect, triangular lattice cavities is a doubly degenerate dipole termed the x-dipole and the y-dipole [62]. These two degenerate modes have orthogonal polarizations and have been observed experimentally. The lattice, however, can be intentionally distorted near the missing hole, thereby reducing the symmetry to break the polarization degeneracy of the dipole modes. This distortion has also been demonstrated experimentally [60, 63]. To obtain the truly single-mode operation inside the two-dimensional photonic crystal defect cavity, Park et al. proposed a new design in which a nondegenerate monopole mode is experimentally observed by reducing and pushing away the nearest six air holes from the defect cavity [64]. The measured polarization data of the monopole mode showed no preferred direction as indicated using the 3D FDTD calculation. The quality factor here was estimated to be larger than 1900. This value was obtained from the spectral linewidth at transparency. As a result of this large Q value, a low-threshold pump power of less than 0.3 mW was obtained. Various modified single-defect cavity designs have also been studied, both numerically and experimentally in [65–66].

Room-temperature, pulsed lasing action has also been realized by Ryu et al. using two-dimensional, square lattice photonic crystals [67–68]. In [67], both degenerate dipole modes and a nondegenerate quadrupole mode in the single-defect cavity are observed. The threshold pump conditions for this geometry were 0.8 mW power of optical power with a 15 ns pulse width and a 0.4% duty cycle. A FDTD calculation predicts that the quality factor of the quadrupole mode is much larger than the dipole mode and the experimental measurement yielded a quality factor of about 2000 for the quadrupole mode. Again, this measurement was obtained from the linewidth of the resonance at transparency. The nondegenerate mode has been labeled as the lowest-order whispering gallery (LWG) mode [68]. Furthermore, this mode exhibits an energy null at the center of the cavity and hence opens up a possible route of electrical pumping by putting the current contact at the cavity center. Other work towards electrically pumped photonic crystal lasers is reported by Zhou et al. [69–70]. The heterostructure in this report consisted of an undoped cavity with two compressively strained InGaAs quantum wells and a bottom DBR mirror. The photonic crystal is deeply etched through the cavity and into the bottom DBR region. Later, this group used self-organized InAs quantum dots as the active material and demonstrated photonic crystal, microcavity light-emitting diodes pumped in pulsed mode with a heat sink [71].

There has also been other recent work on incorporating quantum dot active regions into photonic crystal laser cavities. Quantum dot active regions have the potential to reduce any surface recombination loss in these cavities through the incorporation of in-plane potential wells. Two-dimensional photonic crystal defect cavities, using InAs

quantum dots as the active material, were first reported and characterized by Reese et al. [72]. Microcavities formed by removing 37 and 61 air holes out of an otherwise perfect triangular lattice photonic crystal were reported in this work. Measured photoluminescence spectra show several high Q cavity modes among the more than 100 possible resonant modes inside the cavity. Modes with quality factors higher than 1000 are obtained from the spectra. Later, photonic crystal cavities with single and seven air holes removed from the lattice with a cavity quality factor as high as 4000 were observed [3]. Yoshie et al. have published results on two-dimensional, photonic crystal, single-defect cavities using self-organized InAs quantum dots [73]. Later, this same group employed a new cavity design based on fractional edge dislocations to obtain a high-quality, single defect cavity within a two-dimensional triangular lattice photonic crystal slab [74]. Donor modes were observed and the measured quality factor as high as 2800 was achieved in a cavity using the InAs quantum dots as the emitter. Room temperature, optically pumped, InAs quantum dot photonic crystal lasers were first demonstrated using a coupled cavity design [75]. Lasing is observed for both the coupled two-defect and four-defect cavities in a square lattice photonic crystal with the threshold pump powers of 120 and 370 μW, respectively.

Larger cavities have also been formed by removing multiple holes from the lattice. Photonic crystal defect lasers with 19 holes removed from the triangular lattice have been reported by Lee et al. [76]. An 860-nm top-emitting, vertical-cavity, surface-emitting laser (VCSEL) was used to optically pump the photonic crystal lasers. The lowest threshold pump power reported in this geometry was 0.5 mW. The corresponding threshold carrier density was estimated to be 1.2×10^{17} cm^{-3} per quantum well. Approximately 2 μW of peak output power was collected vertically and fiber coupled using this structure. This laser and the previously mentioned laser employ a photonic crystal in a suspended membrane. This has the serious disadvantage of being a very poor geometry in which to dissipate heat. To make a more thermally conductive photonic crystal defect laser structure than the suspended membrane, Hwang et al. proposed a design that involves bonding a AlAs layer to the thin slab and later oxidizing it into a low-index AlO$_x$ layer [77]. They reported pulsed lasing action for defect cavities with 37 or more holes removed from the hexagonal lattice. Another effort of integrating the photonic crystal defect lasers with other materials was made by Monat et al. [78]. They employ the SiO$_2$-SiO$_2$ wafer-bonding technique to integrate the defect lasers onto a silicon wafer. The defect cavity with 61 holes removed from the hexagonal lattice was sandwiched between air and the SiO$_2$ layer. Quality factors of the resonant modes in the cavity can be as high as 700.

Modes and their corresponding radiation patterns have also been investigated in these lasers. Shin et al. reported on investigations of the far fields and near fields of various lasing modes in photonic crystal lasers [79]. The cavities they measured are rather large with "radii" of 11, 13, 21, 29, or 31 missing holes along the K direction of the hexagonal lattice. Cavities with a "radius" of 11 lattice constants have 91 holes removed from the photonic crystal lattice. The cavity in these demonstration is, of course, hexagonal shaped and not circular. These cavities, therefore, support

dozens of resonant modes. By slightly adjusting the alignment of the optical pump beam, different lasing modes can be selectively excited. The observed lasing modes were divided into two categories: one-dimensional modes and two-dimensional modes. The one-dimensional modes were plane wave-like modes that oscillate between two parallel boundaries of the hexagonal cavity. These are TE-polarized as confirmed experimentally from the polarization-resolved emission patterns. Two-dimensional modes are observed for larger lattice constants and for cavities with at least 11 defects along the K direction. A 21-defect cavity, for example, had only one-dimensional lasing modes for lattice constants 370 nm and 400 nm. Two-dimensional lasing modes began to appear when the lattice constant was 440 nm. At the lattice constant 490 nm, only the two-dimensional mode was present. The spectrally resolved, near-field intensity distributions of the resonant modes inside the defect cavity were reported for the first time using a scanning optical microscope. The near-field images of the one-dimensional lasing modes reveal that the intensity decays within a few lattice periods into the photonic crystals. The images of the two-dimensional lasing modes indicated that intensity was mainly distributed along the cavity boundary.

All of the experimental results previously discussed were under pulsed operation at room temperature. The only continuous room temperature operation of photonic crystal defect lasers was reported by Hwang et al. [80]. This demonstration utilized the same structure as in [77], but the cavity size in this case is larger (21 defects along the K direction of the hexagonal cavity forming a cavity approximately 10 μm in diameter). The Al$_2$O$_3$ layer acts not only as the low-index cladding material but also as a thermally conductive layer to dissipate heat more efficiently.

Pulsed operation of photonic crystal lasers above room temperature has also been reported by Lee et al. [81]. The laser cavity design in this demonstration was the same as in [76]. Lasing action was observed for substrate temperatures as high as 50 °C. The effects of temperature on the performance of photonic crystal defect lasers were investigated in [81]. Temperature-dependent measurements of the lasing wavelength and the threshold pump power were reported. It was found that the lasing wavelength increased with substrate temperature at a rate of approximately 0.5 Å/K and the near linear red shift of the lasing wavelength was dominated by the refractive index change of the semiconductor media. The threshold input pump powers measured for substrate temperatures 20 °C, 35 °C, and 50 °C were 3.2 mW, 5.3 mW, and 7.4 mW, respectively.

As described earlier, one advantage of photonic crystal defect lasers is that the lasing wavelength, polarization, and emission direction of the mode can be easily engineered by lithographically changing the geometry of the devices. Using this idea, a 10×10 multi-wavelength photonic crystal laser array of single-defect cavities was demonstrated by Painter et al. [82]. A tuning range from 1500 nm to 1625 nm with a 10-nm wavelength spacing from device to device was reported. Later Cao et al. reported a wavelength separation of approximately 4.6 nm between adjacent devices with lattice constants varying in 2 nm increments [83]. This multi-wavelength array consisted of 31 cavities. This demonstration utilized a larger cavity, 19 holes missing from the lattice.

Although multiple modes exist within such cavities, approximately 20 dB SMSR was reported in that work.

No work has been reported to date on the dynamics of these lasers. It is interesting to consider the effects of the small cavity volume that these defect photonic crystal lasers possess might have on the dynamic properties of these lasers. Experimentally, these questions will most easily be answered for lasers that can be operated CW.

Much work has been done in the last few years to make photonic crystal lasers a reality. There is a great deal of work remaining, however, if photonic crystal lasers are to become a mature, practical, photonics technology. Room temperature, CW, and electrically pumped lasing will be required. To achieve this, the investigation and minimization of absorption losses in these microcavity devices as well as innovative design strategies will be necessary. Strategies for increasing the output power from these lasers may also be required. These are daunting challenges. However, considering how far this technology has come in such a brief time, there is no reason to expect that these challenges cannot be met.

GLOSSARY

Compound semiconductor Semiconductors that are composed of multiple elements.

Finite-difference time-domain A marching-in-time method that simulates the continuous fields by volumetric sampling of the unknown fields within and surrounding the structure of interest.

Finite element method An approximate method for solving partial differential equations by replacing continuous functions by piecewise approximations defined on polygons, which are referred to as elements.

Laser Devices that generate or amplify coherent radiation at frequencies in the infrared, visible, or ultraviolet regions of the electromagnetic spectrum.

Microcavity Spatial distributions of dielectric function that exhibit confinement of light.

Photonic bandgap A range of electromagnetic radiation frequency in which no propagation modes exist.

Photonic crystal Materials with a periodically varying dielectric function.

Quantum dot Nanoscale impurity domains in semiconductors that have quantum confinement effects on electrons in all three dimensions.

Quantum well Thin slab structures in semiconductors that have quantum confinement effects on electrons in the direction orthogonal to the slab.

Resonant cavity Microcavities that exhibit confinement on fields for certain frequencies.

Phthalocyanine Nanostructures

Eunkyoung Kim

Korea Research Institute of Chemical Technology, Yusung, Daejeon, Korea

CONTENTS

1. INTRODUCTION

Phthalocyanine (**1**) is a very important organic macrocycle, with many applications for its photochemical, photophysical, optical, and electrochemical properties, biological functions, and high stability [1].
1 (M = H2, or metal oxo, metal halide, etc.)

Having mainly two characteristic absorption bands, a Soret band (300–400 nm) and a Q-band (600–800 nm), phthalocyanine (Pc) and its derivatives show characteristic color as well as photo- and electrochemical properties. They are extensively used as pigments and dyes, and they are models for biologically important species such as porphyrins, hemoglobin, and chlorophyll. They can be applied in chemical sensors, especially for the detection of NO_2 [2], in optoelectronic devices [3], solar cells [4], and well-behaved field effect transistors [5], molecular metals, conducting polymers, sulfur effluent pollutant control, and in optical storage devices [1]. Their catalytic properties have been studied for some time [6], most recently for redox catalysis such as in fuel cell applications [7–9].

Recently the assemblies of phthalocyanines have attracted intense attention since the elucidation of the structure of the light-harvesting antenna LH2 in a natural purple photosynthetic bacterium [10]. Furthermore, a large number of phthalocyanine doped or bound polymers involving various metals have been prepared to enhance and tailor these properties and to facilitate the exploitation of Pcs in such applications [11]. For example phthalocyanine embedded in some organic polymers has been applied in optical recording materials, which records with the infrared (IR)-laser hole burning technique [12, 13].

An important step in the development of Pcs for these application is the precise manipulation of molecular arrangements. This precise manipulation allows directional transport of electrons, photons, and ions. In this context, a number of Pc molecules have been assembled into controlled nanoscaled structures through covalent and noncovalent bonds, by controlling the intermolecular interactions in all ranges (van der Waals, electrostatic, covalent) and molecular symmetry. For molecular self-assemblies, relatively weak and reversible noncovalent types of interactions are involved. Such interactions are electrostatic, van der Waals, hydrogen bonding, hydrophobic interaction, etc.

Covalently bonded nanoscaled Pc macromers are constructed by a polymerization method. It is a subject of great importance because it controls the aggregation of Pcs and macroscopic properties of nanoscopic molecular devices [14]. Several strategies have been explored to construct Pc polymers using different monomers and polymerization methods. The control of spatial arrangement and orientation of these planar π-conjugated compounds promised the creation or modification of functions and properties of molecular organizations. This chapter provides an overview on nanoscaled Pc assemblies and Pc polymers.

2. PHTHALOCYANINE THIN FILMS

Phthalocyanines having planar structures form thin films with a film thickness at the nanometer level. Thin films containing phthalocyanines have attracted a lot of interest

in the past decade [15–32]. Several strategies were implemented to build up phthalocyanine thin films: spin coating [33–36], casting in matrixes such as bilayer membranes or thermotropic liquid crystals [30, 37], deposition by the Langmuir–Blodgett technique [20, 23, 31, 37b–43], or self-assembly [15, 16, 18, 25–29, 44]. The latter method appears to be very attractive since it provides a stable chemical linkage between the substrate and the macrocycles. Pcs were attached to mineral substrates via electrostatic interactions [16, 25, 26, 45], sulfur-to-gold bonds [18, 27, 46], or complexation between bound ligands and metal centers [15, 28, 47].

Thin films are more generally deposited to a thin film by the vacuum deposition method [48–59]. Vacuum deposition on a highly ordered support such as MoS [60], metal [56, 59], or alkali halide surfaces (100) [61–66] tends to produce well-defined film structures. Organic molecular beam deposition (OMBE) provides various film phases of tri- and tetravalent metallophthalocyanines such as AlPcCl, InPcCl, TiOPc, and VOPc; some of these phases exhibit a highly redshifted Q-band in its electronic spectrum [67, 68]. This redshift originates from lateral stacking of the molecules in the film structure, which has been reported for cyanine aggregates [69–71] and is usually described by exciton coupling [71–73]. On the other hand, bivalent metallophthalocyanines prefer a coplanar central stacking owing to missing axial ligands and provide a blueshifted Q-band [39, 72, 74]. Nonplanar PbPc molecules were found [75] to have three adsorption phases on MoS_2 in ultrahigh vacuum (UHV), instead of the two phases observed for CuPc on the same surface. For CuPc, a close-packed phase with a square unit cell and a rowlike phase were observed. For PbPc, the additional adsorption phase comprised three adjacent close-packed rows separated by one or two isolated single rows. Molecularly resolved images of PbPc on MoS_2 show two different adsorption geometries, with the Pb atom above or below the Pc plane (the molecule is nonplanar). Different phases and structures in the Pc films depending on the metal, substituent, and the film thickness are described.

2.1. Metal-Free Phthalocyanine (H₂Pc)

Two different polymorphic forms of free base phthalocyanine films have been grown on glass substrates by UHV organic molecular beam deposition. Postgrowth annealing of films grown at room temperature leads to transformation from the α to the β_1 phase [76]. The effects of annealing lead to a number of transition states whose morphological, structural, and spectroscopic properties can be identified using atomic force and optical interference microscopy, X-ray diffraction, and Raman and electronic absorption spectroscopy. Detailed morphological studies indicate that the transition occurs via a discrete number of nucleations and is preceded by an elongation of the α crystallites. The film thickness plays a critical role and three regimes have been identified. The $\alpha \rightarrow \beta_1$ transformation is only complete for films thicker than ~940 Å, and thick films lead to a higher degree of orientation and larger domains.

The morphology of the samples annealed for different times was assessed using atomic force microscopy (AFM) (Fig. 1). A film grown at room temperature with no annealing is shown as a reference in (a) and displays the high
Figure 1. AFM images of 2330 Å thick H₂Pc films as a function of annealing time: (a) no anneal, (b) 1.0 h, α phase, (c) 1.0 h, β_1 phase (minor component), (d) 1.25 h and (e) 2.0 h. Reprinted with permission from [76], S. Heutz et al., *J. Phys. Chem. B* 104, 7124 (2000). © 2000, American Chemical Society.

density of spherical islands that characterizes the α phase [77]. The first changes become apparent after annealing for 0.75 h. The underlying surface morphology is similar to that seen for growth at room temperature, but closer inspection reveals some elongation of the spheres and the presence of several larger islands on the surface, with a typical diameter of 0.2–0.3 μm. Elongation of the α spheres becomes more pronounced after annealing for 1 h (b). This elongation prior to transformation has been reported in a previous electron microscopy study of CuPc films on muscovite [78]. Larger islands are also present on the surface, although these have not increased in size and number (number density of islands $\cong 4$ μm^{-1}). A small proportion of the sample displays regions covered in oriented slender crystallites (c). These areas are at least 49 μm^2, the typical area of an AFM image, and are characteristic of a pure β_1 phase film [77]. The organized growth of the β_1 phase therefore starts after 1 h annealing, consistent with the Raman spectra shown in Figure 2. After 1.25 h annealing the surface is completely covered with the long thin crystals of the β_1 phase. The crystallites are parallel to each other over large areas, and a boundary between two domains of different orientations can be seen in (d). Annealing for longer times leads to no appreciable change in the surface morphology until after 2 h (e). At this point, the appearance of smooth areas between remaining islands of β_1 crystals indicates that the β_1 phase crystals have grown together and there only remain a few well-defined thin β_1 crystallites, mostly arranged in columns. However, the domain boundaries are still present and there are some features reminiscent of the oriented crystallites in the smooth areas, indicating that these have been formed by the merging of the slender β_1 crystallites.

Figure 3 shows the effect of film thickness on the larger scale morphology of the β_1 phase. For the thinnest film for which it is possible to induce the $\alpha \rightarrow \beta_1$ transformation, the result is isolated areas of fernlike morphology (a). There are large areas of nontransformed material between the β_1 phase islands, and there is also space between the individual strands of the fernlike islands. When the starting film is slightly thicker, the β_1 islands are larger, but they are still isolated from one another (b). This correlates well with the AFM results, which showed discrete domains of α and β_1 phase H₂Pc. Figure 3c shows a sample that has the features
Figure 2. Resonance Raman spectra of 2330 Å H$_2$Pc films acquired with a 632.8 nm laser source. (a) and (b) are reference spectra for β_1 and α films, respectively. Different annealing times are shown: (c) 0.75 h, (d) 1.0 h, α phase, (e) 1.0 h, β_1 phase, (f) 1.25 h, (g) 1.5 h, and (h) 2.0 h. The ratio of α (d) to β_1 (e) for the film annealed for 1 h is approximately 5:2. Reprinted with permission from [76], S. Heutz et al., *J. Phys. Chem. B* 104, 7124 (2000). © 2000, American Chemical Society.

typical of all films above a critical thickness where the transformation is complete (i.e., 940 Å). The surface is covered entirely by domains of aligned β_1 phase crystals. On close inspection this thicker film can be seen to exhibit the same fernlike fine structure as the thinner films, but there is no
Figure 3. Nomarski micrographs of H$_2$Pc films annealed for 2 h at 325 °C, for different film thicknesses: (a) 560, (b) 990, and (c) 4880 Å. The thinnest film shows nucleation of the β_1 phase and a fernlike morphology. Increasing thickness leads to an increase in the domain size. Reprinted with permission from [76], S. Heutz et al., *J. Phys. Chem. B* 104, 7124 (2000). © 2000, American Chemical Society.

interlying space between the individual strands. It can be seen without any quantitative analysis that the size of the domains increases with film thickness for a given annealing time and temperature. This is a direct consequence of the higher degree of alignment observed of the crystallites for the thickest film.

These observations suggest three regimes of behavior for films of different thickness. The extreme case is for thin films (i.e., less than 560 Å). In this case there is not enough material to facilitate any transformation from the α phase to the β_1. This is consistent with the suggestion that particles of the size found in these films are more stable in the α phase than in β_1. For film thicknesses between 560 and 940 Å, only partial transformation of the film occurs, indicating that the film is thick enough to allow transformation, but there is not enough material on the surface to ensure continuity of the film during transformation. Clearly, the β_1 phase grows at the expense of the α phase directly in contact with it. The transformation occurs via discrete nucleations, since the remaining α areas coexist and do not intermix with completely transformed β_1 phase regions. It is also likely that since the transformation is very close to the sublimation point, the regions that have not been transformed are thin enough to be in the regime where the α phase is more stable than the β_1. For film thicknesses above 940 Å, both the size of the α phase crystallites and the thickness of the film (and hence its continuity) allow complete transformation of the film.

2.2. Copper (II) Phthalocyanine

Vacume deposited thin films of metal phthalocyanines such as copper (CuPc) [52, 58, 59, 79–82], lead (PbPc) [75] cobalt (CoPc), iron (FePc), and nickel (NiPc) [83] phthalocyanines have prepared and their film structures have been examined using scanning tunneling microscopy (STM). For example, a 0.3-nm layer of copper (II) phthalocyanine could be deposited on Au (111) to form a near monolayer [56, 59]. Tanaka and co-workers [81] observed that planar CuPc molecules are bonded in a stable manner on the SrTiO$_3$ surface in UHV, whereas CuPc can diffuse on the much less chemically active Cu (111) surface to create low-dimensional structures. Maeda et al. [58] and Kanai et al. [52] obtained similar results in UHV, showing that CuPc molecules have three adsorption configurations on the dimer row of Si (100) with the molecular plane parallel to the surface, dominated by the interaction between the aromatic rings of CuPc molecules and Si dangling bonds. Kanai et al. [52] also observed a distinctive bias-voltage dependence of the STM images of CuPc molecules on Si (111) in UHV, suggesting that there is a strong interaction between the molecule and the surface.

On the H-passivated Si (111) surface, the stacking and orientation of CuPc in UHV were found to be affected by the surface roughness [79]. On a rough surface, the CuPc molecules are stacked with the molecular columns parallel to the surface, whereas on an atomically flat surface, the CuPc molecules are stacked in columns perpendicular to the surface. Interestingly, CuPc was found [84] to induce faceting of misoriented Ag (110).

In most cases, the predominant features of the molecular image show organic material alone with an apparent hole in the center of the molecule as shown in Figure 4 for a 0.3 nm layer of CuPc on Au (111) [56].

The four-leaf pattern of the phthalocyanine ring is clearly observed, with a hole in the center of the macrocycle. The Cu atom is not participating in the tunneling process. This result was also obtained with Pt/Ir tips and a variety of bias voltages and currents. The image for H_2Pc also shows an apparent hole in the center of the molecule [55]. The explanation for these "holes" was that both the occupied and unoccupied orbitals localized on Cu lay more than 1 eV from the Fermi energy, while the MPc ligand lowest unoccupied molecular orbital (LUMO) lay close to the Fermi energy [57]. As the metal in an MPc system is varied, the corresponding variation in metal d orbital participation near the Fermi surface should produce significant changes in the STM images. Alternatively, dramatic changes in the apparent molecular shape might also occur in systems where interactions between the metal d orbitals and a metallic substrate were significant. In the latter case, the metal surface density of states might "shine through," giving enhanced height to the central metal.

Calculations [85, 86] show that the CoPc dz^2 orbital is roughly half-filled and lies very near the ligand highest occupied molecular orbital (HOMO). Calculations place the filled CuPc dz^2 orbital about 2 eV below the ligand HOMO, and there is no significant d orbital contribution within a band 1 eV above and 2 eV below the ligand HOMO in CuPc [85]. STM images of CoPc and CuPc on Au (111) are fully consistent both with d orbital contribution and with these theoretical results [87]. STM images of CoPc and CuPc show that CuPc molecules have an apparent hole in the center of the ring, while CoPc units have what appears to be a very tall atom in the center. On the basis of crude orbital

energy arguments [88] (see Fig. 5) and the expectation that tunneling from the metal substrate to the STM tip will be most enhanced when the orbitals have a spatial distribution consistent with carrying charge from below to above the molecular plane, the apparent height of Co(II) relative to the Cu(II) in MPc complexes is easily rationalized as due to the half-filled dz^2 orbital.

The influence of steps on the orientation of copper phthalocyanine monolayers on Au (111) was investigated using scanning tunneling microscopy and low-energy electron diffraction [89]. CuPc molecules adsorb with their molecular plane parallel to the surface and form a highly ordered overlayer with a square unit cell. On terraces wider than ~15 nm, the orientation of the monolayer is determined by the underlying substrate and the sides of CuPc square unit cells coincide very closely with the {112} and {110} directions of the Au (111) surface. On narrow terraces, the sides of the CuPc unit cells are aligned along the step edges. This effect is explained in terms of the maximization of coverage which favors the formation of the CuPc domains where the molecules are aligned parallel to the step edges.

Figure 6a shows an STM image of a monolayer (ML) thick CuPc film on a Au (111) surface. A monolayer is defined as the amount of deposited CuPc that entirely covers the substrate surface. As evident from this image,

Figure 4. Top view STM image of a 0.3-nm layer of CuPc on Au (111) obtained with a W tip, +0.94 V sample bias, and 140 pA tunneling current. The image was Fourier filtered to reduce noise. Figure 6. (a) STM image (70 × 70 nm^2, sample bias voltage $V_S =$ −1.36 V, $I = 0.14$ nA) of the 1 ML CuPc film on Au(111). The dashed line marks the direction of the rows of CuPc square unit cells. The solid line follows the [112] direction of the Au(111) substrate which is defined by the line connecting the apexes of the bends of the Au(111) zigzag corrugation pattern. The CuPc molecular rows are aligned with the [112] direction within a ∼2° angle. (b) STM image (35 × 35 nm^2, $V_S =$ −1.50 V, $I = 0.12$ nA) of a 1 ML CuPc film. The square unit cell of the CuPc monolayer is outlined. Dashed lines follow the [112] direction of the Au(111) substrate. Arrows indicate the shifts of the CuPc molecular rows at the bends of the Au(111) zigzag corrugations. Crystalline directions of the Au(111) surface are shown on both images. Reprinted with permission from [89], I. Chizhov et al., *Langmuir* **16**, 4358 (2000). © 2000, American Chemical Society.

CuPc molecules form an almost perfectly ordered layer. The molecular pattern corresponds to a square unit cell with dimensions of 15 Å × 15 Å as determined directly from the STM images (the absolute accuracy of the STM distance measurements is estimated to be ∼10%). The zigzag pattern that appears in the image is due to the corrugation of the underlying reconstructed Au (111) substrate and allows for a straightforward determination of the azimuthal orientation of the molecular layer with respect to the substrate lattice directions. The sides of the CuPc unit cell are very closely oriented to the {112} and {110} crystalline directions of the Au (111) lattice. This is illustrated in Figure 6a where the solid line indicates the direction of the CuPc molecular rows and the dashed line, which connects the apexes of the bends of the Au (111) zigzag pattern, indicates the {112} direction of Au (111). As determined from several STM images, the angle between the CuPc rows and the {112} direction ranges from ∼1° to ∼3° with the average value of ∼2°.

A close-up STM image of the CuPc monolayer (Fig. 6b) shows the distinctive four-leaf shape of the CuPc molecules and their arrangement in a square unit cell (the unit cell is marked on the image). The molecular rows along the {110} direction undergo a lateral shift near the bend of the Au (111) zigzag corrugations, as shown by the solid lines and arrows in Figure 6b. This shift is accompanied by a change in rotational orientation of the individual CuPc molecules, as evident from Figure 6b, but without change in the unit cell dimensions.

Figure 7a covers a wide terrace on the right and narrow terraces in the center and on the left. On narrow terraces, the molecular rows are aligned parallel to the step edges and actually follow the contour of these step edges. The influence of steps on the ordering of CuPc molecules is evident also on wide terraces near the step edges, where a region of disordered CuPc molecules is seen (Fig. 7a). The width
Figure 7. (a) STM image (50 × 50 nm^2, $V_S =$ −1.70 V, $I = 0.12$ nA) of a 1 ML CuPc film in a stepped region of the Au(111) surface. Solid lines show the alignment of the CuPc molecular rows along the step edges on narrow terraces. (b) Close-up STM image (30 × 30 nm^2, $V_S =$ +1.32 V, $I = 0.13$ nA) of the area with two Au steps covered with 1 ML of CuPc. Reprinted with permission from [89], L. Chizhov et al., *Langmuir* **16**, 4358 (2000). © 2000, American Chemical Society.

of the terraces, on which the CuPc molecules are aligned parallel to the step edges, can be as large as 15 nm.

The majority of steps on Au (111) run along the {110} direction. Thus, the orientation of CuPc molecules on narrow terraces formed by steps running along this direction coincides with the orientation of CuPc unit cells on wider terraces, where the orientation is defined by the {112} and {110} directions of the Au (111) substrate. An STM image in Figure 7b is an example of this situation. As on wider terraces, the CuPc molecules form a square grid pattern with a square unit cell and sides parallel/perpendicular to the step edges. However, on Au (111) steps that do not run along these directions, the CuPc molecules form rows which follow the contours of the steps (see Fig. 7a).

2.3. NiPc and FePc

Iron(II) phthalocyanine (FePc) and nickel(II) phthalocyanine (NiPc) can be adsorbed on the Au(111) surface and provide STM images showing submolecular structure [56]. Interestingly, image contrast depended upon the identity of the central metal ion. Unlike NiPc, wherein the central metal appears as a hole in the molecular image, the iron ion in FePc is the highest point (about 0.25 nm) in the molecular image. These data are interpreted as indicating that the Fe(II) d^6 system has significant d orbital character near the Fermi energy while the Ni(II) d^8 system does not. This interpretation is consistent with theoretical calculations that predict a large contribution of iron d orbitals near the Fermi energy.

Figure 8 presents good quality images of both NiPc and FePc that had once been exposed to air. The four-leaf pattern of the phthalocyanine ring is clearly observed, as is the hole (dark area) in the center of every NiPc molecule. On the other hand, the center of every FePc has a large hill (bright spot). The FePc images were always highest in the center, while the NiPc images always appear to have holes where the Ni(II) should be.

A cross section image of a FePc sample (once exposed to air) shows the detailed variation with height observed as a function of position over the FePc as seen in Figure 9.
Figure 8. Top view STM images of a 0.4 nm thick layer of NiPc and of 0.3 nm of FePc on Au(111) obtained with a W tip. Both samples had MPc layers that had once been exposed to air. The gray scale extends over 0.3 nm. For NiPc the sample bias was +0.50 V and the tunneling current was 300 pA. For FePc the sample bias was +0.10 V and the tunneling current was 1.6 nA. The image was Fourier filtered to reduce noise. Reprinted with permission from [83], X. Lu and K. W. Hipps, *J. Phys. Chem. B* 101, 5391 (1997). © 1997, American Chemical Society.

The cross section was chosen to pass through the center of an FePc molecule (bottom center of image), across the benzene rings of two different arms of adjacent FePcs, and again through the center of another FePc, in a repeating pattern. In this image, the benzene rings all appear to be of roughly equal height (about 0.17 nm) and somewhat taller than the carbons of the five-member rings and the peripheral (noncoordinating) nitrogens. The Fe^{2+} ion region appears to be about 0.25 nm high, defining the total molecular height.
Figure 9. Top view and sectional STM image of a 0.3 nm thick layer of FePc adsorbed on Au (111). The FePc was once exposed to air. The image was obtained with a PtIr tip at a sample bias of +0.15 V and a fixed tunneling current of 300 pA. Reprinted with permission from [83], X. Lu and K. W. Hipps, *J. Phys. Chem. B* 101, 5391 (1997). © 1997, American Chemical Society.

Oxygen contamination during sample transfer between UHV systems also affects the images as presented in Figure 10, wherein both a top view and sectional view are shown. While the maximum height of the FePc now appears to be about 0.20 nm, the benzene rings now appear only about 0.11 nm tall, making the relative height of the central metal even greater than in the once air exposed sample. Moreover, the relative resolution is clearly better than in Figure 9, since the drop in apparent height over the inner carbon atoms and the noncoordinating nitrogens is more clearly observed.

It is well known that both the electron density and the local density of surface states near the Fermi energy play a critical role in determining the STM image as observed for other examples [90, 91]. STM imaging of electronegative or electropositive elements, for example, can result in the observation of anomalous heights [92]. Another example is the observation of the dangling bonds on the silicon surface [93]. In the present case of Pc, the occupancy of the *d* orbitals is playing a significant role in the STM image. In these examples, Fe(II) may be acting as a conductor while Ni(II) may not be. Since the STM images reflect contours of constant current, the tip must dip toward the Au surface above the Ni(II) center and pull back from the Fe(II) in order to maintain constant current flow. There are, however, at least three separate mechanisms that could lead to the observed differences in height [83].

A different metalloporphyrin, Ni(II) octaethylporphyrin (NiOEP), was investigated by STM imaging [94]. Figure 11 is a typical constant current image of NiOEP on Au (111) observed at low resolution. In this image the individual NiOEP molecules appear as dots making up well-defined single molecule thick islands (e.g., region A). The regions
Figure 10. Top view and cross-sectional plot of a 0.2 nm thick FePc film on Au(111) prepared and measured in the STM UHV chamber. A PtIr tip was used at a sample bias of −0.50 V and a current of 400 pA. Reprinted with permission from [83], X. Lu and K. W. Hipps, *J. Phys. Chem. B* 101, 5391 (1997). © 1997, American Chemical Society.
Figure 11. A typical constant current image of NiOEP on Au(111) observed at low resolution. The image was obtained with a W tip at a sample bias voltage of −1.2 V and a set point of 300 pA. The image has been flattened. The region marked B is uncovered Au(111) and the region marked A is a single molecule thick layer of NiOEP. The area marked C is a single gold atomic step. Reprinted with permission from [94], L. Scudiero et al., *J. Phys. Chem. B* 106, 996 (2002). © 2002, American Chemical Society.

Figure 12. High-resolution constant current STM image of NiOEP at near-monolayer coverage on Au(111). The image was acquired with a W tip at −0.6 V bias, with a setpoint of 0.3 nA. The image was flattened and low-pass filtered. Inset is a group of CPK models arranged as a single unit cell. Reprinted with permission from [94], L. Scudiero et al., *J. Phys. Chem. B* 106, 996 (2002). © 2002, American Chemical Society.

between the islands (e.g., region B) appear to be uncovered Au (111) surface and the *I–V* curves obtained in these regions are similar to those from porphyrin-free substrates. The large height step (feature C) along the lower right side of the figure is due to a monatomic step of the Au (111) substrate. One can also observe striations running through both the NiOEP islands and portions of the uncovered surface. These are due to reconstruction of the Au (111) surface and appear as pairs of lines. The small grain gold films used in this study (about 0.3 m in diameter) generally have a larger reconstruction line spacing than is seen on large single-crystal Au (111) surfaces. Unlike true single-crystal gold [95], these small crystal grains show reconstruction line spacing ranging from 6.3 to about 9.0 nm.

Figure 12 is a high-resolution image of NiOEP on Au (111) that clearly shows the fourfold symmetry expected for the molecule and the somewhat dark center associated with the central Ni(II) ion. The metal ion contrast has been explained in terms of occupation of the d_z^2 orbital. Also shown as an inset in Figure 12 are space filling (CPK) models of NiOEP placed to form a single primitive surface unit cell with basis vectors of length 1.65 and 2.76 ± 0.20 nm. Note that there are two molecules per unit cell because of the small angular offset (ca. 15) of alternating rows. Another interesting aspect of the NiOEP image is the prominence of the ethyl groups. While the individual hydrogens cannot be resolved, the terminal methyl groups are clearly seen with contrast similar to, but slightly greater than, the OEP ring. Moreover all the ethyl groups are turned up so that there is maximal contact between the OEP ring and the gold surface (as shown in Fig. 13).

The mechanism by which the ethyl groups attain their prominence in the STM image is of interest. The porphyrin ring shows good contrast because of both HOMO- and LUMO-mediated tunneling in the energy region close to EF (vide infra).

Figure 13. CPK model of a typical metal(II) OEP. The four nitrogens that bind the central metal ion are shown in light gray. The molecule is shown both in top and side view. The configuration of the ethyl groups is chosen to be consistent with the structure of NiOEP adsorbed on Au(111). Reprinted with permission from [94], L. Scudiero et al., *J. Phys. Chem. B* 106, 996 (2002). © 2002, American Chemical Society.

2.4. TiOPc

TiOPc is a nonplanar polar molecule [96] with the titanyl group located perpendicular to the macrocycle and the outer phenyl rings making an angle of 7° with respect to the C–N inner ring [97]. Both the nonplanarity and the dipolar character of the molecule result in a specific polymorphism that differs significantly from that of planar phthalocyanines. Crystal structures have been reported so far [1, 97, 98], a monoclinic phase I, a triclinic phase II (hereafter α-TiOPc), and a triclinic phase Y (Fig. 14) [96, 98]. Moreover, in α-TiOPc, the geometry of the molecule was found to be strongly distorted with respect to molecules in solution: the molecular symmetry is reduced from C_{4v} to C_1. This molecular distortion was attributed to strong π–π interactions [96].

As for planar phthalocyanines, polymorphism governs the crystal packing in thin films and is found to depend strongly on the growth conditions (substrate temperature, deposition rate, and nature of the substrate) [99–102]. The optical properties (absorption, photoconductivity, and second harmonic generation) turn out to be correlated with the crystal structure of the films [100, 101, 103]. Thin films of α-TiOPc (phase II) show the largest third-order nonlinear susceptibility ($X^3 = 1.7 \times 10^{-10}$ esu) [104].

Highly oriented films of titanyl phthalocyanine (TiOPc) were obtained by high-vacuum sublimation onto an oriented poly(tetrafluoroethylene) (PTFE) substrate [99b]. In Figure 15, the evolution of the thin film morphology is deficted as probed by AFM as a function of increasing T_s in the range of 75–200 °C for films with thicknesses of 40–50 nm.

For $T_s = 75$ °C, the films consist of a dense packing of small grains (mean radius around 35 nm) completely covering the PTFE substrate. The PTFE macrosteps are decorated by larger grains whose shape reflects that of the crystalline TiOPc phase. This observation suggests that TiOPc films grown at $T_s < 75$ °C onto oriented PTFE consist of an amorphouslike material (hereafter a-TiOPc) with a few microcrystallites localized at the PTFE macrosteps.

Figure 15. Evolution of the film morphology probed by AFM in TiOPc thin films of thickness in the range of 40–50 nm grown onto an oriented PTFE substrate. Films were obtained at different substrate temperatures in the range of 75–200 °C at a constant deposition rate of 0.8–1.0 nm/min. Reprinted with permission from [99b], M. Brinkmann et al., *Chem. Mater.* 14, 904 (2002). © 2002, American Chemical Society.

The grain size distribution is rather broad and suggests that coarsening has already occurred during growth.

For $T_s = 85$ °C (Fig. 15), two type of grains are observed: (i) small spherically shaped aggregates of radius <40 nm and (ii) larger crystalline domains of size 50–150 nm with a wedgelike shape. The majority of the crystalline domains are not preferentially oriented on the PTFE. Similar to the observations for $T_s = 75$ °C, the larger crystalline domains are located along the PTFE macrosteps. A closer examination of the film morphology reveals that the larger crystalline domains do not have flat surfaces but are composed of smaller aggregates that have coalesced. The preferential location of the larger crystalline domains along PTFE terraces suggests that nucleation of a-TiOPc is heterogeneous.

The morphology is found to change drastically around $T_s = 100$ °C. The films show a continuous (coverage close to 100%) and polycrystalline texture consisting of large trapezoidal crystallites. The ratio of the film thickness to the in-plane size of the microcrystallites lies in the range of 0.1–0.3. This indicates that the platelet-shaped microcrystallites lie flat on the PTFE substrate. Well-oriented pyramid-like microcrystallites protrude on the surface of the uniform textured film. These crystallites likely correspond to secondary nuclei grown in a homoepitaxial manner on the underlying TiOPc film. The absence of depletion zones around existing crystallites in conjunction with the continuous film texture suggests again that growth is not driven by Ostwald ripening.

Increasing T_s to 200 °C results in a loss of uniformity in the surface coverage, which decreases to approximately 60–75%. The grains show a variety of shapes and orientations. Amid a majority of flat-lying crystallites, a few

crystallites are in an edge-on orientation and are seen by transmission electron microscopy (TEM) as darker needle-shaped crystals. The latter observation is indicative of a progressive loss of preferential orientation with increasing T_s, in agreement with the appearance of additional diffraction spots in the electron diffraction (ED) pattern. At $T_s =$ 100 °C, an original growth mechanism was observed whereby a-TiOPc microcrystallites were formed by the static coalescence and reorganization of small amorphous aggregates in close contact. Nucleation of a-TiOPc is initiated at the PTFE macrosteps from which oriented crystallization propagates, leading to uniform a-TiOPc films with a twinned texture and a dense (0 1 0) contact plane. The molecules are in an edge-on orientation, with their molecular plane oriented parallel to the PTFE chains. At the mesoscale, the nucleation of crystalline a-TiOPc involves the alignment and oriented coalescence of amorphous prenucleation aggregates along the PTFE macrosteps (i.e., a graphoepitaxial process). At the molecular scale, it is proposed that the TiOPc orientation and the preferential nucleation of the a polymorph are enforced by the topography and structure of the PTFE macrosteps in conjunction with the requirement for a minimal nucleation free energy. The optical absorption of the films in the near infrared is found to be strongly correlated with the structural and morphological modifications in the films. The oriented character of the a-TiOPc films results in a strong polarization of the 850-nm band perpendicular to the PTFE chain axis direction.

A perylene phenethylimide/titanyl phthalocyanine bilayer (PPEI/TiOPc) is a typical example of an n-like/p-like molecular semiconductor heterojunction as depicted in Figure 16 [105]. The complex morphologies of the PPEI, TiOPc, and PPEI/TiOPc thin films, at various stages of solvent-vapor annealing, have been directly and spatially resolved by a variety of fluorescence and transmission near-field scanning optical microscopy experiments.

The topographical image of a 10-nm TiOPc film that was annealed for 24 h is shown in Figure 17a. The image shows that the initially amorphous film has restructured to a highly porous film of nanocrystallites ranging in height from the level of the substrate (0 nm) to over 100 nm. The flat profile of the fiber probe is responsible for making the TiOPc crystals appear bigger in the film plane due to a so-called tip artifact. These images reveal sharp pointed TiOPc nanocrystals that are not fully resolved even with sharp AFM tips. The typical in-plane cross-sections of these TiOPc nanocrystals range from <10 to 30 nm. The heights of the crystals, in contrast, are not distorted by the shear-force images and range up to 100 nm.

2.5. Fluorophthalocyanines

Alkali halide surfaces (100) have proven to be useful substrates for studies of organic pigment thin films [61–66]. In particular thin films of fluorinated Pcs have been prepared on an alkali halide surfaces.

Thin films of hexadecafluorophthalocyaninatozinc (F_{16}Pc·Zn) are prepared on amorphous SiO_2 (quartz glass) and on well-ordered NaCl, KCl, and KBr (100) surfaces and are studied by optical absorption and atomic force microscopy [106]. Figure 18 shows the results of a 0.7-nm thin film of
Figure 16. (a) Schematic drawing of a typical geometry for a molecular semiconductor based heterojunction photovoltaic device. (b) Chemical structures of perylene phenethylimide (PPEI) and titanyl phthalocyanine (TiOPc). Reprinted with permission from [105], M. Adams et al., *J. Am. Chem. Soc*. 119, 10608 (1997). © 1997, American Chemical Society.

F_{16}PcZn on NaCl (100) with the {010} and {001} azimuth directions of the substrate indicated in the figure and two height profiles of single scans. Two different classes of F_{16}PcZn particles are observed. A rather high concentration of small but high (3 nm) particles is seen in areas of high densities of NaCl steps, especially found in the directions {010} and {001}. Such behavior was also observed earlier under comparable conditions for the growth of tetrapyridotetraazaporphyrins (TPyTAP) on alkali halide surfaces [65]. Also found, however, are rather extended flat areas (up to about 200 nm in length or width) with a uniform thickness of about 1.2 nm.

In Figure 19 two films (0.7 and 18 nm average thickness) of F_{16}PcZn on KBr are compared. For the thin film, rather small particles, again growing at step edges of the substrate, are observed to be of approximately spherical geometry. Some larger ensembles of particles are detected with an orientation of 27° relative to the KBr {010}. The thicker film mainly consists of well-defined particles of triangular shape with edges about 100–300 nm long, rather flat when compared to the spherical particles of the thinner film. One angle within the triangles almost always equals 90°; the two others often are found between 45° and 50°. The triangular
Figure 17. (a) Topographic image of a 10 nm TiOPc thin film which was vapor-annealed in CH_2Cl_2 for 24 h. Topographic (b) and corresponding polarized fluorescence [(c) and (d)] images of a bilayer assembly PPEI/TiOPc, where a film of PPEI has been vacuum-deposited onto an annealed TiOPc surface [as in (a)] and subsequently vapor-annealed for only 30 min. Topographic (e) and corresponding polarized fluorescence [(f) and (g)] images of PPEI on glass which has been vapor-annealed for 30 min. (h) Topographic image of 300 nm thick film of PPEI on glass which has been vapor-annealed for 48 h. (i) Fluorescence image of an annealed 300 nm PPEI film similar to that shown in image (h). objects as a whole have a preferential orientation of 15–25° of one of their edges relative to KBr {010}, with angles around 18° and 22° most frequently found.

Atomic force microscopy performed on the films grown on the alkali halide surfaces allows further conclusions to be drawn. On NaCl large plateaus of about 1.2-nm height are seen (Fig. 18) aside from a high number of smaller grains of rather unspecific orientation relative to the substrate. The height of 1.2 nm would be explained by arrays of molecules stacked vertical to the surface with two of the benzene moieties in contact with the surface when the size of a $F_{16}PcZn$ molecule is calculated from the distance of 1.32–1.46 nm as detected earlier in crystal lattices [62, 107].

On KBr, a crystallization of $F_{16}PcZn$ along step edges of the substrate is seen (Fig. 19a) as also observed for the growth of TPyTAP on alkali halides [65]. In thicker films, however, well-shaped domains are formed (Fig. 19b) which show a preferential orientation relative to the substrate lattice. To discuss the characteristic angles of 90° and 45–50° within the $F_{16}PcZn$ crystals as well as the preferential alignment of crystal edges along 18° and 22° relative to the {010} of the KBr substrate, calculations were made by considering
Figure 18. (a) Height image of 0.7-nm $F_{16}PcZn$ on NaCl as obtained by AFM in tapping mode with the substrate [010] and [001] azimuth directions indicated as straight lines and (b) single height scans as marked by the arrows. the relative alignment of crystal lattices. In the range of lattice constants (1.32–1.46 nm) as reported for $F_{16}PcZn$, two commensurate square lattices were found relative to the KBr surface mesh, namely $2\sqrt{2} \times 2\sqrt{2}$, $R = 45°$ (A) and $\sqrt{10} \times \sqrt{10}$, $R = 18.4°$ (B). Both square lattices would explain the angle of 90° often observed within the crystals as arising from the {100} and {010} axes of the $F_{16}PcZn$ lattice. Angles around 45° would then correspond to the angle between {100} and {110} of the $F_{16}PcZn$ lattice. Two $F_{16}PcZn$ molecules would be spaced at 1.32 nm in A and at 1.47 nm in B. A distance of 1.32 nm in A is not consistent with the splitting as observed in the ultraviolet-visible (UV-vis) absorption spectra. A lattice constant that small was only detected for films having a considerably larger splitting of the band, redshifting it to 820 nm, a significantly longer wavelength than measured in the present experiments. Further, a preferred orientation of $F_{16}PcZn$ [100] at 26.6° relative to KBr [010] in B is more compatible with the angles of the $F_{16}PcZn$ crystals relative to the substrate as detected in the AFM images.

Thin films of hexadecafluorophthalocyaninatooxovanadium ($F_{16}PcVO$) were vapor-deposited under OMBE conditions on the (100) surfaces of NaCl, KCl, and KBr and on
Figure 19. AFM height image of (a) 0.7-nm and (b) 18-nm (b) F_{16}PcZn on KBr with the substrate [010] and [001] as straight lines. Reprinted with permission from [106], D. Schlettwein et al., *Chem. Mater.* 12, 989 (2000). © 2000, American Chemical Society.

Figure 20. RHEED in the [012] azimuth orientation of (a) 1.4 nm F_{16}PcVO on KBr, (b) 1.6 nm F_{16}PcVO on KCl, and (c) the pattern of expected spots considering the appropriate extinction rules of diffraction. quartz glass and were analyzed by AFM and reflection high energy electron diffraction (RHEED) [108]. Beginning at submonolayer coverages and extending to a film thickness of several tens of nanometers the film structure is determined *in-situ* by RHEED. Figure 20 shows the results obtained at 1.4 and 1.6 nm F_{16}PcVO in the {012} azimuth directions of KBr and KCl. Highly ordered growth of crystalline domains of F_{16}PcVO with dimensions in the micrometer range leading to films of quite uniform thickness is observed. On KBr a commensurate $\sqrt{10} \times \sqrt{10}$, $R = 18.4°$ square lattice is seen in RHEED of the first monolayers with the molecules parallel to the substrate surface which is also preserved at higher film thickness. On KCl a surface lattice of the same size is formed which is, however, understood as a result of point-on-line coincidence. Diffraction of transmitted electrons yields a constant three-dimensional crystal structure of the films on KBr and KCl with a tetragonal unit cell of $a = b = 1.47$ nm and $c = 0.62$ nm. On NaCl with its smaller lattice constant no ordered relative orientation is possible and hence an increased part of the film appears amorphous. On quartz glass, on the other hand, ordered films are formed with the molecular planes predominantly oriented cofacially parallel to each other and vertical to the surface.

In Figure 21a an AFM image as obtained at a 24 nm film of F_{16}PcVO on quartz glass is shown with a typical cross section in Figure 21b. The film consists of two different kinds of domains, rather small walls and larger plateaus. The walls of 50–100 nm diameter are found to reach about 5–10 nm height above a rather flat level and are oriented at angles close to 90° relative to each other which is quite remarkable in view of the amorphous substrate that the film was grown on. Even the plateaus show orientation parallel to each other with some preferred angles (about 40° and 50°) at, however, less pronounced edges when compared to the films on KBr or KCl. The detailed positions of the molecules are proposed as the structure deficted in Figure 22, as concluded from RHEED and UV-vis analysis.

Metallophthalocyanines have been demonstrated to possess remarkable semiconducting properties [109, 110]. However, the transistor properties of metallophthalocyanines have received less attention presumably because of their low reported mobilities (ca. 10^{-4} cm^2/V^{-1} s), for example, in the case of nickel phthalocyanine (Ni-Pc) [111–113]. It is known that in order for a material to transport electrons (*n*-channel), it needs to have an accessible LUMO
level for electron injection and sufficient π-overlaps to achieve reasonable charge carrier mobilities [114]. Therefore, molecules with strong electron-withdrawing groups and extended π-systems are good candidates for *n*-channel semiconductors.
Copper octafluorophthalocyanine (F_8CuPc) has been found to form a rectifying junction with *p*-type unsubstituted MPcs [115, 116]. Among the metallophthalocyanines with strong electron-withdrawing groups, hexadecahalogenated metallophthalocyanines (Fig. 23) were found to function as air-stable *n*-channel semiconductors with a maximum electron field-effect mobility of 0.03 cm^2 V^{-1} s^{-1} (Fig. 24) [117]. The same field-effect mobilities as in vacuum (10^{-3} Torr) can be obtained when measured in air.

Electron-withdrawing groups are known to lower the HOMO and LUMO energy levels of molecules. The LUMO level of $F_{16}MPc$ has previously been shown to be ca. 1.6 eV lower than its unsubstituted counterpart by ultraviolet photoelectron spectroscopy (UPS) measurement and UV-vis data and this makes it less susceptible to oxidation. In addition, since all the $F_{16}MPcs$ adopt the edge-on conformations in their thin films the fluorine atoms are in contact with air and could help to block moisture from penetrating through the films.

X-ray diffraction measurements (Fig. 25) indicate that the as-deposited thin films of $F_{16}CuPc$ on Si/SiO$_2$ are highly ordered with a sharp diffraction peak at 2θ of ca. 6.02° corresponding to an interplane distance of 14.6 Å, which is similar to the reflection from the (200) lattice planes of α-form CuPc, but in an expanded unit cell as is expected from the larger van der Waals radius of F over H [109]. The major peak visible under electron diffraction (Fig. 25, inset) is around 3–4 Å, which corresponds to the π-stacking distance of the phthalocyanine rings. Therefore, the $F_{16}CuPc$ molecules are standing and essentially perpendicular to the SiO$_2$ surface; this renders the π-overlap direction of $F_{16}CuPc$ the same as the current flow direction, which provides an efficient path for charge transport. The mechanisms for charge transport in these metallophthalocyanines and other polycrystalline organic semiconductors are believed to undergo a hopping mechanism at room temperature. Therefore, the morphology of films can greatly affect charge carrier mobilities due to the grain boundary effect [109]. It is found that the samples deposited at T_d above 75 °C are nodular with a mean diameter of about 50 nm. In contrast to CuPc, the nodules do not change to large, separated crystals around 150 °C but remain in good contact, becoming only more elongated. Thus, the good mobilities at high T_d may be the result of the very smooth, flat films, with close contact of the elongated nodules. These materials should be of great interest as all-organic complimentary circuits and ring oscillators, *n*-channel semiconductors in photovoltaic

devices, and electron-transporting materials in light-emitting diode applications.

2.6. Phthalocyanine Mixed Thin Solid Films

Thin solid mixed films of phthalocyanine (chloroindium, chlorogallium, copper, cobalt, zinc, and metal-free phthalocyanine), bis(*n*-propylimido)perylene, and thio-bis(*n*-propylimido)perylene derivatives (Fig. 26) were fabricated by vacuum co-evaporation onto glass and silver island films [118].

The resonant Raman scattering (RRS) and surface-enhanced resonance Raman scattering (SERRS) spectra of the mixed film bis-perylene tetracarboxylic derivatives (PTCD)/ClInPc obtained with the 514.5 nm laser line and

the baseline corrected spectra are presented in Figure 27. The fundamental mode observed at 542 cm^{-1} is due to the perylene ring deformation. The C–H bend is observed at 1084 cm^{-1}, while perylene ring stretches appear at 1291(sh.), 1302, 1378, and 1456 cm^{-1}. The ring C=C stretches are observed at 1572 and 1586 cm^{-1}, and the symmetric C=O stretch is at 1697 cm^{-1}. The SERRS spectrum obtained for this mixed film is clearly the enhanced version of the RRS spectrum and occurs when the PTCD moiety is physisorbed onto the silver island substrate. Physical adsorption means that there is no strong interaction (bonding) of the organic with the metal surface.

The Raman scattering (RS) of the mixed film of bis-PTCD/ClInPc taken with the 780 nm laser line is presented in Figure 27. It becomes apparent on comparing the Raman spectra of this mixed film that the spectrum at 780 nm (RS)
Figure 27. RRS, SERRS, RS, and SERS spectra of mixed thin solid films of bisPTCD/ClInPc. molecules. Reprinted with permission from [118], A. P. Kam et al., *Chem. Mater.* 13, 4463 (2001). © 2001, American Chemical Society.

contains characteristic bands of both ClInPc and bis-PTCD. In the RS spectrum, the most intense characteristic vibration observed at 1453 cm^{-1} belongs to the ClInPc moiety. The surface-enhanced Raman scattering (SERS) spectrum of the mixed film, obtained with the 780 nm line, also shown in Figure 27, consists of a combination of ClInPc and perylene chromophore vibrations. However, the intensity of the bis-PTCD SERS is again higher than that of the Pc molecule. Therefore, characteristic vibrations of the perylene moiety are used to discuss the SERS (780 nm) spectrum in an attempt to extract the effect of intermolecular interactions from the mixed film spectra. The predominant perylene bands in the SERS (780 nm) spectrum are observed at 1689, 1594, 1577, 1439, 1379, 1295, and 531 cm^{-1}. Taking the 531 cm^{-1} band as a reference, a comparison of the SERS (780 nm) to the RS spectra of bis-PTCD/ClInPc mixed films indicates an increase in the relative intensities of four in-plane ring-stretching vibrations, in particular in that of the 1577 cm^{-1} vibration. Furthermore, in the SERS (780 nm) spectrum, the full width at half-maximum (FWHM) remained constant for all vibrational bands with the exception of 1379 and 1439 cm^{-1}. In the RS spectrum, the bandwidth doubles for the 1379 and 1439 cm^{-1} bands. This indicates the presence of doublets, not resolved in the spectrum due to band overlap. When the vibrational band at 542 cm^{-1} is used to normalize the spectra obtained with the 514.5 nm laser line, the relative intensities of the C–H bend and C=C stretching vibrational bands, at 1084 and 1586 cm^{-1}, respectively, decreased in the SERRS spectrum with respect to the RRS spectrum. A comparative analysis of the FWHM bandwidths shows that the bandwidth of the 1295 cm^{-1} vibrational band in the SERS (780 nm) spectra is double relative to that in the RRS spectrum.

A similar approach in analysis was utilized for the other thio-PTCD/MPc mixed films that were studied. The most noteworthy system is that of the thio-PTCD/CoPc mixed films, in which there are relative intensity deviations when comparisons are made between the RRS and the SERRS

spectra and the RS and the RRS spectra of this mixture. Surprisingly, a comparison of the RS to RRS spectra of thio-PTCD/CoPc mixed films reveals no change in FWHM bandwidths.

The extent of the spectral changes on the perylene moiety upon mixing with phthalocyanine was deduced by comparing relative intensities and FWHM bandwidths for Raman spectra of neat films of bis-PTCD and thio-PTCD. Such analysis reveals similar deviations (for RS, SERS, RRS, and SERRS) in both relative intensities and bandwidths that are observed for the characteristic vibrational bands of the perylene chromophore in the neat films. Therefore, the perylene moiety in mixed films appears to retain the same molecular organization as in the neat film. This provides conclusive evidence for a lack of molecular mixing between phathlocyanine and perylene in these co-evaporated mixed films.

Global images of the SERRS signal from mixed films of bis-PTCD and various phthalocyanine derivatives as well as thio-PTCD/Pc on silver island films were obtained using the 633 nm laser line. The global images from the mixed film samples were captured using the filtered Raman scattered light of the fundamental vibrational wavenumber at 1300 cm^{-1} for bis-PTCD, at 1380 cm^{-1} for thio-PTCD perylene, and at 680 cm^{-1} for phthalocyanine.

Representative images were selected (Fig. 28a and c) to illustrate the three-dimensional distribution of the bis-PTCD SERRS signal from the mixed film on silver islands. The bis-PTCD/ClInPc film presents a homogeneous distribution of aggregates of bis-PTCD (and ClInPc) in the film as shown in the three-dimensional image (Fig. 28a), where the bright coloration corresponds to the higher relative intensity of the SERRS signal from the bis-PTCD center at 1300 cm^{-1}. The aggregation or phase separation with a homogeneous distribution of aggregates is also seen in the three-dimensional images taken from films of thio-PTCD/ClInPc (Fig. 28c). Similar results were obtained for all the other PTCD/Pc mixed films that were fabricated.

The point-to-point maps confirm the results from wide field images showing that the structure of the mixed thin
Figure 28. Global field images [(a) and (c)] and point-to-point bit map images [(b) and (d)] of mixed films of bisPTCD/ClInPc and thioPTCD/ClInPc, respectively, molecules. Reprinted with permission from [118], A. P. Kam et al., *Chem. Mater.* 13, 4463 (2001). © 2001, American Chemical Society.

films is a distribution of aggregates from both materials. Thus global images provide a powerful analytical technique to determine the degree of mixing or phase separation within micrometer spatial resolution.

2.7. Naphthalocyanine Thin Films

The naphthalocyanine (Nc) ligand can also coordinate various metals, as Pc does, in the central position, which are classified by the valency of the central metal. In the epitaxial films deposited on the alkali halide surface, two types of molecular stacking have been found depending upon the central coordination structure, as schematically shown in Figure 29 [119]. Metal-free Nc (H_2Nc) and divalent metal Ncs like ZnNc take on the face-to-face, eclipsed stacking in which the planar molecules are packed in a tetragonal unit cell and piled up cofacially along the molecular column holding the molecular planes parallel to the substrate surface (Fig. 29a). On the other hand, trivalent and tetravalent metal Ncs (MXNcs) like chloroaluminium Nc (AlClNc), fluorogallium Nc (GaFNc), and vanadyl Nc (VONc) crystallize in the slipped stacking (Fig. 29b). This different stacking structure is caused by the axial ligand (X) with halogen or oxygen atoms protruding out of the Nc molecular plane. The interplanar distance between the stacked MXNc molecules, ~0.33 nm, determined from their X-ray diffraction pattern [119c] suggested that the axial ligands alternated up and down to form a dimeric structure as shown in Figure 29b, since the M–X bond would occupy a longer spacing if the MXNc molecules were piled up in the eclipsed stacking as in the case of divalent MNcs. The two types of molecular stacking in the MNc and MXNc films have also been proven from their high-resolution electron microscopy and electron diffraction [118].

These different stacking modes in the organic thin films relate to their superior photoelectric characteristics [120]. Furthermore, the crystal growth and molecular orientation in the epitaxial organic films have a significant influence on their optical, electrochemical, and photovoltaic properties [121].
Orientation-controlled naphthalocyanine thin films showed electrochromism [122]. The amorphous ZnNc film deposited on an indium tin oxide (ITO) coated glass electrode exhibited an irreversible electrochromic oxidation in 0.1 M KCl. This reaction gave rise to swelling of the film surface due to expansion of grains caused by incorporation of charge-compensating anions between the aggregated molecules. Epitaxially oriented films were prepared by deposition onto the (001) cleavage surface of NaCl and then transferred onto the ITO electrode. The epitaxial ZnNc film, in which the planar molecules are piled up in columns taking on the face-to-face, eclipsed stacking, exhibited both electrochromic reduction and oxidation. This electrochromic activity was attributed to a reversible incorporation of counterions through hollow channels between the molecular columns, which was accompanied by rearrangement in the molecular stacking. By contrast, no electrochromic reaction occurred for the epitaxial VONc film, where the alternately slipped dimeric structure did not facilitate a penetration of counterions into the stacked molecules.

Figure 30 shows *in-situ* visible spectral change during the oxidation process for the amorphous ZnNc film electrode. The original green film (at 0 V in Fig. 30) shows absorption peaks at 710 and 780 nm which are assigned to the $\pi-\pi^*$ transition of the conjugating Nc macrocycle [123]. This spectral shape resembles the Q-band absorption of the α-form of vapor-deposited MPc films [124]. It suggests that the original ZnNc film is in a state where some neighboring molecules aggregate with an α-polymorphic interaction similar to that of MPc films. In the irreversible oxidation process, these Q-band absorption peaks start to decrease at potentials above 0.8 V vs Ag/AgCl. Upon further oxidation up to 1.0–1.3 V vs Ag/AgCl, the Q-band disappears while an absorption band goes up at around 500 nm. This absorption spectrum no longer changed even if a reverse negative potential was applied to the film. The amorphous VONc film exhibited an electrochromic behavior similar to that for the amorphous ZnNc film. These electrochromic changes of the amorphous film imply an irreversible incorporation of counterions from electrolyte solution.

Figure 31 shows AFM images taken for the ZnNc amorphous film deposited on ITO at a substrate temperature of 25 °C. The AFM image taken before applying bias potentials (Fig. 31a) indicates that the amorphous ZnNc film consists of grains with size less than 100 nm, and the surface morphology is considerably smooth with a maximum roughness of about 5 nm. This surface morphology was not changed in the negative potentials at which the cyclic voltammogram indicated no reduction peak. On the other hand, an application of positive potentials gave rise to a significant change in the film structure. Figure 31b shows an AFM image taken at 1.0 V vs Pt at which the film is totally oxidized. On the surface, swelling bumps and cracks appeared, which seems to suggest that the film is upheaved. Upon oxidation the films accumulate charges, and counteranions, Cl^- in this case, penetrate into the film. This incorporation of charge-compensating Cl^- ions gives rise to an expansion of grains as previously pointed out [125, 126], which is considered to result in swelling the film surface. When a further anodic bias was applied up to 1.2 V vs Pt, the film was seriously damaged and peeled off the ITO substrate as seen in the *in-situ* electrochemical processes (EC)-AFM image in Figure 31c.

Using a polycrystalline ZnNc film deposited on ITO at substrate temperature of 250 °C, a microscopic change in the film structure upon electrochromic oxidation was observed at high resolution by EC-AFM. The polycrystalline film was composed of larger grains of submicrometer size. The ED pattern taken from this original film indicated the Debye–Scherrer rings corresponding to the spacings of 0.33 and 1.4 nm. It suggests that the crystalline grains consist of the molecular columns lying on the substrate with an intercolumnar distance of 1.4 nm; therefore, most of the planar ZnNc molecules are standing normal to the substrate surface. This columnar structure of the original, polycrystalline ZnNc film can be observed in the EC-AFM image before applying bias potentials as is shown in Figure 32a. The stripe images with a distance of 1.4 nm agree with the columnar structure confirmed by the ambient AFM and transmission electron microscopic techniques. The polycrystalline ZnNc film exhibited a reversible electrochromic activity similar to that of the epitaxially oriented film mentioned in the previous section. When the film was biased at reduction potentials up to −1.0 V vs Pt in the EC-AFM, the columnar image was still observed similar to that at 0 bias potential as shown in Figure 32b. On the other hand,
Figure 32. EC-AFM images (scales in nm) of polycrystalline ZnNc film electrode at (a) 0 bias potential and (b) −1.0 V vs Pt in an electrolyte solution of 0.1 M KCl, showing the moleuclar columns with a spacing of 1.4 nm. when a positive potential was applied to oxidize the film, the columnar structure was no longer observed.

3. PHTHALOCYANINE STACKS, MOLECULAR ARRAYS, AND SELF-ASSEMBLIES

3.1. Phthalocyanine Stacks, Pc Nanorod, and Nanoscaled Fibrous Assemblies

Disc-shaped rigid Pcs and MPcs can easily stack through strong $\pi-\pi$ interaction and form one-dimensional rodlike assemblies with interesting electronic and optic properties [127–130]. Cofacially stacked Pc aggregates are present even in dilute solution for some examples [130].

Pc-based superstructures were constructed by $\pi-\pi$ interaction of Pc molecules in which the cores of copper and nickel octaazaphthalocyanines are fused to four nonracemic [7] helicenes according to Figure 33 [127].

A calculation by molecular mechanics shows that the energy is minimized when the Pc molecules stack in a chiral superstructure with a core-to-core distance of ca. 3.4 Å as shown in Figure 33b. Atomic force microscopic images shown in Figure 34 are in accord with the calculated structure (Figure 33b) if on the surface of mica the stacks are isolated and perpendicular to the surface. In Langmuir films, however, the molecules stack in the opposite way, with the stacking axis parallel to the water.

The copper complexes produced nanosized fibrous assemblies from aqueous solutions through two noncovalent bondings: $\pi-\pi$ interaction among phthalocyanine rings and hydrogen bonds among diol units, as shown in Figure 35. The formation of fibrous assemblies strongly depends on the central metal of the phthalocyanine complex. The optically active (S)-CuPc(OH)$_{16}$ is stacked and arranged in a left-handed helix. The chirality of diol units in (S)-CuPc(OH)$_{16}$ also affects the intercolumnar lattice of phthalocyanine stacks.

Soc*. 121, 3453 (1999). © 1999, American Chemical Society.

The X-ray diffraction pattern of (S)-CuPc(OH)$_{16}$ film is remarkably different from that of the racemic mixture, possibly due to the reflections from a discotic lamellar structure [131]. The chirality of amphiphilic copper phthalocyanine affected the lattice of the assembly of phthalocyanine stacks and stabilization of micellar fibers: (i) the chiral amphiphilic phthalocyanine can form a helical arrangement in the phthalocyanine stack, and (ii) the intercolumnar lattice of the phthalocyanine stacks transferred from the hexagonal lattice to the lamellar structure introducing chiral side chains as substituent groups. As a result of the intercolumnar hydrogen bonding, the phthalocyanine stacks assemble to form the hexagonal lattice. On the other hand, the chirality of the diol unit controls the direction of hydrogen bonding among hydroxyl groups. The regularity of the hydrogen-bonding direction results in the helical arrangement of the phthalocyanine rings. The X-ray reflection peak at 0.26 nm for (S)-CuPc(OH)$_{16}$ in Figure 36 corresponds to the regular packing of the diol units.

The polymeric hydrogen bonding between diol units may be formed within the phthalocyanine stack, contributing to the formation of the helical arrangement. The helical arrangement will induce the distance separating

of phthalocyanine stacks and alter the intercolumnar structure. Engelkamp et al. reported the helical arrangement of optically active phthalocyanines and proposed three types of helical structures [132]. The X-ray reflection of the stacking distance was only observed at 0.34 nm, and the CD spectra of (S)-CuPc(OH)$_{16}$ implied that the dipoles of the phthalocyanine rings were arranged in the form of a left-handed helix. Pathways for the formation of fibrous assemblies are speculated in Figure 37.

Similarly, crown ether-substituted Pcs were used to create nanoscaled fibrous assemblies possessing an electron conduction wire and ion transport channels [133]. Furthermore, side-chain-modified Pcs [(2,3,9,10,16,17,23,24-octakis((2-benzyloxy)ethoxy)phthalocyaninato)copper, CuPcOC$_2$OBz] form long rodlike stacks on substrates [134]. CuPcOC$_2$OBz exhibits cofacial stacking in its aggregates, with a ring spacing of ca. 3.36 Å, as determined by wide-angle X-ray diffraction measurements [129]. These molecules showed cofacially stacked Pc aggregates even in dilute solution, as evidenced by broadened and blueshifted visible solution spectra [130]. Visible absorption spectra, consistent with
monomeric CuPcOC$_2$OBz, are observed in CHCl$_3$ for solutions below ca. 10^{-6} M, while more concentrated solutions (10^{-4} M) show a high degree of aggregation. H$_2$PcOC$_2$OBz exhibits similar behavior. Figure 38 shows STM images of CuPcOC$_2$OBz.

In films of metallophthalocyanine stacks, the Pc rings are spaced by van der Waals distances and exciton coupling of neutral–electronic transitions between neighboring macrocycles becomes very efficient. The characterization of the dynamics of the exciton motion together with the related exciton–exciton annihilation at high excitation densities has been an area of active theoretical and experimental research [135–139]. For large exciton densities, nonexponential bimolecular exciton–exciton annihilation has been observed by femtosecond spectroscopy studies in H$_2$Pc thin films [136], FAlPc thin films [137], VOPc films [138], and Langmuir–Blodgett films of SiPc polymers [139]. The analyses of these data are based on the assumption of unidimensional exciton transport, a condition not well fulfilled in films because of the interactions between the Pc stacks. In addition, local heating of thin films may affect the exciton dynamics. These factors impede considerably the elucidation of exciton transport dynamics in metallophthalocyanine films. On the other hand, linear polymers of (phthalocyaninato)siloxane in solution strictly limit the exciton transport to one dimension and heating effects can be avoided in flowing solutions.

Chemical modification of the core of phthalocyanines provides a high versatility in molecule structure and hence intermolecular interactions. The film structure as well as electrical and optical characteristics can be adjusted in a rather wide range. Perfluorinated phthalocyanines (F$_{16}$Pc) is an example showing such influence on the position of molecular energy levels as well as solid-state structure. A cofacial parallel orientation of molecules and layered growth, for example, could be obtained for F$_{16}$Pc in thin films on SiO$_2$ [107, 140–142]. Figures 39 and 40 show the morphology and the space-filling model of F$_{16}$PcZn, respectively.

Structural variations in F$_{16}$Pc thin films can be expected to lead to significant changes in electrical properties as observed for films of unsubstituted phthalocyanines in a series of time-of-flight measurements. The result revealed

changes in defect and excess electron mobilities dependent on temperature-induced structural reorganization in the films detected by changes in optical absorption spectra [142–145]. The high electronegativity of the F atoms leads to a stabilization of the frontier orbitals as seen by shifts in the redox potentials in solution and in thin films [146] and by UPS [147, 148]. This ease of reduction leads to *n*-type doping of films during film preparation by physical vapor deposition even under UHV conditions [149, 150]. The decrease in conductivity following exposure to air is explained by compensation of this *n*-doping by oxygen [142, 149–151] while the mobility of charge carriers was found to be constant during this change [141].

Single-crystalline substrates offer a regular structure that was found to influence the growth of molecular materials considerably [152]. Commensurate or coincident lattices of crystalline molecular thin films can be formed and were found in many examples of Pc and related materials [153]. Alkali halide surfaces are most suitable to provide a well-ordered optically transparent substrate. Epitaxial relationships could be established in the past for Pc and related molecules. Especially the optical absorption properties are changed considerably by the intermolecular orientation and hence chromophore coupling [60, 65, 154, 155].

Amphiphilic disklike molecule $CuPc(C_{10}EO_3)_8$ compounds contain a central phthalocyanine core, eight decoxy spacers, and eight peripheral triethylene glycol chains (Fig. 41) [156]. These compounds contain a central Pc core, eight decoxy spacers, and eight peripheral eight triethylene

glyco chains. The nonionic surfactants and block polymers containing oligo- and poly(ethylene glycol) headgroups have been widely used as templates for the preparation of mesoporous silica [157]. The introduction of triethylene glycol chains into the disklike molecules can induce the assembly of inorganic sources. The synthesized phthalocyanine derivatives exhibited excellent solubility in polar and nonpolar solvents except for hydrocarbons. Figure 42 shows the UV-vis spectra of $CuPc(C_{10}EO_3)_8$ in CH_2Cl_2 and a mixture of CH_2Cl_2 and ethanol. The UV-vis spectrum in CH_2Cl_2 had a strong sharp peak at 677 nm, typical of nonaggregated phthalocyanine [158]. When ethanol was admixed, the Q-band was broadened, and the maximum was blueshifted. These spectral changes can be ascribed to the formation of phthalocyanine stacks having a coafacial arrangement. By increasing polarity of the solvent, the hydrophobic phthalocyanine cores come closer and form a coafacial one-dimensional stack in polar solvents.

3.2. Phthalocyanine Molecular Arrays

Single molecular arrays of Pc have been obtained with templates of two-dimensional (2D) alkane lamella of nanometer scale using $C_{18}X$ (X = Cl, Br, I, CN) and $C_{18}SH$. When Pc
Figure 42. Powder XRD patterns of the organic-inorganic composite containing $CuPc(C_{10}EO_3)_8$ and silica and assigned Miller indices (*hkl*). Reprinted with permission from [156], M. Kimura et al., *J. Am. Chem. Soc.* 123, 2438 (2001). © 2001, American Chemical Society.

and alkane derivatives ($C_{18}SH$ and $C_{18}X$, X = Cl, Br, I, CN) were coadsorbed from solution onto HOPG (highly oriented pyrolitic graphite), a new phase of homogeneous molecular assembly of Pc with $C_{18}SH$ and $C_{18}X$ was found in addition to the typical segregated domains [159, 160]. By adjusting the molar ratio of Pc to alkane derivatives to about 1:3, homogeneous intercalation of Pc in the length scale of sub-micrometers can become the main form of Pc on a graphite surface. Figure 43a shows a homogeneous molecular assembly of Pc with $C_{18}SH$. In the image, the bright lines correspond to Pc molecular lines. The line width is about 1.5 nm, consistent with the side width of the Pc molecule. The dark bands in the image correspond to $C_{18}SH$ lamellae and the 2.5 nm width of them is in accordance with the molecular length of $C_{18}SH$. On the surface the molecular lines can extend to several hundred nanometers. On the large-scale image, the domain boundary can be detected. The angle between the orientations of these domains is measured to be nearly 60° or 120°, indicating that the orientation of the domain is determined by the registry of alkane chains of thiols to the substrate. By altering the molar ratio of Pc to $C_{18}SH$, multirow bands of Pc (phase III) or single molecular line of Pc (phase II) surrounded by $C_{18}SH$ lamellae (phase I) can be obtained corresponding to concentrations of Pc above or below the optimal ratio, respectively (Fig. 43b and c). High-resolution images obtained on the multirow band regions of Pc are consistent with the adsorption structure of Pc reported on HOPG [51]. Pcs joggle together in the molecular array as in the 2D domain. Though the uniform assembly structures can become dominant by adjusting the molar ratio of Pc to alkane derivatives to nearly 1:3, one can still observe structures as shown in Figure 43b and c, in some area of the surface. This is attributed to the fluctuation of the molar ratio of Pc to alkane derivatives during the volatilization of the solvent, and this is considered to be an indication that the deposition from solution is a dynamic equilibrium process, where kinetic factors are attributed to the nonuniform regions.

The homogeneous assembly of Pc with $C_{18}SH$ is stable enough to endure repeated scanning and high-resolution images could be obtained on this assembly as shown in Figure 44. The Pc molecule in the line can be observed to

Figure 44. High-resolution image of the uniform assembly of Pc with $C_{18}SH$ (560 mV, 1.019 nA). The imaging condition was optimized for the observation of Pc. Parameters defining this assembly were defined on this image. Reprinted with permission from [159], S. B. Lei et al., *J. Phys. Chem. B* 105, 12272 (2001). © 2001, American Chemical Society.

tilt for 32 ± 4° from the lamellae direction and the $C_{18}SH$ molecules adsorb on the surface with its carbon chain parallel to the surface and nearly perpendicular to the Pc lines 75 ± 6°. The repeating period (l) is measured to be 4.0 ± 0.2 nm, in accordance with the length of one $C_{18}SH$ molecule plus the width of one Pc molecule. It can also be counted that on each side of one Pc molecule there exist three $C_{18}SH$ molecules (Fig. 44), so the Pc vs $C_{18}SH$ ratio can be measured to be 1:3 from the STM image in the intercalated structure.

According to these STM results, the groove between $C_{18}X$ lamellae appears to be a favorable site for Pc molecules to stay. On the basis of the observations, it was suggested that when $C_{18}X$ is excessive, the co-adsorption of Pcs with $C_{18}X$ results in uniform assembly of $C_{18}X$ and Pc molecules that are surrounded by lamellae formed by $C_{18}X$. As the stoichiometry of Pc increases, Pc molecule arrays extend in the boundary of $C_{18}X$ lamellae and the size of uniform assemblies also increases until Pc is excessive. At this time, Pc molecules crystallize along the Pc arrays of the uniform assembly and multirow Pc bands formed. This provides a qualitative illustration of the assembly process and rigorous elucidation of this process needs quantitative simulations.

Many of phthalocyanine 3D and 2D nanostructures are connected by hydrogen bonding [161]. The hydrogen bonds have the advantage of selectivity and directionality, which are important in building biological nanostructures. Although phthalocyanine nanostructures have been constructed using other interactions, such as van der Waals and hydrophobic interaction, they received little attention due to lack of directional selectivity [162, 163].

3.3. Pthalocyanine Self-Assemblies

Thin films of phthalocyanines [47, 164–168] and porphyrins [15, 168–171] obtained by the self-assembly method rely on the covalent anchoring of the macrocycles on various

Figure 43. (a) A large-scale image of the uniform assembly of Pc with $C_{18}SH$ when the molar ratio has been adapted to 1:3 (667 mV, 1.019 nA). (b) Coexistence of phase I (domain of pure thiol) and phase II (uniform assembly) when the molar ratio was below 1:3 (−431 mV, 677 pA). (c) Coexistence of phase II and phase III (pure Pc domain) when the molar ratio was above 1:3 (715 mV, 1.136 nA), (inserted) high-resolution image obtained on the Pc domain. substrates by a predetermined number of sites. It is thus possible to reach a high degree of control on the organization of the molecules within the film, allowing complex molecular architectures to be built [15, 47, 168, 172]. Such structures could find interesting applications for energy transfer devices [173, 174] or two-dimensional conjugated polymers.

For example ruthenium phthalocyanine (RuPc) monolayers were obtained by self-assembly on pyridino-functionalized metal oxide substrates, by coordination between the ruthenium ions and the pyridino groups [175]. Figure 45 shows formation of RuPc multilayers.

Figure 46 shows an AFM image of a [SiO$_2$/Py/RuPc] sample. The film appears homogeneous and regular even on a large scale, with an experimental roughness of 0.5 nm (as for the pristine [SiO$_2$/Py] sample) consistent with the absence of stacked or aggregated macrocycles. This observation indicates that unspecifically adsorbed materials are actually removed by washing. The observed thickness (AFM contact mode) is 1.8 nm, consistent with the expected one for a SiO$_2$/Py/RuPc layer.

The recently developed technique of layer-by-layer (LBL) assembly of oppositely charged materials has been used to fabricate multilayers on various substrates. LBL assembly has been applied in the construction of materials with well-controlled, nanometer-scale architecture [45, 176]. The key to the construction of multilayers is the interface between adjacent layers, and hence, interface properties are crucial to the self-assembled systems [177] and their physical properties.

Using a layer-by-layer self-assembly technique, multilayers of nickel phthalocyanine tetrasulfonate (NiPc) and poly(diallyldimethylammonium chloride) (PDDA) onto transparent substrates were prepared [45, 178]. In an aqueous solution, PDDA forms a uniform, nanometer-thick thin film on a silica substrate, because PDDA is attracted to the negatively charged substrate surface [179].

A negatively charged NiPc macrocycle binds to the dispersed positively charged polymeric PDDA monolayer. Multilayer thin films can be obtained by alternately dipping the sample in solutions of PDDA and NiPc. The idealized structure of NiPc and PDDA layers is shown in Figure 47. The

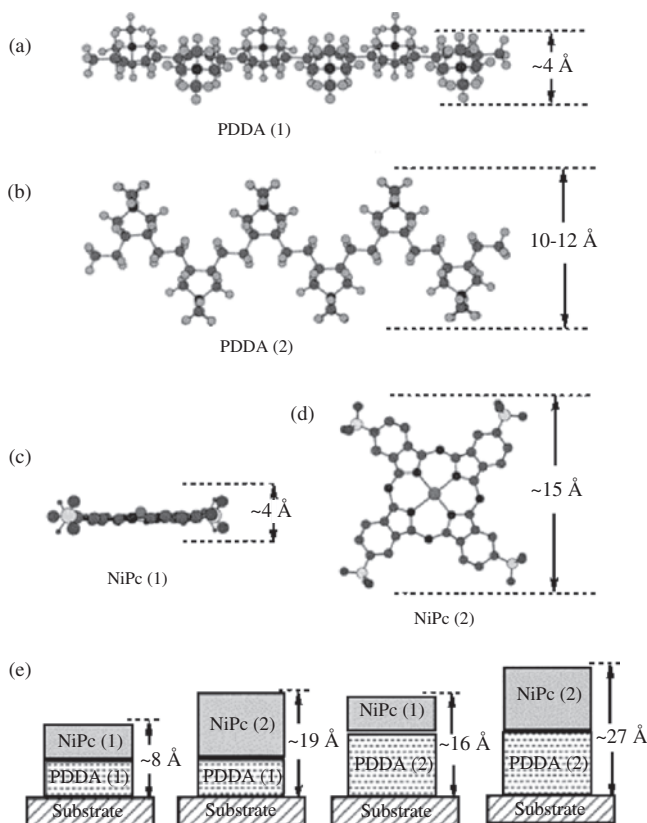
Figure 46. AFM study of a [SiO$_2$/Py/RuPc] sample. The left image shows that no significant difference can be observed on the topography of the surface upon grafting of the phthalocyanine; the experimental roughness remains around 0.5 nm, as for the pristine [SiO$_2$/Py] surface. The right image allows a measurement of the thickness of the film, which was found to be 1.8 nm (see the line cut below the image). The poor quality of the right image comes from the pollution of the tip resulting from scratching the film to draw the square feature. Reprinted with permission from [175], V. Huc et al., *Langmuir* 17, 1928 (2001). © 2001, American Chemical Society.


Figure 47. The idealized linear structure of PDDA lying flat or PDDA(1) gives a thickness of ~4 Å (a). The idealized linear structure of PDDA standing up or PDDA(2) yields a higher thickness value of ~10–12 Å (b). The structure of NiPc lying flat or NiPc(1) gives a thickness of ~4 Å (c). The structure of NiPc standing on edge or NiPc(2) yields a higher thickness value of ~15 Å (d). Four idealized layer–pair combinations between PDDA and NiPc yield ~8, 16, 19, and 27 Å thickness values, respectively (e). Reprinted with permission from [45], D. Q. Li et al., *J. Am. Chem. Soc.* 120, 8797 (1998). © 1998, American Chemical Society.

Huc et al., *Langmuir* 17, 1928 (2001). © 2001, American Chemical Society.

growth of multilayer films was monitored by measuring the absorption of 630 and 665 nm light (Fig. 48) [45].

Surface topography and amplitude images of 3-, 9-, and 27-layer-pair films are shown in Figure 49. As the film thicknesses increase from 3 layer-pairs to 9 and 27 layer-pairs, root mean square (rms) roughnesses also increase from 5.3 to 6.9 and 14.7 Å.

Similarly Li et al. deposited multilayers of nickel phthalocyanine tetrasulfonate and PDDA onto indium tin oxide (ITO) and ITO/TiO$_2$ substrates, respectively [178]. To probe charge-transfer properties of these self-assembled multilayers on conductive and semiconductive surfaces, Kelvin probe and surface photovoltage measurements have been carried out. The formation of both ionic multilayers and covalent multilayers was well characterized [45, 179, 180].

An *en face* self-assembly of monomeric PcCoDS monolayers on dioctadecydiammonium bromide (DODAB) was reported [181]. The water-soluble anionic dye, cobalt phthalocyanine disulfonate (PcCoDS), was used to prepare π-electron terminated model monolayers with a high surface free energy. The water-soluble PcCoDS self-assembles into an π-electron rich overlayer. In water, the large hydrophilic central atom, cobalt, and two polar charged anionic peripheral substituents in PcCoDS (Fig. 50b, d) reduce the tendency to adsorb edge-on or to form large aggregates [182, 183]. UV-vis spectroscopy measurements of phthalocyanine self-association established that PcCoDS adsorbs onto DODAB Langmuir–Blodgett (LB) films predominantly in the monomeric form [183–186].

The adhesion between the dye monolayers was nearly two orders of magnitude greater than that between pure DODAB films. Adhesive contact altered the optical absorption spectrum, as observed upon the cofacial dimerization of phthalocyanine dyes. The adhesion also increased in proportion to the dye coverage. The dye-dependent increase in the range of the van der Waals force between the membranes is

predicted by Lifschitz theory for the multilayer system. Flocculation measurements were then used to confirm that the measured intermembrane forces alter vesicle aggregation in aqueous solutions.

Changes in the surface pressure versus area isotherms of DODAB monolayers on water, after the addition of PcCoDS to the subphase, indicated that PcCoDS binds to DODAB monolayers (Fig. 51a). The DODAB on a pure water subphase exhibited a stable isotherm (Figure 51a, curve 1) as was evident from the absence of changes in the surface pressure at constant film area. After the addition of 0.05 mM PcCoDS to the subphase, the isotherm was measured every 10 min, without exceeding the collapse pressure. The monolayer expanded noticeably 20 min after the dye addition.

The samples exhibited two peaks at 615 and 670 nm characteristic for the Q-band in phthalocyanines (Fig. 52)

[183–188], which showed different features depending on the preparation procedures.

Strong interactions between plate-shaped, aromatic phthalocyanine macrocycles promote their association into cofacially stacked structures [183–188]. As a result, phthalocyanine species typically self-assemble on surfaces with the macrocycles nearly perpendicular to the substrate plane [182, 189] and thus present their edges to the medium.

The spectral features within the Q-band measured with the different phthalocyanine assemblies reflected differences both in the organization within the films and in the forces between the macrocycles and the substrates. On positively charged, hydrophilic poly-L-lysine, the dye exhibits a low apparent coverage and/or a macrocycle orientation perpendicular to the substrate. The film also contained a high fraction of aggregated PcCoDS. Similar Q-band properties were observed for substituted PcCu sulfonate assembled electrostatically on poly-L-lysine [184]. The dye self-association was also very pronounced on protonated, aminosilane layers. However, the greater dye coverage suggests that both electrostatics and the substrate hydrophobicity are important for binding and orienting the macrocycles. The high dimer fractions in PcCoDS layers on both poly-L-lysine and aminosilane modified surfaces is attributed to the molecular disorder and microroughness of the substrates [190]. The roughness of the glass substrates might also contribute to the aggregation.

Pc thin films prepared by chemical linkage between the substrate and the macrocycles show that ligand exchange occurs upon the binding of the Pc ring to the surface in several examples [15, 47, 185–191]. Exceptional stability was observed in ruthenium phthalocyanines axially complexed by pyridine ligands, the preparation of which is shown in Figure 53.

Figure 54 exhibits STM images recorded at ambient temperature on the [SC$_6$H$_4$NH$_2$-RuPc] bilayer. The images taken after the grafting of RuPc complexes clearly evidence small grains (ca. 2 nm in diameter) of ca. round shape superimposed on the larger pattern exhibited by the STM image of the same sample before the grafting. Those small objects can be assumed to be the Pc rings, locally ordered by groups of 6–7 molecules.

Thin films of silicon phthalocyanine dichloride (SiPcCl$_2$) could be deposited from solution on to the H-passivated Si(111) surface [192]. In a high coverage film, clusters of about 5.5 nm × 4.5 nm in size are observed. These clusters are believed to partially stack on each other, suggesting a tilted growth mechanism of the layers on the surface. In a low coverage film, well-ordered monolayers are found, with a close structural similarity to the bulk crystal structure

of SiPcCl$_2$. The bulk crystal structure of SiPcCl$_2$ (Fig. 55) was determined directly from powder X-ray diffraction data using the Monte Carlo method. The results of STM manipulation and the observation of well-ordered SiPcCl$_2$ layers on the Si(111) surface indicate a weaker interaction between the SiPcCl$_2$ molecules and the substrate than between the SiPcCl$_2$ molecules (Fig. 56a).

The scanning tunneling spectroscopy (STS) *I–V* curve was analyzed to investigate the nature of the SiPcCl$_2$ films on the surface. The *I–V* curve measured in the ordered area in Figure 56b shows marked rectifying behavior. This behavior was duplicated at all points tested over both the monolayer and multilayer films; no local states were observed at different positions on the films. Such rectifying behavior has been observed by Pomerantz et al. [80] and Ottaviano et al. [193] in STS studies of CuPc on graphite and NiPc on Si(111), respectively. This behavior is to be expected for a film that acts as an organic *p*-type semiconductor (due to oxygen doping) on a *p*-doped semiconductor surface. Thus rectifying behavior could be attributed to the H-passivated silicon surface.

Application of two-dimensional PC monolayer assemblies for light harvesting is discussed in [21]. The air/water interface structure was characterized with X-ray specular reflectivity and on solid substrates by optical absorption spectroscopy.

3.4. Discotic Mesophase Phthalocyanines

Rodlike self-assembling organic materials have attracted significant attention due to their unique electro- and photoactive properties. These properties have been shown to be dependent on both the long-range order and molecular orientation within thin films of these materials, as evaluated in field-effect transistors [118, 194], photovoltaics [195], and polarized emission light-emitting diodes [196].

Discotic mesophase phthalocyanines, such as CuPcO·C₂OBz in Figure 38, self-assembled in parallel columnar structures [134, 197]. Discotic mesophase materials in general are attractive for these technologies if the coherence length achievable in rodlike aggregates of these materials exceeds the expected separation distance between source/drain (OFET) or anode/cathode (PV) contacts. (Generally a minimum coherence length of 100 nm is required.) Under these conditions, charge mobilities along the rod axis greater than 0.01 cm² V⁻¹ s⁻¹ are expected [198].

It was reported that thin films of CuPcOC₂OBz contain the Pc oriented nearly "edge-on" to the substrate plane, with coherence lengths in individual rods averaging ca. 40 nm. A key feature of these molecules which leads to the stiff nature and coherence of each bilayer film is the benzyl termination in the eight side chains, which appears to reinforce the interactions between adjacent Pc rings and

between adjacent Pc columns [134, 197]. No other Pc material capable of forming a discotic mesophase, held in place by noncovalent interactions, has to date demonstrated such long-range order and thin film coherence. The structural perfection in the individual Pc columns rivals that seen in the rodlike polymers of silicon phthalocyanines developed by Wegner and co-workers [199].

Phenyl–phenyl interactions between a surface modifier and the Pc assembly played a critical role in the efficient transfer of coherent thin films of these Pc assemblies to metal, silicon/silicon oxide, and transparent conducting oxide substrates [134]. Molecular assemblies with phenyl termination are believed to interact through both cofacial and edge-to-face arrangement of the aromatic groups [200], which can strongly affect the type and coherence of the resultant molecular aggregate structures [201]. Modification of gold surfaces with a new phenyl-terminated thiol (2), which mimics the side chain composition of these Pcs, leads to a greater efficiency in transfer of CuPcOC₂OBz to a gold surface, vs the efficiency of transfer seen for a CH₃-terminated alkanethiol self-assembled monolayer [197]. Such phenyl surface modifications also influence the orientation of individual Pcs as determined by reflection–absorption IR spectroscopy (RAIRS). Analogous modification of the oxide surfaces of silicon wafers, with a mixture of 1,1,1,3,3,3-hexamethyldisilazane (HMDS) and 1,3-diphenyl-1,1,3,3 tetramethyldisilazane (DPTMDS), shows a higher degree of transfer vs the unmodified surfaces. The presence of phenyl groups in the surface modifier leads not only to higher efficiency in transfer but also to more ordered/optically anisotropic thin films.

Structure of benzyloxyethanethiol
Representative RAIRS spectra are shown in Figure 57 and show the greatest contrast observed between film transfers over three experimental trials. The small IR signal in Figure 57a and the corresponding AFM image are evidence that only small portions of a bilayer of CuPcOC₂OBz are transferred effectively to this type of surface. The remaining material is left on the LB trough or picked up as highly folded and defective film segments. Figure 57a shows a corner section of the Pc bilayer film whose dimensions were less than 250 μm × 250 μm and a larger bare Au region features typical of transfer to an unmodified Au surface. Film segments, transferred to the unmodified Au surface, may interact through nonspecific interactions with carbonaceous contamination.

Figure 57b reflects the improved transfer of a single bilayer of CuPcOC₂OBz due to nonspecific hydrophobic interactions with the methyl-terminated octanethiol, although a continuous film is still not achieved, as seen in the corresponding AFM image. Bilayer islands are seen across the surface, with average dimensions of 500 μm × 500 μm. Comparable results are obtained using octadecanethiol; therefore, chain length in the self-assembled monolayer (SAM) cannot by itself be a contributing factor in determining Pc transfer efficiency to a methyl-terminated Au surface.
Figure 57. RAIRS spectra of a single bilayer film of CuPcOC$_2$CBz onto (a) a clean Au slide, (b) a Au slide modified with octanethiol, and (c) a Au slide modified with benzyloxyethanethiol. The Pc-O-C (1204, and 1283 cm^{-1}) and out-of-plane bending transitions (Pc–H = 745 cm^{-1}) have been marked. Corresponding AFM images, shown in the lower half of the figure, are considered representative for transfer to each type of surface and were obtained by tapping mode AFM in an aqueous solution. The majority of the surface shown with (a) is bare Au, with only a small amount of CuPcOC$_2$CBz (upper left-hand corner) present on the surface in this region. Larger, islandlike deposits of CuPcOC$_2$CBz in (b) are typical for Au substrates that have been hydrophobized and had rms roughness values of ca. 3 nm, while the coherent, conformal deposits in (c) are typical for those obtained on hydrophobized Au surfaces with the addition of phenyl moieties and had rms roughness values of ca. 2 nm. Reprinted with permission from [197], R. A. P. Zangmeister et al., *Langmuir* 17, 7071 (2001). © 2001, American Chemical Society.

Figure 57c shows the marked improvement in a single bilayer transfer of CuPcOC$_2$OBz to the Au surface modified with benzyloxyethanethiol. The transfer efficiency on Au surfaces modified with benzyloxyethanethiol is consistently a factor of ca. 10 vs the bare gold surface and a factor of ca. 3 vs the gold surfaces modified with CH$_3$-terminated SAMs. These estimates are made from AFM imaging and the maximum IR absorbance for each film at 1283 cm^{-1}. The corresponding AFM image to Figure 57c shows a complete bilayer transfer of CuPcOC$_2$OBz over a 100 μm × 100 μm area. Images of continuous film features are acquired from scans taken at random over the entire sample, within the physical limits of the imaging scan head (ca. 1 mm^2). The entire area of the transferred Pc film is ca. 1 cm^2. The scan image shown in Figure 57c also reveals small "ridges" in the bilayer film. This image was specifically chosen to show the maximal corrugation observed in the Pc film. The ridges run from the lower left to the upper right sides of the image, and the average step height of these ridges was 7 ± 2 nm, or approximately 2–3 Pc column diameters [134].

4. PHTHALOCYANINE LB FILMS

The Langmuir–Blodgett technique, which often utilizes derivatized Pcs for solubility, produces controllable morphologies on large areas. Properties of LB films consisting of Pcs are significantly influenced by the orientation

and aggregation of Pcs [202, 203]. Thus many spectroscopic measurements have been carried out in order to elucidate molecular ordering of Pcs in thin films [204–215]. Various studies indicate that substituents in Pcs play an important role in determining the orientation of Pcs. Pcs form aggregated columns and exhibit an edge-on conformation with respect to substrates in monolayers, except for the case where an amphiphilic porphyrazine was used, as observed by Palacin et al. [32]. It was also reported that the introduction of tetracarboxyl residues in Pc rings results in high in-plane anisotropy [23, 216–219].

Selectively oriented multilayers of precisely controlled thickness can be reproducibly prepared by customizing the hydrophobic and hydrophilic regions of the molecule by derivatization of the phthalocyanine rings. Although the electronic and optical properties of many of these films have been studied extensively, the nature of the interaction of Pc films with the substrate, water, or layer interfaces is less well understood. Because underivatized phthalocyanines or those with added nonpolar groups tend to form irregular or poorly transferred films, an amphiphilic transfer promoter such as octadecanol is typically added to facilitate reproducible film transfer and to stabilize and homogenize films deposited by the Langmuir–Blodgett technique.

LB films have been obtained from both substituted and unsubstituted phthalocyanines [220], though a comprehensive understanding of their organization at the air–water iinterface has yet to be developed for deriving a packing arrangement–property relationship in the ultrathin LB films [221]. Monomolecular films of substituted amphiphilic phthalocyanines can readily be obtained using the method of Langmuir–Blodgett [24, 39, 74, 220, 222].

A survey of the literature on phthalocyanine monolayers at the air–water interface shows considerable dispersion in the results for similar phthalocyanines and in some cases even for the same phthalocyanine [223–230]. Experimental conditions such as subphase temperature, spreading solvent, and even the type of measuring system can cause major changes in the monolayer characteristics of these "nonclassical" monolayer materials.

The major characteristic of Langmuir and LB films (i.e., the out-of-plane orientation of the molecules) is a direct consequence of the amphiphilic character of the molecules and the organizing role of the air–water interface [231]. The key parameter is the ratio ς between the projection on the water surface of the volume filled by the aliphatic chain(s) vs the area filled at the air–water interface by the polar head(s) (Fig. 58). ς is strongly related to the *critical packing parameter* introduced by Ninham for short-chain surfactant molecules that self-organize in water either as micelles, lamellar structures, vesicles, or reverse micelles [232, 233]. Phthalocyanine derivatives, however, do not generally fit with those geometrical rules, and their orientation at the air–water interface is totally monitored by the location and nature of the substituents grafted on the periphery of the macrocycle. Unsubstituted Pcs are very likely to form aggregates at the air–water interface, because no attractive interaction with the water subphase is possible for those purely aromatic molecules. Similar disordered LB films were obtained with soluble Pcs, bearing bulky alkyl or aryl substituents because the Langmuir monolayers built from

$\varsigma = 1$ $\varsigma > 1$ $\varsigma <= 1$
Figure 58. Schematic definition of the ratio ς. Three typical cases are given: a single-chain compound such as a fatty acid ($\varsigma = 1$), a double-chain compound with a small polar head ($\varsigma > 1$), and the four-chain phthalocyanine ($\varsigma < 1$). those nonamphiphilic molecules are actually multilayers [234–242]. It is commonly assumed that those molecules are not really suitable for LB film formation since they show little evidence of conventional hydrophilic/hydrophobic character in their chemical constitution [243]. Highly ordered LB films containing Pcs described in the literature are all based on truly amphiphilic Pc derivatives (i.e., phthalocyanines bearing both polar groups and aliphatic chains).

Two extreme orientations of Pc derivatives in Langmuir monolayers and LB films can be discussed: in the first one, the Pc rings lie parallel to the water surface (or the substrate in the resulting LB films); in the second one, the Pc rings exhibit an edge-on orientation. The latter geometry favors face-to-face interactions between neighboring Pc rings and is particularly useful in conductiometric applications. The former geometry cannot be obtained without the LB technique and was used to form a true two-dimensional polymer exhibiting outstanding mechanical properties [244].

Another unique characteristic of the LB technique is the ability to induce in-plane anisotropy in the lamellar structure. As rationalized by Minari et al. [245] and Schwiegk et al. [246], the in-plane anisotropy observed in some LB films arises from the flow effect during the transfer of the floating monolayer onto solid substrates. Rigid rod polymers [247, 248] and linear aggregates of discotic mesogens [249–252] are the two major families of molecules that exhibit in-plane anisotropy in LB films. In both cases, the molecular or supramolecular objects to be dynamically aligned during the transfer exhibit an anisotropic shape at the air–water interface [253, 254].

4.1. Pc Rings with a Tetrapyridinium Porphyrazine Bearing Four Octadecyl Chains (Flat-Lying Pc Rings)

The Pc ring is rigid, conjugated, and hydrophobic. It is prone to aggregation in face-to-face dimers, at least when the central metallic ion does not bear any bulky axial ligand. Thus, anchoring the Pc ring parallel to the water surface requires strong polar substituents, either in the center or on the periphery of the macrocycle. However, phthalocyanines bearing strong polar groups on their periphery were much more studied and many Langmuir and Langmuir–Blodgett films were built [32, 255–268].

Pc rings with a tetrapyridinium porphyrazine bearing four octadecyl chains on its periphery (MS_{18}, with M the metallic ion located in the center of the macrocycle) is the first example of a Langmuir monolayer based on flat lying [260]. As shown by the surface–pressure isotherms (Fig. 59) and by various orientational studies performed by electron spin resonance (ESR), linear dichroism, and X-ray diffraction on the LB films built up from that monolayer, the porphyrazine rings lie almost parallel to the water surface but as dimers. Figure 59 shows that the formation of the face-to-face dimers is irreversible, since the decompression isotherm does not match the first compression isotherm [268]. UV-visible spectra recorded on LB films formed before and after the plateau of the first compression isotherm confirm that MS_{18} is in a monomeric state at low pressure and dimerizes at high surface pressure (Fig. 59, inset). The dimerization brings the ς ratio closer to 1, since the dimer bears eight octadecyl chains for a dimeric polar head filling 310 Å² at the air–water interface and allows the monolayer to be transferred correctly onto solid substrates. Orientational studies performed on the resulting LB films indicate that the macrocycles are slightly tilted with respect to the substrate. Similar results were also observed with tetrapyridinium porphyrins that share many geometrical characteristics with the described porphyrazines [269]. Thus, taking into account that the geometry of the porphyrazine rings is fixed by the
Figure 59. Surface pressure vs molecular area isotherms recorded with CuS_{18} at room temperature on a KBr 0.05 M water solution. Solid line: first compression, 30 min after spreading. Dotted line: decompression isotherm. Schematic views of the monomeric and dimeric monolayers are given. Inset: UV-visible absorption curves observed on LB films deposited from the CuS_{18} monolayer on a KBr 0.05 M water solution. Solid line: 16 LB layers deposited at 10 mN m⁻¹ (left vertical axis). Dotted line: 110 LB layers deposited from the same monolayer at 30 mN m⁻¹ (right vertical axis). The solid line spectrum is characteristic of the monomeric state of CuS_{18}. anchoring of the four pyridinium groups to the water surface, the molecules are forced to dimerize for the monolayer to reach a reasonable compactness.

4.2. Pc Ring with Esters, Amides, and Ethers (Tilted with Respect to the Water Surface)

Contrary to the pyridinium groups involved in the previous examples, weak polar groups grafted on the periphery of the Pc ring such as esters [41, 256], amides [255, 262], or ethers [130, 236, 240, 257, 270, 271] are not polar enough to anchor the macrocycle parallel to the water surface. The macrocycles are thus tilted with respect to the water surface and able to self-organize in columnar assemblies. The actual orientation of such molecules at the air–water interface generally depends on their association numbers (i.e., the average number of molecules involved in the self-assembled stacks. When the association number is small (typically less than 10), the monolayer is quite disordered. Indeed, a competition occurs between the self-association in columnar assemblies and the affinity of the polar groups for the water surface. The tilt angles are thus small (30–60°; with respect to the plane of the interface) and the monolayer exhibits a polycrystalline behavior, since the self-assembled columns are not long enough to be in-plane oriented. When the association number is high (typically higher than 100), the Pc rings form well-defined columnar assemblies at the air–water interface, which can be in-plane oriented by the transfer process.

The LB films of tetraamido metallophthalocyanines, bearing four tertiary amide groups on their periphery, exhibited in-plane dichroism when the metallic ion was either Cu or Ni and the multilayers deposited at high surface pressure [263]. On the contrary, no in-plane dichroism was observed with Co and Zn. In the former case, the tilt angle was high (i.e., the macrocycles were almost perpendicular to the plane of the substrate). In the latter case, the tilt angle was low.

These results indicate that if designing a phthalocyanine ring able to lie parallel to the water surface at the air–water interface only requires enough strong polar groups located on the periphery of the aromatic cores, designing flat-lying phthalocyanines able to form stable monolayers and well-organized LB films requires one also to take into account the ς factor of the monolayer (i.e., the actual role played within the monolayer by each component of the molecule).

4.3. Edge-on Pcs in Langmuir and LB Films

The orientation obtained from Pc molecules bearing weak polar groups is very difficult to predict, since it results from the competition between the affinity of the polar substituents for the water surface and the aggregation ability of the Pc derivatives. Three different strategies were designed to get edge-on Pc rings in LB films: (i) using unsymmetrically substituted phthalocyanines, which bear strong polar groups only on one part of its core; (ii) preparing LB films from polymeric phthalocyanines such as phthalocyaninatopolysiloxanes; or (iii) relying on mesogenic phthalocyanines, able to form stable columnar assemblies at the air–water interface.

Cook's team developed both synthetic pathways leading to unsymmetrically substituted phthalocyanines and characterization of the resulting LB films [24, 259, 272].

The Pcs are unsymmetrically substituted, generally bearing only one or two substituent groups that contain a terminal hydrophilic moiety, grafted on the same benzenoid ring of the phthalocyanine and alkyl or alkoxy chains on the three other benzenoid rings (Fig. 60a). The area per molecule lies in the range 80–120 Å^2, depending on the number and the length of the chains, which is consistent with the molecules standing more or less perpendicular to the water subphase. X-ray diffraction, UV-visible, and infrared absorption measurements performed on the LB multilayers indicate that, in the case of Pc rings bearing alkyl chains on three of their four benzenoid rings, highly ordered multilayers are formed: the Pc rings are perpendicular to the plane of the substrate and tilted from the axis of the dipping direction with an average angle of 25°. On the contrary, LB films based on Pc rings bearing alkoxy chains are almost disordered. These results show that properly designed phthalocyanines can form well-ordered mono- and multilayers exhibiting edge-on macrocycles.

A similar design strategy was followed recently in the triazolephthalocyanine family, where one of the four benzene ring is replaced by a triazole (Fig. 60b) [273]. As in the previous example, columnar assemblies are expected to form spontaneously at the air–water interface and to be aligned during the transfer process, but this self-organization requires nickel(II) ions in the subphase.

Well-ordered Langmuir and Langmuir–Blodgett films with high order parameters were observed from mesomorphic Pc bearing four hexyl chains grafted to the benzenoid rings through ester functions (MPcE$_6$, inset in Fig. 61). As shown by Albouy [274], the MPcE$_6$ molecule forms columns in the bulk solid state, with a basic repeat distance of 3.365 Å. The packing of the columns in a two-dimensional square lattice exhibits a regular distance of 20.8 Å, and a typical domain dimension along the axes perpendicular to the columns is 290 Å. In the columns, there is no tilt of one molecule with respect to its neighbors, which means each
Figure 60. Examples of phthalocyanine derivatives specifically designed for an edge-on orientation in Langmuir and LB films. column keeps a fourfold symmetry. In the crystal cell, the benzenoid rings are pointing to the diagonal of the square cell.

A columnar structure, similar to the bulk state one, is found within LB films and the columns are aligned with the dipping direction. This latter result was confirmed by Bourgoin et al. [275], using infrared linear dichroism. The experimental order parameter is 0.94, which indicates that the average angle between the columns and the axis of transfer is less than 10°. Interestingly, the LB multilayers keep their lamellar structure and their in-plane anisotropy upon severe annealing. When the LB multilayers are heated at 200 °C for 2 h under nitrogen, the in-plane anisotropy is actually improved and the order parameter even reaches unity, as evidenced by infrared linear dichroism on the band at 740 cm^{-1} polarized within the plane of the Pc ring (Fig. 61).

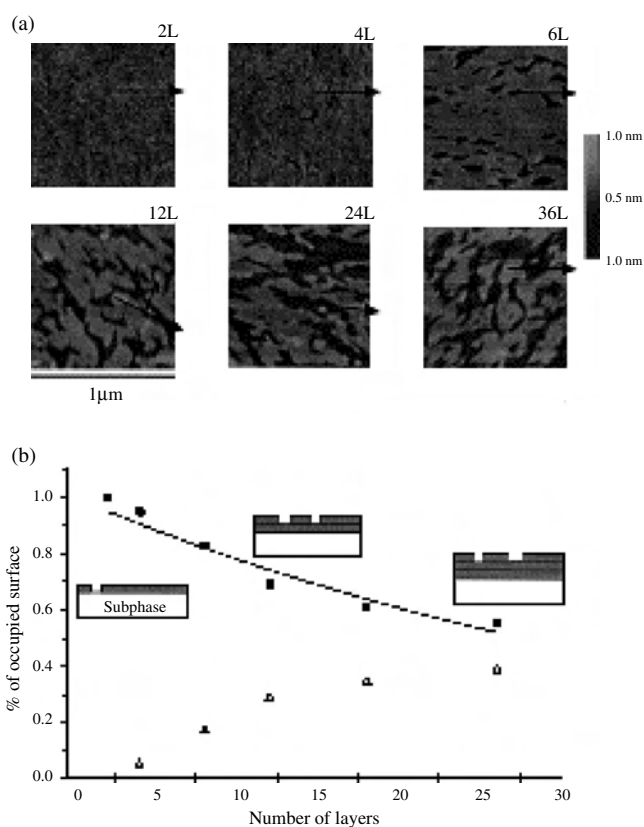
Another peculiar behavior of these LB films is revealed by AFM [275]. In the tapping mode, the morphology of the outer surface of the lamellar assembly can be investigated. Figure 62a gives the topographic images recorded for several thicknesses of $NiPcE_6$ LB films. The darker areas are one monolayer deeper than the brighter ones. It is clear from the images that the area occupied by defects (the darker regions) increases regularly with the number of deposited layers. These defects arise from a solid state reorganization that occurs during and after the transfer of the monolayers onto the substrate. As the transfer ratio is actually slightly lower than 1, each freshly deposited layer exhibits monolayer-thick defects. However, the topographic images in Figure 62 indicate that the defects in the underlayers are filled by the upper ones. Thus all the defects "add" in the topmost layer. According to this simple model, the nth layer should fill α^n of the total area of the sample, with α the transfer ratio. Figure 62b shows that the model is in correct agreement with the results, assuming $\alpha = 0.975$. This result implies that PcE_6 molecules are able to slide easily from one column to a neighboring one.


Figure 62. (a) Topographic images ($1 \mu m \times 1 \mu$m) recorded on 2-, 4-, 8-, 12-, 18-, and 26-layer samples of $NiPcE_6$ LB multilayers. The vertical scale is common to all the images. The black arrow is the direction of the transfer. (b) Percentage of the surface occupied by the topmost nth layer (solid squares) and the (n-1)th layer (open triangles). The solid curve gives the theoretical percentage α^n derived from the model detailed in the text. Inset: Schematics of the summation of the defects in the topmost layer. It is noteworthy that the LB films based on PcE_6 molecules, that were built up by the Langmuir–Blodgett technique via a Y-type deposition, do not exhibit the classical Y-type structure, with a bilayer periodicity. The actual periodicity is one monolayer and these films behave as lamellar liquid crystals, owing to the mesomorphic properties of the molecule in the bulk. The upstroke and downstroke depositions occur only on hydrophobic substrates, which is clearly evidenced by selective deposition on patterned substrates [276]. It is even possible to peel off the multilayers one monolayer after the other using the AFM tip as a plow [277]. This example is thus at the limit between LB films and bulk materials, since the molecular packing is exactly the same in both cases. It should, however, be remembered that the in-plane orientation arises from the LB transfer, without any rubbing of the substrate before the deposition, and that the in-plane orientation is stable upon severe annealing. The LB technique appears to be a good alternative to sample preparation for in-plane alignment of liquid crystals.

4.4. Octasubstituted Amphiphilic Phthalocyanines

Unsubstituted and lightly substituted phthalocyanine molecules show a strong propensity to form columnar structures in which the planar aromatic nucleus of one molecule is either fully cofacial or partially offset from the nucleus of its neighbor [278].

Y-type Langmuir–Blodgett films of the octasubstituted amphiphilic phthalocyanines **12** and **13** deposited onto hydrophobic glass show a columnar arrangement of the molecules in the surface layer [279].

12 R = -(CH₂)₉CH₃

$12 R = -(CH_2)_9CH_3$

$13 R = -(CH_2)_5CH_3$

Structures of compounds **12** and **13**
This columnar arrangement is observed on the surface of films with one, two, and three Y-type bilayers. Figure 63A
Figure 63. Higher magnification friction images of the surface of a two-bilayer film. The scanning direction was along the *y* axis in parts A and C and along the *X* axis in parts B and D. Panel A shows a 1000 Å × 1000 Å area with domains of different columnar orientations. The insert is the 2D Fourier transform showing spots that correspond to the different domains with an intercolumnar distance of 21 ± 2 Å. The horizontal and vertical lines through the center and the spots are noise due to the raster scanning and the finite image size. (B) Smaller area where the columnar packing and individual molecules within the columns can be observed. (C) Small area scanned with the tip at more than 60° with respect to the columnar axis (see text for explanation). (D) A zone in (B). Reprinted with permission from [279], M. Velez et al., *Langmuir* 14, 4221 (1998). © 1998, American Chemical Society.

depicts an area where columns with different orientations come together. The inset is the Fourier transform of the image showing spots that correspond to the spacing and orientation of the different columnar domains. The intercolumnar distance is measured in Fourier space and corresponds to 21 ± 2 Å ($n = 60$ images). When the surface of these columns is scanned in the direction of their longitudinal axis, the friction images show the edges of individual molecules (Fig. 63B, D). The distance between the molecules averaged 5.0 ± 0.6 Å from 118 individual measurements done on nine different images. In these higher resolution images, if the scanning direction of the tip is more perpendicular to the columnar axis, a thinner column between the 21 Å spaced columns appears (Fig. 63C), but there is no evidence of the individual molecules within the columns. After repeated scanning in this tip–column orientation, the distances between the columns and their integrity are perturbed.

The Y-type deposition of the molecules onto a hydrophobic surface implies that the first molecular monolayer deposited has the hydrophobic tails, the R groups, in contact with the surface with the hydroxyl headgroups exposed for H-bonding with the hydroxy headgroups of the second monolayer. The bilayer so formed then has a hydrophobic surface of R groups exposed at the commencement of the second dip. It was observed during the AFM experiments on films of **12** that the technique was able to distinguish between the hydrophobic surface of a bilayer and the surface remaining once parts of the outer monolayer were removed by the tip, exposing the hydroxy headgroups of the monolayer below [280]. Thus the friction images (Fig. 64C) indicate that the most external surface of the bi- or multilayers interacts less with the tip (more hydrophobic behavior) than the surface exposed after removing the outermost monolayer.
Figure 64. (A) AFM topographical image of a 4.8 μm × 4.8 μm area of a two-bilayer film before and after (B) its central part has been scanned (total height range is 10 nm). (C) Friction image of the same area shown in (B). Lighter regions represent areas that have a stronger interaction with the scanning tip. Reprinted with permission from [279], M. 4.5. Metal-Free Asymmetrically Substituted Phthalocyanine

Langmuir–Blodgett films of a metal-free asymmetrically substituted phthalocyanine, 1,8-naphthalimide-tri-tert-butylphthalocyanine (NaBuPc), showed that the asymmetrically substituted Pc not only possesses good solubility in common organic solvents but also possesses an ideal LB film forming ability [281].

Chemical structure of NaBuPc
The atomic force microscopy topography of a NaBuPc LB monolayer on a muscovite substrate is shown in Figure 65. The molecular structure of individual molecules was observed for this LB film, which indicates a smooth and steady film can be obtained through the LB technique. From this picture the diameter of NaBuPc molecules was measured to be about 0.84 nm. If we further assume that the molecules of NaBuPc are cubic in structure, the area per molecule should be about 70 Å^2. This is completely in accordance with the result estimated from the surface pressure–area isotherm of NaBuPc, indicating that a highly oriented LB film was obtained on this substrate.

Figure 66 depicts a small-angle X-ray diffraction (SAXRD) pattern of a 28-layer Y-type LB film of NaBuPc on glass. The SAXRD pattern shows several reflections at 2 = 2.14, 4.54, and 9.98 corresponding to (001), (002),
Figure 65. AFM image of the NaBuPc LB film, scan size: 16×16 nm^2, AFM: contact mode, set point: 0 V, scan rate: 20.35 Hz. Reprinted with permission from [281], Y. Q. Liu et al., *J. Phys. Chem. B* 104, 11859 (2000). © 2000, American Chemical Society.
Figure 66. Small-angle X-ray diffraction pattern of a 28-layer LB film of NaBuPc on glass. Reprinted with permission from [281], Y. Q. Liu et al., *J. Phys. Chem. B* 104, 11859 (2000). © 2000, American Chemical Society.

and (005) Bragg diffraction, respectively, demonstrating a well-defined layered structure of the LB film. From the diffraction pattern, the bilayer d spacing of the LB film is calculated to be about 40 Å; thus, the thickness of a single-layer film is 20 Å. As mentioned the NaBuPc molecules are densely stacked in a face-to-face orientation and edge-on to the water surface with a tilt angle of about 72 using a naphthalimide group as the hydrophilic moiety. The longer diagonal distance across the NaBuPc molecule is approximately 21.1 Å. Therefore, the thickness of the NaBuPc monolayer on the water surface should be about 20 Å. The thickness values obtained both from surface pressure–area isotherms and from SAXRD agree well. The SAXRD result, on one hand, provides additional evidence for the configuration of NaBuPc molecules at the air–water interface. On the other hand, it indicates that the orientation of the phthalocyanine molecules was maintained during the LB transfer process.

For second-harmonic generation (SHG) nonlinear optical (NLO) materials, there are three requirements: (1) a highly polarizable electron conjugation system; (2) an electron-donating substituent and an electron-withdrawing substituent on the aromatic ring or other conjugated system; (3) a noncentrosymmetric structure. Phthalocyanine is an 18-electron conjugated molecule, and the other two requirements can be realized by chemical modification of phthalocyanine molecules and by the LB technique with X- or Z-type deposition models.

The LB films of NaBuPc exhibited SHG activity. The SH intensity of NaBuPc relative to a Y-cut quartz wedge is about 1.76 and the second-order susceptibility and the molecular hyperpolarizability values of a three-layer LB film are 8.32×10^{-9} and 5.97×10^{-30} esu, respectively.

At room temperature, the response and recovery curves of the gas sensor of a five-layer LB film of NaBuPc in 10 ppm NO$_2$/N$_2$ atmosphere are shown in Figure 67. When NO$_2$ was introduced into the test cell, the resistance of the sensor decreased. The equilibrium was reached in less than 1 min, demonstrating relatively large adsorption and desorption velocities for NO$_2$ molecules on NaBuPc films. This is probably due to the fact that the LB sensor films are ultrathin.
**Figure 67.** Influences of NO_2 on the resistance of the NO_2 gas sensor consisting of a five-layer LB film of NaBuPc in 10 ppm NO_2/N_2 at room temperature. Reprinted with permission from [281], Y. Q. Liu et al., *J. Phys. Chem. B* 104, 11859 (2000). © 2000, American Chemical Society.

They can be rapidly saturated by the gas molecules, reaching a maximum response value.

Different metals, substituents, transfer promoters, or solvents have been shown to produce different orientations of the plane of the phthalocyanine relative to the surface. For example, Fryer et al. [282] assert that copper tertbutyl substituted phthalocyanines [$CuPcBu_4$] lie with the plane of the molecule inclined but close to normal to the surface, which is consistent with previous work done by Lloyd et al. [283]. However, the lead analog lies parallel to the surface [240]. Without an amphiphilic promoter, islands of crystals within a disordered structure are observed for both metal chelated $PcBu_4$'s.

4.6. Metallophthalocyanines Bearing Amide Side Chains

Metallophthalocyanines in Figure 68 (MPcs) [M being one of the following metal ions: Co(II), Ni(II), Cu(II), or Zn(II)], bearing amide side chains and being highly soluble
Figure 68. Tetraamidometallophthalocyanines MPc. M(II) = Co(II), Cu(II), Ni(II), or Zn(II). Reprinted with permission from [284], S. Fouriaux et al., *J. Phys. Chem.* 100, 16984 (1996). © 1996, American Chemical Society.

in organic solvents, have been synthesized by starting from the corresponding phthalonitrile. All four compounds can form Langmuir and Langmuir–Blodgett films, but interestingly, their behavior as monolayers was shown to be very much dependent on the central metal ion [284]. The study of Π–A isotherms, low-angle X-ray diffraction patterns, and IR dichroism showed that cobalt and zinc phthalocyanines are coordinated with water molecules and therefore orient with an angle of around 60° normal to the air–water interface or to the substrate. On the other hand, nickel phthalocyanine is not coordinated with water; it forms columns that orient in the transfer direction during the deposition process. The copper phthalocyanine is an intermediate case. For low surface pressures, it behaves like Co and Zn compounds; the square planar copper (II) is certainly liganded with water molecules. At higher surface pressures, the water molecules are ejected and the macrocycles can orient more vertically (angle of around 30° between macrocycle and normal to the air–water interface) and form oriented columnar structures when deposited onto substrates.

The Π–A isotherms at 21 °C are shown in Figure 69. For a given temperature, ZnPc, NiPc, and CuPc present very nicely reproducible curves whereas that of CoPc shows a rather large instability.

The curves corresponding to CoPc and ZnPc are very similar: a not very clear solid phase followed by a slow collapse at around 26 mN/m. The area per molecule in the middle of the solid phase (18 mN/m) is respectively of 140 and 120 Å^2. Theoretical molecular dimensions derived from molecular models (Chem 3D molecular modeling calculation program) give section values of 40 Å^2 if macrocycles are oriented vertically and of 170 Å^2 if they are flat at the air–water interface. The molecular sections observed in the solid phase suggest that CoPc and ZnPc belong to the second type. Metallomacrocycle/water interactions are dominant over Π interactions.
Figure 69. Surface pressure/molecular area isotherm (21 °C) of the MPcs. The measurements were performed in equilibrium conditions by steps of 2 mN/m. Reprinted with permission from [284], S. Fouriaux et al., *J. Phys. Chem.* 100, 16984 (1996). © 1996, American Chemical Society.

For NiPc, there is a slow increase corresponding to the liquid phase until rather high surface pressures (14 mN/m). For higher pressures, there is an almost vertical part in the curve corresponding to the solid phase of a rather rigid monolayer for a molecular area of around 60 Å^2. A clear collapse is observed at 30 mN/m.

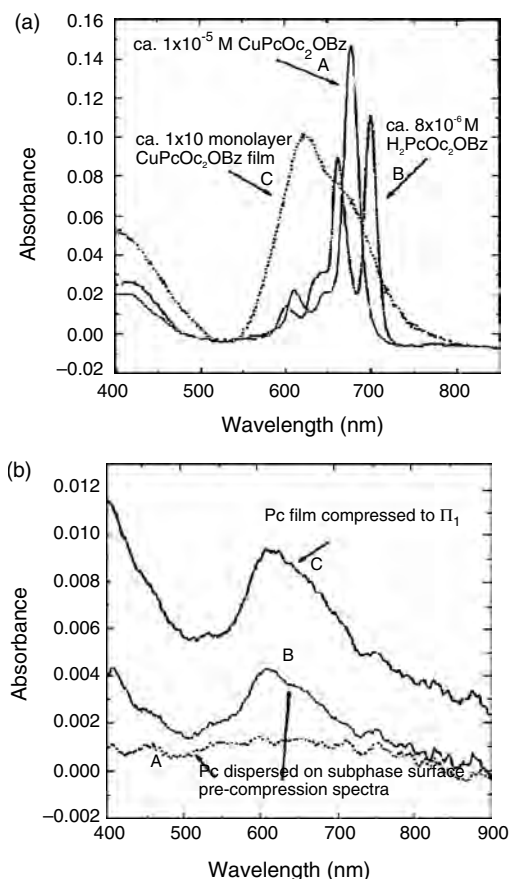
The behavior of the CuPc monolayer seems to be intermediate between that of ZnPc and that of NiPc. For low pressures, the CuPc Π–A isotherm can be superimposed on that of ZnPc; however, at 16 mN/m, after a very short solid phase, a first collapse is observed followed by a clear second solid phase between 25 and 30 mN/m. At these surface pressures, the area per molecule is similar to that observed in the case of the nickel compound.

It is noticeable that, for low surface pressures, the Π–A curves of CuPc and NiPc were found to be very much dependent on the subphase temperature. Interestingly, the arrangement of the macrocycles at the air–water interface appeared to be very much dependent on the nature of the central metal.

For the nickel compound, the macrocycles start also to interact when they are still almost in a horizontal position; however, the area per molecule (60 Å^2) that is obtained in the solid phase corresponds to macrocycles almost vertically oriented at the air–water interface. In this case, π–π interactions between macrocycles should be more important than in the previous case.

For low surface pressures, the Π–A curve of the copper phthalocyanine is similar to that of ZnPc, suggesting that the macrocycles are oriented almost flat at the interface; however, for surface pressures around 16 mN/m, the layer becomes unstable. This first collapse leads to a new solid phase whose area per molecule is very similar to the one observed in the case of NiPc. This can be easily interpreted as a reorientation of the macrocycles. However, for similar compounds [213], the presence of several solid phases in the Π–A curve has been interpreted as multilayer formation. This explanation would fit very well to our case since the area per molecule shifts from 130 Å^2 in the first solid phase to about one-half its value in the second solid phase.

This strong metal dependence of molecular organization at the air–water interface and after deposition onto solid substrates can be interpreted from the coordination number of these central metal ions. Indeed, as Co(II) and Zn(II) are penta- or hexacoordinate ions, it can be expected that CoPc and ZnPc, in contact with water molecules, will be strongly coordinated by one or two apical OH$_2$ which prevent π–π interactions between macrocycles and favor their rather horizontal organization in the monolayers (see Fig. 70a). The presence of water in the films of CoPc and ZnPc analyzed by IR spectroscopy confirms this hypothesis. The absence of clear diffraction peaks by low-angle X-ray reflection spectroscopy can then be understood, since uncharged macrocycles are very poor LB film candidates if they cannot aggregate via π–π interactions. In the other hand, Ni(II) is a tetracoordinate ion fully satisfied with a phthalocyanine ligand. π–π interactions are then possible and NiPc forms very good quality LB films with 100% transfer ratio and clear interlayer spacing corresponding to macrocycles standing almost vertical on the substrate (see Fig. 70b). Finally, Cu(II) is square planar, which is a deformed octahedral
Figure 70. Interaction of MPc with water. Reprinted with permission from [284], S. Fouriaux et al., *J. Phys. Chem.* 100, 16984 (1996). © 1996, American Chemical Society.

structure. At low surface pressures, CuPc is certainly coordinated by one or two apical OH$_2$; the absence of clear X-ray diffraction bands confirms this. However, contrary to the case of CoPc and ZnPc, the OH$_2$ ligands are ejected from the monolayer during the first collapse at 16 mN/m. Consequently, for higher surface pressure, the macrocycles can fully afford π interactions and reorient in a more vertical position.


4.7. CuPcOC$_2$OBz and H$_2$PcOC$_2$OBz

(2,3,9,10,16,17,23,24-Octakis((2-benzyloxy)ethoxy)phthalocyaninato)copper and its dihydrogen analog form highly ordered Langmuir–Blodgett thin films, where the phthalocyanine rings orient with the plane of the ring nearly perpendicular to the compression direction on the LB trough [271]. The resultant thin films show remarkable mechanical stability on the trough, and atomic force microscopy studies show that the transferred thin films, in their fully compressed states, consist of stable bilayers of the Pc. X-ray diffraction studies indicate partial overlap of the benzyl-terminated side chains in adjacent Pc columns.

Solutions of CuPcOC$_2$OBz produced well-defined Langmuir surface pressure–area isotherms with two distinct phase transitions [130]. These films, once compressed, show a remarkable degree of mechanical stability, which affects their transfer to various substrates and which ultimately exerts some control over their spectroscopic and electrochemical properties. Langmuir films transferred to optically transparent ITO electrodes, at pressures corresponding to both of the observed phase transitions, show a high degree of reversibility for the oxidation processes of these Pc thin films, in perchlorate supporting electrolytes. Studies suggest the oxidation of both aggregated and monomerlike Pcs occurs within the thin films. There is evidence that the onset of oxidation of the Pc aggregates results in film phase transformations, which yields less aggregated or even monomeric Pcs, which are oxidized at correspondingly higher potentials.

Spectroscopic characterization of CuPcOC$_2$OBz and H$_2$ · PcOC$_2$OBz indicates that these Pcs do not behave as typical LB amphiphiles. Solution and thin film spectra, shown in Figure 71a, illustrate the spectroscopic properties of monomeric and aggregated forms. Monomeric CuPcOC$_2$OBz in dilute solution has a narrow absorbance band with a maximum at 677 nm, while H$_2$PcOC$_2$OBz

Figure 71. (a) Solution and thin film spectra: solid line (A), CuPcO C$_2$OBz ca. 1×10^{-5} M in CHCl$_3$; dot-dash line (B), H$_2$PcOC$_2$OBz ca. 8×10^{-6} M in CHCl$_3$; dotted line (C), CuPcOC$_2$OBz ca. 10 monolayers on ITO. (b) Time/pressure dependent CuPcOC$_2$OBz on trough spectra: dotted line (A), dispersed Pc precompression (ca. 15 min after Pc introduction to trough); solid line (B), dispersed Pc precompression "Pc island" (ca. 18 min); dot-dash line (C), partial compression ca. 10 mN/m. exhibits the expected splitting of the monomer peak with absorbance maxima at 662 and 700 nm. The strongly blueshifted Q-band spectrum seen for concentrated solutions and thin films of these materials, with an absorbance maximum at ca. 625 nm, arises from cofacial aggregation of the Pcs, as predicted by the molecular exciton model for dyes in close proximity [60, 154, 155, 285]. On-trough spectroscopic characterization of these Pc films at submonolayer coverage indicates that the aggregation behavior of these molecules, seen in concentrated solutions, is sustained for noncompressed Langmuir films after initial spreading on the LB trough.

Figure 71b shows on-trough Q-band spectra, collected prior to and after film compression. The intensity and absorbance maxima of the spectra vary with time. Spectra recorded at random time intervals, after solvent evaporation, show either a presence or absence of Pc. The absence of absorbing species occurs because the Pc is not homogeneously distributed on the subphase surface. When absorbing species are present aggregated Pcs are indicated.

Islandlike regions of aggregated Pc are thought to be diffusing on the subphase surface and occasionally drifting into the light path of the spectrometer. On-trough spectra found for the compressed CuPcOC$_2$OBz and H$_2$PcOC$_2$OBz films are comparable to those found for Langmuir–Blodgett and cast films of these materials.

CuPcOC$_2$OBz and H$_2$PcOC$_2$OBz on water form Langmuir films exhibiting two distinct phase transitions (Fig. 72). An area of ca. 120 Å^2/molecule at the first phase transition (1) suggests the Pc molecules are cofacially stacked into columnar aggregates, on edge, with Pc rings oriented at a small angle to the normal of the subphase surface. The second phase transition (2), at ca. 60 Å^2/molecule, is smaller than the area required for a single Pc in a closest packed monolayer of these materials. The observed molecular area at this transition suggests the formation of a Pc bilayer of ordered columns, on the subphase surface.

Fully compressed films of CuPcOC$_2$OBz and H$_2$PcOC$_2$ · OBz are quite rigid and affect the response of the Whilhelmy balance. Reproducibility of pressure–area isotherms on LB troughs of different geometry is dependent on the position, and motion, of the compression barriers and the placement of the Whilhelmy balance.

The AFM image shown in Figure 73 reveals a region of film, labeled B, that has folded back onto itself along the patterned edge. The corrugated texture seen in region A is typical of images in continuous bilayer film regions. Roughness analysis averaged over a 1 μm^2 area in this region gave
Figure 72. Room temperature pressure–area isotherms (ca. 23 °C): solid line, CuPcOC$_2$OBz; dashed line, H$_2$PcOC$_2$OBz. 1 = two-dimensional liquid–solid condensed phase transition; 2 = monolayer–bilayer phase transition. Inset shows the structure of the octakis (benzyloxyethoxy)-substituted Pcs. Reprinted with permission from [271], P. E. Smolenyak et al., *Langmuir* 13, 6568 (1997). © 1997, American Chemical Society.

extraordinary stability in the x, y plane of these thin films, through intra- and intercolumnar arene–arene interaction.

The degree of order and stiffness in these thin films, as aligned on the LB trough, and as transferred by the horizontal dipping method, leads to a strongly dichroic material, one that sustains its mechanical properties even as a single bilayer thin film. X-ray scattering analysis of LB films of this material suggests that the Pc rings are packed closer together than would be expected without interdigitation of the side chains, by ca. 4 Å. A column-to-column distance of ca. 24 Å is consistent with the partial overlap of the terminal benzene rings.

## 4.8. Application of Pc LB Films

Three substituted phthalocyanines, two asymmetrical and one symmetrical, named amino-tri-*tert*-butyl-phthalocyanines (AmBuPc), 1,8-naphthalimide-tri-*tert*-butyl-phthalocyanine (NaBuPc), and tetra-*iso*-propoxy-phthalocyaninato copper(II) (*i*-Pro-CuPc), were used as semiconductor layers in OFETs based on their LB films [289]. These substituted Pcs possess good solubility in common organic solvents. From the long-wavelength absorption edge of their UV-vis absorption spectra and their electrochemical data, the highest occupied molecular orbital and the lowest unoccupied molecular orbital were determined and the energy band diagram of their OFETs was deduced. The narrower energy gaps of them indicated stronger electron donor–acceptor ability than other symmetrical Pcs because of the substituents at the peripheral ring. The results of their OFETs demonstrated that the LB films of these substituted Pcs can be used as semiconducting layers of OFETs functioning as *p*-channel accumulation devices. From the electrical characteristics of their OFETs, the channel carrier mobilities of AmBuPc, NaBuPc, and *i*-Pro-CuPc were calculated to be about 2.84×10^{-5}, 4.42×10^{-4}, and 3.25×10^{-4} cm^2 V^{-1} s^{-1}, respectively.

Optical SHG from films of phthalocyanine derivative deposited on metal (aluminum) and glass substrate has been investigated [290]. Inspite of the existence of the inversion center, for both Al and glass substrates, the bulk characteristic of the SHG was confirmed by the thickness dependence of the SH intensity. Drastic enhancement of the signal intensity for Pc/Al sample was also observed.

The optically active phthalocyanines substituted with chiral $2'$-methyoxy-1,1$'$-binaphthoxyl were synthesized according to Figure 74 [291].

The metal-free and metal phthalocyanines modified with optically active binaphthyl can form stable monolayers at the air–water interface. In these layers, the phthalocyanines planes are stacked in an edge-on arrangement.

Figure 75 shows an AFM image of the nine-layer LB film of (*R*)-Pc-2 after vertical transfer to a mica substrate at 20 mN m^{-1}. This higher resolution image provides evidence for the long-range highly ordered striped arrangement of the molecules of (*R*)-Pc-2 in the surface layer. The AFM image depicts that most of molecules are stacked in an edge-on arrangement, which is consistent with the result that the Q-band is broad and blueshifted to 640 nm for (*R*)-Pc-2 in the UV-vis spectra. In addition, the striations

Figure 73. Tapping mode AFM image of a patterned bilayer film edge and edge defects on an HOPG substrate. Region A corresponds to a single bilayer. Region B shows the bilayer folded back onto itself. Region C is the uncoated HOPG substrate. Feature D appears to be a "buckled" region in the continuous bilayer. Bilayer film thickness calculated from the height data of the boxed areas was ca. 70 Å. Reprinted with permission from [271], P. E. Smolenyak et al., *Langmuir* 13, 6568 (1997). © 1997, American Chemical Society.

a mean of 13.0 Å. Values of 10.0–13.0 Å were typical for film regions away from defect sites. The feature labeled D in Figure 73 appears to correspond to a "buckled" region in the continuous bilayer. These features were commonly encountered and are thought to be precursors of fibers that form upon collapse of the on-trough film bilayer [129]. A film thickness of ca. 76 Å relative to the graphite surface, labeled C, was determined for the pattern edge shown in the lower left boxed region of the image. The upper right boxed region shows the contact between regions A and B, where a step edge of ca. 80 Å was determined. Step heights of 55–75 Å relative to the graphite surface were typical for the edge sites of these patterned films. X-ray scattering measurements of collapsed LB films of this material indicate an intercolumnar distance of 28 Å. Small-angle X-ray data for multilayer horizontally CuPcOC$_2$OBz films transferred to Si(100) indicate a monolayer repeat distance of 24 Å. Using this value, a thickness of ca. 50–60 Å is expected for a closest packed single bilayer film in intimate contact with the graphite surface.

The extraordinary stability of these compressed films is thought to be due to the terminal benzyl functionality on the peripheral substituents of the CuPcOC$_2$OBz and H$_2$PcOC$_2$OBz molecules. Interaction of the Pc macrocycle electrons is the principal director of order in these systems, while the benzyl functionality introduces an additional opportunity for interaction not previously observed in peripherally substituted Pc systems. Cofacial columnar aggregation of the macrocycles in liquid crystalline Pcs is well known, but only few materials are sufficiently stable to allow for mechanical on-trough patterning [286–288]. The terminal benzyl functionality could contribute to the

Figure 74. The synthesis of the optically active (R or S)-Pc. Reprinted with permission from [291], H. Liu et al., *Synthetic Metals* **131**, 135 (2002). © 2002, Elsevier Science.

in the AFM image show a strong tendency to form helical strips as a result of the substitution groups of chiral 2′-methoxy-1, 1′-binaphthoxyl of neighboring molecules partially offset from each other. On the other hand, Figure 75 also provides an image of individual molecules which are parallel to the surface with a diameter of 2.52 ± 0.2 nm, which is in agreement with the calculation by molecular modeling.

Pcs are electron donating molecules and they undergo charge transfer interactions with electron acceptor gases (such as NO_2). This produces partially charged species which must interact with their surroundings in order to become stable. A possible model which describes the mechanisms of gas sensing suggest that uniform films are preferable in gas sensing. To date, the most extensively studied Pcs with respect
to gas sensing applications are CuPcs and PbPcs although other metals including Ni and Zn have also been studied [292]. A range of deposition techniques, such as evaporation, laser vacuum sublimation, and the LB technique, have also been reported in the literature using these compounds.

Conductometric gas sensing with devices fabricated by ultra-fast LB deposition using a gadolinium bis-phthalocyanine [Gd(Pc)$_2$] are shown in Figure 76 [292a].

The devices fabricated for these experiments consisted of a Gd(Pc)$_2$ LB film on gold interdigitated electrodes. The interdigitated electrodes consisted of 25 pairs of 2×2 mm^2 gold (on chrome) electrodes mounted on glass (Fig. 77). The fingers on each device were 10 μm in diameter and separated by 25 μm gaps.

Figure 78 shows the surface topography of the film on two different scan sizes (100×100 μm and 5×5 μm). In particular, Figure 78a reports an image of the morphology of the LB layers deposited onto interdigitated electrodes. Figure 78b and c reports the morphology of the sample on the gold finger and between the finger respectively. The film surface appears quite rough with a rms roughness value of (21 ± 2.5) nm. Large grains with a diameter ranging between 0.5 and 1.0 μm and height 10–100 nm have been revealed on different regions of the surface. Although Figure 78 shows surface roughness and nonuniformity in the nanoscale, in the macroscale a layer by layer repeatability becomes evident. The change in optical absorbance of the sample as a function of the number of excursions of the dipping arm [i.e., layers of Gd(Pc)$_2$] was increased. Figure 79 shows the magnitude of the response to NO_2 at concentrations ranging from 0.25 to 1.0 ppm. Both the speed and the magnitude of the response are shown to be concentration dependent. From the initial value of $\sim$0.14 μA, the current rises sharply upon exposure to NO_2 and then stabilizes as the device approaches equilibrium. Surface adsorption is responsible for the initial fast response and diffusion effects for the slower process.

The feasibility of using thin films, either LB or evaporated films of lanthanide bisphthalocyanines for the detection of

volatile organic compounds (VOCs) such as alcohols, aldehydes, esters, and acids, has been demonstrated [293].

Several examples in the literature demonstrate the success of using arrays of sensors formed by metal oxide semiconductors or conducting polymers coupled with pattern recognition techniques for the detection of food and beverage odors [294]. Sensor arrays formed by conducting polymers able to discriminate among olive oils with well-defined organoleptic characteristics have been described [295]. Similarly a sensor array based on Langmuir–Blodgett bisphthalocyanines films including unsubstituted bisphthalocyanines with different central metal atom ($PrPc_2$ and $LuPc_2$) and a octatertbutyl substituted bisphthalocyanine

($PrPc_2^t$) has been designed aiming to discriminate among diverse virgin olive oils [296].

Langmuir–Blodgett films of $LuPc_2$, $PrPc_2$, and $PrPc_2^t$ have been deposited onto glass substrates covered with ITO microelectrodes. The high conductivity of the $LnPc_2$ allows one to obtain films with measurable resistances even if only 5 monolayers are deposited onto electrodes with a spacing of 75 μm. The resistance increases during the first days after the preparation, due to drying processes, and after 10–15 days, a plateau is reached and the sensors are stable [293].

The response of $LnPc_2$-based sensors toward the headspace of olive oil samples is illustrated in Figure 80 for $LuPc_2$. The exposure of the LB films to the olive oil aroma causes a fast increase of the resistivity of the films [expressed as the fractional change of resistance ($\Delta R/R$) $\times$ 100]. The change is reversible and the baseline is reached after a few seconds. As observed in the figure, the sensors show a degree of selectivity toward the different classes of olive oils. The intensity of the response produced by the lampante olive oil
Figure 80. Typical response of a $LuPc_2$ LB film expressed as the fractional change in resistance ($\Delta R/R$) $\times$ 100 toward: (a) refined olive oil, (b) lampante olive oil, (c) extra virgin olive oil, and (d) ordinary olive oil. Reprinted with permission from [296], N. Gutierrez et al., *Sens. Actuators B* 77, 437 (2001). © 2001, Elsevier Science.

was higher than that observed for the ordinary, the extra virgin, and the refined olive oils.

Sensors generated from different bisphthalocyanines show different sensitivities toward the headspace of the olive oil. Besides the differences in the intensity of the responses, the unsubstituted bisphthalocyanines $PrPc_2$, and $LuPc_2$ showed a similar pattern of responses and follow the previously described trend, lampante > extravirgin > ordinary > refined. In contrast, the sensors based on the tertbutyl substituted $PrPc_2^t$ show a different pattern of response. In this case, the change in conductivity provoked by the headspace of the ordinary olive oil is bigger than the variation produced by the extra virgin olive oil. This behavior can be related to the electron donor character of the tert-butyl groups, which can affect the redox process between the volatile components and the sensitive material. The difference can also been related to the different structure of the monolayer due to the presence of the tertbutyl groups that can affect the mobility of the charge carriers.

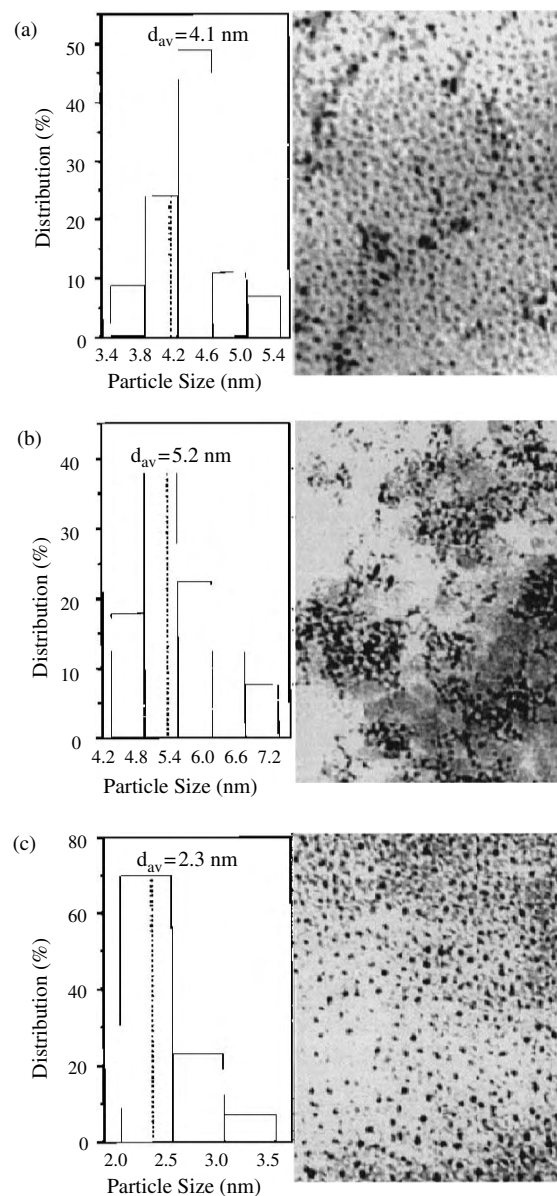
5. PHTHALOCYANINE NANOCOMPOSITES AND HYBRID MATERIALS

Complex films composed of nanoscopic particles of Pcs with nanostructured materials have been successfully prepared by coating the mixture of nanostructured materials with Pcs on glass substrates [297–301].

A "ship-in-a-bottle" synthesis where encapsulation of copper phthalocyanines into mesoporous channels of silicate MCM-41 was achieved by chemical vapor deposition (CVD) using 1,2-dicyanobenzene (DCNB) [297]. Silanol protons of MCM-41 were ion-exchanged with copper ions before CVD, and when the initial amount of DCNB was much larger than that of copper ions, CuPc molecules in the channels were found to form a cofacial structure that was confirmed by diffuse reflectance spectra.

Complex films composed of nanoscopic particles of phthalocyanine and titanium dioxide have been prepared by coating the mixed colloids of titanium dioxide and phthalocyanine on glass substrates [298]. Nanoscopic colloids of TiO_2 were prepared by hydrolyzing titanium isopropoxide [299]. Nanoscopic phthalocyanine colloids were synthesized by adding a solution of Pc (H_2Pc or VOPc) dissolved in concentrated H_2SO_4 to the aqueous solution of a surfactant $[C_{16}H_{33}N(CH_3)_3Br]$ to give a transparent blue colloidal solution. The obtained colloidal solution was then washed to neutral pH with water by using an ultrafilter. A colloidal mixture of titanium dioxide/phthalocyanine solution was prepared by mixing the TiO_2 colloid with the H_2Pc colloid.

The mixed colloidal solution was transparent indicating that the dispersion of nanoparticles is in nanoscale. The colloidal mixture could be coated on a glass by the spin coating technique and the resultant film was dried to give transparent titanium dioxide/phthalocyanine complex films. Figure 81 shows the TEM photographs and particle size distributions of the TiO_2, H_2Pc, and VOPc colloids. The particle sizes of TiO_2 (3.4–5.4 nm; d_{av} = 4.1 nm) are a little larger than those of VOPc (2.0–3.5 nm; d_{av} = 2.3 nm) and similar to those of H_2Pc (4.2–7.2 nm; d_{av} = 5.1 nm). The



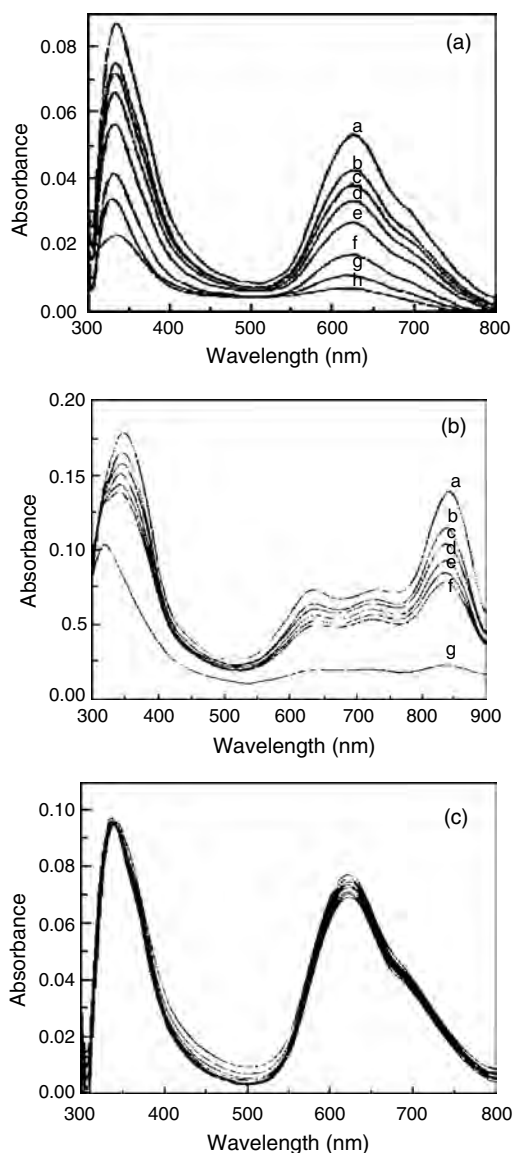


Figure 81. TEM micrographs of colloids: (a) TiO_2, (b) H_2Pc, (c) VOPc. Reprinted with permission from [298], W. Liu et al., *Langmuir* 15, 2130 (1999). © 1999, American Chemical Society.

particles in the TiO_2 colloid and the VOPc colloid are well separated from each other without heavy aggregation. The first particles of H_2Pc can be clearly observed although there are some aggregates that may be formed during the desiccation process of TEM samples. This suggests that the dispersability of the H_2Pc particles is poorer than that of metal phthalocyanine (such as VOPc) particles.

The obtained transparent blue complex films are bleached when illuminated with UV light due to the UV-light-induced catalysis of the titanium dioxide particles for the oxidizing decomposition of phthalocyanine. These nanoscopic materials are important for UV-light-induced decoloration of a new kind of UV-light recording material that is a complex film composed of nanoscopic particles of titanium dioxide and phthalocyanine.

Figure 82a–c shows the UV-vis spectra of the VOPc/TiO$_2$, H$_2$Pc/TiO$_2$, and H$_2$Pc/PVA complex films, respectively, which are illuminated and measured under the same conditions. The complex films of VOPc/TiO$_2$ and H$_2$Pc/TiO$_2$ are obviously bleached after being illuminated by the UV light; however, the spectra of the H$_2$Pc/PVA film did not change significantly. This clearly shows the light-induced catalytic activity of the TiO$_2$ particles in the complex films. Further evidence for the light-induced catalytic decomposition process is that the complex film decolored very slowly when covered by a piece of quartz glass having a coating film of TiO$_2$ on it, while the complex film covered by quartz glass

itself decolored just as the quartz glass did not exist. These results prove that the light in the UV region (about 280 nm) absorbed by TiO$_2$ leads to the light-induced decoloration of the film.

Since the dispersion is in nanoscale, the titanium dioxide/phthalocyanine film has high transprancy, which is requisite for optical device application. Similarly, a phthalocyanine-sensitized nanostructure was reported [300]. In this example, phthalocyanine substituted with ester groups was anchored onto nanostructured TiO$_2$ films. Thus TiO$_2$ film is pretreated with (CH$_3$)$_3$COLi to change the surface hydroxyl groups (-OH) into oxygen anions (-O$^-$), to allow the surface to be more reactive toward the ester functionalities of the dye. The dye can then be anchored onto the semiconductor surface through the produced carboxylate group(s). The amount of anchored dye on the semiconductor shows a dependence on both the time of base treatment and the time of dye treatment. Electrodes treated with the free base phthalocyanine and zinc Pc were characterized by absorption spectroscopy, photocurrent action spectroscopy, and photocurrent–photovoltage measurements. The homogeneous blue–green color and the absorption bands in the far-red region are indicative of an attachment of the dye on TiO$_2$ film. A monochromatic incident photo-to-current conversion efficiency of 4.3% was achieved at 690 nm for a cell where the base-treated electrode was treated with ZnPcBu.

6. PHTHALOCYANINE POLYMERS

Covalently bound phthalocyanine nanostructures are constructed by polymerization. The type of Pc polymers are (1) linear polymer (**14–15**) including block or random copolymer and comblike side chain, (2) ladder (network) type (**16**), and (3) cofacial one-dimensional type (**17**) (Figs. 83 and 84). As described in the previous section, many examples of ordered stacks, produced through only noncovalent bonds, are known. These stack structures have low kinetic stability. Therefore, the covalent linkage of side chains needs to be enhanced to increase the stability of ordered stacks. Only a few examples of such polymeric Pc materials are known to date [302, 303].

6.1. Synthesis of Soluble Phthalocyanine Polymers

Network type phthalocyanine polymers are synthesized from tetramerization of dianhydride and urea as has been well documented [1, 11, 304]. These polymers are usually insoluble and thus structures of them are not well characterized. In order to increase solubility a solubilizing group was introduced into the network polymer as a spacer, or a linear type of phthalocyanie polymers has been synthesized by using a mixture of dianhydride (for the construction of Pc ring) and monoanydride (for linearity).

Soluble phthalocyanine polymers were prepared from tetramerization of hexafluoroisopropylidene-benzenetetra-carboxylicacid dianhydride and urea in the presence of Ti(OBu)₄ and (NH₄)₂MoO₄ [305]. Modification of end groups and bridging groups between the phthalocyanine rings of the polymer has allowed development of soluble phthalocynine polymers. A general scheme for the synthesis of poly(titanyloxo-phthalocyanines), PTiOPc, is summarized in Figure 85. The resultant polymer was deep blue–green in color with a metallic glint and soluble in DMF. It was noteworthy that PTiOPc with carboxylic acid end groups (**19**) showed higher solubility in DMF than the imide type. Polymers with imide end groups (**18**) were stable up to ∼350 °C

and temperatures for 10% weight loss (T_{10}) were 386, 454, 386, and 458 °C for **18a**, **18b**, **18c**, and **18d**, respectively.

Figure 86 shows UV-vis spectra of poly(titanyloxo-phthalocyanines) in DMF solution (∼1.0 × 10⁻⁶ M). In dilute chloroform solution, poly(titanyloxo-phthalocyanines) are present mainly as monomers, characterized by the sharp absorption bands in the Soret (350–400 nm) and in the Q-band region (around 680 nm) [306, 307]. For the sample with carbonyl bridged (**18b**), the Q-band is broadening and the maximum shifts slightly to around 670 nm, which is ascribed to the Q-band(s) of the polymer aggregates [304]. The intensity of the Q-band(s) of the polymer was significantly reduced when the bridging group was sulfone (**18d**), possibly due to the insolubility of the polymer **18d** in DMF. However, the absorbance of the sulfone-bridged polymer was much increased after end group modification to carboxylic acid (**19d**) as shown in Figure 86b.

It was noteworthy that PTiOPc with carboxylie acid end groups showed higher solubility in DNF than the imide type.

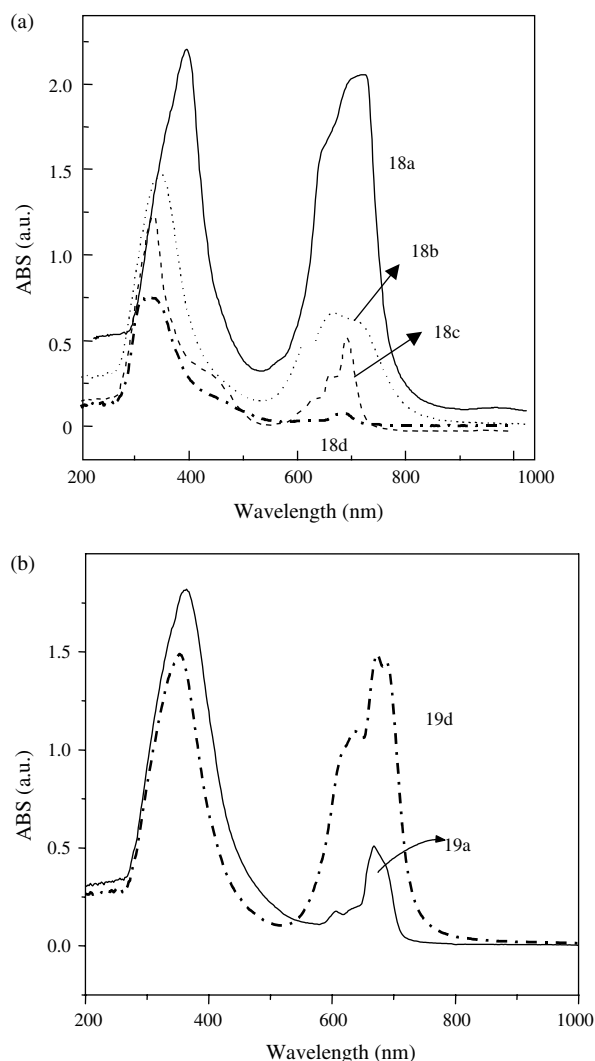

Figure 86. UV-vis spectra of poly(titanyloxo-phthalocyanines) in DMF solution. (a) Imide end group. (b) Carboxylic acid end group. Reprinted with permission from [305c], D. S. Han et al., *Synthetic Metals* 101, 62 (1999). © 1999, Elsevier Science.

The surface of the film prepared by the spin coating method showed a homogeneous surface with an average pore size of less than 0.2 μm.
The soluble phthalocyanine polymers could be processed to a thin film without binder by the spin coating method. The resultant film was transparent, indicating that the aggregation of Pc polymer is much reduced and the dispersion of Pc is in nanoscale.

Irradiation of the films of poly(titanyloxo-phthalocyanines) under the potential of 0.6 V (vs Ag/Ag/Cl) resulted in photocurrent generation. Figure 87 shows photoamperommetric measurement of an ITO glass coated with **18b** prepared by the solution coating method.

As potential was stepped from −0.2 to 0.6 V, current pulse was decayed under dark. Photocurrent was generated when the electrode was irradiated and the anodic current was decayed in the dark. The photocurrent generation was repetitive by a light and dark switching under a potential of 0.6 V. Such current generation can be ascribed to a redox process of hydroquinone and quinone [304], which can quench the photogenerated hole carrier from PTiOPc film. Relative efficiency (η_{rel}) was defined as the ratio of photocurrent of the polymer film (i_p) and that of TiOPc (i_r): $\eta_{rel} = i_p/i_r i_p$ and i_T were detemined as i_p (or i_T) $= i/(Al)$, where I, A, and l are observed photocurrent, area, and thickness of the film (cm), respectively. Thus $\eta_{[e]}$ reflects relative charge carrier generation efficiency of PTiOPc. The current intensity was linearly dependent on the film thickness up to 1.5 μm.

Table 1 summarizes the photocurrent generation for different poly(titanyloxo-phthalocyanines). Films of PTiOPc showed higher photoconductivity than that of the monomeric α-type titanium oxophthalocyanine (α-TiOPc) dispersed in polyvinyl butyral (PVB).

Photocurrent could be affected by the charge generation efficiency of the phthalocaynine chromophores in the polymers and by the charge mobility between the polymer chains. Particularly important are the structure and arrangement of the polymer in film. In the film of **18b**, smaller bridging of C=O induces ordering of polymer chains, resulting in high photocurrent generation. On the other hand, large hexafluoroisopropylidene groups in **18a** favor amorphous irregular structures, resulting in low photocurrent for **18a**. Indeed

Table 1. Photocurrent generation of the films of PTiOPc.

Polymer	Thickness (μm)	i_{hv} (μA/cm^2)	η_{rel}
TiOPc	1.05	2.67	1
18a	0.23	1.07	1.8
18b	0.54	10.27	7.5
18c	0.51	2.00	1.5
18d	0.64	5.33	3.3
19a	1.29	2.07	0.6
19b	0.47	4.67	3.9
19c	0.54	2.00	1.5
19d	0.58	2.67	1.8

Note: Film prepared by a milling method using a mixture of α-TiOPc (40 wt%) and PVB (60 wt%).

XRD of the polymer films indicated higher ordering in **18b** than in **18a** as shown in Figure 88.

6.2. Polymeric Pc Nanocomposite

Although the previous soluble phthalocyanine polymers could be used in the preparation of photoconductive film with high optical clarity, the hardness of the film (pencil strength $<B$) and adhesion property on a surface has limited extensive application of PTiOPc, particularly in a process requiring multilayer film preparation. To improve such mechanical properties of PTiOPc phthalocyanine polymer hybrid silica nanocomposite was investigated using a sol–gel process [308].

The fundamental requirement for the sol–gel method is that phthalocyanine molecules must have nanosized particles or dissolve into the solution for the sol–gel process. Otherwise, the film would show bulk phase separation between the macrocycles and the host, impeding effective transfer of photocarrier. To improve photocurrent generation efficiency plus solubility, the end group of the polymer **19** was modified to an alkyl or a polyethylene glycol unit.

Figure 87. Photocurrent of an ITO glass coated with **20b** (film thickness of 0.54 μm). Reprinted with permission from [305c], D. S. Han et al., *Synthetic Metals* 101, 62 (1999). © 1999, Elsevier Science.

Figure 88. XRD of PTiOPc film. Reprinted with permission from [305c], D. S. Han et al., *Synthetic Metals* 101, 62 (1999). © 1999, Elsevier Science.

The solution for the silica hybrid film consisted of soluble PTiOPc and a sol solution prepared from the hydrolysis of *r*-glycidoxypropyl-trimethoxysilane and methyl trimethoxysilane. A general scheme for the synthesis of phthalocyanine polymers and silica hybrid film is summarized in Figure 89. Phthalocyanine polymers modified with alkyl group showed higher solublility in organic solvent than the unsubstitute PTiOPc, to allow a sol–gel process. Thin films prepared by using a mixture of phthalocyanine polymer in silica solution showed homogeneous surface morphology. Surface roughness of PTiOPc–silica hybrid film was estimated as lower than 10 nm by an α-step and scanning electron microscopy (SEM).
Interestingly, PTiOPc–silica nanocomposite film showed high pencil hardness of 3-H when coated on a glass substrate. Furthermore the film was adherent on a substrate to allow a multilayer coating process. Absorption spectra of the PTiOPc–silica hybrid films were characterized by the appearance of a Q-band at ∼690 nm similar to that of PTiOPc films. Irradiation of the Q-bands of PTiOPc–PSiO film under the potential of 0.6 V (vs Ag/AgCl) resulted in photocurrent generation. Figure 90a shows chronoamperometric measurement of an ITO glass coated with PTiOPc–PSiO film.

As potential was stepped from −0.2 to 0.6 V, current pulse was decayed under dark. Photocurrent was generated when the electrode was irradiated. The current generation was repetitive by a light/dark switching under the bias potential of 0.6 V. Such current generation can be rationalized by a redox process of hydroquinone/quinnone [304], which can quench the photogenerated hole carrier from PTiOPc–PSiO film.

As shown in Figure 90b, the photocurrent generation was dependent on the content of PTiOPc up to 40 wt%. Such a photocurrent generation was related to the absorbance of
Figure 90. (a) Photocurrent of an ITO glass coated with PTiOPc–silica hybrid. (b) Plot of the photocurrent vs content of PTiOPc (wt%). Reprinted with permission from [308a], D. S. Han et al., *Synthetic Metals* 117, 203 (2001). © 2001, American Chemical Society.

the film, indicating that the photocurrent generation originates from the carrier generation by photoexcited phthalocyanine units. Above 40 wt%, however, the dependence of photocurrent on the content became less important, possibly due to a saturation effect. Interestingly, the photocurrent generation from PTiOPc–silica hybrid was larger than the film of TiOPc doped PVB matrix as compared in Table 2. However, the photocurrent was not much affected by the end groups or substituent on the phthalocyanine ring. This result implies that the octyl or PEGM units do not alter the macroscopic structure for photocarrier generation. The quenching of the carrier by hydroquinone is very fast in a liquid electrolyte system, in which the charge transport is usually diffusion controlled.

Photocurrent generation of phthalocyanine polymer–silica hybrid films in double layered solid cells was determined from an all-solid-type photoconductor, assembled using benzidine, oxadiazole, or butadiene derivatives as CTM. The structure of the solid cell is shown in Figure 91. Irradiation of the solid type cell resulted in photocurrent generation higher than 10 nA/cm^2 when potential was stepped from 7 to 10 V. Figure 92 shows chrono-amperometric measurement of a cell structured as PTiOPc-CR(R$_2$,R$_3$ = octyl)/PSiO/BT.

Interestingly the current generation from the solid cell was much affected by the CTM as summarized in Table 3.

Furthermore, the current generation from the solid cell prepared from PEGMe end groups (PTiOPC-CR; R_2,R_3 = PEGMe) was larger than that from octyl end groups (PTiOPc-CR; R_2,R_3 = octyl). Such an end group effect on the photocurrent may be attributed to the effective carrier transport by the ethylene oxy group in solid media, since ethylene oxy group could host a hole carrier by an electron donating oxygen center. If so, the hole carrier generated from the PTiOPc unit could be transported through the ethylene oxy group to CTM. Addition to this plasticizing effect by the PEGMe group may have an effect on the photocurrent generation.

Those two effects are important in a solid medium, in which carrier generation is subjective to the polymer segmental motion and free volume around the carrier.

6.3. Phthalocyanine Centered Polymers

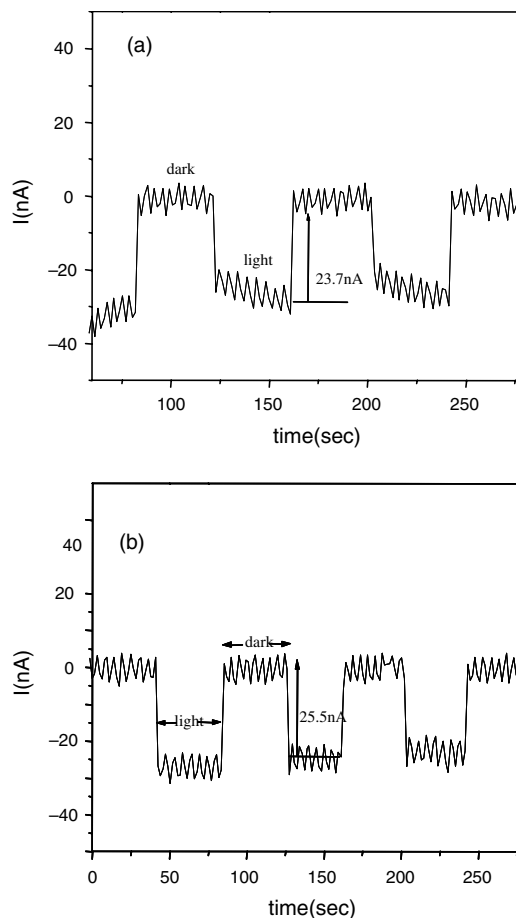
One-dimensional polymers of octasubstituted phthalocyanines were synthesized from the tetramerization of a dinitrile phthalocyanine precursor, 4-(2,3,4,5,6-pentaphenylbenzene)phthalonitrile [309], to give β-tetrakis (2,3,4,5,6-pentaphenylbenzene) phthalocyanine (Fig. 93) [309].
Figure 91. Structure of a solid photocell (CGM:PTiOPc-CR, CTM:BT, OXD, and BZ).


Figure 92. Photocurrent generation from a solid cell prepared from PTiOPc-CR (R_2, R_3 = PEGMe) in contact to CTL containing (a) BZ and (b) BT.

The polyphenylated Pcs and MPcs exhibit different physical properties, but all maintain similar electronic properties. All the materials synthesized are soluble in common organic solvents such as aromatic and chlorinated hydrocarbons, ethers, and hydrocarbons such as hexane and cyclohexane. The high solubility is outstanding for Pcs and MPcs. The unsubstituted polyphenylated Pc **20a** is crystalline, but Pcs **20b** and **20e** are more amorphous and form films readily from solution.

The ground-state electronic absorption spectra of **20b** and **20d**, in toluene, are shown in Figure 94. The metal-free derivative **20b** shows a split Q-band with λ_{max} at 712 nm. This absorption is redshifted ~40 nm compared to unsubstituted Pc. Alkoxy substitution of the pentaphenylbenzene substituent has no additional effect on the λ_{max} of the Q-band absorption. As expected, the positions of the Q-band and B-band are influenced by the presence of a metal. The lead derivative **20d** has the farthest redshifted Q-band, placed at 724 nm.

Third-order NLO value ($X^{(3)}$) of Pc **20a** was determined as $X^{(3)} = 0.52 \times 10^{-10}$ esu and $\langle\gamma\rangle = 6.12 \times 10^{-32}$ esu (measured at 1064 nm), which is among the highest $X^{(3)}$ values reported for tetrasubstituted Pcs. The $X^{(3)}$ is comparable to naphthalocyanines [310]. Such an enhancement in the $X^{(3)}$ value is believed to originate from the polyaromatic

substituents on the phthalocyanine core, as evidenced by the redshifted Q-band in the electronic absorption spectrum.
The Pc-centered poly(oxyethylenes) with four to eight side chains were prepared by the synthetic route shown in Figure 95 [311]. Pc-centered poly(oxyethylenes) containing four or eight side chains, with average lengths of 8, 12, and 16 oxyethylene subunits, were prepared from poly(oxyethylene) monomethyl ethers of average molecular masses 350, 550, and 750 Da, respectively.

The Pc-centered poly(oxyethylenes) have interesting properties due to the strong tendency of the Pc cores to self-associate. In particular, the macromolecules containing four polymer side chains **21–23** display columnar lyotropic behavior despite the absence of a stable thermotropic mesophase. Figure 96 shows a photomicrograph (×100, crossed polarizers) of the lyotropic mesophases formed from an aqueous solution of **21** at 50 °C. A concentration gradient was established by evaporation of water from the edge of the slide (left). The columnar nematic mesophase (N_c), forming as droplets, lies at the boundary of the isotropic solution (right) and the C_H mesophase. A dark band of isotropic, dry

material has formed between the edge of the slide and the C_H mesophase.

Only Pc **24** exhibits a pure (i.e., nonbiphasic) thermotropic mesophase and shows a columnar structure with two-dimensional hexagonal ordering of the Pc stacks (as indicated by two small-angle diffraction rings with d-spacings in the ratio 1:$\sqrt{3}$) by X-ray diffraction study. The intercolumnar distance was calculated to be 38.8 Å. A sharp diffraction ring corresponding to a d-spacing of 3.4 Å is consistent with the strong intracolumnar periodicity associated with the D_{ho} mesophase commonly encountered in alkoxy-substituted Pcs [312]. In addition, the mixture of homeotropic regions and fanlike optical texture exhibited by the mesophase **24**, observed by polarizing

optical microscopy, is characteristic of a D_{ho} structure [313]. Pc material containing four uniform side chains has a well-defined thermotropic mesophase stable up to 170 °C, suggesting that the thermotropic columnar mesophase is severely destabilized by the presence of side chains of nonuniform length.
6.4. Poly(norbornenes) Containing Copper Phthalocyanines

Kimura et al., synthesized poly(norbornenes) containing copper phthalocyanines (polymer **29–32**) as a pendant group through a ring-opening metathesis reaction [314]. Figure 97 shows the synthetic scheme of the polymers with the initiator $(PCy_3)_2Cl_2Ru(=CHC_6H_5)$ [315].

The amphiphilic block copolymer **33** was synthesized by the treatment of **31** with formic acid [316]. The amphiphilic character of **33** favors the alignment of the phthalocyanine planes parallel to the water surface, as indicated in Figure 98 which shows the π–A isotherm of **33** on pure water as the subphase. Surface pressure begins to rise at a molecular area of ca. 10 nm^2, and the pressure is slowly increased up to

Figure 98. Surface pressure vs area per molecule isotherms for **33** on triply distilled water at 25 °C. Redrawn with permission from [314], M. Kimura et al., *Langmuir* 18, 7683 (2002). © 2002, American Chemical Society.

25 mN/m on further compression. The limiting molecular area per molecule of **33** is estimated as ca. 8 nm^2 which is nearly twice the molecular dimension of the phthalocyanine plane (3.9 nm^2) estimated by the Corey–Pauling–Koltun molecular model (Fig. 99).

The amphiphilic diblock copolymer **33** showed spherical objects with a diameter of approximately 8 nm in a TEM image (Fig. 100a), in which the dark image is ascribed to highly concentrated phthalocyanine moieties. Similarly AFM images also show many particles with an average size of 14.0 nm (Fig. 100b). These results support that the amphiphilic diblock copolymer **33** self-organized in aqueous media to produce micellar aggregates by segregation between a hydrophobic polymeric phthalocyanine segment and a hydrophilic ionized segment, as shown in Figure 99.

6.5. Poly(phthalocyanine-*co*-sebacic anhydride)

Phthalocyanine-containing biodegradable copolymers, poly (phthalocyanine-*co*-sebacic anhydride) (Pc-SA), have been synthesized [317]. The synthetic scheme is summarized in Figure 101.

Figure 97. Synthetic scheme of poly(norbornenes) containing copper phthalocyanines. Redrawn with permission from [314], M. Kimura et al., *Langmuir* 18, 7683 (2002). © 2002, American Chemical Society.

Nanoparticles with an average hydrodynamic radius of 166 nm have been prepared from the copolymer Pc-SA-5, which has a Pc to sebacic acid molar ratio of 0.01, via a microphase inversion method. The collapse of polymer chains in the formation of Pc-SA-5 nanoparticles leads to aggregation of the Pc rings inside. The aggregation tendency decreases upon degradation of the nanoparticles in alkaline media, giving ultimately monomeric species. The degradation kinetics of Pc-SA-5 nanoparticles have been investigated by a combination of static and dynamic laser light scattering. It has been found that the rate of degradation increases with the pH and temperature. By using absorption and fluorescence spectroscopies, the release of Pc can be monitored, which occurs almost simultaneously with the degradation. The results suggest that this novel polymer-based colloidal system is potentially useful for the delivery and release of photosensitizers in photodynamic therapy.

The absorption spectra of the copolymers Pc-SA-n (n = 1–5) in chloroform given in Figure 102 are typical for monomeric phthalocyanines [318, 319]. The spectra show the B-band at 343 nm, the Q-band at 673 nm, and the two vibronic bands at 607 and 640 nm. As expected, the intensities of these bands are higher for copolymers with a higher Pc content. Upon excitation at 610 nm, all these copolymers
Figure 101. Synthesis of poly(phthalocyanine-*co*-sebacic anhydride), Pc-SA-5. Reprinted with permission from [317], J. Fu et al., *Langmuir* 18, 3843 (2002). © 2002, American Chemical Society.

Figure 102. UV-vis spectra of Pc-SA-n (n = 1–5) in chloroform with a concentration of 3.30×10^{-4} g cm^{-3}. Reprinted with permission from [317], J. Fu et al., *Langmuir* 18, 3843 (2002). © 2002, American Chemical Society.

fluoresce at ca. 680 nm. The fluorescence quantum yield decreases initially with increasing Pc content, attaining a saturated value of ca. 0.22. This observation suggests that as the Pc content increases, the macrocycles in the polymer matrix exhibit a higher aggregation tendency.

A Zimm plot for the sodium dodecyl sulfate (SDS)-stabilized Pc-SA-5 nanoparticles in water showed that the nanoparticles are composed of loosely aggregated polymer chains with a large number of water molecules entrapped inside. The average hydrodynamic radius of the Pc-SA-5 nanoparticles in water was determined to be 166 nm by dynamic laser light scattering. The results show that this biocompatible polymer-based colloidal system is potentially useful for the delivery and release of photosensitizers in photodynamic therapy (PDT).

6.6. Poly(vinylcarbazole) Bonded Pc

Wang et al. have reported a linear type copolymer containing CuPc, the structure of which is shown in Figure 103 [320]. The copolymer consisting of poly(vinylcarbazole-*co*-acrylamide)-bonded CuPc(NO$_2$)$_2$ was synthesized by the reaction of the diazonium salt of dinitro-diamino copper phthalocyanine with vinylcarbazole and acrylamide as described in Figure 104. The polymer (VK-AA) showed
Figure 103. Structure of the polymer-bonded phthalocyanines. Reprinted with permission from [320], M. Wang et al., *J. Photochem. Photobiol. A* 88, 183 (1995). © 1995, Elsevier Science.
Figure 104. Synthesis of VK-AA copolymer containing CuPc. Reprinted with permission from [320], M. Wang et al., *J. Photochem. Photobiol. A* 88, 183 (1995). © 1995, Elsevier Science.

good photoconductivity, much better than that of the corresponding phthalocyanine monomer $CuPc(NO_2)_4$.

Figure 105 shows the photoinduced discharge curve of the polymer films prepared from **35** and **36** in contact with a charge transport layer. Polymers **35** and **36** have good charge acceptance (V_0) of 588 and 523 V respectively and low residual potential (V_r) of 76 and 62 V respectively. The surface potentials decrease suddenly at the beginning of exposure. The rates of dark discharge (R_d) are 19 and 25 $V\,s^{-1}$, the rates of photodischarge (R_p) are 250 and 312 $V\,s^{-1}$, the half-discharge times ($t_{1/2}$) are 0.438 and 0.975 s, and the percentages of potential discharge after 1 s of exposure (ΔV_1) are 71.4% and 79.2% for **35** and **36** respectively. These values indicate that both polymers **35** and **36** have good charge

Figure 105. PIDC of P/R from polymers **35** (—) and **36** (– · –) and $CuPc(NO_2)_4$ (---). CTM is TPD:PVK:PMMA – 5:2.5:1 (by weight). Reprinted with permission from [320], M. Wang et al., *J. Photochem. Photobiol. A* 88, 183 (1995). © 1995, Elsevier Science.

acceptance, small R_d, and large R_p, showing good photoconductivity. Compared with the $CuPc(NO_2)_4$ monomer, polymers **35** and **36** have bigger values of R_p, smaller R_d, and shorter $t_{1/2}$, indicating that polymers **35** and **36** have much better photoconductivity than the $CuPc(NO_2)_4$ monomer.

It was suggested that bigger conjugated systems are formed between $CuPc(NO_2)_2$ and the P(VK-*co*-AA) main chain, which could enhance the activity of electrons so that they could be excited more easily [321]. Furthermore, there are strong electron acceptor groups (-NO_2) on the phthalocyanine rings and also electron donor groups ($\equiv$N:) on the same polymer chain P(VK-*co*-AA). The interaction of the electron acceptor and electron donor groups may help the charge carriers move, hence increasing the photoconductivity [321, 322].

Similarly a linear type of Pc polymer was synthesized starting from the monomer of vinylcarbazole bonded to copper phthalocyanine (VKCuPc), which was synthesized by diazo-reaction of vinylcarbazole (VK) and the diazonium salt of dinitro-diamine copper phthalocyanine $[CuPc(NO_2)_2(NH_2)_2]$ [323].

VKCuPc monomer is stable at room temperature owing to the steric effect caused by the huge phthalocyanine ring. It can be initiated by azoisobutyronitrile (AIBN) to homopolymerize without air at 80 °C in the following way:
However, the polymerization degree is low because of the sterically hindered phthalocyanine ring. The average n value is only about 3 measured by vapor pressure osmomety. The content of Cu determined from the atomic absorption analysis is 6.12 wt%, slightly smaller than the theoretical value (7.33 wt%), which may explain the low polymerization degree. PVKCuPc is soluble in DMF and THF.

Table 4 shows the photoconductivity of the P/Rs from PVKCuPc, VKCuPc monomer, and CuPc. PVKCuPc has good charge acceptance ($V_0 = 589$ V), a small rate of dark discharge ($R_d = 26$ $V\,s^{-1}$), and a fast rate of photodischarge ($R_p = 187$ $V\,s^{-1}$). The percentage of potential discharge

Table 4. Photoconductivity of PVKCuPc, VKCuPc monomer, and CuPc.

CGM	V_0 (V)	R_d ($V\,s^{-1}$)	R_p ($V\,s^{-1}$)	ΔV_1 (%)	$t_{1/2}$ (s)	$t_{1/2}^{-1}$ (s^{-1})
PVKCuPc	589	26	187	59.8	0.625	1.600
VKCuPc	375	15	156	50.5	0.938	1.066
CuPc	598	35	147	36.4	4.840	0.210

Note: CTM is TPD:PVK:PC = 5:5:1 (by weight). The thicknesses of the interface layer (IFL), charge generation layer (CGL), and charge transport layer (CTL) are about 1.5, 1.5, and 10 μm respectively.

Source: Reprinted with permission from [323], M. Wang et al., *J. Photochem. Photobiol. A* 94, 249 (1996). © 1996, Elsevier Science.

after 1 s of exposure is $\Delta V_1 = 59.8\%$, and the time of half-discharge is $t_{1/2} = 0.625$ s.

The differences of the photoconductivity of PVKCuPc, VKCuPc monomer, and CuPc may result from their different structures as described for polymers **35** and **36** [320]: that is, in the case of VKCuPc monomer, a bigger pi-conjugated system is formed between the phthalocyanine ring and VK, which could enhance the cativity of electrons so that they could be more easily excited [322]. Hence the photoconductivity increases greatly compared with that of CuPc. When VKCuPc monomers are homopolymerized, the photoconductivity of PVKCuPc increases further, compared which that of VKCuPc monomer.

7. POLYMERIC STACKS

One-dimensional polymeric stacks were prepared using reactive octasubstituted phthalocyanines [324, 325]. The key to this strategy is the placement of the reactive site(s) along the side chains of the disklike monomer, rather than at the periphery, because the later approach can result in cross-linking of the discotic columns [302b].

The stacking of phthalocyanines can be controlled by putting certain metals in the middle [197], as shown in Figure 84 (compound **17**). The bridging ligands can be organic ligands with unsaturated or heteroatom containing aromatic molecules for high charge transport. A better conductor has been made by substituting biphenyl to separate the porphyrin rings. The spacing of this material will also control the nature of the conductivity. These materials can also be doped to make them semiconductors.

7.1. Polymeric Pc Stacks by Olefin Metathesis

Among the synthetic targets selected prepare polymeric Pc stacks by cross-linking of the discotic columns is Pc **38** in Figure 106, which preserves the freedom to utilize a variety of transition metals, M, at the Pc core. Pc **38** contains eight β-alkyl styryl groups that can react via photostimulated [2 + 2] cycloaddition. The precedence for this strategy comes from the observations of Zhao and co-workers, who demonstrated that photolysis of LB multilayers of fatty acids and lipids derived from β-substituted styrenes produced dimers via cyclobutane formation [326]. The thin film behavior of

Figure 106. Disklike monomers for 1D polymers. Redrawn with permission from [324], A. S. Drager et al., *J. Am. Chem. Soc.* 123, 3595 (2001). © 2001, Elsevier Science.

38 at the air–water interface was similar to that reported for **37** [134].

Figure 107A shows a typical image of rodlike structures found in the cast film. Rod lengths were measured within a 500 nm × 500 nm area that includes the image area of Figure 107A. Only rods with distinct end points were measured and are included in a histogram (Figure 107B) that shows the large variation of rod lengths, with a mean rod length of 72 nm. Both the matrix-assisted laser desorption ionization (MALDI) and AFM data indicate the presence of macromolecules consistent with Pc rod lengths of 10–40 nm. In addition the AFM data clearly suggest that considerably larger Pc rods are formed during irradiation, with lengths up to 290 nm. The observed column-to-column distance between adjacent Pc rods was 6.4 ± 0.2 nm, which is approximately twice the expected column diameter for **37** [134]. The Pc polymer rods are arranged in domains of 8–10 rods each, aligned along the three principal crystallographic axes of HOPG, suggesting that these rods adopt epitaxial relationships with the HOPG substrate.

Phthalocyanine polymers **39** and **40** (Fig. 108) were prepared from two phthalocyanine monomers CuPc(-CH=CH$_2$)$_8$ and CuPc(-CH=CH$_2$)$_2$ bearing eight and two terminate olefin groups, respectively, through olefin metathesis reaction using a ruthenium initiator (PCy$_3$)$_2$Cl$_2$Ru(=CHC$_6$H$_5$) developed by Grubbs et al. [325]. The polymers resulting from two Pc monomers **39** and **40** bear the Pc rings in the polymeric network and the main polymer chain, respectively, by the intermolecular formation of carbon–carbon double bonds. A linear polymer **40** prepared from CuPc(-CH=CH$_2$)$_2$ produced a rodlike nanostructure in which the copper phthalocyanine moieties were stacked with the regular stacking distance.

Matrix-assisted laser desorption ionization-time of flight-mass (MALDI-TOF-Ms) spectroscopy for polymerized samples indicated that all of the olefin groups were intramolecularly linked through the olefin metathesis reaction at a high-diluted condition (Fig. 109). The GPC analysis of **40** revealed a high molecular weight $M_n = 55,000$ with a wide polydispersity PDI = 3.0 (relative to monodispersed

Figure 107. (A) Tapping mode AFM image (sample in water) of cast photolyzed material on HOPG. The image is 250 nm × 250 nm, with a height scale of 2.0 nm. A Fourier domain transformation (inset) of the AFM image indicates the three-fold symmetry packing of the rod-like structures. (B) A histogram of molecular object length measured within a 500 nm × 500 nm scan area. Only complete molecular objects with defined end points were measured with lengths ranging from 5 to 290 nm, with a mean length of 72 nm. Redrawn with permission from [324], A. S. Drager et al., *J. Am. Chem. Soc.* 123, 3595 (2001). © 2001, Elsevier Science.

polystyrene standards). The intermolecular formation of carbon–carbon double bonds through the olefin metathesis reaction gave a high molecular weight polymer material containing a Pc moiety.
Figure 109. MALDI-TOF-Ms spectra of polymerized samples from $ZnPc(-CH=CH_2)_8$ at the two initial concentrations: $[ZnPc(-CH=CH_2)_8]$ = 60.0 mM (a) and $[ZnPc(-CH=CH_2)_8]$ = 7.5 mM (b). The X-ray diffraction pattern of linear polymer **40** is shown in Figure 110. The regular spacing of 0.34 nm among Pc moieties within the columns can be derived from the oriented reflection in the wide-angle region. This value of 0.34 nm is a common stacking distance in planar aromatic compounds [132b, 327]. The 0.34 nm spacing value indicates the formation of highly ordered stacks among Pc moieties within **40**. The diffuse halo at around 0.43 nm is characteristic for liquidlike order of the alkyl chains. The small-angle reflection at 2.05 nm is related to ordering of the columns [328]. The covalent linkage of side chains in $CuPc(-CH=CH_2)_2$ results in the formation of a columnar structure consisting of one-dimensional ordered stacks of numerous Pc moieties.

The morphologies of the aggregates examined by TEM showed irregular nanostructures for polymer **39** (Fig. 111a) and rodlike structures for linear polymer **40** with a width of ca. 2.0 nm (Fig. 111b). The rods in each domain were almost orientated along a regular direction. Therefore, the covalent linkage of side chains in the unsymmetrical Pc monomer allows the direct observation of columnar densely packed Pc stacks bearing 300–500 nm lengths. These long ordered Pc stacks might open new possibilities toward the construction of molecular wires.

7.2. Cofacial Arrangement of Phthalocyanine Rings in Phthalocyaninato–Polysiloxanes

There has been much research on LB films of Pcs and their applications in electronic devices following the first report by Baker et al. [234]. Among the many types of Pcs,

Figure 111. Transmission electron micrographs of **39** (a) and **40** (b). The inset shows the rodlike structure of **40** under magnification. Reprinted with permission from [303], M. Kimura et al., *Macro-molecules* 34, 4706 (2001). © 2001, American Chemical Society.

phthalocyaninto-polysiloxane are one of the most attractive ones; they are rigid-rod polymers which are promising for design of molecular devices because of their one-dimensionality and high stability [329–332]. Since Orthmann and Wegner fabricated LB films of 2,9,16,23-tetra(methoxy)-3,10,17,24-tetra(octanoxy)-phthalocyaninato polysiloxane in 1986 [333], reports about this compound used in devices have increased rapidly.

Indeed the latest strategy developed to obtain edge-on phthalocyanines in LB films relies on the phthalocyaninato-polysiloxanes [43, 333, 334]. The Pc rings are linked through a siloxane chain by their centers, thus forming a rigid rod of approximately 50 molecules long. The periphery of the macrocycles is bearing both short (methoxy) and long (octyloxy) aliphatic chains to provide solubility in organic solvents and prevent any well-defined crystal formation in the solid state. As for the columnar assemblies spontaneously formed by mesogenic Pcs, the rigid rods are "floating" at the air–water interface, without any strong interaction with the water subphase. The rods are aligned by the transfer process [246] and form in-plane oriented LB multilayers. The order parameter generally lies in the 0.35–0.70 range, but higher figures are obtained with other rigid rod oligomers such as polyglutamates or cellulose [247]. As for comparison between the rigid rod phthalocyaninato-polysiloxanes and the mesogenic Pc columnar assemblies described previously, it is likely that the rigid rods are more efficiently aligned by the flow effect during the transfer process but cannot reorganize as easily in the solid state as the mesogenic Pcs. The phthalocyaninato-polysiloxanes and the other rigid rod systems developed by Orthmann and Wegner are more stable than the mesogenic Pcs and were successfully used as seeding surface for liquid crystal alignment [335], as molecular thick membranes after a cross-linking step in the solid state [248, 336], as photochromic or nonlinear optical devices [337, 338], and as an oriented matrix for the formation of well-aligned conducting polymer chains [339].

Tetra(methoxy) tetra(octyloxy) phthalocyaninato polysiloxane forms macroscopically oriented LB films with the long axes of the rigid rod polymer molecules oriented parallel

to the direction of film tranfer. The dichroic ratio of the absorption of the phthalocyanine chromophore is 2.3 and is used as the order parameter to quantify this orientation. Quantitative analysis of the "grazing-incidence reflection" IR spectra shows that the side-chain segments are randomly distributed around their polymer chain axes [43].

Several phthalocyanine-polysiloxanes containing pyridine moieties with potential use for organizing electroactive monomers have been synthesized. The compounds are slightly soluble in organic solvents due to their polycationic nature. However, when soluble enough, these oligomers give Langmuir–Blodgett films macroscopically in-plane oriented in which the long axis of the rodlike molecules lies parallel to the dipping direction [340].

Monolayer behaviors and LB films of dihydroxo (phthalocyaninato) silicon and its polymer, 2,9,16,23-tetra-teradecanophthalocyaninato polysiloxane (III), a one-dimensional polymer, and its precursor dihydroxo(2,9,16, 23-tetra-tetradecanophthalocyaninato) silicium (II), shown in Figure 112 were prepared [231].

There are face-to-face as well as J-like arrangements (Fig. 113) for the monomer both at the air–water interface and in the LB films according to the data by surface pressure–area isotherms and Brewster angle microscopy (BAM) experiments. In the case of the polymer, it can form more homogenous monolayers in which the macrocycle ring of the repeat unit of the rigid rod molecules and its alkoxy chains are perpendicular to the water surface. It was also revealed that both the compounds can form stable and reproducible monolayer at the air–water interface and that aggregation of the molecules during the compression process may be responsible for the hysteresis in the isotherms. This type of arrangement has an analogous appearance as that of the rigid rod polymer, which is characterized by a columnlike structure (Fig. 113, left).

Figure 114. The structure of PcPS Langmuir–Blodgett films with hexagonal packing of the PcPS rods. Reprinted with permission from [341], P. Gattinger et al., *J. Phys. Chem. B* 103, 3179 (1999). © 1999, American Chemical Society.

Cofacial arrangement properties of phthalocyaninatopolysiloxanes have been analyzed by electrical dark conductivity experiments and by pulse-radiolysis time-resolved microwave conductivity (PR-TRMC) measurements [341, 342]. PcPS (**41**) consists of phthalocyanine rings which are covalently connected in a cofacial geometry. The strong steric interaction between the disk-shaped repeat units forces the polysiloxane backbone to become rigid, resulting in a repeat distance of 0.33 nm [341]. This close cofacial arrangement also induces an electromagnetic coupling of the chromophore units. In the polymer the Q-band is considerably broadened and blueshifted to 540–560 nm while the monomer exhibits the Q-band at 680 nm. These spectral changes can be explained by the theory of molecular excitons as given by Kasha et al. [285].

41 (PcPS, with R=C_8C_{17} and R=$C1_{18}H_{37}$)

On peripheral alkoxy chain substitution, the polymers are soluble and can be processed by the Langmuir–Blodgett technique into thin films [334a, 342a, 343]. The backbone of the hairy rod molecules is oriented parallel to the substrate surface. Consecutive transfer of monolayers leads to PcPS LB films with a layered structure and a monolayer thickness of approximately 2.2 nm. Upon annealing the structure of PcPS films changed to a highly oriented hexagonal packing of the cylinders of cofacially stacked conjugated macrocycles in a disordered matrix of aliphatic side chains as shown in Figure 114 [344, 345]. TEM measurements have shown that PcPS LB films consist of microdomains with dimensions of several tens of nanometers and a strictly parallel alignment of the molecules. The flow conditions on the

Langmuir trough generate a preferential alignment of the long axis of the PcPS molecules along the dipping direction [346]. This structural order is responsible for the pronounced anisotropy of various properties of these films [43, 246, 286b, 347].

Due to its excellent thermal and particularly good electrochemical stability [348] PcPS has been examined with respect to electrical and photoelectrical properties [246, 286b, 347, 349]. In contrast to films of monomeric Pc, where different polymorphic structures can be present depending on the method of preparation, the covalent link in PcPS forces the macrocycles into a strict cofacial stacking. Even though there is no orbital overlap between the Pc macrocycles it is expected that electron motion within the core of the stack will be rapid compared to the motion perpendicular to the polymer backbone which would involve tunneling through the aliphatic side chains. This makes PcPS a model system for the study of charge transport in materials with an intrinsically one-dimensional conductivity. The layer-wise deposition of the PcPS molecules enables the control of the molecular orientation within the films.

Depending on the voltage, either an Ohmic or space-charge-limited current (SCLC) should be observed [347a]. At low fields the current density j is described by Ohm's law

$$j_\Omega = ne\mu \frac{U}{d} \tag{1}$$

whereas at higher fields Child's law for SCLC applies:

$$j_{SCLC} = \frac{9}{8} e_0 e_\mu \frac{U^2}{d^3} \tag{2}$$

Here, μ, d, and e denote the mobility, the electrode separation, and the dielectric constant. n is the charge carrier density initially present in the material at low voltages, which is introduced by doping, impurities, or by thermal activation. In the well-annealed samples the Ohmic conductivity is low and a SCLC regime could be clearly resolved, as shown in Figure 115.

The double-logarithmic plot of Figure 115b reveals the transition from ohmic to space-charge-limited behavior. The straight lines represent the ohmic and space-charge-limited regime according to Eqs. (1) and (2), respectively. The onset of the transition from the Ohmic to the SCLC region shifts only slightly to lower fields with increasing temperature.
Figure 115. I/U characteristics of a film of 11 LB layers of C_1C_8 on interdigitated electrodes recorded at different temperatures. The electrode distance is 10 μm. Reprinted with permission from [341], P. Gattinger et al., *J. Phys. Chem. B* 103, 3179 (1999). © 1999, American Chemical Society.

According to Eq. (2) the charge carrier mobility μ can be deduced from the current density in the SCLC regime. The data of Figure 115 yield a temperature dependence of the mobility with values ranging between 3.6×10^{-7} at 27 °C and 2.1×10^{-5} cm^2/V s at 97 °C. Knowing μ, the initial density of charge carriers n can be calculated from the Ohmic part of the curve according to Eq. (1). For the set of data shown in Figure 115 values for n are approximately 1×10^{13} cm^{-3} (1.9×10^{13} cm^{-3} at 27 °C, 8.9×10^{12} cm^{-3} at 97 °C). In contrast to the increase in mobility by two orders of magnitude upon raising the temperature, the carrier density n in the Ohmic region remains almost constant.

From the PR-TRMC transients for the C_1C_{18} derivative, the end-of-pulse conductivity per unit dose (D J/m^3) and $\Delta\sigma_{eop}/D$ were determined and used to determine the one-dimensional, intracolumnar mobility $\sum\mu_{1D}$ that can be derived using the following relationship:

$$\sum\mu_{1D} = 3E_p(\Delta\sigma e_{eop}/D)/F_{eop} \qquad (3)$$

The values of the pair formation energy $E_p = 25$ eV and the end-of-pulse pair survival probability $F_{eop} = 0.35$ (C_1C_8) and 0.46 (C_1C_{18}) were estimated [351] and used to calculate the values of $\sum\mu_{1D}$ given in Figure 116. As can be seen, $\sum\mu_{1D}$ ($\approx 2 \times 10^{-2}$ cm^2/V s) is almost independent of temperature from 0 to 120 °C. In addition, similar values are found for both the C_1C_8 and C_1C_{18} compounds. This supports the assumption that the mobility does indeed refer to intracolumnar charge transport (i.e., it is independent of the average distance between the columns L which varies from 22 to 37 Å). The average value of $\sum\mu_{1D}$, given by the horizontal straight line in Figure 116A, is 0.018 cm^2/V s.

Similarly, in a C_9C_9 polysiloxane derivative the mobility was also found to display only a small temperature dependence [352]. The independence of μ_{1D} on the side chain length indicates that only transport parallel to the chain axis is involved. The absolute value of μ_{1D} for the C_9C_9 polysiloxane derivative, however, was a factor of 3 larger than the average value for the C_1C_8 compounds, possibly due to an additional degree of disorder in the C_1C_8 and C_1C_{18} compounds resulting from the random nature of substitution of the two different alkoxy side chains.

Figure 116. (A) The temperature dependence of the one-dimensional, intracolumnar mobility calculated from e_{eop}/D for C_1C_8 (filled circles) and C_1C_{18} (open circles). Data for the monomeric C_9C_9 compound (open squares) are included for comparison. (B) The temperature dependence of the first half-life of the conductivity transients for C_1C_8 and C_1C_{18} using the same symbols as in (A). Reprinted with permission from [341], P. Gattinger et al., *J. Phys. Chem. B* 103, 3179 (1999). © 1999, American Chemical Society.

For comparison, mobility data for the monomeric, uniformly substituted C_9C_9 compound [351] are displayed in Figure 116A. These are significantly larger than for the polymeric compounds over the entire temperature range and clearly display the sharp decrease at the crystalline solid to liquid crystal transition which has been found to be characteristic of the n-alkyl, substituted monomeric compounds.

TEM measurements on monomolecular layers of the C_1C_{18} compounds have shown the existence of microdomains of several tens of nanometers in length and width with strictly parallel alignment of the molecules [350, 353]. The independence of μ_{1D} on the side chain length indicates that only transport parallel to the chain axis is involved (Fig. 117). Mobilities over macroscopic distances of PcPS LB films parallel to the preferential chain orientation are approximately 10^{-7}–10^{-6} cm^2/V s at room temperature.

Charge carrier transport perpendicular to the polymer chains involves tunneling through the aliphatic side chain regions. From PR-TRMC relaxation times a temperature-independent value of $\mu_{2D} = 10^{-5}$ cm^2/V s is derived. This is three orders of magnitude smaller than the intracolumnar mobility μ_{1D} and proves that charge transport on a microscopic scale, for example, within a domain of highly oriented PcPS chains must be highly anisotropic. In agreement with this, the dark conductivity "strictly" perpendicular to the polymer backbones is smaller by approximately three orders
Figure 117. Schematic representation of charge transport within a domain of parallel oriented PcPS molecules. Redrawn with permission from [341], P. Gattinger et al., *J. Phys. Chem. B* 103, 3179 (1999). © 1999, American Chemical Society.

of magnitude than the corresponding in-plane conductivity and it follows an Arrhenius-type temperature dependence with $E_a \sim 0.36$ eV. This value is similar to that of the temperature dependent in-plane conductivity.

Langmuir–Blodgett multilayer structures of PcPS exhibit high photoconductivity and strong light absorption in the visible, properties that are the basis for the successful development of photoactive devices such as photodiodes and sensors. The photogeneration of charges in PcPS films has been the subject of intense research for many years [220a, 349a, 354]. There are several issues of central importance in studying the photogeneration of charge carriers as well as the transport dynamics of excited states and charge carriers. The proper characterization of the relaxation dynamics of the initially excited electronic states and, in particular, of the exciton transport dynamics is of great interest in this regard.

(Phthalocyaninato)polysiloxane composed of siloxane-polymerized, cofacially stacked phthalocyanines, staggered at an angle of 36°, is a one-dimensional molecular conductor [354]. The linear stacking and the rather small ring–ring interplanar spacing of about 0.33 nm [43, 135, 354] favor efficient intermacrocycle interactions, so that optical excitation is expected to lead to extensive excitonic coupling between the extended-conjugated electron systems of the phthalocyanine cycles [43, 348, 349b].

[Tetramethoxytetrakis(octyloxy)phthalocyaninato]polysiloxane is a linear polymer consisting of an average of 32° cofacially stacked oxo-bridged silicon phthalocyanine rings with stacking distances of dSi–O–Si = 0.33 nm and constitutes fairly rigid rods of ca. 11 nm length [43, 135]. The temporal evolution of the singlet exciton states created at different excitation energy densities between ca. 0.5 and 2.5 mJ/cm^2 was studied by femtosecond transient absorption spectroscopy [355]. Both photoinduced bleaching and transient absorption were observed, and decay dynamics, which strongly depend on the excitation energy density, are nonexponential. At higher excitation densities, the observed relaxation dynamics in PcPS are dominated by exciton–exciton annihilation. The excited state lifetime of singly excited chains is ca. 4.5 ps, drops to about 0.5 ps for doubly excited chains, and becomes less than the instrumental

resolution of 150 fs at higher excitation densities. An analysis of the decay dynamics was made in terms of a model, which has been successfully utilized to rationalize the exciton transport dynamics in VOPc films and PbPc films, and in which the exciton–exciton annihilation rate is time dependent ($t^{-1/2}$) [354, 356]. For low excitation densities the decay behavior can be well reproduced, while at higher densities the recovery of the ground state is faster than predicted. This fast recovery is supposed to originate from the creation of charge-separated states, which efficiently quench all excited states of a polymer chain.

Figure 118 displays the time evolution of the transient spectra of PcPS in tetrahydrofuran solution recorded between -0.6 and $+15$ ps. The wavelength of the pump laser is 555 nm (18,020 cm^{-1}) and the excitation density is ca. 0.5 mJ/cm^2. Analogous transient absorption measurements on solutions of PcPS indeed demonstrated that the spectra were independent of the polarization conditions.
Figure 118. Time evolution of transient spectra of PcPSi in tetrahydrofuran excited with a 120 fs pump pulse at 555 nm (18,020 cm^{-1}) with an exitation density of ca. 0.5 mJ/cm^2. The spectrum at $D = -0.6$ ps constitutes the baseline with T1 except for the range of the scattering light of the pump pulse between 18,020 and 17,700 cm^{-1} where $T > 1$. Bleaching and absorption bands are recognized as increases and decreases with respect to the baseline, respectively. Reprinted with permission from [355], J. Ern et al., *J. Phys. Chem. A* 103, 2446 (1999). © 1999, American Chemical Society.

8. CONCLUSION

The nanostructure of phthalocyanines and their polymers has been controlled through covalent and noncovalent bonds, by controlling the intermolecular interactions in all ranges. Thus phthalocyanine thin films, nanorods and stacks, molecular arrays of Pc with templates, self-assembly, layer-by-layer assembly of oppositely charged materials, Langmuir–Blodgett films, and other methods have been developed for construction of nanostructured phthalocyanines, as a noncovalent method. Complex film composed of nanoscopic particles of Pcs with nanostructured materials is also an example of a noncovalent method of nanostructured Pcs. Since the dispersion is in nanoscale, the titanium dioxide/phthalocyanine film has high transprancy, which is requisite for optical device application.

Having planar structures in the central ring, phthalocyanines easily form thin films with a film thickness on the nanometer level, by deposition methods. STM images of the thin films were highly dependent on the electron density and the local density of surface states near the Fermi energy.

Disk-shaped rigid phthalocyanines and metallophthalocyanines can easily stack through strong π–π interaction and form one-dimensional rodlike assemblies with interesting electronic and optic properties. Such cofacially stacked Pc aggregates are present even in dilute solution for some examples. In the Langmuir and Langmuir–Blodgett films containing phthalocyanine derivatives, it is shown that the molecular parameters of the amphiphilic Pc derivative (i.e., the nature, the number, and the location of the polar substituents, the number and the location of the aliphatic chains) strongly affect the orientation of the molecules at the air–water interface and in the LB multilayers. Two extreme examples are given: LB films containing Pc molecules lying parallel to the substrate and LB films containing Pc molecules standing edge-on. In both cases, good-quality and well-ordered LB films are only obtained when the packing parameter ς is sufficiently close to unity. It is shown that "sacrificial" single-chain amphiphilic molecules, mixed with the Pc derivatives, can significantly improve the quality of the mono- and multilayers and in some cases modify the inner structure of the film. Methods for the identification of the nanostructures are developed using various techniques such as STM, AFM, surface-enhanced Raman scattering spectrum, and UV-vis spectral methods. Such methods enable the precise manipulation of molecular arrangements and photoelectronic properties of Pcs in nanoscale.

In films of metallophthalocyanine stacks, the Pc rings are spaced by van der Waals distances and exciton coupling of neutral–electronic transitions between neighboring macrocycles becomes very efficient. On the other hand, linear polymers of (phthalocyaninato)siloxane in solution strictly limit the exciton transport to one dimension and heating effects can be avoided in flowing solutions.

Chemical modification of the core of phthalocyanines by electron withdrawing groups such as fluorine provides a high versatility in molecule structure and hence intermolecular interactions. The film structure as well as electrical and optical characteristics can be adjusted in a rather wide range.

Several polymeric nanostructures are achieved by cofacial arrangement of Pc stacks by bridging with an organic spacer, linear, or network type by, for example, using olefin metathesis and condensation polymerization methods. The stacking of phthalocyanines can be controlled by putting certain metals in the middle. The bridging ligands can be organic ligands with unsaturated or heteroatoms containing aromatic molecules for high charge transport. A better conductor has been made by substituting biphenyl to separate the porphyrin rings. Among those, phthalocyaninto-polysiloxanes are one example showing edge-on phthalocyanines structures, which are linked through a siloxane chain by their centers, thus forming a rigid rod nanostructures. These are promising for designing molecular devices because of their one-dimensionality and high stability.

Although polymeric Pc nanostructures are rare, compared to the monomeric stacks, the polymer stacks ensure increased stack stability, processibility, and wider applications. The control of spatial arrangement and orientation of these nanostructured Pc materials allowed directional transport of electrons, photons, and ions, to improve photoelectronic properties of phthalocyanines.

Judging from the unique properties of Pc and availability of nanoscaled manipulations, there will be increasing applications of nanoconstruction based on Pc in the future.

GLOSSARY

Fermi energy (E_F)   When a number of electrons are put into an energy level, electrons will occupy higher energy levels when the lower ones are filled up. E_F is the energy level of the highest occupied state at zero temperature.

Langmuir–Blodgett film   A set of monolayers, or layers of organic material one molecule thick, deposited on a solid substrate. An LB film can consist of a single layer or many, up to a depth of several visible-light wavelengths.

Layer-by-layer (LBL) assembly   Assembly of oppositely charged materials.

Molecular self-assemblies   Spontaneous formation of molecules into covalently bonded, well-defined, stable structures via electrostatic, van der Waals, hydrogen bonding, hydrophobic interaction, etc.

Molecular wire   A common name to indicate a long, highly conjugated molecule.

Monolayer   A one-molecule thick insoluble layer of an organic material spread onto an aqueous subphase.

Plasma Chemical Vapor Deposition of Nanocrystalline Diamond

Katsuyuki Okada

National Institute for Materials Science, Tsukuba, Ibaraki, Japan

CONTENTS

1. INTRODUCTION

Covalently bonded disordered thin-film materials have been of considerable interest from fundamental and applied perspectives in the last twenty years, since the chemical vapor deposition (CVD) of diamond was developed, followed by fullerenes and carbon nanotubes [1, 2]. Amorphous and nanostructured carbon films are being extensively studied for electron emitters, cold-cathode sources, hard low-friction coatings, etc. From fundamental perspectives, on the other hand, the structure of these materials contains both three-fold coordinated (sp^2-bonded) and four-fold coordinated (sp^3-bonded) carbon atoms. Nanocrystalline diamond films have also drawn remarkable attention [3] because they have a low coefficient of friction and low electron emission threshold voltage. The small grain size (approximately 5–100 nm) gives films valuable tribology and field-emission properties, compared with those of conventional polycrystalline diamond films. Furthermore, it has been proposed that applications for microelectromechanical systems (MEMS) devices, metal-semiconductor field effect transistors MESFETs, electrochemical electrodes, and biochemical devices can be created by taking advantage of these excellent properties [4–6].

Recent plasma dry processes (e.g., deposition, coating, etching) require a wide area and high density plasma at low pressures (<1 Torr) [7]. An electron cyclotron resonance (ECR) plasma was first developed to meet these conditions. Subsequently, a helicon-wave excited plasma was employed.

It was found [8] that the density of an inductively coupled plasma (ICP) becomes high at low pressures. Amorim et al. [9] reported that the plasma density of ICP after the transition from a low-density E-discharge to a high-density H-discharge reaches 10^{12} cm^{-3}. It is necessary in plasma-enhanced chemical vapor deposition (PE-CVD) to get a sufficient radical flux for deposition. Thus the ICP is thought to be a promising method for PE-CVD at low pressures.

In this review article, the synthesis of nanocrystalline diamond by low-pressure ICP-CVD and its spectroscopic characterizations are mainly described. Plasma diagnostics with a Langmuir probe are also reviewed.

2. GROWTH OF NANOCRYSTALLINE DIAMOND

2.1. Conventional Microwave Plasma CVD

A microwave plasma is most commonly used for the PE-CVD of diamond films [10], in which the conventional pressure of deposition is on the order of a few 10 Torr. A CH_4/H_2 mixture, in which the CH_4 content ($[CH_4]$) is usually less than 5%, leads to micrometer-size polycrystalline diamond films. One methodology for synthesizing nanocrystalline diamond films is to increase the $[CH_4]$ to 10% while the substrate temperature is kept constant [11–13]. The resultant morphology changes from faceted microcrystals to ball-shaped nanocrystals.

Another methodology is to substitute a noble gas for hydrogen while the $[CH_4]$ is kept constant. Gruen et al. [14, 15] demonstrated the synthesis of nanocrystalline diamond films in a CH_4/Ar or C_{60}/Ar microwave discharge, without the addition of hydrogen. Extensive characterizations with X-ray diffraction (XRD), transmission electron microscopy (TEM), and electron energy loss spectroscopy (EELS) showed [16] that the films consist of a pure crystalline diamond phase with a grain size ranging from 3 to 20 nm. They also proposed from the plasma diagnostics [17] and the theoretical calculations [18] that the C_2 dimer could

be responsible for the growth of the very fine-grained diamond films, whereas the CH_3 radical is generally believed to be a precursor for the diamond growth.

Recently Butler et al. [4] reported the deposition of nanocrystalline diamond films with the conventional deposition conditions for micrometer-size polycrystalline diamond films. The substrate pretreatment by the deposition of a thin H-terminated a-C film, followed by the seeding of nanodiamond powder, increased the nucleation densities to more than $10^{12}/cm^2$ on a Si substrate. The resultant films were grown to thicknesses ranging from 100 nm to 5 μm, and the thermal conductivity ranged from 2.5 to 12 W/cm K.

In addition to microwave plasma, direct current (dc) plasma [19], hot-filament [20], magnetron sputtering [21], and radiofrequency (rf) [22–24] plasmas were utilized for nanocrystalline diamond deposition. Amaratunga et al. [23, 24], using CH_4/Ar rf plasma, reported that single-crystal diffraction patterns obtained from nanocrystalline diamond grains all show {111} twinning.

From a theoretical point of view, the stability of nanocrystalline diamond was discussed by several authors. Badziag et al. [25] pointed out that, according to semi-empirical quantum chemistry calculations, sufficiently small nanocrystalline diamond (3–5 nm in diameter) may be more stable than graphite by forming C-H bonds at the growing surface. Barnard et al. [26] performed the *ab initio* calculations on nanocrystalline diamond up to approximately 1 nm in diameter. The results revealed that the surfaces of cubic crystals exhibit reconstruction and relaxations comparable to those of bulk diamond, and the surfaces of the octahedral and cubooctahedral crystals show the transition from sp^3 to sp^2 bonding.

2.2. Low-Pressure Plasma CVD

Whereas a microwave plasma is most commonly used for the PE-CVD of diamond films, an ECR is the only plasma that is used for diamond deposition below 1 Torr [27–29]. Although Bozeman et al. [30] reported diamond deposition at 4 Torr with the use of a planar ICP, there have been a few reports that describe the synthesis of diamond by low-pressure ICP. Okada et al. [31–33] first reported the synthesis of nanocrystalline diamond particles in a low-pressure CH_4/CO/H_2 ICP, followed by Teii and Yoshida [34], with the same gas-phase chemistry.

In the PE-CVD of diamond films, the addition of oxygen to a CH_4/H_2 system was intended to get a high growth rate and/or an improvement of the quality of resultant films [35–38]. Several authors proposed the role of oxygen in the diamond growth. Mucha et al. [37] pointed out that oxygen additions to a CH_4/H_2 system increase the concentration of atomic hydrogen; correspondingly, amorphous and graphitic carbon, which would otherwise inhibit diamond growth, is better suppressed. From a detailed chemical kinetics model that describes both gas-phase and surface processes occurring in diamond CVD, Frenklach and Wang [38] postulated that OH radicals and atomic oxygen are considered to gasify sp^2 carbon and to suppress the formation of aromatic species in the gas phase. Teii et al. [39] pointed out that the OH radicals resulting predominantly from loss reactions of the

by-product O atoms with H_2 and CH_4 are highly responsible for the enhanced diamond growth.

A 13.56-MHz low-pressure ICP system [31–33] has been utilized as a radical source for PE-CVD and applied to the preparation of diamond films from a CH_4/H_2 plasma. CO has been added to a CH_4/H_2 plasma to clarify the effect of oxygen-containing radicals on the diamond growth. A schematic view of the apparatus is given in Figure 1. It consisted of a water-cooled quartz tube surrounded by a Teflon tube and a stainless-steel growth chamber. An inductively coupled plasma was generated by applying 13.56-MHz rf powers of 1 kW to a three-turn helical coil wound around the Teflon tube. The chamber was pre-evacuated to 5×10^{-5} Torr by a turbo molecular pump (200 liters/s). A Faraday shield was inserted between the rf coil and the quartz tube to rule out electrostatic coupling from the rf coil to the plasma. The quartz tube was wrapped with a grounded copper plate slitted at regular intervals along the azimuthal direction. A substrate holder was manipulated from the top of the chamber. Molybdenum plates and silicon (100) wafers (ϕ 10 mm) were used as a substrate. The substrate was heated by a tungsten filament. The substrate temperature (T_s) was monitored with a sheathed thermocouple and kept at a prescribed temperature within ± 1 °C by a proportional integral derivative (PID) controller. The deposition conditions were as follows. The flow rates of CH_4 and H_2 were kept at 4.5 and 75 sccm, respectively, whereas
Figure 1. Schematic description of the low-pressure inductively coupled rf plasma CVD system. Adapted with permission from [33], K. Okada et al., *J. Mater. Res.* 14, 578 (1999). © 1999, Materials Research Society.

the flow rate of CO ([CO]) was varied between 0, 1.0, 5.0, and 10 sccm, respectively. The total gas pressure (Pr) was varied from 45 to 50 mTorr. The T_s was kept at 900 °C. The deposition duration was 2 h.

3. SPECTROSCOPIC CHARACTERIZATION

3.1. SEM and TEM

Figure 2 presents the SEM photographs of the resultant deposits on a Si(100) substrate. Figure 2a, b, c, and d correspond to [CO] = 0, 1.0, 5.0, and 10 sccm, which are labeled as samples A, B, C, and D, respectively. The morphology of sample A was scale-like as shown in Figure 2a, and crystal facets were not clearly seen. When CO was added to a CH_4/H_2 plasma, particles 200–300 nm in diameter with scale-like deposits appeared as shown in Figure 2b. With the increase in [CO], only particles were deposited as shown in Figure 2c and d. The background of the particles was the substrate. The diameter of the particles was 200–700 nm. The detailed observation reveals that the particles consist of small particles about several tens of nanometers in diameter, and that the sizes are almost the same regardless of increasing [CO]. It is therefore speculated that increasing [CO] makes the supersaturation degree of carbon large, and then the number of encountered particles is increased.

The TEM image of sample B is shown in Figure 3a. Figure 3b shows the transmission electron diffraction (TED) pattern corresponding to Figure 3a. In the TEM image, a scale-like deposit was mainly observed. The ring pattern in the TED indicates that the deposit is composed of a large number of microcrystallites. Figure 4a presents the TEM image of sample C. The corresponding TED pattern is presented in Figure 4b. Only particles 200–500 nm in diameter were observed in the TEM image. The TED pattern was spotty compared with that of Figure 3b. The TEM images clearly show that each particle is composed of small particles about several tens of nanometers in diameter. The interplanar spacings (d values) obtained from the TED patterns are summarized in Table 1, where they are compared with the experimental values reported for diamond. The agreement between the values obtained and those for diamond is within the experimental error. No reflections due to nondiamond planes were observed in the patterns of sample C, whereas the reflections of nondiamond planes were observed in the pattern of sample B. Although these reflections are not always assigned to graphite, it is speculated that they are attributed to disordered microcrystalline graphite. From the TEM image of sample B, the size of the disordered microcrystalline graphite was estimated to be about several hundred nanometers. It is therefore concluded that scale-like deposits consist of disordered microcrystalline graphite, whereas particles are composed of only diamond microcrystallites.

3.2. XRD

The X-ray diffraction (XRD) pattern for sample D is shown in Figure 5. D(111) and D(220) denote the diffraction peaks of the diamond plane. The diffraction peaks of the silicon
Figure 2. SEM micrographs of the obtained deposits. (a) $[CH_4]/[CO] = 4.5/0$ sccm. (b) $[CH_4]/[CO] = 4.5/1.0$ sccm. (c) $[CH_4]/[CO] = 4.5/5.0$ sccm. (d) $[CH_4]/[CO] = 4.5/10$ sccm. substrate also appeared. Although the incident X-ray angle was quite shallow, it reached the substrate because of the imperfect coverage of the deposit as shown in Figure 2d. The peaks corresponding to graphite were not observed. Although no clear crystal facets can be seen in the SEM observations, the diffraction pattern clearly reveals that the deposit is neither amorphous carbon nor graphite, but diamond. The crystallite size was estimated to be approximately

[b] Values are calculated from $a = 0.3567$ nm.

20 nm from the full width at half-maximum (FWHM) of the diamond peaks with the use of Scherrer's equation [40]. It accordingly implies that the particles that are several hundred nanometers in diameter consist of smaller particles several tens of nanometers in diameter. This is consistent with the TEM observation.

The addition of CO to CH$_4$/H$_2$ plasmas is considered to produce oxygen-containing radicals, such as atomic oxygen, the OH radical, and the CO radical itself, in plasmas. As mentioned previously, the morphological change from a scale-like deposit to a particle took place with the CO additive. Furthermore, the number of particles encountered increased with an increase in [CO]. According to the TED and XRD patterns, nondiamond carbon was effectively removed with an increase in [CO]. We therefore presume that oxygen-containing radicals produced by the addition of CO play an effective role in the removal of nondiamond carbon in the diamond growth conditions and that the CO

additive makes the supersaturation degree of carbon large. This is consistent with the previously reported hypotheses [37, 38] that OH radicals and atomic oxygen gasify sp^2 carbon and that they suppress the formation of amorphous carbon and graphitic carbon.

3.3. Raman Spectroscopy

Raman spectroscopy is a nondestructive method for the study of the vibrational band structure of materials. It has been extensively used for the characterization of diamond [41–44], graphite [45], and diamond-like carbon (DLC) [42, 43, 46–49]. So far Raman scattering is the most popular technique for identifying sp^3 bonding in diamond and sp^2 bonding in graphite and DLC. Although Raman scattering should represent the phonon density of state (PDOS), weighted by a coupling parameter, Raman spectroscopy of sp^2-bonded carbon with excitation wavelength in the visible range (514, 488 nm, etc.) does not provide a good representation of the PDOS [50]. Since the local sp^2-bonded carbon energy gap of ∼2 eV is comparable to the energy of visible Raman excitation, the sp^2-bonded carbon network exhibits the electronic π-π^* transition resonance enhancement in the Raman cross section [43, 48–50]. On the other

hand, the sp³-bonded carbon does not exhibit such a resonance effect because of the higher local gap of ~5.5 eV. As a result, the Raman spectra obtained with visible excitation are completely dominated by the sp²-bonded carbon. However, Raman spectroscopy with ultraviolet (UV) excitation has recently been used to characterize DLC [50–53]. The advantage of UV Raman spectroscopy is to eliminate the resonance effect of sp²-bonded carbon. Excitation of 244 nm (5.1 eV) is far from the energy of previously mentioned sp²-bonded carbon resonance. It is accordingly expected that the resonance Raman scattering from sp²-bonded carbon is suppressed and that the signal from sp³-bonded carbon is possibly increased. UV Raman spectra of tetrahedral amorphous carbon (t-aC) films containing sp³ bonding dominantly exhibit a peak at ~1150 cm⁻¹ attributed to an sp³-bonded carbon network [50–52]. Okada et al. [54] first applied UV Raman spectroscopy to the characterization of bonding structures of nanocrystalline diamond. Sun et al. [55] reported UV Raman characteristics of nanocrystalline diamond films with different grain sizes from 120 to 28 nm. They pointed out that the downshift and broadening of the diamond peak with decreasing grain size are consistent with the phonon confinement model. On the other hand, Prawer et al. [56] reported the visible Raman spectra of nanocrystalline diamond powder with a size of ~5 nm. The peaks at 500, 1140, 1132, and 1630 cm⁻¹ are compared with the calculated VDOS of diamond, and the origin of features in the vibrational spectrum from nanocrystalline diamond is suggested.

In Raman measurements [57], the 514-nm line of an Ar⁺ laser, the 325-nm line of a He-Cd laser, and the 244-nm line of an intracavity frequency-doubled Ar⁺ laser were employed. The incident laser beam was directed onto the sample surface under the back-scattering geometry, and the samples were kept at room temperature. In the 514-nm excitation, the scattered light was collected and dispersed in a SPEX 1403 double monochromator and detected with a photomultiplier. The laser output power was 300 mW. In the 325- and 244-nm excitations, the scattered light was collected with fused silica optics and was analyzed with a UV-enhanced CCD camera, using a Renishaw micro-Raman system 1000 spectrometer modified for use at 325 and 244 nm, respectively. A laser output of 10 mW was used, which resulted in an incident power at the sample of approximately 1.5 mW. The spectral resolution was approximately 2 cm⁻¹. That no photoalteration of the samples occurred during the UV laser irradiation was ensured by confirming that the visible Raman spectra were unaltered after the UV Raman measurements.

Figure 6 shows the 514-nm excited Raman spectra. Figure 6a, b, and c corresponds to sample A, sample B, and sample D, respectively. The Raman spectrum of sample A exhibits two peaks at ~1355 cm⁻¹ (D peak) and ~1580 cm⁻¹ (G peak) assigned to sp² bonding [45]. New peaks appear at ~1150 cm⁻¹ and ~1480 cm⁻¹ in sample B. The former peak is due to sp³ bonding. Nemanich et al. [42, 44] assigned the peak at ~1150 cm⁻¹ to microcrystalline or amorphous diamond. Prawer and Nugent [58] attributed the peak at 1100–1150 cm⁻¹ to the surface phonon mode of diamond from the EELS studies of the nanophase diamond powder. On the
Figure 6. 514-nm excited Raman spectra of the deposits obtained with different gas mixtures. (a) [CH₄]/[CO] = 4.5/0 sccm. (b) [CH₄]/[CO] = 4.5/1.0 sccm. (c) [CH₄]/[CO] = 4.5/10 sccm. other hand, Ferrari and Robertson [59] have recently proposed another interpretation, that the peak at ~1150 cm⁻¹ is not attributable to nanocrystalline diamond but to sp² bondings of a trans-polyacetylene oligomer of a given conjugation length. The peak at ~1480 cm⁻¹ is probably related to amorphous sp² structures [44], though it is downshifted from the G peak. Both the D and G peaks become relatively small compared with those of sample A. A peak at ~950 cm⁻¹ is derived from scattering by two transverse-optical (TO) phonons of silicon substrate [43]. The incident laser beam reached the substrate because the substrate was not fully covered with the deposit as shown in Figure 2b. In the Raman spectrum of sample D, the G peak turns into a shoulder and the D peak becomes faint, whereas the peak at ~1480 cm⁻¹ has a maximum intensity and the peak at ~1150 cm⁻¹ still remains. However, the three spectra in Figure 6 do not clearly exhibit the 1332 cm⁻¹ diamond peak. These features of Raman spectra imply that the deposit from CH₄/H₂ predominantly contains sp² bonding; the addition of CO to CH₄/H₂ produces a mixture of sp² and sp³ bondings; the increase in [CO] brings about the increase in sp³ bonding. These tendencies are consistent with the TEM and XRD observations, which reveal that the increase in [CO] improves the crystallinity of the deposit.

Figure 7 shows a sequence of Raman spectra from sample D with different excitation wavelengths. Figure 7a, b, and c corresponds to 514 nm, 325 nm, and 244 nm, respectively. Compared with the spectrum of 514-nm excitation, the 325-nm excited Raman spectrum exhibits a clear peak at 1332 cm⁻¹ and the remarkable enhancement of the
Figure 7. Raman spectra of sample D ([CH$_4$]/[CO] = 4.5/10 sccm) with different excitation wavelengths. (a) 514 nm. (b) 325 nm. (c) 244 nm. Reprinted with permission from [57], K. Okada et al., *J. Appl. Phys.* 88, 1674 (2000). © 2000, American Institute of Physics.

peak at ~1580 cm^{-1}, while the peak at ~1150 cm^{-1} turns into a shoulder. In a 244-nm excited Raman spectrum, the peak at 1332 cm^{-1} is only enhanced, whereas the peak at ~1580 cm^{-1} is weakened. Neither a peak nor a shoulder can be recognized at ~1150 cm^{-1}. The Raman spectra in Figure 7a are superimposed on a broad photoluminescence background. The luminescence background diminishes with increasing excitation photon energy as shown in Figure 7b and c.

The TED and XRD patterns revealed that the deposit is not amorphous carbon but nanocrystalline diamond. Nonetheless, the 514-nm excited Raman spectra do not exhibit a clear diamond peak at 1332 cm^{-1}, though the peak due to the sp^3-bonded carbon network appears at ~1150 cm^{-1}. The Raman cross section of the sp^2-bonded carbon network with visible excitation is resonantly enhanced [43, 48–50]. It consequently makes the 1332 cm^{-1} diamond peak overlap with the peaks due to sp^2-bonded carbon.

The suppression of the dominance of the resonance Raman effect in the 514-nm excitation and the possible increase in the signal from sp^3-bonded carbon are expected to occur in higher photon energies. Wagner et al. [43] mentioned that a resonance enhancement of scattering by sp^3-bonded carbon is expected at an incident photon energy of 4.8 eV, which is close to the onset of the σ-σ^* transition in both sp^2- and sp^3-bonded carbon. Gilkes et al. [51] stated that the 244-nm photon energy is sufficient to excite the σ-σ^* transition of both sp^2 and sp^3 sites. The enhancement of the peaks at both 1332 cm^{-1} and ~1580 cm^{-1} in the 325-nm excitation suggests that the resonance

enhancement of the Raman cross section due to sp^2-bonded carbon still remains and that the σ-σ^* transition in both sp^2- and sp^3-bonded carbon is possibly induced. The remarkable enhancement of the peak at 1332 cm^{-1} and the diminution of the peak at ~1580 cm^{-1} in the 244-nm excitation reveals that the resonance Raman effect due to sp^2-bonded carbon is suppressed, whereas the resonant enhancement due to the σ-σ^* transition of sp^3-bonded carbon is predominantly attained.

The 244-nm excited Raman spectra of t-aC films exhibit the appearance of the peak at ~1150 cm and the increase in the intensity proportional to the amount of sp^3 bonding in the films [50, 51]. However, the diamond peak at 1332 cm^{-1} is enhanced in this study because the deposit obtained is not amorphous carbon but nanocrystalline diamond. The peak at ~1150 cm^{-1} is probably disappearing because of the striking enhancement of the diamond peak at 1332 cm^{-1}.

3.4. HREELS

High-resolution electron energy loss spectroscopy (HREELS) is a method for the study of the vibrational motion of atoms and molecules on and near the surface by the analysis of the energy spectrum of low-energy electrons back-scattered from it [60]. With developments in modern ultra-high-vacuum (UHV) technology and increasing interest in the physical properties of clean and adsorbate-covered surfaces and of the chemical phenomena occurring on these surfaces, scientific interest in HREELS has increased dramatically, and the method has been widely used in recent years [60–65].

HREELS experiments [66] were performed in a UHV chamber. The chamber was pre-evacuated by polyphenylether-oil diffusion pump; the base pressure reached ~2 × 10^{-8} Torr. The HREELS spectrometer consisted of a double-pass electrostatic cylindrical-deflector-type monochromator and the same type of analyzer. The energy resolution of the spectrometer is 4–6 meV (32–48 cm^{-1}). A sample was transferred from the ICP growth chamber to the HREELS chamber in the atmosphere. It was clipped by a small tantalum plate, which was suspended by tantalum wires. The sample was radiatively heated in vacuum by a tungsten filament placed at the rear. The sample temperature was measured by an infrared ($\lambda = 2.0$ μm) optical pyrometer. All HREELS measurements were taken at room temperature. The electron incident and detection angles were each 72° to the surface normal. The primary electron energy was 15 eV.

Figure 8 presents the HREELS spectra of heated films. Figure 8a, b, and c corresponds to sample A, sample B, and sample D, respectively. In Figure 8a without CO additive, the spectrum has a faint peak at ~1500 cm^{-1} derived from the C=C stretching mode of threefold bonded carbon atoms [60]. The whole spectrum is similar to that of a single crystal graphite (0001) surface [63]. With CO additive as shown in Figure 8b, one can see a peak at ~1100 cm^{-1}, which is assignable to the C-C stretching mode of fourfold bonded carbon atoms [42, 60]. The peak at ~1500 cm^{-1} disappeared. With increasing [CO] as shown in Figure 8c, the intensity of the peak at ~1100 cm^{-1} became strong. In addition, a shoulder centered at ~700 cm^{-1} appeared. These features of the VDOS are consistent with the theoretical results
Figure 8. HREELS spectra of the nanocrystalline diamond and diamond-like carbon films with various $[CH_4]/[CO]$. (a) $[CH_4]/[CO] = 4.5.0/0$. (b) $[CH_4]/[CO] = 4.5/1.0$. (c) $[CH_4]/[CO] = 4.5/10$ sccm. The elastic peak for (c), reduced by a factor of 25, is shown for comparison. Reprinted with permission from [66], K. Okada et al., *Diamond Relat. Mater.* 10, 1991 (2001). © 2001, Elsevier Science.

for random network models of t-aC. Tight binding molecular dynamics (TBMD) simulations for a sample with 75% fourfold atoms predict two major broad peaks at ~700 cm^{-1} and ~1100 cm^{-1}, respectively, corresponding to the bending and stretching vibrations in the network [67]. A rather similar form of the PDOS is obtained in *ab initio* calculations with a 90% sp^3 fraction [68].

According to the characterizations by TEM and XRD, the sample prepared from a CH_4/H_2 plasma was composed of nanocrystalline diamond and disordered microcrystalline graphite. Then nondiamond carbon was effectively removed with an increase in [CO]. It is therefore concluded that the VDOS of the nanocrystalline diamond and DLC films extracted from the HREELS data is in qualitative agreement with the characterizations of TEM and XRD. Although the HREELS probes only the region near the surface, the agreement suggests that the surface dynamics do not differ dramatically from those of the bulk.

3.5. EELS Mapping

EELS in TEM has been demonstrated to be a powerful technique for performing microanalysis and studying the electronic structure of materials [69]. The energy loss near edge structures (ELNES) is sensitive to the crystal structure. The C-K edge of diamond and that of graphite are typical examples. For trigonal sp^2-bonded carbon, the spectrum within the first 30 eV of the edge can be separated into two broad features, corresponding to the π^* states between 282 and 288 eV and the σ^* states between 290 and 320 eV, whereas for tetrahedral sp^3-bonded carbon only the σ^* peak is observed between 289 and 320 eV [70]. Therefore, one can easily distinguish between diamond and diamond-like carbon with the help of ELNES. Muller et al.

[71] acquired the mapping of sp^2 and sp^3 states across the silicon-diamond interface by scanning transmission electron microscopy (STEM) and parallel acquisition electron energy loss spectroscopy (PEELS). Bruley's two-window technique [72], by integrating intensities of the π^* and σ^* peaks, has demonstrated the quantitative analysis of the sp^2 content in the samples. Bursill et al. [73–75] carefully performed the structural analysis on nanocrystalline diamond powder and studied the surface and bulk plasmon response derived from the low-loss spectra by using high-resolution TEM (HR-TEM)/PEELS and STEM/PEELS. Prawer et al. [56, 76] also reported the EEL spectra of nanocrystalline diamond synthesized by detonation and ion implantation.

The HR-TEM observations [77] were performed on a Hitachi HF-3000 at 297 keV, and the EELS measurements [77] were made with a post-column energy filter (GATAN, GIF2002). The vacuum of the microscope was less than 1.2×10^{-6} Pa, in which the samples were not contaminated with carbon during TEM observations. Two-dimensional arrays of charge-coupled devices (CCDs) were used for the digital recording of TEM images, EEL spectra, and chemical maps. The typical CCD readout times were 5 s for the acquisition of EEL spectra and 50 s for chemical mappings, respectively. The energy resolution of the instrument was approximately 0.5 eV measured as the zero-loss FWHM.

Figure 9a shows a HR-TEM image of an outer part of a nanocrystalline diamond particle. Lattice fringes clearly appeared in the enlargement of the left-hand side of the sample as shown in Figure 9b. The d values were 0.206 nm, corresponding to (111) spacings of diamond. The diffractogram derived from the Fourier transformation of the HR-TEM image exhibited a ring pattern, which means the observed sample is polycrystalline. Furthermore, careful observation reveals that the particle consists of smaller subgrains approximately 20–50 nm in diameter. Thus the boundaries are not surface steps of a single crystal. The size of subgrains is comparable to the grain sizes of nanocrystalline diamond films previously reported by several authors [15, 23, 29, 78], in which the grain sizes were found to be in the range of 3–50 nm.

The EEL spectrum corresponding to Figure 9a is shown in Figure 10. It exhibits a peak at 290 eV due to σ^* states, and a slight peak appears at ~285 eV, corresponding to π^* states. The ELNES above 290 eV is similar to that of diamond [70] and is obviously different from that of graphite or sp^3-rich

Figure 9. (a) High-resolution transmission electron microscope image of an outer part of a nanocrystalline diamond particle and (b) enlargement of the left-hand side of (a).
Figure 10. Electron energy loss spectrum corresponding to Figure 9a. a_1, a_2, b, and c indicate the four energy windows: 272–277 eV, 277–282 eV, 282–287 eV, and 287–292 eV, respectively.

tetrahedral amorphous carbon [72]. The intensity of the π^* peak is much lower than that of the σ^* peak. Although the σ^* peak in general includes contributions from both sp^2 and sp^3 bondings, the σ^* peak of the EEL spectrum in Figure 10 is considered to be mainly due to sp^3 bondings. The use of a narrow energy window positioned on the ELNES signal allows the mapping of the variation in intensity as a function of position within the microstructure. The conventional so-called *three-window method* [69] was employed to remove the background contribution. The two pre-edge images (272–277 eV and 277–282 eV) (indicated by a_1 and a_2 in Fig. 10) were used to obtain an extrapolated background image. The subtraction of the extrapolated background image from the post-edge images (282–287 eV and 287–292 eV) (indicated by b and c) produces the π^* image and the σ^* image, respectively, with removal of the background contribution.

The π^* image and the σ^* image corresponding to the TEM image of Figure 9a are shown in Figure 11a and b, respectively. Since the intensity of the π^* image was weak compared with that of the σ^* image, the former was multiplied by 5. The π^* image reveals that the intensity is strong around the subgrains, whereas the σ^* image shows that the intensity is strong within the subgrains. Although sp^2-bonded graphitic layers do not appear clearly with the limitation of resolution of the HR-TEM image, these energy-filtered π^* and σ^* images imply that sp^2 bondings are localized around 20–50-nm subgrains. The sp^2 bondings around the subgrains are considered to contribute the slight peak at $\sim$285 eV in
the ELNES. The width of the sp^2 bondings is estimated to be approximately 1 nm from the π^* image in Figure 11a. Fallon and Brown reported [79] the presence of amorphous carbon at the grain boundaries of CVD diamond films by TEM observation and EELS analysis. The amorphous carbon is shown to contain almost complete sp^2 bonding and to be nonhydrogenated. It was also demonstrated from a theoretical point of view [80] that sp^2 bondings are energetically stable in grain boundaries of nanocrystalline diamond. It is consequently considered that the sp^2 bondings are possibly localized in the grain boundaries of 20–50-nm subgrains.

4. PLASMA DIAGNOSTICS

A Langmuir probe has been utilized to measure plasma parameters (plasma potential (V_p), electron temperature (T_e), electron density (N_e), and electron energy distribution function (EEDF)) [81–84]. Although there has been much controversy about the interpretation of Langmuir probe characteristics of rf plasmas, the recent development of a sophisticated Langmuir probe system [85] enables one to obtain reproducible plasma parameters precisely. However, only a few works have been carried out on actual process plasmas used for etching or deposition, because it is difficult to maintain the initial condition of probe tips and/or chamber walls for the measurement reproducibility. Cali et al. [86] reported the Langmuir probe characterization of a low-pressure capacitively coupled CH_4/H_2 rf plasma. The structure of an EEDF can help one to understand the electron distribution and the heating mechanism in a rf plasma. The EEDF of a low-pressure rf plasma generally consists of two Maxwellian distributions, fast and slow electrons [87]. This feature is due to the stochastic electron heating on the oscillating plasma-sheath boundary.

A Langmuir probe was inserted [88] through one of the side flanges of the chamber as shown in Figure 1. The probe was a cylindrical tungsten wire, which was 0.19 mm in radius and 10 mm in length. The probe tip was supported by a ceramic tube, which was 2.5 mm in diameter and was enclosed by a stainless-steel casing capacitively coupled to the probe tip. Since the mean free path of an electron is large compared with the diameter of the ceramic tube for all investigated pressures, the collisionless sheath approximation can be applied [89]. When the plasma was in the high-density regime (10^{11} to 10^{12} cm^{-3}), the tip length was shortened to 4 mm to prevent the probe tip from glowing red. The rf fluctuations of the plasma potential were compensated for by self-resonant inductors [85]. The reference probe, which was a stainless-steel casing mounted on the probe shaft, automatically compensated for the plasma-ground sheath impedance, fluctuations in the plasma sheath impedance, plasma potential shifts, and low-frequency noise [85]. The plasma-ground sheath impedance can be significant when nonconducting layers (e.g., carbon layers in this study) coat the chamber wall. A single I–V characteristic curve was taken, averaging 120 samples per data point. Between scans the probe tip was cleaned by electron bombardment by pulse biasing it to +150 V. Before every probe measurement, the chamber was cleaned with an O_2 plasma, which removed contamination of thin carbon layers on the chamber wall. This probe and chamber cleaning made the

Figure 11. (a) π^* image corresponding to Figure 9a. (b) σ^* image corresponds to Figure 9a.

obtained I–V characteristics reproducible, without the need for time-dependent hysteresis.

Figure 12a–c shows the variation in the V_p, the T_e, and the N_e of a CH_4/H_2 plasma with pressure. The V_p and N_e decrease with increasing pressure up to 40 mTorr and inversely increase at 50 mTorr. The N_e increases with increasing pressure up to 40 mTorr and inversely decreases at 50 mTorr. The pressure dependence of the V_p, the T_e, and the N_e of a CH_4/H_2 plasma is the same as that of an Ar plasma up to 40 mTorr. Therefore, these features in a CH_4/H_2 plasma up to 40 mTorr can be explained by the same hypotheses of Ar plasma [83, 84], whereas the opposite feature at 50 mTorr should let us assume different phenomena in a CH_4/H_2 plasma.

Figure 13a–e shows the EEDFs of a CH_4/H_2 plasma as a function of pressure. The shape of the EEDF at 50 mTorr corresponding to Figure 13a is different from that of an Ar plasma at the same pressure. There is a hump at ∼6 eV. The hump gradually disappears with decreasing pressure. The shape of the EEDF at 30 mTorr in Figure 13c is almost a straight line, which means a Maxwellian distribution. The shape of the EEDF at 20 mTorr in Figure 13d deviates from a straight line and comes close to a Druyveysten distribution. It still keeps a Druyveysten distribution at 10 mTorr in Figure 13e. Accordingly, the transition from a Maxwellian distribution to a Druyveysten distribution occurs at 20 mTorr in a CH_4/H_2 plasma.

Turner and Hopkins [90] previously reported an unusual structure of the EEDF. They found a dip at ∼4 eV in the EEDF of a N_2 plasma. They interpreted the dip as the electric absorption of a N_2 molecule corresponding to the resonant peak of the vibrational excitation cross section.
Figure 13. Electron energy distribution functions of a CH_4/H_2 plasma as a function of pressure. (a) 50 mTorr. (b) 40 mTorr. (c) 30 mTorr. (d) 20 mTorr. (e) 10 mTorr. Reprinted with permission from [88], K. Okada et al., *J. Vac. Sci. Technol., A* 17, 721 (1999). © 1999, American Institute of Physics.

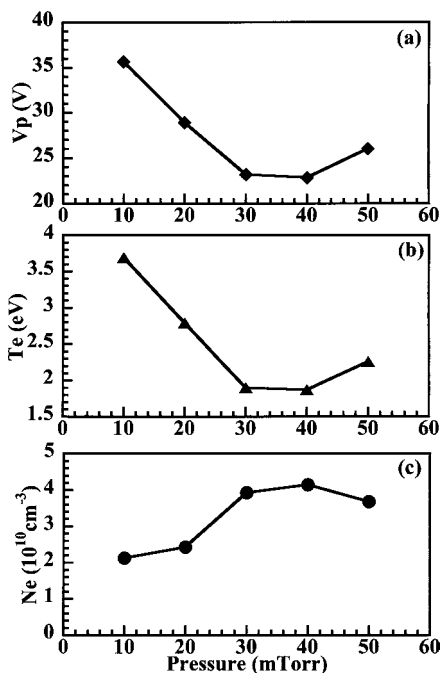
Cali et al. [86] reported a similar dip at ∼6 eV in the EEDF of a CH_4/H_2 plasma. In the CH_4 vibrational excitation cross sections, $\sigma_v(1, 3)$ and $\sigma_v(2, 4)$ have a peak at ∼6 eV [91]. The dip can be attributed to the electric absorption of a CH_4


Figure 12. Variation of the plasma parameters of a CH_4/H_2 plasma with pressure. (a) Plasma potential. (b) Electron temperature. (c) Electron density. Reprinted with permission from [88], K. Okada et al., *J. Vac. Sci. Technol., A* 17, 721 (1999). © 1999, American Institute of Physics.
Figure 14. Variation of the plasma parameters of a $CH_4/CO/H_2$ plasma with [CO] content. (a) Plasma potential. (b) Electron temperature. (c) Electron density.
Figure 15. Electron energy distribution functions of a $CH_4/CO/H_2$ plasma as a function of [CO] content. (a) [CO] = 0 sccm. (b) [CO] = 1.0 sccm. (c) [CO] = 5.0 sccm.

molecule analogous to the vibrational absorption of ∼4 eV electrons of a N_2 molecule. Although the unusual structure in the EEDF of a CH_4/H_2 plasma at 50 mTorr is not a clear dip but a hump, it is presumably equivalent to the energy corresponding to the resonant peak of the vibrational excitation cross section of a CH_4 molecule. Since the electron mean free path becomes longer with decreasing pressure and the EEDF is expected to be relatively insensitive to the electron impact cross sections [90], the hump gradually disappears with decreasing pressure. Thus the hump is considered to bring about the opposite feature of the V_p, the T_e, and the N_e of a CH_4/H_2 plasma at 50 mTorr.

Figure 14a–c shows the variation in the V_p, the T_e, and the N_e of a $CH_4/CO/H_2$ plasma with [CO]. While the V_p and T_e increase with increasing [CO], the N_e decreases with increasing [CO]. Figure 15a–c shows the EEDFs of a $CH_4/CO/H_2$ plasma as a function of [CO]. The hump at ∼6 eV still appears with the addition of CO, and the spectrum shape retains almost the same feature. The inclinations below 6 eV become slow with increasing [CO], which means that the T_e increases with increasing [CO]. It is consistent with the result of Figure 14b. The electron impact dissociation of CO produces O^- ($CO + e \rightarrow C + O^-$) in a $CH_4/CO/H_2$ plasma. It is therefore assumed that the increase in negative ions reduces the N_e relatively to satisfy the charge balance in a plasma, and that the decrease in N_e leads to the increase in V_p and T_e.

GLOSSARY

Electron energy distribution function The distribution function of electrons in a plasma. That of a low-pressure radiofrequency plasma generally consists of two Maxwellian distributions, that is, fast and slow electrons.

Electron energy loss spectroscopy An analytical technique used to characterize the chemistry, bonding, and electronic structure of thin samples of materials. It is normally performed in a transmission electron microscope. The inelastically scattered electron beams are spectroscopically analyzed to give the energy spectrum of electrons after the interaction.

Inductively coupled plasma Plasmas generated by application of radiofrequency power to a nonresonant inductive coil and maintained by an inductive electromagnetic field. Low-pressure ICP is a high-density plasma source.

Langmuir probe One of the most useful tools for diagnosing a plasma, in which a metal probe is inserted in a discharge and is biased positively or negatively to draw electron or ion current. The plasma potential, electron temperature, electron density, and electron energy distribution function are obtained from the current-voltage characteristics.

Nanocrystalline diamond Diamond crystallites or films in which the crystal grains range between several nm and several hundred nanometers in diameter.

Plasma CVD Plasma chemical vapor deposition. Technique for synthesizing materials in which chemical components in vapor phase excited by plasma react to form a solid film at some surface.

Raman spectroscopy A nondestructive method for the study of the vibrational band structure of materials, which has been extensively used for the characterization of diamond, graphite, and diamond-like carbon. Raman spectroscopy is so far the most popular technique for identifying sp^3 bonding in diamond and sp^2 bonding in graphite and diamond-like carbon.

CONTENTS

1. INTRODUCTION

Many complicated biological tasks, such as transforming chemicals in localized areas, transporting materials between cells or organs, and defending against foreign enemies, are handled by functionalized biopolymers. As can be seen from enzymes, hemoglobin, liposomes, etc. [1, 2], nature has tailored each of the biomacromolecules with a suitable structure and arranged or assembled the structural components in an organized way. To achieve an organizational structural hierarchy, the living world relies on a noncovalent architecture. Self-assembly is the organizational motif that is ubiquitously utilized by biological systems and underlies the formation of a wide variety of complex biological structures. The process obviously affords high flexibility, high efficiency, etc., but, importantly, still allows precise control over the formation of structural morphologies [3, 4].

Many of the concepts of biological self-assembly are derived from studies of tobacco mosaic virus, which is a helical assembly composed of 2130 identical protein units [5]. Though forming this complex protein requires a delicate management among the molecular interactions (van der Waals, electrostatic, hydrophobic, and steric interactions, hydrogen and coordination bonds, etc.), the assembly mechanism has exemplified that the association process is entropically driven [5, 6] and the final bioassembly occupies the state of a thermodynamic minimum. In general, the success of organizing structures by self-assembly depends on how successfully these interactions can be utilized to bind molecules together. Supramolecular chemistry is inspired by the study of the basic features of these secondary interactions, which contributes to our understanding not only of living systems, but also nonliving systems. Based on these interactions, supramolecular chemistry has assembled a number of well-defined, regular nonbiological architectures [7–16], which are expected to generate new properties and to create new materials [17–19].

Making precise nano- and mesoscopic structures is still one of the greatest challenges now facing scientists and technologists. Molecular self-assembly is one of the feasible ways of approaching this goal. Although self-assembly originated from the study of small molecules, it should also be a strategy that is applicable to big molecules. Through cooperative self-assembly processes, macromolecular chains may also be hierarchically organized into large and complex but precise and ordered structures. Nature has presented wonderful examples in this regard: the α-helix and β-sheet of proteins assemble into defined tertiary and quaternary structures. The natural process is truly amazing, and judiciously designed nonnatural systems should be able to mimic the bioprocesses to self-assemble into biomimetic structures. There are many successful reports addressing this idea. In this article, we will review the biomimetic hierarchical structures generated by unsubstituted and substituted polyacetylenes.

2. UNSUBSTITUTED POLYACETYLENE

Polyacetylene is the simplest linear conjugated macromolecule and is one of the best-known organic conductors [20–24]. The discovery of the metallic conductivity of doped polyacetylene has opened up a fascinating field of research, conductive macromolecules, which have brought us to a plastic-electronics revolution, with many exciting implications in high technologies, as evidenced by the award of the Nobel Prize in chemistry in 2000. High-molecular-weight

polyacetylene can be synthesized from the acetylene poly-merization initiated by the Ziegler–Natta catalyst (Chart 1) [25, 26], but under "normal" conditions, only a feature-less morphology can be produced [27–29]. The fundamental norm lasted until Akagi, Shirakawa, and co-workers inves-tigated the asymmetric polymerization of acetylene [30]. Through mixing of a chiral nematic mesogen (R)- or (S)-**2** (Chart 2) with an organometallic catalyst, multistranded helical polyacetylene fibers, a few hundred nanometers in diameter, were successfully prepared. It was observed that the polymerization conducted in the presence of the (R)-form nematic liquid crystals led to the formation of left-handed helical fibrillar morphologies (Fig. 1), whereas that in the presence of the (S)-form gave polymer fibrils twisting in the opposite direction. With control over optical purity or the type of chiral dopant, it was possible to generate helical morphologies with different helical pitches.

Chart 2

Another helical structure of polyacetylene was prepared at high temperatures ($\sim$250 °C) [31]. Similar to the Akagi and Shirakawa reaction, Qin et al. also used an asymmetric condition to build the helical polymers (Fig. 2). However, the catalyst system used by Qin is different from that used by Akagi and Shirakawa: the former used a native asymmetric catalyst, copper tartrate, and the latter used an achiral cata-lyst blended with a chiral dopant. The fibers obtained were obviously different; the former afforded single-stranded and more regular helical structures. Interestingly, the fibers were formed in such a way that two helical strands simultaneously grew on a single copper nanocrystal. The two strands were opposites in an absolute helical sense but identical in cycle

number, node diameter, node length, helix pitch, and fiber diameter. A small amount of the acetylene monomer may have initially bound to the chiral catalyst in an asymmetrical way, and the chiral chains propagated with other monomer molecules also inserted in an asymmetrical fashion.

3. POLYACETYLENES WITH AMINO ACID ESTER PENDANTS

The two examples discussed above clearly demonstrate that the formation of regular helical structures closely relates to the asymmetrical force field. Chirality is a structural fea-ture of many natural constituent components (amino acids, saccharides, etc.), and biological systems exhibit helicity at all organizational levels (e.g., α-helix of proteins, double helix of DNA, triple helix of collagen, and spiral bacterium of *Spirillum*). Obviously, rather than using an external stimu-lus, nature has put an asymmetrical field in internal building units, permitting better control over the final assembly struc-tures. Many scientists have taken this approach and used asymmetrical building blocks to construct chiral polymers [32–64].

The (unsubstituted) polyacetylene chain is symmetrical and achiral. However, when pendant groups are introduced, the chain symmetry is broken. Theoretical computation sug-gests that the chain segments of a substituted polyacetylene bearing bulky appendages can take on helical conformations [65]; a majority of the chain segments with long persistence lengths will rotate in one preferred screw sense when the appendages are chiral species. In addition to fusing the chi-ral species into the polymer structure at the molecular level by covalent bonds, the polyacetylene chains could also spi-rally rotate in asymmetrical force fields when the π electrons of the conjugated backbone and/or the functional groups of the achiral substituents experience molecular interactions with external chiral species [66]. With the aim of prepar-ing asymmetrical polyacetylenes for the study of hierarchiral structures, Shinohara, Shigeka, and co-workers synthesized an optically active polyphenylacetylene bearing menthoxy-carbonylamino groups (Chart 3), which possessed a high molecular mass (1×10^6 Da) and a high stereoregularity (Z content $\sim$90 mol%) [67]. Under the influence of the

chiral pendants, the achiral main chain of **3** became CD active and absorbed strongly in the long-wavelength region (~400 nm). A possible reason for this is the formation of a secondary structure with an excess of one-handed helical structure. Further investigation of its higher-order structure by scanning probe microscopy revealed that the polymer afforded a helical quaternary structure. From Figure 3a, it can be seen that the two polymer strands are intertwined to form a right-handed double-helical structure. Each strand is also helically rotating and has a width of 9 Å, which matches the width of the polyphenylacetylene backbone with a *Z* configuration, as suggested by the molecular mechanics calculation.
Chart 3

The α-helix of the polypeptide chain exemplifies nature's ability to construct complex chiral structures by making use of hydrogen bonding provided by each amino acid residue. Inspired by this phenomenon, in 1997, our group embarked on a research program on the development of
new biomimetic polymers, using amino acids as chiral ingredients. Through the incorporation of the naturally occurring building blocks into the conjugated polymer structure, we synthesized a variety of new amphiphilic polyacetylenes [66], examples of which are given in Charts 4 and 5. The amino acid substituents not only conferred helical conformations on the polyacetylene chains but also endowed them with hydrogen bonding capacity, which is an important secondary force for self-assembly. The polymers were therefore able to self-fold into higher-order structures. An example of the organizational morphologies is shown in Figure 4. By a simple process of solvent evaporation, polymer **4**, which bears isoleucine appendages, organized into helical cables with left-handed twists. The atomic force microscope (AFM) image revealed that the helical fibrils were, on average, >500 nm in length and ~20.5 nm in width. These sizes are much bigger than the dimensions of a single chain, indicating that nanofibrils are assemblies of multiple strands of polymer chains. Similar to the fibrous proteins of α-keratin [68], the helical chains of **4** may have been plaited together via a folding process aided by noncovalent interactions such as interstrand hydrogen bonding [69]. The involvement of noncovalent forces in the assembly process was clearly confirmed by the partially unraveled helixes generated by the repeated horizontal scans of the AFM tip on the surface of mica in the direction perpendicular to the long axes of the nanofibers. The unraveled morphology was obviously due to the breakage of the physical bonds that had glued the chain segments together.

Similarly, polymer **5**, which bears smaller pendants of alanine groups, also formed helical fibrils. The structural details are different, however; the helical cables of **5** are right-handedly winding, which is different from the left-handed twisting observed in **4**, and the cables of **5** (~100 nm in diameter) are on average thicker than those of **4**. Why the assembly behavior of **5** is different from that of **4** is unclear, but it may be related to the packing process benefiting from
Figure 4. AFM (A) height and (B) phase images of left-handed helixes formed upon natural evaporation of a methanol solution of **4** (36.6 μM) on newly cleaved mica. Reprinted with permission from [62], B. S. Li et al., *Polym. Prepr.* 42, 248 (2001). © 2001, American Chemical Society.

the molecular structure of **5**. The smaller pendants in **5** may facilitate close packing and interchain hydrogen bonding between the polymer chains due to a less pronounced steric effect arising from the side groups. Thus, more polymer chains can associate together to form single strands, as verified by the thicker strands, which eventually fold up to form the multistranded cables.

With the proline appendages, **6** is incapable of forming hydrogen bonds. It is thus of interest to know whether the macromolecular chains can associate into defined structures without the involvement of this noncovalent interaction. Although **6** in methanol displayed only weak CD activity [70], when its dilute solution (38.9 μM) was dropped onto freshly cleaved mica, tortuously twisted cables of double-stranded helical fibrils were formed, an example of which is shown in Figure 6. The morphology is composed of two helical strands (~150 nm in width), which braid together to form the final supercoils. Each of the strands seems to be the result of winding of many single-stranded fibers, and the whole structure bears a good likeness to the superhelical structure formed by the menthol-containing polymer (**3**) already discussed (cf. Fig. 3). The similarity suggests that the

Figure 6. AFM deflection images of tortuously twisted nanofibers formed upon natural evaporation of a methanol solution of **6** (38.9 μM) on freshly cleaved mica. Reprinted with permission from [42], K. K. L. Cheuk, Ph.D. Dissertation, Hong Kong University of Science & Technology, 2002.

cyclic molecular structures in the polymers favor the formation of the loose double-helical quaternary structure.

Molecular information, such as amino-acid sequence and chain chirality and amphiphilicity, encoded in the primary structures of biomacromolecules plays a primary role in determining their native folding structures; for example, L-glutamic acid segments in proteins often give α-helix structure, whereas L-isoleucine segments most frequently induce β-sheet formation [1, 2, 71]. The folding structures can, however, be varied or denatured by the changes in the environmental surroundings of the biopolymers, because of the noncovalent nature of the supramolecular assembly. Loss of body fluid, for example, can transmute organizational structures of proteins by dehydration or deprivation. Similar phenomena have also been observed in the self-assembly processes of the amino acid-containing polyacetylenes. For example, whereas a methanol solution of **7** gave pearl-shaped structures upon natural evaporation, its tetrahydrofuran (THF) solution gave helical cables with a clear left-handed twist under similar assembly conditions (Fig. 7). The polymer chains of **7** may take an extended conformation in THF because THF is a good solvent of both the backbone and the pendants of the polymer. During the aggregation process accompanying solvent evaporation, the extended helical chains may twine around each other via interchain

hydrogen bonding to give twisted strands, further association of which in different multiplicities (doublet, triplet, etc.) will give thicker fibrils of different diameters—this assembly mechanism is clearly suggested by the image shown in Figure 7B. It is envisioned that evaporation of a methanol/THF solution of **7** may generate transition morphologies containing both micellar and fibrillar structures. This was indeed the case; as shown in Figure 7C, the organizational morphologies obtained from the mixture solvent system showed combined features of the assembly structures obtained from the individual solvent systems.

4. POLYACETYLENES WITH AMINO ACID PENDANTS

Whereas the amino acid pendants of polymers **4–7** are esterified, polymers **8–11** carry "free" amino acid pendants. The change in the molecular structure is expected to affect the assembly structures of the polymers. Different from its "polyester" counterpart **5** (cf. Fig. 5), "polyacid" **8** formed pigtail-like nanofibers upon the natural evaporation of its methanol solution under ambient conditions (Fig. 8). A number of fibrils were bundled together to form plaits with loose tails. Each fibril comprised many polymer chains that were stuck together through interchain hydrogen bonds.

"Polyacid" **9** also formed helical fibrils. Close examination by transmission electron microscopy (TEM), however, revealed that the fibrils possessed a hollow structure (Fig. 9); that is, the fibrils were actually nanotubes. The tubes wound around each other to give twisted hollow structures. As marked by the rectangle in Figure 9A, there are many hollow rings or spherical vesicles in addition to the twisting tubes. These structures are remarkable, because nanotubes and vesicles have seldom been formed by homopolymers,
Figure 9. TEM images of vesicles and nanotubes formed upon natural evaporation of a methanol solution of **9** (19.3 μM) on a carbon-coated grid under ambient conditions. Reprinted with permission from [42], K. K. L. Cheuk, Ph.D. Dissertation, Hong Kong University of Science & Technology, 2002.

although they have been observed in a few copolymer systems [13, 73–79]. The coexistence of the vesicular and tubular structures suggests that the vesicles are the building units of the nanotubes; stringing the former together leads to the formation of the latter.

In the polar solvent of methanol, the polyacetylene main chains of **9** may associate together with their pendants facing outward, in an effort to minimize the exposure of their hydrophobic backbones to the polar environment [80]. Curling of the bi- or multilayer sheets would result in the formation of a closed vesicular structure. Following the mechanism of coalescence [81], the vesicles may fuse together to form the tubular structure, the shells of which are covered by the isoleucine pendants. During the thickening of the solution accompanying the solvent evaporation, the tubes may grow in length by the linear fusion of more vesicles, and the lengthened nanotubes may twine round each other via hydrogen bonding of the pendants on the outer shells to give the helical cables of nanotubes.

The previous mechanism should be solvent dependent; changing the solvent or environment would affect the assembly process because of the perturbation of the interactions between the polymer chains. A more comprehensive study was conducted on the self-assembly processes of **10**, which carries leucine pendants [66]. When methanol was used, twisted cables of helical fibrils were formed, an example of which is shown in Figure 10A. Close inspection of the cable structure reveals that the fibrils fold back to form knobs or β bends at two ends of the cable. When a dilute solution was used, the aggregation of the macromolecules was further suppressed and the resultant morphology looked like long threads or helical chains, each pair of which twist over and under each other to form a double helix (inset of Fig. 10A). When the solvent was changed to chloroform, the morphology obtained from the solution of similar concentration (9.6 μM) became distinctly different. Instead of forming helical cables, the chloroform solution gave oval eggs or

Figure 8. AFM height image of pigtail-like nanofibers formed upon natural evaporation of a methanol solution of **8** (46.0 μM) on newly cleaved mica. Reprinted with permission from [62], B. S. Li et al., *Polym. Prepr.* 42, 248 (2001). © 2001, American Chemical Society.

**Figure 10.** AFM images of self-assembly morphologies formed upon natural evaporation of dilute solutions of **10** on newly cleaved mica. (A) A multistranded cable from a 12.8 μM methanol solution (inset: duplex braids from a 2.6 μM solution). (B) Spherical vesicles from a 9.6 μM chloroform solution with 0.5% methanol. spherical vesicles (Fig. 10B). This difference is, however, not totally unexpected. Unlike methanol, chloroform is a poor solvent of amino acids, and the polymer chains would self-fold to minimize their exposure to the solvent. When the solvent evaporates, the elementary "foldamers" may cluster together to form compactly packed larger spheres in an effort to minimize their surface area in contact with the air. The morphology changed not only with solvent but also with pH. The addition of KOH to the methanol solution disassembled the helical cables and gave extended filaments (Fig. 10C). The complexation of the K$^+$ ions with the polymer chains partially dissociates the amino acid groups, thus hindering the hydrogen bond formation. The electrostatic repulsion of the closely located charged chains cannot easily bend but takes an extended conformation.

Concentration is also a critical parameter in determining the final morphological structure; overcrowding may cause post-fusion of the polymer aggregates, leading to the formation of even higher-order structures. For example, evaporation of a dilute solution of **10** gave crescent helical fibers (Fig. 11A). The closely located helical cables may be interconnected by interstrand hydrogen bonds of the amino acid groups, but the solvent molecules, on the other hand, try to push the polymer chains apart; the balance of the two antagonistic forces results in the formation of a fence-like structure. If the concentration of the polymer solution is increased, more polymer chains will stick together to construct more closed fences or cages, and the neighboring cages may merge to form a continuous structure. Indeed, when a THF solution of **10** with a relatively high concentration (28.9 μM) was used, a mesoporous, honeycomb-like, thin solid film comprising interconnected cages was formed (Fig. 11B). The interconnection of the cages was three-dimensional in nature, as clearly revealed by a scanning electron microscope image of the tilted sample (Fig. 11C). Figure 11D shows a partial view of a long fiber of **10**
Figure 11. (A) AFM image of crescent helices formed by a diluted solution of **10** (12.8 μM). (B) Scanning electron microscope (SEM) image of a honeycomb pattern generated from a concentrated THF solution of **10** (28.9 mM), whose 3D nature is clearly revealed by the enlarged side view (C) with the sample tilted 60° from the electron beam axis. (D) SEM micrograph of a twisted fiber formed upon diffusion of ether into a methanol solution of **10** (3.9 mM). A and D are reprinted with permission from [85], F. Salhi et al., *J. Nanosci. Nanotechnol.* 1, 137 (2001). © 2001, American Scientific Publishers. B and C are reprinted with permission from [66], B. Z. Tang, *Polym. News* 26, 262 (2001).

obtained from a diffusion process. When ether was diffused into a methanol solution of **10**, left-handed helical ribbons were formed. The image proves that the polymer is capable of building a large helical structure, even in the micrometer domain.

The folding structures of biopolymers are affected by external perturbations in addition to internal factors. The supercoiling of DNA is affected, for example, by small changes in the local ionic strength, which can cause the reversal of the helical twist in the DNA coils [82]. Similar phenomena have been observed in our nonnatural polymer system. The pH effect on the assembly behaviors of polymer **11** is shown in Figure 12. Changing the medium pH from "neutral" to "basic" changed the organizational
Figure 12. AFM deflection images of (A and B) helical nanofibers formed by **11** upon natural evaporation of its methanol solution (7 μg/ml) on freshly cleaved mica under ambient conditions. The nanofibers can be unraveled by adding a 1 M equivalent of KOH (i.e., KOH/**11** = 1:1) to the methanol solution of the polymer (4 μg/ml), as shown in C–E. Reprinted with permission from [83], Li et al., *Nano-Letters* 1, 323 (2001). © 2001, American Chemical Society.

morphology of the polymer from continuous helical cables to discrete random threads [83]. The random threads showed almost no macroscopic screw sense. This example illustrates how ionization of the carboxyl groups by the potassium ions breaks the hydrogen bonds, which are believed to maintain the long, thick helical structure of the polymer chains.

By partially hydrolyzing "polyester" **7**, we succeeded in generating a valine-containing polymer consisting of both ester and acid repeat units, poly[(4-ethynylbenzoyl-L-valine methyl ester)-*co*-(4-ethynylbenzoyl-L-valine)]. This hybrid polymer afforded self-assembly structures with organizational features of both the "polyester" and the "polyacid." While "polyester" **7** assembled into pearl-shaped morphological structures upon natural evaporation of its dilute methanol solution (cf. Fig. 7), under similar conditions
Figure 13. AFM images of string beads formed upon natural evaporation of methanol solutions of a partially hydrolyzed **7**, poly[(4-ethynylbenzoyl-L-valine methyl ester)-*co*-(4-ethynylbenzoyl-L-valine)], on the surfaces of newly cleaved mica. Scale bars (nm): 100; concentration: ~2 μg/ml; temperature: ~23 °C. Reprinted with permission from [72], Li et al., *Macromolecules* 36, 77 (2003). © 2003, American Chemical Society.

"polyacid" **11** associated into helical ropes (cf. Fig. 12). The hybrid polymer gave an intermediate structure with spherical beads strung together on a filamentary string (Fig. 13). In methanol, the coiled chains of **7** may pack together to minimize the exposure of its hydrophobic backbones to the polar solvent, forming micelle-like structures with their outer shells decorated by the hydrophilic amide and ester functional groups. On the other hand, the strong solvation power of the methanol solvent toward **11** may force the helical chains to take on an extended conformation. During the solvent evaporation, the micelles may grow in size and stick together to give the clustered pearls, whereas the individual helical chains may aggregate in a side-by-side fashion to form spirally twisting fibrils. This aggregation is reminiscent of protein folding. Particular types of amino acids tend to form a relatively small number of local structural motifs [84], whereas aggregate in the proteins in such a way that the hydrophobic and hydrophilic regions are respectively out of, and in, contact with water.

5. POLYACETYLENES WITH ETHYLENE OXIDE PENDANTS

The previous results clearly show that not only molecular asymmetry but also chain amphiphilicity plays important roles in the self-assembly processes of chiral acetylene polymers. In this section we focus our discussion on the self-organization of polymers solely with the latter property (amphiphilic achiral species). A few examples of such amphiphilic polyacetylenes are given in Chart 6, in which polar hydrophilic substituents are appended to nonpolar polyacetylene backbones.

Chart 6

When a tiny drop of a THF/hexane solution of **12**, which bears short ethylene oxide pendants, was deposited on a glass slide, a microporous thin film (~2–10 μm in pore diameter) was instantly formed upon solvent evaporation (Fig. 14A). When the solvent was changed to a mixture of dichloromethane (DCM) and hexane and when the solution concentration was increased, a three-dimensional porous thin solid film with a smaller pore size (~1 μm in diameter) was formed (Fig. 14B). When a dilute solution was used, the evaporation process afforded the elementary building blocks for a three-dimensional higher-order structure: bagel-like vesicles [86, 87], whose sizes varied from several hundred nanometers to a few micrometers (Fig. 14C and D). This primary structure may help us understand the assembly mechanism: when deposited on a glass substrate in the three-dimensional space, the horizontally oriented vesicles may merge into porous layers that are parallel to the substrate accompanying the solvent evaporation, whereas
Figure 14. Microporous films formed by natural evaporation of (A) THF/hexane (∼1:1 by volume) and (B) DCM/hexane (∼1:1 by volume) solutions of **12** on glass slides. Concentrations of **12**: (A) ∼1, (B) ∼2 mg/ml. (C, D) Vesicular structures formed by the evaporation of a dilute solution of **12** (∼0.3 mg/ml) in the DCM/hexane mixture. Nanotechnol.* 1, 137 (2001). © 2001, American Scientific Publishers.

convergence of the vesicles with other orientations would produce the interlayer pores, leading to the formation of the multilayer porous structure.

The self-association of **12** is also solvent-sensitive: when relatively polar solvents were used, discrete microspheres, rather than regular pores, were formed. Upon solvent evaporation, a THF solution of **12** afforded spheres with an

Eng.* 82, 54 (2000).

average diameter of ∼1.5 μm (Fig. 15A and B) [85]. Similarly, a DCM/acetone mixture of **12** also gave microspheres (Fig. 15C and D). The hydrophobic polyacetylene main chains of **12** may have aggregated together to form the core of the spheres that are surrounded by its hydrophilic ethylene oxide side chains under polar conditions, whereas the amphiphilic polymer may have formed bi-, tri-, or multilayers and/or even vesicular structures [76, 87] to reduce the surface area in the nonpolar environments.

Biomineralization has attracted much interest in recent years [88–95]. Molding of inorganic crystals into appropriate shapes and sizes has created a variety of different material properties. The amphiphilic polyacetylenes were found to regulate the growth of organic crystals. For example, evaporation of a DCM/acetone mixture of **12** and carbazole gave regular spherical microcrystals of carbazole ∼20 μm in diameter (Fig. 16). Under similar conditions, when a drop of a DCM/ethanol solution of carbazole/**13**, which contains crown ether appendages, was deposited on a glass slide, isolated sickle-like crystals, ∼20 μm in length, were formed (Fig. 17). Replacing **13** with **14**, which bears long oligo(ethylene oxide) appendages, led to the generation of
Figure 17. POM images of the microcrystals of carbazole formed inside microreservoirs of **13** by natural evaporation of DCM/ethanol (∼1:1 by volume) solutions of **13**/carbazole on a glass slide. Cheuk et al., *Polym. Mater. Sci. Eng.* 82, 54 (2000).

crystal bars, ~8 to 20 μm in length (Fig. 18). The formation of these defined crystal structures is probably achieved by a micelle-like self-assembly process. When solvent evaporates, carbazole molecules pack together to form a crystal. However, in the presence of amphiphilic polymers, the packing process may be slowed down because the carbazole molecules may be wrapped in the amphiphilic chains. The polymer backbones may solvate the carbazole molecules in the inner core, with the polar ethylene oxide groups exposed to the solvent environment. The separate micelle-like complexes may thus in turn give the microcrystals that are covered by, or sheathed in, the amphiphilic polymer chains. Different pendants bring about different degrees of repulsion or steric effects. The different properties of the micelle-like aggregates may have eventually guided the carbazole molecules to grow in different patterns.

6. CONCLUSIONS

It is generally agreed that it is difficult to form supramolecular assemblies of defined architecture from synthetic homopolymers [96]. In this review, we have proved, however, that homopolyacetylenes can self-organize into macromolecular architectures with well-defined three-dimensional structures. Both the unsubstituted and substituted polyacetylenes spontaneously assembled into various mechanically robust organizational morphologies reminiscent of natural hierarchical structures: helixes, vesicles, fibrils, etc. This clearly demonstrates that synthetic homopolymers with rationally designed molecular structures can be used to fabricate biomimetic morphologies, whose size, shape, and pattern can be readily tuned by simple morphosynthetic processes. The organizational morphologies changed with the variations in the pendant hydrophilicity, solvent polarity, and pH value, suggesting a proteomimetic adoptability [97] and demonstrating the tunability of the hierarchical structures by internal perturbations and external stimuli.

Unlike "conventional" vinyl polymers, the acetylene polymers consist of alternating double bonds, whose structural cousins are highly photoconductive [98–100]. Cytotoxicity assays have revealed that the amphiphilic polyacetylenes are biocompatible, and some of them can even stimulate the growth of living cells [101–103]. Their photoelectronic and biological properties make the polyacetylenes promising candidates for biomaterials; they may be found to be useful in potential applications in such biotechnological systems as artificial nervous networks, photosynthesis devices, and phototherapy processes.

GLOSSARY

Achiral An object that is superposable on its mirror image.

Amphiphilic A molecule with a hydrophilic end that dissolves in polar solvents and another, hydrophobic end that dissolves in nonpolar solvents.

Chiral An object that is nonsuperimposable to its mirror image.

Circular dichroism (CD) A change from planar to elliptic polarization when an initially plane-polarized light wave traverses an optically active medium.

Helicity The sense of twist of a helix, propeller, or screw.

Micelle An aggregate formed by amphiphilic molecules in, e.g., water such that their polar ends are in contact with water and their nonpolar portions are on the interior.

Vesicle A small, thin-walled bladderlike cavity.

Z (*zusammen*) One of the stereochemical descriptors for alkenes or for other double-bond systems with at least two nongeminal substituents (other than H) at the two ends of the double bonds. If the pertinent substituents are on the same side, the descriptor is *Z. E. (entgegen)* denotes that the substituents of highest Cahn-Ingold-Prelog (CIP) priority at each end of the double bond are on opposite sides. In the polyacetylene system, there exist four theoretically possible stereostructures for the repeat units, that is, *E–s-E*, *E–s-Z*, *Z–s-Z*, and *Z–s-E* isomeric structures.

Z content The content (%) of the stereoisomers with a *Z* configuration.

Polyaniline Fractal Nanocomposites

Reghu Menon, A. K. Mukherjee

Indian Institute of Science, Bangalore, India

CONTENTS

1. INTRODUCTION

Typical composites consist of two components, in which the host material determines mechanical and processing properties of the system and the guest material imparts special physical and chemical properties to the intricately mixed host–guest blend. The host material is supposed to have a wide range of facile processing options so that the guest material can be easily incorporated into the host system to obtain the desired properties. Toward this end, polymers are considered to be excellent host systems, because a wide range of physical and chemical properties can be observed in polymers; moreover, they can be easily processed and blended with a variety of materials. Hence, several polymer composites have been extensively studied for the past few decades for use in various applications [1]. Some of the well-known composites are glass, carbon, or metal fiber reinforced polymers [2] and elastomers reinforced with various types of particles like carbon [3].

In previous generation polymer composites, the size of the guest material was usually on the order of microns. In such composites, it was difficult to optimize the physical properties, because intimate and homogenous mixing of guest–host materials is hard to achieve; moreover, the processibility is not versatile enough for subtle applications. Hence it is highly desirable to have nanoscopic and even molecular level mixing of guest–host materials, so that it is easier to fine-tune the physical and chemical properties, and this could pave the way for several innovative applications.

In recent years, the advent of well-defined nanoparticles of metallic, magnetic, semiconducting, and insulating materials has facilitated the preparation of a wide range of well-tailored nanocomposites with specific properties [4–6]. Moreover, it is possible to attain much lower values for the percolation threshold (according to classical percolation theory, the volume fraction of spherical particles required to make quasi-contact with each other in a composite is nearly 16%, which is considered to be the threshold for percolative processes among particles) in composites containing nanoscopic materials rather than mesoscopic ones [7]. This is mainly due to the self-organizational properties of nanoparticles, as shown by Michels et al. for carbon nanoparticle composites [8]. Furthermore, it is possible to obtain an aspect ratio (ratio of the length to the diameter of the particle, which is 1 for a spherical particle) above 1 for nanoparticles. It is well known that by increasing the aspect ratio of particles it is possible to bring down the value of the percolation threshold (f_c), which means that the quasi-contact between particles can be attained at a much lower volume fraction of filling than the conventional 16% for spherical particles [9–11]. The advantage of attaining a lower volume fraction of filling and percolation threshold is that the pristine mechanical and processing properties of host matrix can be retained in the blend, and the design of composites becomes easier with lower cost.

Although conventional polymer composites are highly tractable with excellent mechanical properties, host polymer matrices such as polyethylene have rather poor electrical and thermal properties. In typical composites, the host matrix plays the role of inert support for the active guest material, which effectively determines the electrical and optical properties of composites. Moreover, in previous generation composites, inorganic or ceramic guest materials were not that compatible with the organic polymer host matrix, and this usually led to the formation of inhomogeneous composites with poor mechanical and physical properties. In recent years several organic/polymeric materials (for example, conducting polymers, ferroelectric polymers, photoconductive polymers, light-harvesting polymers, photorefractive polymers, and nonlinear optical materials) have shown interesting electrical and optical properties (analogous to those in inorganic materials) [12–14], and these materials are much

more compatible with the polymer matrix. Hence a new opportunity has come for making nanoscopic and molecular level polymer composites that show a wide range of solid-state physical properties.

The conducing polymer consists of polyconjugated chains $[(-C=C-C=C-C=C-)_n]$ with alternating single (σ-bonds) and double bonds (π-bonds). The π-electrons are highly delocalized and easily polarizable, and these features play important roles in the electrical and optical properties of polyconjugated systems. Moreover, the intrinsic quasi-one-dimensional nature and the extent of both intra- and interchain delocalization of π-electrons play significant roles in the structural, electrical, and optical properties of polyconjugated systems. The chemical structure of some of the well-known conducting polymers including polyacetylene (PA), polyaniline (PANI), polypyrrole (PPy), polythiophenes (PTs), poly(p-phenylene vinylene), poly(p-phenylene) (PPP), polythienylene vinylene (PTV), and others, are shown in Figure 1 [13].

Polyconjugated chains are stiff and less tractable, unlike conventional polymers, which are highly processible. Usually polyconjugated systems are made processible by substituting solublizable side groups to the main chain or with the help of modified counterions in dopant species. For example, in the case of polythiophenes, the alkyl group substitution makes them soluble, and in the case of polyaniline, the surfactant counterion in protonic acids makes it soluble in several organic solvents [15]. Hence by co-dissolving conjugated and host polymers in a suitable solvent, it is possible to make conducting polymer nanocomposites in an insulating polymer matrix. Also, chemical modification of guest materials such as inorganic semiconductor nanoparticles (e.g., cadmium, selenide, and titanium dioxide) [16], fullerene (C_{60})

[17], or carbon nanotubes [18, 19], can disperse well in conjugated polymer solutions, so that nanocomposites of these materials in conjugated polymer matrices can be prepared. These types of composites have interesting optical properties and application in optoelectronic devices.

In this chapter, a general introduction to conducting polymer nanocomposites is given, with some detailed descriptions for several of them. From the fundamental science point of view, the main objective of this chapter is to tie up the concepts of nanocomposites, conducting polymers, morphology, fractal structures, percolation process, and charge transport in novel nanosystems. In conducting polymer nanocomposites many of the above-mentioned ideas come together in a very interesting manner unlike in nanoparticle systems. In one of the most exciting types of conducting polymer nanocomposites the chains self-assemble to form an interpenetrating fibrillar fractal network, which is rather unique in nanosystems. In such a nanoscale fibrillar fractal network, the electrical charge transport properties have several interesting features. However, the optical and magnetic properties are not that different from those observed in bulk systems, because it is well known that in conducting polymers the optical and magnetic properties are mainly governed by molecular level features that are nearly identical in both macro- and nanosystems.

Among, the various conducting polymers, only for surfactant counterion processed polyaniline is this nanoscale fibrillar fractal network formed well in a controllable fashion and also being investigated systematically. In this unique nanoscale fibrillar fractal network the conducting polyaniline chains are self-assembled by subtle interactions of the polymer chain, surfactant counterion, and solvent. Although a wide range of nanostructures, from a fibrillar fractal network to phase-segregated aggregates, can be obtained by changing the host polymer matrix and processing parameters, among them the most interesting morphological and electrical properties are observed only with the nanoscale fibrillar fractal network. Hence this chapter is largely devoted to the structural and electrical charge transport properties of this special type of polyaniline fractal nanocomposites. Moreover, they have several interesting electrical and optical applications, as mentioned later in the chapter.

2. PREPARATION OF CONDUCTING POLYMERS AND COMPOSITES

Usually the synthesis of conjugated polymers is carried out by one of two procedures: chemical synthesis or electropolymerization. The chemical route is further subdivided into catalytic polymerization, noncatalytic polymerization, precursor methods, and organometallic coupling. Various synthetic routes for the preparation of some of the well-known conjugated polymers are given below [20].

PA can be synthesized by the following routes: catalytic polymerization, noncatalytic polymerization, catalytic polymerization of monomers other than acetylene, and precursor methods. For the catalytic polymerization routes, five types of catalysts can be used to yield PA in the form of a uniform film. These are Zeiglar–Natta catalyst [Ti(o-n-C_4H_9)$_4$ and (C_2H_5)$_3$Al], Luttinger catalyst (NaBH
Figure 1. Structures of various conjugated polymers.

and nickel chloride) [21], metathesis catalyst [WCl$_6$ and (C$_6$H$_5$)$_4$Sn in toluene] [22], single component catalyst [Cp$_2$Ti(PMe$_3$)$_2$] [23], Rh and Re catalysts [e.g., Rh(COD)Cl and Rh(NBD)Cl, where COD is cycloocta-1,5-diene and NBD is bicyclo[2.2.1]hepta-2,5-diene] [24]. For the non-catalytic route, irradiation of acetylene gas with ultraviolet or ionization radiation has shown to produce PA [25]. Monomers such as 1,3,5,7-cyclooctatetraene with a metathesis catalyst W[OCH(CH$_2$Cl)$_2$]$_n$Cl$_{6-n}$-(C$_2$H$_5$)$_2$AlCl (n = 2 or 3) also yield PA [26] through the ring open polymerization reaction. The precursor route makes use of a prepolymer that can be thermally converted to PA [27]. The process basically consists of three steps. The first step is the synthesis of the monomer 7,8-bis(trifluoromethyl)tricyclo[4.2.2.0$^{2.5}$]deca-3,7,9-triene by the thermal reaction between hexafluorobut-2-yne and cyclooctatetraene. The second step is the polymerization reaction carried out in presence of ring open metathesis polymerization initiators to form a high molecular weight precursor polymer. The third step is the thermal conversion of the precursor polymer to PA.

PPP can be synthesized by the following routes: direct oxidation of benzene, direct synthesis, organometallic coupling, precursor methods, and electropolymerization. The procedure of direct oxidation of benzene consists of dehydro coupling of benzene nuclei by catalyst–oxidant systems, leading to the formation of C—C bonds. The reagent for the polymerization is either a binary system of a Lewis acid such as AlCl$_3$ and an oxidant such as CuCl$_2$ [28], CuCl [29], MnO$_2$, PbO$_2$, and NO$_2$ [30] or a simple reagent with both Lewis acid and oxidizing properties such as FeCl$_3$, MoCl$_5$, AsF$_5$, and SbF$_5$ [31–36]. The direct synthesis route makes use of Bergman cyclization of enediynes followed by thermal treatment of an enediyne yielding a PPP derivative with a molecular weight of 1500–2000 [37]. The organometallic synthesis is basically classified into two categories: the Yamamoto–Colon route or Suzuki coupling. The first method makes use of Ni(II) complexes such as NiCl$_2$2(bpy), where bpy is 2,2′-bipyridine, and NiBr$_2$(PPh$_3$)$_2$ [38–43] whereas the second method involves coupling of Pd catalysts with various bromobenzene derivatives with benzene boronic acid [44, 45]. Precursor-based synthesis of PPP has also been carried out. Some of the precursors are Marvel's precursor [46, 47], ICI precursor [48], and Grubb's precursor [49, 50]. PPP has also been synthesized through anodic electrochemical oxidation. The electropolymerization has been carried out in various media and electrolytes. For example, Rubinstein [51, 52] used a strongly acidic medium—an HF/H$_2$SO$_4$ two-phase system. Organic aprotic media such as dichloromethane, nitrobenzene, nitromethane, phenylacetonitrile, acetonitrile, and propylene carbonate, along with various simple and complex electrolytes such as P$_2$O$_2$, CuCl$_2$, LiBF$_4$ + CuCl$_2$, and LiAsF$_2$ + CuCl$_2$ [53–61], have also been used for the electrosynthesis of PPP.

The basic synthesis procedures for PT can be considered in parallel with those for PPP. PT and poly-(3-alkylthiophene) (P3AT) can be prepared through direct oxidative coupling with various oxidizing agents such as Fe(III), Mo(V), and Ru(III) [62–66]. Polyalkoxythiophenes were prepared by Cu(ClO$_4$)$_2$ oxidation of bithiophenes [67]. The organometallic coupling reactions can be basically classified into two catagories: Ni-catalyzed coupling and

Pd-catalyzed coupling. The former can be subdivided into four methods, viz., the Yamamoto method [68], the Colon method [69], the McCullogh method [70], and the Rieke method [71]. The latter can be further subdivided into two routes: the Curtis method [72] and the Stille method [73]. The most conductive PTs have been prepared electrochemically in rigorously anhydrous aprotic solvents of high dielectric constant and low nucleophilicity such as acetonitrile [74], benzonitrile [75], nitrobenzene [76], and propylene carbonate [77] in the presence of small anions derived from strong acids such as ClO$_4^-$, PF$_6^-$, BF$_4^-$, and AsF$_6^-$ associated with lithium and tetraalkylammonium cations [77–80]. Partial crystallinity has been observed in poly-3-methylthiophene grown in acetonitrile with CF$_3$SO$_3^-$ [81, 82].

For the synthesis of PPy, two routes have been used: chemical synthesis and electropolymerization. Because pyrrole is one of the most easily oxidized monomers, a variety of oxidizing agents are available for the preparation of pyrrole such as FeCl$_3$, Fe(NO$_3$)$_3$, Fe(ClO$_4$)$_3$, Fe$_2$(SO$_4$)$_3$, K$_3$Fe(CN)$_6$, FeBr$_3$, CuCl$_2$, and CuBr$_2$ [83–90]. Effective catalytic processes have also been favored for mass production at low cost and extensive post-treatment steps. CuCl/AlCl$_3$/O$_2$ is a typical system [91] applied to synthesize PPy chemically. The electrochemical synthesis method has also been adopted for the preparation of PPy, and it is basically an oxidative process. Therefore, it is of fundamental importance that the electrode does not oxidize to compete with pyrrole. Most PPy has been prepared with inert electrodes, such as platinum [92], gold [93], and glassy carbon [94]. Among the organic solvents, acetonitrile and propylene carbonate have been most extensively used for their poor nucleophilic characters, along with electrolytes such as tetraethylammonium tetrafluoroborate and tetrabutylammonium hexafluorphosphate [95, 96]. High-quality films have been obtained even with nucleophilic aprotic solvents such as dimethylsulfoxide, dimethylformamide, and hexamethylphosphoramide [97–99].

Because this chapter is mainly concerned with PANI and its composites, a detailed description of the synthesis of PANI is given here. The anhydrous salt of LiCl was dissolved while 125 ml of 1.0 M HCl was stirred in to prepare a 2.0 M salt solution. Dissolution of the salt is exothermic. Aniline (C$_6$H$_5$NH$_2$, 5.0 ml, 0.0548 mol) added to 75 ml of the 2.0 M salt/HCl solution which was then cooled while being stirred at 0 °C in an ice bath to obtain a homogeneous solution. Ammonium peroxydisulfate [(NH$_4$)$_2$S$_2$O$_8$, 2.75 g, 0.0126 mol] dissolved in the remaining 50 ml of the 2 M HCl solution and cooled to 0 °C, and then added to the aniline/salt/HCl solution with constant stirring for 1 min. A homogeneous solution was obtained. The temperature remained between 0 and 3 °C throughout the entire polymerization reaction. By using the potential profiling technique [100, 101], which involves placement of a platinum electrode and a saturated calomel reference electrode in the reaction vessel to measure the potential changes during the reaction, the open circuit potential (V_{oc}) was continuously monitored. The synthesis was discontinued when V_{oc} reached a value of 0.43 V. The approximate time taken to reach 0.43 V was 3 h. An intense blue-green precipitate with a coppery glint was formed in each case. This precipitate was collected on a Buchner funnel with water (9 cm

diameter, Whatman no. 4 filter paper) using an aspirator. It was washed approximately 10 times with 1.0 M HCl (80 ml portions) until the filtrate became colorless. Care was taken to ensure that the precipitate cake was always covered by a thin layer of the washing solution and that it was never allowed to develop cracks during this washing process, which would impair the washing efficiency. This as-synthesized emarldine hydrochloride was partially dried for 15 min by sucking air through the filter cake in the Buchner funnel, then transferred to a Petri dish, and dried for 24 h in a desiccator under dynamic vacuum.

Similar to the preparation of conducting polymers, the preparation for composites is also divided into two categories: electrochemical route and chemical route. For small-scale preparation, the electrochemical route is used whereas the chemical route allows large-scale synthesis of composites. The electrochemical route encompasses two methods: electrode coating or codeposition. The former method uses three electrodes (reference, working, and counter) in a one-compartment cell containing the electrolyte and the monomer solution. To obtain blends, the working electrode is coated with a film of insulating polymer, before the anodic deposition of conducting film. The codeposition method is similar to the electrode coating method, but the insulating polymer host is dissolved in the electrolyte solution, which also contains the monomer of the conductive polymer. As the conductive polymer film is anodically deposited on the surface of the electrode, it becomes soaked with the insulating polymer solution. Blends of poly(vinyl chloride) (PVC) with pyrrole [102], thiophene [103], and 3-methylthiophene [104] can be prepared by the electrochemical method. There are two methods for the chemical synthesis of conductive polymer blends: mechanical mixing of the blend components (PANI–PVC blend [105]) and polymerization of the conductive polymer in the insulating polymer matrix. An oxidizing agent is used to polymerize the heterocyclic monomer that is either embedded in the insulating polymer matrix or mixed with it in a common solvent. Various PPy blends with latex [106], poly(2-vinyl pyridine) [107], and others are prepared by this method.

This chapter also focuses on blends of PANI; thus, the procedures for preparation of various PANI blends is given in detail. Conductive blends of PANI with low-density polyethylene (PE), high-density PE, polystyrene, and polypropylene [108] can be prepared by melt processing of PANI doped with dodecylbenzenesulfonic acid (DBSA) in a miniature counter-rotating double-screw extruder; this thermoplastic blend, with conductivity values of ∼0.1 S/cm, is commercially known as Neste complex. A PANI–PVC blend is also prepared by the above-mentioned procedure and is commercially known as Versicon [109]. Blends of PANI with cellulose acetate can be prepared by two methods. In one of the methods, a fine powder of chemically prepared PANI is suspended in an acid solution of insulating polymer, and the films obtained by casting this solution are brittle in nature. The electrode coating method was also used and it improved the adhesion of PANI to an optically transparent electrode, facilitating spectroelectrochemical measurements [110]. Fibrils of PANI were prepared by the polymerization of aniline in a gel

of poly(acrylic acid) using $FeCl_3$ as oxidant [111]. Scanning electron micrography revealed a diameter of 50 nm for the fibrils having a length of 1–5 μm. Monofilaments of conductive fibers from a blend of PANI and poly(p-phenylene-terephthalamide) were obtained at different concentrations of PANI through the process of wet-spinning from a solution of the component polymers in sulfuric acid into a 1 N sulfuric acid solution [112]. Electroactive polymer blends of PANI and polystyrene or poly(methylmethacrylate-co-butadiene-co-styrene) (MBS) are prepared via various techniques [113]. The methods used were in-$situ$ oxidative polymerization in aqueous dispersion of the insulating host, coagulation of latex of the thermoplastic in an acidic dispersion of PANI, or dry blending (casing from a solution containing both components). A blend of polyaniline and nitrilic rubber has been prepared by coating a platinum working electrode with a thin film of nitrilic rubber (29% acrylonitrile) and polymerizing aniline by the potentiodynamic method. Because aniline polymerization must be performed at low pH, nitrilic rubber was chosen for its resistance to acid attack [114]. The melt mixing procedure was used to disperse PANI doped with DBSA in poly(styrene-co-butadiene-co-styrene) (SBS rubber) [115] and thermoelastic polymer poly(styrene-ethylene/butylene-styrene) [108]. Conductivity values of 2 and 0.1 S/cm at volume fractions of PANI of 50 and 2%, respectively, can be obtained [108, 115]. PANI doped with poly(p-styrene sulfonic acid) can also be viewed as a polymer blend and can be electrochemically deposited onto a working electrode surface using an aqueous solution containing p-styrene sulfonic acid as an electrolyte [116].

3. CONDUCTING POLYMER NANOCOMPOSITES

Conducting polymer nanocomposites can be prepared in several ways. Either conjugated polymers can be dispersed in a host matrix such as conventional polymers, inorganic glassy materials, porous materials, on layered structures, or molecular/nanoparticle guest materials such as C_{60}, carbon nanotubes, titanium dioxide, cadmium selenide, or biological materials, can be dispersed in a conjugated polymer matrix. Moreover, the morphology of the composite can be easily altered by varying the self-organization/self-assembly features of the guest–host matrix, and this also significantly affects its physical properties. Typically, undoped conjugated polymers are semiconductors with bandgaps varying from 1 to 4 eV. The conductivity can be varied by 10 orders of magnitude, from insulator to metal, by doping, as shown in Table 1 [27, 75, 117–154]. The electrical and optical properties can be fine-tuned by varying the π-electron delocalization, interchain interactions, or disorder. Hence it is possible to obtain a wide range of interesting electrical and optical properties in conducting polymer nanocomposites.

Of the various types of conducting polymer nanocomposites, the doped conjugated polymers in the insulating polymer matrix have been the most extensively studied. In these composites, either the dispersion of insoluble conducting polymer particles or the formation of a tenuous interpenetrating network of soluble conducting polymers in an insulating polymer matrix can be achieved. In the latter,

Table 1. Room temperature conductivity of various doped conducting polymers [117–154].

Polymer	Dopant	Conductivity (S/cm)
Polyacetylene (Naarmann route)	I_2	10^5
Polyacetylene (liquid crystal)	I_2	1.2×10^4
Polyacetylene (Shirakawa)	I_2	10^3
Polyacetylene (Durham)	I_2	$10–10^2$
Polypyrrole	$[Ti(Obu)_4–AlEt_3]$	1–100
	I_2	1–100
	$FeCl_3$	1–100
	AsF_5	1–100
	Rb	1–100
	PF_6	200–1500
	$HClO_4$	4×10^2
	p-Toluenesulfonic acid	200–230
	$HClSO_3$	2×10^2
	ClO_4^-, BF_6, TsO, and HSO_4	50–200
Poly(3-methylthiophene)	PF_6	1975
	ClO_4	750
Poly(3-methylthiophene)	SO_3CF_3	30–100
Polythiophene	PF_6	370
	BF_4	270
	ClO_4	10–100
	AsF_6	97
Poly(3-octylthiophene)	$FeCl_3$	1–180
Poly(thieneylthiophene)	I_2	315
Poly(p-phenylene)	AsF_5	500
	Naphthyl K^{+e}	50
Poly(2-butoxy-5-methoxy– 4-phenylene vinylene)	$FeCl_3$	5.7×10^2
Poly(2,5-diheptyl- 1,4-phenylene vinylene)	SbF_5	2.8×10^4
Poly(phenylene vinylene)	$FeCl_3$	35
Polyaniline	HCl/CSA/DBSA/MSA	10^1–220
	H_3PO_4	58
	Diphenyl phosphate	65
	Phosphoric acid	40

the aspect ratio of the conducting polymer network can be controlled by varying the processing conditions, because the nanoscopic level self-assembly of the conducting polymer chains depends on molecular scale interactions. In this way, it is possible to attain very low percolation thresholds and also to observe a novel charge transport mechanism in these nanoscopic networks of conducting polymer chains. Moreover, these conducting networks have interesting applications, as discussed in Section 4. Hence this chapter is largely focused on the morphology and charge transport properties of conducting polymer networks in an insulating polymer matrix, although a brief overview of several other types of conjugated polymer nanocomposites is given.

Over the past 10 years, several types of conducting polymer nanocomposites with interesting electrical properties have been prepared, for example, poly(3-octylthiophene)/polyethylene (P3OT–PE), polyacetylene/polyvinyl butyral (PA–PVB), poly(3,4-ethylenedioxythiophene)/polystyrene sulfonate (PEDOT–PSS) or polyvinyl pyrrolidone (PEDOT–

PVP), and polyaniline–camphor sulfonic acid/polymethyl methacrylate [PANI–CSA/PMMA] [155–158]. Several of these composites show a finite conductivity at volume fractions of conducting polymers as low as 1%, which is much below the classical percolation threshold of 16% conducting material in the matrix. To a large extent, the distribution of conducting networks in the insulating matrix depends on the interaction between conducting and insulating polymers, which in turn is quite sensitive to the processing parameters. For example, in solution and gel processing routes the conducting polymer can get adsorbed to the connected gel network, and this leads to the formation of a two-dimensional network of conducting pathways in the insulating matrix [159]. Similarly, the chemical functionality of the guest–host matrix can influence the morphology from fractal networks to phase-segregated granular type formations. The structure of the conducting polymer chain plays a significant role in composite formation. The connectivity and conductivity of network are influenced by the flexiblity

and mobility of the conducting polymer chains in the matrix. Either via the molecular level interaction of functional groups in guest–host polymer chains or via cross-linking of the guest and host polymers through covalent bonds, it is possible to control the extent of interpenetration in the network. In this way, the domain size, the nature of the interfacial region, and morphology can be controlled. Some typical examples are given in the following paragraphs.

PA is the simplest of all of the conducting polymers because of its chemical structure, and doped films of PA have shown conductivity on the order of 10^5 S/cm, typical to that observed in conventional metals. However, PA is intractable and unstable at ambient atmosphere. Recently, fairly stable blends of PA were synthesized by blending it with PVB as the host insulating polymer matrix, with conductivity values of $\sim$1 S/cm [156].

PEDOT is another well-known conducting polymer because of its stability, semitransparent conducting properties, wide range of bandgap tuning (1.4–2.5 eV), and processibility. PEDOT when doped with poly(styrene sulfonic acid) (PSS) yields a soluble polyelectrolyte complex with positively charged PEDOT chains and negatively charged PSS ions, and it forms a fine dispersion in several solvents including water. The conductivity of PEDOT–PSS composites can be enhanced by several orders of magnitude (from 10^{-4} to 10^2 S/cm) under special processing conditions as mentioned in the literature [160]. In recent years, PEDOT composites have received a lot of attention because of their special electrical and optical properties [148].

Conducting polymer blends of PPy can be prepared by several different techniques. For example, PPy–Nafion and PPy–PMMA are made by interfacial polymerization [161, 162], PPy–nylon and PPy–cellulose [163, 164] are made by vapor-phase polymerization of pyrrole in the insulating polymer matrix containing the required oxidant, PPy–PVC and PPy–poly(vinyl alcohol) can be prepared by solution-phase polymerization of monomer, host polymer, and oxidant in a common solvent [165, 166], and PPy–PVC and PPy–Aramid can be prepared by electropolymerization of the monomer adsorbed into the host matrix [167]. All of these techniques usually yield PPy composites at $\sim$1 S/cm.

Nanocomposites of poly(2-methoxy, 5-(2′-ethyl-hexoxy)–p-phenylene vinylene) (MEH–PPV) in PE can be prepared by the solution or gel processing route [168]. Both MEH–PPV and PE are dissolved in xylene at elevated temperatures and form a gel upon cooling down to room temperatures. Free-standing films of MEH–PPV–PE, containing a volume fraction of MEH–PPV as low as 0.1%, can be prepared by stretch orienting the gel. These films show a high degree of anisotropy in polarized absorption and photoluminiscence along the direction of tensile drawing with ratios in excess of 150:1 and 60:1, respectively. The MEH–PPV chains are highly oriented in the PE matrix and the delocalized π-electronic states are over 100 Å, which corresponds to several tens of monomer units [168, 169].

During the last decade, much work has been carried out in the field of conjugated polymer composite-based photosensors and photovoltaic devices [170]. For example, blends of conjugated polymers as the electron donor with C_{60} as the acceptor have shown very interesting photoinduced charge transfer processes [171–174]. A nanocomposite of a conducting polymer and C_{60} has a high interfacial area for efficient charge separation through the control of morphology of phase separation in the interpenetrating network of donor and acceptor. Polyblends of PPV and C_{60} have shown a conversion efficiency of 2.9% [175]. Also, interpenetrating networks of two conjugated polymers, for example, MEH–PPV as a donor and a cyano group-substituted PPV as an acceptor have a quantum efficiency of 15% [175]. Furthermore, quite efficient large area photodiodes have been fabricated from these molecular-scale composites. Also, poly(3-octylthiophene) and fullerene composites have shown interesting photophysical properties [176]. Recently, composites of PPV derivatives and carbon nanotubes have improved the performance of devices, because the presence of nanotubes can enhance the mobility of carriers [19].

Conducting polymer nanocomposites with inorganic nanoparticles have been prepared and have several interesting physical properties. For example, PPy–ZrO_5, PPy–Fe_2O_3, and PANI–TiO_2, the dielectric properties can vary significantly [5].

Nanocomposites of PANI or PPy with Fe_2O_3 have shown interesting magnetic properties [5]. For example, laser action has been reported in films of MEH–PPV–TiO_2 in polystyrene [177]. It has been observed that the presence of TiO_2 nanocrystals significantly narrows the emission spectrum of MEH–PPV. For MEH–PPV/CdS the presence of CdS has improved the quantum yield for charge separation [178]. CdSe dispersed in MEH–PPV has enhanced the photoluminecence characteristics of the latter owing to efficient charge transfer [179]. It has been observed that the incorporation of semiconductive inorganic nanocrystals such as CdS or CdSe in MEH–PPV-based devices has improved the device performance.

Conducting polymers such as PPy or PANI, can be incorporated into the porous structure of zeolite systems. Composites of PPy with zeolites such as faujasite and mordenite [180, 181] have conductivity on the order of 10^{-4} S/cm. PANI has been incorporated in layered zeolites such as $V_2O_5 \cdot nH_2O$ [182] (known as oxide bronze) to form a layered conducting polymer–zeolite nanocomposite system, in which the conductivity is nearly 4 orders of magnitude larger with respect to the pristine oxide, with a room temperature conductivity as high as 0.1 S/cm. Conducting polymer composites have been prepared with various types of elastomers too. For example, blends of poly(3-methyl thiophene)/nitrile rubber has been prepared by the electrode coating method, with a conductivity of $\sim$0.1 S/cm [183]. Composites of poly(3,4-dialkylpyrrole) or poly(3-alkylthiophene) with natural or nitrile rubber have conductivity as high as 1 S/cm [183].

Among the various conducting polymer nanocomposites, only for surfactant counterion-processed PANI systems has a systematic and rigorous investigation been carried out. In particular, for the PANI–CSA/PMMA fractal nanocomposite, a detailed study on the morphology and charge transport has been done, as described in Section 4.

4. CONDUCTING POLYANILINE FRACTAL NANOCOMPOSITES

PANI is ideal for making conducting polymer nanocomposites owing to its ease of processing and inexpensive method of synthesis with high yield, good stability, and wide variation of conductivity. The conductivity of PANI can be varied by 10 orders of magnitude by altering the protonation level, with a high value of conductivity of ∼500 S/cm by doping with camphor sulfonic acid (CSA). The chemical structures of protonated PANI (emarldine salt) and CSA are shown in Figure 2. Emarldine base is a semirigid polymer that is sparingly soluble in a few solvents such as N-methylpyrrolidone and concentrated sulfuric acid. However, by doping emarldine base with functionalized protonic acids (e.g., CSA or DBSA) the conducting form of PANI can be made soluble in several solvents such as *meta*-cresol or xylene. Functionalized protonic acids have a chemical structure consisting of $H^+(M\text{-}R)^-$ where the counterion consists of an ionic group such as SO_3^- and a functional group such as dodecylbenzyl or camphor [15]. The role of the counterion $(M\text{-}R)^-$ is to act as a surfactant in which M^- attaches ionically to the positively charged polymer and the R group imparts solubility in solvents and also makes it processable. This counterion-induced processibility of PANI in various organic solvents has opened up the possibility of codissolving it with a host polymer matrix in a suitable solvent, and this yields a nanoscopic/molecular level control on the morphology of the composite. This has significantly improved the electrical and optical properties of PANI blends. Moreover, the conducting PANI blends can be easily cast from solution to obtain free-standing films and fibers.

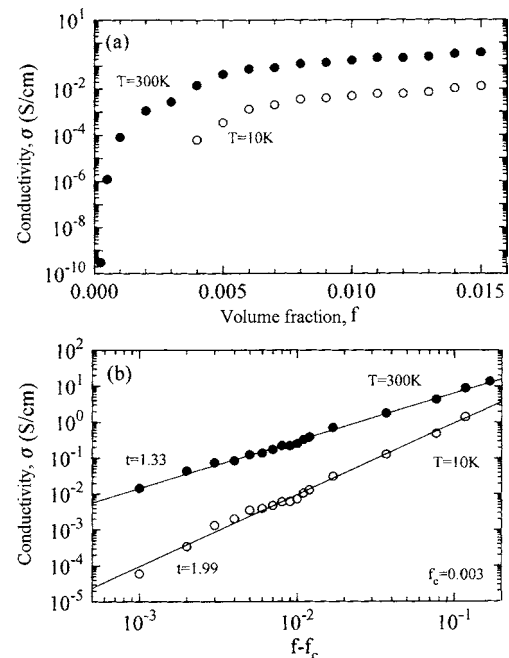
Conducting PANI nanocomposites have been prepared with some well-known polymers such as polymethylmethacrylate, nylon, polycarbonate, polystyrene, polysulfone, polyvinyl acetate, polypropylene, polyvinyl chloride, and acrylonitrile–butadiene–styrene copolymer [15]. In each of these polyblends the morphology of the PANI network is slightly different, because the molecular level interactions come into play and this determines the nanoscale structures. In some of the polyblends guest–host chains are highly interpenetrating; whereas in others a phase-segregated structure can be observed. For example, polyblends with ultra-high molecular weight polyethylene, polyvinyl alcohol, or polyacetonitrile (PAN) are optically clear and transparent for low volume fractions of PANI, because the typical width of PANI interconnects in the network are less than 200 Å; as a result the scattering loses are less [184]. Moreover, these polyblends can be stretched to high draw ratios, and this makes the PANI chains well aligned within the matrix. This has been verified by X-ray diffraction and polarized absorption spectra studies [15]. These types of polyblends can be used in flexible infrared (IR) polarizers. PANI chains form well-ordered conducting lines in a PAN matrix because the chains can be easily aligned by tensile drawing, and the scattering losses are less in the IR range [184]. The phase-segregated morphology in the PANI–PAN blend is being facilitated by the polar CN groups in the host polymer, which is a classic example to show how the molecular level interactions can alter the morphology and physical properties of these systems. Whereas, in the less polar PMMA host matrix, the

interpenetrated nanostructure can be controlled by varying the processing parameters such as the surfactant counterions, molecular weight of PMMA, and solvents, and this helps to investigate the interesting correlation between morphology and physical properties. This correlation is rigorously studied for PANI–PMMA composites, as discussed in Section 4.1.

4.1. Morphology of PANI–PMMA Fractal Nanocomposites

Cao and co-workers [185–188] were the first to perform a detailed systematic study of the nature and properties of surfactant counterion-processed PANI composites. Although composites with several host polymer matrices have been prepared, those with PMMA are the best in terms of very fine controls on composition, morphology, and physical properties. For example, by varying the molecular weight of PMMA, the diffusion of PANI–CSA in PMMA (hereafter PANI–PMMA) can be controlled, and this affects the formation of nano- or microstructures during the slow liquid–liquid phase separation process at temperatures around 50 °C. Hence, the dynamics of the diffusion of PANI–CSA in PMMA plays a significant role in the formation of the self-assembled interpenetrating fibrillar network that determines its physical properties. For example, in optimally processed composites with nanoscopic level intricate connectivity, it is possible to obtain conductivity values of ∼1 S/cm for a 1% volume fraction of PANI–CSA in PMMA, which is one of the amazing properties of these systems. The best results are obtained by using modest molecular weight PMMA with

Figure 2. Chemical structures of (a) emarldine base, (b) emarldine salt, and (c) 10-camphor sulfonic acid.

meta-cresol as the solvent. The extent of polarity of the surfactant counterion, host polymer, and solvent and processing conditions such as temperature and solution viscosity play significant roles in nanoscopic level morphology and the associated physical properties.


Transmission electron micrographs of PANI–PMMA nanocomposites containing volume fractions (f) of 0.25 and 0.5% of PANI–CSA are shown in Figure 3. These micrographs clearly show the distribution pattern of PANI, as expected for a percolating medium, with the formation of "links" (PANI–CSA fibrils), "nodes" (intersection point of two fibrils), and "blobs" (bundled-up dense regions), especially for 0.5% PANI–CSA. The links have diameters of ∼100–500 Å. However, as f is lowered to 0.25%, the number of links connecting the blobs rapidly decreases, as shown in Figure 3b. This suggests that as the links thin down, by lowering the volume fraction of PANI–CSA, the network falls apart to disconnected blobs. What exactly triggers this instability and makes the network unsustainable is not yet clearly understood. It seems that there is some critical diameter
around 100 Å for the links to hold the network together; and below this number the links become fragile and a significant volume fraction of PANI–CSA tends to stay within the blobs. Hence, in this processing route, with several optimized parameters such as the molecular weight of PMMA, the percolation threshold volume fraction (f_c) is between 0.5 and 0.25% of PANI–CSA and the conductivity near the percolation threshold is ∼10^{-3} S/cm, as shown in Figure 4 [186]. These values are quite remarkable with respect to the composites consisting of intractable PANI particles dispersed in PMMA, in which the conductivity at f_c ∼8% is ∼10^{-8} S/cm [186]. Moreover, it seems that the processing parameters can be optimized further, and this could yield PANI nanocomposites with f_c ∼0.1%, and conductivity at f_c of ∼1 S/cm.

Detailed investigations of transmission electron micrographs of PANI–PMMA composites have been carried out for a wide range of compositions of PANI–CSA [186]. When these micrographs are examined at different magnifications, the structure of the interconnected fibrillar network appears to be self-similar at all length scales, and this is especially so near the percolation threshold. This finding is consistent with the view that all systems exhibit self-similarity near the percolation threshold due to its fractal structure, which has been verified by numerical analysis of transmission electron micrographs. The numerical analysis is performed by mapping the mass distribution as a function of distance in the micrographs [186]. Usually in a homogeneous medium, the mass $M(r)$ increases as a function of distance (r) from a chosen origin; for example, in two dimensions, $M(r) \propto r^2$. Similarly, for a fractal structure the mass distribution is given by $M(r) \propto r^D$, where D is the fractal dimension. Typically, $M(r)$ is estimated by scanning and digitizing

Figure 3. Transmission electron micrographs of PANI–CSA/PMMA blends for volume fractions, (a) $f = 0.005$ and (b) $f = 0.0025$ of PANI–CSA. Scale: 1 cm = 50 nm. Reprinted with permission from [186], R. Menon et al., *Phys. Rev. B* 50, 13931 (1994). © 1994, American Physical Society.

the surface area of the network as a function of successively larger scanned areas, from any arbitrary starting point in the micrograph, which are then sampled and averaged out, as given in [185]. The log–log plots of surface area versus distance yield straight lines, and the slope of these lines depends on the volume fraction of PANI–CSA in the composite. For example, the typical values obtained from the above analysis for D with $f = 3.7$, 1.96, and 0.96% are 1.99, 1.75, and 1.53, respectively [186]. Hence, by decreasing f of PANI–CSA toward the percolation threshold, the value of D also decreases, and this suggests the presence of a self-similar structure with holes on every length scale. The estimate of D for the two-dimensional scanned slice of the three-dimensional object is ~ 1.5. The fractal dimension of the three-dimensional network at the percolation threshold (i.e., $f_c \sim 0.5\%$) can be estimated by adding 1 to the value of D obtained from the above analysis for the two-dimensional slice; that is, $1 + 1.5 = 2.5$. This number suggests that the network is open, porous, and self-similar on every length scale. Hence, this yields a large surface area for a fractal network, which is quite useful for several applications, as described in Section 5.

4.2. Electrical Properties of PANI–PMMA Fractal Nanocomposites

The typical values of room temperature conductivity and resistivity ratios $\rho_r [\rho_r = \rho \, (4.2 \, \text{K}) / \rho \, (300 \, \text{K})]$ for PANI–PMMA composites at various f values of PANI–CSA are presented in Table 2. The conductivity versus f plot is shown in Figure 4. The smooth and continuous increase in conductivity as a function of f is rather special to these systems. This suggests that as the connectivity of conducting channels gets denser, the movement of charge carriers becomes easier. When one compares this with classical percolating systems, in which the conductivity increases abruptly at the percolation threshold and then quickly saturates at higher values of f, it is possible to get very fine control of the value of conductivity as a function of f in PANI–PMMA nanocomposites. Hence the conductivity can be easily varied by nearly 10 orders of magnitude as a function of f. The precise determination of a percolation threshold can be obtained by fitting the data to the well-known "scaling

law" of percolation theory [i.e., $\sigma(f) \approx \sigma_T |f - f_c|^t$, where σ_T is a conductivity constant and t is the critical exponent (usually $t \approx 1$ and 2 for two- and three-dimensional systems, respectively)] [189]. The fit is shown in Figure 4b. At 10 K, $t = 1.99 \pm 0.04$ ($f_c = 0.3 \pm 0.05\%$), which is close to $t = 2$ for three-dimensional systems, although the room temperature data give $t = 1.33 \pm 0.02$ ($f_c = 0.3\%$), which can be attributed to thermally assisted hopping transport of charge carriers among the weakly connected parts of network. The temperature dependence of t is an interesting feature of PANI–PMMA nanocomposites, which is not usually observed in classical percolating systems.

The temperature dependence of conductivity of PANI–PMMA composites for a wide range of f values ($0.002 \le f \le 1$) is shown in Figure 5 [186]. The temperature coefficient of resistivity (TCR) for 100% PANI–CSA is quite weak with the typical metallic positive TCR above 150 K, and the resistivity minima vary according to the extent of disorder present in the system [190]. Upon increasing the dilution of PANI–CSA with PMMA, although the negative TCR became stronger at low temperatures, the intrinsic metallic positive TCR of PANI–CSA at temperatures above 200 K was observed even in samples containing volume fractions of PANI–CSA as low as $f \sim 0.3\%$, which is remarkable. For $f > 0.006$, the temperature dependence of conductivity was weak for $T > 50$ K, as shown in Figure 5. The temperature dependence of conductivity is characterized by the resistivity ratios (ρ_r) at various volume fractions as shown in Table 1. For $f > 0.006$, the network is well connected and the barrier due to disorder is rather weak at $T > 50$ K. However, at very low temperatures, the charge carriers have to hop across the random disorder potential barriers, and the exponential temperature dependence of conductivity is indicative

Table 2. Room temperature conductivity [$\sigma(300 \, \text{K})$] and resistivity ratio [$\rho(4.2 \, \text{K})/\rho(300 \, \text{K})$] of PANI–CSA/PMMA blends at various volume fractions (f) of PANI–CSA.

of thermally activated hopping transport among localized states at various energy levels.

Usually in disordered systems, the low temperature dependence of resistivity due to hopping transport is exponential in behavior {i.e., $\rho(T) = \rho_0 \exp[(T_0/T)^\gamma]$, where $\gamma = 1/(d + 1)$ and d is the dimensionality of the system, and $T_0 = q/[k_B N(E_F)L_c^3]$, where q is a numerical coefficient, $N(E_F)$ is the density of states at the Fermi level, L_c is the localization radius of states (rate of fall-off of the envelope of the wavefunction of localized states) near the Fermi level}. As temperature decreases, the average hopping length $[r \sim L_c(T_0/T)^\gamma]$ increases as $T^{-1/4}$; hence, this type of transport is usually referred as variable range hopping (VRH). In VRH, a carrier just below the Fermi level jumps to a state just above it, and the farther it jumps the greater is the choice of states available, and usually it jumps to a state for which the energy $\{E \sim [4.2r^3 N(E_F)]\}$ required is as small as possible. Whereas in nearest-neighbor hopping $[\rho = \rho_0 \exp(A/k_B T)]$ with a constant activation energy (A), the average hopping length is on the order of the mean separation between localized states, and it does not vary with temperature. The value of T_0 in VRH gives an estimate of how far the system has moved to the insulating side. Moreover, the localization length can be determined from T_0, which gives some idea about the length scale of the localized wavefunctions and the extent of disorder present in the system [13].

The values of γ and T_0 give some idea about the hopping transport mechanism in disordered systems. However, for the convoluted and multiply connected PANI–CSA network, the complex fractal morphology plays a significant role in the hopping mechanism. For example, in these systems the value of γ systematically increases from 0.25 to 1 upon varying f from 0.012 to 1, which is not expected in the conventional VRH model. Nevertheless, this behavior is expected in systems in which the fractal structure modifies the wavefunctions of the localized states, and accordingly γ varies as the fractal dimensionality of the system changes. Details about the charge transport mechanism in fractal structures, as in PANI–PMMA, are described in [186]. Hence, conducting polymer nanocomposites offer the possibility of investigating novel charge transport mechanisms in fractal network structures.

Among various charge transport properties, magnetoresistance (MR), the change of resistance as a function of magnetic field, which especially occurs at low temperatures, is well known for providing additional information on the nanoscopic scale charge transport mechanism. In particular, this gives insight into the underlying relationship between nanostructure and scattering and relaxation mechanisms of charge carrier dynamics. The classical transverse MR is mainly due to the bending of the charge carrier trajectory by a Lorentz force, and it is proportional to the square of the field, with the proportionality constant expressed as a function of charge transport scattering time [185]. In typical metals the dominant contribution to the weak positive MR (usually less than a 5% increase in resistance at 4.2 K) is due to the classical orbital motion of charge carriers. Moreover, the MR gives information about the second derivative of the density of states at the Fermi level. Because MR probes the local charge carrier dynamics in conducting systems, the MR

data can be used to determine the nanoscopic transport property parameters, for example, the elastic and inelastic scattering length and scattering time. Furthermore, the MR results are supplementary to conductivity data; hence it is essential to check the internal consistency of the models used to understand the charge transport properties.

The MR data at 4.2 K for PANI–PMMA nanocomposites are shown in Figure 6 [187]. The normalized variation in MR is plotted as a function of H^2 for PANI–PMMA samples with $0.015 < f < 0.004$ that are just above the percolation threshold, and in these the fractal structure is observed to be prominent. The H^2 dependence of the positive MR at low fields is due to the shrinkage in the overlap of wavefunctions of localized states in the presence of a magnetic field, which is usually observed in VRH transport. The positive MR decreases considerably by lowering f from 0.015 to 0.004, as shown in Figure 6. The MR shows a maximum at $f \sim 0.015$ at 4.2 K. As the system approaches the percolation threshold, the connectivity of the network decreases; as a result the carriers find it increasingly difficult to hop from site to site in the presence of the magnetic field, and the value of MR decreases considerably for $f < 0.015$. Whereas for $f > 0.015$ the connectivity increases at higher volume fractions, and the effect of field on hopping transport gradually decreases; hence the value of MR is less. This shows that MR is an ideal probe to investigate the role of nanoscopic level morphology in the charge transport properties in conducting polymer nanocomposites. The detailed analysis of MR results is described in [186].

Thermoelectric power [or thermopower (S)] is another phenomena to explore the charge transport mechanism in metallic and semiconducting systems. In the thermoelectric effect or Seebeck effect, a temperature gradient at the
Figure 6. Magnetoresistivity versus square of magnetic field for $f =$ 0.015 (●), 0.012 (∗), 0.01 (+), 0.008 (□), and 0.006 (△). The inset shows magnetoresistivity versus volume fraction at 4.2 K. ends of a sample gives rise to an electric field opposite to the direction of the temperature gradient [192]. Usually the sign of thermopower is consistent with a positive or negative charge of the carrier. The diffusion thermopower (S_d) in metallic systems is a function of the first derivative of density of states at Fermi level. Although the temperature dependence of thermopower [$S(T)$] is supposed to be linear in metals, it is usually complicated by scattering processes. However, in high quality metallic conducting polymers a quasilinear temperature dependence of thermopower has been observed down to 8 K, which is quite remarkable when the extent of disorder present in these systems is considered. In several conducting polymer composites a linear temperature dependence of thermopower has been observed, but only down to 100 K [13].

The $S(T)$ of PANI–PMMA nanocomposites is shown in Figure 7 [193]. The thermopower at room temperature is nearly 8 μV/K for all volume fractions, and it is positive for $T > 80$ K. The data show the typical metallic linear temperature dependence over a wide range of volume fractions of PANI–CSA in PMMA; however, there is a clear deviation from linearity below 100 K, and this deviation increases as f is lowered. The characteristic U-shaped dependence of $S(T)$ below 100 K indicates the onset of the breakup of the conducting network into disconnected regions, and the thermally activated hopping transport [$S_{\text{hop}}(T) \propto T^{1/2}$ for VRH] across these regions dominates over the metallic diffusion thermopower [$S_d(T) \propto T$]. Because thermopower is a zero current transport coefficient, it is relatively less sensitive to the electrical conduction paths between the disconnected regions, and this is mainly due to the fact that nanoscopic level thermoelectric voltages sum up together as long as the thermal gradients take place across the conducting paths. Hence investigating the low temperature U-shape in thermopower can give some insight into how well the conducting network is connected at the nanoscopic level. Thus $S(T)$ is another useful probe to investigate the correlation between

morphology and charge transport mechanism in conducting polymer nanocomposites.

5. APPLICATIONS

Conducting polymer nanocomposites are used for a wide range of applications as indicated in the following [194]:

1. PANI nanocomposites have a wide range of applications for antistatic coating, electromagnetic interference shielding, and anticorrosive coatings. In particular, the fibrillar fractal network of PANI nanocomposite has high conductivity at low volume fractions of PANI and hence is ideal for these types of electrical applications.

2. PEDOT–PSS is most widely used by photographic film and electronics packaging industries. An antistatic coating of PEDOT–PSS on films (photographic/electronics packaging) having a surface resistance less than 10^9 Ω/m^2, eliminates the risk of static charge buildup, which may damage the films. Interestingly, more than 100 million square meters of photographic films are coated by PEDOT–PSS every year. Also, PEDOT–PSS is widely used for transparent conducting electrodes [157].

3. Conducting polymer-coated fibers such as polyester or nylon have applications in electromagnetically camouflaged nets in stealth devices [183].

4. Conducting polymer composites with various nanocrystals have had interesting applications in light-emitting diodes, solar cells, lasing medium, and electrochromic devices. For example, MEH–PPV/perylene bis(phenethylimide)-based photovoltaic cells show an open circuit voltage of 0.58 V and their performance is better than that of MEH–PPV/CN–PPV-based photovoltaic devices [195]; PPV/carbon nanotube-based photovoltaic devices show a quantum efficiency of 1.8%, which is twice that of standard ITO-based devices, with an open circuit voltage of 0.9 V [19]. Nanocomposites based on MEH–PPV and TiO_2 nanocrystals show higher quantum efficiency of 12% [16]. TiO_2 dispersed in an MEH–PPV/polystyrene blend acts as a lasing medium that shows excited emission at wavelengths of 532 and 435 nm [177]. Blends of PPy and epichlorohydrin and ethylene oxide (Hydrin C) show excellent electrochromicity and are used in electrochromic devices [183].

5. Networks of PANI blends filled with semiconducting polymers can be used as grid electrodes in a polymer grid triode [196]. The open structures of fibrillar fractal networks of PANI nanocomposite have large active surface area for devices.

6. Conducting polymer nanocomposites have shown potential for use in molecular sensors, biosensors, and molecular electronics applications [197, 198].

6. CONCLUSIONS

In conclusion, conducting polymer nanocomposites have broadened the horizon of conventional polymer composites. In usual polymer composites the physical and chemical properties of the composite are limited, and the volume fraction of guest material is above the percolation threshold

(16% volume fraction), which restricts the processability and mechanical properties of the composite. Moreover, it is hard to attain uniform distribution of nano or meso particles in composites due to various problems with compatibility, and this usually leads to inhomogeneity in the physical properties. It is possible to overcome several of these shortcomings with the breakthrough in the self-assembled fibrillar fractal network of guest polymer chains in the host matrix. This is very well illustrated for the conducting PANI–CSA fibrillar fractal network in a PMMA matrix in which the nanoscale morphology and the associated physical properties can be controlled rather well. The connected network forms at a volume fraction of PANI–CSA as low as 0.3%, with conductivity values of $\sim 10^{-3}$ S/cm. The network is quite robust in that it remains well connected even after the removal of the host polymer. This large open area conducting fractal network is quite useful as an electrode in various applications, for example, in polymer grid triodes. It is possible to obtain excellent control of the electrical and optical properties of this network by subtle variations in the composition of the nanocomposite as demonstrated by the temperature dependence of conductivity, magnetoresistance, thermoelectric power, and optical transmission features. Further molecular scale engineering and functionalization of conjugated polymer chains, and fabrication of this type of self-assembled fractal networks can widen the scope of this category of nanostructured systems, which are rather unique compared with other types of nanosystems.

GLOSSARY

Conducting polymer   A long chain carbon polymer consisting of alternating single and double bonds, in which delocalized π-electrons determine the physical and chemical properties.

Fractal   A system that looks self-similar at all length scales, in which the dimensionality has noninteger values [integer value means 1, 2 and 3 dimensions for Euclidean geometry].

Localization   A phenomenon in which the wavefunctions associated with the electronic states get localized, to a few interatomic distances, by the random disorder potential fluctuations so that there is hardly any overlap with nearest-neighbor wavefunctions.

Lorentz force   The force ($\mathbf{F}$) experienced by a charge carrier q in electric ($\mathbf{E}$) and magnetic field intensity ($\mathbf{B}$), and it is given by the following relation: $\mathbf{F} = q(\mathbf{E} + \mathbf{v} \times \mathbf{B})$ where $\mathbf{v}$ is the velocity of charge.

Magnetoresistance   The variation of resistance as a function of magnetic field. It is mainly due to the bending of charge carrier trajectory by Lorentz force, which is usually proportional to the square of the field, with the proportionality constant expressed as a function of scattering time.

Nanocomposite   A nearly homogenous mixture of two or more components, in which the physical size of components is typically below 100 nm, and this imparts special size-dependent properties.

Percolation threshold   The minimum volume fraction of guest component in a composite, at which the physical properties increase by several orders of magnitude due to the connectivity of guest material. For example, for conducting

spherical particles, at around 16% volume fraction, the electrical conductivity increases by several orders of magnitude.

Resistivity   A basic property of a material that signifies the measure of resistance offered by it to the flow of charge carriers. Resistivity (ρ) is defined as $\rho = R(A/l)$, where R is the resistance, l is the length of the sample, and A is the cross-sectional area. The SI unit is $\Omega \cdot$ m.

Thermopower   In the Seebeck effect, a temperature gradient at the ends of a sample gives rise to an electric field in the opposite direction as the temperature gradient. It is a measure of the rate of change of potential difference across a material as a function of unit change in temperature gradient.

Polymer Electrolyte Nanocomposites

Mikrajuddin Abdullah[1], Wuled Lenggoro, Kikuo Okuyama

Hiroshima University, Hiroshima, Japan

CONTENTS

1. INTRODUCTION

Rechargeable cells are key components in mobile technologies, such as portable consumer electronics and electric vehicles [1]. A search for batteries that provide high energy density and multiple rechargeability has been a subject of considerable attentions. Even though battery technology developed one hundred years ago, progress and improvements in technology have been slow, particularly when compared to the growth of computer technology [2].

A Li-based battery provides a high density and flexibility of design. Today's lithium battery has a high specific energy (>130 W h kg^{-1}), a high energy density (>300 W h L^{-1}),

[1] Permanent address: Department of Physics, Bandung Institute of Technology, Jalan Ganeca 10 Bandung 40132, Indonesia.

high cell voltage (3.5 V), as well as a long cycle life (500–1000) charge/discharge. Worldwide production of such devices exceeded 200 million in 1997 and it will be approximately three times that number during 2001 [1]. Since lithium produces an explosion reaction with water-based electrolytes, a search for nonaqueous electrolytes is critically important to the production of the next-generation lithium battery, using electrolytes in an solid phase in an effort to develop more environmentally friendly materials. Polymer electrolytes are potential candidates for replacing the conventional aqueous electrolytes in lithium batteries. Polymers containing esters, ethers, or mixtures thereof which have the ability to dissolve salts are the base materials for polymer electrolytes. Polymer electrolytes are generally prepared by mixing high molecular weight polymers (HMWPs) with a salt solution. The polymer serves as solid solvent, thus permitting the salt to dissociate into anions and cations. Since the mass of a cation is much smaller than that of an anion, the electrical conductivity is dominated by cation transfer. Lithium salts are usually used for this purpose since they are the most electropositive of materials (-3.04 V relative to the standard hydrogen electrodes) as well as the lightest metal (atomic mass 6.94 g/mol, and density 0.53 g/cm^3) and thus facilitate the design of storage systems with high energy density (Watt hour/kg) [1]. Table 1 shows a comparison of the electrochemical properties of several metals.

Until presently, however, no polymer electrolyte-based lithium batteries are commercially available in the market. Therefore, worldwide research is being focused on the development of high power and high energy density polymer electrolytes with a major attention to safety, performance, and reliability. A battery contains two electrodes: positive and negative (both sources of chemical reactions), separated by an electrolyte that contains dissociated salts through which ion carriers flow. Once these electrodes are connected to external circuits, chemical reaction appears at both electrodes to result in a deliverance of electrons to the external circuits. The properties of a battery thus strongly depend on the electrolyte, anode, and cathode. With the use of polymer electrolytes in lithium batteries, high specific energy and specific power, safe operation, flexibility in packaging, and low cost in fabrication as well as low internal voltage drop at relatively large current withdraw is expected [3].

Table 1. Electrochemical properties of several metals that have potential applications for use in batteries.

Metal	Atomic weight [g/mol]	Valence charge	Specific charge [A h kg^{-1}]	Electrode potential [V]
Li	6.94	1	3862	3.05
Na	22.99	1	1166	2.71
Mg	24.31	2	2205	2.38
Zn	65.38	2	820	0.76
Cd	112.41	2	477	0.40
Pd	207.20	2	250	0.13

Realization of commercial polymer electrolyte batteries is actively investigated in many companies worldwide. A major effort to develop advanced polymer batteries for electric vehicles began in the early 1990s by 3M and Hydro-Quebec [4]. The battery contains a lithium metal anode, a polyethylene oxide (PEO)-based polymer electrolyte, and a vanadium oxide (VO$_x$) cathode. The reversibility of lithium intercalation and deintercalation in the VO$_x$ is quite good but the average discharge of the cell is low. PolyPlus Battery company in the United States is developing polymer electrolyte-based lithium battery which would operate at room temperature with specific energy as high as 500 W h kg^{-1} [3]. In a prototype cell, using cathode made of lithium intercalated disulfide polymer, a specific energy as high as 100 W h kg^{-1} and charge and discharge cycles almost reproducible for over 350 cycles were observed at 90 °C [5]. Moltec company reported a specific density of 180 W h kg^{-1} for an AA-sized battery based on organosulfur cathode [6]. Ultrafine Battery company reported a room-temperature solid polymer battery based on intercalation type electrode with a specific energy 125 W h kg^{-1} and charge/discharge cycling time of 500 [3]. This performance is still below the consumer expectation threshold. In 1995, Turrentine and Kurani in the United States did a survey on demand for alternative fuel cell for vehicles and found that consumers agreed to buy electric vehicles which would run for at least 200 km per battery [7].

2. CONDUCTIVITY ENHANCEMENT IN POLYMER ELECTROLYTES

It is believed that in the polymer electrolytes, the cations are coiled by polymer segment leaving the anions to occupy separate positions [8]. Battery performance is limited by the speed of cation diffusion. The transport of cations takes place if there is a relaxation of the polymer segments so that cations are released from a segment and then occupy another segment. Segmental relaxation requires the presence of free volume in the polymer matrix, a condition that can be attained if the polymer is in an amorphous state. Unfortunately, most HMWPs crystallize at ambient temperatures. Ions are transported with difficulty in a crystalline matrix since no chain relaxation occurs and, as a result, the conductivity of polymer electrolytes in this phase (at ambient temperature) is depressed. The transport of ions in this state is dominated by the jumping of cations to the nearest location, which depends on the blocking potential (activation energy). This is similar to the jump of charge carriers in crystalline solids. The characteristic time for jumping is proportional to the exponential of the blocking potential. This results in a conductivity of the order of 10^{-8} S/cm, a value that is far below the desired value of about 10^{-4} S/cm [9]. When it enters the amorphous state, that is, at temperatures above the melting point, a high conductivity appears. For a commonly used polymer, that is, polyethylene oxide, the melting temperature is 65 °C. This is, of course, impractical since the operating temperature for most electronic devices is room temperature. In addition, at temperatures above the melting point, the polymer becomes soft, causing the solid-state properties to degrade. Initiated by the work of Wright and Armand [10–12], several kinds of polymer electrolytes have been intensively investigated around the world. Table 2 displays examples of polymer electrolytes and their measured conductivities at 20 °C [13].

Improvements in the electrical conductivity of polymer electrolytes at ambient temperature is therefore of critical importance for technological applications. Several approaches have been explored to realize this aim. Some frequently used methods will be explained briefly here.

2.1. Preparing Low Degree of Crystallinity Polymers

By considering that the presence of amorphous state is strictly important for improving the conductivity, the main strategy is to enhance the amorphous state at low temperatures. The first approach is to prepare low degree of crystallinity polymer from initial. It includes cross-linking of two polymers [13, 14], synthesis of new polymer, cross-linking high molecular weight polymer through γ-irradiation [15, 16], addition of plasticizers in polymer electrolytes, addition of fillers, and bending of two polymers [17, 18]. Another strategy is to prepare an amorphous polymer so as to obtain a polymer that is composed of four to five monomeric units. For this system, the chains must be sufficiently long to effectively complex cations but too short to crystallize at low temperatures. Thus the matrix would still be in the amorphous state even at low temperatures. The polymer host serves as a solvent and does not include any organic liquids.

2.2. Addition of Side Chains

An alternative way to decrease the crystallinity of polymer matrix is to introduce side chain to the polymer main chain. Theoretically, chain ends and branch can be thought of as impurities, which depress the melting point of the polymer. Simple mathematical formulation can be used to explain the melting point lowering by the presence of chain ends and branch. If X_i is the mole fraction of impurities (chain ends, side chains, and branch), then the melting point of polymer, T_m, decreases according to [19]

$$\frac{1}{T_m} - \frac{1}{T_m^o} = \frac{R}{\Delta H_u} \ln(1 - X_i) \qquad (1)$$

where T_m^o = melting point of polymer containing only polymer chain with infinite chain length, R = gas constant, and ΔH_u = enthalpy of fusion per mole of repeat unit. Chung and Sohn showed that the XRD intensity of polymer

decreases with the increase in the length of chain of comb-shaped polymer [20].

Despite depressing the melting point of polymer, the presence of side chain also promotes the solvating of a salt as reported by Ikeda and co-workers [21, 22]. The side chain has shorter relaxation time compared to the main chain. The coupling of the side chain with the ion carrier, therefore, results in an increase in the conductivity. Watanabe et al. designed comb-shaped polyether host with short polyether side chain [23]. However, the mechanical properties decreased even as the conductivity increased. High conductivity with good mechanical properties was obtained by designing a polymer of high molecular weight with trioxyethylene side chain as reported also by Ikeda et al. [24]. With 18 mol.% of side chain, the conductivity was measured to be 1.5×10^{-4} S/cm at 40 °C and raised to 1.4×10^{-3} S/cm at 80 °C.

Composite of polymer with room-temperature molten slat is also an interesting approach to improve the conductivity of polymer electrolytes. Watanabe et al. reported the composite consisting of chloroaluminate molten salt that possesses a conductivity of 2×10^{-3} S/cm at 303 K [25, 26]. However, the disadvantage of chloroaluminate is its hygroscopic properties such that it is impractical in application. The use of non-chloroaluminate molten salt, therefore, is required to avoid the hygroscopic problem. Tsuda et al. reported a conductivity of 2.3×10^{-2} S/cm in composite of polymer and room-temperature molten fluorohydrogenates [27].

2.3. Addition of Plasticizers

Another approach to improve the conductivity is by addition of additional material into the host polymer. This approach appears to be the simplest since a pre-produced polymer can be used to make the polymer electrolytes. Previously, low molecular weight polymers were usually used to reduce the operation temperature of polymer electrolytes. The low molecular weight polymers which were added to the matrix of HMWP to reduce the crystallinity at low temperatures are frequently known as liquid plasticizers.
Feullade and Perche demonstrated the idea of plasticizing the polymer with an aprotic solution containing alkali metal salt in which the organic solution of the alkali metal salt remained trapped within the matrix of solid polymer matrix [28]. Such mixing results in formation of gels with ionic conductivity close to the liquid electrolytes. Less evaporating solvents such as ethylene carbonate (EC), propylene carbonate (PC), dimethyl formamide (DMF), diethyl phthalate (DEP), diethyl carbonate (DEC), methyl ethyl carbonate (MEC), dimethyl carbonate (DMC), γ-butyrolactone (BL), glycol sulfide (GS), and alkyl phthalates have been commonly investigated as plasticizers for the gel electrolytes.

Figure 1 shows the effect of plasticizer content tetraglyme (tetraethylene glycol dimethyl ether) on the glass temperature of a system of PEO-co-PPO (3:1):LiClO$_4$ [29]. The decrease in the glass temperature can be simply explained using a Fox equation:
$$\frac{1}{T_g} = \frac{W_1}{T_{g1}} + \frac{W_2}{T_{g2}} \tag{2}$$

where W_1 and W_2 denote the weight fractions of component 1 and component 2, respectively, and T_{g1} and T_{g2} are their corresponding glass transitions. This equation tells that the glass temperature of the composite locates between the glass temperature of the components. This relation is also applicable for copolymer where T_{g1} and T_{g2} denote the glass temperature of polymers forming the copolymer. Reduction in the glass temperature means the enhancement in the amorphous state at low temperature, and therefore improves the conductivity at low temperatures. Figure 2 shows the enhancement of conductivity by the addition of plasticizer tetraglyme on the system of PEO-co-PPO (3:1):LiClO$_4$, measured at 25 °C [29]. The decrease in the glass transition results in the improvement in the fraction of amorphous state at room temperature, therefore improving the conductivity.

However, an improvement in conductivity is adversely accompanied by a degradation in solid-state configuration and a loss of compatibility with the lithium electrode [9],

Figure 2. Effect of plasticizer weight fraction on the conductivity at 25 °C of a PEO-co-PPO (3:1):LiClO$_4$ using plasticizer tetraglyme (tetraethylene glycol dimethyl ether). Data points were extracted from [29], D. R. MacFarlene et al., *Electrochim. Acta* 40, 2131 (1995).

particularly when the fraction of plasticizers is too high. For example, the modulus of elasticity and elastic strength significantly decreases by addition of plasticizers. This is because the plasticizers are usually low molecular weight polymer having low mechanical strength. Therefore, addition of plasticizers decreases the mechanical strength of the host polymer. Figure 3 shows the effect of plasticizer troglyme content on the elastic modulus and tensile strength of PEO-co-PPO (3:1):LiClO$_4$ [29]. The use of moderate or large quantities of plasticizer results in the production of

Figure 1. Effect of plasticizer weight fraction on the glass temperature of a PEO-co-PPO (3:1):LiClO$_4$ using plasticizer tetraglyme (tetraethylene glycol dimethyl ether). Data points were derived from [29], D. R. MacFarlene et al., *Electrochim. Acta* 40, 2131 (1995).

gel electrolyte. The presence of some plasticizer may also give rise to problems caused by its reaction with the lithium anode. The poor mechanical stability was accounted to be mainly due to the solubility of the polymer matrix in the plasticizer [30]. Cross-linking of the polymer with ultraviolet radiation [31], thermally [32], by photopolymerization [33], or electron beam radiation polymerization [34] was found to reduce the solubility of polymer in the solvent and also helped to trap liquid electrolytes within the polymer matrix.

3. DEVELOPMENT OF POLYMER ELECTROLYTE NANOCOMPOSITES

Currently, one popular approach to improve the conductivity involves dispersing ceramic fillers (solid plasticizers) in the polymer matrix, producing what is currently known as composite polymer electrolytes. This approach was first introduced by Weston and Steele [35]. Ceramic filler was used to reduce the glass transition temperature and crystallinity of the polymer and thus allow the amorphous polymer to maintain the liquid-like characteristic at the microscopic level. Ceramic fillers that are frequently used have particle sizes in the range of about several ten nanometers up to several micrometers. Fortunately, such filler materials are commercially available in various sizes at low prices. Figure 4 shows the effect of filler content on the conductivity of polymer electrolytes PEO:LiClO$_4$ [9]. Table 3 displays examples of polymer electrolyte nanocomposites and their conductivities at around room temperature.

The inorganic filler also acts as a support matrix for the polymer, so that even at high temperature, the composite remains solid. However, at the microscopic level, it maintains a liquid-like structure, which is important for sufficient conductivity. The filler particles, due to high surface area, prevent the recrystallization of polymer when annealed above the melting point. The acid-base interaction between the filler surface group and the oxygen of the PEO leads to a Lewis acid characteristic of the inorganic filler and favors
Figure 4. Arrhenius plot of electrical conductivities of: (solid) ceramic-free PEO:LiClO$_4$, (triangle) PEO:LiClO$_4$ containing 10 wt.% Al$_2$O$_3$ (5.8 nm), and (square) PEO:LiClO$_4$ containing 10 wt.% TiO$_2$ (13 nm). the formation of complexes with PEO. The filler then acts as cross-linking center for the PEO, reducing the tension of the polymer for self-organization and promoting stiffness. On the other hand, the acid-base interaction between the polar surface group of the filler and electrolyte ions probably favors the dissolution of the salt.

Another potential application of polymer electrolyte nanocomposites is for making solar cells [55]. Dye-sensitized solar cells have attracted great scientific and technological interest as potential alternatives to classical photovoltaic devices. The cell operation mechanism involves absorption of visible light by the chemisorbed dye, followed by the electron injection from the excited synthesizer into the semiconductor conduction band. The selection of liquid electrolytes, usually containing organic solvent such as acetonitrile and propylene carbonate, assures the perfect regeneration of the dye by direct interaction of the dye oxidized state and I$^-$/I$_3^-$ redox couple and leads to impressively high solar-to-electrical conversion efficiencies (7–11%) [56, 57]. However, the stability and long-term operation of the cell are affected by solvent evaporation or leakage. Thus commercial exploitation of these devices needs the replacement of the liquid electrolyte by a solid charge transport medium, which not only offers hermetic sealing and stability but also reduces design restriction and endows the cell

with shape choices and flexibility. Katsaros et al. investigated solid-state dye-sensitized solar cells using composite polymer electrolytes using PEO and TiO_2 in the presence of I^-/I_3^- redox couple [55]. Initially, dye:$Ru(dcbpy)_2(NCS)_2$ (dcbpy is 4,4'-dicarboxylic acid-2-2'-bipyridine) was attached on the surface of TiO_2 nanoparticles by immersion of the TiO_2 thin-film electrode overnight in ethanolic solution of the complex, followed by drying. The functionalized TiO_2 nanoparticles, I^-/I_3^-, and PEO were put in acetonitrile, followed by heating and drying to evaporate the solvent. Maximum incident photon to current efficiencies as high as 40% were obtained at 520 nm, only two times lower that than obtained using liquid electrolytes [58]. The overall conversion efficiency was 0.96%. For all-solid-state devices, such efficiency can be considered to be sufficiently high [59].

4. PREPARATION METHODS

Now we will briefly explain several methods of preparation of polymer electrolyte nanocomposites that are commonly used. Which method should be used, of course, depends on the materials and the form of sample to be formed. One method can only produce sample in the form of thick film, and another one can produce a sample in the form of film of submicrometer thickness.

4.1. Casting Method

This method is frequently used due to its simplicity. It can produce polymer film from several micrometers up to several millimeters thickness. Generally, this method includes the following steps:

(a) dispersion of ceramic fillers in a salt solution,
(b) addition of a specified amount of polymer to the mixture,
(c) mixing by means of stirrer or ultrasonic equipment to disperse the particles homogeneously in the polymer matrix,
(d) casting the mixture on a substrate,
(e) finally drying in vacuum or in an atmosphere of argon.

All these steps are usually performed in a glove box filled with argon gas and excluding oxygen and water to levels below 20 parts per million (ppm), to avoid the possible occurrence of a "dangerous reaction" between water and lithium. The solvent must be water-free and should be common solvent for both the salt and the polymer. Since the melting point of several polymers is as high as 65 °C, the solvent must also easily evaporate so that drying can be performed at temperatures of around 65 °C. Organic solvents such as acetonitrile, cyclopentanone, and propylene carbonate, plus inorganic solvents such as thionyl chloride ($SOCl_2$), are typically used.

Sometimes, the insertion of salt is performed after casting the film. For example, Ardel et al. prepared PVDF 2801 (Kynar)-based polymer electrolyte composites according to the following steps [60]. First, Kynar was dissolved into cyclopentanone. Nanoparticles of silica were added and the mixture was mixed for 24 h at room temperature to get homogeneous slurry. After complete dissolution, the slurry was cast on the Teflon support and spread with the use of doctor blade technique. To prevent surface irregularities, the film was then covered with a box pierced with holes that allowed a slow evaporation of the cyclopentanone. After complete evaporation of the cyclopentanone, the polymer membrane was soaked in a lithium ion solution for 48 h. Several fresh lithium solutions for each soaking can be used to ensure a complete impregnation of lithium ion into the membrane.

4.2. Spin Coating

The spin-coating method is very similar to the casting method. Instead of casting the film on a substrate, in this method, the mixture is dropped on a substrate and placed in a spin coater that can be rotated at adjustable rotation speed. The film thickness can be controlled easily by adjusting the viscosity (concentration) of the mixture and the speed of rotation. However, this method is only available if the viscosity of the mixture is not too high. For a gel mixture, the spin coater rotation is not enough to spread the mixture droplet to form thin film.

4.3. Hot Press

Hot press technique equipment is illustrated in Figure 5. The equipment consists of: (A) weighing cylinder, (B) heating chamber, (C) basement, and (T) temperature controller. Proper amounts of polymer, salt, and filler are mixed in a mortar for about several minutes. The powder mixture is then sandwiched between two sheets of Mylar or other materials, and positioned inside the heating chamber that is controlled at temperatures lightly above the melting point of the polymer. If PEO is used as polymer matrix, temperature of 80 °C is suitable [61]. The sample is then pressed overnight with a pressure that can be controlled by weighing cylinder. After heating and pressing, the sample is then slowly cooled to room temperature. The sample is then separated from the Mylar sheet and placed in a glove box.

Figure 5. Illustration of hot press equipment: (A) weighing cylinder, (B) heater, (C) base, and (T) temperature controller.

4.4. *In-situ Preparation*

In-situ preparation explained here is the preparation of nanoparticles in the polymer matrix. Mikrajuddin et al. produced polymer electrolytes of polyethylene glycol with lithium ion by *in-situ* production of ZnO nanoparticles in the polymer matrix [62, 63]. The preparation methods will be briefly described as follows. Zinc acetate dihydrate, $(CH_3COO)_2Zn \cdot 2H_2O$ 0.1 M in 100 mL ethanol 99.5, was heated with stirring in distillation equipment at temperature of 80 °C to produce about 60 mL condensate and 40 mL of hygroscopic solution. Lithium hydroxide monohydrate, $LiOH \cdot H_2O$, of various concentrations was suspended in 40 mL ethanol and stirred until all the granular material dissolved. Polyethylene glycol (PEG) (Mn = 2,000,000) was suspended into each LiOH solution and then stirred with heating at around 60 °C until homogeneous gel-type mixtures were obtained. The mixture temperatures were then left to go down several minutes, after which 10 mL of hygroscopic $CH_3COO_2Zn \cdot 2H_2O$ solution was added into each mixture. The new mixtures were then homogeneously mixed and then dried in an oven that was kept at temperature of 40 °C during three days. The schematic of sample preparations is displayed in Figure 6.

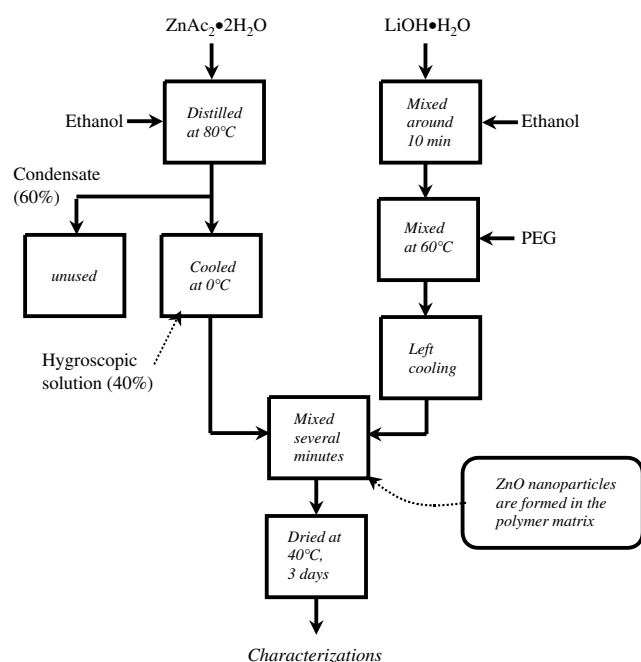
There are many differences between the present method and the commonly used ones. In the present approach: (a) Nanoparticles are grown *in-situ* in polymer matrix. (b) The size of dispersed particles is controllable. (c) Ion carriers are inserted *in-situ* in the polymer matrix during the growing process. (d) Finally, since the grown nanoparticles are luminescent, we obtain a new class of polymer electrolytes, namely luminescent polymer electrolytes with nanoparticles as luminescence centers. Based on the TEM picture, we found that the size of ZnO nanoparticles was 5 nm.


Figure 6. Diagram of *in-situ* preparation of PEG:Li containing nanoparticles of ZnO. Adapted with permission from [62], Mikrajuddin et al., *J. Electrochem. Soc.* 149, H107 (2002). © 2002, Elsevier.

Chandra et al. produced polymer electrolytes PEO:NH$_4$I containing nanometer-sized semiconductor particles PbS, CdS, Pb$_x$Cd$_{1-x}$S [54]. Methanolic solution of PEO and NH$_4$I was first stirred roughly at 40 °C for 8–10 h, which resulted in viscous solution of the ion conducting complexes of PEO/NH$_4$I. To this solution, a solution $Pb(CH_3COO)_2$, $Cd(CH_3COO)_2$, or $Pd(CH_3COO)_2 + Cd(CH_3COO)_2$ in a desired fraction was added. The stirring was continued until the viscosity was back to the value it was before adding the acetate compounds. Subsequently, H_2S was bubbled through it giving PbS, CdS, or Pb$_x$Cd$_{1-x}$S. The final viscous solution was poured in a petri dish for obtaining solution-cast film. Then the film was dried in vacuum.

5. IMPORTANT PARAMETERS

To bring polymer electrolytes as well as polymer electrolyte composites, these materials should provide enough values of several properties as follows.

5.1. Electrical Conductivity

Conductivity defines the density of current that can be transported in the material by applying a certain electric field. If electric field E is applied in the material, the current density will be proportional to the applied electric field, where the proportional constant is the conductivity, or,

$$J = \sigma E \tag{3}$$

with J the current density (A/m^2) and σ (S/m or S/cm) the electrical conductivity. It is clear that high conductivity material will produce high current density upon applying a certain electric field. The value of conductivity is determined by the density of mobile ions (ion carriers) in the material (n), the scattering time of the ion (τ), the ion charge (q), as well as the mass of ion carrier (m), according to a relation

$$\sigma = \frac{nq^2\tau}{m} \tag{4}$$

This equation gives the reason why most polymer electrolytes use lithium ions as ion carriers. The mass of lithium is the smallest among all metals, so it produces the highest conductivity.

For industrial application, the conductivity of polymer electrolytes must be as high as 10^{-2} S/cm. However, until presently, this conductivity can only be achieved at high temperatures in which the polymer is present in the soft phase, or even liquid phase. The conductivity at room temperature of most reported polymers is still below 10^{-4} S/cm.

5.2. Transference Number

Since the electrochemical process in lithium batteries involves the intercalation and de-intercalation of lithium cations throughout host compound lattice, solid polymer electrolytes with cation transference number (t^+) approaching unity are desirable for avoiding a concentration gradient during repeated charge-discharge cycles. The reported t^+ value for dried polymer electrolytes range from 0.06 to 0.2 [64]. For a gel polymer system, t^+ value of 0.4–0.5 has

been found for poly(bis-methoxy ethoxy)phosphazene [65], and 0.56 in a system of UV-cured gel polymer electrolytes based on polyethylene glycol diacrylate/polyvinylidene fluoride [66].

Transference number of a particle is defined as the ratio of the conductivity due to it and the total conductivity. Assume the total conductivity σ is due to ionic, σ_{ion}, and to electronic, σ_e, then

$$\sigma = \sigma_{\text{ion}} + \sigma_e \qquad (5)$$

The ionic and electronic transference numbers are then

$$t_i = \frac{\sigma_{\text{ion}}}{\sigma} \qquad (6)$$

and

$$t_e = \frac{\sigma_e}{\sigma} \qquad (7)$$

For pure ionic, $t_i = 1$, and for pure electronic, $t_e = 1$. For polymer electrolyte composites, a general condition satisfied is $0 < t_i, t_e < 1$.

5.3. Crystallinity

Crystallinity plays an important role in determining the conductivity of polymer electrolytes. At crystalline phase, the transport of ion carriers is very difficult so that the conductivity is very low. At amorphous phase, there is a segmental motion of polymer chain that also assists the displacement of ions. As a result, the transport of ions is relatively easy. Thus, high conductivity will result. One major route to improve the conductivity of polymer electrolytes is by increasing the fraction of amorphous states. Addition of ceramic fillers, addition of plasticizer, and production of branch polymer are efforts to improve the amorphous state in the polymer.

5.4. Mechanical Strength

One objective of the use of polymer electrolyte is to make a battery or fuel cell with a strength comparable to that of liquid electrolytes. Therefore, it is expected that the improvement of conductivity is not accompanied by a decrease in the mechanical strength. It is why the addition of ceramic filler has received more attention, since the conductivity and the mechanical strength can be improved simultaneously. In contrast, the use of liquid plasticizer, although it can enhance the conductivity much higher than the addition of ceramic filler, involves such a degradation in the mechanical strength as to make this approach less interesting.

5.5. Storage Time

Battery or fuel cell made from polymer electrolytes should have to operate several weeks or several months. Thus, the properties of polymer electrolytes should not change too much during this time. For example, the conductivity should not depend so much on the storage time. Ideally, the properties should be time independent. However, in reality, the properties tend to degrade with storage time.

6. CHARGE TRANSPORT CHARACTERIZATIONS

Electrical conductivity is the critical parameter for polymer electrolyte composites. One target of the present research in this field is to produce polymer electrolyte nanocomposites that exhibit a high electrical conductivity, especially at room temperature. Conductivity at around 10^{-2}–10^{-3} S/cm is required to bring this material into industry. The electrical conductivity relates to the value of current that can be produced by the battery. The potential produced by the battery depends on the reaction of the battery with the electrode. Even though the electrode reaction can produce high electrical potential, the use of low conductive electrolytes can produce only small amount of electric current. And since the power can be calculated simply by the relation *Power = Voltage × Current*, the use of low conductive materials will produce a low specific energy battery.

6.1. d.c. Conductivity

Ideally, the d.c. conductivity should be measured in order to be sure that the values pertain to long-range ion movement instead of dielectric losses such as would be associated with limited or localized rattling of ions within cages. However, the difficulty in making a d.c. measurement is in finding an electrode material that is compatible with the electrolyte composites. For example, if stainless steel electrodes are attached to an electrolyte composite, as displayed in Figure 7a, and small voltage is applied across the electrodes, Li^+ ions migrate preferentially toward the cathode, but pile up without being discharged at the stainless/electrolyte interface. A Li^+ ion deficient layer forms at the electrolyte/stainless steel interface.

The cell therefore behaves like a capacitor. There is an accumulation of ions at interface region of electrode and composite. A large instantaneous current I_o presents when the cell is switched on, whose magnitude is related to the applied voltage and the resistance of the electrolytes but then falls exponentially with time, as illustrated in Figure 7b. The characteristic time of current decreasing is relatively fast so that it is difficult to make an accurate measurement.

Therefore, the a.c. method is commonly used in the present to make measurement over a wide range of frequencies. The d.c. value can be extracted from the a.c. data. Many a.c. measurements are performed with blocking
Figure 7. (a) Polymer electrolyte composites sandwiched between two blocking electrodes. (b) The decay of current when a constant d.c. voltage is applied between two electrodes.

electrode such that no discharge or reaction occurs at the electrode/electrolyte interface. Because the current will flow back and forth, no ions pile up on electrode surface, especially when using a high a.c. frequency. This is why the a.c. resistance (impedance) tends to decrease with increase in the frequency. The electrodes that are commonly used are platinum, stainless steel, gold, and indium tin oxide (ITO) glass. The complex impedance method is widely used to determine the resistance of the sample. The principle of the method is based on measurements of cell impedance, which are taken over a wide range of frequency and then analyzed in the complex impedance plane which is useful for determining the appropriate equivalent circuits for a system and for estimating the values of the circuit parameters.

Impedance is nothing but the a.c. resistance of the cell. The value in general contains the real and the imaginary part. An electrochemical cell, in general, exhibits resistive, capacitive, as well as inductive properties. The resistive property contributes to the real part of the impedance, while the capacitive and the inductive properties contribute to the imaginary part of the impedance. Therefore, an electrochemical cell can be considered as a network of resistor, capacitor, as well as conductor. Which arrangement for which cell is usually determined after performing a measurement, by analyzing the form of impedance curve. A capacitor that presents as an open circuit in a d.c. network and an inductor that appears as a straight conductor wire in a d.c. circuit, both appear as imaginary resistors in the a.c. circuit. Until presently, the inductive properties of the electrochemical cell are ignored so that the polymer electrolyte composite is considered only as a network of resistor and capacitor.

The complex impedance can be written in a general form as

$$Z(\omega) = Z'(\omega) - iZ''(\omega) \tag{8}$$

where ω is the frequency, $Z'(\omega)$ is the real part of impedance, contributed by resistive part, $Z''(\omega)$ is the imaginary part of impedance, contributed by capacitive part, and $i = \sqrt{-1}$, the imaginary number.

As an illustration, Figure 8 shows examples of simple RC circuits and the corresponding plot of impedance (Nyquist plot). For a serial arrangement of a resistor and a capacitor, as displayed in Figure 8b left, the impedance can be written as

$$Z = R - \frac{i}{\omega C} \tag{9}$$

or

$$Z' = R \tag{10a}$$

$$Z'' = \frac{1}{\omega C} \tag{10b}$$

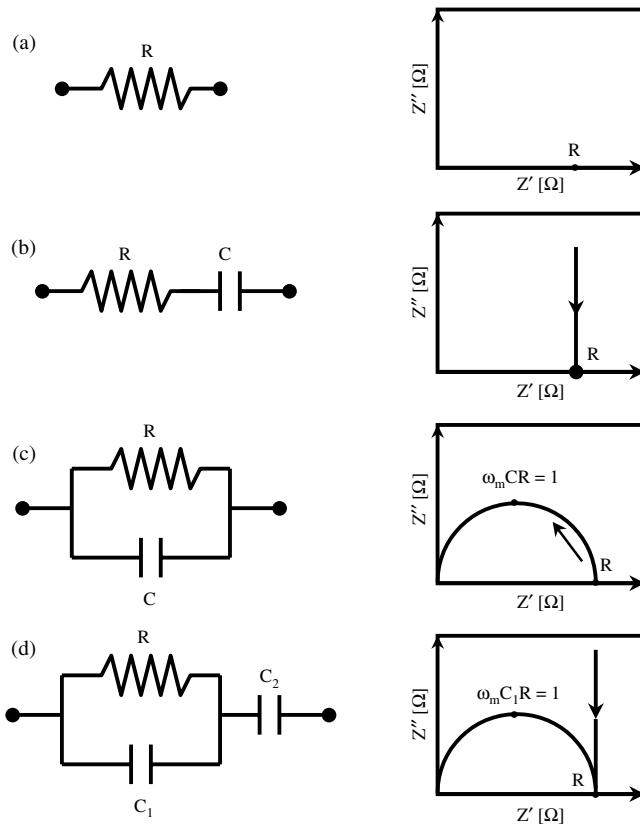
It is clear that the real part of impedance is constant, independent of the frequency, while the imaginary part depends on the frequency. For very small frequency, the imaginary part is very large and this value decreases inversely with frequency. For frequency approaches to infinity, the imaginary part of impedance closes to zero and the impedance


Figure 8. Examples of simple RC circuits and the corresponding impedance (Nyquist) plots.

value at this very high frequency equals to resistance. Thus the Nyquist plot for this arrangement appears as a vertical straight line, starting from a lower frequency value at the upper part downwards when the frequency increases, as shown in Figure 8b right. The intersection of this line with horizontal axis (the real value of impedance) corresponds to the resistance.

For a parallel arrangement of resistor R and capacitance C, as appears in Figure 8c left, the real and imaginary parts of the impedance are given by

$$Z' = \frac{R}{1 + (\omega RC)^2} \tag{11a}$$

and

$$Z'' = R\frac{\omega RC}{1 + (\omega RC)^2} \tag{11b}$$

and the corresponding Nyquist plot appears in Figure 8c right. The Nyquist plot appears as an arc. The intersection of this arc with the vertical axis at a low frequency (right arc) corresponds to the resistance. The frequency at the peak of the arc, ω_m, satisfies the relation

$$\omega_m RC = 1 \tag{12}$$

From the intersection point at the low frequency region and the position of the arc peak, the resistance and the capacitance of the system can be determined.

More complex arrangements, have a more complex expression for the impedance. For example, a combination of serial and parallel circuit as appears in Figure 8d left has the impedance as

$$Z = \left(\frac{1}{R} + i\omega C_1\right)^{-1} + \frac{1}{i\omega C_2} \quad (13)$$

with the corresponding Nyquist plot appearing in Figure 8d right. It contains a vertical line that intersects the horizontal axis at $Z' = R$, and an arc with the peak satisfies $\omega_m R C_1 = 1$. Again, from these two values, one can determine R and C_1. The value of C_2 is determined by measuring the vertical component of impedance at a certain frequency, say ω^*. If the vertical component of impedance at this point is $Z''*$, the value of C_2 satisfies

$$Z''* = \frac{1}{\omega^* C_2} \quad (14)$$

Sometimes, the form of curve is not as simple as that described here. However, in principle, we can find some circuit arrangement such that the theoretical Nyquist plot is in agreement with the measured data. Some computer software is commercially available for extracting the equivalent circuit for measured data. As an example, the impedance measurement of a system of $PEO:LiCF_3SO_3$ containing $Li_{1.4}Al_{0.4}Ge_{1.6}(PO_4)_3$ fillers is displayed in Figure 9a [67]. The corresponding a.c. circuit that can produce this impedance data appears in Figure 9b, with R_b = bulk resistance, R_{pb} = phase boundary resistance, R_{int} = interfacial resistance, C_{pb} = phase boundary capacity, C_{int} = interfacial capacity, Z_d = diffusive impedance. The corresponding parameter values that can properly fit the measured data are
Figure 9. (Top) Impedance plot $PEO:LiCF_3SO_3$ containing $Li_{1.4}Al_{0.4}Ge_{1.6}(PO_4)_3$ obtained from experiment. Data points were extracted from [67], C. J. Leo et al., *Solid State Ionics* 148, 159 (2002). (Bottom) The suggested RC circuit for data in (a). See text for the explanation of symbols.

$R_b = 593\ \Omega$, $R_{pb} = 1637\ \Omega$, $C_{pb} = 31$ nF, and $C_{int} = 1.9\ \mu F$ [67].

From the measured resistance of polymer electrolytes, the electrical conductivity can be calculated using a simple equation

$$\sigma = \frac{1}{R_e}\frac{\ell}{A} \quad (15)$$

where R_e = resistance of polymer electrolyte, ℓ = material thickness (electrode spacing), and A = material cross section.

The common procedure for measuring the temperature dependence of conductivity is as follows.

(a) Heat the sample at a required temperature. Sometimes, it needs a half hour or more to equilibrate the sample temperature.
(b) Measure the impedance at all range of frequency. Sometimes, it can take from tens of mHz up to several MHz. The computerized measurement is usually performed since a great number of data should be collected for each setting temperature.
(c) Change the setting temperature, and again collect the impedance data in all frequency regions.
(d) Analyze the collected data and find the equivalent circuit.
(e) Determine the resistance of the electrolytes based on the impedance plot and the equivalent circuit at each setting temperature.
(f) Calculate the conductivity at each setting temperature.

6.2. a.c. Conductivity

Despite the d.c. conductivity, the a.c. conductivity sometimes gives important information such as the dielectric properties of the composites. The frequency dependence of a.c. conductivity in polymer electrolytes can be written as [38]

$$\sigma_{ac}(\omega) = \sigma_{dc} + A\omega^n \quad (16)$$

where σ_{dc} = d.c. conductivity, A and n are the material parameters, $0 < n < 1$, and ω is an angular frequency.

The curve might consist of three regions, a spike at low frequency, followed by a plateau at medium frequency, and another spike at high frequency. The high frequency part corresponds to bulk relaxation phenomena, while the plateau region is connected to d.c. part of conductivity. The lower spike is connected to electrode/electrolyte phenomena. Fitting the curve with Eq. (16), one can determine the parameters A and n, and from those parameters, the hopping frequency [68],

$$\omega_p = \left(\frac{\sigma_{dc}}{A}\right)^{1/n} \quad (17)$$

By fitting the experimental data of $\sigma_{ac} - \omega$, one can determine the σ_{dc} and ω_p at each temperature. Using this approach, Siekierski et al. [69] found in a system of

PEO$_3$:LiClO$_4$ + α-Al$_2$O$_3$, that both σ_{dc} and ω_p satisfy the Arrhenius expression

$$C = C_o \exp\left[-\frac{E}{kT}\right] \tag{18}$$

where C is either σ_{dc} or ω_p, and C_o is the corresponding prefactor.

Furthermore, the temperature-dependent dielectric constant can also be obtained from the σ_{ac} data. The real part of the dielectric constant, ε', can be expressed as

$$\varepsilon' = \frac{\sigma_{ac}''}{\omega \varepsilon_o} \tag{19}$$

where σ_{ac}'' is the imaginary part of the a.c. conducttivity, and ε_o is the permitivity of vacuum. The complex dielectric constant can be written as $\varepsilon(\omega) = \varepsilon'(\omega) + i\varepsilon''(\omega)$, and the imaginary part can be obtained from the real part using a Kramer–Kronig relation

$$\varepsilon''(\omega) = -\frac{2\omega}{\pi} P \int_0^\infty \frac{\varepsilon'(s)}{s^2 - \omega^2} \, ds \tag{20}$$

where P denotes the principal part of the integral [70]. On the other hand, if the imaginary part has been known, the real part can be determined using a relation

$$\varepsilon'(\omega) = \frac{2}{\pi} P \int_0^\infty \frac{s\varepsilon''(s)}{s^2 - \omega^2} \, ds \tag{21}$$

6.3. Diffusion Coefficient

Electrical conductivity can also be determined by measuring the diffusion coefficient. From the temperature-dependent diffusion coefficient, the temperature dependence of electrical conductivity can be determined using Nerst–Einstein equation

$$\sigma = \frac{ne^2 D}{kT} \tag{22}$$

where n = charge carrier concentration e = electron charge, and D = diffusion coefficient.

Salt diffusion coefficient can be obtained by galvanostatically polarizing a symmetric cell containing no-blocking electrode for a short period of time. For example, assume a cell containing Li-based polymer electrolytes and lithium electrodes at both sides. When the current is turned off, the induced concentration profile is allowed to relax. At long time after the current interrupt, the following equation is applicable [71]:

$$\ln \Delta\Phi = \frac{\pi^2 D_s}{L^2} t + A_1 \tag{23}$$

where $\Delta\Phi$ = measured cell potential, D_s = salt diffusion coefficient, L = electrolyte thickness, t = time, and A_1 = a constant.

It appears that D_s is proportional to the slope of curve ln $\Delta\Phi$ with respect to t. The dependence of salt diffusion constant on the salt concentration is displayed in Figure 10 [71] for system of PEO:NaCF$_3$SO$_3$ at 83 °C. The D_s decreases
Figure 10. Effect of salt concentration on the diffusion coefficient for PEO:NaCF$_3$SO$_3$ system at 83 °C. Data points were extracted from [71], Y. Ma et al., *J. Electrochem. Soc.* 142, 1859 (1995).

as the salt concentration increases from about 8×10^{-8} cm s for dilute solution.

Diffusion coefficient can also be determined from the Nyquist plot as discussed by Strauss et al. [72]. The medium frequency arc is attributed to the solid/electrolyte interface. At lower frequencies, the impedance is affected by concentration gradient (diffusion) and ionic aggregates. The diffusion impedance of symmetric electrolyte with no-blocking electrode, such as Li/CPE/Li, can be written as

$$D = \frac{RTL}{n^2 F^2 C_b Z_{DC}} \tag{24}$$

where R = the gas constant, n = ratio of EO/cations, F = Faraday number, C_b = bulk concentration of cation, T = temperature, and L = electrolyte thickness.

Lorimer also introduced another formula for calculating the diffusion constant, that is [73],

$$D = \frac{\omega_m L^2}{2.54} \tag{25}$$

where ω_m = the frequency at the maxima of low frequency arc, and L = electrolyte thickness. The values predicted by Eq. (25), however, are around 6–10 times as large as that predicted by Eq. (14). The error can be contributed by the shift of ω_m due to the formation of ion pairs [72].

6.4. Transference Number

Transference number can be calculated by analyzing the arc impedance spectrum of symmetrical cell with no blocking electrode. The transference number can be calculated by comparing the width of the skew low frequency semicircle, Z_d, with the value of the bulk resistance, that is [74],

$$t_+ = \frac{1}{1 + Z_d/R_b} \tag{26}$$

Transference number can also be determined by measurement of the electrochemical potential of the cell as illustrated in Figure 11 [75]. Suppose the polymer composite is

Electrode 1   Electrode 2

μ_1 CPE μ_2
Figure 11. A simple experiment for determining the transference number to electrodes with differential chemical potentials.

Table 4. Transference number of several composites.

Composites	Transference number	Temperature	Ref.
PEO:LiCF$_3$SO$_3$ + γ-LiAlO$_2$ (4 μm)	0.29	90 °C	[79]
PEO:LiBF$_4$ + γ-LiAlO$_2$ (4 μm)	0.26	90 °C	[79]
PEO:LiClO$_4$ + TiO$_2$ (13 nm)	0.5–0.6	90 °C	[79]
PEO:LiClO$_4$ + Al$_2$O$_3$ (6 nm)	0.31–0.33	90 °C	[80]
(PEO)$_{30}$LiClO$_4$	0.18–0.19	100 °C	[80]
(PEO)$_8$LiClO$_4$	0.19–0.20	90 °C	[80]
(PEO)$_8$LiClO$_4$ + SiO$_2$	0.22–0.23	100 °C	[80]

sandwiched between two electrodes with different chemical potential μ_1 and μ_2. The electrochemical potential across this cell is given by

$$E = \frac{1}{|z|F} \int_{\mu_1}^{\mu_2} t_i \, d\mu = \frac{1}{|z|F} t_i (\mu_2 - \mu_1) \qquad (27)$$

where $|z|$ = absolute value of the valence of the mobile ion in the electrolyte; and F = Faraday number.

For pure ionic composite, $t_i = 1$ so that

$$E_{\text{pure}} = (\mu_2 - \mu_1)|z|^{-1}F^{-1} \qquad (28)$$

Thus

$$E = t_i E_{\text{pure}} \qquad (29)$$

By measuring E and calculating E_{pure}, we can obtain t_i.

Another method based on a combination of d.c. polarization and a.c. impedance has been introduced by Evans et al. This method involves measuring the resistance and current across a symmetrical Li/electrolyte/Li cell polarized by a d.c. voltage [76]. The t^+ is given by

$$t^+ = \frac{I_S(V - I_o R_o)}{I_o(V - I_S R_S)} \qquad (30)$$

where V = d.c. voltage applied to the cell, R_o = initial resistance of the passivating layer, R_S = steady-state resistance of the passivating layer, I_o = initial current, and I_S = steady-state current.

The d.c. polarization potential usually used is several tens of millivolts. This equation is applicable for ideal, dilute solutions. However, Doyle and Newman state that although this equation is not strictly applicable in concentrated electrolytes, the ratio of steady-state to initial current provides useful information on the contribution by organic additives to the ionic conductivity of polymer electrolytes [77]. The simplification of Eq. (30) was also used, that is, $t^+ = I_{SS}/I_O$. However, significant errors resulted from neglect of kinetic resistances at the electrode/electrolyte interface [78]. Transference numbers of some composites appear in Table 4.

7. SPECTROSCOPIC CHARACTERIZATIONS

7.1. NMR Spectroscopy

A moving ion would substantially modify the interaction of electromagnetic waves with matter. Investigating this interaction gives a better understanding of ion dynamics on

a microscopic scale. An example of method for studying the ion dynamics is nuclear magnetic resonance (NMR) spectroscopy. This method probes the spin of ion using an electromagnetic wave in radio frequency. In amorphous single-phase polymer electrolytes, there is usually found a straight relationship between polymer segmental motion and ionic mobility by observing a strong correlation between the onset of NMR line-narrowing and the glass transition [81]. NMR has contributed significantly to the understanding of the physical properties of the composite polymer electrolytes mainly because it offers the possibility to selectively study the ionic and polymer chain dynamics. For example, measurement of the temperature dependence of ^{7}Li lineshapes and spin-lattice relaxation allows the determination of the activation energy and the correlation time of the cation motion. Gang et al. described the ^{7}Li line-narrowing in the composite of PEO:LiBF$_4$ + γ-LiAlO$_2$ (10–30 wt%) in the temperature range of 270–270 K [82]. Dai et al. reported wide line and high resolution solid-state ^{7}Li NMR [83].

In material, each spin interacts with other spins, giving rise to spin-spin interaction or relaxation time T_2. Furthermore, a new thermal equilibrium distribution of the spin, which has to be mediated through lattice, is forced by the magnetic field. The characterization time required for the excess energy to be given to the lattice or for attainment of new thermal equilibrium is expressed in terms of spin-lattice or thermal relaxation time T_1. Under simultaneous application of static and radio frequency magnetic field in perpendicular direction,

$$H_z = H_o \qquad (31a)$$

$$H_x = 2H_1 \cos \omega t \qquad (31b)$$

The interaction of this magnetic field with the nuclear spin results in the Bloch susceptibility [84]

$$\chi' = \frac{1}{2}\chi_o \omega_o T_2 \frac{T_2(\omega_o - \omega)}{1 + T_2^3(\omega_o - \omega)^2 + \gamma^2 H_1^2 T_1 T_2} \qquad (32a)$$

$$\chi'' = \frac{1}{2}\chi_o \omega_o T_2 \frac{1}{1 + T_2^2(\omega_o - \omega)^2 + \gamma^2 H_1^2 T_1 T_2} \qquad (32b)$$

where $\omega_o = \gamma H_o$, and γ is the gyromagnetic ratio of the spin. For low RF field H_1, $\gamma^2 H_1^2 T_1 T_2 \ll 1$, then Eqs. (32a) and (32b) give the familiar absorption curve with half-width

$$\Delta \omega = \omega_o - \omega \cong 1/T_2 \qquad (33)$$

However, the exact lineshape and linewidth can be determined using Van Vleck method of moment. This method

allows the connection of the absorption line with the motional behavior of the nuclei. The second moment, M_2 is given by

$$M_2 = \int_{-\infty}^{\infty} (\omega - \omega_o)^2 f(\omega)\, d\omega$$
$$= \frac{3}{4}\gamma^4 \hbar^2 I(I+1) \sum \frac{(1 - 3\cos\theta_{ij})^2}{r_{ij}^6} \qquad (34)$$

where I is the nuclear spin [85].

Nuclear spin and NMR frequencies of some nuclei at $H_o = 10,000$ Gauss are given in Table 5 [86]. Based on this data, we can select the magnetic field H_o at around 10,000 Gauss (1 Tesla) and frequency ω_o of around 16.574 MHz, so that the absorption of the target spin can be observed. For example, in order to detect the absorption of lithium ion in the lithium-based polymer electrolyte, the magnetic field H_o can be set at around 16,574 Gauss.

If the spins are in motion, such as in fluid or intramolecular motion of liquid-like lattice, the value of M_2 is small because of the small time-average local field component (the average of $\cos^2\theta_{ij} = 1/3$). The linewidth decreases as

$$(\omega - \omega_o) \propto M_2^{1/2} \qquad (35)$$

If τ_c is the fluctuation time, $M_2^{1/2}\tau_c \ll 1$ corresponds to rigid lattice and motional narrowing corresponds to $M_2^{1/2}\tau_c \gg 1$. The region with $1/\tau_c$ approximate to $M_2^{1/2}$ represents, the region of the onset of motional narrowing. Motional narrowing is used to study the ionic motion. Considerable line-narrowing takes place above a certain temperature, indicating diffusional motion.

A rough estimation of the activation energy for motion can be obtained by using a modified Bloembergen, Purcell, and Pound expression [87]:

$$\nu_c = \frac{1}{\tau_c} = \frac{\alpha\gamma\Delta\omega}{\tan\left[\frac{\pi}{2}\left(\frac{\Delta\omega^2 - B^2}{A^2 - B^2}\right)\right]} \qquad (36)$$

where ν_c = jump frequency, $\Delta\omega$ = measured linewidth at temperature T, A = unnarrowed linewidth of the rigid lattice, B = fully narrowed linewidth, and α is a constant.

Table 5. Nuclear spin and resonance frequency at 10,000 Gauss of several nuclei.

Nuclei	Nuclear spin	Magnetic resonance frequency (MHz) at 10,000 Gauss
^{1}H	1/2	42,577
^{6}Li	1	6,265
^{7}Li	3/2	16,574
^{17}O	5/2	5,72
^{19}F	1/2	40,055
^{23}Na	3/2	11,262
^{39}K	3/2	1,987
^{41}K	3/2	1,092
^{63}Cu	3/2	11,285
^{65}Cu	3/2	12,090
^{107}Ag	1/2	1,220
^{109}Ag	1/2	1,981

Fitting ν_c/α with Arrhenius expression,

$$\frac{\nu_c}{\alpha} = \frac{\nu_o}{\alpha} \exp\left[-\frac{\Delta E}{kT}\right] \qquad (37)$$

one obtains the value of ΔE based on the Arrhenius plot of ν_c/α.

Another expression for determining the activation energy is given by Hendrickson and Bray [88]:

$$\ln\left(\frac{1}{\Delta\omega - D} - \frac{1}{A}\right) = -\frac{\Delta E}{kT} + \ln\left(\frac{1}{B} - \frac{1}{A}\right) \qquad (38)$$

where D is a temperature-independent constant of a line-broadening term.

The relation between spin-lattice relaxation time T_1 and the fluctuation time τ_c can be written as [89]

$$\frac{1}{T_1} = S\left(\frac{\tau_c}{1 + \omega_o^2\tau_c^2} + \frac{4\tau_c}{1 + 4\omega_o^2\tau_c^2}\right) \qquad (39)$$

where S is a constant. For an approximate case, in which relaxation from a pair of nuclei of fixed internuclear spacing r only is considered, one obtains [90]

$$S = \left(\frac{2}{5r^6}\right)\gamma^4\hbar^2 I(I+1) \qquad (40)$$

The spin-spin relaxation time T_2 is given by [87]

$$\frac{1}{T_2} = S\left(\frac{5}{2}\frac{\tau_c}{1 + \omega_o^2\tau_c^2} + \frac{\tau_c}{1 + 4\omega_o^2\tau_c^2} + \frac{3}{2}\tau_c\right) \qquad (41)$$

To study dynamics, the relaxation time is measured as a function of temperature so that τ_c can be calculated. Using an Arrhenius relation

$$\tau_c = \tau_o \exp(\Delta E/kT) \qquad (42)$$

the activation energy can be calculated.

Many NMR experiments have been performed on polymer electrolyte nanocomposites [91–95]. Figure 12 shows the Arrhenius plot of spin-lattice relaxation time for PEO_8:$LiClO_4$ polymer electrolytes and the composite prepared with 5.3 wt.% γ-Al_2O_3 detected at a Larmor frequency of $\omega_o = 155.4$ MHz [96]. The attempt frequency $1/\tau_o$ can be interpreted as a vibrational frequency, of order of optical phonon frequency (10^{12}–10^{12} Hz). It can be calculated (e.g., using Mathematica software) that the function $1/T_1$ finds a maximum value at $\omega_o\tau_c = 0.613$. The maximum value of $1/T_1$ appears at temperature of $T \cong 330$ K for both samples. Using a Larmor frequency of $\omega_o = 155.4$ MHz, one obtains $\tau_c = 0.613/(1.554 \times 10^8) = 3.94 \times 10^{-9}$ s. For composite of PEO:$LiClO_4$+ carbon black, Franco et al. estimated the relation time of about 4.4×10^{-9} s based on the ^{1}H resonance measurement [97]. Using Eq. (42) and assuming $1/\tau_o \approx 10^{12}$, we have $\Delta E \cong 0.24$ eV for both samples.

The electrical conductivity can be determined from Eq. (42) and different form of Nernst–Einstein equation, that is,

$$\sigma = \frac{Nd^2q^2}{6\tau_c kT} \qquad (43)$$
Figure 12. Arrhenius plot of spin-lattice relaxation time ($1/T_1$) of ^{7}Li NMR spectra for (open circle) PEO:LiClO$_4$ and (solid circle) PEO:LiClO$_4$ containing carbon black. Data points were extracted from [96], A. C. Bloise et al., *Electrochim. Acta* 46, 1571 (2001).

where N = lithium concentration per unit volume, d = average ionic jump distance, and q = ionic charge.

For example, the value of N in PEO$_8$:LiClO$_4$ was determined from the molecular weights of PEO and LiClO$_4$ and the density of the electrolytes ($\rho \approx 1.3$ g/cm^3) [96], to result in $N \approx 1.7 \times 10^{21}$ cm^{-3}. Considering the average Li-Li distance of ~ 4 Å [96], the conductivity at 300 K is about 7.1×10^{-4} S/cm.

Temperature-dependent linewidth of composite of PO$_{1.5}$LiI + 6 v% Al$_2$O$_3$ is displayed in Figure 13 [83]. It can be seen that there is a drastic change in the line-width when temperature is changed from 30 °C to 50 °C. It is assumed that the onset of the motional narrowing is at temperature of 40 °C. At −20 °C the sample exhibits a rigid limit lineshape with baseline due to a distribution of ^{7}Li nuclear quadrupole satellite transition [98]. As the temperature is raised, partial line-narrowing results.

Forsyth et al. reported the effect of filler content on the ^{7}Li linewidth for a composite of copolymer trihydroxypoly(ethylene oxide-co-propylene oxide) with an EO/PO
ratio of 3:1 containg LiClO$_4$ and TiO$_2$ nanoparticles [99]. The linewidth increases with increase in the filler content and reaches a plateau after about 10 wt.%, as observed in Figure 14. Although the linewidth relates to the mobility of lithium ion, in which the line-narrowing represents mobile ion, an interpretation that the increase of linewidth relates to decrease in the mobility of lithium ions will be contradictory with the reported result. The reported result confirmed that addition of filler at lower content increases the lithium ion mobility and therefore increases the conductivity. A possible interpretation is the lithium ion environment changes with the addition of filler and the linewidth changes are more likely to reflect the changing environment rather than the changing mobility. A possible interpretation is chemical shift dispersion, that is, lithium ion occupying many different state environments (but magnetically degenerate) such that a distribution of chemical shift is obtained.

The broad signal of resonance is attributed to crystalline state, while the narrow component is attributed to amorphous phase. This difference contribution can be used to predict the crystallinity of polymer in composite. For example, Singh et al. observed the ^{1}H resonance of a system of PEG$_{46}$:LiClO$_4$ + nanoparticles of Mn$_{0.03}$Zn$_{0.97}$Al$_2$O$_4$ [95]. They fitted the broad part of the signal with a Gaussian function and the narrow component with the Lorentzian function. The crystallinity of the polymer equals to the fraction of the area of narrow and broad components of the signal. For pure PEG they found a crystalline of about 83% using this method.

7.2. Raman Scattering

Raman spectroscopy is important to probe molecules with anisotropic polarizability. The vibrating atoms are not able to follow the incident radiation frequency if it is much higher than the phonon frequency. However, the electron cloud of the vibrating atom can interact with the frequency of the incident radiation. These oscillating dipoles can absorb energy from the radiation field and re-emit radiation of the same frequency. This radiation is detected as scattered light

Figure 13. Temperature dependence of ^{7}Li NMR linewidth of PEO$_{1.5}$ LiI containing 6 vol.% Al$_2$O$_3$. Data points were extracted from [83], Y. Dai et al., *Electrochim. Acta* 43, 1557 (1998).

Figure 14. Effect of filler weight fraction on the ^{7}Li NMR linewidth of copolymer of trihydroxypoly(EO-co-PO) with (EO/PO = 3/1) containing LiClO$_4$ and TiO$_2$ nanoparticles. Data points were extracted from [99], M. Forsyth et al., *Solid State Ionics* 147, 203 (2002).

and is known as Rayleigh scattering. Moreover, the oscillating dipoles see the force field of the vibrating atomic nuclei also as the nuclei oscillate around the equilibrium position; the deformability of the electron cloud varies with the oscillation frequency of the nuclei.

The Raman scattering is described in a simple term here. If a time-dependent electric field, $E(t)$, is applied to a molecule, it produces an induced dipole moment, $\mu(t)$,

$$\mu(t) = \alpha(t)E(t) \qquad (44)$$

where $\alpha(t)$ is the polarizability of molecule. If the incident frequency and the polarizability of the molecule change between $\alpha_{\min}$ and $\alpha_{\max}$ of frequency ω_{int} as a result of its rotation and vibration, we can write [100]

$$\mu(t) = \left(\alpha + \frac{1}{2}\Delta\alpha \cos \omega_{\text{int}} t\right) E_o \cos \omega t \qquad (45)$$

with

$$\Delta\varepsilon = \alpha_{\max} - \alpha_{\min} \qquad (46)$$

Therefore, we obtain,

$$\mu(t) = \alpha E_o \cos \omega t + \frac{1}{2}\Delta\alpha E_o$$
$$\times [\cos(\omega + \omega_{int})t + \cos(\omega - \omega_{int})t] \qquad (47)$$

The induced dipole moment has then components as follows: unshifted frequency, ω, known as Rayleigh line; lower frequency, $\omega - \omega_{\text{int}}$, known as Stokes line; and higher frequency, $\omega + \omega_{\text{int}}$, known as anti-Stokes line.

Raman spectra can be used to determine the concentration of free ions in the electrolytes. For example, the Raman spectra of LiCF$_3$SO$_3$ have been tabulated as appear in Table 6 [101]. A composite containing SO$_3$, the Raman spectrum of the $\nu_S(SO_3)$ spectral region of the triflate anion of poly(ethylene oxide) dimetyl ether (400) complexed with LiCF$_3$SO$_3$, along with the three-component curves fit are shown in Figure 15. It was explained that the component observed at 1032 cm^{-1} corresponds to free anions not interacting directly with lithium cations. The component of 1042 cm^{-1} has been attributed to contact pair and the component of 1052 cm^{-1} has been attributed to Li$_2$CF$_3$SO$_3$ triple ions [102].

Because of the multicomponent nature of the spectrum, it can be concluded that the ion-ion interaction is present in

Figure 15. Raman spectra of LiCF$_3$SO$_3$. Reprinted with permission from [102], A. Ferry et al., *Electrochim. Acta.* 43, 1471 (1998). © 1998, Elsevier Science.

the system even down to the concentration of O:M = 563:1. The relative amount of anions not interacting directly with lithium ions, that is, spectroscopically free, increases with increasing concentration from approximately 22% at O:M 563:1 to 40% at O:M = 110 and then falls off slightly at higher concentration. The 1042 cm^{-1} band initially decreases in relative intensity with increasing concentration and then levels off at 54% in the upper concentration range.

The fraction of free ion obtained from Raman spectra in a system of PPO:NaCF$_3$SO$_3$ is displayed in Figure 16 [103], for a system of hydroxyl end capped PPO with NaCF$_3$SO$_3$.

7.3. FTIR Spectroscopy

Atoms in solid vibrate at frequency approximately 10^{12}–10^{13} Hz. Vibration mode involving pairs of groups of bonded atoms can be excited to higher energy by absorption of radiation at appropriate frequency. In the infrared (IR) technology, the frequency at the incident radiation is varied and the

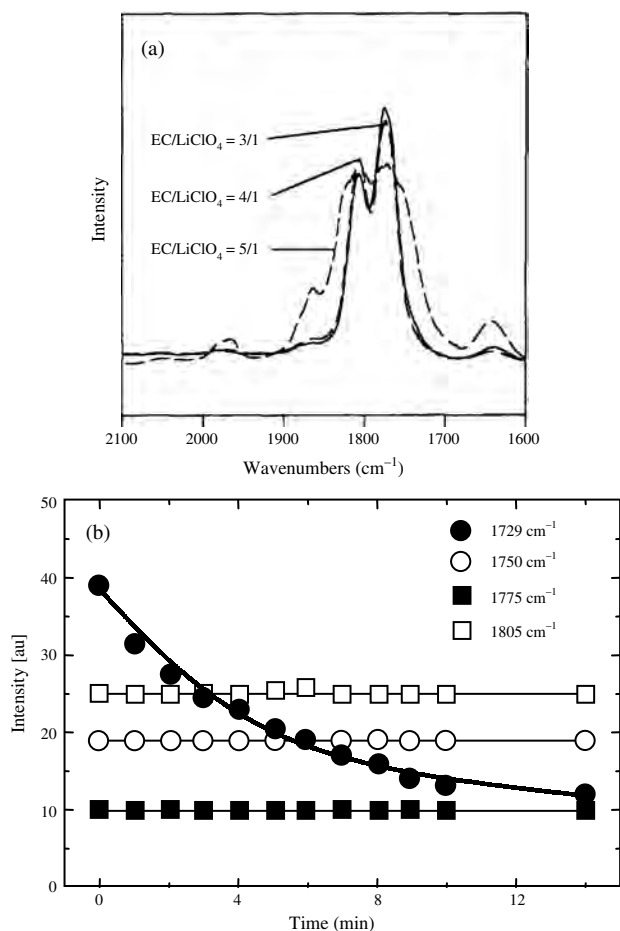
quantity of radiation absorption or transmission by sample is observed. In the Raman technique, on the other hand, the sample is illuminated with monochromatic light, usually generated by a laser. In order for a particular mode to be IR active, the associated dipole moment must vary during the vibrational cycle. Therefore, centrosymmetric vibrational modes are IR inactive. The principal selection rule for a vibrational mode to be Raman active is that the nuclear motions involved must produce a change in polarizability.

In-situ FTIR spectroscopy can also be used to determine the conductivity of ion in composites. For example, a system of poly(methyl methacrylate-co-alkali metal methacrylate)-ethylene carbonate:LiClO$_4$ is displayed in Figure 17a. A typical spectrum of carbonyl stretches region to appear in four peaks at 1730 cm^{-1}, 1751 cm^{-1}, 1775 cm^{-1}, and 1806 cm^{-1} [104]. The evolution of carbonyl peak was observed with time under the application of d.c. field such that the ion transport in the composite is shown in Figure 17b [104]. The change in the intensity of carbonyl group in the ethylene carbonate represents the different chemical environments within the composites. The intensities of the peak at 1730 cm^{-1}, 1775 cm^{-1}, and 1806 cm^{-1} were found to be fairly


constant with time under the electric field. It indicated that these three peaks might not be correlated with movement of charge carriers. However, the intensity of the 1750 cm^{-1} peak decreased with the time, eventually reaching a limit value. The decrease in the intensity of the 1750 cm^{-1} peak related to the change in the concentration of the plasticizer solvating the salt. The change in the peak intensity corresponding to various chemical environments is due to the migration of the charge carrier. The concentration of the plasticizer to solvate the salt was found to decrease, which implies that the movement of cations in the electrolytes is strongly correlated with the motion of the plasticizers.

The change in the peak intensity of the plasticizer solvating salt can be analyzed solving the following transport equation [104]:

$$\frac{\partial C}{\partial t} = D\frac{\partial^2 C}{\partial x^2} - \mu E\frac{\partial C}{\partial x} \tag{48}$$

where C = concentration of charge carriers, represented by the intensity of the 1750 cm^{-1} peak, D = diffusion coefficient, μ = mobility of the charge carriers, and E = electric field.

The solution of Eq. (48) at a fixed position, $x = 0$, can be expressed as

$$C(x = 0, t) = A + B\exp\left[-\frac{(\mu E)^2}{4D}t\right] \tag{49}$$

where A and B are constants. From the slope of curve intensity of 1750 cm^{-1} peak, one can determine the mobility of the ion carriers. Measuring the mobility at various ion concentrations, we can determine the mobility at various ion concentrations as appears in Figure 18 [104].

The ion movement can also be analyzed based on the change in the intensity of 624 cm^{-1}, arising from ClO$_4^-$ stretching band [105]. Kim et al. showed the dependence of 624 cm^{-1} intensity on time at 25 °C and found that the mobility calculated from that data is similar to that obtained from the 1750 cm^{-1} absorption of ethylene carbonate [104]. The change of anionic mobility with the ion content of ionomers was found to be nearly the same as that of cation mobility.

Figure 17. (a) IR spectra of poly(methyl methacrylate-co-alkali metal methacrylate)-ethylene carbonate:LiClO$_4$ and (b) the decay of the observed peaks when the applied d.c. potential was switched off. Data points we extracted from [104], C. H. Kim et al., *Electrochim. Acta* 43, 1421 (1998).

For the infrared spectra of PEG:LiClO$_4$:AlBr$_3$ 1 mass%, the ν_4(ClO$_4^-$) spectra can be separated into two contributions with maxima at 623 and 633 cm^{-1} [106]. The 623 cm^{-1} band is attributed to free anions and the 633 cm^{-1} peak is related to bound or contact (ClO$_4^-$) [107]. The fraction of free anions can be calculated as the fraction of area under 623 cm^{-1} mode to the total area of ν_4(ClO$_4^-$) envelope. Compared to composite in the absence of AlBr$_3$, there is a dramatic increase in the fraction of free anions when AlBr$_3$ is dispersed in the electrolytes.

7.4. X-ray Photoelectron Spectroscopy

X-ray photoelectron spectroscopy (XPS) is a powerful technique for studying the surface of solids. The data obtained using this technique are mainly used to extract the information regarding the bonding energies of various core-level electrons from different elements of solid materials. These values are then interpreted as the bonding between the element under consideration with their neighbor. Information about the local structure and interaction of an element with its neighbor can be extracted from the XPS data [108]. In the development of battery, the interaction between the electrolyte and the electrode determines the performance of the battery. Understanding this interaction is important to optimize the preparation parameters for realizing high-performance batteries. Therefore, surface studies, for example using XPS, may be of great significance to understand the interaction of polymer electrolytes with electrode.

In principle, this technique measures the kinetic energy of electrons that are emitted from matter as a consequence of bombardment with ionizing radiation or high-energy particles. If the process results in an ionization of electrons from the bombarded material, the kinetic energy of the electron will satisfy

$$E_k = h\nu - E_b \tag{50}$$

where $h\nu$ = energy of incident radiation, and E_b = binding energy of electron.

For a given atom, a range of E_b values is possible corresponding to ionization of electrons from different inner and outer valence shells. Measurement of the value of E_k, and therefore E_b, provides a means of identification of atoms. In the XPS method, the ionizing radiation is usually MgK$_\alpha$ (1254 eV) or AlK$_\alpha$ (1487 eV) monochromatic radiation.

Using XPS method, Vosshage and Chowdary investigated the interaction of salt with the polymer chain in the systems of PEO$_n$LiCF$_3$SO$_3$ and PEO$_n$Cu(CF$_3$SO$_3$)$_2$ [108]. There is evidence of the interaction of the carbon from –CH$_2$-CH$_2$-O- polymer chains with the cation of the salt through the ether oxygen of PEO and anion of the salt. A complexation between the action of the salt and the oxygen of the PEO is identified using this method. It is also observed that for the PEO$_n$Cu(CF$_3$SO$_3$)$_2$ system, the change in the nature of the complex occurs at low salt concentrations. However, for PEO$_n$LiCF$_3$SO$_3$ system, such a change is identified at higher salt concentration.

Liu et al. prepared polymer electrolyte nanocomposites using SiO$_2$ filler and 2-[methoxy(polyethylenoxy)-propyl] trimethoxy silane coated SiO$_2$ [109]. The XPS method has

been utilized to confirm the success of coating. During treatment with 2-[methoxy(polyethylenoxy)-propyl] trimethoxy silane, the OH- groups of the surface of the SiO$_2$ react with partially hydrolized silane. For the untreated SiO$_2$, the XPS data can be fitted by band centering at 284.6 eV, which is often characteristic of adventitious CH$_2$ species in the measurement chamber. On the other hand, the coated SiO$_2$ can be fitted with two bands, centered at 284.6 eV and 286.2 eV. The former corresponds to the adventitious CH$_2$ species while the latter corresponds to C-O-C group that appears as a result of the functionalization reaction.

7.5. X-ray Diffraction

X-rays are electromagnetic radiation with a wavelength around 1 Å (10–10 m). The X-rays which are used in almost all diffraction experiments are produced by accelerating an electron beam through 30000 V and permitting it to strike a metal target, such as copper. The incident electron has sufficient energy to ionize some of the copper 1s (K shell) electrons. An electron in an outer orbital (2p or 3p) immediately drops down to occupy the vacant 1s level and the energy released in the transition appears as X-radiation. The transition energies have fixed values and so create the spectra of characteristic X-radiation. For copper, the 2$p \to$ 1s transition, called K$_\alpha$, has a wavelength of 1.5418 Å and the 3$p \to$ 1s transition, K$_\beta$, has a wavelength of 1.3922 Å.

If the average crystalline size is below a critical limit (∼200 nm diameter), a broadening of diffraction X-ray beam occurs [110]. The commonly accepted formula for particle size broadening is the Scheerer formula

$$d = \frac{0.9\lambda}{B \cos\theta_B} \tag{51}$$

where d = crystalline radius, λ = X-ray wavelength, θ_B = Bragg angle, B = the line-broadening, given by Warren formula

$$B^2 = B_M^2 - B_S^2 \tag{52}$$

where B_M = measured peak width in radiation at half peak height, B_S = width of a peak of a standard material mixed with the sample, whose particle size is considerably greater than 200 nm and which has a diffraction peak near the relevant peak of the sample. For relatively large particle, the width of peak (unbroadened peak) is very small, so that $B_M \gg B_S$. Therefore, it is often possible to approximate B with B_M.

Figure 19 shows the XRD spectra of polyethylene glycol-based polymer electrolyte nanocomposites containing ZnO nanoparticles [62]. Using $\langle 110 \rangle$ with a position at around $2\theta_B \cong 56.7°$, and the width of the peak of around $\Delta(2\theta_B) \cong 1.25°$, we obtain $\theta_B \cong 0.5$ rad and $\Delta\theta_B \cong 0.022$ rad. Thus the predicted nanoparticle size is around $d \cong 7.2$ nm.

The degree of crystallinity of polymer can be determined also by wide-angle X-ray scattering (WAXS). Figure 20 illustrates the XRD spectra of polymer, where the relatively sharp peaks are due to scattering from the crystalline regions and the broad underlying hump is due to scattering from noncrystalline region. The degree of crystallinity can be predicted based on the measurement of the area under the sharp peak (A_c) and the broad hump (A_a) and using a
Figure 19. XRD pattern of PEG containing Li ions and ZnO nanoparticles. Data were extracted from [62], Mikrajuddin et al., *J. Electrochem. Soc.* 149, H107 (2002).

simple equation

$$x_c = \frac{A_c}{A_c + A_a} \tag{53}$$

Shin et al. observed the effect of filler content on the XRD pattern on PEO in a system of $PEO_{10}LiCF_3SO_3$ containing $TinO_{2n-1}$. As observed in Figure 21, the PEO peak intensities decrease by the increase in the volume fraction of filler content [111]. It indicates that the crystallinity of the sample decreases by increasing the volume fraction of filler content. Similar results have also been reported by Leo et al. in a system of $PEO:LiCF_3SO_3$ containing filler of $Li_{1.4}(Al_{0.4}Ge_{1.6})(PO_4)_3$ [112]. With addition of filler, the intensity of the crystalline peaks has decreased and a noticeable broadening of the area under the peak was observed. It is a clear indication of the reduction of the crystallinity of the polymer.

8. MICROSCOPIC ANALYSIS

8.1. Scanning Electron Microscopy

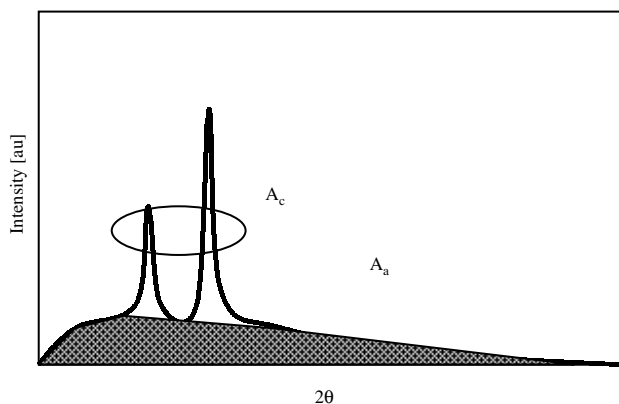
The morphology of the sample surface can be observed using scanning electron microscopy (SEM). The surface smoothness and the presence of holes in the scale down to


Figure 20. Typical form of XRD pattern of high molecular weight polymer.

several tens of nanometers can be viewed using the advanced field emission SEM. Wen et al. compared the SEM picture of $PEO:LiClO_4$ and $PEO:LiClO_4$ containing alumina whisker. For $PEO:LiClO_4$, great amounts of microcracks were observed on the surface, as observed in Figure 22a [113]. The size of islands are several micrometers, compared to the PEO spherulite [114]. Addition of 10 wt.%
Figure 22. SEM photograph of (a) $PEO:LiClO_4$, (b) $PEO:LiClO_4$ containing 10 wt.% whisker, and (c) $PEO:LiClO_4$ containing 20 wt.% whisker. Reprinted with permission from [113], Z. Wen et al., *Solid State Ionics* 148, 185 (2002). © 2002, Elsevier Ltd.

whisker in the polymer electrolytes inhibited the formation of microcracks inside the composite polymer electrolytes (Fig. 22b). Further addition of the amount of the whisker, for example 20 wt.%, is more effective in avoiding the formation of microcracks (Fig. 22c).

Golodnitsky et al. observed the SEM picture of filler-free PEO_n:LiI and PEO_n:LiI containing alumina [115]. PEO_n:LiI containing high concentration salt is made up of units whose area is hundreds of square microns. Addition of alumina causes a minor reduction in the grain size. In a PVdF gel polymer electrolyte containing CuO filler, Wang and Gu found that the surface presented a multitude of PVdF grains and pores of average size of about 2–4 μm in diameter [116]. They assumed the CuO nanoparticles distributed uniformly in the polymer matrix.

8.2. Transmission Electron Microscopy

In the case of polymer electrolyte nanocomposites, transmission electron microscopy (TEM) is usually used for determining the dispersion of nanoparticles in the polymer matrix and the size of nanoparticles. Capiglia et al. showed that larger filler (submicron size) is quite well dispersed in the polymer matrix while the smaller filler (tens of nanometers size) is not well distributed in the polymer matrix [61]. Instead, the small filler is condensed in large blocks of size up to 1 μm. Based on the TEM photograph, Mikrajuddin et al. showed that PEG based polymer electrolyte nanocomposites made by *in-situ* growth of ZnO nanoparticles in the polymer matrix and *in-situ* insertion of lithium ion during nanoparticles growth have particle size of about 6 nm [63]. This result is consistent with the calculation of the particle size using size-dependent bandgap equation [117–119]. Chandra et al. also observed the size of nanoparticles synthesized *in-situ* in polymer electrolyte nanocomposites using TEM and found that small content nanoparticles (about 1 wt.%) have smaller size [54].

8.3. Atomic Force Microscopy

There are not many reports on the atomic force microscopy (AFM) investigation of polymer electrolytes. Instead of investigating the polymer electrolytes themselves, Granvalet-Manchini et al. investigated the change in the surface of lithium electrode when making contact with polymer electrolytes [120]. After about three days' contact with polymer electrolytes, self-assembled polymer layer is developed on the surface of lithium electrode.

8.4. Optical Microscopy

Optical microscopy characterization of polymer electrolyte nanocomposites was not reported too much. To date, Kim et al. reported the optical micrograph of a system of PEO_{16}: $LiClO_4$ containing various filler content, taken under crossed polarizers [121]. They observed well-defined spherulitic morphologies. The spherulites were observed in thin films deposited on the glass substrate whose typical thickness was about 20 μm. They proposed that the size and the morphology of the spherulites can be related to the melting point or glass temperature of the composites. This was based on the

fact that the spherulites have a lamellar structure for almost all polymers and the increase in the lamella thickness results in the increase in the melting temperature [122].

9. THERMAL CHARACTERIZATIONS

9.1. Thermogravimetry

Thermogravimetry (TG) is a technique for measuring the change in the weight of a substance as a function of temperature or time. The result usually appears as a continuous chart record, as displayed in Figure 23. The sample, usually a few milligrams in weight, is heated at a constant rate, typically 1–20 °C/min. It has constant weight until it begins to decompose at temperature T_i. Decomposition usually takes place over a range of temperature T_i to T_f and second constant plateau is then observed above T_f, which corresponds to the weight of residue.

A TGA curve of composite made by PEO:LiBF$_4$ containing 2-[methoxy(polyethylenoxy)-propyl]trimethoxy silane-coated SiO$_2$ nanoparticles is displayed in Figure 24 [109]. At temperatures below 180–200 °C, the sample experiences only a small weight loss due to removal of residual water on the surface of SiO$_2$. At increasing temperatures, the OH groups on the SiO$_2$ surfaces begin to decompose to give rise to slight increase in the weight loss. In addition to the decomposition of the OH groups, another weight loss take place at about 350 °C that can be attributed to the decomposition of silane molecules that are bonded on the surface of SiO$_2$. Liu et al. suggested that the adsorption of containing 2-[methoxy(polyethylenoxy)-propyl]trimethoxy silane on the surface of SiO$_2$ is likely to give a sub-monolayer coverage [109].

9.2. Differential Thermal Analysis

Differential thermal analysis (DTA) is a technique in which the temperature of a sample is compared with that of inert reference material during a programmed change of temperature. The temperature of sample and reference should be the same until some thermal event such as melting, decomposition, or change in crystal structure occurs in the sample.

**Figure 23.** Typical form of TGA curve.

Figure 24. TGA curve of PEO:LiBF$_4$ containing 2-[methoxy (polyethylenoxy)-propyl]trimethoxy silane coated SiO$_2$ nanoparticles. The curve was replotted from [109], Y. Liu et al., *J. Power Sources* 109, 507 (2002).

If the sample temperature lags behind the reference temperature, the process is called endothermic. On the contrary, if the sample temperature leads the reference temperature, the process is known as exothermic. The sample size is usually a few milligrams and heating and cooling rate is usually 1–50 °C/min. The difference in the sample and reference temperature will appear as Figure 25.

If calorimetric data is required, it is better to use differential scanning calorimetry (DSC). DSC is very similar to DTA. A sample and an inert reference are also used in DSC system but the cell is designed differently. The sample and the reference are maintained at the same temperature during the heating program and extra heat input to the sample (or to the reference if sample undergoes an exothermic change) is required to maintain this balance. Enthalpy changes are therefore measured directly.

Examples of DSC curves for various PEO:LiCF$_3$SO$_3$ + clay composites are displayed in Figure 26 [123]. From this figure, we can extract several parameters like the glass temperature, the melting point, and enthalpy. These values were found to depend on the filler content, as summarized in Table 7. A pure PEO has one first-order endothermic transition at around 70 °C, corresponding to the melting of the

Figure 25. Typical form of DTA curve.
Figure 26. DSC curve of PEO:LiCF$_3$SO$_3$ containing clay. Reprinted with permission from [123], H.-W. Chen and F.-C. Chang, *Polymer* 42, 9763 (2001). © 2001, Elsevier Ltd.

PEO crystalline phase. When salt is added, a second minor endothermic transition was observed at around 140–150 °C, due to the melting of crystalline complex phase formed by PEO and LiCF$_3$SO$_3$ [124–126]. The melting temperature of the crystalline PEO phase depends on the filler content. The T_m initially shifted to higher temperature when the filler content increased, and reached the highest value at 9 wt.% clay, and then decreased with further increase in the clay content.

Table 7. The parameters of polymer electrolyte nanocomposites extracted from the DSC curve.

Samples	T_g (K)	T_m (K)	ΔH (J/g)	X_c	T_{mc} (K)
PEO		70.50	165.5		
PEO:LiCF$_3$SO$_3$	−46	69.84	59.9	36.2	152.0
PEO:LiCF$_3$SO$_3$+ clay 3 wt%	−50	71.58	68.9	41.6	149.7
PEO:LiCF$_3$SO$_3$+ clay 9 wt%	−43	77.4	77.8	47.0	156.9
PEO:LiCF$_3$SO$_3$+ clay 30 wt%	−46	54.93	40.1	24.2	142.6
PEO:LiCF$_3$SO$_3$+ clay 50 wt%	−48	45.99	29.1	17.6	132.4

The PEO crystallinity (expressed by the area covered by transition curve) is also dependent on the clay content. The PEO crystallinity initially increases with increasing clay content up to 9 wt.% and then decreases with further increase in the clay content.

Melt-crystallized polymers are never completely crystallized. This is because there are an enormous number of chain entanglements in the melt and it is impossible for the organization to form 100% crystalline polymer during crystallization. The degree of crystallinity is therefore of great technological importance. The degree of crystallinity can be deduced from the DTA data, in which the melting enthalpy can be obtained. The crystallinity can be calculated using a simple equation [127]:

$$X_c = \frac{\Delta H_m}{\Delta H_{m,c}} \times f_{PEO} \qquad (54)$$

where ΔH_m = melting enthalpy measured, $\Delta H_{m,c}$ = melting enthalpy of 100% crystalline (for PEO, $\Delta H_{m,c} = 196.4$ J/g), and f_{PEO} = weight fraction of PEO in polymer electrolytes.

10. DENSITY METHOD

Another method for determining the crystallinity is based on the knowledge of density of crystalline and amorphous phases as well as the density of the polymer specimen. The crystallization of polymer from melt is accompanied by the reduction in the volume due to an increase in density. The crystals have a higher density than the molten or noncrystalline polymer since the last two contain also free volume. Based on this difference, the density method can be utilized to determine the degree of crystallinity.

If V is volume of polymer specimen, and V_a and V_c are volumes of amorphous and crystalline regions, respectively, we have $V = V_a + V_c$. The relation of polymer specimen mass and the amorphous and the crystalline region masses is given by

$$\rho V = \rho_a V_a + \rho_c V_c \qquad (55)$$

where ρ = density of polymer specimen, ρ_a = density of amorphous region, and ρ_c = density of crystalline region.

By defining the crystallinity as $x_c = \rho_c V_c / \rho V$, we obtain

$$x_c = \frac{\rho_c}{\rho}\left(\frac{\rho - \rho_a}{\rho_c - \rho_a}\right) \qquad (56)$$

The density of polymer specimen can be determined by simply measuring the volume and weighing the mass. The density of crystalline region can be calculated from the knowledge of the crystal structure. The density of amorphous phase can be determined by measuring the density of almost completely amorphous polymer, such as polymer obtained by rapid cooling from polymer melt.

Equation (56), however, is valid if polymer specimen contains no holes which are often present in molded samples. In addition, since packing of the molecules in amorphous region is random, it is likely that the density of amorphous phase depends on the thermal treatment of the specimen.

11. ELECTRICAL PROPERTIES

11.1. Effect of Filler Content on Conductivity

The role of the ceramic filler is to influence the recrystallization kinetics of the polymer matrix chains, thereby ultimately promoting localized amorphous regions and thus enhancing the transport of cations [9]. To produce a high fraction of amorphous state in the composite, the as-prepared composite is first heated above the melting point so that all parts of the polymer are converted to the amorphous state. During the cooling process, the matrix part around particles remains in the amorphous state, even when the temperature drops below the melting point. Therefore, a high electrical conductivity would be expected to appear at ambient temperatures. Indeed, enhancement in conductivity of up to about three orders of magnitude at low temperatures and about one order of magnitude at high temperatures has been reported for the system of poly(ethylene oxide)-LiClO$_4$ containing ceramic fillers [9]. In addition, composites containing ceramic fillers in the nanoscale particle size exhibit both excellent mechanical stability (promoted by the network of the fillers into the polymer bulk) and high ionic conductivity (promoted by the high surface area of the dispersed filler).

The volume fraction of filler particles affects the conductivity of a composite. The symbols in Figure 27 display the effect of filler loading on the electrical conductivity of a poly(ethylene oxide)/NaI containing filler of Θ-Al$_2$O$_3$ [128]. The conductivity increases with an increase in the volume fraction of fillers, reaches a maximum at a certain value of filler particles, and then decreases toward zero for further increases in the volume fraction of fillers. This observation
Figure 27. Effect of filler volume fraction on the electrical conductivity at 25 °C for composites of (open circle) PEO:LiClO$_4$+PAAM and (solid circle) PEO:NaI+Θ-Al$_2$O$_3$. Date points were extracted from Y. Liu et al., *J. Power Sources* 109, 507 (2002). Curves were obtained from theoretical calculation to fit the data using ($t/R = 0.6$) for fitting the open circle data and ($t/R = 1.16$) for fitting the solid circle data. Curves were replotted from [128], J. Przyluski et al., *Electrochim. Acta* 40, 2102 (1995).

can be explained as follows. By increasing the fraction of fillers, the total amount of amorphous state around the fillers increases since the surface area increases, thus increasing the conductivity. If the filler content is so high, some of the filler agglomerates (making contact) so that the surface area is reduced, thus reducing the fraction of amorphous state around the filler, thereby reducing the conductivity. At a specified amount of filler fraction, the continuous network of amorphous state disappears so that the transport of cations is blocked. The conductivity of composites can be approximated with the conductivity of filler particles.

The effective medium approximation was used to explain the conductivity enhancement in polymer electrolyte composites [128]. Dispersed ceramics create an amorphous layer around the particles, which have a high conductivity. The composite is considered to be a two-phase system: particles and amorphous layer as one phase and the rest of the polymer as the other phase. The conductivity of the second phase (polymer matrix) is equal to the conductivity of the polymer electrolytes free of dispersed particles. The conductivity of the particle–amorphous layer can be calculated using Maxwell–Garnett equation [129],

$$\sigma_c = \sigma_1 \frac{2\sigma_1 + 2Y(\sigma_2 - \sigma_1)}{2\sigma_1 + \sigma_2 - Y(\sigma_2 - \sigma_1)} \qquad (57)$$

where σ_1 = conductivity of the interface layer, σ_2 = conductivity of dispersed grain, and Y = volume fraction of filler in the composite, according to equation [128]

$$Y = \frac{1}{(1 + t/R)^3} \qquad (58)$$

where t = thickness of the conducting layer, and R = radius of filler.

The system is analogous to a system containing conducting particles dispersed in a polymer matrix in which the conducting particles correspond to the particle–amorphous layer. The improved conductivity of grain and polymer medium is calculated by the Nakamura [130] or Nan and Smith [131, 132] equation,

$$\sigma_c^a = 2\sigma_c \frac{V_c}{3 - V_c} \qquad (59a)$$

$$\sigma_a^e = 2\sigma_e \frac{1 - V_c}{2 + V_c} \qquad (59b)$$

where $V_c = V_2/Y$, and V_2 = volume fraction of filler in a bulk electrolyte.

The dependence of composite conductivity on the load fraction of dispersed particles and particle size can be calculated using the effective medium theory [133]:

$$\left(\frac{V_2}{Y}\right) \frac{\sigma_c^a - \sigma_m}{\sigma_m + p_c(\sigma_c^a - \sigma_m)} + \left(1 - \frac{V_2}{Y}\right) \frac{\sigma_e^a - \sigma_m}{\sigma_m + p_c(\sigma_e^a - \sigma_m)} = 0 \qquad (60)$$

where σ_m is the conductivity of the composite and p_c is the continuous percolation threshold for the composite grain. P_c can be taken to be 0.28 on the basis of general percolation theory [131, 132]. Lines in Figure 27 are the theoretical prediction for a system of PEO:LiClO$_4$ + PAAM and

PEO:NaI + Θ-Al$_2$O$_3$ [128]. The data were collected at 25 °C. The theoretical curves were calculated using $t/R = 0.6$ for solid line and $t/R = 1.16$ for dashed line.

However, this theory cannot explain the enhancement of conductivity at high temperatures compared to polymer electrolytes which are free of filler as shown in Figure 4. An alternative approach has been used to explain conductivity enhancement due to filler dispersion [134]. The presence of a filler induces the formation of an amorphous layer around the filler particles as well as the presence of an ionic layer around the particles. Typically, an amorphous layer around the filler particles is effectively created if the polymer containing a filler is heated above the melting point and then cooled down. The presence of a ceramic filler inhibits the recrystallization of a polymer layer around the particles so that layer remains in the amorphous state after the polymer reaches room temperature. That means that, without heating above the melting point, the conductivity of polymer electrolytes containing a filler is close to that of filler-free polymer electrolytes. However, by assuming the presence of an ionic layer around the filler which has a conductivity higher than that when the ionic layer is absent, the conductivity is then enhanced even though all parts of the polymer are in the crystalline phase or in the amorphous phase. This assumption explains the enhancement in conductivity at high temperatures even when all parts of the polymer are in the amorphous state.

This approach is similar to the observation of conductivity enhancement in solid-state ionic composites, into which ceramic fillers are dispersed [135]. The ionic transport in solid-state ionics is very similar to polymer electrolytes. Polymer electrolytes in the crystalline phase can be thought of as analogous to solid-state ionics having a low conductivity, and polymer electrolytes in the amorphous phase can be analogous to solid-state ionics having a high conductivity. Therefore, since the ionic layer is assumed to be present in solid-state ionic materials when the fillers are dispersed, a similar layer would be expected to appear in polymer electrolytes containing a ceramic filler. The conductivity of the ionic layer can be roughly approximated with $\sigma_l = \sigma_\infty + \Delta\sigma$, in which σ_∞ is the conductivity of the medium around the particles in the absence of an ionic layer, and $\Delta\sigma$ is the excess conductivity due to the presence of a charged layer. Thus, if the polymer around the filler is in the crystalline state, the conductivity of the layer around the particles would be higher than the conductivity of this crystalline state. If the polymer medium around the particles is in the amorphous state, the conductivity of the ionic layer would be higher than the conductivity of the amorphous polymer. Mikrajuddin et al. calculated the loading effect on the electrical conductivity of composites by assuming a simple cubic packing of filler particles and obtained a bell-shaped conductivity variation [134], similar to that obtained experimentally.

Most of fillers used for making polymer electrolyte composites are restricted to nonconductive materials. Recent reports of the addition of small amount of conducting materials such as carbon (1.5 wt.%) with surface area of 60 m^2/g showed an enhancement of conductivity and interfacial stability compared to carbon-free composites [136].

## 11.2. Effect of Salt Concentration on Conductivity

Another potential approach is to increase the concentration of salt ions in the matrix. However, this approach is unpredictable. Figure 28 shows the effect of ion content on the electrical conductivity of a system of PEG:LiClO$_4$ + α-Al$_2$O$_3$ at 25 °C [137]. By increasing the concentration of salt ions, the electrical conductivity initially increases, followed by a decrease after passing a specified salt concentration. Explanations have been proposed to explain this observation. Doeff et al. explained this behavior in terms of a trade-off between an increasing number of charge carriers and ion aggregation and increased viscosity due to ionic cross-linking, which lowers the conductivity as the salt concentration passes a critical value [138]. Dupon et al. explained this dependence as being due to strong ion pairing, which effectively traps the mobile cations, and therefore significantly reduces the ionic conductivity relative to non-ion-paired complexes on a similar structure [139].

Marcinek [137] found that up to LiClO$_4$ concentration equal to 0.25 mol/kg, the conductivity of both systems PEG:LiClO$_4$ and PEG:LiClO$_4$ + α-Al$_2$O$_3$ system of PEG:LiClO$_4$ + α-Al$_2$O$_3$ do not differ from each other by more than 30–40%. However, for high salt concentrations, the conductivity of electrolytes containing α-Al$_2$O$_3$ are much higher. The difference rises up to 30–40 times for a system with the highest salt concentration.

11.3. Effect of Temperature on Conductivity

Since the transport of ions in the amorphous state is assisted by chain segment relaxation, the temperature dependence for ion transport in this state follows the temperature dependence of chain relaxation. A Vogell–Tamman–Fulcher (VTF) dependence of electrical conductivity then results, that is,

$$\sigma(T) = \frac{A}{\sqrt{T}} \exp\left[-\frac{B}{T - T_o}\right] \tag{61}$$

Figure 28. Effect of salt concentration on the conductivity at 25 °C of PEG:LiClO$_4$ + α-Al$_2$O$_3$. Data points were extracted from [137], M. Marcinek et al., *Solid State Ionics* 136–137, 1175 (2000).

in which A, B, and T_o are constants and T is the temperature. The value of the constant parameter depends on the type of composites as well as the conditions used in preparing the polymer. The value of T_o depends on the glass transition of the polymer. A generally accepted relation is $T_o = T_g + 50$, in which T_g denotes the glass transition of the polymer [140]. The glass transition of most polymers is related to the melting point that satisfies $T_g/T_m = 0.5$–0.8 [19]. Parameter B can be expressed as a linear function of T_o [134].

The value of VTF parameters was found to depend on the concentration of salt. For example, in a system of PPG4000:AgCF$_3$SO$_3$, the value of VTF parameters at various salt concentrations was reported by Eliasson et al. [141]. The VTF parameters also depend on the salt type, as reported by Florzanczyk et al. [142].

On the other hand, since the transport of ions in the crystalline state is dominated by ion carriers jumping to the nearby locations, the temperature dependence of conductivity then follows the Arrhenius law,

$$\sigma(T) = A \exp\left[-\frac{E_a}{kT}\right] \tag{62}$$

in which E_a is the activation energy. The value of E_a/q, in which q is the charge of the ion carrier, represents the blocking potential that must be overcome for an ion carrier to jump to the nearest locations. For polymer electrolytes only (free of ceramic fillers), a VTF behavior of conductivity is observed at temperatures above the melting point; Arrhenius behavior prevails at low temperatures. A drastic depression of electrical conductivity occurs at temperatures where the VTF behavior changes to Arrhenius behavior [9]. Since the dispersion of filler particles will generate amorphous states even at low temperatures, VTF behavior is observed even at low temperatures for conductivity, as can also be seen in Figure 2. Continuing the VTF behavior up to ambient temperature overcomes a drastic depression of conductivity so that high conductivity prevails at low temperatures.

11.4. Effect of Particle Surface on Conductivity

As observed in Figure 4, at high temperatures where all parts of the polymer are in an amorphous state, the conductivity of a composite is higher than that of polymer electrolytes which are free of fillers. This indicates that the amorphous layer around filler particles should not be the only contributor to conductivity enhancement. It has been proposed that the surface properties of the dispersed filler also play a significant role in the electrical conductivity of polymer electrolyte nanocomposites. Prior to use, the fillers are usually cleaned by drying at certain temperatures in vacuum or washing with a solution followed by drying in vacuum to remove contaminants on the surface. Matsuo and Kuwano observed an enhancement in conductivity by a factor of five to ten when a lithium dodecylsulfate surfactant was added to the surface of an SiO$_2$ in a system of PEG-LiCF$_3$SO$_3$-SiO$_2$ [43]. Prior to the synthesis of composites, the silica nanoparticles were dispersed in a

solution of the surfactant to produce a self-assembly of surfactant molecules on the particle surface. Figure 29 shows the effect of surfactant content (lithium dodecylsulfate, LDS ($C_{12}H_{25}OSO_3Li$)) on the electrical conductivity of a system of poly(ethylene oxide)-$LiCF_3SO_3$-SiO_2. The ionic conductivity rapidly increases with increasing LDS content and then decreases after reaching a critical value at a certain weight fraction of LDS. The weight fraction of LDS to produce the conductivity peaks is the amount necessary for producing a monolayer on the surface of SiO_2. Further increases in LDS content led to a reduction in conductivity.

Functionalization of SiO_2 in a poly(ethylene glycol)-based polymer electrolyte using 2-[methoxy(polyethylenoxy)-propyl] trimethoxy silane was reported to enhance electrical conductivity as well as the tensile strength of composites (the tensile strength was increased by about 1 Mpa compared to that using pristine SiO_2) [109]. A small improvement in conductivity compared to pristine SiO_2 was observed for small loading levels of surfactant. It was assumed that silane moieties attached on the SiO_2 surface effectively prevent coagulation of the SiO_2 particles during blending because of steric repulsive forces. It then increases the dispersibility of SiO_2 powder in the PEO matrix [109]. The relaxation of chain segments is also improved by adding treated SiO_2. In poly(ethylene oxide)-based electrolytes, Li^+ ions are coordinated to oxygen atoms in the polymer chains. Movement of the dissociated Li^+ ions can be constrained by multiple oxygen atoms coordinated to the same Li^+ central ion. Upon the addition of functionalized SiO_2, the oxygen atoms from the short polyether units on the surface of SiO_2 compete with the oxygen atoms from the polymer chains for complexion with Li^+. The result is a more relaxed coordination between oxygen atoms and Li^+ ions, which in turn, facilitates the transport of Li^+ ions through the polymer.

Croce et al. observed a difference in conductivity when acidic, neutral, and basic Al_2O_3 were used as fillers [143]. A specific interaction between the surface group of ceramic particles and both the PEO segment and lithium salt ions was assumed to exist, which can be attributed to Lewis acid-base interactions. This interaction may act as cross-linking centers for the PEO segments and for the X^- anions to lower the PEO reorganization tendency and thus promoting the structure modification of the polymer chains. The effect promotes Li^+ conducting pathways at the ceramic surface. Second, Lewis acid-base interactions between the electrolyte ionic species lower ionic coupling. The expected result is the promotion of salt dissociation via a type of "ion-ceramic complex" formation. The surface of the filler also affects the transference number of ion in the composites. Table 8 shows the effect of acid-base properties of the filler on the transference number in a system of $P(EO)_{20}$:$LiCF_3SO_3$ containing Al_2O_3 [143].
Capiglia et al. investigated the properties of composite electrolytes consisting of SiO_2 powder with different surface features in PEO:$LiClO_4$ system. They removed the hydroxyl groups on SiO_2 by calcinations at 900 °C in order to reduce the hygroscopic properties of the particles. The reduction of hydroxyl group on the particle surface was found to increase the ionic conductivity [144]. Walls et al. prepared series of SiO_2 material with hydrophilic and hydrophobic surface groups and used them as filler in PEGDM system. They showed clearly a cause and effect relationship between the observed properties and the surface chemistry [145]. Fan et al. attached different surface group to the silica and used the functionalized particles in PEGDM-based composite electrolyte. They found that the silica surface chemistry affected mostly the rheological properties, but not the ionic conductivity [146].

11.5. Effect of Particle Size on Conductivity

The use of nanometer- and micrometer-sized Al_2O_3 in a system of PEO:$LiBF_4$ improved the electrolyte mechanical and electrochemical performance with decreasing size of ceramic filler. Nanometer-sized particles provide an order increase in conductivity compared to micrometer-sized filler [36]. Chandra et al. observed a decrease in the conductivity at 333 K of two orders of magnitude when particle size was increased from 10 to 100 μm. However, only a small decrease was observed at 373 K when the particle size was increased in the same range [147]. Wieczorek et al. reported a decrease in conductivity when the particle size is increased from 2 to 7 μm [148]. Figure 30 shows the Arrhenius plot of electrical conductivity of a system of PEO-based polymer electrolyte nanocomposites at different filler sizes [148].

The dependence of conductivity on the filler size can be described qualitatively using a space-charge layer concept

Figure 29. Effect of surfactant weight fraction on the electrical conductivity of PEG:$LiCF_3SO_3$ containing LDS coated SiO_2 nanoparticles. Data points were extracted from [43], Y. Matsuo and J. Kuwano, *Solid State Ionics* 79, 295 (1995).

Figure 30. Arrhenius plot of (square) PEO:LiBF₄, (diamond) PEO: LiBF₄ containing 10 wt.% Al₂O₃ (micrometer size), and (circle) PEO:LiBF₄ containing 10 wt.% Al₂O₃ (nanometer size). Data points were extracted from [148], W. Wieczorek et al., *Electrcochim. Acta* 40, 2251 (1995).

that is commonly used to explain similar effect in a composite of solid-state ionics. The origin of space-charge layer is ascribed to the difference in the free energy formation of the individual vacancies in case of Schottky disorder and of the vacancies and the interstices in the case of Frenkel disorder. The space-charge layer for a two-phase composite of solid-state ionics has been introduced by Maier, who found the enhanced conductivity of the composite material as [149]

$$\sigma = (1 - \phi)\sigma_o + (3\sqrt{2})\beta_L \left(\frac{\phi}{r}\right)\sqrt{\frac{\varepsilon\varepsilon_o RT}{V^m}}\mu_v\sqrt{N_{vo}} \quad (63)$$

where σ_o = conductivity of filler-free polymer electrolytes, ϕ = volume fraction of filler, β_L = a constant to account for the topology of filler, r = filler particle radius, ε = dielectric constant, ε_o = permittivity of vacuum, V_m = bulk molar volume of the matrix phase, μ_v = the mobility of dominant defect, and N_{vo} = the mole fraction of dominant defect at the interface. This equation can fit the data of conductivity of NaCl containing various sizes of Al₂O₃ [150].

11.6. Effect of Plasticizers on Conductivity

The plasticizers have a great influence on the electrical, chemical, and electrochemical properties of the polymer electrolyte composites. The addition of ethylene carbonate results in a more homogeneous and transparent film. Golodnitsky et al. observed a conductivity enhancement by a factor of two in system of LiI:PEO₉PMMA₀.₅ + 6 vol.% Al₂O₃ when ECl is added [151]. Enhancement about seven times was observed in a system of LiI:PEO₆PMMA₀.₅ + 6 vol.% Al₂O₃ if PEG₀.₅ is added as appears in Table 9 [151].

Leo et al. [152] observed the different temperature dependence of conductivity when plasticizer is added into the polymer composites. Different weight percent of plasticizer alters the shape of log σ against $1/T$. The temperature dependence of conductivity below 50 °C shows an Arrhenius

Table 9. Effect of EC and PEG plasticizers on the electrical conductivity at 120 °C.

Electrolytes	Plasticizer	Filler	Conductivity (S/cm)
PEO₉PMMA₀.₅:LiI		Al₂O₃ 6 wt.%	0.6×10^{-3}
PEO₉PMMA₀.₅:LiI	ECl	Al₂O₃ 6 wt.%	1.2×10^{-3}
PEO₆PMMA₀.₆:LiI		Al₂O₃ 6 wt.%	0.4×10^{-3}
PEO₆PMMA₀.₆:LiI	PEG₀.₅	Al₂O₃ 6 wt.%	1.0×10^{-3}

type for all plasticizer content. However, above 50 °C, the temperature dependence of conductivity seems to change with the change in the content of plasticizer. For 5 wt.% plasticizer (ethylene carbonate), there is a temperature T_m above which the Arrhenius plot of conductivity was observed and below which a qualitative change in the curve was observed. The discontinuity in the slope of the curve of the unplasticized composite disappears. At higher plasticizer content, a distinct change in the temperature-dependent conductivity was observed.

11.7. Effect of Storage Time on Conductivity

Shin et al. measured the effect of storage time on the electrical conductivity of polymer electrolyte composites of PEO₁₀:LiCF₃SO₃ containing 5–15 wt.% of Ti$_n$O$_{2n-1}$ stored at 90 °C. The conductivity increased with increase in the storage time until approximately 5 h, when the conductivity reached a steady-state value. The conductivity of polymer electrolytes containing ceramics reaches the steady-state value faster than ceramic-free polymer electrolytes [153]. The conductivity of PEO₈:LiClO₄ containing 10 wt.% SiO₂ is relatively stable up to two weeks storage as displayed in Figure 31 [154]. Croce et al. suggested that the recrystallization may occur with kinetics which appear to be critically dependent on the annealing condition [9].
Figure 31. Effect of storage time on the conductivity of PEO₈:LiClO₄ containing 10 wt.% SiO₂. Data points were extracted from [154], G. Appetecchi et al., *Electrochim. Acta* 45, 1481 (2000).

Appetecchi et al. compared the conductivity of EC-DMC-PAN:LiPF$_6$ containing 6 wt.% Al$_2$O$_3$ and EC-DMC-PAN:LiPF$_6$ free of Al$_2$O$_3$. They found that, after 30 days aging at 75 °C, there was no significant change in the conductivity of ceramics containing polymer electrolytes, while the ceramic-free polymer suffered a depression in conductivity to become about 10% of the initial value [155].

12. MECHANICAL PROPERTIES

12.1. Effect of Filler Content

Weston and Steele used ceramic filler to improve the mechanical properties of PEO films [156]. Addition of ceramic filler to improve the mechanical properties of polymer is not new. The addition of carbon black filler can extend the lifetime of tires from 5,000 miles if no carbon black is used to a potential 80,000 miles in some current tires. Figure 32 shows the effect of filler content on the elastic modulus of a system of poly(ethylene glycol) dimethyl ether:LiN(CF$_3$SO$_2$)$_2$ containing fumed silica with a surface group modified to become Si-C$_8$H$_{17}$ instead of Si-OH. Increasing the concentration of the filler generates a stronger network structure with the modulus increasing by two orders of magnitude [157].

Although addition of filler is effective in hardening the polymer electrolytes at lower temperature, the effectiveness becomes lower at temperatures higher than the melting point of the matrix. Wen et al. used a whisker to improve the mechanical strength of polymer electrolyte composites. The work is based on the morphology of whisker which has a special shape similar to rigid network formed inside the polymer electrolytes. The mechanical strength of the polymers was evaluated with their thermal creep behavior, indicated by the relative resistance change of the polymer electrolyte films after being kept for some time under a certain pressure [113]. Addition of ceramic filler in a composite of PEO$_8$:LiClO$_4$ remarkably affected their
thermal creep properties, in particular at high temperatures. The electrolytes containing whisker filler are much more mechanically stable than those containing nanosized γ-Al$_2$O$_3$. However, at low temperatures (below the melting point), the thermal creep properties of both composites are similar.

Leo et al. observed improvement of mechanical strength of PEO-based polymer electrolytes by a factor of three when 7.5 wt.% Nasicon glass-ceramic fillers is added [152]. This filler content also increased the glass temperature of about 14 °C. It is suggested that the addition of filler increases the stiffness of polymer segment, thereby suppressing the polymer chain motion [158].

12.2. Effect of Particle Surface

Inorganic fillers are actually bonded to the molecular chain and thereby immobilize the polymer chain. The degree of adhesion between the polymer matrix and the fillers, the surface area of the filler, and the packing characteristic of the filler are important factors that determine the mechanical characteristics of the composites [159]. Liu et al. compared the effect of tensile strength of composites of PEO:LiBF$_4$+SiO$_2$ containing pristine SiO$_2$ and organic coated SiO$_2$ [109]. The SiO$_2$ was coated using 2-[methoxy(polyethylenoxy)-propyl] trimethoxy silane. Figure 33 shows the effect of filler loading on the tensile strength. It can be seen that the trend in the tensile strength variation is similar for both composites. However, the tensile strength of composite made using coated SiO$_2$ filler is always larger than that of material made by pristine SiO$_2$. A double enhancement was observed in all filler loading region. Functionalized SiO$_2$ might be considered as a filler which carries a pendant coupling agent. The coupling agent has two types of functional groups, one capable of forming chemical bond with the surface of the filler and the other capable of entangling with PEO chains [160].

Figure 32. Effect of weight fraction of filler on the elastic modulus of PEG dimethyl ether:LiN(CF$_3$SO$_2$)$_2$ containing C$_8$H$_{17}$ coated fumed silica. Data points were extracted from [152], C. J. Leo et al., *Solid State Ionics* 148, 159 (2002).

13. THERMAL PROPERTIES

13.1. Effect of Filler Content on the Glass Temperature

Franco et al. observed the reduction in the glass transition temperature in composite of PEO:LiClO$_4$ containing carbon black (conducting filler) [97]. $T_g = 220$ K was observed for composite containing 10 wt.% carbon black, 210 K for that containing 20 wt.% carbon black, and 202 K for that containing 30 wt.% carbon black. Choi and Shin measured the effect of the filler loading on the glass temperature of a system of PEO$_{16}$LiClO$_4$+SiC. T_g first decreases rapidly with the increase in the filler content and then reaches a plateau beyond which it further drops as can be seen in Figure 34 [161].

On the contrary, Chung and Sohn observed also an enhancement of glass temperature as the concentration of salt increases in a system of polymer comb-shaped polymer matrix by attaching triethoxyethylene side chain on the main chain of polyethylene oxide [162]. Wieczorek et al. observed that the SiO$_2$ filler which enhanced the conductivity raised the T_g [163], while the α-Al$_2$O$_3$ filler which reduced the conductivity above room temperature lowered the T_g [164]. The data indicated that the variation of T_g neither exhibits systematic results nor meets the expected variation of conductivity.

Filler content also affects the melting enthalpy of composites. Figure 35 shows the effect of filler loading on the melting enthalply extracted from DCS curve for system of PEO$_{16}$:LiClO$_4$+SiC, and the normalization relative to the mass fraction of pure (PEO)$_{16}$:LiClO$_4$ [161]. Using Eq. (54) and remembering $\Delta H_{m,c}$ is proportional to mass fraction of pure (PEO)$_{16}$:LiClO$_4$, curve (b) reflects the crystallinity of the composite. It is clear that the crystallinity increases with the loading of the filler at low loading and then decreases with further increase in the filler content. Choi and Shin proposed the enhancement of crystallinity with the loading content of filler is due to the role of the filler which may act as nucleation centers of crystalline polymer phase. The

Figure 35. Effect of filler content on the melting enthalpy (solid circle) and crystallinity (open circle) of PEO$_{16}$:LiClO$_4$ containing SiC. Data points were extracted from [161], B. Choi and K. Shin, *Solid State Ionics* 86–88, 303 (1996).

nucleation effect was considered to be sufficient to overcome the hindrance of crystallization due to the enhancement of the segmental motion of the PEO [161].

13.2. Effect of Salt Concentration on the Glass Temperature

Marcinek et al. observed the effect of salt concentration of the system of PEG:LiClO$_4$ + α-Al$_2$O$_3$ and found that the glass temperature also increases with the salt concentration as appears in Figure 36 [137]. For concentrations up to 0.25 mol/kg salt concentration, the T_g is almost constant. At higher salt concentrations, the plot of T_g with respect to the logarithm of salt concentration likely increases with an exponential trend. They also compared the variation of glass temperature of system free of filler and found that at up to 0.26 mol/kg salt concentration, the T_g of both samples is almost similar.

Figure 34. Effect of filler content on the glass temperature of PEO$_{16}$:LiClO$_4$ containing SiC. Data points were extracted from [161], B. Choi and K. Shin, *Solid State Ionics* 86–88, 303 (1996), and line is for eye guide.

Figure 36. Effect of salt concentration on the glass temperature of PEG:LiClO$_4$. containing α-Al$_2$O$_3$. Data points were extracted from [137], M. Marcinek et al., *Solid State Ionics* 136–137, 1175 (2000).

At higher salt concentration, the T_g of filler-free samples is higher that that of sample containing filler. Sun et al. found that the glass temperature of a system of poly(N,N-dimethylaminoethyl methacrylate)-tetraglyme:LiClO$_4$ polymer electrolytes increases strongly with the increasing salt concentration over the first 0.5 mol/kg addition of LiClO$_4$. Further addition of salt results in only a minor increase in the glass temperature [165].

14. LUMINESCENT COMPOSITES

Most fillers used in polymer electrolyte nanocomposites are "optically inactive," that is, they do not have any luminescence properties. It would be interesting to investigate the properties of composite if the fillers loaded in polymer emit luminescence. This approach would have interesting applications such as the possibility of obtaining information regarding the degradation of battery or fuel cells using such composites, for example based on the luminescence intensity emitted by the filler. Changes in properties of the polymer when the battery or fuel cell degrades from the initial performance would be expected. This indicates that the properties of the medium around the filler would change when the battery or fuel cell degrades. It would affect the detected luminescence intensity emitted by the filler change. Based on this detected luminescence, the current performance of the battery or fuel cell could be determined.

Zinc oxide (ZnO) is one of the promising materials for preparing composite polymer electrolytes that are luminescent. ZnO nanoparticles play a role as an agent for reducing the tendency of the polymer matrix to crystallize and simultaneously as luminescence centers. Since the luminescence spectra of ZnO are dependent on crystalline size (quantum size effect), the emitted wavelength can be controlled by adjusting the size of the ZnO nanocrystallites. ZnO particles of different sizes can be produced easily using, for example, a colloidal process, so that the "color" of the composite can be easily tuned. A "blue composite" can be prepared using smaller ZnO nanoparticles, while a "yellow composite" can be produced using large ZnO particle size. This composite has also considerable potential for fabricating devices that simultaneously produce both electrical current and light, such as luminescent electrochemical cells, self-powered displays, etc.

Figure 37 (right) shows an example of a photoluminescence (PL) spectrum of composite polymer electrolytes containing ZnO nanoparticles [62]. The sample produced a highly intense green luminescence. The color of those samples can clearly be observed by the naked eye even using a hand-held UV lamp as background illumination in the laboratory. The PL peaks can be shifted to lower or higher wavelengths by altering the concentration of the precursors. The luminescence spectrum was produced by an electron transition from the bottom of conduction band to a state located near the center of the band.

The corresponding excitation spectra of the samples are shown in Figure 37 (left). A peak is related to the band-edge transition. The wavelength peak is smaller than that observed for bulk ZnO, which shows a peak at 365 nm (energy about 3.4 eV). The shift of the band-edge peak to lower wavelengths indicates the presence of a quantum size
Figure 37. Left: Excitation spectra of PEG:Li containing ZnO nanoparticles. Right: The corresponding luminescence spectra. Data were extracted from [62], Mikrajuddin et al., *J. Electrochem. Soc.* 149, H107 (2002).

effect of the optical bandgap. Using the size-dependent optical bandgap equation, the size of ZnO nanoparticles in the matrix is estimated to be around 6 nm.

The *in-situ* growth of nanoparticles in the polymer matrix ensures the dispersion of nanoparticles in polymer bulk easily without the need for an intensive mixing process. The selection of a precursor containing lithium ions permits the insertion of cations during the growth process. This approach has been used to produce composite polymer electrolytes containing ZnO nanoparticles using lithium hydroxide as one precursor and a hygroscopic solution of zinc acetate as another precursor. A high molecular weight polyethylene glycol was first mixed with a solution of lithium hydroxide and then further mixed with a hygroscopic solution of zinc acetate. Since lithium did not participate in the formation of zinc oxide, lithium ions were left in the polymer matrix and were then able to take part as ion carriers.

15. CONCLUSION

Stable and high electrical conductivity polymer electrolytes are required for fabricating flexible and environmentally friendly fuel cells and batteries. Some important parameters critical to polymer electrolytes in order to bring this material into industries have been discussed in this review. Although high electrical conductivity of polymer electrolytes usually appears at high temperatures, many efforts to improve the electrical conductivity at room temperature have been introduced by researchers all around the world. They include the synthesis of amorphous polymer matrix, addition of second phase in the host polymer matrix (plasticizers) like low molecular weight polymers, and addition of size chains. The most popular approach now is the addition of ceramic filler in nanometer scale. This approach becomes interesting since the addition of nanometer-sized ceramic filler improves not only the electrical conductivity of polymer electrolytes but also the mechanical properties. This material, usually named

as polymer electrolyte nanocomposite, attracts a lot of attention because of the simplicity in the processing. Various kinds of polymer in a lot of molecular weights as well as various kinds of ceramic filler in a lot of sizes are available in the market. The process of production of composites is relatively simple, that is, by just mixing the polymer, salt, and filler in a common solution, ended with drying. Methods of preparation of polymer electrolyte nanocomposites were briefly discussed in this review.

Characterizations of the prepared films are important to understand the properties as well as to find the optimum preparation conditions. Various methods of characterization, including electrical, spectroscopic, microscopic, and thermal characterizations, were discussed briefly. Detailed explanations of the methods might be found in some analytical chemistry books.

In the final part, we discussed some parameters which affect the properties of polymer electrolyte composites. It was found that the properties of the composites are sensitive to the preparation condition as well as material used for making the composites. For example, the electrical conductivity is greatly dependent on the volume fraction of fillers, surface property, filler size, type of salt, side chain, etc. Also the mechanical properties are affected by filler content, surface property, and salt concentration.

GLOSSARY

Anion An ionic species having a negative charge.

Battery A device that stores energy and makes it available in an electrical form.

Blending Physically mixing several types of materials so thoroughly that they appear to be indistinguishable from each other in the product.

Casting method A method of forming sheets of composite materials by pouring fluid materials onto a flat surface.

Cation An ionic species having a positive charge.

Charging Supply electric current to a battery.

Copolymerization Polymerization with two or more different monomers.

Cycle life The number of charge/discharge cycles that are possible before failure occurs.

Differential scanning calorimetry A materials characterization laboratory technique by which the temperature of a sample of the substance in question is raised in increments while a reference is heated in the same rate. The amount of heat that is required to heat the sample and the reference to each temperature is recorded and can be plotted. From these plots, melting points, phase change temperatures, chemical reaction temperatures, and glass transition temperature of polymers can be determined.

Discharging Withdrawing charge from a battery.

Doctor blade technique A technique using a flat bar used for regulating the amount of liquid material on the rollers of a coating machine, or to control the thickness of a coating after it has been applied to a substrate.

Electrical conductivity A measure of how well a material accommodates the transport of electric charge.

Energy density The energy obtainable per unit volume.

Energy efficiency (energy released on discharge)/(energy required for charge).

Filler Inorganic particles added to polymer matrix.

Fourier transform spectroscopy 1A measurement technique whereby spectra are collected based on the response from a pulse of electromagnetic radiation. Fourier transform spectroscopy is more sensitive and has a much shorter sampling time than conventional spectroscopic techniques.

Free volume The extrapolated differences in volume between a glass and the extrapolation of the melt curve is called the free volume. The free volume is associated with the space between molecules in a sample.

Glass transition temperature (T_g) The temperature below which molecules have very little mobility. On a larger scale, polymers are rigid and brittle below their glass transition temperature and elastic above it. T_g is usually applicable to amorphous phases and is commonly applicable to glasses and plastics.

Hot press The forming of a compact material at temperatures sufficiently high to cause concurrent sintering.

Melting point The temperature at which it changes state from solid to liquid. When considered as the temperature of the reverse change, the temperature is referred to as the freezing point.

Nuclear magnetic resonance (NMR) A physical phenomenon described independently by Felix Bloch and Edward Mills Purcell in 1946. It involves the interaction of atomic nuclei placed in an external magnetic field with an applied electromagnetic field oscillating at a particular frequency. Magnetic conditions within the material are measured by monitoring the radiation absorbed and emitted by the atomic nuclei. NMR is used as a spectroscopy technique to obtain physical, chemical, and electronic properties of molecules. It is also the underlying principle of Magnetic Resonance Imaging. NMR is one of the techniques used to build quantum computers.

Number average molecular weight A way of determining the molecular weight of a polymer. Polymer molecules, even ones of the same type, come in different sizes (chain lengths, for linear polymers), so we have to take an average of some kind. The number average molecular weight is the common average of the molecular weights of the individual polymers. It is determined by measuring the molecular weight of n polymer molecules, summing the weights, and dividing by n. The number average molecular weight of a polymer can be determined by osmometry, end-group titration, and colligative properties.

Plasticizers Materials added to polymer matrix to improve the fraction of amorphous state.

Polymer electrolytes Electrolytes which using polymer as a media to dissociate ions.

Rechargeable batteries Batteries that can be restored to full charge by the application of electricity. They come in many different designs using different chemistry.

Small angle x-ray scattering A laboratory technique in which photons are elastically scattered from a sample. The sample can not be too thick. Liquids can be examined. Features on the nanometer length scale can be examined.

Specific energy The energy obtainable per unit weight.

Weight average molecular weight A way of determining the molecular weight of a polymer. Polymer molecules, even if of the same type, come in different sizes (chain lengths, for linear polymers), so we have to take an average of some kind. For the weight average molecular weight, this is done as follows: weigh a number of polymer molecules, add the squares of these weights, and then divide by the total weight of the molecules. Intuitively, if the weight average molecular weight is w, and you pick a random monomer, then the polymer it belongs to will have a weight of w on average. The weight average molecular weight can be determined by light scattering, small angle neutron scattering (SANS), and by sedimentation velocity.

Wide angle x-ray scattering An X-ray diffraction technique that is often used to determine the crystalline structure of polymers.

Polymer Nanostructures

Liming Dai

The University of Akron, Akron, Ohio, USA

CONTENTS

1. INTRODUCTION

As the term implies, polymer (or macromolecule) refers to a molecule of extraordinarily large size (typically >1000 in molecular weight). Although polymer molecules are large, they are made up of individual, repeating units termed monomers. The overall properties of a given polymeric material depend on: (i) the constituent monomer units and the way they are arranged in the macromolecule and (ii) the spatial arrangement of the constituent macromolecular chains and the nature of the intermolecular interactions that hold them together [1]. These interesting structure–property relationships provide a broad basis to allow the development of various polymeric materials (e.g., polymer fibers, films, powders) with different properties from the same macromolecules.

Polymers have been widely used in all aspects of our daily life. After all, our clothes are made from synthetic fibers, car tires from rubbers, and computer chips from plastics. It is now difficult to imagine what our life would be like if there were no polymers. With the recent significant advances in nanoscience and nanotechnology, various nanostructured polymers have been devised for a wide range of advanced applications. Examples include the use of polymer nanoparticles as drug delivery devices, polymer nanofibers as conducting wires, and polymer thin films and periodically structured polymeric structures for optoelectronic devices.

Like most other nanomaterials [2, 3], nanostructured polymers could also possess interesting mechanical, electronic, optical, and even magnetic properties that are different from those of the bulk materials, depending on their size, shape, and composition.

The development of nanostructured polymers has opened up novel fundamental and applied frontiers, which has attracted tremendous interest in recent years. This chapter provides an overview on the rapidly developing field of polymer nanostructures. We will first discuss the preparation of polymer nanoparticles, with an emphasis on their potential applications for controlled drug delivery. We will then describe the preparation of fiberlike polymers (i.e., nanowires, nanotubes, and nanofibers) of potential applications in electronic devices. Finally, we will examine the use of polymer thin films (nanofilms or nanosheets) in organic optoelectronic devices, along with the periodically structured polymers as photonic crystals.

2. POLYMER NANOPARTICLES

Polymer nanoparticles are of special interest in medical applications. In particular, the recent development of polymer nanoparticles as effective drug delivery devices is revolutionizing the way in which medical treatments are performed. Encapsulating or incorporating drugs in polymer nanoparticles allows effective delivery of the drug molecules to the target site and their controlled release, leading to an increase in the therapeutic benefit and reduction of the side effects [4]. Significant advances in polymer science and biomedical engineering have facilitated the development of new synthetic approaches to polymer nanoparticles.

Depending on the method of preparation, polymer nanospheres or nanocapsules can be obtained. These polymer nanoparticles, usually having a diameter ranging from 10 to 300 nm, can be prepared by various techniques, including *in-situ* polymerization, dispersion of preformed polymers, and self-assembling. The *in vitro* and *in vivo* performances of various polymer nanoparticles as drug delivery devices have recently been discussed in several excellent review articles [5, 6]. In what follows, we provide a status summary of the preparation of polymer nanoparticles.

2.1. Polymer Nanospheres by Polymerization

While conventional emulsion polymerization has been widely used to produce polymer particles with the size range of 0.1–1 μm, miniemulsion and microemulsion polymerization methods have recently been developed for the preparation of polymer nanoparticles in the ranges of 50–200 and 15–50 nm, respectively [7, 8]. Using polymerizable amphiphilic PEO macromonomers [i.e., $CH_3O–(CH_2CH_2O)_n–(CH_2)_{11}–OOCC(CH_3)=CH_2$, $n = 10, 15$, or 40; designated as C1–PEO–C11–MA-n] as stabilizers in dispersion/emulsion polymerizations, for example, Gan and co-workers have successfully prepared polymer [e.g., polystyrene (PS), poly(methyl methacrylate) (PMMA)] microlatexes with particle sizes ranging from 15 to 200 nm [9–11]. A large amount of surfactants, however, is normally required for these emulsion polymerization, though high solid-contents up to 40 wt% have been reported [12, 13]. The relatively high content of surfactant in the dispersions often limits their biomedical applications [14–16].

Recently, considerable efforts have been devoted to investigating ways to minimize the amount of surfactant used and to maximize the solid content. In this context, both solution and interfacial polymerization methods have been used to encapsulate drug molecules in polymer nanoparticles. For example, Couvreur and co-workers [16], synthesized poly(alkylcyanoacrylate) nanoparticles by polymerizing methyl or ethyl cyanoacrylate in aqueous acidic medium in the presence of polysorbate-20 as a surfactant. The polymerization follows an anionic mechanism and the schematic representation of the procedure used for the production of poly(alkylcyanoacrylate) nanoparticles is given in Figure 1.

For controlled release purposes, drug molecules can be dissolved in the polymerization medium either before or after the polymerization reaction. The resulting suspension of polymer nanoparticles is then purified by ultracentrifugation or by resuspending the nanoparticles in an isotonic surfactant-free medium.

More recently, Lowe and Temple [17] have used the interfacial polymerization technique originally proposed by Al-Khouri Fallouh, et al. [18] to prepare poly(isobutyl cyanoacrylate) nanoparticles for encapsulating calcitonin. In this case, isobutyl cyanoacrylate monomers and calcitonin were dissolved in an ethanol solution containing Mygliol@ 812 oil. The oil solution was then added dropwise into an aqueous solution of poloxamer 188 under stirring for the interfacial polymerization to take place at the surface of the Mygliol@ droplets. The resulting poly(isobutyl cyanoacrylate) nanoparticles were separated from other preparation additives by diafiltration [19]. Calcitonin was found to be incorporated into the poly(isobutyl cyanoacrylate) nanocapsules with an efficiency of 90%.

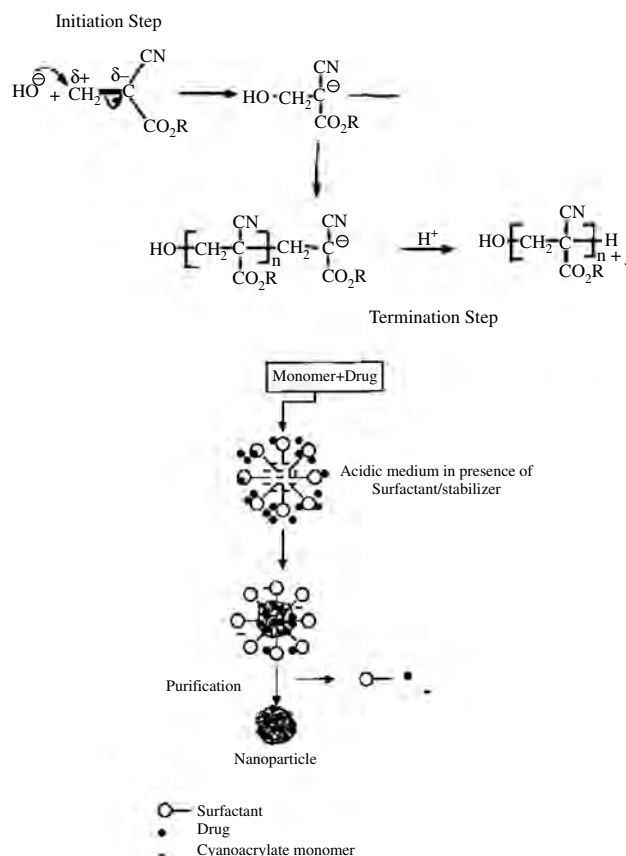
Along with these efforts in preparing polymer nanoparticles via polymerization, nanoparticles with tailor-made surface properties (e.g., chemical, electrical, mechanical) by surface engineering have been reported [20]. For instance, Dokoutchaev and co-workers [21] have developed several methods to deposit metal colloids (e.g., Pt, Pd, Ru, Ag, Au) onto the surface of polymer micro- and nanoparticles.


Figure 1. Schematic representation of poly(alkylcyanoacrylate) nanoparticle production by anionic polymerization of alkylcyanoacrylate. Reprinted with permission from [16], P. Courvreur et al., *J. Pharm. Pharmacol.* 31, 331 (1979). © 1979, Kluwer/Academic Plenum.

Examples include the controlled hydrolysis of surface acetoxy groups to generate hydroxyl functionalities for specific adsorption silver and ruthenium nanoparticles [22], electrostatic deposition of Au colloids on positively charged polymer micro/nanoparticles [21, 23], and simple adsorption of Pd nanoparticles on poly(vinylpyridine) nanospheres [24]. As shown in Figure 2, these polymer micronanospheres (0.2–3 μm in diameter) functionalized with metal nanoparticles
Figure 2. (1–10 nm in diameter) possess a high ratio of surface area to volume and are promising for various potential applications, especially as efficient catalysts, chemical/electronic/optical sensors, active substrates for surface enhanced Raman scattering, and photocatalysts for solar energy conversion.

2.2. Dispersion of Preformed Polymers

Several other related methods involving the dispersion of preformed polymers, such as those based on the use of emulsifying agents [25–28] and supercritical fluids [29–33], have also been used to prepare polymer nanoparticles.

2.2.1. Polymer Nanosphere by Emulsifying Dispersion

In this case, a preformed polymer is dissolved in an organic solvent, which is then emulsified into an aqueous solution, with or without the presence of drug molecules, to make an oil (O) in water (W) emulsion (O/W emulsion) by using a surfactant/emulsifying agent [25, 26]. Upon the formation of a stable emulsion, the organic solvent is evaporated at room temperature by continuous stirring or by heating to produce the polymer nanoparticles.

In order to control the size of the resultant nanoparticles, a modified version of the W/O method has been developed that uses both water-insoluble organic solvent and water-soluble solvent (e.g., acetone, methanol). In this case, the spontaneous diffusion of water-soluble solvent could cause an interfacial turbulence between the two phases to create smaller particles. Therefore, the increase in the concentration of water-soluble co-solvent was shown to cause a considerable decrease in the nanoparticle size [27].

2.2.2. Polymer Nanospheres by Supercritical Fluid Method

These methods inevitably involve the use of organic solvents that are hazardous to the environment and physiological systems [28]. The need for environmentally safer encapsulation has been a driving force for the development of new methods for the preparation of polymer nanoparticles with desired physicochemical properties. In this regard, the supercritical fluid technique has been an attractive alternative for generating polymer nanoparticles of high purity without any trace amount of the organic solvent [29]. As detailed discussions on supercritical fluid technology are beyond the scope of this chapter, interested readers are referred to specialized reviews and monographs [31–33]. Briefly, in a typical supercritical fluid method the solute of interest is solubilized in a supercritical fluid. The solution is then expanded through a nozzle to reduce the solvent power of the supercritical fluid, resulting in the precipitation of the solute. Although the supercritical fluid method has advantages due to its solvent-free nature, further research breakthroughs are required before any commercial applications will be realized as most polymers exhibit little or no solubility in supercritical fluids.

2.3. Self-Assembling of Preformed Polymers

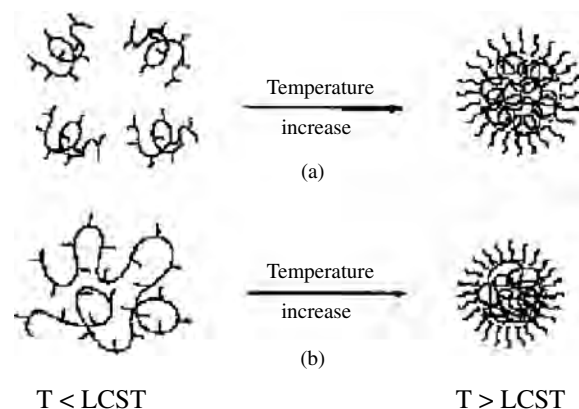
Self-assembly involves the aggregation of molecules or macromolecules to thermodynamically stable structures that are held together by weak noncovalent interactions. These weak noncovalent interactions include hydrogen bonding, π–π stacking, electrostatic forces, van der Waals forces, and hydrophobic and hydrophilic interactions. Because of the fast dynamic and very specific noncovalent interactions involved, self-assembling processes are usually very fast. The resulting supramolecules could undergo spontaneous and continuous de-assembly and re-assembly processes under certain conditions due to the noncovalent nature. Supramolecular materials can, therefore, select their constituents in response to external stimuli or environmental factors and behave as adaptive materials. Although self-assembling (or complexion) of small molecules has for decades been an active research area, self-assembling of polymeric chains is a recent development. Various supramolecular aggregates with unusual structures [34–38], including shell–core and shell–hollow core, have been successfully prepared which are difficult to form by conventional chemical reactions.

2.3.1. Shell–Core Polymer Nanoparticles

Self-assembling of diblock copolymers in a selective solvent, in which only one block is soluble, can form shell–core nanoparticles (Fig. 3).

To demonstrate this concept, several groups have carried out detailed studies on various amphiphilic copolymers, including poly(ethylene oxide)-*block*-poly(propylene oxide), PEO-PPO, and poly(*N*-isopropylacrylamide)-*block*-poly(ethylene oxide), PNIPAM-*b*-PEO [39–44]. It was demonstrated that the formation of shell–core architectures in the copolymer systems can be induced by changes in temperature, solvent composition, ionic strength, and/or pH. For example, self-assembled shell–core polymer nanoparticles consisting of PNIPAM core and PEO shell have been prepared in water above ~32 °C. While both PNIPAM and PEO blocks dissolve in water at room temperature, PNIPAM becomes hydrophobic and undergoes an "coil-to-globule" transition at temperatures higher than ~32 °C [45, 46]. By
Figure 3. Schematic representation of a core–shell nanostructure formed by a self-assembly of coil-rod diblock copolymer chains in a selective solvent. Reprinted with permission from [39], G. Zhang et al., *Acc. Chem. Res.* 34, 249 (2001). © 2001, American Chemical Society.

controlling the heating rate, Zhu and Napper [45] have prepared core–shell nanoparticles of a narrow size distribution from PNIPAM-*b*-PEO block copolymers.

The core–shell formation from appropriate diblock copolymers has also been induced by certain chemical reactions. Of particular interest, Wu et al. [47] have used the soluble poly(4-methylstyrene-*block*-phenylvinylsulfoxide), PMS-*b*-PVSO, as the starting material in THF. Thermal elimination of phenylsulfenic acid converted the soluble and flexible PVSO block into an insoluble rodlike polyacetylene (PA) block [48, 49], leading to the formation of core–shell nanoparticles with the conducting PA core surrounded by the THF soluble PMS shell (Fig. 4). Nanoparticles with conducting polymers either as the core or shell have also been prepared by colloidal chemistry [50].


Although the block copolymer approach to the core–shell nanoparticles is an effective method and has recently been extended to include the use of triblock copolymers to form polymer nanoparticles with a multilayered shell structure [50], the general application of this method is largely limited by the rather delicate synthesis of diblock copolymers with well-defined chemical and physical structures.

To eliminate the use of block copolymers, Qiu and Wu [51] investigated the temperature-induced self-assembling of PNIPAM and PEO *graft* copolymers. They have demonstrated that the size of nanoparticles formed by the PNIPAM chains grafted with short PEO chains is inversely proportional to the number of the PEO short chains on individual PNIPAM polymer backbones (Fig. 5a) [51]. By suppressing the interchain association, these authors have even prepared single-chain core–shell nanoparticles, as schematically shown in Figure 5b [52].

Apart from the formation of core–shell nanoparticles from pure grafted polymers, the self-assembling in mixture systems of a homopolymer and a graft copolymer has also been effectively exploited as an alternative "block-copolymer-free" approach to polymer core–shell nanoparticles. Based on the homopolymer and graft polymer approach, Liu and co-workers [53] have recently reported an interesting approach to hollow nanospheres (i.e., shell–hollow core nanoparticles). These authors first prepared core–shell nanoparticles by self-assembling a polymer pair of poly(ε-carprolactone) (PCL) and a graft copolymer of methylacrylic acid and methyl methacrylate (MAF) in water. The resulting nanoparticles have a PCL core stabilized by the MAF shell with its short PCL branches anchored onto the core (Fig. 6a).
Figure 5. Schematic representation of the formation of (a) core–shell polymer nanoparticles from PNIPAM-*g*-PEO graft copolymers and (b) a single chain core–shell nanostructure through the coil-to-globule transition of the chain backbone of PNIPAM-*g*-PEO. Reprinted with permission from [52], X. Qiu and C. Wu, *Phys. Rev. Lett.* 80, 620 (1998). © 1998, American Chemical Society.

These authors then chemically cross-linked the miceller shell to form the so-called "shell-cross-linked knedel-like nanoparticles" [54], while they biodegraded the core with an enzyme to produce the hollow core (Fig. 6a). The morphologies of the nanoparticles before (A&B) and after (C&D) core degradation are shown by the TEM micrographs in Figure 6b. Careful examination of the nanoparticles shown in Figure 6b indicates that the particles have expanded significantly to from ca. 100 to 300 nm in diameter and a shell thickness from ca. 10 to 100 nm, suggesting a swelling effect associated with the core removing process.

Closely related to this study, Blomberg and co-workers [55] have successfully prepared hollow polymeric nanocapsules through surface-initiated living free-radical polymerization. In particular, these authors first attached trichlorosilyl-substituted alkoxyamine initiating groups onto the surface silanol groups of silica nanoparticles. They then carried out living free-radical polymerization from the surface initiating groups, resulting in the formation of core–shell morphology (Fig. 7a).

Thermal or chemical cross-linking of the polymeric shell, followed by removal of the silica core with HF led to stable hollow polymeric nanocapsule (Fig. 7b). Figure 8a and b shows field-emission scanning electron microscopic (FESEM) images for cross-linked poly(styrene-*co*-vinylbenzocyclobutene)-modified nanoparticles before and after removal of the silica core, respectively.

Similar hollow nanospheres have been previously prepared through self-assembling *block* copolymers in selective solvents followed by cross-linking of the micellar shell and
Figure 8. FESEM images for cross-linked poly(styrene-*co*-vinylbenzo-cyclobutene)-modified nanoparticles before (a) and after (b) removal of the silica core. Reprinted with permission from [55], S. Blomberg et al., *J. Polym. Sci. A* 40, 1309 (2002). © 2002, Wiley–VCH.

removing the core via chemical degradation [56–59], though the "block-copolymer-free" approaches discussed may be regarded as a simpler and more economic approach. Given that the hollow polymer nanospheres can be used to encapsulate a large variety of guest molecules, including many catalysts and drugs, there has been increasing interest in the research and development of polymer hollow nanoparticles. Clearly, a promising potential for future research and application exists in this area.

3. POLYMER NANOWIRES, NANOTUBES, AND NANOFIBERS

Just as polymer nanoparticles have broadened the potential applications of polymer materials, polymer wires, tubes, and fibers of diameters down to a nanometer scale have also been studied for a large variety of potential applications. Polymer nanowires, nanotubes, and nanofibers are useful as both "building blocks" for nanodevices and "connecting components" between the nanoscale entities and the macroscale world. In this regard, conducting polymer nanowires, nanotubes, and nanofibers are of particular interest as they have been shown to possess the processing advantages of plastics and the optoelectronic properties of inorganic semiconductors or metals. We provide an overview on the syntheses, properties, and potential applications of polymer nanowires, nanotubes, and nanofibers, with an emphasis on those based on conducting polymers.

3.1. Tip-Assisted Syntheses of Polymer Nanowires

The use of a scanning tunneling microscope (STM) and scanning electrochemical microscope (SECM) for generation and manipulation of polymer structures as small as a few nanometers has been well documented [49, 60]. The polymerization of pyrrole onto specific regions of graphite substrates at a submicrometer resolution was achieved by using the STM tip as an electrode. Polypyrrole strips with a linewidth of 50 μm and length of 1 mm were produced by a SECM [61], as were micrometer-sized polypyrrole towers [62]. By spin-coating a solution of Nafion and anilinium sulfate onto a Pt electrode in a SECM unit, Wuu et al. [63] polymerized aniline into a micrometer scale structure. Borgwarth et al. [64] successfully prepared a 20 μm wide polythiophene line by using the tip of a SECM as an electrode for region-specific oxidation of bromide into bromine, followed by the diffusion of the bromine into a conductive substrate covered with a thiophene derivative, to produce localized oxidative polymerization of thiophene monomers.

Aiming for polymer structures at the nanometer scale, Nyffenegger and Penner [65] produced electrochemically active polyaniline particles with a size ranging from 10 to 60 nm in diameter and 1 to 20 nm in height by using the Pt tip of a scanning tunneling microscope as an electrode for the electropolymerization of aniline. Maynor and co-workers [66] used an electrochemical reaction at an atomic force microscope tip for region-specific deposition of conducting polymer *nanowires* with diameters in the range from 50 to 500 nm on semiconducting and insulating substrates.

Bumm et al. [67] demonstrated the use of a STM tip to probe electrical properties of individual conjugated conducting molecules ("*molecular wires*") dispersed into a self-assembled monolayer film of nonconducting alkanethiolate molecules. In a closely related but separate study, He and co-workers [68] have electrochemically deposited a conducting polyaniline nanowire bridge between a STM tip and a gold electrode by region-selectively coating the STM tip with an insulation layer so that only a few nm^2 at the tip end was exposed for localized growth of the polyaniline bridge (Fig. 9) [68].

Upon stretching the polymer nanowire by moving the STM tip away from the Au electrode, these authors observed a stepwise decrease in the conductance (Fig. 10), resembling that reported for metallic nanowires [69, 70].

The initial increase in the conductance seen in Figure 10a is attributed to the stretching-induced alignment of the polymer chains in the nanowire, since aligned conducting polymers have been demonstrated to show higher conductivities. The observed smaller conductance step height ($<2e^2/h$) and wider plateaus than those of metal nanowires may indicate the occurrence of polymer chains sliding in the polyaniline nanowires during stretching. The conductance of the polyaniline nanowires with various diameters was measured as a function of the electrochemical potential by stopping the stretching at different conductance steps.

In analogy to the control of the gate voltage in semiconductor devices [70], He et al. [68] measured the current–voltage curves by sweeping the tip–substrate bias voltage (V_{bias}) while maintaining the electrochemical potential of the substrate electrode (or the tip electrode) at different values. The resulting I–V_{bias} curves show a nearly linear relationship when the substrate potential is kept between 0.30 and 0.55 V (Fig. 11a and b). As seen in Figure 11c, however, the polyaniline nanowire exhibits rectifying characteristics at 0.25 V; the current is small at negative bias whereas it increases when the bias is positive. The observed rectifying characteristics become more pronounced when the potential is reduced to 0.2 V. The observed transition from ohmic to rectifying characteristics can be understood by considering

Figure 10. (a) Conductance of a polyaniline nanowire during an entire stretching process. The arrows point to the initial increase and followed by a stepwise decrease in the conductance. (b) A zoom in of the stepwise decrease. For clarity, curves (a) and (b) are shifted upward by 2 and 3 divisions, respectively. The substrate and tip potentials were held at 0.45 and 0.5 V, respectively. Reprinted with permission from [68], H. X. He et al., *Appl. Phys. Lett.* 78, 811 (2001). © 2001, American Institute of Physics.

Figure 9. Schematic drawing of the experimental setup. The electrochemical potential of the nanowire was controlled with respect to a reference electrode (RE) in the electrolyte. A counter-electrode was used as in a standard electrochemical setup. In comparison to a field effect transistor, the RE, WE1, and WE2 electrodes are analogous to the gate, source, and drain electrodes. Reprinted with permission from [68], H. X. He et al., *Appl. Phys. Lett.* 78, 811 (2001). © 2001, American Institute of Physics.

Figure 11. (a–c) Current (I) through a polyaniline nanowire as a function of the tip–substrate bias voltage (V_{bias}, drain–source voltage). (d) A model that explains the observed I–V_{bias} characteristics. The shaded bell curves represent conductivity of the nanowire at points near the tip and the substrate electrodes, respectively. Reprinted with permission from [68], H. X. He et al., *Appl. Phys. Lett.* 78, 811 (2001). © 2001, American Institute of Physics.

the situation described in Figure 11d, which shows that the polyaniline nanowire has one end attached to the tip and the other connected to the substrate. Therefore, the electrochemical potentials of the two ends are fixed at E_{sub} and E_{tip}. As polyaniline is in the oxidized conducting form at the electrochemical potentials close to or slightly higher than 0.3 V [71], both portions of the polyaniline nanowire near the substrate and tip are conducting at $E_{sub} = 0.40$ V with a small V_{bias} ($E_{tip} = E_{sub} + V_{bias}$) so that the I–V curve is ohmic. At 0.25 V, however, a negative sweep moves the E_{tip} to potentials lower than the redox potential of polyaniline (ca. 0.3 V) so that the polymer is in the nonconducting reduced form while a positive sweep of bias moves E_{tip} to the highly conductive region, leading to the rectifying behavior. The controllable conductance of the conducting polymer nanowires, together with their mechanical flexibility and rectifying characteristics, should have important implications for the use of polymer nanowires in various micro/nanoelectronic devices and many other applications.

3.2. Template Syntheses of Polymer Nanowires, Nanotubes, and Nanofibers

Polymer nanowires with interesting nanometer-scale architectures have also been fabricated using porous membranes or supramolecular nanostructures as templates. For instance, Smith et al. [72] have recently developed a process for producing nanocomposites with well-defined poly(p-phenylene vinylene) (PPV) nanowires within self-organizing liquid–crystal matrixes. This process involves self-assembling of a polymerizable liquid–crystal monomer (e.g., acrylate) into an ordered hexagonal array of hydrophilic channels (ca. 4 nm in diameter) filled with a precursor polymer of PPV, followed by photopolymerzation to lock in the matrix architecture and thermal conversion to form PPV nanofibers in the channels. As a result, significant fluorescence enhancement was observed, most probably due to the much reduced interchain-exciton quenching achieved by separating the PPV molecules from the polymer matrix.

More generally, polymer nanowires and nanotubes with improved order and fewer structural defects can be synthesized within a template formed by the pores of a nanoporous membrane [73] or the nanochannels of a mesoporous zeolite [74]. Template synthesis often allows the production of polymeric wires or tubules with controllable diameters and lengths (Fig. 12) [75]. Template synthesis of conjugated polymers, including polyacetylene, polypyrrole, polythiophene, polyaniline, and PPV, may be achieved by electrochemical or chemical oxidative polymerization of the corresponding monomers. While the electrochemical template synthesis can be carried out within the pores of a membrane that is precoated with metal on one side as an anode [73], the chemical template synthesis is normally performed by immersing the membrane into a solution containing the desired monomer and oxidizing agent, with each of the pores acting as a tiny reaction vessel.

It is noted with interest that if the pores of polycarbonate membranes are used as the template, highly ordered polymeric tubules are produced by preferential polymerization along the pore walls [76] due to the specific solvophobic
Figure 12. Scanning electron micrographs of microfibrils prepared in the alumina template membrane: (A) PS, (B) poly(vinylidene fluoride) (PVDF), (C) poly(phenylene oxide), and (D) PMMA. Reprinted with permission from [75], V. M. Cepak and C. R. Martin, *Chem. Mater.* 11, 1363 (1999). © 1999, American Chemical Society.

and/or electrostatic interactions between the polymer and the pore wall [73]. These conducting polymer tubules show a wide range of electrical conductivities, increasing with decreasing pore diameter [77, 78]. This is because the alignment of the polymer chains on the pore wall can enhance conductivity, and the smaller tubules contain proportionately more of the ordered material.

By wetting ordered porous templates with polymer solution or melts, Steinhart et al. [79] have developed another simple technique for the fabrication of polymer nanotubes with a monodisperse size distribution and uniform orientation.

Figure 13 shows polymer nanotubes formed by melt-wetting of ordered porous alumina and oxidized macroporous silicon templates with narrow pore size distribution. The method can be used to produce polymer nanotubes of narrow size distribution from almost all melt-processable polymers, their blends, or multicomponent solutions. More recently, conjugated conducting polymer nanotubes were synthesized using "template-free" polymerization that involves a self-assembled supramolecular template [80, 81]. These studies are of particular interest because high-temperature graphitization of the polymer nanotubes could transform them into carbon nanotubes of superior electronic and mechanical properties [82], as demonstrated by polyacrylonitrile nanotubules synthesized in the pores of an alumina membrane or in zeolite nanochannels [83, 84].

On the other hand, Kageyama and co-workers [85] prepared crystalline nanofibers of ultrahigh molecular weight polyethylene by extruding the polymer through porous nanoscale reactors as it was synthesized. In particular, these authors coated the hexagonal pores (27 Å) of mesoporous silica fiber reactors with the classic polymerization catalyst titanocene. After activating the catalyst, they then pressurize the vessel containing the reactors with ethylene gas. Being confined within the narrow pores, the resulting polymer chains were forced to grow out of the framework, much like spaghetti extruding from a pasta maker [86] (Fig. 14).

3.3. Electrospinning of Polymer Nanofibers

While the potential applications of polymer nanowires and nanotubes have yet to be fully exploited, polymer nanofibers have been demonstrated to be attractive for a large variety of potential applications, including as high performance filters, scaffolds in tissue engineering, wound dressings, sensors, and drug delivery systems [87–90]. However, the large-scale fabrication of polymer nanowires/nanofibers at a reasonably low cost has been a big challenge toward the realization of commercial applications of polymer nanofibers. Electrospinning, a technique which was first patented in 1934 [91], has recently been reexamined, notably by Reneker and co-workers [87–90], as an effective method for large scale fabrication of ultrafine polymer fibers.
The electrospinning process involves the application of a high electric field between a droplet of polymer fluid and a metallic collection screen at a distance of 5–50 cm from the polymer droplet. An electrically charged jet flows from the polymer droplet toward the collection screen when the voltage reaches a critical value (typically, ca. 5–20 kV) at which the electrical forces overcome the surface tension of the polymer droplet. The electrical forces from the charge carried by the jet further cause a series of electrically driven bending instabilities to occur as the fluid jet moves toward the collection screen. The repulsion of charge on adjacent segments of the fluid jet causes the jet to elongate continuously to form ultrafine polymer fibers. The solvent evaporates and the stretched polymer fiber that remains is then collected on screen as a nonwoven sheet composed of one fiber many kilometers in length. The electrospun polymer fibers thus produced have diameters ranging from several micrometers down to 50 nm or less. This range of diameters overlaps conventional synthetic textiles and extends through diameters two or three orders of magnitude smaller.

Reneker and co-workers have made significant advances on both theoretical and experimental fronts. They have carried out detailed theoretical studies on the formation of electrically charged polymer jet and its bending instability [92–94] and have also prepared a large number of novel polymer fibers with diameters from few nanometers to micrometers by electrospinning various synthetic and natural polymers from either solution or melts. Various polymers ranging from conventional synthetic polymers, through conducting and liquid crystalline polymers, to biopolymers have been electrospun into polymer nano/microfibers [89, 95]. A typical microscopic image of the resulting polymer nanofibers is shown in Figure 15 [96].

The electrospun fiber mats possess a high surface area per unit mass, low bulk density, and high mechanical flexibility. These features make the electrospun fibers very attractive for a wide range of potential applications. Among them, the use of electrospun polymer fibers for electronic applications is of particular interest. The high surface to volume ratio associated with electrospun *conducting polymer* fibers makes them excellent candidates for electrode materials since the rate of electrochemical reaction is proportional

to the surface area of an electrode and diffusion rate of the electrolyte. Reneker and co-workers [97] have reported the pyrolysis of electrospun polyacrylonitrile nanofibers into conducting carbon nanofibers. They have also prepared conducting polymer nanofibers by electrospinning polyaniline from sulfuric acid into a coagulation bath and characterized them by scanning tunneling microscopy, electron microscopy, and electron diffraction.

Norris et al. [98] prepared camphorsulfonic acid doped polyaniline (HCSA-PANI) and polyethylene oxide composite thin fibers (ca. 0.95–2 μm in diameter) by the electrospinning technique from a mixed solution. The four-point probe method [99] was used to measure the conductivity of the nonwoven fiber *mat* and was cross-checked with measurements of the conductivity of cast films produced from the same solution. Figure 16 shows the effect of the weight percentage content of HCSA-PANI on the room temperature conductivity obtained from the HCSA-PANI/PEO electrospun fibers and film [98]. As can be seen in Figure 16, the conductivity of the electrospun fiber mat was lower than that for a cast film, though they have very similar ultraviolet-visible (UV-vis) absorption characteristics. The lower conductivity values for the electrospun fibers than those of cast films can be attributed to the porous nature of the nonwoven electrospun fiber mat as the four-probe method measures the volume resistivity rather than the conductivity of an individual fiber. Although the measured conductivity for the electrospun mat of conducting nanofibers is relatively low, their porous structure, together with the high surface-to-volume ratio, enables faster de-doping and re-doping in both liquids and vapors.

In order to measure the conductivity of an individual nanofiber, MacDiarmid and co-workers [96] have also collected a *single* electrospun HCSA-PANI/PEO nanofiber on a silicon wafer coated with a thin layer of SiO_2 and deposited two separated gold electrodes 60.3 μm apart on the nanofiber (two-probe method). The current–voltage (I–V) curves thus measured for single 50 wt% HCSA-PANI/PEO fibers with diameters of 600 and 419 nm are shown in Figure 17a (i.e., Fiber 1 and Fiber 2, respectively), which give a more or less straight line with a conductivity

Figure 17. (a) Current–voltage curve for a single 50 wt% HCSA-PANI/PEO nanofiber. (b) Temperature dependence of the conductivity for a single 72 wt% HCSA-PANI/PEO nanofiber. Reprinted with permission from [96], A. G. MacDiarmid et al., *Synth. Met.* 119, 27 (2001). © 2001, Elsevier Science.

of ca. 0.1 S/cm. The temperature dependence of the conductivity for a single 72 wt% HCSA-PANI/PEO electrospun fiber with a diameter of 1.32 μm given in Figure 17b also shows a linear plot with a room-temperature conductivity of 33 S/cm (295 K). This value of conductivity is much higher than the corresponding value of about 0.1 S/cm for a cast film (Fig. 16), suggesting a highly aligned nature of the PANI chains in the electrospun fiber.

4. POLYMER NANOFILMS

Polymer thin films with their thickness at the nanometer scale (i.e., polymer nanofilms or nanosheets) are an important class of materials from the point views of both scientific fundamental and practical applications. For instance, the immobilization of a thin layer of biomacromolecules onto the surfaces of polymeric biomaterials could produce bioactivities [100], while conjugated polymer thin films play vital roles in organic optoelectronic devices, including polymer thin film transistors [101–103], photoconductors [104], photovoltaic cells [105], and light-emitting diodes (LEDs) [106, 107]. In this section, we choose polymer thin films formed by solution casting, plasma deposition, Langmuir–Blodgett deposition, and physical adsorption as a few examples to illustrate their importance to various practical applications with a focus on polymer LEDs.

4.1. Polymer Nanofilms by Solution Casting

The syntheses of soluble conjugated polymers offer excellent possibilities for advanced device fabrications using various solution-processing methods (e.g., spin-coating) [49]. The

simplest single layer LED devices consist of a thin solution-cast layer of electroluminescent conjugated polymer (e.g., poly[2-methoxy-5-(2′-ethyl-hexyloxy)-*p*-phenylene vinylene]) sandwiched between two electrodes (an anode and a cathode). Among the two electrodes, at least one should be transparent or semitransparent. In practice, a transparent indium-tin-oxide (ITO) coated glass is often used as the anode and a layer of low work-function metal (e.g., aluminum, calcium) acts as the cathode.

Upon application of an electrical voltage onto the electroluminescence (EL) polymer layer in a LED device, electrons from the low work-function cathode (e.g., Al) and holes from the high work-function anode (e.g., ITO) are injected respectively into the lowest unoccupied molecular orbital and the highest occupied molecular orbital of the polymer, resulting in the formation of a singlet exciton that produces luminescence at a longer wavelength (the Stokes shift) through radiative decay. To maintain a low operation voltage, a very thin polymer layer (ca. 100 nm) is usually used. The wavelength (and hence the color) of the photons thus produced depends on the energy gap of the organic light-emitting material, coupled with a Stokes shift. Since conjugated polymers can have π–π^* energy gaps over the range between 1 and 4 eV (1240–310 nm), polymer-based LEDs should, in principle, emit light across the whole spectrum from ultraviolet to near infrared with a good color tunablity by controlling the energy gap through molecular engineering [106, 107]. Indeed, polymer LEDs with a wide range of emission colors and with reasonably high quantum efficiencies (a few percentage) are now reported. For detailed discussion on the current state of the art in the development of polymeric LEDs, interested readers are referred to specialized reviews and conference monographs [108–111].

Although the solution-processing technique provides a simple and attractive approach for polymer thin film formation, it may cause a number of problems related to the quality of polymer films thus formed. These include difficulty in choosing suitable solvent(s) for preparing pinhole-free single layer or multilayer polymer thin films, in controlling the film thickness and polymer chain conformation. Consequently, various other methods, including plasma polymerization, the Langmuir–Blodgett technique, and layer-by-layer adsorption, for the formation of polymer nanofilms have been developed.

4.2. Polymer Nanofilms by Plasma Polymerization

To circumvent those problems intrinsically associated with the solution-processing technique, plasma polymerization has been used as an alternative thin-film-formation method. Radio-frequency glow-discharge is formed when gaseous monomers are exposed to a radio-frequency electric field at low pressure (<10 Torr) [112, 113]. During the glow-discharge process, energy is transferred from the electric field to free electrons, which inelastically collide with molecules leading to generation of more electrons, ions, and free radicals in the excited state. These plasma species are very reactive toward surfaces, causing surface modification in the case of plasma treatment and polymer deposition in

the case of plasma polymerization. Although the electrons activated for generating charged particles may have a very high electron temperature (e.g., 2 eV = 23, 200 K), they are not at thermodynamic equilibrium with gas molecules in the so-called "cold" plasma process [112]. Therefore, plasma treatment and plasma polymerization can be carried out with the gas molecules being at ambient temperature, and thus without thermal degradation of the sample surface and/or the plasma-polymerized layer. Plasma polymerization has been widely demonstrated to generate thin, cohesive, adhering, pinhole-free polymer thin films, which are often used as protective coatings or adhesion promoting layers and have potential applications in optical wave guides, sensor technology, and electronic/photonic devices [113]. Although plasma polymerization, in most cases, produces an electrically insulating organic film, a few approaches to semiconducting plasma polymer films have been reported. Along with others [114, 115], we have plasma-polymerized polyaniline thin films (ca. 350 nm) [116]. The plasma polyaniline films thus prepared are smooth and free of oxidant and solvents, having improved physicochemical characteristics compared with polyaniline films formed by electrochemical polymerization or chemical synthesis followed by spin-coating, solvent casting, or melt extrusion. The presence of conjugated sequences in the plasma-polyaniline films was confirmed by UV-vis, Fourier transform infrared and electron spin resonance measurements, which allow the conductivity of the plasma-polyaniline films to be enhanced by 3 orders of magnitude through HCl treatment. It was further demonstrated that the atomic ratios of C/N both higher and lower than that of aniline (C/N = 6) can be obtained by choosing appropriate discharge conditions, indicating the possibility of tailoring the structure and properties of the plasma-polyaniline films by optimizing the discharge conditions.

Although the advantages of the plasma-generated semiconducting polymer thin films for electronic applications remain to be demonstrated, an oxygen or nitrogen plasma treatment of a PPV layer at the PPV/Al interface in a LED device with the Cr/PPV/Al structure has been demonstrated to cause the disappearance of the rectifying behavior and an increase in the current by many orders of magnitude [117]. Similarly, the efficiency, brightness, and lifetime of LEDs were shown to be significantly improved by an air or argon plasma treatment on the ITO surface, presumably due to the removal of contaminants coupled with an increase in the work function of ITO [118, 119]. A hydrogen plasma, on the other hand, was found to increase the turn-on voltage and reduce the efficiency largely due to a decrease in the work function of ITO [118–121]. Thus, the plasma technique shows much promise for interfacial engineering in LEDs [120, 121]. Furthermore, a few studies have reported the use of plasma polymers as emitting layers in LED devices [122]. There is no doubt that the plasma polymerization of semiconducting organic films and plasma surface modification demonstrated previously will have potential implications for making novel electronic and photonic devices. The ease with which multilayered polymer nanofilms and microsized patterns of organic materials can be made by the plasma technique could add additional benefits to this approach [123].

4.3. Polymer Nanofilms by Langmuir–Blodgett Deposition

Although the solution-processing and plasma polymerization techniques discussed provide simplified approaches for polymer nanofilm formation, they provide no means of controlling the orientation of polymer chains in the resulting films. The Langmuir–Blodgett (LB) method involves the formation of a Langmuir film at the gas/liquid interface, followed by a dipping process to transfer the polymer thin film onto a solid substrate [124]. In addition to the ease with which the number of molecular layers (and hence the thickness of films) can be controlled at the molecular level, the LB technique has another major advantage for controlling the film structure in three dimensions [125] as the orientation of polymer chains in each of the layers can be independently controlled by anisotropic compression of the corresponding Langmuir film during the dipping process [126]. The oriented and/or patterned LB films [127] can be further used as substrates, for example, for controlling liquid crystal alignment [127]. As a consequence, the LB technique has been widely used for making manometer-thick multilayer films with well defined structures and ordered molecular organizations from amphiphilic conjugated polymers, nonconjugated precursor polymers, and even certain non-surface-active conjugated polymers.

LB films of highly anisotropic conducting polymers can be prepared through: (a) the manipulation of amphiphilic macromolecules comprising an alkyl chain as the hydrophobic group and with a conjugated polymer being attached to its hydrophilic end [128], (b) the manipulation of mixed monolayers consisting of a surface-active agent (e.g., dopant) and non-surface-active conjugated polymer [129], or (c) the direct synthesis of conducting polymers at the air–water interface or within a preformed multilayer film. To mention but a few examples, Shimidzu et al. [130–133] have prepared conducting LB films containing polypyrrole [130], polyaniline [131], or poly(3-alkylthiophene) [132]. Among them, multilayer LB films (200 layers) of a substituted polypyrrole showed an anisotropic conductivity as high as 10^{10} (i.e., $\sigma_{\parallel} = 10^{-1}$ S/cm and $\sigma_{\perp} = 10^{-11}$ S/cm) [131]. Well characterized LB films of various conjugated polymers including poly(3-alkylthiophene) have also been reported by Cheung et al. [129] for which the readers are referred to the excellent review by Rubner and Skotheim [134].

More recently, PPV-type LB films have also recently been prepared from the sulphonium precursor of PPV [135, 136] and some of its soluble derivatives [137–139]. Also, LEDs with polarized EL emissions have been fabricated using certain LB films as the EL material [140, 141]. On this basis, Grüner et al. [142] have precisely determined the location of the exciton recombination zone [143] in LEDs by making multilayer LB films of soluble PPP derivatives with two regions of perpendicular macroscopic orientation, followed by quantifying the emission profile through the analysis of the EL anisotropy.

4.4. Polymer Brushes by End Adsorption

End-adsorbed polymer brushes consist of another major class of oriented polymer thin films, in which the constituent polymer chains aligned *perpendicularly* on the substrate surface [144–147]. Just as the in-plan orientation of polymer chains in the LB films has brought new properties and hence broadened the scope for using polymer thin films in optoelectronic devices, the surface-bound polymer brushes have facilitated polymer thin films for many technological applications [144–150], such as in controlling the stability of colloidal dispersions, regulating the permeability of a cell membrane, metabolism, the transmission of information, the biocompatibility of biomaterials, and molecular separation by liquid chromatography. For instance, capsule membranes with end-grafted temperature/pH-responsive polymer chains [e.g., poly(N-isopropylacrylamide) or poly(glutamic acid)] may be used as thermoselective drug release devices and/or pH-sensitive gates via a conformational change of the end-grafted polymer brushes [151, 152]. Furthermore, end-adsorbed polymer chains have also been shown to be useful for regulating the frictional forces between solid surfaces, the spreading properties of liquids, and the stability of thin films on solid surfaces [153, 154]. Knowledge of macromolecular conformations and conformational transitions of surface-bound polymer chains is essential for a detailed understanding of their performance at the molecular level. Recent developments, on both experimental and theoretical fronts [144–147, 155–158] in the investigation of adsorbed polymer brought the goal of structural testing against theories within reach.

Generally speaking, the conformation of polymer chains adsorbed at the liquid/solid interface differs from that in a bulk solution [144–147]. This is particularly true for end-adsorbed polymer chains in a good solvent, where random coils of the macromolecules in solution may become highly stretched polymer "brushes" at the liquid/solid interface.

While end-adsorbed homopolymers and diblock copolymers form polymer brushes in which the chains can only exist in a "tail" conformation (Fig. 18a), end-adsorbed triblock copolymers, ABA (the A blocks represent short "sticking" segments, whereas the B block does not adsorb), can form either a "loop" or a "tail" depending on the sticking energy of the A block and the surface coverage at the liquid/solid interface [159] (Fig. 18b). Adsorbed homopolymer, on the other hand, forms a more complicated conformational structure (Fig. 18c) due to the random adsorption of its constituent monomers onto the surface.

Along with others, we have carried out the structural investigation of adsorbed polymers at the liquid/solid interface using surface force apparatus [159–161] (SFA) and neutron reflectometry [162–164]. The surface force apparatus contains two molecularly smooth mica sheets, mounted in a crossed cylinder configuration, being used as substrates for polymer adsorption [160]. The surface separation, D, can be varied by mechanical or piezoelectric transducers and is measured with the aid of interferometry to an accuracy of ca. 3Å. The corresponding force, $F(D)$, between the mica substrates is measured directly by observing the deflection of a leaf spring of known spring constant bearing one of the mica sheets. The results are presented in the form $F(D)/R$ vs D, where R is the geometric mean radius of curvature of the two mica surfaces, and the value of $F(D)/R$ gives the interaction energy per unit area of surface, $E(D)$ [159–161].

The use of SFA for measuring the interactions between adsorbed homopolymer surfaces at a high surface coverage
Figure 18. Conformations of adsorbed polymer chains. (a) "Tail-like" conformation of end-adsorbed homopolymer or diblock copolymer. (b) "Loop-like" or "tail-like" conformation of end-adsorbed triblock copolymer. (c) "Tail–loop–train" conformation of adsorbed homopolymer.

in a wide variety of solvency conditions has been reviewed elsewhere [165, 166]. Without repetition of the numerical discussions, the main results from the SFA studies are summarized in Fig. 19, which shows only schematic smooth curves instead of the actual $F(D)$ data for reasons of clarity.

As can be seen from curve (a) of Figure 19, the interaction between surfaces bearing adsorbed polymer chains in a poor solvent (e.g., polystyrene in cyclohexane at $T = 24\ ^\circ C$, $T_\theta = 35\ ^\circ C$) is characterized by a deep, long-ranged (ca. $3R_g$, R_g is the radius of gyration of a polymer coil) [167–169] attractive force, well-originating from the monomeric attraction in the poor solvent, followed by a repulsion at
Figure 19. Summary of interaction profiles between surfaces with adsorbed homopolymers in various solvency conditions at high surface coverage. Reprinted with permission from [165], J. Klein, in "Molecular Conformation and Dynamics in Condensed Systems" (M. Nagasawa, Ed.). Elsevier Science, Amsterdam, 1988. © 1988, Elsevier Science.

lower D values due to reduced available configurations for the adsorbed polymer chains in the gap because of excluded volume effects. At the theta temperature, T_θ, the attractive forces disappear [curve (b) of Fig. 19], reflecting the absence of the segment–segment interactions at the theta point. The onset distance for interactions reduces from $3R_g$ for the poor solvent case to around $2R_g$. In a good solvent, the interaction becomes monotonically repulsive with a longer ranged onset distance of 6–$8R_g$ [region (c) of Fig. 19], attributable to the repulsive monomer–monomer interactions (i.e., the osmotic repulsion) associated with the positive second virial coefficient in the good solvent.

Using a symmetric polystyrene–polyvinylpyridine (PS–PVP) diblock copolymer, Hadziioannou and co-workers [170] demonstrated that the nonadsorbing PS chains can be held onto the mica surface by the covalently linked adsorbing PVP blocks, with the PS chains being stretched out to form a polymer brush at the mica/toluene interface. To mimic a layer of end-grafted polymer chains more closely, Taunton et al. [155] used end-functionalized PS–X homopolymers and highly asymmetric PS_m–PEO_n diblock copolymers for the surface force measurements, where PS–X denotes linear polystyrene chains with one end terminated by the zwitterionic group $[\text{-}(CH_2)_3N^+(CH_2)_2\text{-}(CH_2)_3SO_3^-]$ and PS_m–PEO_n denotes polystyrene–poly(ethylene oxide) diblock copolymers [m and n are weight-averaged degrees of polymerization for polystyrene and poly(ethylene oxide) blocks, respectively, and n is small]. These authors demonstrated that the strong interaction between the zwitterionic or ethylene oxide groups and the mica surface can also terminally anchor the nonadsorbing PS block, as a dangling chain, at the mica/solvent (e.g., toluene) interface. At a higher surface coverage the PS chains are shown to be strongly stretched, to give a monotonic repulsive interaction between two such polymer "brushes," consistent with theoretical predictions [155, 171, 172].

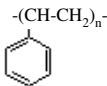
We have explored the conformational transitions of the end-adsorbed PS–PEO diblock copolymer chains by directly measuring the interactions of a *single* layer of the end-adsorbed PS–PEO diblock copolymer chains against a *bare* mica surface in pure toluene (good solvent) and pure cyclohexane (poor solvent, $T_\theta = 34\ ^\circ C$) [159]. The results are given in Figure 20 on a log-linear scale, in which no attraction is observed and strong repulsive forces are seen.

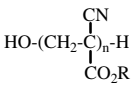
The effective layer thickness of ca. 1000 Å deduced from Figure 20a indicates that the PS_{1420}–PEO_{51} chains are terminally attached to the mica surface via the short PEO segments with the PS chains extending into the solution to form a polymer brush. Figure 20b gives the force–distance curve that was measured on the same end-adsorbed PS layer after the toluene was thoroughly replaced by pure cyclohexane. In comparison with Figure 20a, Figure 20b shows a steeper repulsive wall commencing at a much shorter separation distance, which demonstrates unambiguously that the end-adsorbed PS brush has collapsed in the poor solvent to form a more compact polymer layer at the cyclohexane/mica interface. Furthermore, the transitions between Figure 20a and Figure 20b with changing solvent quality are characterized by fast dynamics, suggesting potential applications, for example in polymeric valves, sensors, and liquid chromatography [173, 174].
Figure 20. Force–distance profiles on a log-linear scale for an end-adsorbed PS_{1420}–PEO_{51} diblock copolymer single layer against a *bare* mica surface during the first few compression–decompression cycles: (a) in toluene before and after having been immersed in cyclohexane; (b) in cyclohexane. The open double-arrow indicates that the transition between (a) and (b) is practically reversible. The inset shows the corresponding force profiles as (a) and (b), respectively, on a linear–linear scale. Reprinted with permission from [159], L. Dai et al., *Macromolecules* 28, 5512 (1995). © 1995, American Chemical Society.

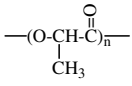
Although the surface force apparatus serves as a good experimental technique for probing conformations and conformational transitions of macromolecular chains within the adsorbed polymer thin film at the liquid/solid interface [159, 175], the force measurements cannot determine the distribution of segment density normal to the surface. Neutron reflection experiments provide information on the density profile normal to the interface [164, 176]. In this regard, we investigated the segment density profiles of the surface-bound polymers normal to the interface by reflectometry, choosing neutrons as the radiation because of important contrast effects which can operate at the molecular level [164]. For terminally anchored polymer chains in a good solvent, two regimes are anticipated. If the grafting density is low, the tethered chains do not interact with each other and exist as separate "mushrooms." If the grafting density is high, with a distance between anchor points less than the Flory radius of the chains (i.e., $s < R_F$), the polymers take up a more extended configuration to form a semidilute "brush" [162, 163].

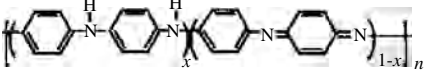
In the mushroom regime, each chain may be thought of as occupying roughly a hemisphere, with a radius comparable to the Flory radius for a polymer coil in a good solvent [162, 163, 177]. In the brush regime, however, the reflectivity profile of an end-adsorbed PS_{1700}–PEO_{167} from toluene onto quartz can be fitted by a parabolic function, consistent with the theoretical prediction for semidilute polymer brushes [178–180]. Our recent neutron reflectivity measurements on telechelic *triblock* copolymer chains [181] have demonstrated, to a very good approximation, that ABA-type end-tethered chains behave in a manner equivalent to their AB-type counterparts of half their molecular weight and they adsorb predominantly in a loop conformation for

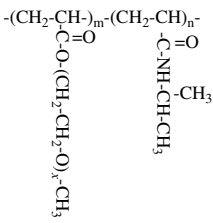
copolymers with sufficiently strong sticking A blocks, consistent with the SFA measurements [159, 175].

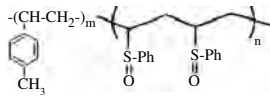
5. NANOSTRUCTURED POLYMERS WITH SPECIAL ARCHITECTURES


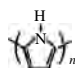






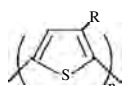






Just as microchips have revolutionized computers and electronics, nanotechnology has the potential to revolutionize many industrial sectors. As discussed, various polymer nanostructures (e.g., polymer nanoparticles, nanofibers, nanofilms; see Table 1) have been prepared to possess useful physicochemical properties for device applications. However, considerable efforts are required to design, construct, and operate new devices at the nanometer scale, as the technology for making proper connections from nanoscale entities to the macroscale world still remains a big challenge. In particular, electrically conducting nanofibers with diameters at the nanometer scale and lengths in kilometers are both useful "building blocks" for nanodevice construction and ideal connections between the nanoscale entities and the macroscale world. Effective fabrication of *ordered* nanostructured polymers is a pre-requisite for the intergration of nanostructured materials into useful "building blocks" and various functional units/nanodevices of practical significance. As we shall see later, techniques, including colloidal self-assembling, phase separation, and nanopatterning, have been devised to construct polymer materials and functional systems of multidimensional *ordered* nanostructures.

5.1. Self-Assembly of Ordered Nanoporous Polymers

Polymers with periodically modulated mechanical, optical, electronic, or magnetic properties have potential applications in many areas, including sensors, displays, microelectronics, data storage devices, and nonlinear optics [182, 183]. For instance, polymers with periodic dielectric media, like photonic crystals, could be used to manipulate and control light [184, 185]. Therefore, the fabrication of thin films with three-dimensional (3D) periodic arrays by incorporation of large quantities of monodisperse domains in an organized fashion within appropriate matrices or using self-organization (i.e., self-assembling) of colloid nanoparticles has rapidly become the forefront of development in materials science. Consequently, many novel nanostructured polymers of multidimensional periodic structures have been reported. To mention but a few examples, Kumacheva and co-workers [186] have used the self-assembling approach to producing nanostructured polymers with a 3D periodic structure (Fig. 21).


As can be seen in Figure 21a, Kumacheva et al. [186] first synthesized a core–shell latex consisting of a hard core-forming polymer and a soft shell-forming polymer. They then packed these core–shell latex particles into thin layers of 3D structures by, for example, precipitation, centrifugation, or electrodeposition followed by latex drying. The resulting materials were finally annealed at high temperature to melt the soft shells, leading to the formation of nanostructured polymer thin films consisting of 3D nanoparticle assemblies. The laser confocal fluorescent microscopy

images of the surface and the bulk morphology of the 3D nanostructured polymer films thus prepared are given in Figure 21b, which shows a highly ordered structure in the *z*-direction as well as in the lateral domains. These highly ordered nanostructured polymers with 3D periodic structures have been demonstrated to be promising media for data storage.

On the other hand, Jenekhe and Chen [187] have prepared multidimensional ordered mesoporous polymer materials by self-assembling hollow spherical micelles made by self-organized rod–coil diblock copolymers in a selective solvent. Figure 22a schematically shows the approach used with the morphology of the resulting materials given in Figure 22b. Although micropores were observed in this particular case (Figure 22b), the diameter, periodicity, and wall thickness of the ordered arrays of spherical holes were demonstrated to depend on the copolymer molecular weight and composition, indicating the possibilities of forming porous polymer films with nanostructured holes for a variety of applications ranging from size/shape-selective separation to photonic modulation.

5.2. Coaxial Polymer Nanowires and Nanofibers

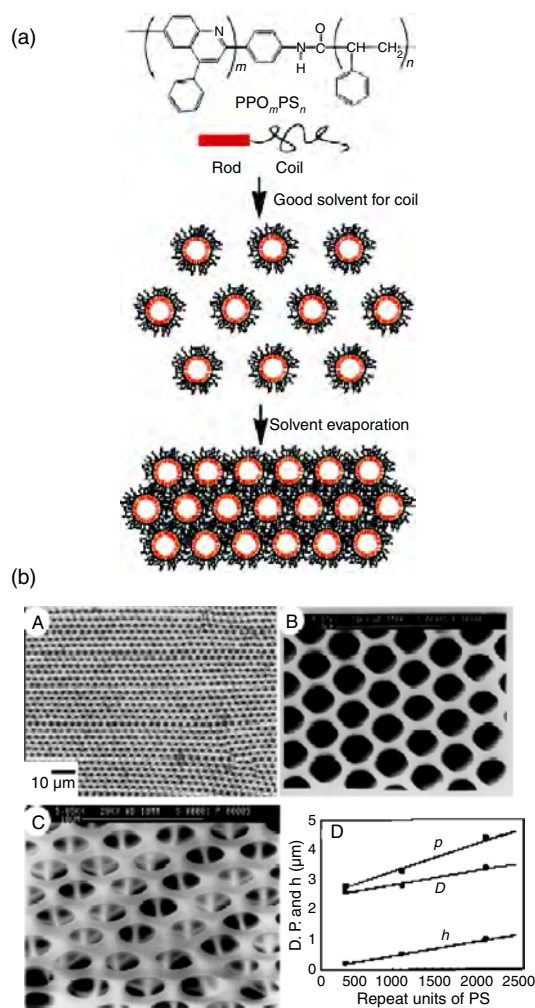
5.2 The formation of ordered structures from metal nanowires and carbon nanotubes has been an active research area for some years. Various nano- and microfabrication techniques have been developed. Examples include the use of electric and magnetic fields for aligning suspended metallic nanowires [188–190], the combination of fluidic alignment with patterned surface structures (e.g., microchannels)


Figure 22. (a) Schematic illustration of its hierarchical self-assembly into ordered microporous materials. for nanowire patterning, [191, 192] and the lithographic patterning of aligned carbon nanotubes [193]. The effective fabrication of ordered polymer nanowires or nanofibers is a more recent development. While a few aligned polymer nanowires prepared by synthesizing them at a scanning microscope tip or by using a template were described (Section 3), the possibility of forming aligned *electrospun* nanofibers by using a rotating cathode collector has recently been reported [194, 195]. Nonconducting electrospun polymer fibers have also been used as "templates" for coating with appropriate conducting polymers and for deposition of a metal layer from solution or vapor [196]. MacDiarmid and co-workers [96] reported the uniform coating of an electrospun polyacrylonitrile nanofiber with a layer of conducting polypyrrole (20 to 25 nm thick) by immersing the

electrospun fibers in an aqueous solution of polymerizing polypyrrole. These authors also prepared gold coated poly-acrylonitrile nanofibers through treatment of the electro-spun fibers with a solution of AuS_2O_3 and ascorbic acid.

Reneker and co-workers [197] coated electrospun poly(*meta*-phenylene isophthalamide) nanofibers with sub-nanometer thick coatings of various other materials (e.g., carbon, Cu, and Al) by chemical and physical vapor deposition. They also prepared nanotubes consisting of pure aluminum or mixtures of aluminum and aluminum oxide by coating the electrospun poly(*meta*-phenylene isophthalamide) nanofiber with an aluminum layer, followed by selectively removing the polymer nanofiber core via solvent dissolution or thermal degradation [197]. During thermal degradation of the poly(*meta*-phenylene isophthalamide) nanofiber cores, the aluminum coated layer was subjected to a limited degree of oxidation, which produced nanotubes of mixed aluminum and aluminum oxide. The aluminum coated layers did not oxidize when the template fiber core was removed by dissolution. Figure 23A(a–c) shows TEM images of aluminum-coated poly(*meta*-phenylene isophthalamide) fibers with the coating thickness increasing from ca. 10 to 100 nm. As seen in Figure 23B(a–c), aluminum nanotubes remained after dissolution of the fiber cores of poly(*meta*-phenylene isophthalamide) with N,N-dimethylacetamide solvent. The electron diffraction pattern associated with the aluminum nanotubes shown

in Figure 23B(a) is given in Figure 23B(d), in which all the d-spacings are characteristic of the aluminum crystal unit cell.

Another interesting area closely related to the fabrication of polymer nanowires and nanofibers is the synthesis of coaxial nanowires of polymers and carbon nanotubes. We have recently prepared large-scale aligned carbon nanotubes perpendicular to the substrate surface by pyrolysis of iron (II) phthalocyanine ($FeC_{32}N_8H_{16}$, designated as FePc) under Ar/H_2 at 800–1100 °C and developed a novel approach for chemical modification of aligned carbon nanotubes [198]. Radio-frequency glow-discharge plasma treatment activated the surface of the nanotubes for subsequent reactions characteristic of the plasma-induced surface groups. We then successfully grafted polysaccharide chains onto the plasma-activated aligned carbon nanotubes through Schiff-base formation, followed by reductive stabilization of the Schiff-base linkage with sodium cyanoborohydride (Fig. 24).

The resulting amino-dextran grafted nanotube film showed zero air/water contact angles. The (acetaldehyde) plasma treated carbon nanotube film gave relatively low advancing (90°), sessile (78°), and receding (45°) air/water contact angles compared to the advancing (155°), sessile (146°), and receding (122°) angles for an untreated sheet of aligned carbon nanotubes. The glucose units within the surface-grafted amino-dextran chains (Fig. 24) can be further converted into dialdehyde moieties by periodate oxidation [199], thereby providing a method for creating multilayer coaxial structures.

In addition to the chemical grafting of polymer chains onto the carbon nanotube surface, we recently used the aligned carbon nanotubes as nanoelectrodes for making novel conducting coaxial nanowires by electrochemically depositing a concentric layer of an appropriate conducting polymer uniformly onto each of the aligned nanotubes to form the aligned conducting polymer coated carbon nanotube coaxial nanowires (CP-CNT) [200]. The SEM image for these CP-CNT coaxial nanowires given in Figure 25b shows the same features as the aligned nanotube array of Figure 25a, but the tubes had a larger diameter due to the presence of the newly electropolymerized polypyrrole coating. The presence of the conducting polymer layer was also clearly evident in TEM images [200] (Fig. 25c). The aligned CP-CNT coaxial nanowires were demonstrated to show much stronger redox responses than the conventional conducting polymer electrode [200]. The coaxial structure allows the nanotube framework to provide mechanical stability [201, 202] and efficient thermal and electrical contact with the conducting polymer layer [203, 204]. The large interfacial surface area per unit mass obtained for the nanotube-supported conducting polymer layer is potentially useful in many optoelectronic applications, for example in sensors, organic light-emitting diodes, and photovoltaic cells where the charge injection and separation are strongly limited by the interfacial area available in more conventional devices [49].

To demonstrate the potential sensing applications for the CP-CNT coaxial nanowires, we have also immobilized glucose oxidase (GO_x) onto the aligned carbon nanotube substrate by electropolymerization of pyrrole in the presence of glucose oxidase [205]. The glucose oxidase-containing polypyrrole-carbon nanotube coaxial nanowires were used to monitor the concentration change of hydrogen peroxide (H_2O_2) generated from the glucose oxidation reaction by measuring the increase in the electro-oxidation current at the oxidative potential of H_2O_2 (i.e., the amperometric

method) [205]. The amperometric response was found to be much higher than that of more conventional flat electrodes coated with glucose oxidase-containing polypyrrole films under the same conditions. The CP-CNT nanowire sensors were also demonstrated to be highly selective for glucose with their amperometric responses being almost unchanged even in the presence of some interference species including ascorbic acid, urea, and D-fructose. Therefore, the CP-CNT nanowires could be used for making new glucose sensors with a high sensitivity, selectivity, and reliability, which is clearly an area in which future work would be of value.

5.3. Multilayered Polymer Nanofilms

Polymer-based multilayer thin films have recently received significant attention due to their potential use as photonic crystals for manipulation and control of light. Indeed, certain multilayer polymer nanostructures with the phase-separated lamellar domains of different refactive indices have been used as 1D optical reflectors for reflecting a band of frequencies for both TE and TM polarized light regardless of angle of incidence [206, 207]. Apart from the multilayer film formation by polymer phase separation to be discussed, the construction of multilayer polymer nanofilms has also been achieved by the LB technique (Section 4.3) and a layer-by-layer self-assembly process developed by Ferreira and Rubner [208]. The principle of the layer-by-layer process lies in the alternate spontaneous adsorption of oppositely charged polymers from dilute solutions. This technique has been successfully used to generate multilayer thin films comprised of sequentially adsorbed layers of partially doped polyaniline and a polyanion (e.g., sulphonated polystyrene), leading to conductivities comparable to those obtained with spin-cast films (0.5–1.0 S/cm) after having been doped with strong acids such as HCl and methanesulfonic acid [209]. Based on the layer-by-layer adsorption process, Rubner et al. [210–212] have also constructed multilayer LEDs from PPV and poly(styrene sulfonic acid), (SPS), or poly(methacrylic acid) (PMA) and found that the type of polyanion used has a significant effect on the performance of the LED devices fabricated with Al and ITO as electrodes. In particular, LEDs fabricated from PMA/PPV multilayers were found to exhibit luminance levels in the range of 20–60 cd/m^2 with a thickness dependent turn-on voltage and rectification ratios greater than 10^5, whereas the SPS/PPV counterparts showed nearly symmetric I–V curves with a thickness independent turn-on voltage and much lower luminance levels. The observed difference in the device performance can be attributed to a doping effect associated with the sulfonic acid groups in SPS. Furthermore, these authors have recently extended the layer-by-layer adsorption process to include the hydrogen-bonding interactions between the polyaniline and poly(vinylpyrrolidone), poly(vinyl alcohol), poly(acrylamide), or poly(ethylene oxide) [213]. By using preordered/prepatterned substrates, the layer-by-layer absorption process should, in principle, lead to the construction of oriented/patterned conjugated polymers.

Another interesting area closely related to the polymer–polymer multilayer structure is the intercalation of polymer chains into the layered structures of clay nanoparticles,
leading to the formation of organic–inorganic hybrid multilayer films [214]. Organic–inorganic hybrid composites constitute a new class of materials, possessing properties characteristic of both constituent components with potential synergetic effects [215–217]. Owing to their unusual properties, organic–inorganic hybrid nanocomposites have attracted increased attention in recent years. Consequently, various polymers including poly(ethylene oxides) [218, 219], poly(olefins) [220], polyimide [221], polypyrrole [222], and polyaniline [223, 224] have been incorporated into clay nanoparticles through either a solution or a melt intercalation process [225, 226]. The most widely used clay is montmorillonite, which consists of an alumina octahedral and two silica tetrahedral sheets stacking into the layered structure with a gallery gap of ca. 1 nm between the layers. The galleries are normally occupied by cations (e.g., Na^+, Ca^{2+}, Mg^{2+}), which can be easily replaced through alkylammonium ion exchange reaction to form the so-called organoclay. The alkylammonium ions in the organoclay layered structure facilitate the intercalation of polymer chains. At high intercalation levels, the clay may exfoliate into their nanoscale building blocks to disperse uniformly in the polymer matrices, forming exfoliated polymer–clay nanocomposites. The organic–inorganic hybrid nanocomposites thus prepared have been demonstrated to show improved environmental stability, mechanical strength, and lower permeability for gases with respect to corresponding pure polymers [227–229].

On the other hand, certain electroluminescent organic–inorganic hybrid materials have also been prepared by sol–gel chemistry [230]. In this context, we have recently intercalated conjugated conducting and light-emitting polymers into clay nanoparticles at an intercalation level below the critical value required for the clay exfoliation to explore the conformational effects on their optoelectronic properties. As is well known, the band gap energies of conjugated polymers, and hence the related optoelectronic properties, depend strongly on their chain conformations [71]. Therefore, the conformational changes of light-emitting polymer backbones could be exploited as an alternative approach to color tuning, in addition to chemical modification of the polymer structure, in polymer light-emitting diodes. On this basis, we intercalated light-emitting poly[1,4-(2,5-bis(1,4,7,10-tetraoxaundecyl)phenylenevinylene)] (EO_3-PPV), into clay nanoparticles for light-emitting measurements [231].

The intercalation process is experimentally revealed by a steady increase in the height of the clay galleries as determined by X-ray diffraction [231]. The photoluminescent (PL) spectra of the composites at several different intercalation levels are given in Figure 26. As can be seen, the PL emission shows a redshift with increasing intercalation level. Included in the inset of Figure 26 is the dependence of the PL peak position (λ_{max}) on the polymer content, which shows that the λ_{max} continuously increases with increasing polymer content to a limiting value of ca. 610 nm, characteristic of EO_3-PPV, at ca. 20% (w/w), then remains unchanged despite further intercalation. These features could be attributed to an intercalation-induced conformational transition from a "compact coil" to "expanded coil," which should lead to an increase in the effective con-
Figure 26. PL emissions from the EO_3-PPV intercalated clay nanoparticles at different intercalation levels. Reprinted with permission from [231], B. Winkler et al., *J. Mater. Lett.* 18, 1539 (1999), © 1999, Plenum.

jugation length, and hence a concomitant decrease in the bandgap energy.

Our results from a single layer LED device based on the EO_3-PPV intercalated nanoparticles showed an EL spectrum similar to the PL emission. As expected, the similarity between the EL and PL emissions suggested that the same singlet excitons were generated upon both the PL and EL excitation.

Closely related to the preparation of layered nanocomposites consisting of polymer thin films interspersed with clay sheets, Matsumoto and co-workers [232] have moved a step further forward by showing novel polymer sandwiches with different fillings. In so doing, these authors first created layered structures consisting of layers of muconate anions (i.e., reactive dienes with carboxylate group at either end) sandwiched between layers of alkylammonium cations (Fig. 27). They then polymerized the layered muconate anions into molecule-thick polymer sheets by exposure to ultraviolet light. Upon exposure of the "synthetic clay" to acid, the alklammonium cations were removed to free the uncharged polymer sheets. The released polymer sheets can be "glued" together again by one of the many alkylammonium ions for a large variety of potential applications, ranging from molecular recognition to chemical purification.

5.4. Nanostructured Polymers by Phase Separation and Nanopatterning

Apart from the discussed *isolated* polymer nanostructures (e.g., nanoparticles, nanofibers, and nanofilms) and their assemblies, nanostructured polymer domains consisting of an intrinsic part of the polymer morphology (hence cannot be separated from other features of the polymer material) have also been prepared through, for example, polymer phase separation and nanopatterning.

Like the self-assembling technique discussed, polymer phase separation plays an important role in fabrication of nanostructured polymers, as it provides the opportunity for nanoscale structuring that otherwise is difficult by lithographic techniques [233, 234]. The conditions necessary for microphase separation in immiscible polymer mixtures depend on their molecular architectures, nature of
Figure 27. Schematic representation showing how to build molecular sandwiches with different fillings. Reprinted with permission from [232], A. Matsumoto et al., *Nature* 405, 328 (2000). © 2000, Macmillan Magazines Ltd.

monomers, compositions, and molecular weights [235, 236]. By varying polymer structures and phase separation conditions, at least seven well-defined microdomain structures with sizes typically in the range of a few tens of nanometers have been observed in polymer materials (Fig. 28).

Among these well-defined microdomain structures observed in phase separated polymer systems, cylindrical microdomains formed by block copolymers are of particular interest as the selective removal of either the minor or major component can transform thin polymer films into an array of nanopores or nanoscopic posts. The resultant polymer nanostructures could be used as membranes for molecular separation and/or as templates for preparing electronic and magnetic nanostructured materials.

The phase separation of block copolymers has been the subject of intensive study over the past several decades [233–236]. It has recently been demonstrated that cylindrical microdomains in certain phase-separated block copolymer thin films can be oriented normal to the substrate surface by either controlling interfacial interactions between the copolymer and substrate with anchored random copolymers [237, 238] or by applying an external electric field normal to the surface [239–241]. Figure 29A and B shows atomic force microscope (AFM) images for a phase-separated asymmetric polystyrene and poly(methyl methacrylate) (PS-b-PMMA, ca. 30% volume fraction of PMMA) block copolymer thin film (40 nm thick) spin-cast onto Si substrates precoated with a random copolymer of PS and PMMA having a PS fraction of 0.60 [242]. Cylindrical microdomains oriented in the direction perpendicular to the substrate are clearly evident, especially in the phase image of Figure 29B. The corresponding AFM height and phase images for the same PS-b-PMMA film after selectively removing the PMMA component by deep UV radiation and dissolution in a selective solvent (i.e., acetic acid for PMMA) are given in Figure 29C and D, respectively. Both show an ordered array of circular nanoholes perpendicularly oriented in the polymer film.

By adding PMMA homopolymers with appropriate molecular weights into the PS-b-PMMA matrices, Jeong et al. [243] were able to tune the size of the cylindrical microdomains (and hence the circular holes) formed in the block copolymer films without perturbing their spatial order and orientation. They found that pore diameters either larger or smaller than those achievable with the pure copolymer could be obtained by selective removal of the homopolymer and corresponding block of the copolymer or the homopolymer only. By so doing, both 6 and 22 nm diameter pores have been prepared from the same block copolymer film.
Figure 29. AFM image for a PS-b-PMMA block copolymer thin film on a neutral substrate after annealing at 170 °C in tapping mode before [(A) shows the height image and (B) the phase image] and after [(C) shows the height image and (D) the phase image] removal of the PMMA cylinders. Holes at the original locations of the cylinders are clearly seen. Reprinted with permission from [242], T. Thurn-Albrecht et al., *Adv. Mater.* 12, 787 (2000). © 2000, Wiley–VCH.

More interestingly, these authors have recently used the phase-separated PS-*b*-PMMA nanoporous films and nanoscopic posts as templates for producing metal nanodots and nanoporous metal films, respectively, by evaporation metal (e.g., Cr, Au) thin films on these polymer nanostructures, followed by selective removal of the polymer templates [244].

Based on polymer phase separation, Berggren et al. [245] have also demonstrated the formation of submicrometer-sized domains having a range of compositions and emission characteristics by self-organization (i.e., phase separation) in polymer blends consisting substituted polythiophenes with different bandgaps. As a result, a voltage-controlled multiple-color emission was achieved, suggesting an attractive way for making future polymeric electroluminescent color screens.

Like the soluble substituted polythiophenes, polyacetylene can be solubilized by making copolymers with polyisoprene, polystyrene, or polybutadiene via the so-called anionic to Ziegler–Natta route [49]. The polyisoprene–polyacetylene (PI–PA) diblock copolymers thus prepared present an unusual situation where the high flexibility and solubility associated with polyisoprene chains and the stiffness and conductivity characteristic of insoluble conjugated polyacetylene chains are combined into one macromolecule. Due to the large difference in physical properties between these two blocks, the copolymers of PI–PA are expected to show phase separation in solution and domain structure in the solid state [246, 247]. Indeed, we have recently found that I_2 doping of the PI–PA copolymer films leads to the formation of a pseudo interpenetrating polymer network (PIPN) [247]. The aggregated structures (especially the PIPN network) play an important role in regulating the electrical properties of the PI–PA copolymers [247], and the doping-induced phase separation process may have potential implications for making various multiphase conducting polymers with different ordered structures ranging from the nanometer to micrometer scale.

Furthermore, the chain segregation has also been either experimentally observed or theoretically predicted for block copolymers confined between two constituent homopolymer layers [248], two foreign walls [249–252], or end attached at the liquid/solid interface [253, 254], suggesting a considerable scope for patterning of polymer chains through polymer phase separation. To mention but a few examples, Zhao and co-workers [255] have experimentally demonstrated nano-pattern formation by tethered PS-*b*-PMMA brushes upon treatment with selective solvents, while a number of other groups have reported the patterning of polymer brushes by various lithographic techniques [256].

As is well known, photolithographic processing has been widely used for the pattern formation in semiconducting industries (e.g., for delineating the circuit elements in todays's large-scale integrated devices) for many years with an ultimate resolution at the submicrometer scale. Recent work on photolithographic patterning of conducting polymers and carbon nanotubes [100, 257] has demonstrated that photolithographic techniques, coupled with appropriate chemical reactions, could provide effective means for the micro/nanopattern formation of various organic electronic materials [100, 257, 258]. For instance, in 1988, Thakur

reported that the conductivity of nonconjugated cis-1,4-polyisoprene (i.e., natural rubber) could be increased by about 10 orders of magnitude upon "doping" with iodine [259]. In view of the ease with which conducting rubber can be made and the potential challenge of Thakur's claim to modern theory of conducting polymers, Thakur's work received complimentary comments from several scientific journals [260–262]. Meanwhile, various other polymers with isolated (nonconjugated) double bonds, such as *trans*-1,4-polyisoprene, 1,4-poly-(2,3-dimethylbutadiene), and *trans*-1,4-polybutadiene, have also been found to become dark in color and conductive when "doped" with iodine in the solid state. Surprisingly, however, *cis*-1,4-polybutadiene does not change color or become conductive upon "I_2 doping" under the same conditions [260–262]. We were the first to demonstrate that "I_2 doping" of 1,4-polyisoprene produces conjugated sequences of unsaturated double bonds in the polyisoprene backbone through polar addition of I_2 into the isolated double bonds in the polymer chain, followed by HI elimination [263].

The reaction mechanism for the I_2-induced conjugation is shown in Figure 30, and the conjugated sequences thus produced have been shown to be responsible for the high conductivity of the "I_2-doped" polyisoprene. The reactions shown in Figure 30 have been confirmed by optical and other spectroscopic measurements reported by several groups, including ours [263–267].

In our further investigation of conducting polydienes [264], we have found that *cis*- and *trans*-1,4-polybutadiene exhibit different behavior toward the reactions of Figure 30. For *cis*-1,4-polybutadiene the reaction sequence given in Fig. 30 terminated, at room temperature, at product (II), whereas for the *trans*-isomer the reaction sequence proceeded toward product (III) and/or (IV) thus leading to the
Figure 30. Reactions of polydiene with iodine, leading to the formation of conjugated sequences. Reprinted with permission from [263], L. Dai and J. W. White, *Polymer* 32, 2120 (1991). © 1991, Elsevier Science.

formation of conjugated sequences which confer electrical conductivity. Spectroscopic measurements and molecular orbital calculations demonstrated that it was an unfavorable combination of electronic and steric interactions within the iodinated *cis*-1,4-polybutadiene backbone (product II) that inhibited the elimination of hydrogen iodide through the E-2 elimination mechanism [reaction (2) of Fig. 30] at room temperature and hence halted the formation of conjugated sequences in the case of *cis*-1,4-polybutadiene [264]. However, *cis*-1,4-polybutadiene can be photoisomerized into the *trans*-isomer [268], and the isomerized material is then amenable to "I$_2$ doping." This discovery provides means for photolithographic generation of conducting patterns from *cis*-1,4-polybutadiene films through region-specific photoisomerization of the *cis*-isomer into its *trans*-counterpart and subsequent I$_2$-induced conjugation of the photoisomerized *trans*-1,4-polybutadiene chains [269]. The conducting patterns thus formed are colored and show strong fluorescence emission, which enables visualization of the conducting polymer regions.

An example of the conducting patterns thus generated is shown in Figure 31a. It is a close replication of the photomask structure, and conducting wires on a micrometer scale are clearly evident. A corresponding fluorescence microscopic image of the conducting pattern is given in Figure 31b. It shows the same features as the optical micrograph (Fig. 31a), but with inverse intensities in the image. The dark regions characteristic of the "I$_2$-doped" *trans*-1,4-polybutadiene in Figure 31a gave rise to bright fluorescence emission in Figure 31b, consistent with the fluorescence emission originating from the conjugated structures [270, 271]. The dark regions in Figure 31b represent nonfluorescent components associated with the *cis*-isomer. The resolution obtained in this study is limited by the light wavelength and photomask structure, which can, in principle, be improved for generation of polymer patterns with a submicron resolution.

More recently, we have also demonstrated that lithographic techniques could be applied to the pattern formation of carbon nanotubes. Although carbon nanotubes synthesized by most of the common techniques often exist in a randomly entangled state, [272, 273] aligned carbon nanotubes have been prepared either by postsynthesis

fabrication or by synthesis-induced alignment [100]. As briefly mentioned in Section 5.2, we, among others [274–278], have prepared large-scale aligned carbon nanotube arrays *perpendicular* to the substrate surface by pyrolysis of iron(II) phthalocyanine onto the pristine quartz glass plates [279]. Subsequently, we have also developed microfabrication methods for patterning the aligned carbon nanotubes with a submicrometer resolution [280]. Our method allows not only the preparation of micropatterns and substrate-free films of the perpendicularly aligned nanotubes but also their transfer onto various substrates, including those which would otherwise not be suitable for nanotube growth at high temperatures (e.g., polymer films) [279]. In one study, we have developed a novel method for photolithographic generation of the perpendicularly aligned carbon nanotube arrays with resolutions down to a micrometer scale [281].

Figure 32a shows the steps of the photolithographic process. In practice, we first photolithographically patterned a positive photoresist film of diazonaphthoquinone (DNQ)-modified cresol novolak onto a quartz substrate. Upon UV irradiation through a photomask, the DNQ-novolak photoresist film in the exposed regions was rendered soluble in an aqueous solution of sodium hydroxide due to photo-generation of the hydrophilic indenecarboxylic acid groups from the hydrophobic DNQ via a photochemical Wolff rearrangement [282]. We then carried out the pyrolysis of FePc, leading to region-specific growth of the aligned carbon nanotubes in the UV exposed regions (Fig. 32b). In this case, the photolithographically patterned photoresist film, after an appropriate carbonization process, acts as a shadow mask for the patterned growth of the aligned nanotubes. This method is fully compatible with existing photolithographic processes [283].

Furthermore, we have also used the micro-contact printing (μCP) and micromolding techniques [284] to prepare micropatterns of carbon nanotubes aligned in a direction normal to the substrate surface [285]. While the μCP process involves the region-specific transfer of self-assembling monolayers (SAMs) of alkylsiloxane onto a quartz substrate and subsequent adsorption of polymer chains in the SAM-free regions (Fig. 33a), the micromolding method allows the formation of polymer patterns through solvent evaporation from a precoated thin layer of polymer solution confined between a quartz plate and a polydimethylsiloxane (PDMS)

Huang et al., *J. Phys. Chem. B* 104, 2193 (2000). © 2000, American Chemical Society.

elastomer mold (Fig. 33b). The DNQ-novolak photoresist patterns formed in both cases were then carbonized into carbon black for region-specific growth of the aligned nanotubes in the polymer-free regions by pyrolysis of iron(II) phthalocyanine under Ar/H_2 atmosphere at 800–1100 °C (Fig. 33c), as is the case for the aforementioned photolithographic patterning. The spatial resolution is limited by the resolution of the mask used and submicrometer features were obtained.

Subsequently, we found that 3D micropatterns of well-aligned carbon nanotubes can also be prepared by pyrolysis of FePc onto appropriate photopatterned substrates [286]. In this particular case, the photopatterning was achieved by photolithographic cross-linking of a chemically amplified photoresist layer spin-cast on a quartz plate or a Si wafer, coupled with a solution development to generate a negative photoresist pattern. Owing to an appropriate surface characteristic, the patterned photoresist layer was found in this case to support the aligned carbon nanotube growth by pyrolysis of FePc, as were the photoresist-free substrate surfaces. The difference in chemical nature between the surface areas covered and uncovered by the photoresist film, how-

ever, caused a region-specific growth of the nanotubes with different tubular lengths and packing densities (Fig. 34).

As can be seen from this discussion, micropatterns of aligned nanotubes with resolutions down to a submicrometer scale, suitable for fabrication of various electronic and photonic devices, have been prepared by lithographic techniques. These lithographic patterning methods, coupled with the ease with which polymer chains can be chemically and/or electrochemically attached onto the carbon nanotube wall (Section 5.2), should allow the formation of the nanostructured polymer-nanotube coaxial nanowires in a patterned fashion, attractive for constructing various on-tube optoelectronic devices and sensor arrays.

On the other hand, three-dimensional polymer nanopatterns have also been prepared by some nonconventional lithographic techniques. Notably, a mask-induced self-assembling (MISA) process has been applied to the nanopattern formation in polymer films [287–290]. In this process, a mask with protruded patterns is placed at a certain distance above the top surface of a polymer melt (e.g., PMMA, PS), in the presence or absence of an external field (e.g., thermal or electrical field), allowing attraction of an excess amount of polymer chains to the area below the mask protrusions. Subsequent solidification of the polymer melt thus leads to the formation of polymer patterns with a lateral dimension identical to that of the mask protrusions. Using the MISA patterning technique, 3D polymer patterns with feature size down to nanometer scales can be prepared [288]. Figure 35A shows schematically a typical procedure for the MISA patterning. An AFM image of polymer nanopatterns produced by the MISA technique is given in Figure 35B, which shows well-defined 3D nanopatterned structures.

As can be seen, the MISA method is a straightforward and feasible technique for fabricating polymer patterns with submicrometer/nanometer features. Continued research efforts in this embryonic field could give birth to a flourishing area of nanopatterning technologies.

Figure 35. (A) Schematic of MISA: (a) a thin polymer film cast on a flat silicon substrate, (b) a mask with protruding patterns placed a distance above the polymer film, and (c) the polymer film self-constructs into a mesa under a mask protrusion. The mesa has a lateral dimension identical to that of the mask protrusion, a height equal to the distance between the mask and the substrate. (B) AFM image of the PMMA pillars formed by MISA. Each PMMA pillar is formed under each dot protrusion on the mask. Reprinted with permission from [288], S. Y. Chou et al., *Appl. Phys. Lett.* 75, 1004 (1999). © 1999, American Institute of Physics.

6. CONCLUDING REMARKS

An overview of the recent progress in research and development of nanostructured polymers was presented. As can be seen, nanostructured polymers, including nanoparticles, nanowires, nanotubes, nanofibers, nanofilms, and their derivatives, possess interesting biomedical, electronic, optical, and mechanical properties for use in many potential applications. In order to realize their commercial applications, nanopatterning of polymer materials and self-assembling of nanostructured polymers have also been developed for effective incorporation of polymer nanostructures into nanodevices, and proper connections of the nanoscale structures and devices to the macroscale world. With the promising approaches already reviewed in this chapter, and more to be developed, practical applications of nanostructured polymers are imminent.

ABBREVIATIONS

AFM   Atomic force microscopy.
CP-CNT   Conducting polymer-carbon nanotube.
DNQ   Diazonaphthoquinone.
EL   Electroluminescence.
EO$_3$-PPV   Poly[1,4-(2,5-bis(1,4,7,10-tetraoxaundecyl)phenylenevinylene)].
ESR   Electron spin resonance.
FePc   Iron(II) phthalocyanine.
FTIR   Fourier transform infrared.
GO$_X$ Glucose oxidase.
HCSA   Camphorsulfonic acid.
ITO   Indium tin oxide.
LB   Langmuir–Blodgett.
LED   Light-emitting diode.
MAF   Graft copolymer of methylacrylic acid and methyl methacrylate.

MISA   Mask-induced self-assembling.
NR   Neutron reflectivity.
PAN   Polyacrylonitrile.
PANI   Polyaniline.
PCL   Poly(ε-carprolactone).
PEO   Poly(ethylene oxide).
PI-PA   Polyisoprene–polyacetylene diblock copolymer.
PIPN   Pseudo interpenetrating polymer network.
PL   Photoluminescence.
PMA   Poly(methylacrylic acid).
PMMA   Poly(methyl methacrylate).
PMS   Poly(4-methylstyrene).
PNIPAM   Poly(N-isopropylacrylamide).
PPV   Poly(p-phenylene vinylene).
PS   Polystyrene.
PTFE   Polytetrafluoroethylene.
PVDF   Poly(vinylidene fluoride).
PVP   Polyvinylpyridine.
PVSO   Poly(phenylvinylsulfoxide).
SECM   Scanning electrochemical microscope.
SEM   Scanning electron microscope.
SFA   Surface force apparatus.
SPS   Poly(styrene sulfonic acid).
STM   Scanning tunneling microscope.
TEM   Transmission electron microscope.
μCP   Microcontact printing.
UV-vis   Ultraviolet-visible.

GLOSSARY

Carbon nanotube   An elongated tubular structure consisting of carbon hexagons arranged in a concentric manner with a diameter at the nanometer scale.

Electroluminescence   The emission of light by a substance upon the excitation by an applied voltage.

Fluorescence   The emission of light by a substance immediately after the absorption of energy from light of usually shorter wavelength.

Nanostructure   Structural entities with at least one dimension down to a nanometer scale.

Polymer   A chain-like molecule of large size in which the atoms are held together by covalent bonds.

Polymer brush   An assembly of end-anchored polymer chains at the liquid-solid interface in which each of the constituent polymer chains adopts an extended linear chain conformation.

Self-assembling   The spontaneous generation of well-defined supramolecular architectures through non-covalent aggregation of macromolecular or low molecular weight compounds.

Template synthesis   The production of materials with controllable structures by synthesizing them within the pores of a template membrane.

Polymer/Clay Nanocomposites

Masami Okamoto

Toyota Technological Institute, Tempaku, Nagoya, Japan

CONTENTS

1. INTRODUCTION

Polymer/clay *nanocomposites* (PCNs) are a new class of materials which have attracted much attention from both scientists and engineers in recent years due to their excellent properties such as high dimensional stability, heat deflection temperature, gas barrier performance, reduced gas permeability, optical clarity, flame retardancy, and enhanced mechanical properties when compared with the pure polymer or conventional composites (micro- and macrocomposites) [1–15]. The first successful PCN appeared about 10 years ago through the pioneering efforts of a research team from Toyota Central Research & Development Co. Inc. (TCRD) in the form of a Nylon 6/clay hybrid [1, 2].

Earlier attempts to prepare polymer/clay composites are found in almost half-a-century old patent literatures [16, 17]. In such cases, incorporation of 40 to 50 wt% clay mineral (bentonite, hectorite, etc.) into a polymer was attempted but ended with unsatisfactory results: The maximal modulus enhancement was only around 200%, although the clay loading was as much as 50 wt%. The failure was obvious because they failed to achieve good dispersion of clay particles in the matrix, in which clay minerals existed as agglomerated tactoids. Such a poor dispersion of the clay particles could improve the material rigidity but certainly sacrifice the strength, the elongation at break, and the toughness of the material [16, 17].

A prime reason for this impossibility of improving the tactoid dispersion into well-dispersed exfoliated monolayers of the clay is obviously due to the intrinsic incompatibility of hydrophilic layered silicates with hydrophobic engineering plastics. One attempt at circumventing this difficulty was made by Unitika Ltd. [18] about 30 years ago in preparing Nylon 6/clay composites (not nanocomposites) via *in-situ* polymerization of ε-caprolactam with montmorillonite, but the results were not very good.

The first major breakthrough of the problem was brought about in 1987, when Fukushima and Inagaki of TCRD, via their detailed study of polymer/layered silicate composites, persuasively demonstrated that *lipophilization*, by replacing inorganic cations in galleries of the native clay with alkylammonium surfactant, successfully made them compatible with hydrophobic polymer matrices [19]. The modified clay was thus called *lipophilized* clay, *organo-phillic* clay, or simply *organo*-clay (organoclay). Furthermore, they found that the lipophilization enabled one to expand clay galleries and exfoliate the silicate layers into single layers of a nanometer thickness.

Six years later, in 1993, Usuki, Fukushima, and their colleagues at TCRD successfully prepared, for the first time, *exfoliated* Nylon 6/clay hybrid (NCH) via *in-situ* polymerization of ε-caprolactam, in which alkylammonium-modified organoclay was thoroughly dispersed in advance [1, 2]. The resulting composite of the loading of only 4.2 wt% clay possessed a doubled modulus, a 50% enhanced strength, and an increase in heat distortion by 80 °C compared to the neat Nylon 6, as shown in Table 1. This invention opened up a

Table 1. Mechanical and thermal properties of Nylon 6/clay hybrid.

Properties	Nylon 6 nanocomposite	Neat Nylon 6
Clay content (wt%)	4.2	0
Specific gravity	1.15	1.14
Tensile strength (MPa)	107	69
Tensile modulus (GPa)	2.1	1.1
Impact (kJ/m^2)	2.8	2.3
HDT (°C at 1.8 MPa)	147	65

new era of engineering materials, which we may call "polymer/clay *nanocomposites*."

Thus, along the stream of development in PCN technologies, many studies have been devoted to PCNs since their intrinsically excellent properties of polymer should have attractive potential for continuous expansion of application versatility.

Apart from this, rheological behavior, especially elongational and shear flow behavior in the molten state and crystallization behavior under supercooled state of PCNs, has not well been reported yet, although such knowledge should be indispensable in relation with their performance in processing operations. One objective of this chapter is to focus on a profound understanding of PCNs for their innovations in practical material production. For this purpose, it is indispensable to illuminate the nanostructure as well as rheological properties of PCNs to assess appropriate processing conditions for designing and controlling their hierarchical nanostructure, which must be closely related to their material performance.

2. STRUCTURE OF CLAY AND ITS MODIFICATION WITH SURFACTANTS

The commonly used clays for the preparation of PCNs belong to the same general family of 2:1 layered or phyllosilicates. (see Table 2.) Their crystal structure consists of layers made up of two silica tetrahedral fused to an edge-shared octahedral sheet of either aluminum or magnesium hydroxide. The layer thickness is around 1 nm and the lateral dimensions of these layers may vary from 30 nm to several micrometers and even larger depending on the particular layered silicate. Stacking of the layers leads to a regular van der Waals gap between the layers called the *interlayer* or

Table 2. Chemical formula and characteristic parameter of commonly used 2:1 phyllosilicates.

2:1 Phyllosilicates	Chemical fourmula[a]	CEC (mequiv /100 gm)	Particle length (nm)
Montmorillonite	$M_x(Al_{4-x}Mg_x)Si_8O_{20}(OH)_4$	110	100–150
Hectorite	$M_x(Mg_{6-x}Li_x)Si_8O_{20}(OH)_4$	120	200–300
Saponite	$M_xMg_6(Si_{8-x}Al_x)Si_8O_{20}(OH)_4$	86.6	50–60

[a] M = monovalent cation; x = degree of isomorphous substitution (between 0.3 and 1.3).

gallery. Isomorphic substitution within the layers (for example, Al^{+3} replaced by Mg^{+2} or by Fe^{+2}, or Mg^{+2} replaced by Li^{+1}) generates negative charges that are counterbalanced by alkali and alkaline earth cations situated inside the galleries, as shown in Figure 1.

The most commonly used layered silicates are montmorillonite (MMT) hectorite and saponite having different chemical formulas, respectively, $M_x(Al_{4-x}Mg_x)Si_8O_{20}(OH)_4$, $M_x(Mg_{6-x}Li_x)Si_8O_{20}(OH)_4$, and $M_x(Si_{8-x}Al_x)Si_8O_{20}(OH)_4$ ($x = 0.3–1.3$). The type of clay is characterized by a moderate surface charge (cation exchange capacity) (CEC of 80–120 mequiv/100 gm) and layer morphology. These clays are only miscible with hydrophilic polymers, such as poly(ethylene oxide) (PEO) [20] and poly(vinyl alcohol) (PVA) [21]. To improve miscibility with other polymer matrices, one must convert the normally hydrophilic silicate surface to organophilic, which makes possible intercalation of many engineering polymers. Generally, this can be done by ion-exchange reactions with cationic surfactants including primary, secondary, tertiary, and quaternary alkyl ammonium or alkylphosphonium cations. The role of alkylammonium or alkylphosphonium cations in the organosilicates is to lower the surface energy of the inorganic host and improve the wetting characteristics with the polymer matrix and results in a larger interlayer spacing. One can evaluate that about 100 alkylammonium salt molecules are localized near the individual silicate layers ($\sim 8 \times 10^{-15}$ m^2) and active surface area (~ 800 m^2/g). Additionally, the alkylammonium or alkylphosphonium cations could provide functional groups that can react with the polymer matrix or in some cases initiate the polymerization of monomers to improve the strength of the interface between the inorganic and the polymer matrix [22, 23].

Vaia et al. [24] have shown that alkyl chains can vary from liquidlike to solidlike, with the liquidlike structure dominating as the interlayer density or chain length decreases (see Fig. 2), or as the temperature increases by using Fourier transform infrared spectroscopy (FTIR). This is due to the relatively small energy differences between the *trans* and

Figure 2. Alkyl chain aggregation models. (a) Short chain lengths: the molecules are effectively isolated from each other. (b) Medium lengths: quasi-discrete layers form with various degrees of in-plane disorder and interdigitation between the layers. (c) Long lengths: interlayer order increases leading to a liquid–crystalline polymer environment. Open circles represent the CH$_2$ segments while cationic head groups are represented by filled circles. Reprinted with permission from [24], R. A. Vaia et al., *Chem Mater.* 6, 1017 (1994). © 1994, American Chemical Society.

gauche conformers; the idealized models described earlier assume all *trans* conformations. In addition, for the longer chain length surfactants, the surfactants in the layered silicate can show thermal transition akin to melting or liquid–crystalline to liquidlike transitions upon heating.

3. PREPARATIVE METHODS AND STRUCTURE OF POLYMER/CLAY NANOCOMPOSITES

So far there have been much literature available devoted to developing PCNs with different combinations of organoclays and matrix polymers such as epoxy polymer resin [5], polyurethanes (PU) [6], PEI [7], polybenzoxazine [8], polypropylene (PP) [9, 14, 15, 25], polystyrene (PS) [10, 11], poly(methyl methacrylate) (PMMA) [11, 12], and poly(ε-caprolactone) (PCL) [13] liquid crystalline polymers (LCP) [26] by employing somewhat different technologies appropriate to each. The technologies are broadly classified into three main categories.

3.1. Intercalation of Polymer or Prepolymer from Solution

This is based on a solvent system in which polymer or prepolymer is soluble and the silicate layers are swellable. The layered silicate is first swollen in a solvent, such as water, chloroform, toluene, etc. When the polymer and layered silicate solutions are mixed, the polymer chains intercalate and displace the solvent within the interlayer of the silicate. Upon solvent removal, the intercalated structure remains, resulting in PCNs.

3.2. *In-situ* Intercalative Polymerization Method

In this method, the organoclay is swollen within the liquid monomer or a monomer solution so that the polymer formation can occur in between the intercalated sheets.

Polymerization can be initiated either by heat or radiation, by the diffusion of a suitable initiator, or by an organic initiator or catalyst fixed through cation exchange inside the interlayer before the swelling step by the monomer.

3.3. Melt Intercalation Method

This method involves annealing, statically or under shear, a mixture of the polymer and organoclay above the softening point of the polymer. This method has great advantages over either *in-situ* intercalative polymerization or polymer solution intercalation. First, this method is environmentally benign due to the absence of organic solvents. Second, it is compatible with current industrial process, such as extrusion and injection molding. The melt intercalation method allows the use of polymers which were previously not suitable for *in-situ* polymerization or the solution intercalation method.

Other possibilities are exfoliation–adsorpsion [21, 27] and template synthesis [28, 29]. Nowadays this solvent-free method is much preferred for practical industrial material production for its high efficiency and possibility of avoiding environmental hazards.

3.4. Structure of PCNs

The *in-situ* polymerization is employed for the first time in NCH production [1, 2], and the melt intercalation is the direct blending of organoclay into modified polymer matrix such as used in PP/clay nanocomposite [9, 14, 15, 25, 30]. Since Vaia et al. [31] found that the melt compounding of polymers with clay is possible without using organic solvent, nanocomposite preparations via this method have been widely used in practice, especially for polyolefin-based nanocomposites. This process involves annealing, statically or under shear, a mixture of the polymer and organoclay above the softening point of the polymer. During the anneal, the polymer chains diffuse from the bulk polymer melt into the galleries between the silicate layers. Depending on the degree of penetration of the matrix into the organically modified layered silicate galleries, nanocomposites are obtained with structures ranging from *intercalated* to *exfoliated*. Polymer penetration resulting in finite expansion of the silicate layers produces intercalated nanocomposites consisting of well-ordered multilayers with alternating polymer/silicate layers and a repeat distance of few nanometers (intercalated; see Fig. 3) [30]. On the other hand, extensive polymer penetration resulting in disordered and eventual delamination of the silicate layers produces *near to* exfoliated nanocomposites consisting of individual silicate layers dispersed in polymer matrix (exfoliated) [32]. Under some conditions, the intercalated nanocomposites exhibit flocculation because of the hydroxylated edge–edge interaction of silicate layers (intercalated and flocculated). The length of the oriented collections in the range of 300–800 nm is far larger than original clay (mean diameter $\cong$ 150 nm) [33, 34]. Such flocculation presumably is governed by an interfacial energy between polymer matrix and organoclays and is controlled by ammonium cation–matrix polymer interaction. The polarity of the matrix polymer is of fundamental importance in controlling the nanoscale structure.

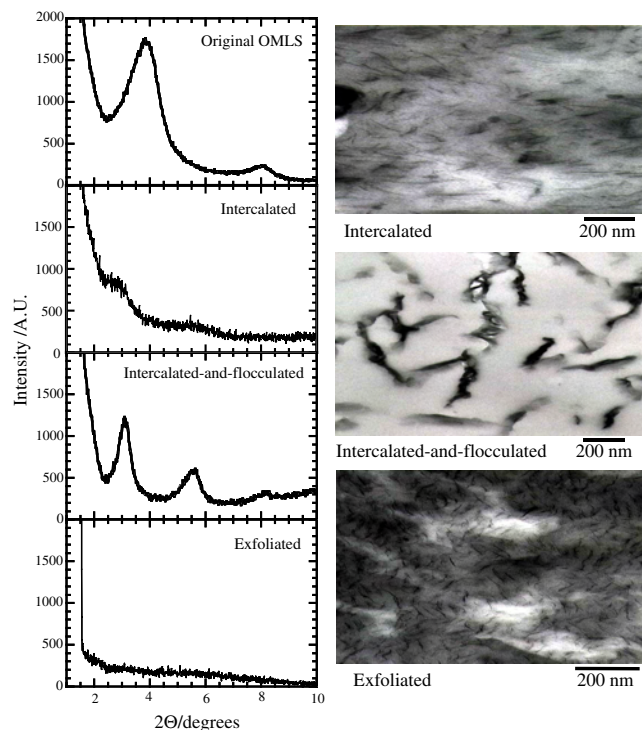
4. CHARACTERIZATION OF POLYMER/CLAY NANOCOMPOSITES

Generally the structure of the PCNs has typically been established using a wide-angle X-ray diffraction (WAXD) analysis and transmission electron microscope (TEM) observation. Due to its easiness and availability WAXD is most commonly used to probe the PCN structure and sometimes to study the kinetics of the polymer melt intercalation. By monitoring the position, shape, and intensity of the basal reflections from the distributed silicate layers, the PCN structure, either *intercalated* or *exfoliated*, may be identified. For example, in case of *exfoliated* nanocomposites, the extensive layer separation associated with the delamination of the original silicate layers in the polymer matrix results in the eventual disappearance of any coherent X-ray diffraction from the distributed silicate layers. On the other hand, for *intercalated* nanocomposites, the finite layer expansion associated with the polymer intercalation results in the appearance of a new basal reflection corresponding to the larger gallery height.

Although WAXD offers a convenient method to determine the interlayer spacing of the silicate layers in the original layered silicates and in the intercalated nanocomposites (within 1–4 nm), little can be said about the spatial distribution of the silicate layers or any structural inhomogeneities in the PCNs. Additionally, some layered silicates initially do not exhibit well-defined basal reflection. Thus, peak broadening and intensity decreases are very difficult to study systematically. Therefore, conclusions concerning the mechanism of nanocomposite formation and their structure based solely on WAXD patterns are only tentative.

On the other hand, TEM allows a qualitative understanding of the internal structure, spatial distribution of the various phases, and defect structure through direct visualization. However, special care must be exercised to guarantee a representative cross section of the sample. The WAXD patterns and corresponding TEM images of three different types of nanocomposites are presented in Figure 4.


5. TYPES OF POLYMERS USED FOR POLYMER/CLAY NANOCOMPOSITE PREPARATION

5.1. Vinyl Polymers

These include the vinyl addition polymers derived from common monomers like methyl methacrylate (MMA) [11, 33, 35–44], methyl methacrylate copolymers [12, 33, 45, 46], other acrylates [47–49], acrylic acid [50, 51], acrylonitrile [52–55], styrene (S) [10, 11, 31, 56–80], 4-vinylpyridine [81], acrylamide [82, 83], and tetrafluoro ethylene [84]. In addition, selective polymers like PVA [21, 85–87], poly(*N*-vinyl pyrrolidone) [88, 89], poly(vinyl pyrrolidinone) [90–93], poly(vinyl pyridine) [94], poly(ethylene glycol) (PEG) [95], poly(ethylene vinyl alcohol) [96], poly(vinylidene fluoride) [97], poly(*p*-phenylenevinylene) [98], polybutadiene [99], poly(styrene-*co*-acrylonitrile) (SAN) [100], ethyl vinyl alcohol copolymer [101], polystyrene–polyisoprene diblock copolymer [102, 103], and others [104] have also been used.

5.1.1. PMMA/Clay Nanocomposites

Okamoto et al. [11, 33] used organically modified smectite clays for the preparation of PMMA and PS nanocomposites. Organically modified smectite clays (SPN and STN) were prepared by replacing Na$^+$-smectite with QA (quaternary), oligo (oxypropylene) diethylmethylammonium cation (SPN) or methyltrioctilammonium cation (STN) by exchange reaction. In a typical synthesis, both lipophilized smectite clays were (SPN and STN) dispersed in MMA and S via ultrasonication at 25 °C for 7 h to obtain suspensions. After that *t*-butyl peroxy-2-ethylhexanate and/or 1,1-bis(*t*-butyl peroxy)

cyclohexane as an initiator was added to the suspensions and then free-radical polymerization was carried out in the dark at 80 °C for 5 h (for MMA) and at 100 °C for 16 h (for S) in a silicon oil bath. For comparison authors also prepared PMMA and/or PS including QA as the reference under the same conditions and procedure. WAXD analyses were performed directly from the suspensions of MMA/SPN, MMA/STN, and S/SPN, and corresponding nanocomposites.

From WAXD patterns of MMA/STN suspension (see Fig. 5a), the higher order peaks of interlayer spacing corresponding to $d_{(002)}$ and $d_{(003)}$ are clearly observed along with basal spacing $d_{(001)}$ peak, suggesting MMA intercalated into the STN gallery without the loss of layer structure, while the corresponding nanocomposite, PMMA/STN, exhibits rather broad Braggs peaks, indicating the formation of disordered intercalated structure.

In contrast, for MMA/SPN suspension (see Fig. 5b), the absence of any Bragg diffraction peaks indicates that the clay has been completely exfoliated or delaminated in the suspension. A similar pattern was observed in case of corresponding PMMA/SPN nanocomposite but with a small remnant shoulder as shown in Figure 5b.

Further studies by the same group [33] have demonstrated the effect of the nature of co-monomers on the structure of PMMA nanocomposites prepared via *in-situ* free-radical co-polymerization of MMA in presence of lyophilized smectite clays (each containing 10 wt%). They used three different types of co-monomers (each 1 mol%) such as N, N-dimethylaminopropyl acrylamide (PAA), N, N-dimethylaminoethyl acrylate (AEA), and acrylamide (AA) for the free-radical polymerization of MMA. Figure 6 represents the results of WAXD patterns of various nanocomposites (each containing 10 wt% of SPN clay). The same behavior of the stacked is observed but the thickness of the aggregation slightly decreased compared to that of PMMA/SPN10. In case of PMMA-PAA(1)/SPN10 (see Fig. 7c), individual silicate layers connected through the edge are clearly observed in the PMMA-PAA(1) matrix and large anisotropy of the dispersed clay is observed. In contrast, the PMMA-AA(1)/SPN10 nanocomposite (see Fig. 7d) exhibited less stacking of 4–5 silicate layers with a distance of about 5 nm as a fine dispersion in the PMMA-AA(1) matrix. The coherent orders of the silicate layers in this system are higher than that in other systems and are consistent with the WAXD patterns (see Fig. 6). They also prepared PMMA/SPN10 nanocomposite with a high content (3 mol%) of AA and AEA co-monomers and then tried to find out the effect of nanocomposite morphology on co-monomer amount. The length versus thickness schemes of randomly dispersed silicate layers in the nanocomposites nicely demonstrate the characteristic effects of the polar group in each co-monomer on the morphology (see Fig. 8). Incorporation of 1 mol% of AEA co-monomer possessing a dimethyl amine group appears to lead to a slight edge–edge interaction. On the other hand, the introduction of the AA co-monomer having an amide group appears to play an important role in delaminating the silicate layers. However, incorporation of 3 mol% of AEA and AA lead to the stacking of the layers compared to the corresponding 1 mol% copolymer matrix systems. We believe this behavior may be due to the formation of strong hydrogen bonding between the polar groups. For the PAA co-monomer having both polar groups, a much stronger flocculation takes place.

Figure 5. WAXD patterns of various monomer/organoclay suspensions and corresponding polymer/clay nanocomposites. The dashed lines indicate the location of the silicate (00*l*) reflection of organoclay from suspensions and nanocomposites. The asterisk indicates the position of (00*l*) reflections from suspensions and nanocomposites. The arrows indicate a small shoulder or a weak peak. Reprinted with permission from [11], M. 5.1.2. PS/Clay Nanocomposites

The same method recently was used by Zeng et al. [77] for the preparation of PS-based nanocomposites. S-monomer was first intercalated into the interlayer space of organoclay. Upon the intercalation, the complex was subsequently polymerized in the confinement environment of the interlayer space with a free-radical initiator, 2,2-azobis isobutyronitrile. Akelah and Moet [57, 60] have used this *in-situ* intercalative polymerization technique for the preparation of PS-based nanocomposites. They modified Na$^+$-MMT and Ca^{+2}-MMT with vinylbenzyltrimethyl ammonium cation by the ion exchange reaction and these modified MMTs were used for the preparation of nanocomposites. They first disperse and swell modified clays in various solvent and co-solvent mixtures such as acetonitrile, acetonitrile/toluene, and acetonitrile/THF by stirring for 1 h under N$_2$ atmosphere. To the stirred solution S and *N-N'*-azobis (isobutyronitrile) (AIBN) were added, and polymerization of S was carried at 80 °C for 5 h. The resulting composites were isolated by precipitation of the colloidal suspension in methanol, filtered off, and dried. In this way, intercalated PS/MMT nanocomposites were produced and the extent of intercalation completely depends on the nature of solvent used. Although the PS is well intercalated, a drawback of this procedure remains that the macromolecule produced is not a pure PS but rather a copolymer between S and vinylbenzyltrimethylammonium cations. For the preparation of PS based nanocomposites, Doh and Cho [63] have more commonly used MMT. They compared the ability of several tetra-alkylammonium cations incorporated in Na$^+$-MMT through the exchange reaction to promote the intercalation of PS through the free-radical polymerization of S initiated by AIBN at 50 °C. They found that the structural affinity between S monomer and the surfactant of modified MMT plays an important role in the final structure and the properties of nanocomposites. This concept has, however, been nicely achieved by Weimer et al. [67] for the preparation of PS/MMT nanocomposites. They modified Na$^+$-MMT by anchoring an ammonium cation bearing a nitroxide moiety known for its ability to mediate the controlled/"living" free-radical polymerization of S in bulk. The absence of WAXD peaks in the low angle area together with the TEM observations of silicate layers randomly dispersed within the PS matrix attest to the complete exfoliation of the layered silicate.

PS was also the first polymer used for the preparation of nanocomposite using the melt intercalation technique with alkylammonium cation modified MMT [31]. In a typical preparative method, PS first was mixed with host organoclay powder, the mixture was pressed into a pellet, and then the pellet was heated in a vacuum at 165 °C. This temperature is well above the bulk glass transition temperature of PS ensuring the presence of a polymer melt. The WAXD patterns of the hybrid before heating show peaks characteristic of the pure organoclay and during heating the organoclay peaks were progressively reduced while a set of new peaks corresponding to the PS/clay appeared. After 25 h, the hybrid shows the WAXD patterns corresponding predominantly to that of intercalated structure. The same authors also carried out the same experiment under the same experimental conditions using Na$^+$-MMT, but WAXD patterns did

not show any intercalation of PS into the silicate galleries emphasizing the importance of polymer/clay interactions. They also attempt to intercalate PS in the toluene with the same organoclay as used for melt intercalation resulting in intercalation of the solvent instead of PS. Therefore, direct melt intercalation enhances the specificity for the polymer by eliminating the competing host–solvent and polymer–solvent interaction. The schematic illustration of polymer chains intercalated in organoclay is presented in Figure 9.

Syndiotactic polystyrene (s-PS)/organoclay nancomposites have also been prepared by the solution intercalation technique by mixing pure s-PS and organoclay with adsorbed cetyl pyridium chloride [75]. The WAXD analyses and TEM observations clearly established the near exfoliate structure of the prepared nanocomposites.

5.1.3. SAN/Clay Nanocomposites

Kim et al. [100] used this method for the preparation of SAN/clay nanocomposites using PCL as a compatibilizer. They used a two-step mixing sequence for the preparation of SAN nanocomposites. PCL/clay master batches with different degrees of intercalation were first prepared and then were melt-mixed with SAN, where PCL is miscible with SAN. The intercalation behavior of PCL in the master batches was investigated in terms of the type of organoclay and mixing conditions. Longer mixing time and lower mixing temperature were required for the preparation of PCL master batches with exfoliated structure. As the degree of exfoliation of organoclay becomes better, the stiffness reinforcement effect of the organoclay increases in both PCL/clay master batches and their blends with SAN.

5.1.4. PVA/Clay Nanocomposites

More recently, Strawhecker and Manias [87] have used this method in attempts to produce PVA/MMT nanocomposite films. PVA/MMT nanocomposite films were cast from MMT/water suspension where PVA was dissolved. Room temperature distilled water was used to form a suspension of Na^+-MMT. The suspension was first stirred for 1 h and then sonicated for 30 min. Low viscosity, fully
Figure 9. Schematic illustration of polymer chains intercalated in organoclay. Reprinted with permission from [31], R. A. Vaia et al., *Chem. Mater.* 5, 1694 (1993). © 1993, American Chemical Society.

hydrolyzed atactic PVA was then added to the stirring suspensions such that the total solid (silicate plus polymer) was ≤5 wt%. The mixtures were then heated to 90 °C to dissolve the PVA and again sonicated for 30 min, and finally films were cast in a closed oven at 40 °C for 2 days. The recovered cast films were then characterized by both WAXD and TEM. Both the *d*-spacing and their distribution decrease systematically with increasing MMT wt% in the nanocomposites. The TEM photograph of 20 wt% clay containing nanocomposite reveals the coexistence of silicate layers in the intercalated and the exfoliated states.

5.1.5. Block Copolymer/Clay Nanocomposites

Krishnamoorti et al. [102, 103] prepared the block copolymer-based layered silicate nanocomposites. Disordered polystyrene–polyisoprene block copolymer/layered silicate nanocomposites were prepared by solution mixing of appropriate quantities of finely ground dimethyldioctadecylammonium cation modified MMT (2C18-MMT) and an anionically synthesized monodisperse polystyrene-1,4-polyisoprene (7 mol% 3, 4 and 93 mol% 1,4) diblock copolymer (PSPI18) in toluene at room temperature. The homogeneous solution was dried extensively at room temperature and subsequently annealed at 100 °C in a vacuum oven for ~12 h to remove any remaining solvent and to facilitate complete polymer intercalation between the silicate layers. The WAXD patterns of PSPI18/2C18-MMT or PS/2C18-MMT clearly indicate the formation of intercalated structure, whereas composite prepared with 1,4-polyisoprene showed no change in gallery height. The intercalation of PS into the silicate layers may be due to the slight Lewis base character imparted by the phenyl ring in PS, leading to the favorable interactions with the 2C18-MMT layers. Further, the interlayer gallery spacing for the PSPI18/2C18-MMT composites is independent of the silicate loading. All the hybrids exhibit clear regular layered structure, demonstrated by the presence of the d_{001} and higher order diffraction peaks. This independence in gallery height on the silicate loading is consistent with the results obtained by Vaia and co-workers on model PS-based nanocomposite systems.

5.2. Condensation Polymers and Rubbers

Several technologically important polycondensates have also been used in the nanocomposite preparation with layered silicate. These include Nylon 6 [1, 2, 105–125], several others polyamides [126–132], PCL [13, 133–140], poly(ethylene terephtalate) (PET) [141–147], poly(butylene terephthalate) (PBT) [148], polycarbonate (PC) [149, 150], PEO [20, 151–168], ethylene oxide copolymers [169], poly(ethylene imine) [170], poly(dimethyl siloxane) (PDMS) [171–176], LCP [26, 177] polybenzoxazole (PBO) [178], butadiene copolymers [179–181], epoxidized natural rubber [182, 183], epoxy polymer resins (EPR) [184–204], phenolic resins [205], PU [206–209], polyurethane uera (PUU) [210], polyimides [211–226], poly(amic acid) [227–229], polysulphone [230], and polyetherimide [231, 232].

5.2.1. Nylon/Clay Nanocomposites

TCRD first reported [1] the ability of α, ω-amino acid [COOH–(CH$_2$)$_{n-1}$–NH$_2^+$], with $n = 2, 3, 4, 5, 6, 8, 11, 12, 18$] modified Na$^+$-MMT to be swollen by the ε-caprolactam monomer at 100 °C and subsequently to initiate its ring-opening polymerization to obtain Nylon 6/MMT nano-composites. For the intercalation of ε-caprolactam, they chose the ammonium cation of ω-amino acids because these acids catalyze ring-opening polymerization of ε-caprolactam. The number of carbon atoms in α, ω-amino acids has a strong effect on swelling behavior as reported in Figure 10, indicating the extent of intercalation of ε-caprolactam monomer is high when the number of carbon atoms in ω-amino acid is high. Figure 11 represents the conceptual view of swelling behavior of α,ω-amino acid modified Na$^+$-MMT by ε-caprolactam.

In a typical synthesis, 12-aminolauric acid modified MMT (12-MMT) and ε-caprolactam were mixed in a motor. The content of 12-MMT ranged from 2 to 70 wt%. These were then heated at 250–270 °C for 48 h to polymerize ε-caprolactam, using 12-MMT as catalyst. A small amount of 6-aminocaproicacid was added to the mixture to confirm the ring-opening polymerization of ε-caprolactam, and 12-MMT content in the mixture become less than 8 wt%. A typical procedure used was as follows: A 3 L three-necked separable flask, coupled with a mechanical stirrer, was used as the reaction vessel. In the vessel, 509 g of ε-caprolactam, 29.7 g of 12-MMT, and 66 g of 6-aminocaproic acids were placed under nitrogen. The mixture was heated at 100 °C in an oil bath while being stirred for 30 min, followed by heating at 250 °C for 6 h. The products were mechanically

crushed, washed with 2 L of water at 80 °C for 1 h, and dried at 80 °C overnight. A conceptual scheme for the synthetic method is presented in Figure 12 [105]. Further works have demonstrated that intercalative polymerization of ε-caprolactam could be realized without the necessity to render the MMT surface organophilic. In attempts to carry out the whole synthesis in one pot [107], the system has proved to be sensitive to the nature of the acid used to promote the intercalation of ε-caprolactam. Reichert et al. have also used same method for the preparation of Nylon 12/MMT nanocomposites [127].

For the preparation of Nylon 6/clay nanocomposites people generally used an *in-situ* intercalative polymerization technique. Liu et al. [114] first used this technique for the preparation of commercially available Nylon 6 with C$_{18}$-MMT nanocomposites by using a twin-screw extruder. They prepared nanocomposites with MMT content from 1 to 18 wt%. WAXD patterns and TEM observations respectively indicated that nanocomposites prepared with MMT less than 10 wt% lead to the exfoliated structure but more than 10 wt% MMT leads to the formation of intercalated structure. WAXD and differential scanning calorimetry (DSC) analyses also showed that exfoliated structures strongly influenced the nature of the Nylon 6 crystallization, favoring the formation of γ-crystals in addition to the crystals of the α-form observed in the native Nylon 6 matrix, and they also have a strong heterophase nucleation effect. After that VanderHart et al. [121] prepared Nylon 6/clay nanocomposites using the melt intercalation method.

Recently, Fornes et al. [119] have reported the preparation of Nylon 6/clay nanocomposites using a twin-screw extruder under molten state. They used three different molecular grades of Nylon 6 for the preparation of nanocomposites with bis(hydroxyethyl)(methyl)-rapeseed quaternary ammonium [(HE)$_2$M$_1$R$_1$] modified MMT and tried to

find effects of matrix molecular weights on structure, properties, rheology, etc. Nanocomposites were prepared using a Haake, co-rotating, intermeshing twin-screw extruder, which was operated at 240 °C with a screw speed of 280 rpm and a feed rate of 980 g/h.

They reported the WAXD patterns of $(HE)_2M_1R_1$ based MMT and the nanocomposites based on the three Nylon 6 matrixes of low molecular weight (LMW), medium molecular weight (MMW), and high molecular weight (HMW), having an approximate MMT concentration of 1.5 wt%. TEM images of various nanocomposites corresponding to the WAXD patterns are presented in Figure 13. WAXD patterns and TEM observations collectively revealed a mixed structure for the LMW based nanocomposites, while the MMW and HMW based nanocomposites revealed well-exfoliated structures. The average number of platelets per stack is shown to decrease with increasing matrix molecular weight. The mechanical properties of the nanocomposites were consistent with the morphological structure found via WAXD and TEM analyses.

In further study [123], they examined the effect of organoclay structure on Nylon 6 nanocomposite morphology and properties. In order to understand this, a series of organic

Figure 13. Bright field TEM images of melt compounded nanocomposites containing ~3 wt% MMT based on (a) HMW, (b) MMW, and (c) LMW Nylon 6. Reprinted with permission from [119], T. D. Fornes et al., *Polymer* 42, 9929 (2001). © 2001, Elsevier Science.

amine salts were ion exchanged with Na$^+$-MMT to form organoclays varying in amine structure or exchange level relative to the MMT. Each organoclay was melt-mixed with a HMW Nylon 6 using a twin-screw extruder operated under the same conditions as described previously; some organoclays were also mixed with LMW Nylon 6. The structure and corresponding nomenclature of various amine compounds that were used for the modification of Na$^+$-MMT using an ion exchanged method are presented in Figure 14. They conclude that three distinct surfactant effects were identified that lead to greater extents of exfoliation, higher stiffness, and increased yield strengths for nanocomposites based on the HMW Nylon 6: (a) one long alkyl tail on the ammonium ion rather than two, (b) methyl groups on the amine rather than 2-hydroxy-ethyl groups, and (c) an equivalent amount of amine surfactant on the clay opposed to an excess amount.

Very recently, Gilman et al. [79] reported the preparation of Nylon 6- and PS-based nanocomposites of MMT modified with trialkylimidazolium cation in order to expect high stability of OMLS at high processing temperature. Figure 15 represents various kinds of imidazolium salts used for the modification of MMT. For the preparation of nanocomposites they used a miniextruder, which was operated at 10 °C above the melting point of the polymer with a residence time of 3–5 min and screw speed of 200–300 rpm. WAXD analyses and TEM observations respectively established the formation of exfoliated structure in case of Nylon 6-based nanocomposite whereas there was intercalated structure with the PS/MMT system.

5.2.2. PCL/Clay Nanocomposites

For the preparation of PCL-based nanocomposites, Messersmith and Giannelis [133] modified MMT with protonated aminolauric acid and dispersed the modified MMT in liquid ε-caprolactone before polymerizing at high temperature. The nanocomposites were prepared by mixing up to 30 wt% of the modified MMT with dried and freshly distilled ε-caprolactone for a couple of hours followed by ring-opening polymerization under stirring at 170 °C for 48 h. The same authors [13] have also reported on the ε-caprolactone polymerization inside a Cr^{+3}-exchanged fluorohectorite at 100 °C for 48 h.

Pantoustier et al. [137, 138] used this *in-situ* intercalative polymerization method. They used both pristine MMT and ω-amino dodecanoic acid modified MMT for the comparison of prepared nanocomposite properties. For nanocomposite synthesis, in a polymerization tube, the desired amount of pristine MMT was first dried under vacuum at 70 °C for 3 h. A given amount of ε-caprolactone was then added under nitrogen and the reaction medium was stirred at room temperature for 1 h. A solution of initiator [Sn(Oct)$_2$ or Bu$_2$Sn(Ome)$_2$] in dry toluene was added to the mixture in order to reach a [monomer]/[Sn] molar ratio equal to 300. The polymerization was then allowed to proceed for 24 h at room temperature. After polymerization, a reverse ion-exchange reaction was used to isolate the PCL chains from the inorganic fraction of the nanocomposite. A colloidal suspension was obtained by stirring 2 g of the nanocomposite in 30 mL of THF for 2 h at room

temperature. Separately, a solution of 1 wt% of LiCl in THF was prepared. The nanocomposite suspension was added to 50 mL of the LiCl solution and left to stir at room temperature for 48 h. The resulting solution was centrifuged at 3000 rpm for 30 min. The supernatant was then decanted and the remaining solid washed by dispersing in 30 mL of THF followed by centrifugation. The combined supernatant was concentrated and precipitated from petroleum ether.

The polymerization of CL with pristine MMT gives PCL with a molar mass of 4800 g/mol and a narrow distribution. For comparison, authors also conducted the same experiment without MMT, but there is no polymerization of CL. These results demonstrate the ability of MMT to catalyze and to control CL polymerization at least in terms of molecular weight distribution which remains remarkably narrow. For the mechanism of polymerization, authors assume that the CL is activated through the interaction with acidic site on the clay surface and the polymerization is likely to proceed via the activated monomer mechanism by the cooperative function of Lewis acidic aluminum and Bronstrated acidic silanol functionalities on the initiator walls. On the other hand, in the polymerization of CL with the protonated ω-amino dodecanoic acid modified MMT, the molar mass is 7800 g/mol with a monomer conversion of 92% and again a narrow molecular weight distribution. The WAXD patterns of both nanocomposites indicate the formation of intercalated structure. In another recent publication [139, 140], the same group prepared PCL/MMT nanocomposites by using *in-situ* ring-opening polymerization of CL using dibutyl tin dimethoxide as an initiator/catalyst.

5.2.3. PET/Clay Nanocomposites

There are many reports on the preparation and characterization of PET/clay nanocomposites [141–147] using this method. Unfortunately no reports give a detailed description of the preparative method. There is one report concerning the preparation of a PET nanocomposite by *in-situ* polymerization of a dispersion of organoclay in water; however, characterization of the resulting composite was not reported [141]. This report claims that water serves as a dispersing aid for the intercalation of monomers into the galleries of the organoclay and discloses that a wide variety of small molecules can serve as dispersing aids in place

of, or in combination with, water. There is another route developed by Nanocor, Inc. [167] that was based on novel exfoliation of clays into ethylene glycol, one of the basic monomers for PET. The key to this approach includes finding a suitable surfactant that gives exfoliation of clay into ethylene glycol and also finding polymerization conditions that permit polymerization while retaining the exfoliation of the clay. Recently Imai et al. [147] reported the preparation of higher modulus PET/expandable fluorine mica nanocomposites with a novel reactive compatibilizer. Details regarding synthetic route are presented in [147].

Davis et al. [146] first reported the preparation of PET-based nanocomposites using the melt intercalation method. They used 1,2-dimethyl-3-N-alkyl imidazolium salt modified MMT (hexadecyl–MMT) for nanocomposite preparation with PET. PET/MMT nanocomposites were compounded via melt blending in a corotating mini twin-screw extruder operated at 285 °C. WAXD analyses and TEM (see Fig. 16) observations respectively established that the formation of mixed delaminated/intercalated structure is achieved in the nanocomposites.

5.2.4. PBT/Clay Nanocomposites

Like PET nanocomposites, this method was successfully applied by Chisholm et al. [148] for the preparation PBT/clay nanocomposites. They used sulfonated PBT for the preparation of nanocomposites. Because of the ionic nature of the $-SO_3Na$ groups and the expected insolubility of the $-SO_3Na$ groups in the polyester matrix, it was thought that the presence of the $-SO_3Na$ groups may provide a thermodynamic driving force for the production of nanocomposites derived from MMT. But after preparation and characterizations of nanocomposites it was found that degree of intercalation was not strongly dependent on the amont of $-SO_3Na$ groups; however, the mechanical properties increased significantly with increasing $-SO_3Na$ content.
Figure 16. TEM images of: (a) CD12 showing high levels of dispersion and exfoliation, average tactoids of four sheets per stack and (b) CD13 showing similar levels of dispersion and delamination as compared to CD12. Reprinted with permission from [146], C. H. Davis et al., *J. Polym. Sci. B* 40, 2661 (2002). © 2002, Wiley-VCH.

This behavior indicates that with high $-SO_3Na$ content the number of interactions increases between the clay particles and the matrix via strong specific interactions involving the $-SO_3Na$ groups.

5.2.5. PC/Clay Nanocomposites

Recently, Huang et al. [149] reported the synthesis of a partially exfoliated bisphenol A PC nanocomposite using carbonate cyclic oligomers and ditallowdimethyl-exchanged MMT. WAXD patterns indicate that exfoliation of this organoclay occurs after mixing with the cyclic oligomers in a brabender mixer for 1 h at 180 °C. Subsequent ring-opening polymerization of the cyclic oligomers converts the matrix into the liner polymer without the disruption of the nanocomposite structure. The TEM image revealed that a little exfoliation is obtained, although no indication of layer correlation is observed in WAXD.

Mitsunaga et al. [150] also reported intercalated PC/clay nanocomposites prepared through the melt intercalation method in the presence of compatibilizer. The morphology of these nanocomposites and degradation of the PC matrix after nanocomposites preparation could be controlled by varying surfactants used for the modification of clay and compatibilizers. The intercalated PC/clay nanocomposites exhibited remarkable improvements of mechanical properties when compared with PC without clay.

5.2.6. PEO/Clay Nanocomposites

In 1992, Aranda and Ruiz-Hitzky [20] first reported the preparation of PEO/MMT nanocomposites by using this method. They have carried out a series of experiments to intercalate PEO ($M_w = 10^5$ g/mol) into Na^+-MMT using different polar solvents [e.g., water, methanol, acetonitrile, mixtures (1:1) of water/methanol and methanol/acetonitrile]. In this method the nature of solvents is very crucial to facilitate the insertion of polymers between the silicate layers, polarity of the medium being a determining factor for intercalations. The high polarity of water causes swelling of Na^+-MMT provoking the cracking of the films. Methanol is not suitable as a solvent for high molecular weight PEO, whereas water/methanol mixtures appear to be useful for intercalations, although cracking of the resulting materials is frequently observed. PEO intercalated compounds derived from the homoionic M^{+n}-MMT and M^{+n}-hectorite can satisfactorily be obtained using anhydrous acetonitrile or methanol/acetonitrile mixture as solvents.

The resulting PEO/clay nanocomposites show good stability toward treatment with different solvents (e.g., acetonitrile, methanol, ethanol, water, etc.) in experiments carried out at room temperature for long time periods (>24 h). In addition, the lack of PEO replacement by organic compounds having high affinity toward the parent silicate, such as dimethyl sulfoxide and crown ethers, indicates again the high stability of PEO-intercalated nanocomposites. On the other hand, treatment with salt solutions provokes the replacement of the interlayer cations without disruption of PEO. For example, Na^+ ions in PEO/Na^+-MMT are easily replaced by NH_4^+ or $CH_3(CH_2)_2NH_3^+$ ions, after treatment (2 h) at room temperature with aqueous solution of their

chloride, perchlorate, and thiocyanate salts (1 N solutions), in a reversible process.

After that, Wu and Lerner [151] reported the intercalation of PEO in Na+-MMT and Na+-hectorite by using this method in acetonitrile, allowing stoichiometric incorporation of one or two polymer chains in between the silicate layers and increasing the intersheet spacing from 0.98 to 1.36 and 1.71 nm respectively. Study of the chain conformation using two-dimensional double-quantum nuclear magnetic resonance on ^{13}C enriched PEO intercalated in Na+-hectorite reveals that the conformation of the "-OC–CO-" bonds of PEO is $90 \pm 5\%$ *gauche*, inducing constraints on the chain conformation in the interlayer [157].

Recently, Choi et al. [162] prepared PEO/MMT nanocomposites by a solvent casting method using chloroform as a co-solvent. WAXD analyses and TEM observations respectively established the intercalated structure of these nanocomposites. Various other authors [163, 168] have also used same method and solvent for the preparation PEO/clay nanocomposites.

Vaia et al. [152] also applied the same method to intercalate PEO in Na+-MMT layers. Intercalation of PEO in layered silicate was accomplished by heating the PEO with the Na+-MMT at 80 °C. The WAXD patterns before any heating contain peaks characteristic of both Na+-MMT and crystalline PEO. After heating to 80 °C, the intensity of the peaks corresponding to the unintercalated silicate and crystalline PEO is progressively reduced while a set of new peaks corresponding to the PEO-intercalated MMT are observed signifying the completion of intercalation. Very recently Shen et al. [167] reported the preparation of PEO/OMLS nanocomposites using melt intercalation technique.

In order to discover the effect of thermal treatment on the amount of PEO and PE–PEG diblock copolymer intercalated into the layers of Na+-MMT and on ionic conductivity of PEO/Na+-MMT, Liao et al. [164] prepared PEO/Na+-MMT and PE–PEG diblock copolymer/Na+-MMT nanocomposites using a melt intercalation technique. It was found that PEO can be intercalated into the layers of Na+-MMT by simple mechanical blending and part of PE in PE–PEG diblock copolymers was also intercalated into the layers of Na+-MMT. The interclated amount increases with thermal treatment time, which ultimately improves the ionic conductivity of the PEO/Na+-MMT nanocomposites. Recently, this method was successfully applied by Artzi et al. [101] for the preparation of ethylene-vinyl alcohol copolymer/clay nanocomposites.

5.2.7. PDMS/Clay Nanocomposites

PDMS/clay nanocomposites were synthesized by sonicating a mixture of silanol-terminated PDMS and a commercial organoclay at room temperature for 2 min [171]. Delamination of the silicate particles in the PDMS matrix was accomplished by suspending the organosilicate in PDMS at room temperature and sonicating. WAXD analyses of various nanocomposites revealed no distinct features in the low 2Θ ranges indicating the formation of exfoliated nanocomposites.

5.2.8. LCP/Clay Nanocomposites

Vaia and Giannelis [26] reported the reversible intercalation between organoclay and LCP in the nematic state. Melt intercalation of a model main chain liquid crystalline co-polymer based on 4,4′-dihydroxy-*a*-methylstilbene and a 50:50 mole ratio mixture of heptyl/nonyl alkyl dibromide was accomplished by annealing a powder mixture of the polymer and organoclay within the nematic region of the polymer.

In another report, Chang et al. [177] have prepared nanocomposites of thermotropic liquid crystalline polyester (TLCP) and Cloisite 25A using a melt intercalation method above the melt transition temperature of the TLCP. Liquid crystallinity of the nanocomposites was observed when organoclay content was up to 6 wt%.

5.2.9. PBO/Clay Nanocomposites

Zhu et al. [76] used phosphonium salt for the first time for the modification of clay and then tried to find the differences between organo ammonium and phosphonium salt treatments of clay fillers in nanocomposites toward thermal stability.

This technique was successfully applied by Hsu and Chang [178] in order to prepare PBO/clay nanocomposite from a PBO precursor, polyhydroxyamide (PHA), and an organoclay. The PBO precursor was made by the low temperature polycondensation reaction between isophthaloyl chloride and 2,2-bis(3-amino-4-hydroxyphenyl) hexafluoropropane with an inherent viscosity of 0.5 dl/g. For the preparation of PBO/clay nanocomposite, the organoclay was first dispersed in dimethyacetamide in which PHA was dissolved. The PHA/clay film was obtained from solution casting and dried at 80 °C under vacuum. Finally PBO/clay nanocomposite was obtained by curing the film at 350 °C to form a benzoxazole ring. The WAXD pattern and TEM observation respectively established that silicate layers were delaminated in PBO/clay nanocomposite film.

5.2.10. Thermoset Epoxy/Clay Nanocomposites

The studies of thermoset epoxy (EPR) systems were concerned with the ring-opening polymerization of epoxides to form polyether nanocomposites. This chemistry was followed by studies of both rubbery and glassy thermoset EPR/clay nanocomposites using different types of amine curing agents. The mechanisms leading to the monolayer exfoliation of clay layers in thermoset epoxy systems have been greatly elucidated. In addition, the polymer/clay interfacial properties have been shown to play a dominant role in determining the performance benefits derived from nanolayer exfoliation.

Messersmith and Giannelis [184] first reported the preparation of epoxy resin based nanocomposites of organoclay. They have analyzed the effect of different curing agents and curing conditions in the formation of nanocomposites based on the diglycidyl ether of bisphenol A (DGEBA) and a MMT modified by bis(2-hydroxyethyl) methyl hydrogenated toallow alkylammonium cation. They found that this modified clay dispersed readily in DGEBA when sonicated for a short time period as determined by the increase in viscosity at relatively low shear rates and the transition of the

suspension from opaque to semitransparent. The increase in viscosity was attributed to the formation of a so-called "house-of-cards" structure in which edge-to-edge and edge-to-face interactions between dispersed layers form a percolation structure. WAXD patterns of uncured clay DGEBA also indicate that intercalation occurred during and that this intercalation improves going from room temperature to 90 °C.

After that Wang and Pinnavaia [186] reported the preparation of PCNs of epoxy resin in the DGEBA, and the concomitant delamination of acidic forms of MMT at elevated temperature using the self-polymerization technique. They used a series of acidic cation such as H^+, NH_4^+, and acidic onium ions of the type $[H_3N(CH_2)_{n-1}COOH]^+$, $[H_3N(CH_2)_nNH_2]^+$, $[H_3N(CH_2)_nNH_3]^{+2}$ ($n = 6$ and 12) for the modification of MMT, carried out the polymerization–delamination process over the temperature range of 198–287 °C, and found that the EPR-clay delamination temperature (PDT) was dependent on the heating rate and nature of the cation used for the modification of clay. In general, the PDT increased with decreasing cation acidity and basal spacing of the clay.

The delamination of MMT in the polymerized epoxy resin was confirmed by X-ray powder diffraction (XRD) as shown by the powder patterns in Figure 17a and b where $[H_3N(CH_2)_{11}COOH]^+$-MMT remains crystalline over the temperature range 25–229 °C. However, no diffraction peaks were observed for a 5:95 (w/w) clay/polyether nanocomposite formed from $[H_3N(CH_2)_{11}COOH]^+$-MMT at 229 °C (see Fig. 17c). Only a very diffuse scattering characteristic of the amorphous polyether appears in the XRD pattern of the composite. The absence of a 17-Å peak for $[H_3N(CH_2)_{11}COOH]^+$-MMT suggests that the clay particles have been exfoliated and the 9.6-Å-thick clay layers dispersed at the molecular level. TEM provides unambiguous evidence for the delamination of the MMT in the polyether

Figure 17. XRD powder patterns for a freeze-dried $[H_3N(CH_2)_{11}COOH]^+$-MMT, (b) $[H_3N(CH_2)_{11}COOH]^+$-MMT freeze-dried and then heated at 229 °C, and (c) clay-polyether nanocomposite containing 5 wt% $[H_3N(CH_2)_{11}COOH]^+$-MMT. Reprinted with permission from [186], M. S. Wang and T. J. Pinnavaia, *Chem. Mater.* 7, 468 (1995). © 1995, American Chemical Society.

matrix. PDT values and thermodynamic data for MMT-polyether nanocomposites formed from bifunctional onium ion MMT, onium ion NH_4^+, and H^+ MMT are respectively presented in Tables 3 and 4.

In another study, Lan and Pinnavaia [185] have reported the preparation of PCNs with a rubber-epoxy matrix obtained from DGEBA derivatives cured with a diamine so as to reach subambient glass transition temperatures. It has been shown that depending on the alkyl chain length of modified MMT, an intercalated and partially exfoliated or a totally exfoliated nanocomposite can be obtained. Lan et al. [187] have also studied other parameters such as the nature of alkyl ammonium cations present in the gallery and the effect of the cation exchange capacity of the MMT when DGEBA was cured with *m*-phenylene diamine. The same kind of study was also conducted by Zilg et al. [194] who cured DGEBA with hexahydrophthalic acid anhydride in the presence of different types of clays and also modified them with a wide variety of surfactants.

Recently, Kornmann et al. [201] reported the synthesis of epoxy-based nanocomposites using two different types of MMT clays with different CECs in order to investigate the influence of the CEC of the MMT clay on the synthesis and structure of nanocomposites. The CEC of any clay is a very important factor during nanocomposite synthesis because it determines the amount of surfactants which can be intercalated between the silicate layers. In this context, the swelling behavior is of critical importance to the final nanocomposite structure. For the preparation of nanocomposites both MMT clays were modified with octadecylammonium cation, and a nanocomposite synthesis procedure was the same as that used by previous authors. From WAXD patterns, it has been found that an MMT with a low CEC is exfoliated already during swelling in the epoxy resin prior to curing. A possible mechanism explaining this phenomenon is homopolymerization of the EPR during the swelling phase, causing diffusion of new epoxy molecules into the clay galleries. The large amount of space available between the layers favors the diffusion. The swelling duration of the clay with high CEC is shown to be critical for the synthesis of an exfoliated nanocomposite. Regarding the structure, TEM observations reveal interlamellar spacing of 90 Å (low CEC) and 110 Å (high CEC). However, multiplatelets of nonexfoliated layers were also observed. In summary, these nanocomposites contain clay/polymer composite particles consisting of inhomogeneously distributed silicate layer aggregates with polymer between these layers.

A group of researchers [203] from Australia has recently reported the morphology, thermal relaxation, and mechanical properties of PCNs of high-functionality epoxy resins. Three different types of resins used were bifunctional DGEBA, trifunctional triglycidyl *p*-amino phenol (TGAP), and tetrafunctional tetraglycidyldiamino diphenylmethane (TGDDM) and all were cured with diethyltoluene diamine (DETDA). The structures of all resins and curing agents are presented in Table 5. MMT modified with octadecylammonium cation was used for the preparation of nanocomposites. The PCNs were prepared using the previously reported method. In a typical synthesis, organoclay was first dispersed in the resin at 80 °C using a stirrer at 500 rpm.

Table 3. PDT values and thermodynamic data for polyether/clay nanocomposites formed from bifunctional onium ion-MMT.

Interlayer cation	Initial basal spacing (Å)	PDT[a] (°C)	Heat of reaction (J/g)	Heat of polym[b] (kJ/mol)
$[H_3N(CH_2)_{11}COOH]^+$	17.0 ± 0.1	229 ± 1	572 ± 16	228 ± 6
$[H_3N(CH_2)_5COOH]^+$	13.3 ± 0.0	248 ± 1	565 ± 06	225 ± 2
$[H_3N(CH_2)_{12}NH_3]^{2+}$	13.4 ± 0.1	271 ± 1	566 ± 08	225 ± 3
$[H_3N(CH_2)_6NH_3]^{2+}$	13.1 ± 0.1	273 ± 2	568 ± 07	226 ± 3
$[H_3N(CH_2)_{12}NH_2]^+$	13.5 ± 0.0	281 ± 2	563 ± 07	224 ± 3
$[H_3N(CH_2)_6NH_2]^+$	13.2 ± 0.1	287 ± 2	557 ± 03	222 ± 2

After mixing the resin–organoclay blend for 30 min the curing agent was added and the system kept under vacuum for another 60–90 min at around 70 °C. The blends were then cured for 2 h at 100 °C, 1 h at 130 °C, 12 h at 160 °C followed by a postcure for 2 h at 200 °C.

The morphology of the cured samples was investigated using WAXD and different microscopy techniques. Figure 18a represents the WAXD patterns of the MMT concentration series showing that the organoclay with an initial *d*-spacing of 2.3 nm is mainly exfoliated in the DGEBA-based system. On the other hand, high content (10 wt%) organoclay shows intercalated structure, while for DGEBA-based systems, resins of higher functionality show distinctive peaks even at low organoclay loading, indicating that these nanocomposites have a lower degree of exfoliated structure. WAXD patterns are shown in Figure 18b for TGAP and Figure 18c for TGADDM based nanocomposites of MMT. In case of any nanocomposite system, the peak observed around 2.5 nm correlates to the (002) plane and therefore represents only half the distance of the *d*-spacing.

Figure 19a and b represents atomic force microscopy (AFM) phase contrast images of the DGEBA nanocomposite containing 5 wt% layered silicate. Individual layers cannot be seen by AFM as they usually are by the TEM. A striated structure, however, can be seen with increasing phase intervals at the top of the picture. So from the AFM images it is established that silicate layers are not homogeneously distributed in the matrix, and some stacked layers are present.

Very recently, Chen et al. [204] synthesized epoxy-MMT nanocomposite using a surface initiated method in order to understand the interlayer expansion mechanism and thermal–mechanical properties of these nanocomposites. MMT modified with bis-2-hydroxyethyl methyl tallow ammonium cation (C30B) was used as OMLS for nanocomposite synthesis. 3, 4-Epoxycyclohexylmethyl-3,4-epoxycyclohexane carboxylate was used as epoxy monomer, and hexahydro-4-methylphthalic anhydride (HHMPA), ethylene glycol (EG), and benzyldimethylamine (BDMA) were respectively used as curing agent, initiator, and catalyst during synthesis. In a typical preparative method, the epoxy monomer HHMPA was mixed in a molar ratio of epoxide groups to HHMPA of 1:0.87. The resulting mixture was denoted as the *resin* by the authors. To the resin was added a specific weight percent of the resin weight either as EG, BDMA, or C30B. All materials were then blended using an orbital mixture, until the blend become bubble free and homogeneously mixed. The blended samples were then immediately cured first isothermally for up to 8 h at temperatures ranging from 70 to 140 °C, followed by 8 h at 180 °C, and finally 12 h at 220 °C under vacuum.

The curing mechanism for an epoxy-anhydride system with an alcohol initiator is shown in Figure 20. Amine catalysts like BDMA were added to the mixture to accelerate the reaction by facilitating the ring opening of epoxy groups. Several published papers indicate that intragallery onium ions can catalyze the epoxy curing reaction and thus lead to favorable conditions for obtaining exfoliated PCNs. To understand fully in case of this system, Chen et al. [204] verify that the cross-linking reactions in the presence of C30B were due to hydroxy initiation and not due to catalytic reactions. For this reason, the extent of reaction of a resin containing C30B was compared to the extent of reaction for a neat resin and resins containing either EG

or BDMA. As seen in Figure 21, the curing kinetics of the resin-C30B system more closely resembles the curing kinetics of the resin-EG system than the resin-BDMA system. This is a direct indication that the nanocomposites predominantly cured via initiation by the surfactant hydroxy groups and not by catalytic means. Figure 21 also shows that the curing rate of the pristine resin is significantly lower than the other mixtures. This highlights an important prerequisite for interlayer expansion, which is that extragallery polymerization rates should be slower than intragallery polymerization rates.

Time-resolved high-temperature XRD was used to probe the expansion behavior of the silicate layers during curing of the PCNs, and Figure 22 represents a plot of the results of a PCN containing 15 wt% C30B held isothermally at 70 °C. In Figure 23, the changes in *d*-spacing are plotted against the isothermal cure time for various clay loadings and cure temperature. On the basis of various characterization methods, the authors proposed an exfoliation mechanism of surface-initiated epoxy nanocomposites consisting of three stages. In the first stage, the interlayer expansion induced by intragallery polymerization must overcome any polymer chains that bridge the silicate layers. The interlayer expansion cannot proceed beyond the first stage if the number of bridging units becomes too great. The second stage was characterized by a steady and linear increase in interlayer spacing and accounts for the majority of the total expansion realized. During this stage, the silicate layers could be monitored via isothermal DSC experiments. Also, for samples that exhibited a large increase in interlayer expansion, it was found that the activation energy associated with the interlayer expansion was less than the activation energy associated with the curing. The reverse was true for samples that showed no increase in interlayer spacing. In the

third stage, the interlayer expansion slowed then stopped, and in some cases decreased slightly. This was ascribed to the evolving modulus of the extragallery polymer such that the interlayer expansion stopped when the modulus of the extragallery polymer became equal to or exceeded the modulus of the intragallery polymer.

5.2.11. PU/Clay Nanocomposites

Chen et al. [207] have used a PCL-based nanocomposite synthesis technique for the preparation of novel segmented PU/clay nanocomposites articulated on diphenylmethane diisocyanate, butanediol, and preformed polycaprolactone diol. Even if the mechanism proposed for the chemical link

between the nanofiller surface and the polymer does not appear appropriate, they succeeded in producing a material where the nanofiller acts as a multifunctional chain extender inducing the formation of star-shaped segmented polyurethane. Recently, Wang and Pinnavaia [206] reported the preparation of polyurethane-MMT nanocomposites using a direct *in-situ* intercalative polymerization technique. More recently, Yao et al. [209] reported the preparation of a novel kind of PU/MMT nanocomposite using a mixture of modified 4,4′-di-phenymethylate diisocyanate (M-MDI), modified polyether polyol (MPP), and Na$^+$-MMT. In a typical synthetic route a known amount of Na$^+$-MMT was first mixed with 100 mL of MPP and then stirred at 50 °C for 72 h. Then the mixture of MPP and Na$^+$-MMT was blended with a known amount of M-MDI and stirred for 30 s at 20 °C, and finally curing was conducted at 78 °C for 168 h.

Biomedical PUU/MMT (modified with dimethyl ditallow ammonium cation) nanocomposites were prepared by adding organoclay suspension in toluene dropwise to the solution of PUU in N, N-dimethylacetamide (DMAC) [210]. The mixture was then stirred overnight at room temperature. The solution was degassed, and then films were cast on to round glass Petri dishes. The films were air-dried for 24 h and subsequently dried under vacuum at 50 °C for 24 h. WAXD analyses indicated the formation

of intercalated nanocomposites but they did not report any TEM photographs.

5.2.12. Polyimide/Clay Nanocomposites

Yano et al. [209] have conducted the preparation of polyimide/MMT nanocomposites from a DMAC solution of poly(amic acid) and a DMAC dispersion of MMT modified with dodecylammonium cation. Table 6 shows the dispersibility of various kinds organically modified MMTs in DMAC and the average diameter of organophilic MMTs obtained from the dynamic light scattering experiment. In case of 12CH$_3$-MMT, MMT appeared to disperse in DMAC homogeneously and the average diameter of the dispersed MMT particles was the smallest of all. Another interesting aspect is that as the carbon number of the surfactant increases, the hydrophilicity of the ogranophilic MMT decreases. Table 6 also indicates that 10–12 carbon atoms are appropriate for organophilic MMT to be dispersed in DMAC.

In another report [226] polyimide/MMT nanocomposites were prepared using a solvent cast method from solution of poly(amic acid) precursors and the dodecyl-MMT using

N-methyl-2-pyrrolidone as a solvent. The cured films of the rigid-rod polyimide/MMT nanocomposites as characterized by FTIR, TEM, and WAXD were exfoliated nanocomposites at low MMT content and partially exfoliated structure at high MMT content.

5.2.13. Polyetherimide/Clay Nanocomposites

PEI/MMT nanocomposites were prepared by melt blending of hexadecylamine modified MMT and PEI at 350 °C [231, 232]. WAXD patterns of various nanocomposites show no peaks but TEM observations show relatively stacked silicate layers not homogeneously dispersed in the polymer matrix. According to the authors, due to the strong interaction between PEI and organoclay, the nanocomposites exhibited a substantial increase at glass transition tem-

perature T_g, thermal decomposition temperature, a drastic decrease in solvent uptake, etc., compared to the virgin PEI but they did not check the stability of intercalated salt in organoclay at this high temperature of mixing.

5.3. Polyolefins

PP [9, 14, 15, 25, 30, 233–266], PE [267–273], polyethylene oligomers [274], copolymers like poly(ethylene-co-vinyl acetate) (EVA) [275], and ethylene propylene diene methylene linkage rubber (EPDM) [276, 277] have also been used.

5.3.1. PP/Clay Nanocomposites

Tudor et al. [235] first used this *in-situ* intercalative polymerization method for the preparation of PP/clay nanocomposites. They have demonstrated the ability of soluble metallocene catalyst to intercalate inside silicate layers and to promote the coordination polymerization of propylene. Accordingly, a synthetic hectorite (Laponite RD) was first treated with methylaluminoxane (MAO) in order to remove all the acidic protons and to prepare the interlayer spacing to receive the transition metal catalyst. It has to be noted that MAO is commonly used in association with metallocenes to produce coordination catalysts active in olefin polymerizations. During this first treatment step, WAXD analysis showed no noticeable increase of the layer spacing, although the diffraction peak broadened slightly, but the increase in Al content and complete disappearance of Si–OH signals from infrared spectra agree with the MAO reaction/adsorption inside the layered silicate galleries. Upon the addition of the metallocene catalyst ([Zr(η-C$_5$H$_5$)Me(THF)]$^+$), a cation exchange reaction occurs between Na$^+$ in MAO treated hectorite and the metallocene catalyst as demonstrated by an increase in the interlayer spacing of 0.47 nm, consistent with the size of the species. Details can be seen in Figure 24. Using a synthetic fluorinated mica-type layered silicate that is deprived from any protons in the galleries, the catalyst was even
Figure 24. Schematic illustration of the modification and ion exchange of Laponite with $[Zr(\eta\text{-}C_5H_5)_2Me(thf)]BPh_4$ and propene polymerization. Details regarding the reagent and conditions are shown in relevant reference. Reprinted with permission from [235], J. Tudor et al., *Chem. Commun.* 2031 (1996). © 1996, Royal Chemical Society.

intercalated Directly within the silicate layers without the need for MAO treatment. These two modified layered silicates catalyzed with reasonably high activity with the polymerization of propylene when contacted with an excess of MAO, producing PP oligomers. Unfortunately, the authors did not report any characterization of these composites, so one cannot make claims about the morphology. In another recent publication, Sun and Garces [259] have reported the preparation of PP/clay nanocomposites by *in-situ* intercalative polymerization with metallocene/clay catalysts.

Usuki et al. [239] first reported a novel approach to prepare PP/clay nanocomposites using functional oligomer with polar telechelic OH groups (PP-OH) as compatibilizer.

In this approach, first PP-OH intercalates between the layers of $2C_{18}$-MMT, the second step was the melt mixing of PP-OH/$2C_{18}$-MMT with PP, and the nanocomposite with intercalated structure was obtained. Further study by the same group [14] reported the preparation of PP/MMT nanocomposites by melt blending of PP, maleic anhydride grafted PP oligomer (PP-MA), and clays modified with stearylammonium using a twin-screw extruder. In their study, they used two different types of maleic anhydride modified PP oligomer with different amounts of maleic anhydride groups and two types of organically modified clays to understand the miscibility effect of the oligomers on the dispersibility of the organoclay in PP matrix, and to study the effect of hybridization on their mechanical properties when compared with neat PP and PP/clay nanocomposites without oligomers.

WAXD analyses and TEM observations respectively established the intercalated structure for all nanocomposites. On the basis of WAXD patterns and TEM images, they proposed a possible mechanism for dispersion of intercalated clay layers in the PP matrix. Figure 25 shows a schematic presentation of the mixing process of the three components (i.e., PP, PP-MA, and OMLS) into the nanocomposites. Authors believe that the driving force of the intercalation originates from the maleic anhydride group and the oxygen groups of the silicate through hydrogen bond.

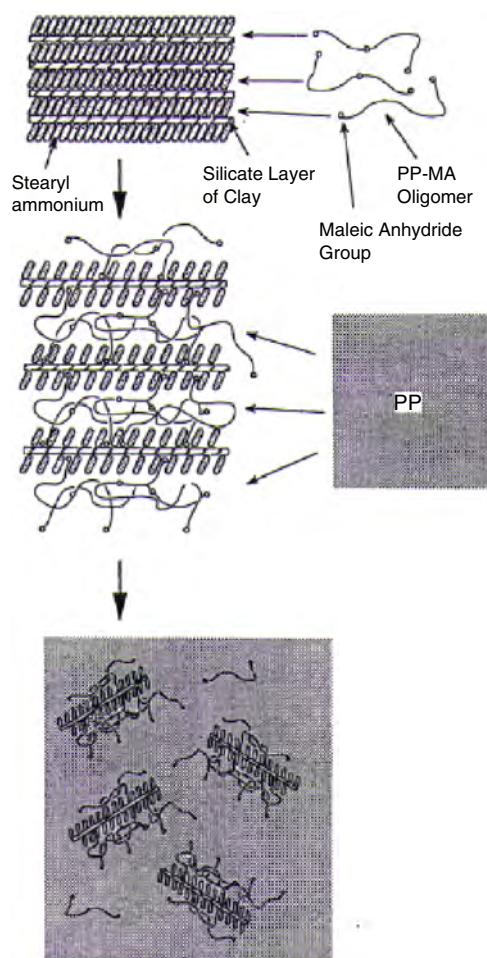
In a recent report, Hasegawa et al. [240] found that PP-MA was able to intercalate into the intergalleries of OMLS, as like the functional oligomer, and they described a facile approach for the preparation of PP/clay nanocomposite using a PP-MA and organically modified clay by a melt intercalation technique. In a typical preparative


Figure 25. Schematic representation of the dispersion process of the organoclay in the PP matrix with the aid of PP-Mas. Reprinted with permission from [239], A. Usuki et al., *J. Appl. Polym. Sci.* 63, 137 (1997). © 1997, Wiley-VCH.

method, PP/clay nanocomposite pellets were prepared by a melt blending of pellets of PP-MA and the powder of C_{18}-MMT at 200 °C using a twin-screw extruder.

The same authors [245] also prepared polyethylene-propylene rubber (EPR)/C_{18}-MMT nanocomposites by melt blending of EPR-g-MA and C_{18}-MMT powder using a twin-screw extruder, and then tried to compare the morphology of EPR based nanocomposites with PP/clay nanocomposites.

Recently, Nam et al. [30] prepared PP/MMT nanocomposites using the same method as used by previous authors. For example a mixture of PP-MA (0.2 wt% MA) and C_{18}-MMT was melt extruded at 200 °C in a twin-screw extruder. They prepared PCNs with three different amounts of clay content (inorganic part) of 2, 4, and 7.5 wt%, which were correspondingly abbreviated as PPCN2, PPCN4, and PPCN7.5 respectively. The WAXD patterns of C_{18}-MMT, PP-MA, and various PPCNs are presented in Figure 26. WAXD patterns clearly established near to exfoliate structure is formed with PPCN2, disordered intercalated nanocomposite is formed in case of PPCN4, while PPCN7.5 represents an ordered intercalated structure. These features are clearly observed with bright field

Figure 27. Bright field TEM images of PPCNs: (a) 2, (b) 4, and (c) 7.5 wt% MMT. The dark lines are the cross sections of silicate layers and the bright areas are the PP-MA matrix. Reprinted with permission from [30], P. H. Nam et al., *Polymer* 42, 9633 (2001). © 2001, Elsevier Science.

TEM images of various PPCNs as shown in Figure 27. In order to understand the hierarchical structure of PPCNs they also used polarizing optical microscopy, light scattering, and small angle X-ray diffraction for the characterization of PPCNs along with WAXD and TEM. On the basis of these analyses they demonstrated the dispersed clay and interfibril structure of PPCNs. The schematic illustration of this structure is presented in Figure 28.

In another publication [253], Liu and Wu have reported the preparation of PPCN via grafting-melt compounding using a new type of co-intercalated organophilic clay which has a larger interlayer spacing than the ordinarily orgonophilic clay that is only modified with alkyl ammonium cation. One of the co-intercalation monomers is unsaturated so it could tether on the PP backbone by virtue of grafting reaction. The co-intercalated organophilic clay (EM-MMT) was prepared as follows: 130 g hexadecylammonium modified MMT (C_{16}-MMT) and 20 g epoxypropyl methacrylate were mixed in a Hake Reocorder 40 mixer for 1 h. Before mixing with clay, the initiator of grafting reaction, dibenzoyl peroxide, and donor agent were disolved in epoxypropyl methacrylate. The nanocomposites were prepared using a twin-screw extruder with a screw speed of 180 rpm and operated at temperature around 200 °C. WAXD patterns

and TEM observations established that the larger interlayer spacing and strong interaction caused by grafting can improve the dispersion effect of silicate layers in the PP matrix.

Recently, Manias et al. [254] reported the preparation of PP/organically modified MMT, having a coexisting intercalated and exfoliated structure by the melt intercalation technique. They prepared nanocomposites two different ways: (a) by introducing functional groups in PP and using common alkylammounium MMT and (b) by using neat/unmodified PP and a semifluorinated surfactant modification for the MMT.

Kaempfer et al. [264] reported the preparation of new PCNs via melt compounding of syndiotactic polypropylene (sPP) containing organoclay and *in-situ* formed core/shell nanoparticles. Melt compounding of sPP with organohectorite, obtained via cation exchange of fluohectorite with octadecylammonium cation, in a co-rotating twin-screw extruder represents an attractive new route to reinforced sPP with considerably higher stiffness. The matrix reinforcement is achieved by *in-situ* formation of silicate nanoparticles via exfoliation combined with simultaneous *in-situ* encapsulation of the resulting nanosilicates in a thin shell of iPP-graft-MA. The resulting anisotropic core/shell type nanoparticles, containing stacks of organohectorite layer as

core and iPP-graft-MA as shell, represent a very effective new class of nucleating agents for sPP crystallization.

5.3.2. PE/Clay Nanocomposites

PE/clay nanocomposites have also been prepared by the *in-situ* intercalative polymerization of ethylene using so-called polymerization filling technique [272]. Pristine MMT and hectorite were first treated with trimethyl-aluminum-depleted methylaluminoxane before being contacted by a Ti-based constrained geometry catalyst. The nanocomposite was formed by addition and polymerization of ethylene. In the absence of a chain transfer agent, ultrahigh molecular weight polyethylene was produced. The tensile properties of these nanocomposites were poor and essentially independent of the nature and content of the silicate. Upon hydrogen addition, the molecular weight of the polyethylene was decreased with parallel improvement of mechanical properties. The formation of exfoliated PCNs was established using WAXD and TEM analyses. In another report, Heinemann et al. [268] prepared (co)polyolefin/clay nanocomposites using this method.

MA grafted polyethylene (PE-MA)/clay nanocomposites were also prepared by a melt intercalation technique [271].

The extent of exfoliation and intercalation completely depends on the hydrophilicity of polyethylene grafted with MA and the chain length of the organic modifier in the clay. When the number of methylene groups in alkylamine (organic modifier) was larger than 16, the exfoliated nanocomposite was obtained, and the maleic anhydride grafting level was higher than about 0.1 wt% for the exfoliated nanocomposite with the clay modified with dimethyl dehydrogenated tallow ammonium cation or octadecylammonium cation.

Very recently, EPDM/clay nanocomposites have been prepared by mixing EPDM with OMLS via a vulcanization process [276]. They used thiuram and dithiocarbamate for the vulcanization accelerator.

5.4. Specialty Polymers

In addition to the aforementioned conventional polymers, several interesting developments have also taken place in the preparation of nanocomposites of layered silicates with some speciality polymers including the *N*-hetrocyclic polymers like polypyrrole (PPY) [278–283], poly(*N*-vinylcarbazole) (PNVC) [284, 285], and polyaromatics such as polyaniline (PANI) [286–300], poly(*p*-phenylene vinylene) [301], and related polymers [302]. PPY and PANI are known to display electric conductivity [303], and PNVC is well known for its high thermal stability and characteristic optoelectronic properties [304–307]. Some research has also been initiated with liquid crystalline polymer based nanocomposites [308–312] and hyperbranch polymers (HBP) [313].

5.4.1. PNVC/Clay Nanocomposites

Biswas and Sinha Ray [284] first reported the preparation of PNVC/MMT nanocomposites by direct polymerization of *N*-vinylcarbazole (NVC) (solid or in solution) in the presence of MMT without the use of any free-radical initiator. Melt polymerization of NVC in MMT (at 70 °C) as well as solution (in benzene) polymerization of NVC in the presence of MMT at 50 °C resulted in the formation of PNVC/MMT nanocomposite with intercalated structure. After repeated benzene extraction of prepared nanocomposites, intercalated PNVC could not be removed, while all the surface-adsorbed PNVC was extracted with benzene. WAXD analyses confirmed intercalation of PNVC in MMT interlayer galleries.

According to the authors, the initiation in the NVC/MMT system was suggested to be cationic involving Brønstrated acid sites in MMT arising from the dissociation of interlayer water molecules coordinated to the exchangeable cations [284]. Yet another possibility, especially with NVC, was that the transition metal oxides (Fe_2O_3/TiO_2) present in MMT could also lead to cationic initiation of NVC. The same authors subsequently reported that direct interaction of MMT with pyrrole led only to ca. 5% yield of PPY in 3 h while ANI could not be polymerized by MMT [281]. According to them, such a trend is possibly not surprising since NVC is relatively more susceptible to cationic polymerization compared to the latter monomers.

Further work by Sinha Ray and Biswas, in the study of a NVC/MMT polymerization/nanocomposite formation

system, the addition of FeCl$_3$ was considered to be interesting. Results of a recent study [285] indicated that in a NVC-MMT polymerization/nanocomposite formation system addition of FeCl$_3$ increased the percentage loading of PNVC in the composite.

5.4.2. PANI/Clay and PPY/Clay Nanocomposites

Polymerization vis-a-vis nanocomposite formation in PY/MMT-water and ANI/MMT-water systems was possible after using FeCl$_3$ and (NH$_4$)$_2$S$_2$O$_8$ [281, 287] as oxidant respectively in the two systems.

Kim et al. [286] first used this method for the preparation of PANI/MMT nanocomposite using docecylbenzenesulfonic acid (DBSA) and camphorsulphonic acid (CSA) as dopant. In a typical synthetic method, Na$^+$-MMT was first dispersed in an aqueous medium and then sonicated by using an ultrasonic generator. The DBSA or CSA dopants were dissolved in distilled water and mixed with ANI monomer solution at a 1:1 molar ratio; then the emulsion solutions were mixed in a four-neck reactor by stirring while the temperature was kept at 25 °C. The oxidant initiator, (NH$_4$)$_2$S$_2$O$_8$ solution, was dropped into the reactor. The WAXD analysis clearly indicates the formation of intercalated nanocomposites.

In another recent publication, Kim et al. [283] reported the preparation of intercalated PPY/Na$^+$-MMT nanocomposite via an inverted emulsion pathway method.

5.4.3. HBP/Clay Nanocomposites

Very recently, Plummer et al. [313] have used this method for the preparation of HBP/MMT nanocomposites. The chemical structure of the HBP is presented in Figure 29. The
Figure 29. Chemical structure of the dendrimer analog of the second pseudo-generation HBP. Reprinted with permission from [313], C. J. G. Plummer et al., *Chem. Mater.* 14, 486 (2002). © 2002, American Chemical Society.

PCNs were prepared by introducing the required amount of Na$^+$-MMT to 10 g of HBP dispersed in 75 mL of boiling deionized water. The mixture was stirred in air at 50 °C with a magnetic stir bar. After evaporation of half the water, the resulting gel was transferred to an open silicone rubber mold and dried in air for 2 days at 50 °C. The remaining solid was then dried for another 2 days at 120 °C under vacuum, ground, and pressed into 25-mm diameter, 1-mm thick disks at 60 °C for WAXD analyses. At high Na$^+$-MMT contents, WAXD analyses indicated 2.5–2.8, 2.8–3, and 3.6–3.9 nm silicate layer basal spacing for the second, third, and fourth pseudo-generation HBPs, respectively, as opposed to 1.06 nm for the as-received Na$^+$-MMT. The corresponding WAXD peaks disappeared as the clay content was reduced to below 20 wt% for all the HBPs, consistent with the previous study by Strawhecker and Manias [87]. TEM images of nanocomposite containing 20 wt% Na$^+$-MMT revealed stacks of 5–10 silicate layers with a relatively well-defined spacing, interspersed with exfoliated silicate layers. At 10 wt% MMT, however, exfoliation was confirmed to dominate.

5.5. Biodegradable Polymers

Recently, some groups have started the preparation, characterization, and materials properties of various kinds of biodegradable polymers/nanocomposites having properties suitable for a widerange of applications. So far reported biodegradable polymers for the preparation of nanocomposites are polylactide (PLA) [34, 314–324], poly(butylene succinate) (PBS) [325–328], PCL [13, 133–140], unsaturated polyester [329], polyhydroxy butyrate [330], and aliphatic polyester [331–334].

5.5.1. PLA/Clay Nanocomposites

Sinha Ray et al. [34, 315] first reported the preparation of intercalated PLA/layered silicate nanocomposites. For nanocomposite (PLACNs) preparation C$_{18}$-MMT and PLA were first dry mixed by shaking them in a bag. The mixture was then melt-extruded by using a twin-screw extruder operated at 190 °C to yield very light gray color strands of PLACNs. Nanocomposites loaded with a very small amount of oligo-PCL as a compatibilizer were also prepared in order to understand the effect of oligo-PCL on the morphology and properties of PLACNs [34]. The compositions of various nanocomposites of PLA with C$_{18}$-MMT are summarized in Table 7. WAXD patterns of a series of nanocomposites are shown in Figure 30. Figure 31 represents the TEM photographs of nanocomposites corresponding to the WAXD patterns. On the basis of WAXD analyses and TEM observation, they calculated form factors (see Table 8), that is, average length (L_{clay}), thickness (d_{clay}) of the stacked intercalated silicate layers, and the correlation length (ξ_{lay}) between them (see Fig. 3). These data clearly established that silicate layers of the clay were intercalated and randomly distributed in PLA matrix. Incorporation of very small amount of oligo-PCL as a compatibilizer in the nanocomposites lead to a better parallel stacking of the silicate layers and also much stronger flocculation due to the hydroxylated edge–edge interaction of the silicate layers. Owing to the interaction between clay platelets and

[c] The degree of crystallinity.

the PLA matrix in the presence of a very small amount of oligo-PCL, the disk–disk interaction plays an important role in determining the stability of the clay particles and hence the enhancement of mechanical properties of such nanocomposites.

In their further research [316–318, 324], they prepared a series of PLACNs with various types of organoclay in order to investigate the effect of organoclay on the morphology, properties, and biodegradability of PLACNs. Four different types of pristine layered silicates were used and each of them was modified with a different type of surfactant. Detailed specifications of various types of organoclay was used by them are presented in Table 9. On the basis of WAXD analyses and TEM observations, the authors concluded the formation of four different types of PLACNs. Ordered intercalated-and-flocculated nanocomposites were obtained when ODA was used as organoclay, disordered intercalated structure was found in case of PLA/SBE4 nanocomposite, PLA/SAP4 nanocomposite shows near to exfoliate nanocomposite, while the coexistence of stacked intercalated and exfoliated nanocomposite structure is found with PLA/MEE4 nanocomposite. So the nature of OMLS has a strong effect on the final morphology of PLA-based nanocomposites.

In a very recent work, Maiti et al. [319] have prepared a series of PLACNs with three different types of pristine layered silicate such as saponite, MMT, and mica, and each of them was modified with alkylphosphonium salts having various chain lengths. In their work they first try to find the effect of alkylphosphonium modifier of different chain lengths on the properties of organoclay and how the different clays behave differently having same organic modifier. Second, they study the effects of dispersion, intercalation, and aspect ratio of clay on materials properties. From the WAXD patterns it is clearly observed that the d-spacing (001) increases with increasing modifier chain length and for a fixed modifier it increases with increasing lateral dimension of the clay particle. We believe there are two reasons to observe this type of behavior: one is the CEC value and the other is the lateral size of various pristine layered silicates, and in both cases layered silicates follow the order

mica > MMT > saponite. According to the authors, out of two factors, the former factor is more important in controlling the d-spacing/stacking of silicate layers than that of the latter. Since mica has a high lateral size and also a high amount of surfactant molecules due to its high CEC value, surfactant chains inside the intergallery have restricted conformation due to physical jamming. According to them this physical jamming is smaller in case of saponite due to its lower CEC and smaller in lateral size. Therefore, the situation for OMLS, based on TEM and WAXD analyses, is schematically illustrated in Figure 32.

Figure 33 compares the WAXD patterns of nanocomposites with different clay dimensions having the same clay [n-hexadecyl tri-n-butyl phosphonium bromide (C_{16})-modified] content (3 wt%). For MMT-based nanocomposite, the peaks are sharp and crystallite sizes are slightly less than those of the corresponding organoclay, indicating an almost ordered structure of MMT in nanocomposite. The peaks of the nanocomposites prepared with mica clay are very sharp, similar to those of corresponding organoclay, and slightly larger crystallite sizes indicate that the number of stacked silicate layers is the same to that of original organoclay but some amount of PLA is intercalated between the galleries, giving rise to a larger crystallite size. On the basis of WAXD patterns and crystallite size, stacking of silicate layers in the organoclays and in various nanocomposites prepared with three different organoclays is presented schematically in Figure 34.

More recently Dubois et al. [320, 322] reported the preparation of plasticized PLA/MMT nanocomposites. The OMLS used was MMT modified with bis-(2-hydroxyethyl)methyl (hydrogenated tallowalkyl) ammonium cations. WAXD analyses have confirmed the formation of intercalated nanocomposites.

5.5.2. PBS/Clay Nanocomposites

Like PLA, PBS is also an aliphatic thermoplastic polyester with many interesting properties, including biodegradability, melt processability, and thermal and chemical resistance. Although these properties show the potential applications of PBS, some of the other properties such as softness, gas

Figure 31. TEM bright field images: (a) PLACN2 (×10000), (b) PLACN4 (×10000), (c) PLACN2 (×400000), and (d) PLACN4 (×40000). barrier properties, flexural properties, etc. are frequently not enough for a wide range of applications. Sinha Ray et al. [325, 326] first reported the preparation of PBS/MMT nanocomposites (PBSCNs) by simple melt extrusion of PBS and OMLS, having properties suitable for a wide range of applications. MMT modified with octadecylammonium chloride was used as organoclay for nanocomposite preparation. In recent publications [327, 328], the same authors also reported the details of structure–property relationships in case of PBSCNs.

Recently, Lee et al. [332] have reported the preparation of biodegradable aliphatic polyester (APES)/organoclay nanocomposites using a melt intercalation method. Two kinds of organoclays, Cloisite 30B and Cloisite 10A with different ammonium cations located in the silicate galleries, were chosen for the nanocompoites preparation. The WAXD analyses and TEM observations respectively showed a higher degree of intercalation in case of APES/Cloisite 30B nanocomposites as compared to that of APES/Cloisite 10A nanocomposites. According to the authors, this behavior may be due the hydrogen-bonded interaction between APES and hydroxyl group in the galleries of Cloisite 30B nanocomposites than for the APES/Cloisite nanocomposites.

6. MATERIALS PROPERTIES OF POLYMER/CLAY NANOCOMPOSITES

PCNs consisting of a polymer and clay (modified or not) frequently exhibit remarkably improved mechanical and materials properties as compared to those of pristine polymers containing a small amount of (≤ 5 wt%) layered silicate. Improvements can include high moduli, increased strength and heat resistance, decreased gas permeability and flammability, and increased biodegradability of biodegradable polymers. The main reason for these improved properties in PCNs is interfacial interaction between matrix and layered silicate as opposed to conventional filler reinforced systems.

6.1. Mechanical Properties

6.1.1. Dynamic Mechanical Analysis

Dynamic mechanical analysis (DMA) measures the response of a given material to a cyclic deformation (here in tension–torsion mode) as a function of temperature. DMA results are expressed by three main parameters: (a) the storage modulus (G') corresponding to the elastic response to the deformation; (b) the loss modulus (G'') corresponding to the plastic response to the deformation, and (c) $\tan \delta$, that is, the (G''/G') ratio, useful for determining the occurrence of molecular mobility transitions such as the glass transition temperature (T_g).

In the temperature dependence of storage modulus G' and loss factor $\tan \delta$ of the relevant PCNs, below the glass transition region, both samples exhibit high G' and restriction of a substantial drop in G' with increasing temperature. G' in the glassy region below T_g is approximately 50–100% higher in the nanocomposite compared with the blend systems without clays. The shift of $\tan \delta$ reaches to higher temperatures and a decrease of the value indicates an increase in nanocomposite T_g. In some cases, the magnitude of the shift estimated by $\tan \delta$ is about 10 °C or more [12]. These indicate that the interaction between polymer and silicate layers at the interface of layers and polymer matrix could suppress the mobility in the polymer segments near the interface. That is, in both systems the intercalated nanocomposites are formed. The large aspect ratio of the structural hierarchy in the nanoscale level might lead to such a large enhancement in G' throughout the glassy and rubbery region. The temperature dependence of G' of the PPCNs is reported (Fig. 35) [30]. For all PPCNs, there is a strong enhancement of moduli in the investigated temperature range, which indicates that the plastic and as well as elastic response of PP toward deformation is strongly influenced in the presence of organoclay. Below, T_g, the enhancement of G' is clear in the intercalated PPCNs. The clay content dependence of G' is also reported (Fig. 36) [30]. G'_{PPCN} and G'_{PP-MA} are the moduli of the intercalated PPCNs and the PP-MA, respectively. The large reinforcement in G' is observed in the figure. The essential factor governing the enhancement of mechanical properties is the aspect ratio of the dispersed clay particles. According to the Halpin–Tai theoretical expression on the enhancement of G' [335], the Einstein coefficient k_E was estimated by selecting an appropriate value for the best fit to the experimentally obtained G'_{PPCN}/G'_{PP-MA} versus volume fraction of the clay plots. The estimated values of k_E are about 60 for PPCN4 and about 31 for PPCN2 and PPCN7.5. In the intercalated PPCNs, the explanation for the enhancement of G' by only the k_E factor as discussed in the previous case of PMMA/clay nanocomposites [33] is hampered because each PPCN exhibits a different value of k_E, despite the different clay contents. In the case of intercalated PPCNs, the enhancement of G' is
Figure 33. WAXD patterns of smectite, MMT, and mica nanocomposites with C_{16} organoclay and same clay content (3 wt%). Reprinted with permission from [319], P. Maiti et al., *Chem. Mater.* 14, 4654 (2002). © 2002, American Chemical Society.

due to both the degree of the intercalation and the aspect ratio of the dispersed clay particles.

The two-dimensional aspect ratios of the dispersed clay particles L_{clay}/d_{clay} estimated from TEM observation are reported to be 37 for PPCN2, 20 for PPCN4, and 12 for PPCN7.5, respectively. In the PPCN4, despite the lower value of L_{clay}/d_{clay} compared to PPCN2 and low addition of the clay compared to PPCN7.5, this nanocomposite shows the highest value of k_E, suggesting that much higher

Nam et al., *Polymer* 42, 9633 (2001). © 2001, Elsevier Science.

efficiency of the intercalation for the reinforcement is attained. The details were also reported in PBS/clay nanocomposites [325].

The remarkable improvement in G' related to the strong interaction between matrix and organoclay is clearly observed in case of Nylon 6/clay nanocomposites [336]. Table 10 represents the temperature dependence of G' and the thermal expansion coefficient (α) of the Nylon 6 matrix and various nanocomposites (N6CNs). They summarized the details in a dynamic temperature RAM test for neat Nylon 6 and various N6CNs. All N6CNs show a very high increment of moduli at all temperature ranges.

Increased G' related to the dimension of the dispersed clay particles is further demonstrated in case of PLACNs [34]. In order to understand the effect of compatibilizer on morphology and mechanical properties, the authors also prepared PLACNs with a very small amount of oligo-PCL. The details of composition and designation of various types of nanocomposites are presented in Table 7. The enhancement in G' clearly appears in different magnitudes at investigated temperature ranges for all PLACNs. This behavior indicates that the elastic properties of PLA are significantly affected in the presence of C_{18}-MMT. Below T_g, the enhancement of G' is also clear in case of various intercalated PLACNs. On the other hand, all PLACNs show much higher increments of G' at high temperature ranges compared to that of PLA matrices. This is due to both mechanical reinforcement by the clay particles and extended intercalation at high temperature [260]. Above T_g, when materials become soft, the reinforcement effect of the clay particles becomes prominent, due to restricted movement of the polymer chains, and hence strong enhancement of G'.

At the other extreme, PLACN4 and PLACN5 exhibit strong enhancement of G' as compared to that of the PLACN2 with comparable clay loading and PLA/*o*-PCL matrices containing 0.2 and 0.5 wt% oligo-PCL (see Table 8 and Fig. 31b). The presence of small amounts of oligo-PCL does not lead to a big shift and broadening of the $\tan\delta$ curves. However, a large increment in G' above T_g became clear, indicating that the large anisotropy of the dispersed particles due to the flocculation enhanced the loss component.

Table 10. Summary of DMA test for Nylon 6 and various N6CNs under different temperature ranges.

Sample	Term	0 °C	25 °C	50 °C	100 °C	150 °C	200 °C

	G' (GPa)	1.2	1.1	0.8	0.41	0.27	0.01
N6CN3.7	$\alpha \times 10^5$ /cm/cm. °C	6.4	6.6	8.7	8.5	14	67
	G' (GPa)	1.9	1.8	1.2	0.74	0.52	0.18
N6CN4.4	$\alpha \times 10^5$ /cm/cm. °C	7.1	7.7	9.8	11	15	42
	G' (GPa)	1.4	1.3	0.95	0.56	0.38	0.14

The G' values of various PLACNs and corresponding matrices without clay at different temperature ranges are summarized in Table 11. PLACNs with a very small amount of oligo-PCL (PLACN4 and PLACN5) exhibit very high enhancement of mechanical properties as compared to that of PLACNs with comparable clay loading (PLACN2). The essential factor governing the enhancement of mechanical properties of the nanocomposites is the aspect ratio of the dispersed clay particles [335]. From the TEM figures (see Fig. 31) it is clearly indicated that, in the presence of a very small amount of oligo-PCL, flocculation of the dispersed clay particles took place again due to the edge–edge interaction of the clay particles. The two-dimensional aspect ratios of the dispersed clay particles L_{clay}/d_{clay} estimated from TEM observation are 22 for PLACN4 and 12 for PLACN2 (see Table 8) and there is hence strong enhancement of mechanical properties.

The increment in G' directly depends upon the aspect ratio of dispersed clay particles and is also clearly observed in case of PBSCNs. The temperature dependence of G' of PBS and various PBSCNs are reported (Fig. 37). The nature of enhancement of G' in PBSCNs with temperature is somewhat different from well-established intercalated PPCNs [30] and well-known exfoliated N6CN systems [105]. In the latter system, there is a maximum of 40–50% increment of G' compared to that of matrix at well below T_g, and above T_g there is a strong enhancement (>200%) in G'. This behavior is common for so far reported nanocomposites and the reason is the strong reinforcement effect of the clay

particles above T_g when materials become soft. But in case of PBSCNs, the order of enhancement of G' is almost same below and above T_g, and this behavior may be due to the extremely low T_g (-29 °C) of PBS matrix. At the temperature range of -50 to -10 °C, the increments in G' are 18% for PBSCN1, 31% for PBSCN2, 67% for PBSCN3, and 167% for PBSCN4 compared to that of neat PBS. Furthermore at room temperature, PBSCN3 and PBSCN4 respectively show higher increments in G' of 82% and 248% than that of neat PBS, while those of PBSCN1 and PBSCN2 are 18.5% and 44% higher. At 90 °C, only PBSCN4 exhibits very strong enhancement of G' compared to that of the other three PBSCNs.

In Figure 38, Okamoto summarized the clay content dependence of G' of various types of nanocomposites obtained well below T_g. The Einstein coefficient k_E derived

Table 11. G' value of various PLACNs and corresponding matrices without clay at different temperature ranges.

Samples	Storage modulus G' (GPa)			
	-20 °C	40 °C	100 °C	145 °C

Figure 38. Plots of $G'_{\text{nanocomposite}}/G'_{\text{matrix}}$ vs vol% of clay for various nano-composites. The Einstein coefficient k_E is shown with the number in the box. The lines show the calculated results from the Halpin–Tai theory with various k_E.

using Halpin and Tai's theoretical expression modified by Nielsen is shown in the figure and represents the aspect ratio ($L_{\text{clay}}/d_{\text{clay}}$) of dispersed clay particles without intercalation.

From this figure, it is clearly observed that PBSCNs show very high increment in G' compared to other nanocomposites having the same content of clay in the matrix. PPCNs are well known for intercalated systems, N6CNs are well-established exfoliated nanocomposites, PLACNs are going to establish intercalated-and-flocculated nanocomposites, while PBSCNs are intercalated-and-extended flocculated nanocomposites systems [327, 328]. Due to the strong interaction between hydroxylated edge–edge groups, the clay particles are sometimes flocculated in the polymer matrix. As a result of this flocculation the length of the clay particles increases enormously and hence the overall aspect ratio. For the preparation of high molecular weight PBS, di-isocyanate end groups are generally used as a chain extender [336]. These isocyanate end group chain extenders make urethane bonds with hydroxy terminated low molecular weight PBS, and each high molecular weight PBS chain contains two such kinds of bonds (see schematic illustration in Fig. 39). These urethane type bonds lead to strong interaction with the silicate surface by forming hydrogen bonds and hence strong flocculation (see Fig. 40). For this reason, the aspect ratio of dispersed clay particles is much higher in case of PBSCNs compared to all nanocomposites, and hence there is a high enhancement of modulus.
Figure 40. Formation of hydrogen bonds between PBS and clay, which leads to the flocculation of the dispersed silicate layers.

6.1.2. Tensile Properties

The tensile modulus of a polymeric material expressing the stiffness has shown to be remarkably improved when nanocomposites are formed with layered silicates. N6CNs prepared through the intercalative ring opening polymerization of ε-caprolactam, leading to the formation of exfoliated nanocomposites, exhibit a drastic increase in the tensile properties at rather low filler content. The main reason for the drastic improvement of modulus in case of N6CNs is to the strong interaction between matrix and silicate layers via formation of hydrogen bonds as shown in Figure 41.

In case of nanocomposites, the extent of improvement of modulus directly depends upon the average length of the dispersed clay particles, hence the aspect ratio. Figure 42 represents the dependence of tensile modulus (E) measured at 120 °C for exfoliated N6CNs with various clay contents obtained by *in-situ* intercalative polymerization of ε-caprolactam in the presence of protonated aminodode-canoic acid-modified MMT and saponite [2, 114]. Moreover, the difference in the extent of exfoliation, as observed for Nylon 6-based nanocomposite synthesized by *in-situ* intercalative polymerization of ε-caprolactam using Na$^+$-MMT and various acids, strongly influenced the final modulus of nanocomposites.

In Table 12 we summarized the tensile modulus of 1pot-NCH together with neat Nylon 6 and N6CN (=NCH) [107]. The excellent modulus in case of 1pot-NCH can be considered to have its origin in the uniformly dispersed silicate layers. Furthermore, 1pot-NCH has much improved mechanical properties compared with NCH. The polymer matrix in nanocomposites prepared by 1pot synthesis is only the homopolymer of Nylon 6, whereas NCH prepared via intercalative ring-opening polymerization is a copolymer of Nylon 6 and a small amount of Nylon 12. The presence of Nylon 12 may give the low modulus. Various kinds of acids have been used to catalyze the polymerization. One

can observe variation of the modulus of the nanocomposites [107]. On the other hand, the WAXD peak intensity (I_m) that is inversely related to the exfoliation of clay particles also depends on the nature of the acid used to catalyze the polymerization process. For an increase in the I_m values, a parallel decrease in the modulus is observed, indicating that exfoliated layers are the main factor responsible for the stiffness improvement, while intercalated particles, having a less important aspect ratio, rather play a minor role.

The effect of MMT content and N6 molecular weight on the tensile modulus of nanocomposites prepared using MMT modified with $(HE)_2M_1R_1$ is shown in Figure 43 [119, 123]. The addition of organoclay leads to substantial improvement in stiffness for the composites based on each three Nylon 6 (e.g., LMW, MMW, and HMW). Interestingly, the stiffness increases with increasing matrix molecular weight at any given concentration even though the moduli of the neat Nylon 6 are all quite similar. In Table 13 we summarized the moduli and other mechanical properties of the virgin materials and selected $(HE)_2M_1R_1$ Nylon 6/clay nanocomposites. The slightly larger modulus of 2.82 GPa for LMW may the result of a higher degree of crystallinity resulting in faster crystallization kinetics during the cooling of the specimen during injection molding.

Similar trends with respect to the level of organoclay content and molecular weight are evident in the yield strength result. The dependence of yield strength on MMT content and molecular weight is shown in Figure 44. Yield strength increases with the content of MMT. However, the levels of strength improvement for the pure Nylon 6 are nearly
identical. The HMW- and MMW-based nanocomposites show a steady increase in strength with content of clay, while the LMW-based nanocomposites show a less pronounced effect. The differences in strength improvement with respect to molecular weight are very prominent at the highest clay content. The increase in strength relative to the virgin matrix for the HMW composite is nearly double that of the LMW composite.

The relationship between MMT content and elongation at break for the different matrices is shown in Figure 45 for two different rates of extension. Figure 45a shows that the virgin polyamides are very ductile at a test rate of 0.51 cm/min. With increasing clay content the ductility gradually decreases; however, the HMW and MMW based composites show reasonable levels of ductility at MMT concentration as high as 3.5 wt%. Elongation at breaks for the LMW based nanocomposites decreases rapidly at low MMT content at around 1 wt%. The larger reduction in the LMW-based systems may be due to the presence of stacked silicate layers. On the other hand, at the higher testing rate of 5.1 cm/min, shown in Figure 45b, similar trends are observed, but the absolute levels of elongation at break values are significantly lower. Interestingly, the strain at break for LMW composites is relatively independent of rate of extension, similar to what has been observed in case of glass fiber reinforced composites. Even at the highest clay content, the HMW composite exhibits ductile fracture, whereas the LMW- and MMW-based nanocomposites fracture in a brittle manner at the highest clay content.

In case of PPCNs, most of the studies report tensile properties as a function of clay content [254]. Figure 46 shows an Instron study of a neat-PP/f-MMT (modified by alkyltrichlorosilane) composite compared to a PP/2C$_{18}$-MMT "conventional" composite. In case of PPVNs, there is a sharp increase of tensile modulus for very small clay loading (≤ 3 wt%) followed by a much slower increase beyond clay loading of 4 wt%, and this is the characteristic behavior of PCNs. With increase clay content, the strength does not change markedly compared to the neat-PP value and there is only a small decrease in the maximum strain at break. PP systems—conventionally filled, with no nanometer-level dispersion by similar fillers—do not exhibit as strong improvement in their tensile modulus. On the other hand, as the PP/layered silicate interaction is improved, for example when MA functional groups are incorporated in the polymer, the stresses are much more effectively transferred from the polymer matrix to the inorganic filler, and thus a higher increase in tensile properties is expected. Figure 47a and b respectively represents MMT content dependence of tensile modulus and strength of various PPCNs prepared by melt extrusion of PP-MA and C$_{18}$-MMT. The modulus of PPCNs systematically increases with increasing clay content. The tensile strength also increases with increasing clay content up to 4 wt% and then levels off.

In case of nanocomposites if the systems are not thermodynamically favorable, these properties will be changed during processing because the nanocomposite structure will be changed during processing. A recent work by Reichert et al. [337] showing a systematic study of the dependencies

on compatibilizer functionality and organic modification revealed that considerable enhancement of tensile properties could be achieved only when appropriate PP-MA compatibilizers are used to pretreat the OMLS in conjugation with specific organic modification of the MMT. Similar materials under different processing conditions showed much smaller improvements in the practical materials properties [337].

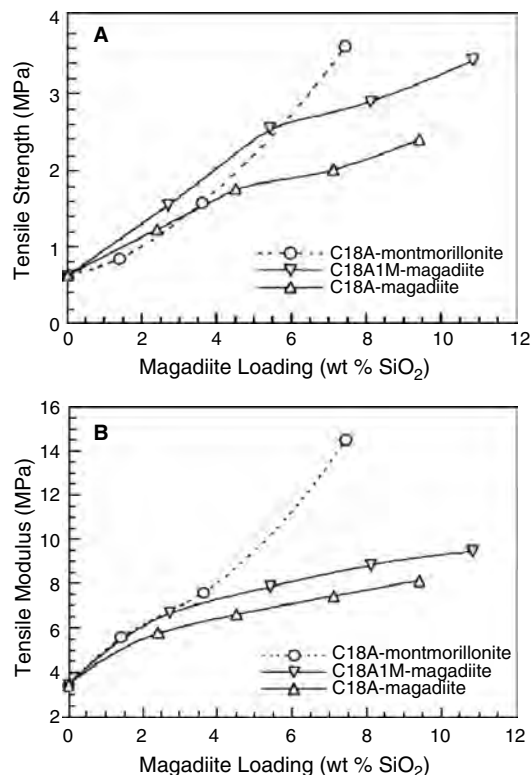
The evolution of the tensile modulus for the epoxy matrix with three different types of layered silicates loading is presented in Figure 48 [191]. A C_{18}-MMT, a C_{18}A-magadiite, and magadiite modified with methyl-octadecylammonium cation (C_{18}A1M-magadiite) were used for nanocomposite preparation. This figure shows much significant increase of the modulus for the MMT-based nanocomposites with the filler content of 4 wt%. According to the present authors, this behavior is due the difference in layer charge in magadiite and MMT. Organomagadiites have a higher layer charge density and subsequently higher alkylammonium content than organo-MMT. As the alkylammonium ions interact with the epoxy resin while polymerizing, dangling chains are formed, and more of this chain is thus formed in the presence of organomagadiites. These dangling chains are known to weaken the polymer matrix by reducing the degree of network cross-linking, then compromising the reinforcement effect of the silicate layer exfoliation.


Figure 48. A comparison of (A) the tensile strengths and (B) tensile moduli for epoxy nanocomposites prepared from C_{18}A-MMT, C_{18}A-magnitide, and C_{18}A1M-magnitide. Mater.* 10, 1820 (1998). © 1998, American Chemical Society.

For thermoset matrices, a significant enhancement in the tensile modulus is observed for an exfoliated structure when alkylammonium cations with different chain length modified MMTs were used for nanocomposites preparations, with the exception that MMT modified with butylammonium only gives an intercalated structure with a low tensile modulus.

Zilg et al. [194] have reported the correlations between polymer morphology, silicate structures, stiffness, and toughness of thermoset nanocomposites as a function of layered silicate type and content. According to them, the main factor for the matrix stiffness improvement resides in the formation of supramolecular assemblies obtained by the presence of dispersed anisotropic laminated nanoparticles. They also described a stiffening effect when the MMT is modified by a functionalized organic cation (carboxylic acid or hydroxyl groups) that can strongly interact with the matrix during curing.

The tensile properties of APES/Cloisite 30B and APES/Cloisite 10A nanocomposites at various clay contents are presented in Table 14 [338]. In comparison to the APES, the tensile strength and modulus have been improved with little decrease of elongation at break. APES/Cloisite 30B nanocomposites exhibit much higher tensile strength and modulus compared to the APES/Cloisite 10A nanocomposites. This is also attributed to the strong interaction between APES matrix and Cloisite 30B. These results further confirm the importance of strong interaction between matrix and clay, which ultimately leads to the better overall dispersion as already observed by TEM observations.

6.1.3. Flexural Properties

Nanocomposite researchers are generally interested on tensile properties of final materials and there are very few reports concerning the flexural properties of neat polymer and its nanocomposite with OMLS. Very recently, Sinha Ray et al. [324] reported detailed measurements of flexural properties of neat PLA and various PLACNs. They conducted flexural properties measurements with injection-molded samples and according to the ASTM D-790 method. Table 15 shows the flexural modulus, flexural strength, and distortion at break of neat PLA and various PLACNs measured at 25 °C. There is a significant increase in flexural modulus for PLACN4 compared to that of neat PLA followed by a much slower increase with increasing OMLS content, and a maximum of 21% in case of PLACN7. On the other hand, flexural strength and distortion at break remarkably increase with PLACN4 then gradually decrease with organoclay loading. According to the authors this behavior

Table 14. Tensile properties of APES/Closite 30B nanocomposites.

Closite 30B content (wt%)	Modulus (kgf/cm^2)	Strength (kgf/cm^2)	Elongation at break (%)
0	106.7	131.7	12.45
1	112.3	139.0	12.25
3	114.4	144.1	11.95
5	118.2	149.8	11.40
10	129.5	157.7	10.90
20	144.4	190.8	11.30
30	173.8	213.5	12.25

Table 15. Comparison of materials properties between neat PLA and various PLACNs prepared with trimethyl octadecylammonium modified MMT.

Materials properties	PLA	PLACN4	PLACN5	PLACN7

Bending strength (MPa)	86	134	122	105
Distortion at break (%)	1.9	3.1	2.6	2

may be due to high organoclay content leading to a brittleness of materials.

6.1.4. Heat Distortion Temperature

Heat distortion temperature (HDT) of a polymeric material is an index of heat resistance toward applied load. Most of the PCNs studies report HDT as a function of clay content, characterized by ASTM D-648. Kojima et al. [2] first show that HDT of pure N6 increases up to 80 °C after PCN preparation with MMT. In their further work [106] they report clay content dependence of HDT of NCH. In case of NCH there is a marked increase in HDT, from 65 °C for the neat N6 to 150 °C for 4.7 wt% nanocomposite; beyond that wt% of MMT, the HDT of nanocomposite levels off. They also conducted HDT tests of various NCHs prepared with clays having different lengths and found that HDT also depends upon the aspect ratio of dispersed clay particles [2]. Like all other mechanical properties, 1potNCH also shows higher HDT than that of NCH prepared by *in-situ* intercalative polymerization.

Since the degree of crystallinity of Nylon 6/clay nanocomposite is independent of the amount and nature of clay, the HDT of Nylon 6/clay nanocomposite is due to the presence of a strong interaction between matrix and silicate surface by forming hydrogen bonds (see Fig. 41). Although Nylon 6 in nanocomposite stabilizes in a different crystal phase (γ-phase) than that found in pure Nylon 6, this different crystal phase is not responsible for higher mechanical properties of Nylon 6/clay nanocomposites because γ-phase is a very soft crystal phase. On the other hand, increased mechanical properties of NCH with increasing clay content is due to the mechanical reinforcement effect.

The nanodispersion of MMT in the PP matrix also promotes a higher HDT [254]. In Table 16 we summarized the HDT of PP and its PCNs based on f-MMT and alkylammonium modified MMT. Like previous systems, there is a significant increase in HDT, from 109 °C for the neat PP to 152 °C for a 6 wt% of clay; after that the HDT of nanocomposite levels off. This improvement in HDT of neat PP after nanocomposite preparation originates from the better mechanical stability of the nanocomposite compared to the neat PP since there is no increment of melting point of neat PP after PCN preparation.

Sinha Ray et al. examined the HDT of neat PLA and various PLACNs with different load conditions. As seen in Figure 49a [324], in case of PLACN7 (inorganic clay content = 5 wt%), there is marked increase of HDT with intermediate load of 0.98 MPa, from 76 °C for the neat PLA to 98 °C for PLACN4 (inorganic clay content = 3 wt%). The value of HDT gradually increases with increasing organoclay

Table 16. HDT of PP/clay nanocomposites and the respective unfilled PP.

Organically modified MMT (wt%)	HDT (°C)	
	PP/f-MMT	PP/alkyl-MMT
0	109 ± 3	109 ± 3
3	144 ± 5	130 ± 7[a]
6	152 ± 5	141 ± 7[b]
9	153 ± 5	

[a] C_{18}-MMT filler, extruder processed.
[b] $2C_{18}$-MMT filler, twin-head mixer.

content, and in case of PLACN7, the value increases up to 111 °C.

On the other hand, imposed load dependence on HDT is clearly observed in case of PLACNs. Figure 49b shows the typical load dependence in case of PLACN7. The increase of HDT of neat PLA due to nanocomposite preparation is a very important property improvement, not only from the industrial point of view but also molecular control on the silicate layers, that is, crystallization through interaction between PLA molecules and SiO_4 tetrahedral layers in the MMT. In case of high load (1.81 MPa), it is very difficult to achieve high HDT enhancement without strong interaction between polymer matrix and organo-MMT [2]. In case of all PLACNs studied here, the values of the melting temperature T_m do not change significantly as compared to that of neat PLA. So the improvement of HDT with intermediate load (0.98 MPa) originates from the better

Figure 49. (a) Organoclay (wt%) dependence of HDT of neat PLA and various PLACNs. (b) Load dependence of HDT of neat PLA and PLACN7. Reprinted with permission from [324], S. Sinha Ray et al., *Polymer* 44, 857 (2003). © 2003, Elsevier Science.

mechanical stability of the PLACNs due to mechanical reinforcement by the dispersed clay particles, higher value of the degree of crystallinity χ_c, and intercalation. This is qualitatively different from the behavior of the NCH system, where the MMT layers stabilize in a different crystalline phase (γ-phase) [106] than that found in the neat Nylon 6, with the strong hydrogen bondings between the silicate layers and Nylon 6 as a result of the discrete lamellar structure on both sides of the clay (see Fig. 41).

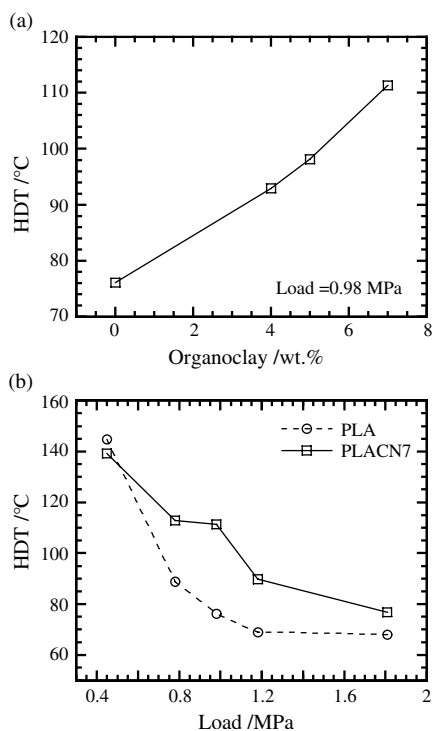
6.2. Thermal Stability

The thermal stability of polymeric materials is usually studied by thermogravimetric analysis (TGA). The weight loss due to the formation of volatile degradation products is monitored as a function of temperature ramp. When the heating is operated under an inert gas flow, a nonoxidative degradation occurs while the use of air or oxygen is allowed following the oxidative degradation of the samples. Generally the incorporation of clay in the polymer matrix enhanced the thermal stability by acting as a superior insulator and mass transport barrier to the volatile products generated during decomposition.

Blumstein [35] first reported the improved thermal stability of a PCN that combined PMMA and MMT. PMMA intercalated (*d*-spacing increase of 0.76 nm) between the galleries of MMT clay resisted the thermal degradation under conditions that would otherwise completely degrade pure PMMA. These PMMA nanocomposites were prepared by free-radical polymerization of MMA intercalated in the clay. TGA data reveal that both linear PMMA and cross-linked PMMA intercalated into MMT layers have a 40–50 °C higher decomposition temperature. Blumstein argues that the stability of the PMMA nanocomposite is due not only to its different structure but also restricted thermal motion of the PMMA in the gallery.

Recently, there have been lots of reports concerned with the improved thermal stability of nanocomposites prepared with various types of organoclay and polymer matrices [339–341]. Recently Zanetti et al. [275] published the details TG analyses of nanocomposites based on EVA. The inorganic phase was florohectorite or MMT, both exchanged with octadecylammonium cation. According to them the deacylation of EVA in nanocomposites is accelerated and may occur at temperatures lower than those for the pure polymer or corresponding microcomposite due to catalysis by the strongly acid sites created by thermal decomposition of the silicate modifier. These sites are active when there is an intimate contact between the polymer and the silicate. Slowing down of the volatilization of the deacylated polymer in nitrogen may be due to the labyrinth effect of the silicate layers in the polymer matrix [342].

In air, the nanocomposite presents a significant delay of weight loss that may derive from the barrier effect due to diffusion of both the volatile thermo-oxidation products to the gas and oxygen from the gas phase to the polymer. According to Gilman et al. this barrier effect increases during volatilization owing to ablative reassembly of the reticular of the silicate on the surface [343].

The thermal stability of the PCL-based nanocomposites has also been studied by TGA. Generally, the degradation


of PCL fits a two-step mechanism [140]: first there is a statistical rapture of the polyester chains by pyrolysis of ester groups with the release of CO_2, H_2O, and hexanoic acid and in the second step, ε-caprolactone (cyclic monomer) is formed as a result of an unzipping depolymerization process. The thermograms of nanocomposites prepared with organoclay and pure PCL recovered after clay extraction are presented Figure 50. Both intercalated and exfoliated nanocomposites show higher thermal stability when compared to the pure PCL or the corresponding microcomposites. The nanocomposites exhibit a 25 °C rise in decomposition temperature at 50% weight loss. The shift of the degradation temperature may be ascribed to a decrease in oxygen and volatile degradation product permeability/diffusivity due to the homogeneous incorporation of clay sheets, to a barrier of these high aspect ratio fillers, and to char formation. The thermal stability of the nanocomposites systematically increases with increasing clay; however, above a loading of 5 wt%, the thermal stability is not improved anymore.

But completely different behavior is observed in case of synthetic biodegradable aliphatic polyester (BAP)/clay nanocomposite systems, in which the thermal degradation temperature and thermal degradation rate are systematically increased with an increasing amount of organoclay up to 15 wt% [344]. Like PS-based nanocomposites, a small amount of clay also increased the residual weight of BAP/OMMT because of the restricted thermal motion of the polymer in the silicate layers. The residual weight of various materials at 450 °C increased in the order BAP < BAP03 < BAP06 < BAP09 < BAP15 (here number indicates wt% of clay). This kind of improved thermal property is also observed in other systems like SAN [345], the intercalated nanocomposites prepared by emulsion polymerization.

Many researchers believe the role of clay in the nanocomposite structure might be the main reason for the difference in TGA results of these systems compared to the systems reported thus far. The clay acts as a heat barrier, which could enhance the overall thermal stability of the system, as well as assisting in the formation of char after thermal decomposition. Thereby, in the beginning stage of
Figure 50. Temperature dependence of the weight loss under an air flow for neat PCL and PCL nanocomposites containing 1, 3, 5, and 10 wt% (relative to inorganics) of MMT-Alk (heating rate: 20 K/min). Reprinted with permission from [140], B. Lepoittevin et al., *Polymer* 43, 1111 (2002). © 2002, Elsevier Science.

thermal decomposition, the clay could shift the decomposition temperature higher. However, after that, this heat barrier effect would result in a reverse thermal stability. In other words, the stacked silicate layers could hold accumulated heat that could be used as a heat source to accelerate the decomposition process, in conjunction with the heat flow supplied by the outside heat source.

6.3. Fire Retardant Properties

The cone calorimeter is the most effective bench-scale method for studying the fire retardant properties of polymeric materials. Fire-relevant properties, measured by the cone calorimeter, such as heat release rate (HRR), peak HRR, and smoke and CO yield, are vital to the evaluation of the fire safety of materials.

Gilman et al. reviewed the flame retardant properties of nanocomposites in detail [346, 347].

Table 17 represents the cone calorimeter data of three different kinds of polymers and their nanocomposites with MMT. From Table 17 we can see that all MMT-based nanocomposites reported here show reduced flammability. Peak HRR is reduced by 50–75% for Nylon 6, PS, and PP-MA nanocomposites [347]. According to the authors the MMT must be nanodispersed for it to affect the flammability of the nanocomposites. However, the clay need not be completely delaminated for it to affect the flammability of the nanocomposite. In general, the nanocomposite flame retardant mechanism is that a high-performance carbonaceous-silicate char builds up on the surface during burning; this insulates the underlying material and slows the mass loss rate of decomposition products.

For a PPCN with 4 wt% organoclay [347], there is a 75% reduction in flammability compared to the neat matrix (see Fig. 51).

6.4. Gas Barrier Properties

Nanoclays are believed to increase the barrier properties by creating a maze or "tortuous path" (see Fig. 52) that retards the progress of the gas molecules through the matrix resin. The direct benefit of the formation of this type of path is clearly observed in polyimide/clay nanocomposite by showing dramatically improved barrier properties with simultaneous decrease in thermal expansion coefficient [211, 213]. The polyimide/layered silicate nanocomposites revealed a several-fold reduction in the permeability of small gases (e.g. O_2, H_2O, He, CO_2, and the organic vapor ethylacetate) with the presence of a small fraction of organoclay. For example, at 2 wt% clay loading, the permeability coefficient of water vapor was decreased tenfold for the synthetic mica relative to pristine polyimide. By comparing nanocomposites made with layered silicates of various aspect ratios the permeability was noted to decrease with increasing aspect ratio.

The O_2 gas permeability was measured for the exfoliated PLA/synthetic mica nanocomposites prepared by Sinha Ray et al. [348]. The relative permeability coefficient value (i.e., P_{PLACN}/P_{PLA} where P_{PLACN} and P_{PLA} stand for the nanocomposite and pure PLA permeability coefficient, respectively) has been plotted as a function of the wt% of clay. The curve fitting has been achieved by using Nielsen theoretical

expression [349] allowing the prediction of gas permeability in function of the length and width of the filler particles as well as their volume fraction with in the PLA matrix (see Fig. 53).

In the Nielsen model [349], platelets of length ($\cong L_{clay}$) and width ($\cong D_{clay}$) of the clay are dispersed parallel in polymer matrix; then the tortuosity factor (τ) can be expressed as

$$\tau = 1 + (L_{clay}/2D_{clay})\phi_{clay} \qquad (1)$$

where ϕ_{clay} is the volume fraction of dispersed clay particles. Therefore, the relative permeability coefficient (P_{PCN}/P_{Neat}) is given by

$$P_{PCN}/P_{Neat} = \tau^{-1} = 1/[1 + (L_{clay}/2D_{clay})\phi_{clay}] \qquad (2)$$

where P_{PCN} and P_{Neat} are the permeability coefficient of PCN and neat polymer, respectively.

The H$_2$O-vapor permeability for the PUU/clay nanocomposites is presented by Xu et al. in terms of P_c/P_o, that is, the permeability coefficient of the nanocomposite (P_c) relative to that of the neat PUU (P_o) [350]. The nanocomposite formation results in a dramatic decrease in H$_2$O-vapor transmission through the PUU sheet. The solid lines are based on the argument of the tortuosity model for the aspect ratio of 300 and 1000. A comparison between the experimental values and the theoretical model prediction suggests a gradual change in the effective aspect ratio of the filler (L_{clay}/D_{clay}).

6.5. Ionic Conductivity

Solvent-free electrolytes are of much interest because of their charge-transport mechanism and their possible applications in electrochemical devices. With this background, Vaia et al. [152] have considered the preparation of PEO/clay nanocomposites to fine tune ionic conductivity of PEO. An intercalated nanocomposite prepared by melt intercalation of PEO (40 wt%) into Li$^+$-MMT (60 wt%) has shown to enhance the stability of the ionic conductivity at lower temperature when compared to a more conventional PEO/LiBF$_4$ mixture. This improvement in conductivity is explained by the fact that PEO is not able to crystallize when intercalated, hence eliminating the presence of crystallites, nonconductive in nature. The higher conductivity at room temperature compared to conventional

Figure 52. Formation of tortuous path in polymer/clay nanocomposites.
Figure 53. Oxygen gas permeability of neat PLA and various PLACNs as a function of organoclay content measured at 20 °C and 90% relative humidity. The filled circles represent the experimental data. Theoretical fits based on Nielsen tortuousity model.

PEO/LiBF$_4$ electrolytes with a single ionic conductor character makes those nanocomposites new promising electrolyte materials. The same type of behavior in ionic conductivity is also observed in case of poly[bis(methoxy-ethoxy) ethoxy phosphazene]/Na$^+$-MMT nanocomposite as prepared by Hutchison et al. [351].

In a recent report, Okamoto et al. [12] have reported the correlation between internal structure and ionic conductivity behavior of PMMA/clay and PS/clay nanocomposites having various dispersed morphologies of the clay layers by using an impedance analyzer in the temperature range of 90–150 °C. The nanocomposites having finer dispersion of the clay layers exhibit higher ionic conductivity rather than the other systems such as PMMA/clay nanocomposite with stacking layer structure. The activation energy of the conductivity in finer dispersed morphology systems becomes larger than the other systems and the corresponding organoclay solids.

6.6. Optical Transparency

Although layered silicates are micrometer in lateral size, they are just 1 nm thick. Thus, when single layers are dispersed in a polymer matrix, the resulting nanocomposite is optically clear in the visible region. Strawhecker and Manias have reported the ultraviolet (UV)/visible transmission spectra of pure PVA and PVA/Na$^+$-MMT nanocomposites with 4 and 10 wt% MMT [87]. The spectra show that the visible region is not affected at all by the presence of the silicate layers and retains the high transparency of the PVA. For the UV wavelengths, there is strong scattering and/or absorption, resulting in very low transmission of the UV light. This behavior is not surprising as the typical MMT lateral sizes are 50–1000 nm.

Like PVA, various other polymers also show optical transparency after nanocomposite preparation with organoclay [254].

6.7. Biodegradability of Green Polymeric Nanocomposites

Another most interesting and exciting aspect of nanocomposite technology is the significant improvement of biodegradability of biodegradable polymers after nanocomposite preparation with organoclay. There is a need for

the development of *green polymeric materials* that would not involve the use of toxic or noxious components in their manufacture and could be degraded in the natural environment or easily recycled. Aliphatic polyesters are among the most promising materials for the production of environmentally friendly biodegradable plastics. Biodegradation of aliphatic polyester is well known, in that some bacteria degrade them by producing enzymes, which attack the polymer. Tetto et al. [352] first reported some results about the biodegradability of nanocomposites based on PCL, where the authors found that the PCL/clay nanocomposites showed improved biodegradability compared to pure PCL. According to them, the improved biodegradability of PCL after nanocomposite formation may be due to the catalytic role of the organoclay in the biodegradation mechanism. But still it is unclear how the clay increases the biodegradation rate of PCL.

Recently, Lee et al. [332] reported the biodegradation of aliphatic polyester based nanocomposites under compost. Figure 54a and b respectively represents the clay content dependence of biodegradation of APES based nanocomposites prepared with two different types of clays. They assumed that the retardation of biodegradation is due to the improvement of the barrier properties of the aliphatic APES after nanocomposites preparation with clay. However, there are no data about permeability.

Very recently, Sinha Ray et al. [318, 324] first reported the biodegradability of neat PLA and corresponding nanocomposites prepared with trimethyl octadecylammonium modified MMT (C^3C_{18}-MMT) with detailed mechanisms. The compost used was prepared from food waste and tests were carried out at temperature of 58 ± 2 °C. Figure 55a shows the real picture of the recovered samples of neat PLA and PLACN4 (C^3C_{18}-MMT = 4 wt%) from compost with time. The decreased M_w and residual weight percentage R_w of the initial test samples with time are also reported in Figure 55b. The biodegradability of neat PLA is significantly enhanced after PCN preparation. Within one month, both extent of M_w and extent of weight loss are at almost the same level for both PLA and PLACN4. However, after one month, a sharp change occurs in weight loss of PLACN4, and within two months, it is completely degraded in compost. The degradation of PLA in compost is a complex process involving four main phenomena, namely: water absorption, ester cleavage and formation of oligomer fragments, solubilization of oligomer fragments, and finally diffusion of soluble oligomers by bacteria [353]. Therefore, the factor that increases the hydrolysis tendency of PLA ultimately controls the degradation of PLA. They expect the presence of terminal hydroxylated edge groups of the silicate layers may be one of the factors responsible for

(a)

after 32 days   after 50 days   after 60 days

PLA

PLACN4

(b)

this behavior. In case of PLACN4, the stacked (~4 layers) and intercalated silicate layers are homogeneously dispersed in the PLA matrix (from TEM image) and these hydroxy groups start heterogeneous hydrolysis of the PLA matrix after absorbing water from compost. This process takes some time to start. For this reason, the weight loss and degree of hydrolysis of PLA and PLACN4 are almost same up to one month (see Fig. 55b). However, after one month there is a sharp weight loss in case of PLACN4 compared to that of PLA. That means one month is a critical value to start heterogeneous hydrolysis, and due to this type of hydrolysis the matrix becomes very small fragments and disappears with the compost. This assumption was confirmed by conducting the same type of experiment with PLACN prepared by using dimethyl dioctadecyl ammonium salt modified synthetic mica which has no terminal hydroxylated edge group, and the degradation tendency was almost the same with neat PLA [354].

They also conducted respirometric testing to study degradation of the PLA matrix in compost environment at 58 ± 2 °C. For this test the compost used was made from bean-curd refuse, food waste, and cattle feces. Unlike weight loss, which reflects the structural changes in the test sample, CO_2 evolution provides an indicator of the ultimate biodegradability of PLA in PLACN4 (prepared with N(cocoalkyl)N, N-[bis(2-hydroxyethyl)]-N-methylammonium modified synthetic mica), that is, mineralization, of the samples. Figure 56 shows the time dependence of the degree of biodegradation of neat PLA and PLACN4, indicating that the biodegradability of PLA in PLACN4 is enhanced significantly. The presence of organoclay may thus cause a different mode of attack on the PLA

component, which might be due to the presence of hydroxy groups. Details degrading the mechanism of biodegradability are presented in relevant literature [317, 354].

6.8. Other Properties

Another property of polymer that is strongly affected by the incorporation of layered silicates is a sharp increase of the scratch resistance [254], dimensional stability [355], and solvent resistance [355] via nanocomposite technology.

7. CRYSTALLIZATION OF POLYMER/CLAY NANOCOMPOSITES

7.1. Spherulitic Texture and Growth

Crystallization of PCNs might be a good tool for controlling the structure od PCNs and thereby the various properties. Maiti et al. [260] have reported an example of the time variation of the diameter of the spherulite D for PP-MA and PP/clay nanocomposites at 135 °C (see Fig. 57). A linear growth of D is seen in a range of t scale for PP-MA, PPCN2, and PPCN7.5. The linear growth rate G $[=1/2(dD/dt)]$, defined as the initial slope of the plots, slightly increases with increasing clay content. From the extrapolation of D vs t plots, we estimated the onset time t_0, which corresponds to the induction time of the crystallization. The t_0 of both PPCNs decreases with clay content compared to the PP-MA matrix without clay. The reduction of t_0 in the PPCNs is attributed to the nature of the clay as the nucleating agent. For PPCNs, G shows almost the same value compared to PP-MA without clay. In spite of the increase in clay content, the dispersed clay particles have not much effect on the crystallization and no big acceleration of G in the crystallization of the PPCNs is seen. In the changes in t_0 with crystallization temperture T_c, the PPCNs show remarkably short time especially at high T_c, suggesting that the dispersed clay particles have some contribution to enhance the nucleation as mentioned. The primary nucleation density of the spherulites (i.e., the number of heterogeneous nuclei N) was given by

$$N = (3/4\pi)(D_m/2)^{-3} \quad (3)$$

where D_m is the maximum diameter of the spherulite (i.e., the attainable diameter before impingement). The calculated values of N at 130 °C were 4×10^{-8} for PP-MA, 50×10^{-8} for PPCN2, and 200×10^{-8} μm^{-3} for PPCN7.5, respectively. The time variation of the volume fraction of the spherulites increases in proportion to NG^3 ($\cong$overall crystallization rate). This fact suggests that the overall crystallization rate of the PPCNs is about one or two orders of magnitude higher than that of matrix PP-MA without clay.

7.2. Formation of γ-Form in PPCNs

Maiti et al. [261] have reported the temperature dependence of the fraction of γ-form f_γ. The value of f_γ was calculated from the area of the specific peak, compared to the total area of α and γ-forms. At low T_c (<100 °C) PP-MA does not exhibit γ-crystals, but their content increases with increasing T_c. The fraction of γ-form consistently increases with clay content in PPCNs, compared to PP-MA, at every T_c. Lotz et al. [356] reported that γ crystals are nucleated on the lateral (010) faces of α crystal and appear to be favored by, or linked to, the absence of chain folding. The mobility of the PP-MA matrix is significantly reduced in the presence of maleic anhydride grafting in the main chain, which causes lowering of chain folding especially at high T_c. In the presence of clay particles in PPCNs, the movements of polymer chains inside the clay particles are restricted. The correlation length of the clay particles is roughly the same as that of radius of gyration of the matrix [30]. Thus, the formation of γ-phase is enhanced in the presence of clay particles.

7.3. Intercalation during Crystallization

In the PPCNs, at high T_c (≥ 110 °C), where the crystallization rate is low enough to solidify the system, the intercalation should be anticipated in the melt state during crystallization [31]. The driving force of the intercalation originates from strong hydrophilic interaction between the MA group and the polar clay surfaces [30, 245]. With increasing T_c, the small peak and shoulder shift toward the smaller angle region in the PPCNs, suggesting that the extent of intercalation takes place with crystallization [260].

Figure 58 shows $d_{(001)}$ of the clay gallery quantitatively, as a function of T_c, obtained from their respective Bragg reflections. Here, in case of PPCN2, the peak is not prominent. The dotted line shows the effect of annealing on the $d_{(001)}$ value of organoclay. The $d_{(001)}$ increases with T_c for both PPCN4 and PPCN7.5 systems and PPCN4 always exhibits a significantly higher value than that of PPCN7.5. These imply that intercalation proceeds at T_c and increases with decreasing clay content. Further decrease of clay content from 4 to 2 wt% in PPCN2 leads to a partially exfoliated system as discussed in Section 3.1. That is, the PPCN with low clay content crystallized at high T_c (≥ 110.0 °C) exhibits a higher amount of intercalation than that with high clay content crystallized at any T_c.
Figure 57. Spherulitic diameter as a function of crystallization time at $T_c = 130.0$ °C. The arrow indicates the induction time of crystallization for PP-MA. Reprinted with permission from [260], P. Maiti et al., *Macromolecules* 35, 2042 (2002). © 2002, American Chemical Society.

At high T_c ($\geq$110 °C) (low crystallization rate), the melt state exists for quite a long time and PP-MA chains have enough time to intercalate before crystallization can occur in the bulk. Then the enhanced intercalation is produced. The extent of intercalation is strongly dependent on the time of the molten state. In other words, the intercalated PPCNs are not equilibriated. By decreasing the clay content in the nanocomposites, the virtual gallery space in the silicate layers decreases and consequently, the PP-MA molecules would try to accommodate, through interaction, in the minimum space causing higher intercalated species. For sufficiently low clay content, a system like PPCN2, having less gallery space, is partially exfoliated due to the high number density of the tethering junction.

There are two possible ways to order polymer chains inside the silicate gallery. Either (1) polymer molecules escape from gallery and crystallize outside (*diffuse out*) or (2) molecules may penetrate into the silicate gallery when they are in the molten state (*diffuse in*). When PPCN4 is directly crystallized from the melt at 70.0 °C for two different times of 30 min and 17 h, the interlayer spacing is the same (2.75 nm). If PPCN4 melt is annealed at 150.0 °C, just above T_m (=145.0 °C) for sufficiently long time and then subsequently crystallized at 70.0 °C for 30 min, the interlayer spacing increases to 2.96 nm. Furthermore, when PPCN4 is crystallized from the melt at 30 °C, where the crystallization rate is slow enough, the interlayer spacing becomes 3.08 nm. All these experiments indicate that the extent of intercalation is strongly dependent on the time of the molten state, and ordering of polymer chains occurs through a *diffuse-in* mechanism. In other words, a slower crystallization rate makes a more intercalated species as molten polymer molecules have sufficient time to diffuse into the silicate gallery. Based on the WAXD and TEM micrographs, the nature of intercalation has been represented by Maiti et al. [260, 261] in Figure 59. Thus, by suitably crystallizing the PPCNs we can control the fine structure (*confined orientation*) of the PCNs.
Figure 59. The illustration for a diffuse-in mechanism by suitable crystallization. Reprinted with permission from [260], P. Maiti et al., *Macromolecules* 35, 2042 (2002). © 2002, American Chemical Society.

7.4. Effect of Intercalation on Enhancement of Dynamic Modulus

According to the prediction of Khare et al. [357], the confinement of polymer chains increases the viscosity and mechanical properties of the system significantly. One can expect some difference in mechanical properties with the change of the degree of intercalation in the PPCNs vis-à-vis the clay content and T_c (see Table 18). It is clear from the table that for a particular T_c, G' increases with increasing clay content. The PP-MA crystallized at 130 °C exhibits a 9.9% increase in G' compared to the sample crystallized at 70.0 °C. PPCN7.5 and PPCN4 show 13.3 and 30.6% increases, respectively, in the same condition. The effect of T_c on G' is in the order of PP-MA < PPCN7.5 < PPCN4. It may be recalled that the T_c dependence of $d_{(001)}$ showed the order of intercalation PPCN7.5 < PPCN4 in Figure 58. This implies that much higher efficiency of the intercalation for the reinforcement is attained in the PPCN4. For PPCN2, owing to the partial exfoliation, the degree of intercalation decreases and hence the modulus decreases compared to the low T_c condition (=70 °C). Here, it should be mentioned that the crystallinity increases a little bit with increasing T_c for both PP-MA and PPCNs and the extent is almost same for all the systems. So it is believed that not the crystallinity but the degree of intercalation does affect the storage modulus.

7.5. Crystallization Controlled by Silicate Surfaces

The formation of γ-form in the presence of clay in the NCH system is well known [117]. The essential difference between the γ-form and the α-form is the molecular packing; in the α-form hydrogen bondings are formed between antiparallel chains while the molecular chains have to twist away

Table 18. Dynamic storage modulus of PP-MA and PPCNs at $T = 50\ °C$ crystallized at different temperatures.

System	$T_c\ °C$	$G' \times 10^{-8}$ (Pa)	% Increase
PP-MA	70	2.92	9.9
	130	3.21	
PPCN2	70	4.79	
	130	4.50	
PPCN4	70	5.16	30.6
	130	6.74	
PPCN7.5	70	7.49	13.3
	130	8.49

from the zigzag planes to form the hydrogen bonds among the parallel chains in γ-form giving rise to lesser interchain interaction as compared to the α-form.

The lamellar morphology and distribution of clay particles in NCH (N6CN3.7) (MMT = 3.7 wt%), crystallized at 170 and 210.0 °C have been reported by Maiti et al. [358] in Figure 60. The white strips (Fig. 60a) represent the discrete lamellar pattern, and after a close look, a black clay particle inside the lamella is clearly observed. In other words, lamellar growth occurs on both sides of the clay particles (i.e., the clay particle is sandwiched by the formed lamella). This is a unique observation of lamellar orientation on the clay layers. In the semicrystalline polymer generally stacked lamellar orientation takes place. The lamellar pattern at high T_c (Fig. 60b) is somehow similar but along with the sandwiched structure, branched lamellae are formed which are originated from the parent sandwiched lamella. There are no clay particles found inside the branch lamella and the γ-phase having irregular chain packing with distortion (γ^*-phase) is formed as revealed by WAXD which one can observe only in case of high T_c crystallized nanocomposites. This epitaxial growth (γ^*-phase) on the parent lamella forms the shish-kebab-type of structure, which virtually enhances the mechanical properties of the nanocomposites. From this sandwiched structure the accurate determination of long spacing and lamellar thickness of N6CN3.7 from small angle X-ray scattering is questionable [116]! It has to be remembered that Nylon 6 has the highest capability of forming hydrogen bonding to form a hydrogen-bonded sheet. The pseudohexagonal packing is favored with the hydrogen
Figure 60. TEM micrographs of N6C3.7 crystallized at (a) 170 and (b) 210 °C. The black strip inside the white part is clay. (b) The typical shish-kebab type of structure.

bonding between the silicate layers and Nylon 6. As a result the induction time of N6CN3.7 becomes very short, as compared to neat Nylon 6. Once one molecular layer is nucleated on the clay surface, other molecules may form the hydrogen bonding on the already formed hydrogen-bonded molecule to the silicate surface giving rise to the discrete lamellar structure on both side of the clay. This unique mechanism can well explain the higher crystallization rate of PCNs along with morphology and developed internal structure. This sandwiched structure (each silicate layer is strongly covered by polymer crystals) makes the system very rigid. As a result the HDT increases up to 80 °C but the surrounding excess amorphous part (lower crystallinity of N6CN3.7 as compared to neat Nylon 6) can easily retain the polymeric properties like impact strength and ultimately makes a improved/perfect system in PCNs.

8. MELT RHEOLOGY OF POLYMER/CLAY NANOCOMPOSITES

8.1. Linear Viscoelastic Properties

The measurement of rheological properties of the PCNs under molten state is crucial to gain a fundamental understanding of the nature of the processability and the structure–property relationship for these materials. Dynamic oscillatory shear measurements of polymeric materials are generally performed by applying a time dependent strain of $\gamma(t) = \gamma_o \sin(\omega t)$ and the resultant shear stress is $\sigma(t) = \gamma_o[G' \sin(\omega t) + G'' \cos(\omega t)]$, with G' and G'' being the storage and loss modulus, respectively.

Generally, the rheology of polymer melts strongly depends on the temperature at which the measurement is carried out. It is well known that for the thermorheological simplicity, isotherms of storage modulus ($G'(\omega)$), loss modulus ($G''(\omega)$), and complex viscosity ($|\eta^*|(\omega)$) can be superimposed by horizontal shifts along the frequency axis:

$$b_T G'(a_T \omega, T_{ref}) = b_T G'(\omega, T)$$
$$b_T G''(a_T \omega, T_{ref}) = b_T G''(\omega, T)$$
$$|\eta^*|(a_T \omega, T_{ref}) = |\eta^*|(\omega, T)$$

where a_T and b_T are the frequency and vertical shift factors, and T_{ref} is the reference temperature. All isotherms measured for pure polymer and for various PCNs can be superimposed along the frequency axis.

In case of polymer samples, it is expected, at the temperatures and frequencies at which the rheological measurements were carried out, that the polymer chains should be fully relaxed and exhibit characteristic homo-polymer-like terminal flow behavior (i.e., curves can be expressed by a power law of $G' \propto \omega^2$ and $G'' \propto \omega$).

The rheological properties of *in-situ* polymerized nanocomposites with end-tethered polymer chains were first described by Krisnamoorti and Giannelis [135]. The flow behavior of PCL- and Nylon 6-based nanocomposites differed extremely from that of the corresponding neat matrices, whereas the thermorheological properties of the nanocomposites were entirely determined by that behavior of matrices [135]. The slope of $G'(\omega)$ and $G''(\omega)$ versus $a_T \omega$

is much smaller than 2 and 1, respectively. Values of 2 and 1 are expected for linear homodispersed polymer melts, and large deviations especially in the presence of a very small amount of layered silicate loading may be due to the formation of network structure in the molten state. However, such nanocomposites based on the *in-situ* polymerization technique exhibit fairly broad molar mass distribution of the polymer matrix, which hides the structure relevant information and impedes the interpretations of the results.

To date, the melt state linear dynamic oscillatory shear properties of various kinds of nanocomposites have been examined for a wide range of polymer matrices including Nylon 6 with various matrix molecular weights [119], PS [71], PS-PI block copolymers [102, 103], PCL [140], PP [25, 248, 265], PLA [34, 324], PBS [326–329], and so on [359–361].

The linear dynamic viscoelastic master curves for the neat PLA and various PLACNs are shown in Figure 61 [324]. The linear dynamic viscoelastic master curves were generated by applying a time–temperature superposition principle and shifted to a common temperature T_{ref} using both frequency shift factor a_T and modulus shift factor b_T. The moduli of the PCNs increase with increasing clay loading at all frequencies ω. At high ω's, the qualitative behavior of $G'(\omega)$ and $G''(\omega)$ is essentially the same and unaffected by frequencies. However, at low frequencies $G'(\omega)$ and $G''(\omega)$

increase monotonically with increasing clay content. In the low frequency region, the curves can be expressed by power law of $G'(\omega) \propto \omega^2$ and $G''(\omega) \propto \omega$ for neat PLA, suggesting that this is similar to those of the narrow M_w distribution homopolymer melts. On the other hand, for $a_T < 5$ rad s^{-1}, the viscoelastic response [particularly $G'(\omega)$] for all the nanocomposites displays significantly diminished frequency dependence as compared to the matrices. In fact, for all PLACNs, $G'(\omega)$ becomes nearly independent at the low $a_T\omega$ and exceeds $G''(\omega)$, characteristic of materials exhibiting a pseudo-solid-like behavior [135]. The terminal zone slopes values of both neat PLA and PLACNs are estimated at the lower $a_T\omega$ region (<10 rad s^{-1}) and are presented in Table 19. The lower slope values and the higher absolute values of the dynamic moduli indicate the formation of "spatially linked" structures in the PLACNs under the molten state [362]. Because of this structure or highly geometric constraints, the individual stacked silicate layers are incapable of freely rotating and hence by imposing small $a_T\omega$, the relaxations of the structure are prevented almost completely. This type of prevented relaxation due to the highly geometric constraints of the stacked and intercalated silicate layers leads to the presence of the pseudo-solid-like behavior as observed in PLACNs. This behavior probably corresponds to the shear-thinning tendency, which strongly appears in the viscosity curves ($a_T\omega < 5$ rad s^{-1}) ($|\eta^*|$ vs $a_T\omega$) [57]. Such a feature strongly depends on the shear rate in the dynamic measurement because of the formation of the shear-induced alignment of the dispersed clay particles [363].

The temperature dependence frequency shift factors (a_T, Williams–Landel–Ferry type [364]) used to generate master curves shown in Figure 61 are shown in Figure 62. The dependence of the frequency shift factors on the silicate loading suggests that the temperature-dependent relaxation process observed in the viscoelastic measurements is somehow affected by the presence of the silicate layers [135]. In case of N6CN3.7, where the hydrogen bonding occurs on the already formed hydrogen-bonded molecule to the silicate surface, the system exhibits large value of flow activation energy (estimated from the slope in Fig. 62a) near one order higher in magnitude compared with that of neat Nylon 6 [365].

The shift factor b_T shows a large deviation from a simple density effect; it would be expected that the values would not vary far from unity [364]. One possible explanation is an internal structure development occurring in PLACNs during measurement (shear process). The alignment of the silicate layers probably supports PCN melts to withstand the shear force, thus leading to the increase in the absolute values of $G'(\omega)$ and $G''(\omega)$.

Galgali et al. [248] have also shown that the typical rheological response in nanocomposites arises from frictional interactions between the silicate layers and not due to the immobilization of confined polymer chains between the silicate layers. They have also shown a dramatic decrease in the creep compliance for the PPCH6 prepared with PP-MA and 6 wt% MMT. On the other hand, for PPCH9 prepared with PP-MA and 9 wt% of MMT, Galgali et al. [248] showed a dramatic three order of magnitude drop in the zero shear viscosity beyond the apparent yield stress, suggesting that the solidlike behavior in the quiescent state is a result of the percolated structure of the layered silicate.

Ren et al. [102] measured the viscoelastic behavior of a series of nanocomposites of disordered PS-PI block copolymer and MMT. Dynamic moduli and stress relaxation measurements indicate solidlike behavior for nanocomposites with more than 6.7 wt% MMT, at least on a time scale in the order of 100 s. According to them, this solidlike behavior is due to the physical jamming or percolation of the randomly distributed silicate layers at a surprisingly low volume fraction due to their anisotropic nature. The fact that alignment of the silicate layers by large shear stresses results in a more liquidlike relaxation behavior supports the percolation agreement.

A solidlike rheological response is also observed for PCL-based nanocomposites with organoclay content of 3 wt% or more [140]. $G'(\omega)$ and $G''(\omega)$ in the terminal region are substantially increased for all the studied nanocomposites compared with neat PCL and or PCL-based microcomposites.

Recently, Fornes et al. [119] have conducted dynamic and steady shear capillary experiments of pure Nylon 6

with different molecular weights and their nanocomposites with organoclay over a large range of frequencies and shear rates. Figure 63 shows logarithmic plots of complex viscosity, $|\eta^*|$ vs ω at 240 °C for pure Nylon 6 and

$(HE)_2M_1R_1$ nanocomposites based on (a) HMW, (b) MMW, and (c) LMW obtained using the parallel plate oscillating rheometer. Figure 63 also shows a plot of steady-state shear viscosity η versus shear rate γ obtained using a capillary rheometer. From the figure we can see a significant difference between the nanocomposites particularly at low frequencies. The HMW-based nanocomposites show very strong non-Newtonian behavior and this is more pronounced at the low frequency region. On the other hand, this non-Newtonian behavior gradually decreases with decreasing molecular weight of the matrix, and with LMW it behaves like pure polymer. This particular trend is more clearly observed in plot of G' vs ω due to the extreme sensitivity of G' toward dispersed morphology under the molten state [119]. The difference in terminal zone slopes may be due to the different extent of exfoliation of the clay particles in three types of matrices.

At the other extreme, the steady shear capillary shows a trend with respect to the matrix molecular weight. The HMW- and MMW-based nanocomposites show lower viscosities compared to that of their corresponding matrices, whereas viscosities of LMW-based nanocomposites are lower than pure matrix. According to them, this behavior also due the higher degree of exfoliation in case of HMW- and MMW-based nanocomposites compared to the LMW-based nanocomposite.

Finally they considered the differences in the melt viscosity among the three systems. Over the range of frequencies and shear rates tested, the melt viscosity of the three systems follow the order HMW > MMW > LMW, and hence the resulting shear stresses exerted by the pure polymers also follows same order. Therefore, during melt mixing, the level of stress exerted on the organoclay by the LMW polyamide is significantly lower than those developed in presence of HMW or MMW polyamides. As a result the breakup of clay particles is much easier in case of HMW polyamide and ultimately improved the clay particle dispersion.

Figure 64 shows schematic suggestions of various roles that shear stress may play during the melt compounding of nanocomposites. Therefore, the role of polymer molecular weight is believed to stem from the fact that a melt viscosity exerts the taller stacks into shorter ones. The final step in exfoliation involves peeling the platelets of the stacks one by one, and this takes time and requires a strong matrix–organoclay interaction to cause spontaneous wetting.

8.2. Steady Shear Flow

The steady shear rheological behaviors of neat PBS and various PBSCNs are shown in Figure 65. The steady viscosity of PBSCNs is enhanced considerably at all shear rates with time and at a fixed shear rate increases monotonically with increasing silicate loading [327]. On the other hand, all intercalated PBSCNs exhibit strong rheopexy behavior, and this becomes prominent at low shear rates, while neat PBS exhibits a time independent viscosity at all shear rates. With increasing shear rates, the shear viscosity attains a plateau after a certain time, and the time required to attain this plateau decreases with increasing shear rates. The possible
Figure 64. Stemwise mechanism of clay platelets exfoliation during melt compounding: (a) organoclay breakup, (b) intercalated organoclay tactoid breakup, and (c) platelet exfoliation. Reprinted with permission from [119], T. D. Fornes et al., *Polymer* 42, 9929 (2001). © 2001, Elsevier Science.

reasons for this type of behavior may be the planer alignment of the clay particles toward the flow direction under shear. When the shear rate is very slow (0.001 s^{-1}), clay particles take longer to attain complete planer alignment along the flow direction, and this measurement time (1000 s) is too short to attain such alignment and hence shows strong rheopexy behavior. On the other hand, under high shear rates (0.005 or 0.01 s^{-1}) this measurement time is considerable enough to attain such alignment, and hence nanocomposites show time independent shear viscosity after a certain time.

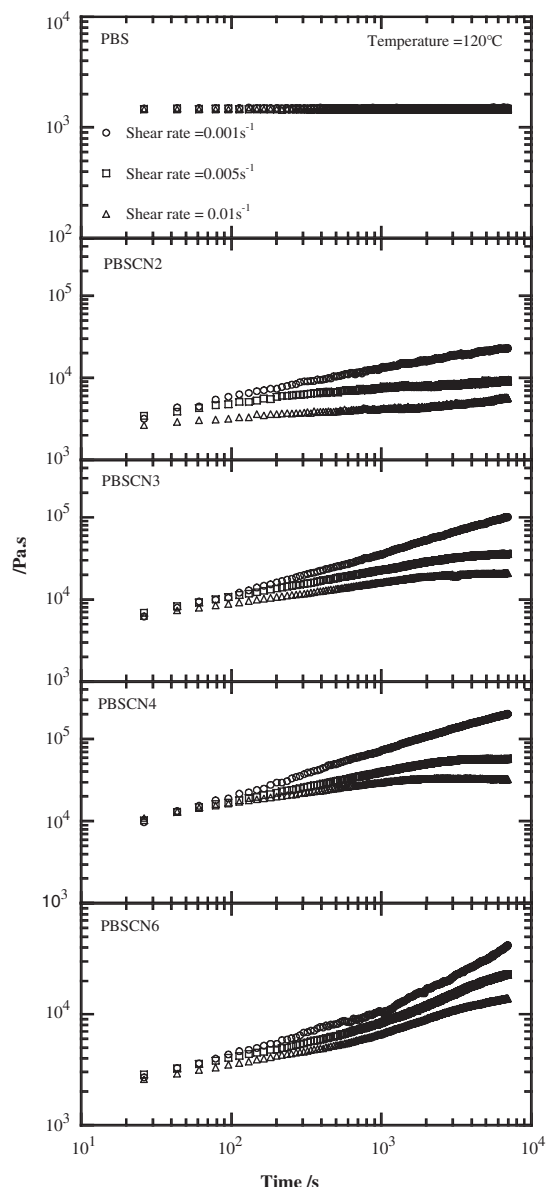
Figure 66 shows shear rate dependence of viscosity for neat PBS and corresponding nanocomposites measured at 120 °C. The neat PBS exhibits almost Newtonian behavior at all shear rates, whereas nanocomposites exhibited non-Newtonian behavior. At very low shear rates, shear viscosity of nanocomposites initially exhibits some shear-tickening behavior and this corresponds to the rheopexy behavior as we observed at very low shear rates (see Fig. 65). After that all nanocomposites show very strong shear thinning behavior at all shear rates and this behavior is analogous to the results obtained in case of dynamic oscillatory shear measurements [324]. Additionally, at very high shear rates, the viscosities of nanocomposites are comparable to that of neat PBS. These observations suggest that the silicate layers are strongly oriented toward the flow direction at high shear rates, and


Figure 65. Time variation of shear viscosity for PBSCN. Reprinted with permission from [327], S. Sinha Ray et al., *Macromolecules* 36, 2355 (2003). © 2003, American Chemical Society.

shear thinning behavior at high shear rates is dominated by that of neat polymer.

The PCNs always exhibit significant deviation from Cox–Merz relation [366], while all neat polymers nicely obey the empirical Cox–Merz relation, which requires that for $\dot{\gamma} = \omega$, the viscoelastic data should obey the relationship $\eta(\dot{\gamma}) = |\eta^*|(\omega)$. We believe there are two possible reasons for the deviation from the Cox–Merz relation in case of nanocomposites: first of all this rule is only applicable for homogenous systems like homopolymer melts but nanocomposites are heterogeneous systems. For this reason this relation is nicely obeyed in case of neat polymer [327]. Second, the structure formation is different when nanocomposites are subjected to dynamic oscillatory shear and steady shear measurements.

8.3. Elongational Flow and Strain-Induced Hardening

Okamoto et al. [256] first conducted elongation tests of PP/clay nanocomposites (PPCN4) under molten state at constant Hencky strain rate $\dot{\varepsilon}_0$ using an elongation flow optorheometry [367], and also they attempted to control the alignment of the dispersed silicate layers with nanometer dimensions of an intercalated PPCNs under uniaxial elongational flow.

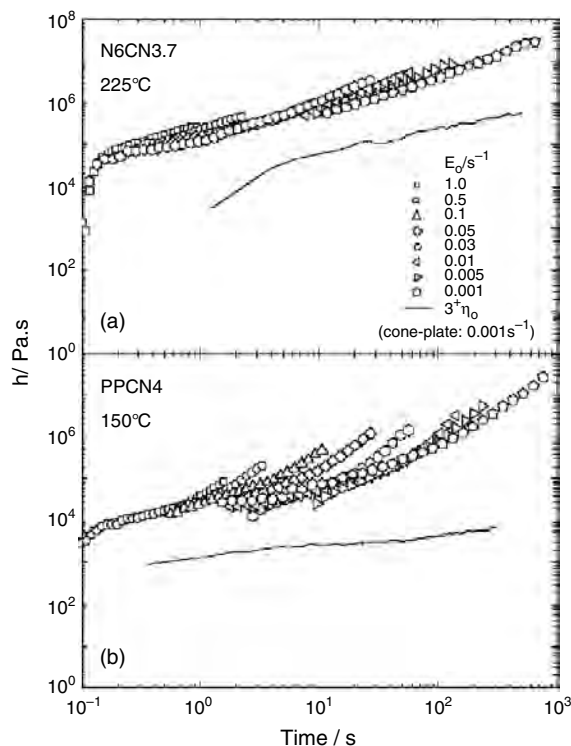
Figure 67 shows double logarithmic plots of transient elongational viscosity $\eta_E(\dot{\varepsilon}_0; t)$ against time t observed for


Figure 67. Time variation of elongational viscosity $\eta_E(\dot{\varepsilon}_0; t)$ for (a) N6CN3.7 melt at 225 °C and for (b) PPCN4 at 150 °C. The solid line shows three times the shear viscosity, $3\eta_E(\dot{\gamma}; t)$, taken at a low shear rate $\dot{\gamma} = 0.001$ s^{-1} on a cone-plate rheometer.

a Nylon 6/clay system (N6CN3.7) and PPCN4 (MMT = 4 wt%) with different Hencky strain rates $\dot{\varepsilon}_0$ ranging from 0.001 to 1.0 s^{-1}. The solid curve represents time development of threefold shear viscosity, $3\eta_0(\dot{\gamma}; t)$, at 225 °C with a constant shear rate $\dot{\gamma} = 0.001$ s^{-1}. In $\eta_E(\dot{\varepsilon}_0; t)$ at any $\dot{\varepsilon}_0$, N6CN3.7 melt shows a weak tendency of *strain-induced hardening* as compared to that of PPCN4 melt. A strong behavior of strain-induced hardening for the PPCN4 melt originated from the perpendicular alignment of the silicate layers to the stretching direction as reported by Okamoto et al. [256].

From TEM observations (see Fig. 60), the N6CN3.7 forms a fine dispersion of the silicate layers of about 100 nm in L_{clay}, 3 nm thickness in d_{clay}, and ξ_{clay} of about 20–30 nm between them. The ξ_{clay} value is one order of magnitude lower than the value of L_{clay}, suggesting the formation of spatially linked like structures of the dispersed clay particles in Nylon 6 matrix. For N6CN3.7 melt, the silicate layers are densely dispersed into the matrix and hence difficult to align under elongational flow. Under flow fields, the silicate layers might translationally move, but not rotationally in such a way that the loss energy becomes minimum. This tendency was also observed in PPCN7.5 melt having a higher content of MMT (=7.5 wt%) [365].

On the other hand, one can observe two features for the shear viscosity curve. First, the extended Trouton rule, $3\eta_0(\dot{\gamma}; t) \cong \eta_E(\dot{\varepsilon}_0; t)$, does not hold for both N6CN3.7 and PPCN4 melts, as opposed to the melt of ordinary homopolymers. The latter, $\eta_E(\dot{\varepsilon}_0; t)$, is more than 10 times larger than the former, $3\eta_0(\dot{\gamma}; t)$. Second, again unlike ordinary polymer melts, $3\eta_0(\dot{\gamma}; t)$ of N6CN3.7 melt increases continuously with t, never showing a tendency of reaching a steady state within the time span (600 s or longer) examined here. This *time-dependent thickening* behavior may be called *antithixotropy* or *rheopexy*. Via slow shear flow ($\dot{\gamma} = 0.001$ s^{-1}), $3\eta_0(\dot{\gamma}; t)$ of N6CN3.7 exhibits a much stronger rheopexy behavior almost two orders of magnitude higher than that of PPCN4. This reflects a fact that the shear-induced structural change involved a process with an extremely long relaxation time as well as for other PCNs having rheopexy behavior [325, 327], especially under weak shear field.

8.4. Alignment of Silicate Layers

The orientation of silicate layers and Nylon 6 crystallites in injection molded N6CN3.7 using WAXD and TEM is examined [111]. Kojima et al. have found three regions of different orientations in the sample as a function of depth. Near the middle of the sample, where the shear forces are minimal, the silicate layers are oriented randomly and the Nylon 6 crystallites are perpendicular to the silicate layers. In the surface region, shear stresses are very high, so both the clay layers and the Nylon 6 crystallites are parallel to the surface. In the intermediate region, the clay layers, presumably due to their higher aspect ratio, still orient parallel to the surface and the Nylon 6 crystallites assume an orientation perpendicular to the silicate. Very recently, Medellin-Rodriguez et al. [117] reported that the molten N6CN samples showed planar orientation of silicate layers along the flow direction, which is strongly dependent

on shear time as well as clay loading, reaching a maximally orienting level after being sheared for 15 min with $\dot{\gamma} = 60$ s^{-1}.

Okamoto et al. conducted TEM observations for the sheared N6CN3.7 with $\dot{\gamma} = 0.0006$ s^{-1} for 1000 s [368]. The edges of the silicate layers laying along the z-axis [marked with the arrows (a)] or parallel alignment of the silicate edges to the shear direction (x-axis) [marked with the arrows (b)] rather than assuming random orientation in the Nylon 6 matrix is observed, but in fact, one cannot see these faces in this plane (Fig. 68). Here, it should be emphasized that the planar orientation of the silicate faces along the x–z plane does not take place prominently. For the case of rapid shear flow, the commonly applicable conjecture of the planar orientation of the silicate faces along the shear direction was first demonstrated to be true by Kojima et al. [111].

In uniaxial elongational flow (converging low) for a PPCN4, the formation of *a house-of-cards* structure is found by TEM analysis [256]. The perpendicular (but *not* parallel) alignment of disklike clay particles with large anisotropy toward the flow direction might sound unlikely but this could be the case especially under an elongational flow field, in which the extensional flow rate is the square of the converging flow rate along the thickness direction, if the assumption of *affine* deformation without volume change is valid. Obviously under such conditions, the energy dissipation rate due
Figure 68. TEM micrograph in the x–z plane showing N6CN3.7 sheared at 225 °C with $\dot{\gamma} = 0.0006$ s^{-1} for 1000 s. The x-, y-, and z-axes correspond respectively to flow, shear gradient, and neutral direction.

to viscous resistance between the disk surface and the matrix polymer is minimal, when the disks are aligned perpendicular to the flow direction.

Moreover, Lele et al. [265] recently reported the *in-situ* rheo-X-ray investigation of flow-induced orientation in syndiotactic PP/layered silicate nanocomposite melt.

Some 20 years ago van Olphen [369] pointed out that the electrostatic attraction between the layers of natural clay in aqueous suspension arises from higher polar force in the medium. The intriguing features such as yield stress thixotropy and/or rheopexy exhibited in aqueous suspensions of natural clay minerals may be taken as a reference to the present PCNs.

8.5. Electrorheology

Electrorheological fluids (ERFs), sometimes referred to as "smart fluids," are suspensions consisting of polarizable particles dispersed in insulating media [370]. A mismatch in conductivity or dielectric constant between the dispersed particle and the continuous medium phase induces polarization upon application of an electric field. The induced particle dipoles under the action of an electric field tend to attract neighboring particles and cause the particles to form fibril-like structures, which are aligned to the electric field direction [371].

Among various materials [372–374], semiconducting polymer is one of the novel intrinsic ER systems since it has the advantage of a wide range of working temperature, reduced abrasion of device, low cost, and relatively low current density. As a result, development of a high-performance ER fluid followed by conducting polymer optimization and tuning has been the subject of considerable interest for practical applications as a new electomechanic interface. Nevertheless, the yield stress and modulus of ER fluids are lower than those of magnetorheological fluids. Thus the performance of conducting polymer-based ER fluids is still insufficient for the successful development of specific application devices.

On this basis of this information, Kim et al. [286] first introduced nanocomposite as ERFs using PANI/clay nanocomposites with intercalated structure. Though PANI/clay intercalated nanocomposites are a new material for application of ER materials, yield stresses of the system showed less than 100 Pa at 1.2 kV/mm (20 wt% suspensions). This value is a little lower than the yield stress of a pure PANI particle system [374]. In other words, no synergistic effect of clay on yield stress was shown.

Recently, Park et al. [375] observed remarkable enhancement of yield stress for electrorheological fluids in PANI-based nanocomposites of clay. In further study [376], they fabricated three kinds of ERFs containing different contents of PANI/clay nanocomposite and pure PANI particles in order to investigate the effect of nanocomposite particles on the enhancement of yield stress more systematically. They observed that there is an optimum content ratio between nanocomposite and pure PANI particles to produce minimum yield stress. Details regarding data collection and explanations are presented in [376].

9. PROCESSING OPERATIONS OF POLYMER/CLAY NANOCOMPOSITES

The flow-induced internal structural change occurs in both shear and elongational flow, but they almost differ from each other, as judged from the previous results on $\eta_E(\dot{\varepsilon}_0; t)$ and $3\eta_0(\dot{\gamma}; t)$ (see Fig. 67). Thus, with these rheological features of the PCNs and the characteristics of each processing operation, which process type should be selected for a particular nanocomposite for the enhancement of its mechanical properties?

For example, the strong strain-induced hardening in $\eta_E(\dot{\varepsilon}_0; t)$ is requisite for withstanding the stretching force during the processing, while the rheopexy in $3\eta_0(\dot{\gamma}; t)$ suggests that for such PCN a promising technology is processing in confined space such injection molding where shear force is crucial.

9.1. Foam Processing Using Supercritical CO_2

Via batch processing in an autoclave, the foam processing on PPCNs having different contents of clay by using supercritical CO_2 as foaming agent under 10 MPa at various temperatures is reported [257]. Figure 69 shows the typical results of scanning electron microscope (SEM) images of the fracture surfaces of the PPCN4 and PP-MA without clay. Both foams exhibit the polygon closed-cell structures having pentagonal
Figure 69. SEM micrographs for (a) PPCN4 and (b) PP-MA foamed at 134.7 °C. Reprinted with permission from [257], M. Okamoto et al., *Nano Lett.* 1, 503 (2001). © 2001, American Chemical Society.

and hexagonal faces, which express the most energetically stable state of polygon cells. The morphological parameters of the cells are listed in Table 20. The function for determining cell density N_c is defined as [377]

$$N_c \cong \frac{1 - \frac{\rho_f}{\rho_p}}{10^{-4}d^3} \qquad (4)$$

The mean wall thickness δ is given by

$$\delta = d\left(\frac{1}{\sqrt{1 - \frac{\rho_f}{\rho_p}}} - 1\right) \qquad (5)$$

where ρ_p, ρ_f, and d are the density of the polymer (prefoamed materials), the density of the foam (post-foamed samples) in g/cm^3, and the mean cell size in mm, respectively. The PPCN4 foam shows smaller d and larger N_c compared to PP-MA foam, suggesting that the dispersed clay particles act as nucleating sites for cell formation and lowering of d with increasing clay content [262]. The final ρ_f is controlled by the competitive process in the cell nucleation, its growth, and coalescence. Cell nucleation, in a heterogeneous nucleation system such as PPCN4 (MMT = 4 wt%) foam, took place in the boundary between the matrix PP-MA and the dispersed clay particles. The cell growth and coalescence are strongly affected by the modulus and the loss modulus ($\cong$viscosity component) of the materials during processing. As mention in Section 8.3, the strain-induced hardening behavior is probably strong enough to increase the extensional viscosity under biaxial flow and to protect the cell from its breakage at high temperature. Therefore, the strain-induced hardening leads to the high cell wall thickness in the PPCN4 foam.

The alignment of the dispersed clay particles under biaxial flow in the foam processing is also observed (Fig. 70). Due to the biaxial flow of material during the foam process, the clay particles either turned their face [marked with the arrows (A) in Fig. 70] or had fixed face orientation [marked with the arrows (B) in Fig. 70] and aligned along the flow direction of materials (i.e., along the cell boundary). The interesting point here is that such aligning behavior of the clay particles may help cells to withstand the stretching force from breaking the thin cell wall, in other words, to improve the strength of foam in mechanical properties. The clay particles seem to act as a secondary cloth layer to protect the cells from being destroyed by external forces. The compression modulus K' of the PPCN foams appears higher than

Figure 70. TEM micrographs for PPCN4 foamed at 134.7 °C (monocell wall). Reprinted with permission from [257], M. Okamoto et al., *Nano Lett.* 1, 503 (2001). © 2001, American Chemical Society.

that of PP-MA foam even though its at same ρ_f level (see Table 20). This may create the improvement of mechanical properties for polymeric foams through PCNs.

Recently, some literature has become available [378] related to the reactive extrusion foaming of various nanocomposites.

9.2. Slow Shear Flow Processing

Very slow shear processing for the Nylon 6/clay system (N6CN3.7) (MMT = 3.7 wt%) is examined with the expectation that it would result in an excellent material having enhanced mechanical properties of the PCN [368]. As anticipated, N6CN3.7 subjected to shear processing shows strong enhancement in relative modulus as compared to the corresponding Nylon 6 matrix (Table 21). For example, after having been sheared with $\dot{\gamma} = 0.0006$ s^{-1} for 1000 s, the modulus of N6CN3.7 at 30 °C was 2.6 times higher, while for the presheared N6CN3.7 the modulus was only 1.8 times higher than that of neat Nylon 6. To improve the modulus, the silicate layers seem to act as an internal bone layer to protect the materials from being bent by external forces.

9.3. Electrospinning Processing

Fibers and nanofibers of N6CN (diameter of 100–500 nm) were electrospun from HFIP solution and collected as nonwoven fabrics or as aligned yarns [379]. The

electrospinning process resulted in highly aligned MMT particles and Nylon 6 crystallites. The cylindrical shaped fibers, nanofibers, and ribbon shaped fibers were also found in the products (Fig. 71). The electrospinning can be expected to align other nanofillers such as carbon nanotubes.

9.4. Porous Ceramic Materials via PCNs

Very recently, a new route for the preparation of porous ceramic material from thermosetting epoxy/clay nanocomposite was first demonstrated by Brown et al. [380]. This route offers an attractive potential for diversification and application of the PCNs. Sinha Ray and co-workers have reported the results on the novel porous ceramic material via burning of the PLA/clay system (PLACN) [315]. The SEM image of the fractured surface of porous ceramic material prepared from simple burning of the PLACN in a furnace up to 950 °C is shown in Figure 72. After complete burning, as seen in the figure, the PLACN becomes a white mass with a porous structure. The bright lines in the SEM image correspond to the edge of the stacked silicate layers. In the porous ceramic material, the silicate layers form a house-of-cards structure, which consists of large plates having lengths of ~1000 nm and thicknesses of ~30–60 nm. This implies that the further stacked platelet structure is formed during burning. The material exhibits the open-cell-type structure having 100–1000 nm diameter voids, BET surface area of 31 m^2 g^{-1}, and low density of porous material of 0.187 g ml^{-1} estimated by the buoyancy method. The BET surface area value of MMT is 780 m^2/g and that of the porous ceramic material is 31 m^2/g, suggesting about 25 MMT plates stacked together. When MMT is heated above 700 °C (but below 960 °C) first all OH groups are eliminated from the structure and thus MMT is decomposed into that of a nonhydrated aluminosilicate. This transformation radically disturbs the crystalline network of the MMT, and the resulting diffraction pattern is indeed often typical of an amorphous (or noncrystalline) phase.
Figure 71. TEM micrograph of a ribbon shaped nanofiber. Reprinted with permission from [379], P. H. Fong et al., *Polymer* 43, 775 (2002). © 2002, Elsevier Science.
Figure 72. SEM image of porous ceramic material after coated with platinum layer (~10 nm thickness). Reprinted with permission from [315], S. Sinha Ray et al., *Nano Lett.* 2, 423 (2002). © 2002, American Chemical Society.

The estimated rough value of compression modulus K is in the order of ~1.2 MPa, which is five orders of magnitude lower than the bulk modulus of MMT (~10^2 GPa) [33]. In the stress–strain curve, the linear deformation behavior is nicely described in the early stage of the deformation (i.e., the deformation of the material closely resembles that of ordinary polymeric foams) [381]. This open-cell-type porous ceramic material consisting of the house-of-cards structure is expected to provide strain recovery and excellent energy dissipation mechanism after unloading in the elastic region up to 8% strain; probably each plate bends like a leaf spring. This porous ceramic material is an elastic and very lightweight new material. This new route for the preparation of porous ceramic material via burning of nanocomposites can be expected to pave the way for a much broader range of applications of the PCNs.

10. CONCLUSIONS

Development of the PCNs is one of the latest evolutionary steps of polymer technology. PCNs offer attractive potential for diversification and application of conventional polymeric materials. Since the possibility of direct melt intercalation first demonstrated by Vaia et al. [31], the melt intercalation method has become the mainstream preparation for intercalated polymer nanocomposites without *in-situ* intercalative polymerization. It is a quite effective technology for the case of the PCN industry. Some of PCNs are already commercially available and applied in industrial products. Biodegradable polymer based PCNs seem to have a very bright future for a wide range of applications such as high performance biodegradable materials. Undoubtedly, the unique properties originating from the controlled nanostructure pave the way for a much broader range of applications.

Although a significant amount of work has already been done on various aspects of PCNs, a lot of research still remains to be carried out in order to understand the structure–property relationship in various PCNs. On the other hand, we have to conduct rheological measurements of various PCNs under molten states in detail, in order to

discover the processing conditions of these materials, and this is the final goal of any polymeric material.

Finally, PCNs show concurrent improvement in various materials properties at very low clay content together with the ease of preparation through simple processes such as melt intercalation, directly by melt extrusion, or injection molding, opening a new dimension for plastics and composites.

GLOSSARY

Clay General family of 2:1 layered- or phyllosilicates. Their crystal structure consists of layers made up of two silica tetrahedral fused to an edge-shared octahedral sheet of either aluminium or magnesium hydroxide. The layer thickness is around 1 nm and the lateral dimensions of these layers may vary from 30 nm to several microns and even larger depending on the particular layered silicate.

Exfoliation Extensive polymer penetration resulting in disordered and eventual delamination of the silicate layers produces *near* to exfoliated nanocomposites consisting of individual silicate layers dispersed in polymer matrix.

Flocculation Conceptually this is same with intercalated nanocomposites, however, silicate layers are sometimes flocculated due to hydroxylated edge–edge interaction of the silicate layers (intercalated and flocculated).

Green polymeric materials These would not involve the use of toxic or noxious components in their manufacture, and could be degraded in natural environment or easily recycled. Aliphatic polyesters are among the most promising materials for the production of environmentally friendly biodegradable plastics.

Intercalation Polymer penetration resulting in finite expansion of the silicate layers produces intercalated nanocomposites consisting of well-ordered multilayers with alternating polymer/silicate layers and a repeat distance of few nanometers.

Montmorillonite One of the most commonly used layered silicates $(M_{1/3}(Al_{5/3}Mg_{1/3})Si_4O_{10}(OH)_2)$. This clay is only miscible with hydrophilic polymers, such as poly (ethylene oxide) and poly (vinyl alcohol).

Nanocomposite Phase mixing of at least two dissimilar materials (e.g., polymer and inorganic filler) occurs on a nanometer scale. The nanocomposite exhibits remarkable improvement of materials properties.

Organo-clay To improve miscibility with other polymer matrices, one must convert the normally hydrophilic silicate surface to organophilic, which makes possible intercalation of many engineering polymers. Generally, this can be done by ion-exchange reactions with cationic surfactants including primary, secondary, tertiary, and quaternary alkyl ammonium or alkylphosphonium cations.

Polymeric Nano/Microgels

Piotr Ulanski, Janusz M. Rosiak

Technical University of Lodz, Poland

CONTENTS

1. INTRODUCTION

Soft nanomaterials—polymeric nanogels and microgels—have had a fast and brilliant career from an unwanted by-product of polymerization processes to an important and fashionable topic of interdisciplinary research in the fields of polymer chemistry and physics, materials science, pharmacy, and medicine. Together with their larger analogs—macroscopic gels, most known in the form of water-swellable hydrogels—they have a broad field of actual and potential applications ranging from filler materials in coating industry to modern biomaterials.

There are at least two ways of defining polymeric *nanogels* and *microgels*. One of them originates from the definition of polymer gels. A *polymer gel* is a two-component system consisting of a permanent three-dimensional network of linked polymer chains, and molecules of a solvent filing the pores of this network. *Nanogels* and *microgels* are particles of polymer gels having the dimensions in the order of nano- and micrometers, respectively. The other definition says that a *nanogel* or a *microgel* is an internally cross-linked macromolecule. This approach is based on the fact that, in principle, all the chain segments of a nanogel or microgel are linked together, thus being a part of one macromolecule. It also reflects the fact that such entities can be synthesized either by intramolecular cross-linking of single linear macromolecules or in a single polymerization event (e.g., initiated by one radical) that in the absence of cross-linking would lead to the formation of a single linear polymer chain.

The latter definition allows us to consider nano- and microgels as a specific form of macromolecules, along with linear, branched, comblike, circular, star-shaped, dendrimer,

and other forms (Fig. 1). Since usually the shape of a nano- or microgel resembles a linear macromolecule in a coiled conformation, these structures are often seen as permanently "frozen" polymer coils.

In fact, molecular weights and dimensions of swollen nanogels are often similar to these of typical single macromolecules in solution, but the presence of internal bonds results in different physicochemical properties, including fixed shape, different rheological behavior, higher resistance to degradation, and the ability to trap other molecules within their structure.

It seems logical to use the term *nanogel* to describe gel particles of submicrometer size and to limit the use of *microgel* to particles over micrometer size. This rule has, however, not established itself in the literature. More often than not, the more popular term *microgels* is used to describe all small gel structures, including those having the dimensions of several tens or hundreds of nm. Anyway, a strict differentiation between these two groups is not always unambiguous (shall we measure the particles in their dry or swollen forms?), reasonable, and useful, since may properties, synthetic methods, etc. are common. Therefore, in the following we will use the word *microgel* as a general term denoting all over-micrometer and submicrometer gel particles, limiting the use of the term *nanogel* to a subclass of small microgels formed by internal cross-linking of single macromolecules (see Section 2.2).

Microgels belong to the large family of cross-linked polymeric *microparticles*. Their distinct property is the ability to swell in a suitable solvent. Certainly, the choice of such a solvent is a function of the chemical structure of the polymer network. Therefore a cross-linked microparticle that remains impermeable and does not swell in contact with a group of solvents may become a microgel in another group of solvents.

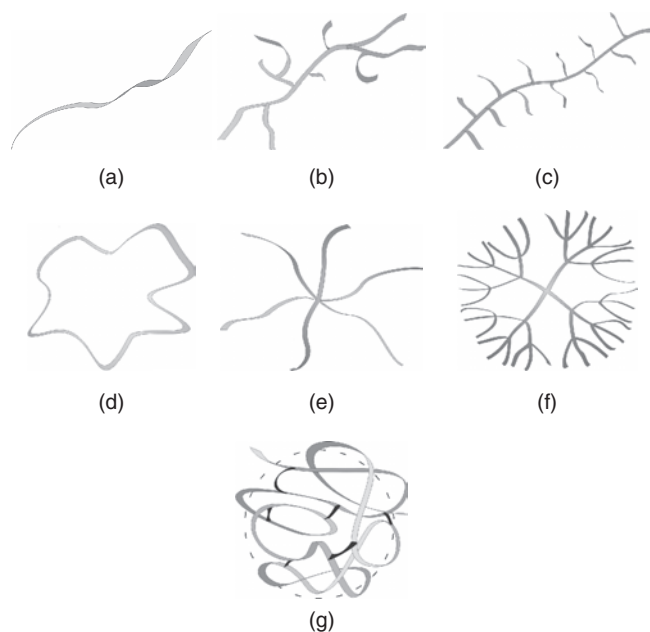
Very important and perhaps most studied so far are microgels composed of hydrophilic polymers, thus capable of swelling in water. Such gels, irrespective of their dimensions, form a large group of compounds named *hydrogels*. Typical hydrogel-forming polymers are those containing hydrophilic groups as —OH, —COOH, —NH$_2$, —CONH$_2$, —CONH—, —SO$_3$H, or ether linkages. In principle, nearly all water-soluble polymers, including those of natural origin,


Figure 1. Macromolecules of various architectures: (a) linear, (b) branched, (c) comblike, (d) circular, (e) star-shaped, (f) dendrimer, (g) microgel.

can be transformed into hydrogels. Macroscopic hydrogels have been extensively studied since the 1960s [1], and to date a number of large-scale applications emerged from this field (contact lenses, drug-delivery systems, wound dressings, etc.) [2–5]. Hydrogels, due their good biocompatibility and ability to mimic the properties of some tissues like cartilage and muscles, are especially suitable for use as biomaterials (see Section 4.1).

All polymer gels, macro- and microscopic, can be divided in two classes with respect to the character of the bonds linking the chains. In a *physical gel* or *pseudogel*, the links may be relatively weak van der Waals forces, hydrophobic or electrostatic interactions, or hydrogen bonds. Such gels are usually weak and can be destroyed (reversibly or not) by, for example, increasing the temperature or changing the solvent. Gelatin-based gels may serve as an example of such structures. It should be noted that many polymers in specific solution conditions tend to aggregate or self-assemble, thus forming physical microgels [6–13]. These phenomena will not be discussed here. *Chemical gels* or *permanent gels* are polymer networks where the links between the chains are covalent bonds. Therefore, such gels cannot be easily destroyed or dissolved, since their destruction would require the covalent bonds to be broken. The scope of this chapter is limited to the permanent gels only.

A further differentiation comes from the fact that, besides homogeneous microgels composed either of a single polymer or a copolymer, there is a growing interest in non-homogeneous, complex structures. These are either single microgel particles of a special architecture (e.g., core and shell of different composition and properties), or materials where microgels serve as building blocks for larger organized structures.

A distinct class of microgels is stimuli-sensitive ("smart," "intelligent") structures. They are able to react, usually by a pronounced change in dimensions and swelling ability, to external stimuli such as temperature, pH, ionic strength, concentration of a given substance, electric field, light, etc. Such structures may find applications in controlled or self-regulating drug delivery, signal transmission, or micromachinery (see Sections 4.1 and 4.3).

First reports regarding microgels date from 1930s, when Staudinger described the formation of a styrene-divinylbenzene microgel [14, 15]. Since then, hundreds of reports have been published on this topic. For a full insight, the reader is directed to the excellent review papers by Funke et al. [16] and Saunders and Vincent [17], covering most of the relevant aspects, as well as to a number of reviews dedicated to more specific issues [18–20].

In this chapter we will first discuss the methods used to synthesize microgels, then list the techniques used in studying their properties, and finally briefly review their actual and potential applications.

2. SYNTHESIS

A multitude of techniques have been described for the synthesis of polymeric microgels. Most of them can be classified in two groups. The first one are techniques based on concomitant polymerization and cross-linking (where the substrates are monomers or their mixtures), called by some authors "cross-linking polymerization." The second group is methods based on intramolecular cross-linking of macromolecules (where the starting material is not a monomer, but a polymer).

2.1. Formation of Microgels by Cross-Linking Polymerization

Cross-linking polymerization is the most common process used to synthesize polymeric networks. The substrate is usually a mixture of monomers, where at least one of the components contains two or more polymerizable functions. For example, in the case of free-radical cross-linking polymerization of vinyl compounds this would require that at least one of the monomers contains two or more vinyl groups. When radicals are generated in such a system, in the process of propagation monomer molecules add one after another to the free radical at the end of the growing chain. Since some monomer molecules bear two or more active groups, upon incorporation in the (initially) linear chain, some of their functionalities are not yet used and form pendant active groups along the macromolecule. Therefore, the propagating chain may react not only with monomer molecules but also with these pendant groups. If the pendant group belongs to another chain, the two chains become linked together (intermolecular cross-linking). If the propagating radical reacts with a pendant group localized on its own chain, a closed loop is formed (intramolecular cross-linking). Intermolecular cross-linking leads to the formation of branched structures and finally to macroscopic gel filling the whole volume of the reaction vessel ("wall-to-wall" gel). In an ideal case,

after all the functionalities reacted, the final product would be a single molecule occupying the whole reaction vessel, with all chain segments linked together (Fig. 2a). On the other hand, pure intramolecular cross-linking leads to separate, highly internally cross-linked single macromolecules, that is, nanometer-size microgels (Fig. 2b). In practice we can speak about prevailing inter- or intramolecular cross-linking. Most microgels synthesized by cross-linking polymerization are formed by combination of these two processes.

2.1.1. Cross-Linking Polymerization in Solution

Most of the work on the microgel synthesis by cross-linking polymerization in solution has been done on the systems reacting according to the free-radical mechanism. An alternative is the synthesis by anionic cross-linking polymerization in solution (Section 2.1.1).

Free-Radical Polymerization Free-radical cross-linking polymerization in solution, although less commonly used than emulsion-based techniques, is a subject of considerable interest, in the areas of both gelation theories and experimental studies. This seems to result from the fact that it is probably the simplest available method for the preparation of microgels, has a broad range of applications, is highly versatile, and does not require the use of surfactants. The latter, employed in most versions of emulsion polymerization techniques (see Section 2.1.2), may be present in the final product and may need to be removed in a separate purification step, thus making the synthetic procedure more complex. On the other hand, microgel formation by cross-linking polymerization in solution requires a very careful choice of reaction parameters. In general, it provides less precise control of the size of the products and yields microgels of broader size distribution than emulsion polymerization.
Figure 2. Two modes of polymer cross-linking: (a) intermolecular, leading to the formation of macroscopic gel in the whole reaction volume ("wall-to-wall" gel), (b) intramolecular, leading to the formation of microgels.

In order to obtain microgels by cross-linking copolymerization in solution, it is necessary to control the competition between propagation of linear chains, intermolecular cross-linking, and intramolecular cross-linking in such a way that microgels of desired average molecular weight and/or dimensions are formed, but no macrogelation occurs. One of the decisive factors is the concentration of the monomer mixture. In a dilute solution where the growing chains are separated, the local concentration of the pendant reactive groups within the macromolecule is much higher than their average concentration in the whole reaction volume. Therefore, reaction of the growing chain end with a pendant group belonging to its own chain is much more probable than a reaction with a pendant group of another chain. Thus, intramolecular cross-linking is promoted and, at a certain stage, the system contains mainly microgels. On the contrary, in a concentrated solution where the coils of both growing and dead chains overlap, the probability of the chain end reacting with a "foreign" pendant group may be higher than with its own one. This promotes intermolecular cross-linking and, in consequence, macrogelation, often not being preceded by a distinct microgelation stage. For a detailed description of the phenomena related to microgel formation in free-radical cross-linking polymerization, consult the review paper by Funke et al. [16] and a recent theoretical study by Okay [21].

In the course of a cross-linking polymerization reaction proceeding through a microgelation stage, two factors tend to shift the competition between intra- and intermolecular cross-linking toward the latter process. The first factor is that the number (and concentration) of microgels increases, making the interparticle contact and reaction more probable. The second is that within a microgel particle the number of pendant groups available for further intramolecular cross-linking events decreases (probably not only due to their actual decay in the cross-linking reaction, but also due to the increasing sterical constraints within the internally cross-linked structure). Therefore, even in the relatively dilute systems where intramolecular cross-linking initially prevails, one can finally expect macrogel formation.

A practical message from this reasoning is that in order to avoid macrogelation and obtain microgels one has to work in a dilute solution (typically below 5%) and stop the synthesis before the formed gel microparticles start to react with each other. The latter means that usually one has to terminate the process well before all of the monomer functionalities have reacted.

The works of Graham and co-workers [22–27] indicates that the previously described general picture is not always fully applicable and that some of the formulated precautions may be too conservative. They postulate that for every system where a carefully selected solvent is used with respect to the solubility of the polymer being formed, a "critical gelation concentration" (CGC) can be found, below which no macrogelation takes place, even at a complete monomer conversion. What is surprising is that this CGC may be in some cases as high as 90% (w/w), although values in the order of 20% seem to be more typical. It has been also shown that by varying the concentration at which microgels are prepared, their molecular weight may be controlled. A reason that is evoked for the existence

of CGCs and for their relatively high values is that in a good solvent (or solvent combination) the dead chains, polymerizing chains, and polymer loops extending out of the microgel particle being formed act as very effective steric stabilizers that prevent contact between the microgel particles. As a result of that, particle–particle interactions and interparticle cross-linking are hampered, thus preventing macrogelation and shifting the competition to the side of intramolecular cross-linking. The previously described hypothesis has been tested for many polymerizing systems [e.g., for radical polymerization of 2-hydroxyethyl methacrylate with diethyleneglycol methacrylate and for step-growth polymerization of poly(ethylene glycol), 1,2,6-hexanetriol, and biscyclohexylmethane-4,4′-diisocyanate] in various solvent compositions.

These observations emphasize the importance of solvent selection in the formation of microgels by this technique. In a recent work, the question of solvent composition and its influence on the microgel formation has been addressed by Frank et al. [28]. They have shown that in the cross-linking copolymerization of divinylbenzene and maleic anhydride at low monomer concentration in methyl ethyl ketone/heptane mixtures, products of three distinct morphologies are formed, depending primarily upon solvent composition. With increasing MEK contents the properties of the obtained cross-linked structures change from microspheres and microgels to macroscopic networks.

Basic, extensive research on the mechanism of cross-linking polymerization in solution has been done by Funke and co-workers [16, 29, 30] and other groups [21, 31–35], mostly on 1,4-divinylbenzene and its copolymers.

Recent studies on the applications of this method to synthesize microgels include copolymerization of various divinyl compounds with derivatives of maleic and fumaric acids [36], synthesis of functionalized microgels based on sulfoethylmethacrylate, able to bind metal ions (the bound ions can be subsequently reduced to form stabilized metal colloids) [37], and synthesis of reactive microgels as a semiproduct in the formation of oxazaborolidine-based dispersed catalysts for enantioselective reduction reactions [38]. Microgelation of the acrylamide/N,N'-methylene bis(acrylamide) system has been extensively investigated by Kara and Pekcan, using special techniques enabling real-time observation of the reaction progress [39–41] and precise monitoring of the accompanying thermal effects [42].

An interesting example illustrating how versatile this method may be is the first report on the synthesis of fullerene-containing microgel structures [43]. Fullerenes, acting as multifunctional monomers, were co-polymerized, in a free-radical process in o-dichlorobenzene solutions, with 4-vinylbenzoic acid, as well as with 2- and 4-vinylpyridine to form submicrometer and micrometer size microgels of interesting rheological and electroactive properties.

A promising modification of cross-linking polymerization in solution may be the use of chain transfer agents [32, 33, 44, 45]. The aim of this approach is to limit macrogelation processes and in this way to allow the synthesis of highly branched chains and possibly also microgels to be carried out to high degrees of monomer conversion and/or at relatively high monomer concentrations. Catalytic chain transfer agents such as cobalt porphyrin have been shown to perform much better in preventing macrogelation than conventional chain transfer agents exemplified by mercaptans [44, 45].

Another new and elegant way to control the kinetics and yields of free-radical cross-linking polymerization reactions is the idea of radical living polymerization [46–52]. In this technique, a spin-trapping agent (iniferter) is present in the polymerizing system that can reversibly combine with the propagating radical at the end of a growing polymer chain. The free chains, spin trap, and their product—blocked, inactive ("dormant") radical—are in equilibrium. As a result, at given polymerization conditions the momentary concentration of active propagating (or cross-linking) radicals can be kept at a much lower level than in the absence of the iniferter. This concentration may be controlled by varying the concentration of the spin trap. The use of living polymerization is rapidly expanding in polymer synthesis due to its many advantages (e.g., precisely controlled average molecular weight and molecular weight distribution) and has also found its way to the field of synthesis of microgels. Abrol and co-workers have demonstrated the application of nitroxides as trapping agents in the free-radical formation of t-butylstyrene-co-1,4-divinylbenzene microgels [53, 54]. It has been found that living free-radical polymerization helps one to avoid the macrogelation problem and provides much better control over the formation of microgels compared to classical free-radical polymerization. Both random (homogeneous) and core–shell type microgels (Fig. 3) can be formed using the living polymerization approach. Ward et al. described the use of this method for cross-linking polymerization of multifunctional glycol methacrylates, with p-xylene bis(N,N'-diethyldithiocarbamate) as the iniferter [55], while Baek et al. carried out detailed studies on the application of metal-ion-mediated living radical polymerization to obtain star polymers with microgel cores [56–60].

A specific case of cross-linking polymerization in solution is precipitation polymerization, when the microgels being formed in solution have a tendency toward deswelling and precipitation. Since the further growth and cyclization reactions are limited mostly to the surface and the inner sphere of such a phase-separated particle (that can be considered a deswollen, collapsed microgel), the resulting products are often nearly monodisperse.

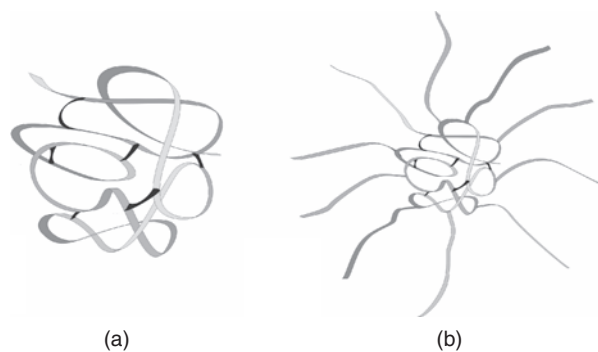
It should be noted that use of the term precipitation polymerization is not limited to solution polymerization. There are also special cases of emulsion polymerization


Figure 3. Microgels of various architectures: (a) random (homogeneous), (b) core–shell.

(especially the surfactant-free emulsion polymerization; see Section 2.1.2) which are frequently classified as precipitation polymerization [18].

It seems that precipitation polymerization is especially suitable for preparing thermosensitive microgels, since one can control the precipitation/deswelling tendency by changing temperature. For example, for a polymer that undergoes a phase transition leading to precipitation above a given temperature (lower critical solution temperature, LCST), it is possible to carry out precipitation polymerization above LCST and subsequently resolubilize the product by lowering the temperature.

In a broad study on stimuli-sensitive microgels, a range of microgels composed of *N*-vinyl caprolactam and its copolymers with sodium acrylate has been synthesized in aqueous solution using this method [61–66]. Precipitation polymerization carried out at temperatures above the LCST is also frequently used to obtain thermoresponsive microgels of poly(*N*-isopropylacrylamide) and poly(*N*-isopropylmethacrylamide) [18, 67–70]. Other examples of utilization for this technique include the synthesis of ionic microgels based on methacrylic and acrylic acids [71–75].

Fukutomi et al. employed a modification of this technique to obtain microgels of poly(vinyl alcohol) [76]. In this case one cannot start from the (nonexistent) monomer. Instead, vinyl acetate was co-polymerized in solution with *N*,*N*′-dimethyl-*N*,*N*′-divinyl-sebacoyldiamide to yield a precipitate of cross-linked poly(vinyl acetate) microparticles. Upon alkaline hydrolysis of this material, poly(vinyl alcohol) microgels were formed.

Recent studies indicate that precipitation polymerization can be also used to fabricate a sort of imprinted microgel structure [77], per analogy to the molecularly imprinted nonswellable microspheres of broad biomedical use, synthesized by a similar technique [78].

Anionic Polymerization In ionic polymerization (cf. [79–82]), the active centers participating in chain growth are not radicals, but ions. In principle, three groups of monomers can be used: hydrocarbon (including vinyl), polar (acrylates, methacrylates), and cyclic (oxiranes, lactones, etc.).

Although the ring-opening polymerization of the latter group of compounds is a promising technique used to obtain microspheres [83], so far only the first two groups have gained some attention in the field of microgel synthesis. The carbanions being the active centers in anionic polymerization usually do not undergo any spontaneous deactivation; thus such a process may be considered as a living polymerization. However, since carbanions react rapidly with any substances bearing reactive H atoms (water, carboxylic acids, alcohols), a prerequisite of performing a living polymerization is high purity of the reactant mixture. Since even traces of water from air can prevent the polymerization and in general the concentration of impurities should be kept at a submicromolar level, this requirement is one of the main difficulties encountered when using this technique. In the case of polar monomers, polymerization is often carried out at a low temperature (e.g., below −75 °C) in order to eliminate side reactions. One of the main advantages of anionic polymerization is the possibility to obtain precisely defined products of narrow molecular weight distribution. Moreover, block copolymers or other structures of special architecture can be synthesized in this way.

In order to obtain a microgel by anionic polymerization, one has to use a bifunctional monomer compatible with this technique. Up to now, most studies in this area concentrated on ethylene glycol dimethacrylate and divinylbenzenes.

Studies on the anionic polymerization of ethylene glycol dimethacrylate (EGDMA) revealed interesting features indicating two distinct phases of the process (cf. [16] and references cited therein). In the first phase, just after the formation of growing chains, no strong increase in molecular weight is observed, while the number of pendant unsaturated groups decreases. In this stage, intramolecular reactions (cyclization) dominate, with only minor participation of intermolecular cross-linking. It has been estimated that ca. 50% of the structural units participate in cyclization. The products are "living" microgels that possess the active centers and reactive vinyl groups. At a later stage, as the free volume decreases, these entities come into contact and undergo intermolecular cross-linking, evidenced by a steep increase in average molecular weight. Other works on this topic have indicated a strong influence of the solvent-initiator system on the reaction kinetics as well as on the general possibility of directing the reaction into the formation of microgels rather than insoluble macroscopic networks and avoiding excessive side reactions [84]. A toluene/*n*-BuLi system works apparently better than most of the other tested combinations.

In contrast to the EGDMA system, in the polymerization of 1,4-divinylbenzene in THF cyclization reactions are not very effective, at least at low concentrations of an initiator (*n*-BuLi, lithium diisopropylamide) [16, 85]. Instead, in the first stage mostly linear polymer is formed, with the pendant vinyl groups left largely unreacted. However, upon an increase in *n*-BuLi concentration over 2%, a gradual increase in cyclization yield is observed resulting in the formation of microgels. At initiator concentration higher than 15%, insoluble macrogels are formed. The tendency to form microgels is a function of both initiator and monomer concentration. The shapes of these complex dependencies (cf. also [86–88]). and the locations of "microgel formation regions" can be satisfactorily predicted based on kinetic considerations [89]. The resulting microgels are in the size range of 3–30 nm.

In comparison with 1,4-divinylbenzene, anionic polymerization of 1,3-divinylbenzene is much faster. Due to the much higher reactivity of pendant vinyl groups in the latter isomer, a strong tendency for cyclization is observed; thus the formation of microgels is favored over reactions leading to the linear chains and macroscopic gels [16].

Another polymer that has been used to obtain microgels by anionic polymerization is 1,4-diisopropenylbenzene [85, 90].

The technique of anionic polymerization, due to the formation of (theoretically) infinitely long-lasting active centers, is particularly useful in the synthesis of structured microgels, mostly based on block copolymers. A typical approach is a two-step procedure. In the first step, only one monomer (A) is polymerized until the monomer is used up but the active centers at the chain ends are still present.

Upon addition of a second monomer (B), the polymerization continues. In a simplest case, a block copolymer of the structure $(A)_n–(B)_m$ is formed. If A is a bifunctional monomer and B is a monofunctional one, this approach leads to the formation of core–shell star-shaped structures, with a microgel as a core and linear chains bound as branches. This technique (called by some authors "core-first") has been applied to the systems where the microgel core is built of 1,4-divinylbenzene [91–95]. A reverse technique ("arm-first"), where the bifunctional monomer is added to the living linear chains, was used, for example, to synthesize products having EGDMA microgel core and poly(t-butyl acrylate) arms [96]. Much work has been done on the microgel formation in another block copolymer system, t-butylstyrene-divinylbenzene (TBS-DVB) [97–101]. Various versions of the synthetic procedure have been tested. In one of them the reaction was performed in n-heptane, which is a good solvent for polyTBS but not for polystyrene or the resulting copolymer. The reaction was started by the formation of reactive polyTBS chains. Upon addition of DVB the block copolymers formed precipitated from the solution and further reaction proceeded in this separated phase. This method yields star-shaped microgels with polyTBS arms having gel nuclei molar fractions up to 35%. One could regulate the properties of these entities by changing the length of the living polyTBS chains used in the synthesis. The choice of solvent is an important factor in these syntheses. By selecting THF as a solvent where no precipitation occurs, the molecular weight distribution can be better controlled.

It may be expected that in the future anionic polymerization will be one of the methods used to construct even more complex microgels of well-defined architecture. For example, in a recent work a complex triblock poly(2-hydroxyethylmethacrylate-b-styrene-b-2-hydroxyethylmethacrylate) was synthesized forming a "flower-type" microgel (cf. [102–106]) with closed-loop arms fixed to a polystyrene shell and an additional function enabling precise ultraviolet (UV)-induced cutting of these loops into two equal linear arms [107].

2.1.2. Emulsion Polymerization

Macroemulsion In the synthesis of microgels by polymerization is solution, the most important difficulty is how to avoid macrogelation (i.e., how to confine the cross-linking reactions into small, separated spaces). This problem can be overcome by using emulsion polymerization, where each micelle may serve as a separate microreactor, protected from the contact with other micelles by the stabilizing action of a surfactant. Thus, in such a confined space the polymerization and cross-linking reactions can be carried out to a high degree of monomer conversion, resulting in a single microgel particle, with no or very limited macrogel formation. Because of this advantage, emulsion polymerization is a very popular method of microgel fabrication.

In a classical free-radical emulsion polymerization [108, 109]. (Fig. 4), the system initially consists of monomer molecules that are dispersed in the liquid phase (usually water) in the form of micelles (of a size in the order of a few nm) and monomer droplets, typically of the size
Figure 4. Classical emulsion polymerization, at moderate surfactant concentration: (a) monomer molecules in solution, (b) inactive monomer micelles, (c) active monomer micelles with growing polymer chain(s), (d) monomer droplet. Arrows denote the monomer transport toward the active micelles.

of 0.1–1 mm. Such a microheterogeneous system is stabilized by the presence of surfactants. The radicals are generated in the liquid phase. In some systems, initiation and first propagation steps also take place in the solution. As the growing chain has the tendency to become phase-separated, surfactant-protected polymer–monomer particles are being formed, where the further polymerization and cross-linking steps take place. In other systems (especially when monomers are poorly soluble in water), initiation may occur within a monomer-filled micelle by an initiator radical that diffuses into the micelle from solution. During the chain growth, monomer molecules diffuse from the droplets and any inactive micelles to the active particles containing growing chain(s). After these outer monomer sources are used up and only the rest of the monomers inside the active particles react, these particles do not grow any longer (or may even contract due to internal cross-linking when multifunctional monomers are present) and, upon nearly complete consumption of the monomer, the process is finally terminated.

Emulsion polymerization of monofunctional monomers leads to the formation of coagulated polymer particles (latexes), while in the presence of multifunctional monomers internally cross-linked particles—microgels—are formed, having the ability to swell in a good solvent.

Extensive comparative studies on both processes, mostly employing styrene and divinylbenzene, revealed marked differences in the kinetics, mechanism, and product properties [16, 110–114]. Cross-linking polymerization leads to the formation of smaller particles, due to intraparticle cross-linking and to the hampered diffusion of monomer molecules into the structure. The number of polymer particles is higher than in the polymerization of monofunctional monomers, due to the fact that the particle growth rate decreases upon cross-linking, the monomer consumption from the inactive micelles is slower, and their lifetime is longer. Thus, in consequence, their chance of capturing a radical and being transformed into a new polymer particle is higher. A stronger tendency to form interparticle aggregates has

been observed, which is attributed to the possibility of the reaction of pendant groups with the propagating radical of the neighboring particle. Moreover, a tendency of polymer formation in the monomer droplets is evidenced, in contrast to the emulsion polymerization of corresponding monofunctional monomers. It has been suggested that this is due to the fact that if some radicals enter a monofunctional monomer droplet, polymerization is rapidly terminated, but in the case of multifunctional monomer, the onset of gelation slows down termination processes, thus favoring further propagation and cross-linking events. Apart from these effects, size distribution of microgels is narrower than for non-cross-linked particles formed of chemically similar monomers.

Recent research on emulsion polymerization in microgel synthesis includes broad studies by Matsumoto and co-workers on allyl methacrylate (an interesting monomer bearing two different vinyl groups), polymerized alone and in the presence of various comonomers (diallyl terephthalate, allyl benzoate, methyl methacrylate) and comparative studies on vinyl methacrylate [115–120]. The same group also investigated microgel formation by emulsion polymerization of lauryl methacrylate/trimethylolpropane trimethacrylate [121]. Ishii synthesized new emulsifiers which, when applied for emulsion co-polymerization of mono- and bifunctional monomers, yielded microgel emulsions of better shelf stability than in the case of a conventional emulsifier, sodium dodecylbenzene sulfonate [122]. Other examples are the synthesis of microgels based on methyl methacrylate/butanediol dimethacrylate [123], N-ethylacrylamide/N,N'-methylenebisacrylamide [124], N-vinylcaprolactam [125, 126], as well as ionic microgels made of methyl methacrylate, 2-ethoxyethyl methactylate, ethylene glycol methacrylate, and 2-(tetradecyldimethylammonio)ethyl methacrylate bromide [127].

The emulsion polymerization technique is also employed as one of the synthetic steps in preparation of complex microgel-based particles of core–shell morphology [128], and in fabrication of reactive microgels having film-forming abilities than can be applied in coating technology [129]. Last but not least, it is applied for the formation of polyorganosiloxane microgels by polycondensation of trimethoxymethylsilane in aqueous emulsions [130–132].

An insight into the kinetics, mechanism, molecular weight distributions, etc. in emulsion polymerization of multifunctional monomers may be gained by performing simulations based on the Monte Carlo method, as demonstrated by Tobita et al. [133, 134] and Jabbari [135]. It is expected that an approach based on a combination of theoretical considerations, simulations, and experimental data (cf. [134]) will lead to a more detailed understanding of this complex process.

Microemulsion

Some of the disadvantages of the classical emulsion polymerization can be avoided by using miniemulsion of microemulsion polymerization (cf. [16, 20, 136, 137], Fig. 5).

In a monomer-containing emulsion, with increasing surfactant concentration the amount of monomer stored in the droplets decreases while more monomer molecules form micelles. When a critical value of emulsifier concentration is reached, no monomer droplets are left, with all the
Figure 5. Polymerization in microemulsion, at high surfactant concentration: (a) monomer molecules in solution, (b) inactive monomer micelles, (c) active monomer micelles with growing polymer chain(s). No monomer droplets present (compare Fig. 4). Arrows denote the monomer transport toward the active micelles.

monomer being present in micelles (and to some extent in the solution). Such a transparent micellar solution is a starting point for the polymerization in microemulsion. In such a system the polymerization in monomer droplets is avoided. In the absence of this side effect known from the macroemulsion technique, nearly monodisperse microgels can be easily synthesized.

Microemulsion polymerization has been used to prepare styrene/1,4-divinylbenzene and styrene/1,3-diisopropenylbenzene microgels of different sizes and swelling abilities [16, 138, 139]. The styrene-based structures formed by this method may be subsequently chemically modified to yield polyelectrolyte microgels of various, defined sizes [140, 141].

Inverse Emulsion

Most of the emulsion polymerization syntheses are performed in systems where the continuous liquid phase is water or aqueous solution, and the monomers and polymers are of relatively hydrophobic character. Certainly, it is possible to reverse this situation and polymerize hydrophilic monomers in organic, hydrophobic liquid phase.

The mechanism and kinetics of microgel formation in inverse emulsion polymerization have been extensively studied in the case of acrylamide [142]. The influences of the kind of solvent, kind and concentration of emulsifier, monomer content, agitation speed, etc. on the rate of process and product properties were described.

Besides synthesizing neutral hydrophilic microgels (cf. [142, 143]), this technique is especially well suited for producing polyelectrolyte microgels of uniform size. For example, spherical gel microparticles of acrylic acid co-polymerized with diethylene glycol diacrylate have been fabricated by inverse miniemulsion polymerization [20]. The products had various diameters, depending on the surfactant concentration, and a polydispersity lower than 10%.

Neyret and Vincent co-polymerized in inverse microemulsion N,N'-methylenebisacrylamide with equimolar or nonequimolar amounts of cationic [2-(methacryloyloxy)ethyl]trimethylammonium chloride (MADQUAT) and anionic sodium 2-acrylamido-2-methylpropanesulfonate

and obtained polyampholyte microgels of very interesting swelling and flocculation properties [144].

Surfactant-Free Emulsion Polymerization Emulsion polymerization, besides its numerous advantages, has also some shortcomings, the most important being the presence of surfactants that usually have to be removed from the products in a separate step after the synthesis. A complete removal of a surfactant is not always possible, since its molecules may be in some cases incorporated (bound or trapped) into the products. This problem is especially pronounced in the case of microemulsion polymerization, where relatively large quantities of emulsifiers must be used in order to force all monomer to be present in micelles.

A way out of this problem, although limited to some particular systems, is the use of a technique called by some authors "surfactant-free emulsion polymerization," where the stabilization of emulsions is provided by the monomer and/or polymer itself. This can be realized in at least two ways: either the initiator of free-radical polymerization is an ion that, when incorporated into a growing oligomeric chain, causes this molecule to be surface active, or the substrates for polymerization are unsaturated (i.e., polymerizable) oligomers bearing ionized groups at one or two ends.

The application of the former technique in microgel synthesis evolved from a method used for preparation of nonswellable polystyrene latex particles [145, 146]. It has been first used by Pelton and Chibante to synthesize temperature-sensitive poly(*N*-isopropylacrylamide) microgels [147], and since then it has become the method of choice in the fabrication of these materials [148–152]. Other examples of microgels that can be obtained in this way are systems based on poly(methyl methacrylate) and polystyrene, alone or as a copolymer with methacrylic acid [153–155].

The synthesis is usually carried out with a persulfate salt as the initiator that decomposes into $SO_4^{\bullet-}$ radicals capable of adding to monomer molecules and initiating chain growth [17]. The growing oligomer radicals bear the anionic sulfate group at the dead end and behave like a surfactant. The presence of surface-active compounds combined with the tendency of polymer chains to undergo a phase separation (cross-linking polymerization of *N*-isopropylacrylamide—NIPAM—is carried out above the LCST) results in formation of stabilized particles containing the growing and cross-linking chains. Internally cross-linked particles obtained in this way form swollen microgels when transferred into a good solvent. In the case of poly(NIPAM), the switching from a poor to a good solvent is accomplished simply by lowering the temperature below the LCST. It is possible to synthesize NIPAM-based copolymer microgels by incorporating water-soluble vinyl monomers like acrylamide [147], acrylic acid [152, 156], *N*-acryloylglycine [157], or 2-aminoethylmethacrylate hydrochloride [158].

The version of surfactant-free emulsion polymerization where self-emulsifying reactive oligomers are used has been extensively studied by Funke and co-workers on unsaturated polyesters [16, 159–161]. In this approach, unsaturated polyester molecules having carboxylic groups at both chain ends were used. For effective self-emulsification, as well as for emulsification of their mixture with comonomers,

the average molecular weight of these compounds must lie within a certain range. Molecules of too low molecular weight do not provide the desired solubilization efficiency, while for too long chains their own solubility is insufficient. For example, in one of the systems studied where the polyesters were made of maleic anhydride and 1,6-hexanediol, the optimum molecular weight of these oligomers for solubilization of styrene as a hydrophobic comonomer was in the range 1.7–2.2 kDa [162].

Also the way the initial emulsion is prepared and the relation between the comonomer ratios and overall monomer concentration must be carefully chosen to avoid formation of insoluble fraction (macrogels or agglomerates) [163].

A common property of the products synthesized by surfactant-free emulsion polymerization is the presence of ionic groups at the microgel surface which may be used for further modification, binding various compounds, or interparticle cross-linking.

2.1.3. Cross-Linking Polymerization in the Bulk

Bulk polymerization is a possible but, in general, not particularly suitable way of synthesizing microgels, primarily since the polymerizing and cross-linking system tends to form a macroscopic "wall-to-wall" gel in the whole reaction volume. According to classical gelation theory [164] involving homogeneous growth of linear chain and their subsequent linking together, formation of distinct microgels as intermediate stages should not take place. However, in reality most polymerizing and cross-linking systems are not strictly homogeneous (see a brief general discussion in [16] and references cited therein). If, before macrogelation is reached, the polymerization and cross-linking processes proceed through stages characterized by inhomogeneous density of cross-links [i.e., when microgels are formed that are not (yet) linked together], there is some chance that they could be potentially separated.

A recent example showing that this may in fact be possible is a study on free-radical bulk polymerization of tetraethoxylated bisphenol A dimethacrylate with styrene or divinylbenzene, where various populations of microgels at different stages of cross-linking (single microgels in the range of 10–40 nm and large microgel clusters) have been observed by atomic force microscopy and by dynamic light scattering upon dissolution of the samples [165, 166]. Also recent works on simulation of polymerization in systems containing multifunctional monomers clearly indicate the onset of structural heterogeneity and the formation of microgels ([167], cf. also [168, 169]).

2.1.4. Polymerization with Nonclassical Initiation

Most of the work on the synthesis of microgels by combined polymerization and cross-linking has been done using classical initiation methods, that is, with chemical initiators, which, when activated (mostly thermally decomposed) give rise to reactive intermediates capable of initiating the chain reactions of polymerization and cross-linking. This

approach, although most commonly used, has some disadvantages. First of all, the initiator or its fragments usually remain in the products, either chemically bound or entrapped within the polymer structure. This may pose serious problems in these applications where purity of the material is of high importance (biomaterials, optics, electronics). Second, in some cases the heating of the reaction mixture in order to activate the initiator may be undesirable. Therefore there is a need for alternative techniques where initiation is provided by other means. One may envisage that the techniques already used in polymerization processes, like photopolymerization, radiation polymerization, initiation by the action of ultrasound, or microwaves, will find an application in the microgel synthesis as well.

Photopolymerization and photocuring are very intensely studied synthetic techniques, widely used in industry (cf. reviews [170, 171]). Photoinduced polymerization combined with cross-linking can be used to produce macroscopic polymer gels based, for example, on 2-hydroxyethyl methacrylate [172], N-isopropylacrylamide [173], acrylic acid, and N-vinylpyrrolidone [174]. Microgels of poly(ethylene glycol) (PEG) were synthesized by photopolymerization, using a method where a mixture of poly(ethylene glycol) dimethacrylates and a photoinitiator was sprayed over a double-layer liquid bath [175]. The droplets formed in the upper layer were subsequently UV-illuminated in the lower layer to form internally cross-linked PEG spheres, able to swell in water. Kazakov et al. proposed an interesting procedure where monomers (acrylamide, N-isopropylacrylamide, vinylimidazole) were encapsulated into liposomes and subsequently polymerized and cross-linked with UV light, resulting in microgels of 30–300 nm size [176].

Radiation-induced polymerization is a well-established, versatile synthetic technique used in polymer science and, to a limited extent, also in technology (for reviews see [177–184]). Polymerization initiated by ionizing radiation (typically gamma rays from isotope sources or fast electrons generated by accelerators) is quite similar to the classical one and can be performed in the bulk, in solution, in emulsion, etc., the main difference being only the initiation step. Ionizing radiation can interact with monomers and polymers by direct or indirect effects. In the former, the energy is absorbed by a monomer molecule, which may result in a radical formation, in the latter the energy is absorbed by the solvent, and reactive products (mostly radicals) resulting from this event may in turn attack monomer to initiate polymerization. In the case of aqueous systems, the species initiating the polymerization is most often the hydroxyl radical.

Ionizing radiation can be used in the synthesis of polymer gels (both macro- and microscopic) in two general ways: either by inducing cross-linking polymerization of monomers or by inducing cross-linking of polymer chains in the absence of monomers. The latter technique has some important advantages and will be discussed separately in Section 2.2.2. It is important to know that at late stages of radiation-induced polymerization, when only low quantities of free monomer molecules are left in the system and the radicals are still generated randomly along the chains, intermolecular recombination (cross-linking) reactions may occur with a

considerable yield even in the total absence of any bifunctional monomer. Therefore, by using ionizing radiation it is possible to obtain a polymer gel starting from monofunctional monomers. More often than not, multifunctional monomers are used anyway, usually in order to increase the yield of cross-linking and thus reduce the radiation dose necessary to produce a gel of a given cross-link density. Applications of this technique range from the formation of gels based on relatively simple compounds (e.g., acrylamide [185] or N-vinylpyrrolidone [4]) to complex stimuli-sensitive "smart" gels targeted for advanced biomedical purposes (cf. [186–190]).

Examples of radiation-induced polymerization employed to synthesize internally cross-linked polymer microparticles are the works of Yoshida et al. [191–195] and Naka et al. [196–198]. Various monomer mixtures, mainly containing diethylene glycol dimethacrylate, were irradiated without any auxiliary substances in organic solution to yield products that were suitable for derivatization or immobilization of biomolecules and intended for biomedical applications. Microgels can be also synthesized by radiation-induced cross-linking polymerization in emulsion, as shown on the example of styrene-based gels co-polymerized with cationic polymerizable surfactants [199].

Ultrasound is often used in microgel or microparticle synthesis, albeit not for initiating chemical reactions, but rather as a tool for solubilization, agitation, homogenization, formation of miniemulsions, etc. It seems that the well-known fact that the same ultrasound can induce polymerization (for reviews see [200–202]) has so far largely escaped the attention of researchers working on microgel synthesis.

Ultrasound waves propagating in a liquid may cause the formation of free radicals. This effect is due to the phenomenon of cavitation (i.e., the formation of small gas bubbles). Their collapse and their compression phase of oscillations in the ultrasonic wave are adiabatic processes leading to local, transient increase in temperature inside the bubble, lasting for fractions of microseconds. Since these temperatures may reach over 3000 K, [203, 204] a fraction of solvent molecules (or other molecules) present in the gas phase is decomposed into free radicals. These can diffuse to the liquid phase and initiate chemical reactions, including polymerization. In the case of aqueous systems, hydroxyl radicals are generated [205–212] that are very efficient initiators of polymerization. The efficiency of cavitation and of radical formation in particular depends on frequency and intensity of ultrasound, as well as on temperature, external pressure, presence of gases in the liquid, etc. [200, 212].

Ultrasound-induced polymerization in solution has been mostly performed on vinyl polymers, namely styrene [213–221], methyl methacrylate [213, 215–219, 222, 223], n-butyl methacrylate [221], vinyl acetate [213], vinyl chloride [224], acrylamide [222, 223], N-vinylcarbazole [225], and N-vinylpyrrolidone [200]. Moreover, the suitability of this technique for synthesis of some special polymers has been demonstrated (e.g., polysilylenes [226] and phtalocyanine polymers [227]).

Although no extensive studies on the possibility of microgel synthesis by ultrasound have been made so far, there are first reports on the possibility of ultrasound-induced

polymerization of bifunctional monomers [228] and fabrication of microspheres [229].

It has been shown that concomitant action of ionizing radiation and ultrasound may lead to interesting results in the synthesis of internally cross-linked microspheres (that would become microgels in a suitable solvent). In a radiation-induced cross-linking polymerization of diethyleneglycol dimethacrylate in ethyl acetate, the action of ultrasound affects the size and shape of formed particles, probably by promoting interparticle interactions [230].

2.2. Intramolecular Cross-Linking of Polymer Chains: Monomer-Free Techniques

In most research work and applications, microgels are synthesized using procedures based on polymerization processes starting from monomers as the basic substrates. This is, however, not the only possible way. An alternative approach to the synthesis of microgels, in particular the *nanogels* of small size (typically <0.1 μm), is intramolecular cross-linking of individual macromolecules. An obvious and important advantage of this method is the absence of monomer. This is of great value when the product is intended for biomedical use, where even small quantities of residual monomer may be potentially harmful and thus unacceptable. Furthermore, intramolecular cross-linking may provide means to obtain cross-linked structures of various molecular weight and size, including very small structures, depending on the molecular weight of the parent polymer. Such nanogels obtained from single macromolecules are interesting physical forms of polymers as they are a sort of "frozen" polymer coil of limited segmental mobility. One can also expect that a combination of intra- and intermolecular cross-linking (cf. [231–233]) will provide a tool for synthesizing nanogels and microgels of independently chosen molecular weight and dimensions (various internal densities). Last but not least, intramolecular cross-linking of individual macromolecules is an interesting reaction. A number of questions regarding this process, particularly its kinetics, have not been answered yet (cf. [234–236]).

Given the commercial availability of a multitude of polymers, including food- and medical-grade products, starting from a polymer rather than from a monomer can be a reasonable synthetic option. Moreover, in some cases, where monomers do not exist [like poly(vinyl alcohol)] or polymerization is either impossible or very difficult (carbohydrates), intramolecular cross-linking of polymers may be the best way to produce microgels.

2.2.1. Chemical Intramolecular Cross-Linking

Intramolecular cross-linking, similar to polymerization, can be performed either as a thermally initiated chemical reaction or as a photo- or radiation-induced process. Chemical intramolecular cross-linking of individual polymer chains can be achieved in at least two ways. One is to prepare linear or branched polymer with pendant reactive (e.g., vinyl) groups and initialize the cross-linking by a suitable initiator. Batzilla and Funke synthesized linear poly(4-vinyl styrene) and subsequently carried out a cross-linking of this polymer

in dilute solution using 2,2′-azobis(isobutyronitrile) (AIBN) as an initiator [237]. Reaction conditions and time could be chosen where intramolecular cross-linking prevailed. In a similar way, microgels can be made of preformed polymers by photo-cross-linking [238].

Another way does not require any special substrate preparation (no polymerizable pendant groups needed). It has been shown that intramolecular cross-linking of single chains of water-soluble polymers can be carried out by reacting them with a suitable cross-linking agent in dilute solutions. The cross-linker must be capable of reacting with the functional groups (—OH, —COOH, etc.) of the polymer and should be at least bifunctional. Synthesis is carried out in solution. Polymer concentration must be chosen sufficiently low to avoid intermolecular cross-linking (i.e., it must be significantly lower than the coil overlap concentration). By varying the concentration of the cross-linker one can influence the internal cross-link density. Burchard et al. used this approach to synthesize internally cross-linked single macromolecules (nanogels) of poly(vinyl alcohol) with glutaraldehyde as the crosslinker [239] and of poly(allylamine) cross-linked with 1,4-dimethoxybutane-1,4-diimine dihydrochloride [240] (cf. also [241, 242]). A similar approach is used to obtain microgels of polysaccharides. For example, hydroxypropylcellulose microgels can be produced by (presumably mostly intramolecular) cross-linking of linear chains with divinylsulfone [243]. Analogous processes are utilized for the synthesis of commercially produced preparations of internally cross-linked hyaluronic acid [244–247].

2.2.2. Radiation-Induced Cross-Linking

Synthesis of nano/microgels by intramolecular cross-linking of individual polymer chains can be also initiated by ionizing radiation. The main advantage of this method is that it can be carried out in a pure polymer/solvent system, free of any monomers, initiators, cross-linkers, or any other additives. Therefore it seems to be especially well suited for the synthesis of high-purity products for biomedical use. In this approach, to be discussed in more detail, pure aqueous solution of a polymer is subjected to a short (a few microseconds), intense pulse of ionizing radiation. In this way, many radicals are generated simultaneously along each polymer chain, and their intramolecular recombination leads to the formation of nanogels. This approach has been first tested on neutral water-soluble polymers—poly(vinyl alcohol) [235], polyvinylpyrrolidone [248], and poly(vinyl methyl ether) [249, 250]—and later expanded to poly(acrylic acid) as an exemplary polyelectrolyte [236, 251].

The main parameter influencing the competition between inter- and intramolecular recombination of polymer radicals in dilute solutions is the average number of radicals present at each macromolecule at the same time [234]. If this number, under the given synthesis conditions, is much lower than 1, there is only a meager chance that a radical will find a reaction partner within the same chain. In such cases, recombination is only possible between radicals localized on two separate macromolecules. On the other hand, when there are tens of radicals present along each chain, the probability of intramolecular encounters and reactions

is higher than that of intermolecular ones. The latter processes are relatively slow, since they require that two large entities—polymer coils—diffuse toward each other.

In the case of the radiation-induced radical formation, these two opposite conditions (i.e., a very low or very high number of radicals per chain) can be fulfilled by means of a proper choice of irradiation conditions. Continuous irradiation at a relatively low dose rate, such as typical irradiation with gamma rays from isotope sources, leads to a steady-state concentration of polymer radicals in the order of 10^{-7} M. When the concentration of polymer coils is significantly higher than this value (this condition is usually easily fulfilled), the average number of radicals per chain is much lower than unity and intermolecular cross-linking is observed (Fig. 6a). In order to promote intramolecular cross-linking, short, intense pulses of radiation can be employed, such as pulses of fast electrons from an accelerator, generating radical concentrations in the order of 10^{-4}–10^{-3} M. If the concentration of polymer coils is low (that is to say, 10^{-6}–10^{-4} M), many radicals are generated on each macromolecule (typically many tens or even over a hundred), and the conditions for intramolecular recombination are fulfilled (Fig. 6b). Certainly, this does not mean that intermolecular reactions are totally eliminated in such a case. Some coils may come into contact before all the radicals decay, and if there is an uneven number of radicals on a chain, at least one of them must finally find a reaction partner at a neighboring macromolecule.

The data on changes in molecular weight, viscosity, and radius of gyration following the pulse irradiation of dilute polymer solutions clearly indicate that strongly internally cross-linked nanogels are formed which, in comparison with the starting macromolecules, have somewhat higher molecular weight but at the same time significantly lower

dimensions [235, 236, 248, 251]. While the main reason for the increase in molecular weight is the intermolecular cross-linking occurring in the system with very low yields in parallel to intramolecular recombination, the latter process is the dominant reason for the reduction in coil dimensions.

A balance between inter- and intramolecular recombination of polymer radicals may be also maintained when continuous irradiation is used. Therefore it is possible to synthesize microgels by cross-linking in a solution using isotope sources, as has been experimentally demonstrated and supported by simulations for poly(vinyl alcohol) by Wang et al. [231–233, 252].

2.3. Disruption of Macroscopic Networks

The idea of obtaining microscopic gel particles by disrupting continuous "wall-to-wall" gels seems to be conceptually the simplest of all synthetic approaches, since the procedures used to obtain macroscopic networks are usually simple, with less parameters to be controlled than in the previously described typical microgel synthesis methods—there is no need to control the micelle size or to observe the precautions necessary to avoid macrogelation. A disadvantage of this "nonelegant" method is that the size distribution is very broad (however, for microgels in the scale of many micrometers it can be reduced, e.g., by using mechanical sieves); one cannot usually expect to produce extremely small gel particles in this way nor obtain products of a regular, spherical shape. On the other hand, the disruption method may be of some advantage for synthesizing microgel fractions of various diameters but precisely the same crosslink density (since they are derived from one specimen of a macroscopic gel) [253]. In the authors' laboratory this method is used routinely to fabricate large amounts of coarse polyvinylpyrrolidone microgel of dimensions below 50 μm, following radiation-induced synthesis of macroscopic gel in the bulk [254]. A gel disruption process has been reported to yield cross-linked polysaccharide microgels (of dimensions in the 100 nm range), as one of the steps to construct polysaccharide/phospholipide biovectors for drug delivery [255].

It should be noted that important final steps of almost all synthetic procedures used to obtain microgels are purification and drying. It has been clearly demonstrated that drying methods and conditions may have significant influence on the final structure and properties of microgels [143, 256].

3. METHODS USED FOR STUDYING MICROGELS

Since most microgels of micrometer and submicrometer size are soluble in a suitable solvent, their properties can be conveniently studied by the methods developed for macromolecules in solution. These include various versions of viscometry, static and dynamic light scattering, gel permeation chromatography (GPC), and, to a lesser extent, ultracentrifugation and osmometry.

Relative changes in hydrodynamic dimensions of microgels, related to their average molecular weight, structure, and size, can be followed by *viscosity measurements* in dilute

Figure 6. Gel formation by recombinaton of polymer-derived radicals under two different experimental conditions: (a) *inter*molecular cross-linking leading to macrogelation (high polymer concentration, low steady-state concentration of radicals ⇒ momentary average number of radicals per chain is lower than one), (b) *intra*molecular cross-linking leading to microgelation (low polymer concentration, pulse-generated high concentration of radicals ⇒ momentary average number of radicals per chain is much higher than one).

solutions, using simple equipment such as an Ubbelohde viscometer.

Determination of an intrinsic viscosity of a polymer solution $[\eta]$ is one of the simplest and most common ways to determine average molecular weight of a polymer (precisely the viscosity-average molecular weight, M_η). Correlation between these values is known as the Mark–Houwink equation, $[\eta] = K M_\eta^\alpha$, where K and α are parameters which are constant for a given linear polymer/solvent pair at a defined temperature and can be found in handbooks (e.g., [257]). Since a microgel particle is more compact than a coil of the same linear polymer, viscosity of microgel solution is lower than that of linear macromolecules of equal concentration. As a result of that, viscosity measurements do not yield proper values of molecular weight for microgels, at least when K and α values for linear chains are used.

Although the Mark–Houwink parameters for some microgels have been determined, their practical use is very limited, since the real dependence of viscosity on molecular weight is influenced by cross-link density, way of synthesis etc., and therefore it may vary from one to another preparation. Anyway, it is worth noting that the values of the exponent α for microgels are low (e.g., 0.16 for microgels of poly(vinyl alcohol) [241], 0.25 for microgels based on polystyrene copolymers [258], 0.09 to 0.24 for divinylbenzene-based gels [16, 29]) when compared with values typical for random coils of flexible macromolecules in good solvents (0.5–0.8), indicating only a weak dependence of viscosity on molecular weight.

Despite the previously described disadvantage, viscosity is a very convenient tool to measure volume changes in gel structures of constant average molecular weight. Examples of such experiments are synthesis of microgels from linear chains by intramolecular cross-linking [231, 232, 235] or changes in volume of stimuli-sensitive microgels [251]. Senff and Richtering provided large data collections and detailed discussions on the temperature influence on viscosity and rheology of thermosensitive poly(N-isopropylacrylamide) microgels [259, 260]. An extensive study of viscosity-related phenomena in polyelectrolyte microgels has been presented by Antonietti et al. [140, 141, 261].

Viscosity measurements are also frequently used to follow the changes in size of microgels during the synthesis based on polymerization and cross-linking, often in parallel with other methods, indicating the changes in molecular weight. Such studies have been done, for example, on polyacrylamide [142], poly(allyl methacrylate) [115–118], poly(t-butyl acrylate) [96], polyurethanes [22], and poly(vinyl methacrylate) [117].

Relatively low viscosity of microgel solutions is one of the factors that makes them suitable for high-solid-content organic coatings (see Section 4.2), since to maintain the desired viscosity level of a solution or dispersion, higher concentration of microgels than linear chains can be used.

Another viscosity-related field of studies is *rheology* of microgel solutions or dispersions. The information gained is related to the compactness and stiffness of gel particles and their susceptibility to flow-induced deformation, solvent permeability, as well as the interactions between the particles. For some compact microgels (e.g., based on polyester copolymers), almost Newtonian flow has been observed even at concentrations of 40 wt% indicating low interparticle interaction and low deformation [16]. Solutions of other microgel structures show pronounced deviations from the Newtonian behavior, mostly behaving as pseudoplastic, shear-thinning fluids. Discussions on structure–rheology relationships of microgel solutions can be found in [19, 259, 260]. Rheological tests provide valuable information on the behavior of the outer layer of complex microgels—for example, in a core–hair structure one can follow the tendency of the hairs to become extended in a given solvent [262]. Data on the solutions of thermoresponsive microgels of poly(N-isopropylacrylamide) show pronounced temperature dependence of rheological properties, reflecting the change in volume fraction occupied by gel microparticles [18, 263]. Changes in rheological properties of the reaction mixture can yield important information on the mechanism and kinetics of cross-linking polymerization [264]. Precise knowledge on how the composition and synthetic procedures influence the rheological properties of final products is essential for fabrication of microgels used in coating technology [265–268].

Static light scattering, based on the laws discovered and methods developed by Rayleigh, Debye, and Zimm, is an absolute method of determination of weight-average molecular weight of any dissolved macromolecular structure [269–271]. In this method, a laser light beam is passed through a solution of macromolecules or microgels, and the (time-averaged) intensity of scattered light is measured, in relation to the intensity of the incident beam, at various angles, for a few different concentrations of the polymer in the sample. Double extrapolation of these data to zero angle and zero concentration yields the weight-average molecular weight. One has to stress that this method is of particular value for studying microgels, since many other methods (viscometry, simple gel permeation chromatography without light-scattering detection) that require calibration can yield incorrect molecular weights of microgels when calibrated on linear polymer samples. Certainly, static light scattering also has some limitations. The most important in the present context is the upper limit of molecular weight that can be determined. Molecules or gel particles of M_w higher than a few million Da cannot be usually analyzed by this method. Another limitation is uncertainty whether one of the calculation parameters, the refractive index increment (dn/dc), undergoes significant changes when linear chains of a given polymer are transformed into microgels. This problem, often neglected, still requires detailed studies. Examples of static light-scattering measurements on microgels are listed, arranged according to the main chemical component of the microgel: hyaluronic acid [247], organosilicon compounds [131], poly(acrylic acid) [236, 251], poly(allyl aniline) [240], poly(allyl methacrylate) [115–118, 120, 272], polyethylene [273], poly(lauryl methacrylate) [121], poly(methacrylic acid) [274], poly(methyl methacrylate) [275], poly(N-isopropylacrylamide) [151, 259, 260, 274], poly(N-vinylcaprolactam) [61, 63, 64, 66, 125], poly(vinyl alcohol) [231, 235, 239], poly(vinyl methacrylate) [117], and polyvinylpyrrolidone [248].

Static light scattering is not only a tool for determining the weight-average molecular weight, but it yields as well

the radius of gyration (a very important parameter in analysis of microgels) and a second virial coefficient, which is useful for investigating polymer-solvent vs. polymer–polymer interactions. For example, a negative value of this parameter indicates a tendency of polymer chains or microgels to undergo reversible aggregation in a given solvent.

Static light-scattering techniques can be also used for real-time study of the kinetics of microgel formation. This can be done by coupling a pulse-radiolysis setup with a laser light scattering photometer [276–279]. Cross-linking and/or polymerization reactions are initiated by short (a few microseconds) pulse of ionizing radiation in the form of fast electrons generated by an electron accelerator, and subsequent changes in the intensity of scattered light caused by changes in molecular weight and/or radius of gyration can be recorded, analyzed, and, when possible, recalculated into rate constants of participating reactions.

It is worth mentioning that *in-situ*, real-time monitoring of microgel formation is possible not only by following the increase in the intensity of scattered light but also by measuring the decrease in intensity of transmitted light. A description of the latter technique and its applications can be found in the works of Kara and Pekcan [39–41].

Dynamic light scattering, based on temporal correlations of the intensity of light scattered by the solution of macro-molecular structures, does not yield (at least directly) molecular weights, but average values and distributions of diffusion coefficients [271, 280–282]. These data can be recalculated into average values and distributions of hydro-dynamic diameters—again very important characteristics of a microgel sample. The range of sizes that can be measured is more shifted toward large structures when compared with static light scattering (up to a few micrometer). It should be stressed that the average radius of gyration determined by static light scattering and the average hydrodynamic radius calculated from dynamic light scattering are different physical parameters. The relation between these two values is a valuable indicator of microgel structure [239, 240]. Examples of application of dynamic light scattering for analyzing microgels can be found in the following papers, arranged according to the main component of the studied material: dextran [283], hydroxypropyl cellulose [243], organosilicon gels [132, 284], polyacrylamide and its derivatives [71, 285], poly(acrylic acid) [285, 286], poly(allyl aniline) [240], poly(*n*-butyl acrylate) [129], polyesters [287], poly(ethylene oxide) [8], poly(2-hydroxyethyl methacrylate-*b*-styrene-*b*-2-hydroxyethyl methacrylate) [107], poly(methacrylic acid) [274], MADQUAT [144], poly(methyl methacrylate) [123], poly(methyl vinyl ether) [250], poly(*N*-isopropylacrylamide) [70, 148–150, 152, 259, 260, 274, 288–295], poly(*N*-vinyl-caprolactam) [126], poly(sodium 2-acrylamido-2-methyl-propanesulfonate) [144], polystyrene [129, 139, 296], poly·(tetramethoxylated bisphenol A dimethacrylate) [165], poly(vinyl alcohol [231, 232, 239]), poly(2-vinylpyridine) [297, 298], and poly(2-vinyl pyridine-*b*-styrene-*b*-2-vinyl pyridine) [299].

Surface charge effects like electrophoretic mobility can be investigated by measuring the *zeta potential* or by *phase analysis light scattering* [67, 144, 300].

A method that in some aspects resembles light scattering is the *small angle neutron scattering* technique (SANS).

Neutrons of suitable energy range are scattered by atomic nuclei of a polymeric sample and give rise to scattering patterns similar to those obtained by light scattering. An advantage of neutron scattering is that it can be used not only in solutions but also in gels and even in the condensed phase, when appropriate samples are used (e.g., containing a small fraction of deuterated macromolecules). This method allowed detection of structural differences in gels of the same chemical composition but synthesized by different methods (chemical and γ-ray initiation) [301]. Temperature-dependent SANS measurements were applied to follow the structural changes in thermoresponsive microgels of poly(*N*-isopropylacrylamide) [17, 148, 294, 302].

Microgels can be also studied by GPC (size exclusion chromatography; for general reviews see [303, 304]). This method is routinely used in research and industry to determine molecular weight distribution and number-, weight-, and *z*-average molecular weights of polymers. In its basic form, GPC is not an absolute method and requires calibration on monodisperse polymer standards of precisely known molecular weight. Since macromolecules or microgels are segregated on GPC columns according to their size (hydro-dynamic volume) and not molecular weight, the same precautions as mentioned previously for viscometry must be applied if the method is to be used for determination of molecular weight distribution of microgels, since linear polymer standards and microgels of the same molecular weight may have very different dimensions and retention volumes. This problem can be partially overcome in modern GPC setups equipped with a light-scattering detector that in principle allows for absolute determination of molecular weight of each polymer or microgel fraction. Still, the use of right-angle laser light scattering detectors with microgel samples may lead to some systematic errors, since the algorithms for recalculation of the data to zero angle are based on the theory of polymer coils, not microgels. On the other hand, detection at a low angle (multiangle or low-angle detectors) usually gives noisy signals, especially in aqueous solutions. Nevertheless, the method is fast, efficient and for sure a valuable tool in microgel analysis. Exemplary applications described in the literature refer to microgels based on poly(allyl methacrylate) [272], poly(divinylbenzene) [305], poly(methyl methacrylate) [23], polystyrene and poly(*t*-butyl styrene) [101, 306], polystyrene and poly(butyl acrylate) copolymers [307], poly(*t*-butyl styrene-*co*-divinylbenzene) [100], and poly(vinyl alcohol) [232]. Gel permeation chromatography may be also applied for preparative purposes. Microgels based on polyethyleneimine and poly(ethylene glycol) have been successfully fractionated by this technique [308].

Chemical composition of microgels can be determined by any regular analytical technique used for polymers. UV-visible or infrared (IR) spectroscopy is often used to control the conversion of monomers during the microgel synthesis. The use of IR spectroscopy may be facilitated by the fact that many microgels form films that may be analyzed directly. Concentration and structures of polymer-derived free radicals during polymerization or cross-linking can be followed, in some cases, by electron paramagnetic resonance [165, 309–312]. Classical methods of instrumental analysis

as conductometric and potentiometric titration may be very useful for analyzing ion-bearing microgels [155, 297].

Nuclear magnetic resonance (NMR) spectroscopy can be used for determination of the chemical structure of microgels [68, 120, 125, 313–316]. Another application of a related technique in the field of polymer systems is the pulsed-NMR measurements of *spin–spin nuclear magnetic relaxation* times. They yield valuable data regarding polymer structure, crosslink, and/or entanglement density in solid polymers [317–319], polymer melts [320], and gels [321–323].

Visualization of microgels can be realized by various microscopic techniques. While the use of optical microscopy is limited to the relatively large structures, most studies are based on transmission electron microscopy (TEM, selected reviews: [324, 325]), scanning electron microscopy (SEM, [325, 326]) and atomic force microscopy (AFM, [327–330]).

Transmission electron microscopy is widely used to study microgels. Usually it does not require any complicated sample preparation. In a typical procedure, a drop of dilute microgel dispersion or solution is cast on a suitable support (often a carbon-film-coated copper mesh) and dried at room temperature (RT). This method is well suited for observation of single gel particles or their monolayers. Exemplary applications of TEM in studying microgels are visualization of simple gel particles based on polyacrylamide [142], poly(2-acrylamiddo-2-methylpropanesulfonate-*co*-(2-(methacryloyloxy)ethyl)trimethylammonium chloride) [144], poly(divinylbenzene-*co*-maleic anhydride) [28], poly(*N*-ethylacrylamide) [124], poly(*N*-isopropylacrylamide) [149, 150, 156], polyurethanes [22], as well as more complex structures and effects, like core–shell microgels [69, 128, 262, 293], loading of nanogels with drugs [308], binding metal or metal oxide particles [37, 331, 332], and template influence on the synthesis of polysilane microgels [333].

More complex microgel structures, multilayers, foils, and surface features of microgel-based materials can be visualized by scanning electron microscopy. SEM enables the analysis of thick, nontransparent (in the sense of TEM) samples and due to its large focus depth gives sharp pictures of structurally complex materials. Sample preparation is not as simple as in TEM, since here coating the sample with a thin layer of a conducting material is necessary. Examples of applications of SEM in the field of microgels include a study on the influence of monomer ratio on the properties of poly(*N*-isopropylacrylamide-*co*-acrylic acid) gel particles [152], thermally induced structural changes in poly(*N*-isopropylacrylamide) microgels [294], various morphologies of poly(divinylbenzene-*co*-maleic anhydride) [28] and poly(divinylbenzene-*co*-4-methylstyrene) gels [305], binding microgels onto TiO_2 pigments [122] and aluminum surfaces [332], structures of microgel-based ion-exchange resins [334], structure of polypyrrole particles obtained by template polymerization in the presence of poly(vinyl methyl ether) microgels [335], and structural effects accompanying inverse emulsion cross-linking polymerization of acrylamide [142].

AFM is a development of scanning tunneling microscopy. These techniques differ from electron microscopy both in operating principles and in many aspects of their application. Sample preparation is simple, no metal sputtering or vacuum environment, etc. is needed and the native sample structure in its natural environment (e.g., air, liquid) can be visualized. AFM has been successfully used for imaging of polymer systems, from surfaces through colloidal particles and dendrimeric structures down to single macromolecules (extensive review: [336]) In the field of microgels, the AFM technique has been used for example, for studying surface topology of vinyl/dimethacrylate networks [165, 166], poly(acrylic acid) films based on linear chains and on nanogels (see Fig. 9 in Section 4.3) [251], films based on polystyrene and poly(*n*-butyl acrylate-*co*-acetoacetoxy ethyl methacrylate) gel particles [129], cluster formation in organosilicon micronetworks [284], structures of polystyrene graft microparticles [337], and the fibrous nature of polysaccharide gels [338]. An interesting modification of the AFM technique allowing for measurement of interparticle forces (that might be possibly used in future for measuring the forces between microgel particles) has been described by Sigmund et al. [339]. Another application of AFM that may be of interest in the present context is the determination of elastic properties of microparticles [340].

4. APPLICATIONS

4.1. Biomaterials

The possibilities of employing macroscopic polymer gels as biomaterials, mostly in the form of hydrogels based on synthetic polymers, have been explored since 1960s, when these materials were first synthesized [1]. Since then, a number of products reached the stage of commercial application, soft contact lenses, drug delivery systems, and wound dressings being the most widely known examples. Given the number of research groups involved and progress being made in this field, one may anticipate that in the future the number of hydrogel-based biomedical products on the market will be constantly increasing.

Broad although not very recent publications on the medical use of hydrogels are the collective works edited by Peppas [2] and DeRossi et al. [341]. Park et al. reviewed the narrower field of biodegradable hydrogels [342]. Out of more recent books and book chapters on this subject [343] provides a more general outlook, while the scope of [344] is limited to silicone-based hydrogels. For exemplary review papers on the medical applications of hydrogels, see [3, 345–352].

Although certainly the characteristics of hydrogels differ from one to another formulation, a few common properties can be listed that make these materials suitable for biomedical applications. In their high water content and hydrophilicity hydrogels are similar to tissues. They also mimic some properties of soft tissues as reversible swelling and elasticity. Due to their network structure they may be loaded with a drug which can be subsequently released at a controlled rate. This rate can be adjusted, one of the main factors being the mesh size. The latter parameter allows also construction of semipermeable membranes or containers, for example an outer shell of a hybrid artificial organ (an implant containing living cells) allowing the transport of water, oxygen, nutrients, and enzymes, but being impermeable to larger entities such as immunoglobulins and other components of the

immune system (cf. [353–355]). Due to their fair to excellent biocompatibility, hydrogels are usually well tolerated as implants.

An example of a mature biomaterial technology based on classical, homogeneous hydrogels is the large-scale production of wound dressings, by a technique combining radiation-induced cross-linking of polyvinylpyrrolidone and concomitant sterilization of the final product [4, 356]. A number of other products based on similar technology (e.g., systems for local delivery of anticancer drugs and for induction of childbirth) have successfully passed clinical tests [347, 355, 357, 358].

While "regular" hydrogels are already common components of biomaterials, current efforts of the researchers are now concentrated on the stimuli-sensitive ("intelligent," "smart") gels (reviews: [5, 18, 341, 359–363]). These materials are able to respond to external stimuli, such as temperature, pH, ionic strength, light, electric field, or even (selective) changes in the concentration of a given chemical species. The latter property can be used, for example, in glucose-responsive insulin-releasing devices [314] or antigen-responsive systems [364]. The response to the stimulus, being induced by conformational changes of the polymer chain segments, usually manifests itself as a pronounced change in the gel volume (strong contraction or expansion) and in the amount of bound liquid (decrease or increase in the degree of swelling). Due to these properties, stimuli-sensitive gels are tested for applications such as sensors, actuators, chemical valves, controllable or self-regulating drug-delivery systems, or even artificial muscles. Certainly, there is still some gap between the artificial hydrogel fish that moves by swinging its tail in a laboratory bath [365] or electrically driven gel finger working in the air [366] and a future implementation of a hydrogel-based muscle, but fast developments in the field of stimuli-sensitive hydrogels allow one to expect that biomaterials based on these materials will be implemented very soon.

Microgels are also intensely studied with respect to their biomedical applications (reviews: [16, 18, 361, 362, 367–370], exemplary patents: [371–375]). Of course, the product range is different than that of macroscopic gels, although there is a significant overlap in the field of controlled drug delivery. The most important microgel applications in the biomedical field are carriers for enzymes, antibodies, etc. used in diagnostics (e.g., immunoassays), drug carriers for therapeutic purposes (local, controlled drug delivery), and, potentially, microdevices (see Section 4.3), artificial biological fluids, and synthetic vectors for drug delivery.

Coupling microgels with selective biochemicals leads to materials applicable in biological testing [16, 18, 376]. This technique has been used for some time with solid nanospheres [368, 376, 377]. In some cases, in comparative tests microgels performed better than polystyrene-based microsphere supports, providing testing material of higher sensitivity [378]. A typical action of the microgel-based immunoassay is based on an aggregation of antibody-bearing microgels with the specific antigens. The large particles formed in this way can be detected by microscopic techniques. In a modified immunoassay, magnetic microgels can be applied, containing an encapsulated polymer core with adsorbed magnetic nanoparticles [371, 379]. Magnetically

labeled cells can be separated from a cell mixture by applying magnetic field, for example in a section of tubing in which the cell mixture is flowing.

Although there is a broad field of potential biomedical applications of conventional microgels, a strong tendency is observed to focus the research on complex microgels and on stimuli-sensitive systems. The preference for using stimuli-sensitive gels is even more pronounced for microgels than for the "wall-to-wall" gels. One of the important reasons is much shorter response time. While the reaction of macroscopic responsive gels to a stimulus is sometimes unacceptably slow (for example, when the molecules of a chemical stimulus have to diffuse into the whole volume of a gel slab), microgels, due to their small dimensions and high surface-to-volume ratio, respond much faster.

Temperature-sensitive microgels are tested for controlled binding of biomolecules. It has been shown that poly(N-isopropylacrylamide)—pNIPAM—microgels can bind various proteins by physical sorption above the phase transition temperature (i.e., at ca. 40 °C) and release them upon lowering the temperature to 25 °C [380, 381]. Proteins can be also covalently bound to such gels, and their activity can be controlled by temperature changes [382]. In complex systems such as described by Yasui et al. [383], one can achieve high enzyme activity within a defined, relatively narrow (a few degrees) temperature range. Pichot and co-workers demonstrated the possibility of using thermo- and pH-responsive microgels for binding nucleic acids [362, 384]. It has been shown that the interaction of temperature-sensitive microgels with elements of the immune system like granulocytes (foreign-body attacking cells) can be moderated by changes in temperature [385]. It is worth noting that the interaction of pNIPAM gel particles was much weaker than that of polystyrene microspheres, which may indicate that, in the context of attack by immune system cells, these microgels have higher biocompatibility than solid microspheres.

Thermosensitive microgels have been also tested as drug carriers. The structure and hydrophilic/hydrophobic properties of the drug have been identified as important factors influencing the phase transitions and uptake/release characteristics of poly(N-vinyl caprolactam) gel particles [126]. In order to achieve the desired release profile, composite microgels may be used, for example combined nonporous silica/pNIPAM gels [386]. The rate of the thermally triggered drug release may then be controlled by changing the composition of this hybrid product. Another interesting example of a composite structure based on drug-loaded thermosensitive microgels is a wound dressing, where drug-bearing pNIPAM gel particles are incorporated into a self-adhesive film [387]. The product combines adhesive and temperature-controlled absorptive functions and is easy to peel off after use.

Compositions containing poly(N-vinylcaprolactam-co-sodium acrylate) microgels and gelatin undergo a reversible macrogelation upon temperature increase above ca. 32 °C [65]. Such materials, liquid (injectable) at RT but forming a gel at the temperature of the human body, are considered for applications in surgery and drug delivery.

Another group of responsive materials tested for use as biomaterials are pH-sensitive and/or ionic-strength-sensitive microgels. For these products, there are at least two mechanisms allowing for controlled drug delivery. One can load

the gel particles with a drug at a pH where the particles are fully swollen (expanded), trap it inside by a pH change leading to the collapse of the microgel, and subsequently allow the drug to diffuse out at a pH-controlled rate. A similar mechanism applies as well to the systems where ionic strength is the stimulus for expansion and collapse, or where both pH and ionic strength effects are operating. Another mechanism is pH-dependent reversible ionic binding of drugs. Drug and protein binding and release from anionic microgels have been studied, for example, by Eichenbaum et al. [73, 74] and Soppimath et al. [388], while Vinogradov et al. [308, 375, 389] described the synthesis and properties of some cationic systems.

A sophisticated drug-delivery system, mimicking the action of secretory granules, has been constructed by Kiser et al. [390–392]. The core is an anionic microgel particle based on methacrylic acid, loaded with a drug. Subsequently, by lowering pH, a collapse of the microgel is induced. In this form, the particle is coated with a lipid bilayer, to simulate the natural secretory granule and to protect the particle from premature swelling. Poration of the lipid bilayer (e.g., by applying electric field) causes the gel to swell, allowing release of the drug. A different synthetic procedure leading to similar systems is based on encapsulation of hydrogel-forming components into liposomes and subsequent polymerization [176]. A further example of this kind is a group of products intended for drug delivery of vaccine formulations, consisting of cross-linked polysaccharide microgel core surrounded by a lipid bilayer [255].

A pH-sensitive microgel preparation based on poly(methacrylic acid-*co*-ethyl acrylate) has been devised for oral delivery of a novel drug being a HIV-1 protease inhibitor [393]. It has been demonstrated that the absorption of this poorly water soluble drug from the tested system was much better than from the suspension of a free drug.

Solid sustained release devices for oral delivery of drugs can be obtained by compressing microgels. Such a system based on polyurethane microgels has been shown to retain its integral structure but become microporous on swelling with water [374].

Microgels can be functionalized not only by coupling them with biomolecules, but also by molecular imprinting. This process leads to microgels bearing structural binding sites specific to target molecules. A general procedure of molecular imprinting of a polymer is as follows. Monomers being in contact with a template molecule are polymerized and cross-linked, the template is removed, and the polymer network contains a complementary binding site able to rebind the same template or analogous molecules. Ye et al. and Biffis et al. demonstrated the applicability of this procedure for synthesizing molecularly imprinted microgels and proved their binding performance [77, 78, 394].

Stability of shape and dimensions of microgels when compared with linear polymer chains may be helpful in their potential use for blocking dental microchannels in cases when there is a need to use a synthetic substitute for the natural gel-like substance performing this function [395].

An interesting and potentially valuable property of microgels is their enhanced resistance against degradation when compared to linear macromolecules [251, 396]. This effect

is illustrated in Figure 7. As a result of any intense or long-lasting stimulus inducing chain breakage (a mechanochemical action, ultrasound, the formation of peroxyl radicals along the chain, etc.), a linear macromolecule is easily degraded to short fragments. The same number of chain breaks formed in a microgel may cause no or very little fragmentation, since the chain segments are linked together in many points and will not fall apart as a result of a single chain break.

This effect has been demonstrated on microgels of poly(acrylic acid) (PAA) [251, 397]. Aqueous solutions of linear chains and microgels of PAA were subjected to the action of ionizing radiation in the presence of oxygen. Under such conditions, no cross-linking takes place in the system. Initially formed carbon-centered radicals are rapidly converted into the corresponding peroxyl radicals, which in turn initiate processes leading to chain scission. As the concentrations of linear and cross-linked chains of similar average molecular weight were identical, the yield of scission events should be equal for both samples. However, the changes in molecular weight and in the radius of gyration in the case of linear and microgel PAA revealed striking differences. While linear PAA is easily degraded even at relatively low doses, which is evidenced by parallel decrease in weight-average molecular weight and radius of gyration, microgels, within the same dose range, seem to remain intact, their molecular weight and radius of gyration being constant.

This degradation resistance combined with suitable rheological properties may be used in fabricating materials for medical applications. A commercialized example of such a product is a polymer drug based on microgels of a natural polysaccharide used to enhance the viscoelasctic performance of synovial fluid [246]. These macromolecules are subjected to mechanochemical stress and to the attack of reactive oxygen species, mainly free radicals. It has been shown that under such conditions internally cross-linked
Figure 7. Enhanced degradation resistance of microgels (b) when compared to linear macromolecules (a). Upon several chain scission events at locations marked with ⊗ a linear chain is cut into pieces, while the segments of a microgel do not fall apart.

macromolecules perform better than the corresponding linear ones [247]. Preliminary tests on a substitute synovial fluid containing microgels made of a synthetic polymer proved the high degradation resistance and proper viscoelastic properties of this product [398].

First tests have been performed on the application of microgels as synthetic, nonvirial vectors in gene delivery. The latter is regarded as a powerful tool for curing some hereditary diseases and treating genetically based disorders. Certainly, the issue is a very complex one, since such vectors must be capable of performing many processes such as binding DNA fragments, attachment to cells, internalization, and intracellular plasmid release. First attempts using microgel-like structures for gene delivery were based mainly on chitosan, but synthetic structures based on 2-(dimethylamino)ethyl methacrylate, *N*-vinylpyrrolidone, and *N*-isoporpylacrylamide have been tested as well, with promising results [369].

There are also projects to design microgel-based intravenous drug carriers that could remain in blood for a suitable period of time, facilitate the cellular uptake, and possibly also selectively deliver the drug to a target site. Animal tests have shown that by varying properties of such structures (chemical composition, hydrophilicity) one can change the biodistribution patterns of the microgels and that drug-loaded microgels were more efficient than equivalent concentrations of free drug in curing melanoma in mice [369].

Some further perspectives in the application of nano- and microsized particles and devices in drug delivery are discussed in [370].

4.2. Coatings

Where actual, large-scale applications of microgels are concerned, the surface coatings industry seems to be the most prominent field. The hundreds of research papers published and patents issued (for a few representative examples see [399–415]) dealing with microgel-containing coatings emphasize the significance of this application. The interest in the use of microgels as components of coatings originated mainly from environment protection needs and regulations. In order to reduce the amount of volatile organic compounds in the coating formulations, the manufacturers tend to increase the total solid content. This is, however, problematic if polymer components of a given molecular weight range are used in binders, since the viscosity of formulations becomes too high. When microgels are used, viscosity can be maintained at a desired level. Another approach besides the high-solid products is to use water-borne coating systems. Microgels can be used both in solvent-borne and water-borne coating products. Besides their advantageous rheological properties, they often exert a reinforcing effect on the cured coating. The use of microgels in coating technologies has been the subject of concise but informative reviews [16, 267] (cf. also book chapters in [416, 417]).

Microgel-containing solutions and dispersions are usually characterized by pseudoplastic, strongly non-Newtonian rheological properties. They are highly viscous at low shear rate (they do not flow at a zero shear rate), but their viscosity decreases remarkably with increasing shear rate. This is in a perfect accordance with the needs for a typical paint application process. In the storage tank (no or low shear rate) the viscosity should be high to prevent pigment settling, during the gun-spraying (high shear rate) low viscosity is desired, and at the object surface (no or low shear rate again) viscosity should increase rapidly so that no sagging effect occurs, even for films of high thickness. Another useful property of microgels is their positive influence on the orientation of flake pigments in metal effect coatings.

Microgels also have a positive influence on the mechanical properties of cured paint films such as stone chip resistance, impact flexibility, and elasticity. This is attributed to the cross-linked polymer structure, the high molecular weight of gel particles, and the microheterogeneous structure of the microgel-containing polymer film that probably allow the impact energy to be more efficiently dissipated [267].

In the automotive industry, the primer coating layer is often applied by electrodeposition. It has been shown that compositions containing amine-based cationic microgels, mostly in the form of aqueous dispersions, can be used for electrocoating [418, 419].

Problems that have been recently investigated with respect to the use of microgels in coatings include deeper understanding of the relationship between microgel structure and rheological properties (and ways to adjust the latter) [265], the influence of substrate composition and synthetic procedures on the shelf stability of the product and affinity between microgels and pigments [122], influence of microgels on the drying time [142], and ability to form films suitable for drying at ambient temperatures [129].

Microgels can be used not only as constituents of regular coatings but also as self-adsorbing and self-organizing film-forming layers for protecting metal surfaces against corrosion. It has been shown that core–shell microgels based on styrene, butyl acrylate, and phosphate-substituted acrylates form a layer of a structured molecular order on a surface of technical aluminum and provide efficient protection against corrosion in standard tests [332, 420].

Although the use of synthetic microgels in coatings started in the late 1960s [421] or, depending on what we consider a true microgel, perhaps rather in the 1970s [422, 423], one should mention that physical and chemical studies on a highly durable ancient oriental lacquer used in Asia for millennia revealed a structure containing self-formed, natural core–shell-like microgel particles [424].

4.3. Miscellaneous

Besides their applications in coatings (biggest market) and in biomaterials (perhaps the most promising direction for the future), microgels are used or tested for use in a number of other fields.

Besides large-scale use of microgels in the coating industry, similar properties make them interesting for the manufacturers of *cosmetics*, namely nail varnishes [425, 426]. In varnishes based on organic solvents, organophilic clays are used to prevent pigment sedimentation. These compounds, however, exert some unwanted side effects and usually require toluene as a component of the formulation. The presence of microgels allows reduction or elimination of the

use of clays while maintaining the proper rheological properties of the varnish and preventing the precipitation of the pigments.

Historically one of the first applications of microgels was in *papermaking* [427–429]. In manufacturing quality products starch and other polysaccharides used as paper and paperboard sizes may be replaced with poly(vinyl alcohol) (PVAL) for better performance. It has been demonstrated that microgels of PVAL show clear advantages over the same polymer in a linear form (e.g., they have lower tendency to penetrate into paper, which is an undesirable effect). Several microgel-containing preparations were used, based either on pure PVAL gels or gel components combining PVAL and polysaccharides. Anionic polysilicate microgels in combination with organic polymers are used to flocculate pulp and filler fines in the water-removal step of the papermaking process [430].

Microgels can be a valuable component of *fibers*. An exemplary application is the admixture of vinylidene chloride gels to an acrylic fiber, significantly improving the flame retardancy [431]. Similar gels have been shown to improve load-bearing properties and flame retardancy of polyurethane *foams* [432].

Microgels can be also applied as supports in *catalysis*. Organo-aluminum compounds coupled to organopolysiloxane microgel particles serve as co-catalysts in the polymerization of olefins [433, 434]. Enantioselective reduction of prochiral ketones can be catalyzed by microgel-bound oxazaborolidines [38]. Good solubility and, at the same time, low viscosity of the solution are the important advantages of microgel-supported catalyst, while the catalytic action and selectivity are comparable to those of low-molecular-weight analogs. Microgels bearing trialkylammonio groups have been demonstrated to catalyze alkaline hydrolysis of aryl laurate esters [127].

By using microgel-supported catalyst, a homogeneous catalysis in a flow reactor may be carried out (Fig. 8). If the inlet and outlet of the reactor are equipped with membranes that the gel particles cannot pass, the reactants are in a constant flow but the catalyst remains in the reactor, despite it being present in a nearly molecular dispersion.

Particular rheological properties as well as higher mechanochemical resistance of microgel solutions when compared to the solutions of linear chains are the basis of their applications in the fields of liquid thickening, *oil recovery*, and *hydraulics*. Solutions of relatively inexpensive polyacrylamide-based microgels are used as thickening agents and agents for restricting the flow of liquids through subterranean formations [435]. Microgel solutions can be applied as a non-Newtonian, shear-resistant, nonleaking hydraulic fluid for hydraulic energy transmission systems and devices absorbing mechanical energy (liquid springs, shock absorbers) [436].

Due to their swelling and water-retaining properties, hydrophilic microgels have been postulated and tested, with good results, for use as *soil conditioners* [437–439]. In the case of preparations consisting only of homogeneous microgels, one may encounter a problem of poor mixing with soil and spontaneous separation (gel particles come up to the surface of soil), due to differences in specific gravity of soil components and gels. This can be avoided if structured
Figure 8. A schematic illustration of a homogeneous catalysis in a flow reactor, based on catalyst coupled to microgel particles, trapped between two membranes.

microgels are used, consisting of solid filler grains of high specific gravity embedded in gel particles [439]. While gel-based soil conditioners are well suited for use in flower pots or on the lawn of a golf course, their price does not allow them to be used in large-scale projects like desert reclamation in countries with very limited financial resources, even if economical synthesis routes are taken into consideration (e.g., radiation-cross-linking of acrylamide in bulk followed by mechanical grinding).

An extensively tested and potentially broad field of microgel application is in *printing* and *photographic technology*. Since the rheological properties of microgel can be tailored to meet specific needs (a sophisticated method of viscosity adjustment may be varying the hair length of core-hair type microgels), they may be useful in liquid photopolymer formulations used to cover the screen in the screen printing technique [262]. Incorporation of microgels in the photosensitive layer of a kind of modern lithographic plate leads to a product that can be developed directly on a printing press, without a postexposure wet development step [440]. This technology allows one to save time and labor as well as reduce the use of volatile organic compounds. Another technology has been elaborated to obtain printing plates for flexographic printing [441, 442]. Microgel-based photosensitive resin allows the plates to be water-developable, thus eliminating the use of harmful halogen-containing solvents used to develop the plates in a conventional technique. A variety of photosensitive compositions for use in printing and manufacture of printed circuit boards employ microgels to enhance physical properties, eliminate cold flow, improve storage stability, enhance photospeed, and render these materials suitabable for water processing [443–446]. A further interesting example is the use of reactive microgels

that constitute a chemically active compound of a hardenable resin composition [447, 448].

Some inks and electrographic liquid developers contain finely dispersed microparticles of magnetic substances. Several problem have to be overcome in producing these "magnetic fluids," one the most important being the poor dispersion stability. This can be significantly improved when incorporating these solid microparticles, during synthesis, into polymeric microgels [449].

Macroscopic polymer gels can be made photosensitive, not only by introducing chromophores that undergo permanent changes (e.g., cross-linking) upon irradiation, but also by incorporating structures that enable reversible photochemical switching of properties (reversible cross-linking) [450]. This indicates that also microgels themselves can be turned into photosensitive materials, either by using suitable monomers or by postsynthesis modification. In fact, coumarin-containing organosilicon microgels have been demonstrated to undergo photoinduced cluster formation [284]. So far, most often microgels are used in photography and imaging as auxiliary substances, either as binding agents improving the physical properties of the film layers or as additives that help to incorporate the photographically active or other (e.g., antistatic) substances into the photographic layers [451, 452].

Debord et al. have demonstrated that relatively simple microgels made of poly(N-isopropylacrylamide) can be manipulated to form colloidal crystals of specific colors depending on the fabrication parameters [70]. In another approach, polymeric nanospheres are incorporated into a stimuli-sensitive hydrogel [453]. Under the action of a chemical stimulus, the distances between the nanospheres can be varied, thus causing shifts of the wavelength of the Bragg peak of the diffracted light. This leads to the changes in color of the specimen. It is expected that such colloidal crystals can find a wide range of applications in *photonics* and *chemical sensing*.

One may expect that in the near future interesting applications will be found for the recently described *electrically conducting microgels* based on pyrrole and aniline polymers bound to a gel core [454]. The products have promising properties in the aspects of electrical conduction, electromagnetic frequency interference shielding, and electrostatic prevention.

Sorption and *binding* of a variety of compounds is an intensely studied application field of polymer gels. Most research in this area concerns the use of hydrogels. Exemplary applications of macroscopic hydrogels being investigated, besides the drug-delivery systems described in Section 4.1, include, for example, binding of metal ions [455], selective removal of pollutants (arsenate and selenite [456], textile dyes [457], organic substances [458]), or collection of uranyl ions from seawater [459]. Reversible sorption of water by hydrogels is tested for an application in sludge dewatering [460].

A number of studies revealed the potential application of microgels in *metal ion binding* and *ion exchange*. An advantage of using micro- instead of macrogels is primarily the binding kinetics—in microgels the binding groups are easily accessible, in contrast to most macroscopic gel structures, where considerable time is needed for the substrates to diffuse into the gel volume. Gel particles bearing carboxylate groups bind divalent alkali earth cations (Mg^{2+}, Ca^{2+}, Sr^{2+}, Ba^{2+}) more effectively than monovalent cations (as Na^+) [75]. Binding of calcium ions has been studied in more detail [63, 65]. Other studies have shown that there may be a pronounced selectivity in binding divalent metal ions. For example, binding of Hg^{2+} cations by poly(N-vinylcaprolactam-*co*-sodium acrylate) microgels is much stronger than binging of Cu^{2+} and divalent alkali metal ions [64]. Strong, albeit reversible, binding of Pb^{2+} by microgels of poly(N-isopropylacrylamide-*co*-sodium acrylate) has been reported as well [149, 288]. These observations indicate that microgel-based systems may be used for selective ion binding. Various microgel-containing selective ion-exchange materials have been fabricated. Examples are commercially available macroporous polymeric anion and cation exchangers where every exchanger particle (having the diameter of a fraction of mm) consists of a large number of submicrometer size microgels (cf. [461–463]). Such systems may be applied for example for eliminating trace concentrations of organic compounds that exist in water in an ionic form.

It is postulated that thermosensitive microgels may serve as valuable binding/separation agents, due to the ability of these materials to absorb various chemical species below the conformational transition temperature and to release them at elevated temperatures due to the contraction of microgels. The compounds being reversibly absorbed include metal ions [288, 464], polymers [465], and surfactants [18, 150, 302, 466–468]. Most studies in this area have been done on poly(N-isopropylacrylamide)-based gels. Besides, the interactions between surfactants and poly(N-vinylcaprolactam) microgels have been investigated [61].

One of the most fascinating prospective uses of stimuli microgels is in *microdevices* and *micromachinery*. Due to their fast response time, they may be used, for example, as self-regulated, pH- or temperature-controlled microvalves. Contrary to conventional microactuators (electromagnetic, electrostatic, thermopneumatic, etc.), microgel-based valves are simple and do not require external power for operation. Fully operational exemplary devices of this kind, having short response times, have been recently presented by Beebe et al. [469].

Microgels can be used as building bricks for constructing complex polymer structures and materials. A simple example may be fabrication of a polymer material (foil, coating, etc.) of a well-developed, rough (in the microscale) surface. This may be carried out just by casting a foil from a microgel solution. Such a surface, even after drying and collapse of microgels due to a loss of solvent, remains structured when compared to analogous sample obtained from solution of linear chains of the same polymer (Fig. 9) [251].

Chen et al. have demonstrated that styrene-based microgels bearing carboxyl group could be easily self-organized into ordered multilayered films or latex crystals [155]. Calcium ions may be used to form large structures of spherical poly(N-vinylcaprolactam-co-sodium acrylate) microgels [63]. Poly(vinyl methyl ether) (PVME) microgels can be used as specific nanoporous templates in the polymerization of pyrrole [335]. The resulting products were large,
Figure 9. Surfaces of films obtained by casting and drying solutions of poly(acrylic acid): (a) film of linear PAA, (b) film of PAA microgels, as observed by atomic force microscopy.

needle-like particles, in contrast to small spherical particles obtained with linear PVME. Microgel-like, internally cross-linked rubber particles have a high reinforcing effect when incorporated into regular rubber materials [470, 471]. Materials constructed of microgels that are embedded in continuous polymer matrix are considered for use as membranes, filters, and absorbents [472].

GLOSSARY

Chemical gel (permanent gel) A gel where the polymer network is composed of polymer chains connected by permanent, covalent bonds.

Critical gelation concentration (CGC) 1. The highest monomer concentration at which no macroscopic gel is formed even at a complete monomer conversion (in the crosslinking processes starting from polymers). 2. The highest polymer concentration at which no macroscopic gel can be obtained (in the crosslinking processes starting from polymers).

Cross-linking A process of formation of permanent links (covalent bonds) between two separate macromolecules or between two segments of same macromolecule.

Cross-linking polymerization A process where polymerization and cross-linking take place side-by-side; a typical phenomenon for polymerization of systems containing multifunctional monomers.

Gel A two-component material consisting of a (permanent or labile) network of linked polymer chains and a solvent filling the pores of this network. In this chapter this term is used to denote only the chemical (permanent) gels.

Hydrogel A two-component material consisting of a (permanent or labile) network of linked hydrophilic polymer chains and water (or aqueous solution) filling the pores of this network. In this chapter this term is used to denote only the chemical (permanent) hydrogels.

Intermolecular cross-linking A process of formation of permanent links (covalent bonds) between two separate macromolecules.

Intramolecular cross-linking A process of formation of permanent links (covalent bonds) between two segments of same macromolecule.

Ionizing radiation Any form of radiation (electromagnetic radiation or fast particles) having sufficiently high energy to cause ionization of matter. Gamma rays from isotope sources and beams of accelerated electrons are commonly used in radiation-based polymer technology.

Lower critical solution temperature (LCST) Lowest temperature at which the polymer-solvent system becomes phase-separated (for polymer-solvent systems that become immiscible upon temperature increase).

Macroscopic gel A continuous gel phase of macroscopic dimensions. It can be easily seen with a naked eye. Macroscopic gel can be filling the whole volume of the sample or the reaction vessel (a "wall-to-wall" gel).

Microgel A gel particle of microscopic dimensions (or in other words, an internally cross-linked polymer microparticle), able to swell, without disintegration, in a suitable solvent. In this chapter this term is used to denote only the chemical (permanent) gel particles. For a more detailed discussion of the microgel definition—see Introduction.

Microparticle (polymeric) Any polymer particle of microscopic dimensions, regardless of the presence or absence of any links and the nature of the forces acting between the individual polymer chains.

Nanogel 1. A gel particle of submicromter size. 2. A subclass of small microgels formed by intramolecular cross-linking of single macromolecules. In this chapter this term is used to denote only the chemical (permanent) gel particles. For a more detailed discussion of the nanogel definition—see Introduction.

Physical gel (pseudogel) A gel where the polymer network is composed of polymer chains connected by weak, usually reversible, binding phenomena (ionic bonds, hydrogen bonds, van der Waals forces, entanglements).

Surfactant-free emulsion polymerization A particular kind of emulsion polymerization where the emulsifying action is provided not by an added surfactant but by the monomer and/or polymer itself.

CONTENTS

1. INTRODUCTION

Science and technology continue to witness enormous attention focused on the production of new materials on the micrometer and nanometer scale that have tunable material, electrical, and optical properties. Polymer particles, polymer particle alloys, or polymeric composites provide one viable avenue for the production of these highly desired systems. Currently, polymer particles can be produced in a variety of ways, some of which allow easily controllable particle size and composition as well as a number of crucial physical properties [1–12]. In addition, recent results have shown that polymeric particles in the micro- to submicrometer range can be formed such that dynamical confinement effects result in interesting nanostructures and properties that cannot be produced using conventional methods [2].

Polymer particle wires and arrays, "supramolecular particle structures," have also been produced which offer another set of exciting possibilities [4]. These combined capabilities open the door to a variety of novel uses, such as electro-optic and luminescent devices, magnetic coatings, thermoplastics and conducting materials, hybrid inorganic–organic polymer alloys, polymer-supported heterogeneous catalysis, high-energy-density materials, information materials, and a whole host of applications in the biomedical field [6–16]. In this chapter we review some of the recent progress in the production and characterization of polymer particles and provide examples of a number of relevant applications. Our intent is to provide a general overview of the various areas and methods relevant to polymeric particles. Since there is a very large literature base for each of the topics discussed in the following sections, we have tried to provide some general references where more extensive literature citations can be found.

## 2. SYNTHETIC ROUTES FOR POLYMERIC NANOPARTICLES

The synthesis of polymeric nanoparticles in large and homogeneous quantities has received considerable attention in polymer and materials science [17–73]. Much of the motivation has been derived from the incredibly broad and often unique applications of polymeric particles (see later sections for details). To date most of the synthetic production of polymer particles generally falls within two primary approaches. The first approach is based on the emulsification of the water-immiscible organic solution of the polymer by an aqueous phase containing a surfactant, followed by evaporation of the solvent. The second approach is based on the precipitation of a polymer after addition of a nonsolvent of the polymer. On the other hand, nanoparticles formed of natural macromolecules are generally obtained by thermal denaturing proteins (such as albumin) or by a gelification process, as in the case of alginates.

In the past, polymer latexes (suspensions or dispersions of polymer particles) were largely made by conventional emulsion polymerization but this method is mostly suitable for only radical homopolymerization of a narrow set of barely water-soluble monomers. To broaden the range of possible polymeric systems a number of new techniques for generating micro- and miniemulsions, phase inversions, secondary dispersions, and suspension polymerizations have been developed and successfully implemented. Figure 1 illustrates some of the types of polymerization methods available for producing polymer particles and the corresponding particle size range. We discuss a number of these techniques and their applicability to the production of polymeric nanoparticles. Our discussion is only meant to give a flavor of the various polymerization routes for producing polymer particles. There are a number of reviews and books dedicated to these methods and more complete details are better obtained from those references and references cited therein [17–26].

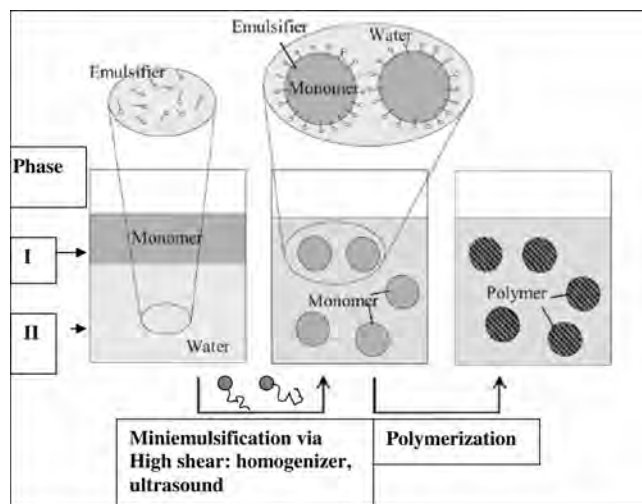
2.1. Emulsion Polymerization

Emulsion polymerization as a conventional preparation method can make polymeric particles in the size range of 100–1000 nm, a range that has been gradually broadened [17, 18, 27–39]. For example, the seeded emulsion polymerization technique was developed to make latexes larger than 1000 nm, while the miniemulsion and microemulsion polymerizations were designed to prepare particles in the ranges 50–200 and 20–50 nm, respectively (see Fig. 1).

Emulsion polymerization is a widely used industrial process for making coatings, paints, adhesives, and resins. Monomers used in emulsion polymerization are typically only sparingly soluble in water although a few percent of water-soluble co-monomers are often added to enhance stability. Both ionic, such as sodium dodecyl sulfate or sodium dodecyl benzene sulfonate, and nonionic surfactants are used to produce the emulsions. A typical polymer emulsion
formulation contains a water-soluble initiator such as potassium persulfate, an organic phase consisting of monomers dispersed in 1–20 micrometer droplets, and a surfactant that is above its critical micelle concentration. The surfactant causes a high concentration of monomer-swollen micelles to form in the aqueous phase. As the system is heated, the initiator decomposes to give aqueous phase radicals that propagate with small amounts of monomer dissolved in the aqueous phase. The newly forming radicals become hydrophobic very quickly and enter the micelles where they initiate polymerization of particles. Particle nucleation continues until all of the micelles either have been nucleated to form polymer particles or have been dispersed. As long as there are monomer droplets in the system, homogeneous nucleation can continue to take place. Once the micelles have been depleted, the polymer particles continue to grow by using monomer diffusing through the aqueous phase. Particle growth is continued until all of the monomers in the aqueous phase have been depleted.

One of the critical elements of emulsion polymerization is the formation of micelles which act as compartmentalized reaction chambers. This is how emulsion polymerization can produce reasonably small particles. Polymerization conducted in dispersed aqueous systems, such as suspension polymerization, produces relatively large polymer particles (20–1000 μm).

2.1.1. Soap-Free Emulsion Polymerization

In emulsion polymerization, surfactants play important roles such as maintaining the polymer particle stability, controlling the particle size, distribution, latex surface tension, and latex rheological properties. Clearly the choice and amount of surfactants significantly affect the polymer latex performance. For example, improper surfactant choice may lead to foaming, which in turn causes surface defects and decreased water resistance. Also the amount of the surfactants is the key factor to control new particle generation in the case of seeded polymerization. Unfortunately, surfactant molecules used in emulsion polymerization do not always stay tightly on the surface of particles but repetitively undergo desorption and absorption. These molecules are not easily removed from the final latex product and can often interfere with applications to systems that are not compatible with this type of latex contaminant. To overcome this type of problem, two techniques were developed, soap-free emulsion polymerization or the use of polymerizable surfactants [30, 31]. Soap-free emulsion polymerization can produce functional polymer particles in the submicrometer size range. Water is usually used as the continuous phase in soap-free polymerization. The polymer particles formed during soap-free emulsion polymerization retain their stability by electrorepulsive forces between ionic fragments on the particle surfaces or sequences.


2.1.2. Miniemulsion Polymerization

Miniemulsion polymerization shares many of the fundamental principles with emulsion polymerization, most importantly compartmentalization [19, 32, 33]. Miniemulsions are specially formulated heterophase systems where stable nanodroplets of one phase are dispersed in a second

Figure 1. Particle size range achieved for different synthetic polymerization techniques.

continuous phase (see Fig. 2). This system is created by using an appropriate combination of high shear treatment, surfactants, and the presence of an osmotic pressure agent that is insoluble in the continuous phase. Nanodroplet stability is obtained by adding an agent that dissolves in the dispersed phase but that is not soluble in the continuous phase. A simple example is a typical oil–water miniemulsion, where oil, a hydrophobic agent, an emulsifier, and water are homogenized by high shear to obtain homogenous and monodisperse droplets in the size range of 30 to 500 nm.

The generality and potential of the miniemulsion method lay in the fact that since each of the droplets is basically an individual batch reactor, a whole variety of polymerization reactions can be performed, thus significantly extending the profile of classical emulsion polymerization. Radical homopolymerization, copolymerization, catalytic chain transfer, controlled free radical polymerization, polyaddition reactions, metal catalyzed reaction, among others have all been utilized to produce polymer particles using the miniemulsion technique. Due to this large range of possible polymerization reactions and the nearly unlimited number of possible monomers that can be used for the formation of particles, a wide variety of polymeric particles have been produced using miniemulsion technology. Examples include numerous homopolymers, in particular polystyrene, poly(methyl methacrylate), poly(vinyl chloride), poly(acrylic acid), poly(n-methylol acrylamide), polyacrylonitrile, etc., polymer–polymer hybrids, encapsulated pigments, carbon black, and liquid, silica, and composite particles.

A useful list of characteristics for determining if a system represents a miniemulsion has been compiled by Antonietti and Landfester [19]. They discuss seven items that should be present.

(1) Dispersed miniemulsions in a steady state are stable against diffusional degradation but critically stabilized with respect to colloidal stability.
(2) The interfacial energy between the oil and water phase is significantly greater than zero and the surface coverage of the droplets by surfactant molecules is incomplete.

(3) The formation of a miniemulsion requires high mechanical agitation to reach a steady state.
(4) The stability of droplets against diffusional degradation originates from an osmotic pressure within the droplets that controls the solvent or monomer evaporation.
(5) Polymerization occurs by droplet nucleation only.
(6) The growth of droplets during polymerization can be suppressed.
(7) The amount of surfactant or inherent surface stabilizing groups required to form a polymerizable miniemulsion is small compared to other polymerizations.

2.1.3. Microemulsion Polymerization

Miniemulsions are defined by the mode of operation instead of a size range and are fairly easy to distinguish among most other heterophase polymerization methods. However, it can be confusing to find in the literature another method called microemulsion polymerization. Microemulsions are formed by mixing water, a hydrophobic compound, and suitable emulsifiers [20, 34, 35]. The medium is a multicomponent liquid that exhibits long-term stability, has low viscosity, and is optically transparent and isotropic. In microemulsions, the polymerization starts from a thermodynamically stable state that is spontaneously formed. This is generally achieved by using large amounts of specialized surfactants or mixtures that have an interfacial tension at the oil–water interface that is near zero. The microdroplets formed consist of a spherical organic core surrounded by a monomolecular shell of emulsifier molecules whose polar groups are in contact with the continuous aqueous phase. Initiation of polymerization is not simultaneously obtained in all of the microdroplets and therefore only some of the droplets contain the first polymer chains formed. These chains influence the stability of the microemulsion and can lead to an increase in the particle size and secondary nucleation. Latexes formed via microemulsions typically consist of relatively small polymer particles in the range of 5–50 nm but the particles are often mixed among numerous empty micelles. However, a variety of elaborate surfactants (mixtures of cationic and anionic salts) have been utilized to significantly alter the final polymer particle size, surfactant content, and distribution. The essential features of microemulsion polymerization are: (1) polymerization proceeds under nonstationary state conditions; (2) size and particle concentration increase throughout polymerization; (3) chain transfer to monomer/exit of transferred monomeric radical–radical reentry events are operative; and (4) molecular weight is independent of conversion and distribution of the resulting polymer broad. Microemulsion and inverse microemulsion polymerization have been used to produce a variety of polyacrylate latex particles, water-soluble nanoparticles, and conductive polymeric particles.

2.1.4. Inverse Emulsions

The advantage gained by emulsion stabilization is not restricted to only direct micro- and miniemulsions but can easily be extended to inverse emulsions [21, 36, 37]. Polymer

Figure 2. Fundamental principles involved in miniemulsion polymerizations.

spheres in the nanometer range, below 200 nm in diameter, can be produced through this standard technique that involves the use of an inverse emulsion—a clear mixture of water in oil also containing a surfactant. The water-in-oil inverse emulsion contains pools of water surrounded by oil molecules. These water droplets can be used as miniature nanoreactors to produce nanoparticles by adding the right amount of monomer into the solution. The chemical thermodynamics governing the emulsion drives the monomer molecules added into the solution directly into the water droplets. The polymerization reaction occurs inside the water droplets, triggered by the addition of an appropriate initiator substance into the system. The microscopic polymerization process inside the tiny water droplet is similar to macroscopic polymerization. One advantage at this stage of particle formation is that drug molecules can be taken up and effectively encapsulated. The nanoparticles formed assume the spherical shape of the water droplet with the size of the resulting nanoparticle being restricted by the diameter of the water droplet.

Applications of the inverse emulsion polymerization to micro- and miniemulsions are the most common. For miniemulsions, osmotic pressure is built up by an insoluble agent such as an ionic compound, in the continuous phase. The droplet size finds an equilibrium state which is characterized by a dynamic equilibrium rate between fusion and fission of the droplets and the droplet size seems to be only dependent on the quantity of the osmotic agent. There appears to be a zero effective droplet pressure that results from a balance between the osmotic pressure and the Laplace pressure. As such, inverse miniemulsions do not appear to be as critically stabilized as that for direct miniemulsions but instead are stable systems. Nevertheless, surfactants can be used in a relatively efficient manner for inverse miniemulsion polymerization, especially when compared to inverse microemulsion and inverse suspension polymerizations.

2.2. Suspension Polymerization

Another polymerization method that has many similarities to the emulsion methods is suspension polymerization [22, 38]. In this synthetic method a water-insoluble monomer is dispersed in the continuous phase as liquid droplets via vigorous stirring. An oil-soluble initiator is used to begin polymerization inside the monomer droplets. Droplets are kept from adhesion and coalescence by the presence of a small amount of stabilizer. Nearly all of the nucleation occurs in the droplets which act as isolated batch polymerization reactors. The larger droplet size causes the droplet pressures to be much smaller which leads to Ostwald ripening at a considerably slower rate than in miniemulsions. The final polymer particle size has been found to depend on the stirring speed, volume ratio of the monomer to water, concentration of the stabilizer, the viscosity of both phases, and the design of the reaction vessel. When a properly designed reactor and well-stabilized suspension is used, monodisperse polymer particles can be produced. The final product is generally limited to polymeric particles in the size range of 20–2000 μm. The main difference between

miniemulsion and suspension polymerization is that suspension polymerization utilizes much larger monomer droplets dispersed in the continuous phase.

2.3. Precipitation and Dispersion Polymerization

Dispersion polymerization can be considered an intermediate technique between homogenous and heterogenous polymerizations [24, 39–43]. All reagents are initially soluble in the medium and produce an insoluble polymer which precipitates out as the polymerization proceeds. By using soluble polymer stabilizers, polymer particles can be produced. The particle stability is primarily controlled by steric effects. A good example of successful dispersion polymerization is the preparation of polyphenol particles. In this work, peroxidase-catalyzed dispersion polymerization was performed by using a water-soluble polymer stabilizer in aqueous 1,4-dioxane and poly(vinyl methyl ether) in a 40% phosphate buffer solution as a steric stabilizer. This work produced relatively monodisperse particles in the submicrometer range. Similar particles of *m*- and *p*-cresols and *p*-phenylphenol have also been produced using the same type of synthetic procedure.

In precipitation polymerization, a polymer is generally precipitated out of solution by adding a nonsolvent of the polymer [25]. The primary polymer particles do not form into colloids but remain in a loose slurrylike form. This occurs since no stabilizer or block copolymer is added to the medium and therefore no steric barrier for particle stability is formed. Polymerization can occur in both the continuous and dispersed phase. Careful control of the kinetics can give polymer materials with a wide range of particle sizes (see Fig. 1). For example polymeric spherical particles with an average size of 160 nm have been prepared by precipitation of the particles which was facilitated by the increasing molecular weight of the polymer or from increased cross-linking.

2.4. Seeded Polymerization

Polymerization based on using a previously formed polymer particle or one that is created during the process but altered by swelling followed by chemical reactions is usually referred to as seeded polymerization. Seeded polymerization can be accomplished using many of the previously discussed synthesis techniques, in particular emulsion and dispersion polymerization [23, 34–42]. Synthesis based on seeded polymerization can be used to produce porous polymer particles as well as composite, core–shell, and hollow structures. The porosity of the particles produced by a seeded polymerization technique has been found to be dependent on the molecular weight of the seed polymer. As the molecular weight of the seed increases, the porous particles produced can become macroporous.

One drawback of seeded polymerization is that the final particle diameter is limited by the size of the initial polymer particle seed. Monodisperse submicrometer polymer particles are not easily obtained using seeded polymerization but particles from 1 to several hundreds of micrometers appear to be readily producible. For example, extremely uniform

polymeric particles have been successfully produced using the seeded polymerization techniques. In a rather elaborate study, a repeated seeded emulsion polymerization in a non-gravitational field was used to generate uniform polymeric microspheres up to 100 μm in size. Ugelstad et al. performed a two-step swelling technique and achieved similar results [42, 43]. This method is characterized by the use of an oligomer of extremely low solubility in water as an effective swelling agent. In order to produce larger particles, from 0.5 to 100 μm, which have applications in areas such as polymer coating emulsions that are resistant to shear thinning, Ito et al. used a seeded emulsion polymerization procedure [47]. Controlled coagulation induced by the formation of secondary polymers with opposite charge to the surface of the seed particles was achieved. They studied and characterized the effects of agitation rate, size of the polymer seed particles, and the pH or the reaction mixture.

A variety of seeded polymerization methods have been used to produce monodisperse micrometer-sized polymeric particles. Many of these studies were based on using a swelling stage during the overall process. For example, a dynamic selling method makes the seed polymer absorb a large amount of swelling monomers by treating the monomer soluble in the medium with slow, continuous, dropwise addition of water. Many of the conventional emulsion and dispersion seeded polymerization techniques use seed particles consisting of linear polymers for the initial swelling stage. This is due to difficulty associated with preparing micrometer-sized seed particles with a cross-linked network structure. Some success has been reported in using a two-stage swelling process of cross-linked seed particles. The effect of seed cross-linking on monomer swelling and final particle morphology reveals a strong dependence.

Core–shell composite polymer particles can also be efficiently produced using seeded polymerization. A seeded dispersion polymerization method was reported to yield micrometer-sized monodisperse polymethyl methacrylate (PMMA)/polystyrene (PS) composite particles consisting of a PMMA core and a PS shell. This study suggested that seeded dispersion polymerization, in which almost all monomers and initiators exist in the medium with seed particles having higher glass transition temperature than polymerization temperature, has an advantage for producing core–shell polymer particles. In particular, polymer layers tend to accumulate in their order of formation, even if the morphology is unstable thermodynamically.

2.5. Self-Assembly of Block and Ionic Polymers

Surfactant-free polymeric nanoparticles, something that is extremely difficult to achieve via most synthetic routes, can be produced by taking advantage of the self-assembly of block copolymers and ionomers in a selective solvent [26, 53–73]. Self-assembly of block copolymers can be successfully induced by a variety of methods including chemical reaction, polymer–polymer complexation, microphase inversion, temperature control, and a microwave method. Most of these techniques produce core–shell nanoparticles

but have the advantage that nanoparticles are surfactant-free. In addition, core–shell structures are often desirable for many uses in biomedicine (see later sections).

Poly(styrene-block-(2,-bis-[4-methoxyphenyl]oxycarbonyl) styrene) nanoparticles have been prepared via self-assembly by using temperature control. The particles are formed with a core–shell structure by using temperature and p-xylene as a solvent. The temperature-induced self-organization is achieved due to the solubility of the rod-shaped poly([4-methoxyphenyl]oxycarbonyl)styrene block in p-xylene (soluble above 100 °C). Temperature controlled self-organization was also used to produce nanoparticles of poly(N-isopropylacrylamide) (PNIPAM) grafted with short poly(ethylene oxide) chains. Both of these polymers are soluble in water at room temperature, but at higher than 32 °C, PNIPAM becomes hydrophobic and undergoes an intrachain coil-to-globule transition and an interchain aggregation to form nanoparticles. By controlling the formation conditions, interchain association can be completely suppressed and a single-chain core–shell nanoparticles are formed.

Core–shell poly(ethylene oxide-block-Є-caprolactone) (PEO-b-PCL) diblock copolymer nanoparticles that are stable in water have also been produced using a microphase inversion technique. In this work, tetrahydrofurane was used as the primary solvent which was suddenly replaced by a nonsolvent, water. This leads to the aggregation of the water insoluble polymeric block, PCL, and to the formation of a core, while the soluble block, PEO, formed a protective corona. Since these core–shell nanoparticles have been shown to be biodegradable in the presence of Lipase PS, they have important applicability to drug delivery.

Complexation between multiple polymer blocks has been used to generate stable core–shell nanoparticles. Polyacrylate and PMMA can be complexed with hydroxyl-containing polystyrene [PS–(OH)] in toluene to form insoluble particles. Successful implementation of this concept was achieved by using poly(styrene–block–methyl methacrylate) diblock copolymer complexed with hydroxyl containing polystyrene. Complexation of the PMMA block and the PS–(OH) led to an insoluble core, while the soluble PS blocks prevent macroscopic precipitation. The final product was stable nanoparticles whose particle size could be regulated by the initial concentrations of the two components and by the mixing order.

Microwave irradiation can also be used to facilitate the formation of polymeric nanoparticles. Stable polystyrene nanoparticles were formed by using microwave radiation in the presence of potassium persulfate in water. This method substantially reduces the reaction time (factor of 20) and produces narrowly distributed nanoparticles. Particle size can be controlled by varying the monomer-to-initiator weight ratio.

2.6. Polyanionic Solution-Based

Both continuous and batch processes have been developed which use a polyanionic solution that is atomized into a swirling polycationic solution to form polymeric nanoparticles [74–81]. This method of production is often referred to as titration since a sequential addition of one polymer into another is performed. By varying the ratios of

polyanion to polycation, a variety of nanoparticle compositions can be produced. One advantage of this method is that all solutions are made using water as a solvent which eliminates the possibility of having trace amounts of organic solvents of surfactants within the nanoparticles (a serious problem for medical applications).

The polyanionic method is intimately effective for generating core–shell nanoparticles. In a typical process, the anionic solution (droplet-forming) forms the core and the cationic solution (receiving solution) forms the corona or shell. This is the most common setup and is often referred to as the standardized system; however, there are examples of the reverse where a droplet-forming cationic solution is mixed with an anionic receiving solution.

A typical batch system is composed of a needle connected to a syringe that is inserted into an ultrasonic hollow titanium probe with a conical tip. The probe is connected to a transducer and power generator which is used for nebulizing the solution. An anionic polymer solution is introduced into the syringe and slowly extruded through the needle and the probe tip where it is atomized by the transducer. The atomized anionic mist is released into air above a container of the cationic solution which is vigorously swirled during the reaction (1–2 min). As mentioned previously the anionic solution is generally used as the droplet-forming internal phase mixture (core polymer) and the cationic solution is used as the receiving batch mixture (corona or shell polymer). A reverse system simply uses the same setup but introduces a cationic mixture into the syringe to form the mist that is received by an anionic solution.

The batch system described can be modified into a continuous system by using two inflow lines, one for the anionic solution and one for the cationic solution, and one overflow line to keep the receiving bath volume constant. This mode of operation produces nanoparticles of similar quality to the batch system.

2.7. Polyelectrolyte Complexes

Polymeric nanoparticles formed from macroscopic homogeneous colloidal systems can be prepared by aggregates of a high molar mass polyion species of weak charge density (called the host) with a much shorter lower mass macromolecular counterion (called guest) [82, 83]. Through continuous addition of the guest reactant, polymer nanoparticles form as colloidal particles that aggregated and precipitate. By altering the ratio of the host to guest, a variety of compositions can be produced. This technique is similar to the polyanionic solution based methods described previously and share similar advantages. In particular, multipolymeric water-soluble mixtures of two interacting pairs enable a template assembly of the nanoparticles. There is no use of organic solvents or surfactants and the process offers a high flexibility in choosing reacting pairs.

3. SUPERCRITICAL FLUID-BASED PARTICLE PRODUCTION

Supercritical fluids (SCFs) are substances that are above their critical temperature and critical pressure [84]. These substances often have densities and solvating capabilities similar to those of a typical liquid but have diffusivity and viscosity comparable to that of gases, making them ideal solvents. These unique properties provide great promise as a versatile, environmentally acceptable replacement for conventional solvents. Indeed SCFs have been used fairly extensively for extractions, in particular for coffee and tea decaffeination, natural product extraction, and chromatography. More recent applications of SCF technology have been in the area of processing such as mixing, impregnation, encapsulation, reaction, crystal growth, etc. [85–97]. The most used SCF has been carbon dioxide (CO_2). This is primarily because supercritical carbon dioxide (scCO_2) has an easily achievable critical point of 31.1 °C and 73.8 bars and is nontoxic, cheap, nonflammable, and environmentally acceptable and may be recycled.

The use of SCFs in polymer science has begun to witness an increase in popularity and a number of successful production techniques for polymeric particles have been reported [75–87]. Recently polymer-based nanoparticles have been produced by these alternative methods using supercritical fluid technology. Particles that have been produced using SCF technology tend to have characteristics that are strongly influenced by the properties of the solute, the type of SCF used, and the processing parameters (such as flow rate of solute and solvent phase, temperature and pressure of the SCF, pre-expansion temperature, nozzle geometry, and the use of coaxial nozzles). For example, polymer properties such as polymer concentration, crystallinity, glass transition temperature, and polymer composition are important factors that determine the final morphology of the particles. An increase in the polymer concentration can lead to the formation of less spherical and fiberlike particles. In an antisolvent process, the rate of diffusion of antisolvent gas is higher in a crystalline polymer compared to an amorphous polymer leading to high mass transfer rates in crystalline polymers that produces high supersaturation ratios and small particles with a narrow size distribution. Since SCFs act as plasticizers for polymers by lowering their glass transition temperatures (Tg), polymers with a low Tg tend to form particles that become sticky and aggregate together. A change in polymer chain length, chain number, chain composition, and branching ratio can alter polymer crystallinity and thus the particle morphology.

Core–shell particle structures can be produced by using an intimate mixture under pressure of the polymer material with a core material either before or after SCF solvation of the polymer, followed by an abrupt release of pressure which leads to solidification of the polymeric material around the core material. This technique has been successfully used to microencapsulate infectious Bursal Disease virus vaccine in a polycaprolactone or a poly(lactic-co-glycolic acid) matrix.

There have been a reasonable number of drug and polymeric microparticles prepared using SCFs as both solvents and antisolvents. Particles from 5 to 100 μm were the first to be produced using an array of solutes including lovastatin, polyhydroxy acids, and mevinolin. Further work in the past decade has lead to the simultaneous co-precipitation of two solutes, a drug, an excipient, and poly(lactic acid) (PLA) particles of lovastatin and naproxen. In these studies, supercritical CO_2 was passed through an extraction vessel containing a mixture of drug and polymer, and the CO_2

containing the drug and the polymer was then expanded through a capillary tube. In another process, PLA and clonidine were dissolved in methylene chloride, and the mixture was expanded by supercritical carbon dioxide to precipitate polymeric drug particles.

Similar to polymeric particles produced using SCF technology, the properties of the drugs such as solubility and partitioning of the drug into SCF determine the properties of the particles formed. For example, if the drug is soluble in a SCF under the operating conditions, it will then be extracted into the SCF and will not precipitate out. It has been observed that steroids with $\log P$ (the log of the partition coefficient) values between 1.6 to 3.9 formed spherical nonporous particles, whereas steroids with $\log P$ of 4.2 or 4.3 were extracted out into the SCF. The properties of the drugs also play an important role during encapsulation of a drug in a polymer matrix. There are strong influences of the properties of the drug on the drug loading. PLA-microparticle formation using an antisolvent process with supercritical CO_2 indicated that an increase in $\log P$ decreases the loading efficiency as well as release rate, possibly because lipophilic drugs can be entrained by supercritical CO_2 during SCF precipitation. Nucleation and growth rate influence the effective encapsulation and morphology of the particles. If the initial nucleation and growth rate of the drug is rapid and the polymer precipitation rate is relatively slow, then the drugs can form needles encapsulated in polymeric coat.

SCF technology is currently claimed to be useful in producing particles in the 5 to 2000 nm range. U.S. Patent 6, 177, 103 describes a process that rapidly expands a solution of the compound and phospholipid surface modifiers in a liquefied gas into an aqueous medium, which may contain the phospholipid. By expanding into an aqueous medium, particle agglomeration and growth are prevented, thereby producing particles of a narrow size distribution. An additional step may be required to remove the aqueous phase if the final product is a dry powder.

To achieve commercial success, the methods or techniques developed need to be scaled up to produce batch quantities for conducting further research or for marketing the product. The advances in the understanding of the mechanism of supercritical particle formation and SCF mass transfer are forming the basis for efficient scale-up of the laboratory-scale processes. While many laboratory investigators were only able to produce milligrams of the product, a scaled process that was capable of producing 200 g of biodegradable PLA particles in the size range of 6 to 50 μm has been developed. Cost of manufacturing at the pilot scale with SCF technology has been claimed to be comparable to several conventional techniques, such as single-stage spray drying, micronization, crystallization, and milling batch operations. Thus from the perspective of scale-up, SCF technology appears to offer some advantages. The processing equipment can be a single stage, totally enclosed process that is free of moving parts and constructed from high-grade stainless steel, allowing easy maintenance. It offers reduced solvent requirements and particle formation occurs in a light-, oxygen-, and possibly moisture-free atmosphere, minimizing these often confounding factors.

4. DROPLET AND AEROSOL TECHNIQUES

Many nonsynthetic methods for producing polymeric particles are based on nebulization or piezoelectric droplet generation of very dilute polymer solutions [98–111]. Over the last several years, advances in microdroplet production technology for work in single-molecule detection and spectroscopy in droplet streams has resulted in generation of droplets as small as 2–3 μm with a size dispersity of better than 1%. In the context of polymer particle generation, droplet techniques are attractive since particles of essentially arbitrary size (down to the single polymer molecule limit) can be produced by adjusting the size of the droplet of polymer solution, or the weight fraction of the polymer in solution. While droplet production in the size range of 20–30 μm (diameter) is more or less routine (several different on-demand droplet generators are now available commercially), generation of droplets smaller than 10 μm remains nontrivial especially under the added constraint of high monodispersity. Small droplets (<10 μm) are especially attractive as a means for producing multicomponent polymer-blend and polymer-composite particles from solution since solvent evaporation can be made to occur on a millisecond time scale, thus inhibiting phase separation in these systems. The primary condition for suppression of phase separation in these systems is that solvent evaporation must occur on a time scale that is faster than the self-organization times of the polymers. This implies time scales for particle drying on the order of a few milliseconds implying droplet sizes <10 μm (depending on solvent, droplet environment, etc.). It was shown recently that a microdroplet approach can be used to form homogeneous composites of co-dissolved bulk immiscible polymers using instrumentation developed in our laboratory for probing single fluorescent molecules in droplet streams. In addition to a new route to forming nanoscale polymer composites, a microparticle format offers a new tool for studying multicomponent polymer blend systems confined to femtoliter and attoliter volumes, where high surface area-to-volume ratios play a significant role in phase separation dynamics.

Several different choices exist for producing micrometer and submicrometer droplets of solution–each with certain trade-offs in terms of volume throughput, nominal size, and size dispersity. There are additional trade-offs associated with sampling and interrogation facility that should be considered as well. Two familiar methods of droplet production include electrospray generation and aerosol generation using a vibrating orifice coupled to a high-pressure liquid stream. In electrospray generation, a liquid stream is forced through a needle biased at approximately 1 kV (nom.). Charge carriers induced on the surface of the liquid stream eventually come close enough during solvent evaporation for Coulomb repulsion to occur (the Taylor cone), resulting in fragmentation, or explosion, of the liquid stream. This results in a cloud of charged liquid droplets whose size can be made quite small (<1 μm). The obvious drawback is that it is difficult to isolate individual particles for study, and size dispersity tends to be highly sensitive to experimental parameters. Another common method of

producing liquid droplets is the technique of vibrating orifice aerosol generation (VOAG). Invented by Berglund and Liu back in the 1970s, the VOAG is unmatched in terms of volume throughput (>100 nanoliters per second) and size dispersity (<0.1% depending on experimental conditions). This technique works by introducing a high-frequency (10 to 100 kHz) instability in a high-pressure liquid stream applied by a piezoelectric transducer (PZT). The resulting fragmentation of the stream produces highly monodisperse droplets that are ultimately limited by the purity of the radio frequency (rf) signal applied to the PZT. Some disadvantages of this mode of production are that the droplets travel at high speeds (several meters/second) and are quite close together (typically no more than 3 droplet diameters apart). This makes isolation and spectroscopic interrogation of individual droplets difficult. A more serious problem is in the significant particle size limitations associated with this technique. A VOAG works best at a size range of 30–50 μm but can function down to about 12–15 μm. Because of the way droplets are produced, however, there is a concomitant increase in the rf frequency that can be problematic.

The method we have chosen in our experiments is an "on-demand" or droplet ejection device. Like a VOAG, it also uses piezoelectric transduction but at much lower frequencies. The physics of droplet production is completely different for the two methods: The VOAG operates by generating a high (and fixed) frequency instability in a liquid stream; the on-demand droplet generator functions by the application of a acoustic wave to a static solution, which forces (ejects) a droplet out of a micrometer sized orifice. We use Pyrex or quartz tubing that is heated, drawn, cut, and polished to produce a tapered orifice that can range in size from 1 to 50 μm. The droplet sizes are comparable (usually slightly larger) to the orifice diameter and, depending on the quality of the orifice, size dispersity less than 1% can be achieved. Droplet production rates tend to be significantly lower than the aforementioned techniques. Ultimately, droplet rates are limited by piezoelectric relaxation times (10 kHz); practically, however, under conditions of high monodispersity, droplet rates are typically much lower (20–100 Hz). The advantages of this technique are small size and on-demand production that makes single droplet/particle manipulation and interrogation straightforward.

4.1. Tailoring the Properties of Polymer Particles

Composite polymer particles, or polymer alloys, with specifically tailored properties could find many novel uses in a number of fields. However, the problem of phase separation from bulk-immiscible components in solution often poses a significant barrier to producing many commercially and scientifically relevant homogeneous polymer blends [112–114]. The typical route taken in trying to form homogeneous blends of immiscible polymers is to use compatibilizers to reduce interfacial tension. A number of different groups have examined phase separation in copolymer systems to fabricate fascinating and intricate meso- and microphase separated structures with a rich variety of morphologies [115, 116].

Recently some interest has focused on trying to suppress phase separation in mixed polymer systems by very rapid solvent evaporation from small (≤10 μm diameter) droplets of dilute polymer solution. Using instrumentation developed for probing single fluorescent molecules in 1–10μm diameter droplet streams [117], detailed exploration of microdroplets to form homogeneous polymer composites without compatibilizers as a possible route to new materials with tunable properties has been accomplished [118]. From these studies it has been shown the primary condition for suppression of phase separation in such systems is that solvent evaporation must occur on a time scale that is fast compared to self-organization times of the polymers. This implies time scales for particle drying on the order of a few milliseconds which would require droplet sizes ≤10 μm (depending on solvent, droplet environment, etc.). In addition to this new route to forming nanoscale polymer particle composites, a microparticle format offers a new tool for studying multicomponent polymer blend systems confined to femtoliter and attoliter volumes where high surface area-to-volume ratios play a significant role in phase separation dynamics.

Figure 3a illustrates qualitatively the effect of phase separation on optical diffraction fringe contrast and definition for two polymer-blend particles prepared from different sized droplets of co-dissolved polymers (polyvinyl chloride and polystyrene) in tetrahydrofuran. The particle on the left is homogeneous as evidenced by uniform fringe intensity, and high-fringe contrast and definition. Moreover, the scattering data can be matched quantitatively to Mie theory calculations that assume a homogeneous and spherical particle. The particle on the left has no discernible fringe structure but does display interesting periodic "island" structure implying some order and uniformity of phase-separated domains.

(a)

(b)
Figure 3. (a) See [118, 119]. (b) See [119].

Figure 3b shows molecular dynamics simulations of a stable polymer-blend particle (10 nm diameter) composed of immiscible components. The leftmost particle remains homogeneous throughout a broad temperature range. For phase separation to occur (right), an enormous amount of thermal energy must be supplied in order to overcome the surface energy barrier. This result agrees qualitatively with the observation that homogeneous blends of bulk-immiscible polymers can be formed in spherical microparticles. The composite particle was calculated to have a *single* melting temperature of 190 K and glass transition temperature of 90 K which is different than either of the polymer components (*Tm* 218 K, *Tg* 111 K for light and *Tm* 162 K, *Tg* 81 K for dark). The segregated particle has two melting points and glass transition temperatures that correspond to within 10 K of the individual components. Formation of homogeneous polymer-blend composites from bulk-immiscible co-dissolved components using droplet techniques has two requirements. First, solvent evaporation must occur on a relatively short time scale compared to polymer translational diffusion. Second, the polymer mobility must be low enough so that, once the solvent has evaporated, the polymers cannot overcome the surface energy barrier and phase-separate. It was previously shown definitively the effects of droplet size and solvent evaporation, and the second requirement is almost always satisfied even for modest molecular weight polymers.

To explore effects of polymer mobility in detail, composite particles of poly(ethylene glychol) (PEG) oligomers (MW 200, 400, 1000, and 3400) with medium molecular weight (14 K) atactic poly(vinyl alcohol) (PVA) were produced [120]. This type of system allowed systematic examination of the phase separation behavior where one component (PEG) had substantially different viscosities (specified as 4.3, 7.3, and 90 cSt at room temperature, respectively).

Higher molecular weight PEG polymer-blend particles were shown to be homogeneous by utilizing bright-field microscopy, optical diffraction, and fluorescence imaging. Blend particles prepared with the 200 molecular weight PEG were observed to form sphere-within-a-sphere particles with a PVA central core. Figure 4 shows diffraction data acquired from particles at successive 10 min intervals from a 10 μm diameter PEG[200]/PVA[14 K] (80:20 w/w) particle. As shown in the first frame, the particle is initially homogeneous. The second and third frames indicate that the composite particle undergoes phase separation into an inhomogeneous particle as evidenced by the fringe distortion. Interestingly, the structure in the two-dimensional (2D) diffraction data for this system is much different than those observed for large phase-separated
PVC/PS particles that presumably coalesce into submicrometer spheroidal domains. On the basis of fluorescence and phase-contrast imaging data, PEG[200]/PVA[14 K] particles form spherically symmetric (sphere-within-a-sphere) heterogeneous structures, which should also produce well-defined diffraction fringes. The interpretation of these data was that diffusional motion of the PVA core in the PEG host particle, combined with rotational diffusion of the particle, breaks the spherical symmetry and thereby introduces distortion in the diffraction pattern. This observation is entirely consistent with our model of polymer-composite formation where heterogeneous particles may be formed provided that the mobility of one of the polymers is low enough to overcome the surface energy barrier. From the 20 min time scale for phase separation in the low molecular weight PEG system, we estimate a diffusion coefficient of 10^{-10} cm^2/s, which is consistent with recent molecular modeling results. For a diffusion coefficient, D, of 10^{-10} cm^2/s and 1200 s time scale, the average diffusion distance $r = (6Dt)^{1/2} = 8.5$ μm, which is comparable to the particle diameter. Composite particles formed from the higher molecular weight PEG (>1000) form homogeneous composite particles with PVA.

Another interesting aspect of this work comes from Mie analysis of the scattering data for homogeneous composite particles. Observations for several different polymer blend systems reveal that the material dielectric constant (manifested in both the real and imaginary parts of the refractive index) can be tuned by adjusting the relative weight fractions of the polymers in the mixture. Both Re(n) and Im(n) for the polymer-blend microparticles are intermediate between the values determined for pure single-component particles and can be controlled by adjusting the weight fractions of polymers. For both miscible and (bulk) immiscble polymers that have been combined in homogeneous microparticles, the measured refractive index was observed to be very close to estimates obtained from a simple mass-weighted average of the two species.

Although the microdroplet technique is well suited for producing nearly arbitrarily small particles (down to a single molecule limit), optical diffraction is obviously not suitable for probing particles smaller than a few hundred nanometers. To complement experimental effort on polymeric particles, investigation of various dynamical and steady-state properties of smaller polymer and polymer blend nanoparticles (1–10 nm diameter) has been examined using molecular dynamics tools. These traditionally reliable and accurate simulations allow development of considerable insight into the structure, and properties of polymer-blend particles, as well as aiding in interpretation of experimental results and guiding future experiments. Results have been reported from classical molecular dynamics techniques; polymer nanoparticles of varying size (up to 300,000 atoms), chain lengths (between 1 and 200 monomers), and intermolecular interaction energy have been examined which allows the systematic study of size-dependent physical properties and time dependence of segregation/equilibration of these particles [119]. Some of these studies are discussed in more detail in later sections of this chapter.

Figure 4. See [119].

5. GAS ATOMIZATION APPROACHES

The production of micro- and nanometer-sized polymer powders from molten polymers is an attractive, facile, low energy, and economic process. Polymer powders with tailored characteristics such as particle shape, size distribution, and purity can be directly prepared from the molten state of polymers such as polyethylene-based waxes that cannot be ground using conventional methods [121–126]. The gas atomization process (GAP) for mass-producing high quality spherical polymer powders involves using high pressure (approximately 7.6 MPa maximum) nitrogen gas and a specifically designed nozzle to atomize a molten stream of polymer into fine droplets that cool to form spherical powders. Powders with properties tailored to varying applications can be efficiently produced in short cycles by changing a few process control variables in a contamination-free environment, making the GAP a useful alternative to conventional grinding processes. These benefits of the process together with its flexibility, high throughput, and facile nature should make it highly attractive to industrial processes that must be capable of mass production and safe, environmentally benign operation.

The targeted applications of the powders include uses as powder spray coatings [1], formulating ingredients for functional coatings, and as raw materials for solid-state compacting of polymer alloys and composites [1, 127]. For these applications, the required properties of the powders include purity, uniform micrometer-sized particles with uniform size distribution, and spherical shape. These properties are essential for free-flowing powders with optimal surface area, leading to products with improved handling and performance capabilities.

Commercial organic polymer powders are produced by conventionally grinding extruded polymer pellets, often under cryogenic temperature conditions. Grinding is undesirable because it is expensive, highly energy-intensive, and susceptible to contamination from the grinding equipment and environmental pollution. Because of the erratic nature of the grinding process, it is almost impossible to control the quality and distribution of the powders and the size and shape of the particles.

The GAP method is an alternative route to mass producing polymer powders that eliminates most of the problems of conventional grinding operations. In addition, the simplicity and versatility of the GAP means that the equipment can be constructed from readily available construction materials such as steel (used in the crucible) and impact-resistant crystal-clear polycarbonate (used in the atomization chamber). The optical clarity of the latter allows direct real time visualization of the atomization of the molten polymer as it exits the crucible. This process involves heating the material in a crucible until the desired atomization temperature is reached. Once the material reaches this temperature, it is forced out of the crucible through a circular channel (the pour tube) into the atomization nozzle, where it is atomized into fine particles by the high pressure nitrogen gas. The particles cool as they fall through the atomization chamber, forming micrometer-sized powders that collect in a vented chamber. Additional details of the GAP process has been reported [121–126].

GAP feasibility studies and process development efforts focused on using commercial polyethylenes (e.g., Hoechst Celanese's PE130 and PE520) [128] as the model material because they are presently the largest volume commodity plastics used in the United States (over 9×10^9 kg are produced annually). The high consumption, low toxicity, low molecular weights (2000 to 10,000 g/mol), and low melting temperatures (approximately 200 °C) of the PE130 and PE520 make them ideal materials for atomization. Thus far, only the low molecular weight polyethylenes have been atomized into fine powders with changeable particle shapes and size distributions (0–250 μm). The studies conducted to date show that the quality and properties of the product powders depend on three key processing variables: (1) polymer melt temperature, (2) gas atomization pressure, and (3) melt stream size or pour tube diameter. Unlike particles produced by conventional grinding, the particles in gas-atomized powders are spherical with smooth surfaces and near uniform sizes. Other particle shapes—such as whiskers and elongated spheres—can be produced under specific processing conditions such as using low atomization pressures (approximately 2 MPa). Typically, the whiskers have diameters of about 100 nm and lengths of a few millimeters.

To expand the GAP method to produce powders from other polymers with tailored powdered characteristics for wide applications, computer simulations of the process are needed. As mentioned, potential applications of the product powders include use as formulation ingredients for functional coatings tailored to specific biochemical engineering application areas, such as personal hygiene and beauty care products, packaging, and other disposable and/or recyclable plastic products. Other applications include polymer dispersions or emulsions in environmentally friendly solvents, feedstock for solid-state compacting of polymer alloys, and powder spray coatings. As an example, the PE520 is designed for use in paints to increase matting effects and to mar resistance of the painted surface. Other advantages of using polymer powder additives in paints are improved sanding ability smoothness, and rheological properties; prevention of pigment settling and metal marking; and water repellence. Because of the flexibility, versatility, and economy offered by GAP, it should be attractive to polymer manufacturers, processors, and end-users.

Because the polymers (PE130 and PE520) can be atomized in a relatively narrow temperature range (190–220 °C), temperature control in GAP must be precise to avoid potential thermal degradation of the molten polymer prior to atomization. This can be achieved by heating the polymer in the crucible under a blanket of nitrogen gas using precisely controlled band heaters with thermocouples strategically placed in the melt. Obviously, polymers that show different rheological properties under conditions that they are likely to encounter during atomization can be expected to atomize differently. At low pressures (approximately 2 MPa), for example, the shear induced by the gas jets on the molten polymer at the instant of melt disintegration is not enough to completely overcome the internal elastic stresses present in the molten polymer. This leads to the formation of whiskers and elongated spheres rather than absolute spheres. For the polyethylenes studied thus far, it has been found that the formation of whiskers and elongated spheres can be

avoided by using high gas atomization pressures (approximately 7.6 MPa). It appears that a mixture of whiskers and spheres would be ideal for making self-reinforced polymer powders that can be used for applications requiring improved mechanical properties. Investigations on expanding the use of GAP to other polymers with vastly different thermal and rheological properties are needed.

More recently, 50/50 blends of PE130 and ultralow melting phosphate glass composition have been successfully atomized under conditions that were used to atomize the pure PE130 polymer. This result confirms the expectation of the broad application of GAP to many fields, such as producing polymer alloys, glass–polymer alloys, *in-situ* composites, and related products with tailored properties. These products could be used in many areas, such as for decorative or protective coatings, for polymer-supported heterogeneous catalysts, and in producing lightweight structural composites. The structural composites can be easily fabricated by applying established solid-state powder compaction methods to the gas-atomized composite powders to form compacts with varying shapes and sizes.

The research conducted thus far has provided valuable insight into GAP diagnostic control systems, dynamics, and mechanisms of powder formation. This knowledge can be used to expand the method to include the production of other kinds of materials with desirable properties for beneficial uses. The desirable properties of the powders include the following: purity, particle shape, particle size, and size distribution. The many initial problems of GAP when applied to polymers and composites are now understood and can be controlled and managed in order to produce powders with tailored characteristics. The technology of GAP has now advanced to a stage of finding more applications in the areas of polymer engineering and composite engineering and of scaling up to mass production of the fine polymer powders.

6. DENDRIMERS, HYPERBRANCHED POLYMERS, OR STAR POLYMERS

Dendrimers, hyperbranched polymers, or star polymers offer capabilities similar to polymeric nanoparticles since they generally form relatively small spherical materials, often with core–shell structures (generally a hollow core) [129–173]. As such it is important to recognize this new class of macromolecular materials in a chapter on polymeric nanoparticles. The interest in dendrimers and hyperbranched polymers has substantially increased since the pioneering work of Vogtel, Tomalia, and Newkome [132–136]. A broad range of dendrimers and hyperbranched polymers are now available and there has been enormous interest in their uses and applications. Many of these applications, such as the development of self-assemblies, electroactive and electroluminescent devices, sensors, molecular devices, catalysts, pharmaceuticals and biochemicals, analytical chemical applications, nanoscale building blocks, micelle mimics, and performance materials are synergistic with those of polymeric particles. This is due to the similarities in fundamental size and shape as well as compositions.

Dendrimers and hyperbranched polymers represent a novel class of structurally controlled macromolecules derived from a branch-upon-branch structural motif. Dendrimers are well defined, highly branched macromolecules that radiate from a central core and are synthesized through a stepwise, repetitive reaction sequence that guarantees complete shells for each generation, leading to polymers that are highly monodisperse. The synthetic procedures developed for dendrimer preparation permit nearly complete control over the critical molecular design parameters, such as size, shape, surface/interior chemistry, flexibility, and topology. These synthetic methods are more closely related to organic chemistry than to traditional polymer synthesis. There are basically two different synthetic strategies for the synthesis of dendrimers: a divergent and a convergent approach to construct dendridritc frameworks. Both methods use step-by-step synthesis (activation or protection of monomers, condensation reactions, purification) and require quantitative coupling reactions to construct high generation dendrimers. More recently, a number of methods have been developed that reduce the number of synthetic steps for producing dendrimers in high yields: a double-stage convergent growth approach; a hypercore monomer approach; double-exponential dendrimer growth; orthogonal coupling strategies.

Hyperbranched polymers offer an advantage over dendrimers in their ease of synthesis. On the other hand the degree of branching and the structure is less controllable than for dendrimers. The simplest branched material is a star polymer in which several linear polymer chains are attached to only one branching point. These polymers can contain chemically the same or different arms linked to a core. Star-block copolymers have also been made in which the arms consist of block or triblock copolymers. Various types of hyperbranched polymers, with multiple branching points, have been synthesized, including polyesters, poly(ether ketones), polyuretanes, polyamides, polycarbosilanes, etc.

Many properties of dendrimers have been found to differ from their linear polymer analogs. In general, dendrimers are more soluble in common solvents and less viscous compared to analogous linear polymers. The solubility depends predominantly on the properties of their surface groups which can to a large degree be controlled. Dendrimers with hydrophobic interiors such as polyethers and polycarbosilanes can be made water soluble by introducing hydrophilic groups into their surface groups. The opposite can also be achieved, that is, changing a water soluble dendrimer into an insoluble material by converting the hydrophilic surface groups into hydrophobic surface groups.

Another interesting and useful feature of dendrimers is the intrinsic viscosity in solution, and melt is lower than linear analogs. The main reason for this difference appears to be due to the lack of chain entanglements. Results have shown that intrinsic viscosity of a dendrimer does not obey the well known Mark–Houwink–Sakurada behavior. This has been associated to a transition from an extended structure for lower generation dendrimers to a globular shape at higher generations. Similar trends are also found for hyperbranched polymers, where the viscosity depends on the degree of branching: polymers having high branching

display behavior similar to dendrimers while those with low branching can have chain entanglements and behave more like linear polymers.

Other properties that differ are hydrodynamic volume which is larger for dendrimers, the degree of crystallinity (dendrimers are amorphous), and the glass transition temperature. The glass transition temperature has been found to be a function of the backbone depending on the structure, the number of end-groups, and the number of crosslinks or branching points. The glass transition temperature decreases with an increase in the number of end-groups but it increases with increasing number of branch points and the polarity of the end-groups. For hyperbranched polymers, the glass transition temperature appears to depend more on the chain length between the branching points. This means that systems with short chain lengths will have low glass transition temperatures even though the total molecular weight may be quite large.

The rich source of possible surface functionality for dendrimers makes them very attractive for nanometer building blocks and carrier molecules. They are also important in technologies such as coatings and inks where their unusual viscosity characteristics play an important role. Xerox has a number of patents which use dendrimers in ink and toner applications. Dendrimers have also found an increasing role as additives to commodity plastics where they improve the drying of plastic fibers.

7. MOLECULAR IMPRINT POLYMERS

With the increased interest in chemical and biosensors within the field of modern analytical chemistry as well as medical and environmental science, methods for generating materials suitable for these applications based on biomimics have been introduced. Systems with large surface areas populated by large numbers of reactive or binding sites are optimal. Polymeric particles offer such possibilities due to their inherent large surface area and the possibility of functionalization. Dendrimers, hyperbranched polymers, or star polymers also provide numerous advantages for this area of interest. Another possibility has come from using synthetic polymers as templates for imprinting an image of a molecule, a technique known as molecular imprinting (an antibody mimic) [174–191]. The final product generally consists of a bulk polymer which is then processed into a fine powder, the smaller the particles comprising the powder the better.

There are basically two distinct approaches to molecular imprinting. A prepolymerization complex between imprint molecule and functional monomers can be formed via noncovalent interactions or they can be covalently coupled. The covalent imprint method offers more homogeneous population of binding sites and a higher yield of binding sites relative to the amount of imprint molecule utilized. Noncovalent imprinting is somewhat more flexible when it comes to selecting the functional monomers, possible target molecules, and the use of the imprinted materials. Hybrid methods have also been suggested which attempt to combine the advantages of covalent and noncovalent molecular imprinting methods.

A common method for preparing molecular imprint polymers is by using solution polymerization followed by mechanical grinding of the polymeric solid to give small particles with diameters generally in the micrometer range. Particles can also be prepared directly in the form of spherical beads by using, for example, a two-phase system using perflurocarbons instead of water as the continuous phase. Polymeric particles synthesized in this way can also be made magnetic by inclusion of iron oxide particles. Another method for synthesizing molecular imprint polymer particles without requiring mechanical grinding is based on using dispersion polymerization. This method can generate aggregates of spherical particles and if the system is sufficiently dilute one can get reasonably controllable and uniform sized particles. Other methods have been reported where the polymeric particles that are imprinted are formed *in-situ*, inside a chromatography column or in a capillary.

8. SIMULATION AND MODELING OF POLYMER PARTICLES

Molecular modeling provides a way of visualizing processes at a submacromolecular level that also connects theory and experiment. Particularly attractive from a computational point of view is that many polymer particles are very close to the size scale where a complete atomistic model can be studied without using artificial constraints such as periodic boundary conditions. Yet these particles are often too small for traditional experimental structure/property determination. Polymeric particles in the micro- and nanometer size range show many new and interesting properties due to size reduction to the point where critical length scales of physical phenomena become comparable to or larger than the size of the structure itself. This size-scale mediation of the properties (mechanical, physical, electrical, etc.) opens a facile avenue for the production of materials with predesigned properties.

The primary computational tool used to date for the study of polymeric nanoparticles, in particular, their atomistic-based structure and dynamics, has been molecular-dynamics-based algorithms for generating and modeling polymer nanoparticles [192–208]. Some efforts using Monte Carlo techniques have also been pursued [209]. Structural and dynamical details of polymer processes at the atomic or molecular level have been studied and linked to experimentally accessible macroscopic properties of materials. A number of these studies will be discussed.

Since the smaller sized particles have more surface atoms than the larger ones (larger surface area to volume ratio), a decrease of the diameter increases the ratio. The large ratio of surface atoms to the total number of atoms leads to a reduction of the nonbonded interactions between the polymer chains on the surface layer; hence the cohesive energy is dramatically dependent on the size. In addition, the ratio of surface chain ends to total number of chain ends for the particles is much larger than that of the bulk system, leading to enrichment of chain ends at surface. This observation is consistent with analysis of thin films. With regard to an effect of the side chain atoms, the increase in these atoms corresponds to a decrease in the ratio of surface atoms and therefore represents an increase of cohesive energy of the system.

The increase in cohesive energy is due to the increase in the number of atoms that are inside the spherical particle versus on the surface. This phenomenon is a result of the finite sized spherical confinement of the particle and is different than what is observed in the corresponding bulk systems (side chains tend to lower the cohesive energy).

The large proportional surface area leads to large surface free energy, which is described by per unit of surface area (J/nm^2). The surface is irregular and has many cavities that may introduce unique (catalytic or interpenetrating) properties of polymer fine particles. The free volume (cavities) and molecular packing can be important in a diffusion rate of a small molecule trapped in the particles. It also suggests that nanoscale polymer particles are loosely packed and can show dynamical flexibility (e.g., compressive modulus of the particles is much smaller than that of the bulk system).

Simulations have also been performed on models for bulk polyethylene (PE). The radial distribution function for the simulated bulk PE, which provides information on the intra- and intermolecular structure, was in very good agreement with experimental data. Comparing a bulk system with the nanoscale spherical particles reveals the effects of conformational changes of the particles due to the size reduction and the shape. The most notable difference was in the amount of gauche conformations as signified by the magnitude of a peak at 3.2 Å. For the smaller particles this peak was almost entirely missing. The larger particles tended to have a somewhat higher concentration of gauche conformations but were still significantly less than the bulk. This reduction in the conformational disorder as the diameter of the particle decreases is a surface induced phenomenon. As the particle diameter decreases the surface area to volume ratio increases and the polymer chains are forced to lie mostly on the surface of the spherical particle. The surface tends to cause the polymer chains to form a pseudocrystalline layer; that is, the polymers fold in a nearly all-*trans* configuration.

Several simulations have been applied to study the morphology of single or multiple chains with different chain lengths and compositions. The surface chains of the polymer nanoparticles tend to straighten and align at temperatures below the melting point; the preferential morphology for the small polymer particle with a long chain length is a rodlike shape. This stretching of the chains leads to a reduction of the cohesive energy and an increase in volume. Studies on the effects of chain length show that the particles with the shortest chain length (see Fig. 5) have the most spherical shape.

For a transition from the amorphous (solid) to the melt phase (liquid) and a glass–rubber transition, the volume increases owing to conformational disorder of the polymer particles. Energy, temperature, and volume are calculated while annealing the system gradually by scaling the momenta with a constant scaling factor. Thermal analysis has provided a great deal of practical and important information about the molecular and material world relating to equations of state, critical points, and other thermodynamics quantities. Figure 6a shows the dependence of the melting point and glass transition temperature on the diameter of the particle. The dramatic reduction of the melting point for the polymer particles is an important example of surface effects and

Figure 5. See [206].

shows the importance of size. Since the large ratio of surface atoms to the total number leads to a significant reduction of the nonbonded interactions (lower cohesive energy), the melting point decreases with decreasing size. Figure 6b

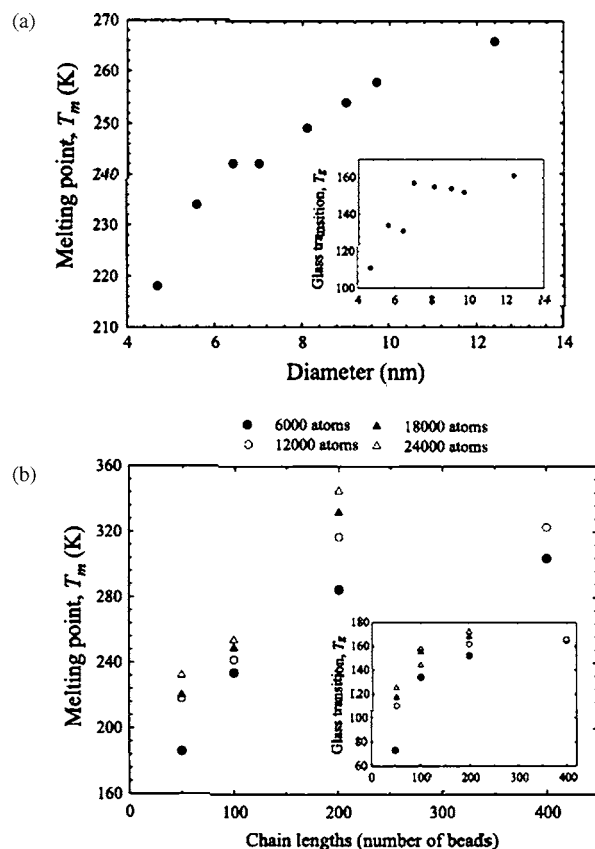


Figure 6. See [194].

shows the effect of chain length on these transition temperatures. A strong dependence of the melting point and the glass transition temperature on chain length is attributed to molecular weight and nonbonded energy of each chain.

From an atomistic thermodynamic analysis, the melting point of a polymer particle (6000 atoms) with chain lengths of 50 and 100 beads was found to be 186 and 232 K, respectively. The melting point was higher than the temperature at which the surface chains experienced a significant change in mobility. There appear to be two steps in the melting transition. The first step (mechanical melting) is at a temperature of 200 K and the second (thermodynamic melting) is 230 K. The first step is an early melting stage at which all chains in the particle start moving. The second step is the fusion stage of a solid. There is a plateau region between the first and second stages. The mobility of the chains in the outer layers increases rapidly after this region. In contrast, the chains in the core layer do not have the second step and increase linearly.

In the past, numerous calculations have been performed for the mechanical property of bulklike crystalline PE polymer using force field semiempirical, *ab initio* calculation, and *ab initio* molecular dynamics (MD) methods. The compressive (bulk) modulus for the amorphous polymer particles was calculated in order to get an idea of their stiffness and strength. The compressive modulus and yield point for the PE particles were investigated by applying an external force in MD simulations. It is known that values of the tensile modulus of bulk polyethylene are between 210 and 340 GPa and the compressive modulus is generally higher than the tensile modulus. In addition, the bulk and tensile strength or yield point are always much smaller than the modulus for a thermoplastic such as polyethylene. In a MD study of polymer nanoparticles, a compressive modulus was found to be several magnitudes of order smaller than the bulk values, and a yield point that was much larger than the modulus. The stress–strain curve actually looked more like a curve for an elastomer. However, the initial deformation caused by the compression (that which gives the modulus) is not reversible. What occurs during this phase is the deformation of a spherical particle to an oblate top. This structure is stable but it lies at a slightly higher energy than that for a spherical particle. Thus, the modulus for compression in this region is actually more a measure of the force required to deform the spherical polymer particle into an oblate top (pancakelike structure). Further deformation tends to be reversible up to the point of rupture. This deformation is actually more closely related to the bulk modulus since the stress is due to the cohesive energy and not a microstructure. This leads to a yield point that is significantly larger than the modulus.

9. APPLICATIONS OF POLYMER PARTICLES

Polymeric particles offer a number of unique properties that make their range of possible applications quite broad: small size and volume; large and specific surface area; high diffusibility and mobility; stable dispersions; uniform size, shape, morphology, surface chemistry; and the fact that they can be produced in various sizes, shapes, and compositions. To date many of the applications include examples from the biomedical, optical and optoelectrical, chemical, and rheological fluid fields. We briefly discuss some of these applications and provide extensive references for anyone interested in further details.

9.1. Biomedical Applications

Dramatic progress in biomedical engineering has recently led to the development of new macromolecular drugs which hold great promise for successful therapeutics. Medicinal uses of polymeric materials have been fairly broad and continue to grow. For example, biodegradable polymers have been used for sutures, artificial skin, and materials for covering wounds. Other medical and biochemical applications have included the use of polymer particles in absorbents, latex diagnostics, affinity bioseparators, and drug and enzyme carriers. In particular, the use of nanoparticles as drug delivery vehicles has enjoyed significant activity and research. Drugs or other biologically active molecules have been dissolved, entrapped, encapsulated, absorbed onto surfaces, and chemically attached to polymeric particles as a means for delivery [14–16, 210–239]. Controlled drug release formulations have been tried in various forms depending on the specific end use. Controlled drug release offers many advantages over other types of delivery including the ability to supply more constant drug levels, to enable more efficient utilization of the drug, and to locally deliver the agent to a confined area. In addition, decreased costs and frequency of administration add to the attractive features of these types of drug delivery systems. To date, polymer micro- and nanoparticles have been the most extensively utilized system for these purposes. When suitably encapsulated, a pharmaceutical can be delivered to the appropriate site, its concentration can be maintained at proper levels for long periods of time, and it can be prevented from undergoing premature degradation. Nanoparticles offer the advantage that they provide a better penetration into the body and are small enough that they can be injected into the circulatory system or delivered via the respiratory system or through traditional oral intake.

9.1.1. Drug Delivery

Modern pharmaceutical development makes extensive use of high-throughput screening, genomics, combinatorial chemistry, and other techniques. This has led to the synthesis of new chemical compounds that are bringing new challenges and opportunities to pharmaceutical development. One of the largest new set of drugs being developed is proteins and peptides, macromolecules which are often poorly permeable, poorly soluble, and unstable in physiological fluids and have unfavorable pharmacokinetics. These drugs generally need special care and require specific delivery systems. One of the most common degradation pathways is physical damage to proteins in the form of aggregation or precipitation. Unfortunately protein aggregates can form during the formulation process, long-term storage, or shipping and delivery. This can have dramatic impact on the final efficacy of the drug.

Currently some of the largest challenges, are in improving solubility, enhancing the chemical/enzymatic stability, reducing adsorption to containers, minimizing aggregation, assisting with refolding of proteins, and improving absorption. Presently, there are at least 75 protein or peptide-based products approved for marketing in the United States alone that can be used in the treatment of cancer, diabetes, multiple sclerosis, and growth deficiencies. With more than 100 other such drugs in human clinical trials, the market for protein-based drugs will continue to grow clearly defining the importance of designing appropriate drug delivery vehicles.

Polymeric nanoparticles offer promising technologies that overcome many of the problems presented for protein/peptide delivery and stability [14–16, 210–239]. Compared to other colloidal carriers, polymeric particles have a higher stability when in contact with biological fluids, and their polymeric nature (system of very large molecules) allows for the desired controlled and sustained drug release. Polymeric particles also represent drug delivery systems suitable for most of the administration routes (inhalation, oral, circulatory system), even if a rapid recognition by the immune system may limit their use as injectable carriers. Indeed there has already been some success in using polymeric-based particles for peptide drug delivery. The first microparticle extended-release formulation of a peptide to be approved by the U.S. Food and Drug Administration consists of poly(lactic-co-glycolic) acid microparticles that encapsulate the leuteinizing-hormone-releasing hormone agonist, leuprorelin acetate. This particular formulation is used for diseases such as endometriosis and prostate cancer. Another approved formulation used the same microparticle to encapsulate recombinant human growth hormone for the treatment of growth hormone disorders.

A substantial amount of research has focused on using polymeric nanoparticles, in particular PEG derivatives, for drug delivery. PEG is a simple, water-soluble, nontoxic polymer that is nonimmunogenic (the immune system does not recognize it and it is not metabolized) and has been approved in a number of products for human administration by mouth, injection, and topical application. PEG-based systems have been shown to entrap up to 45% by weight of a drug within the nanoparticle and to have extended circulation times due to decreased uptake by the mononuclear phagocyte system. A controlled release system that uses an injectable polymer vehicle has been employed by a number of researchers and has also been commercialized by Schering-Plough and Roche. The polymer protects the protein from rapid hydrolysis or degradation within the body thereby prolonging its action. Pioneering research on systems where PEG polymer chains were chemically attached to drug substances showed that by increasing their size there was an associated improvement in their delivery. When PEG is attached to a drug it can often extend the length of action in the body from minutes to hours or days depending on the molecular weight of the PEG molecules.

Further advances using PEG in conjunction with other polymers are already in development to improve injectable polymer systems. In one technique, a low-molecular-weight biodegradable polymer that is a viscous liquid at room temperature is prepared. This is then mixed with the therapeutic protein and injected. PLA-PEG and poly(orthoester) have been used in this system. Low-molecular-weight PLA-PEG has delivered bone morphogenetic protein (a bone growth factor used in the regeneration of bone tissue) into rats, with the polymer being degraded within three weeks and replaced by bone. Simply varying the viscosity of the polymer by changing either polymer concentration or polymer molecular weight may control the release of protein from this system. These polymers break down by hydrolysis, and further studies need to be undertaken to assess protein stability in this system and possible inflammatory responses in target tissues. In a second technique, a biodegradable polymer is dissolved in a physiologically acceptable solvent, suspending the protein particles, and this suspension is then injected into the tissue or patient. On entering the tissue, the solvent diffuses in the aqueous environment while the polymer precipitates out and entraps the protein particles. This injectable polymer depot has been explored using poly(lactic co-glycolic acid) with *N*-methyl pyrrolidone or glycofurol as the solvent. The rate of release may be adjusted by such parameters as the weight percentage of polymer in solution, the ratio of polylactide to polyglycolide, molecular weight, and protein loading. The release kinetics from this system was found to be favorable and there has been no reported loss in activity of human soluble tumor factor receptor.

Some other applications in the research sector of the drug delivery arena have included: the use of chitosan particles as a cancer chemotherapeutic carrier for adriamycin; chitosan particles used for oral substained delivery of nefedipin, ampicillin, and various steroids; ocular drug delivery via a suspension composed of hydrogels and particles which enhances the bioavailability of ocular drugs; a particle gel for extending precorneal residence time of ocular drugs; treatment of infiltrating brain tumors such as oligodendrogliomas by using IdUrd loaded poly(D,L-lactide-co-glycolide) particles and intracranial implantation via sterotactic injection; use of alginate-poly-L-lysine particles for possible treatments of insulin-dependent diabetes mellitus; polyalkycyanoacytate nanocapsules for the delivery of insulin and indomethacin; biodegradable particles for drug delivery based on 1,5-diozepan-2-one and D,L-diactide; glutamate and the tripeptide TRH-impregnated polyanhydride-based particles for stimulation of trigeminal motoneurons; a simple, cost effective, and scalable method that is based on albumin microparticles (biodegradable, nontoxic, and nonimmunogenic) for drug release (such as chlorothiazide); microcapsules of polyelectrolyte complexes for PH controlled release; chitosan/gelatin network polymer particles for controlled release of cimetidine; block copolymers of biodegradable poly(L-lactic acid) and poly(DL-lactide-co-glycolide) with poly(ethylene glycol) for controlled drug delivery and targeting; polymer-based gene delivery systems; drug deliver platforms based on synthetic polypetides; aliphatic polyanhydrides for drug carriers; biodegradable gelatin particles for treatment of kidney disease.

Clearly there has been intensive research into the use of polymer-based systems for controlled drug delivery and release [14–16, 210–239]. While there are currently only a

few clinically approved polymeric systems, the use of polymeric systems for oral extended release has a relatively large research base. Nano- and microparticle systems have been the most extensively used/studied formulations for controlled drug release and the field is primed for technology development for moving these bench studies into the clinical arena. Nanoparticle delivery systems have been demonstrated to provide a better penetration of the particles inside the body. Owing to their size, delivery via intravenous injection is possible and therefore they can be used for intramuscular or subcutaneous applications. In addition, the nanoscale of these systems also can minimize irritant reactions at the injection site. Nanoparticle systems also exhibit greater stability, in both longer shelf storage lives and uptake times. These synthetic systems are extremely versatile and can be designed to elicit the desired kinetics, uptake, and response from the body. Nanoparticulate drug deliver systems have even been recommended for the broad application of vaccination. Currently, immunization often requires multiple injections (MMR, hepatitis, tetanus, etc.) and there may be a high preponderance of people to put off or to miss these boosters, leading to limitations in the efficacy of the immunization. A more efficacious vaccine that would only require a single dosage or an oral controlled release system is highly desired and some success has been reported by using nanoparticulate drug delivery systems [16, 232].

In summary, extensive research has shown that polymeric particles offer enormous advantages to drug delivery systems due to: (1) there is the possibility to functionalize the particle; (2) the large size of the polymer molecule(s) making up the particle make it possible for them to remain at delivery site for longer time (protection against premature metabolism and reduced immungenicity); (3) drugs can be released slowly and/or in a controlled manner by (a) diffusion of a carrier polymer, (b) deposition of the carrier itself, (c) osmotic force, (d) swelling of the carrier/delivery system, and (e) chemical reaction; (4) multiple administration routes, such as inhalation, injection, or oral, are feasible.

9.1.2. Immunoassays

Since the first demonstration in 1979 that proteins could be transferred to microporous nitrocellulose membranes and detected using antibodies, development of rapid immunoassays using these high-surface-area materials has proliferated [16, 240–265]. Initially much investigation centered on understanding the interactions between proteins and polymers and the requirements for blocking nonspecific interactions on the membrane and on developing a series of detection methodologies and strategies. This work has led to a variety of immunoassay delivery systems for detecting a large menu of analytes.

The determination of antigens in biofluids is generally accomplished though heterogeneous immunoassays. The most common methods require the separation of the antigen–antibody complexes from the medium, followed by measurement of the quantity of antigen. One technique, called the sandwich method, uses an immobilized antibody and a labeled antibody. The carriers of the antibodies require large surface areas in order to allow the formation of the desired antigen–antibody complex. Polymer particles have been found to be very applicable in this regard

and plates with immobilized polyacrolein particles have been developed and used to covalently bind antibodies. In addition, polymer particle dispersions offer similar capabilities. Latex agglutination tests are the quickest, easiest methods among immunoassays. They can be sensitive, depending on the method of determination, and are comparable to other methods. Some of the first latex particles to be used were based on poly(styrene) derivatives. The ability of polystyrene to bind protein molecules without significantly changing the biochemical activities is the basis for most polymer particle immunoassays. Polystyrene can be used as the backbone of these particles and is crucial for the easy assimilation of these particles into most binding protocols. Other studies have used poly(hydroxyethyl methacrylate) and poly(glycidyl methacrylate) particles. Results have shown that in addition to the biospecific attractive force between the antigen and antibody, the electrostatic interactions between antibody–polymer particle and antigen–polymer particle have strong influence on agglutination rate. New latex designs consist of particles having a heterogeneous surface in a microdomain structure.

By doping magnetic materials, such as iron oxides, into polymer particles, the resulting particles retain some magnetic properties and can be used as solid supports for immunoassays in single use or automated assays. Automated assays using magnetic particles can quickly wash or separate the reaction components to reduce assay time or increase performance. Sorting of cells or cellular isolation has also been accomplished using these types of magnetic particles. Immunoglobulins targeting the desired material can be attached to the surface of the particles for directed isolation. A suspension of magnetic particles is mixed with a preparation of the target molecule or cell. Once the target has bound to the affinity group, a magnet is used to separate the target-bound particles from the solution. The unbound material can then be washed away from the particles. Depending on the application, the target molecules or cells can then, if needed, be detached from the magnetic particles. Some of the biomedical applications of these types of magnetic particles are: cell separation, mRNA separation, protein purification, immunoassays, afinity purification, ion exchange, PCR clean-up, solid-phase cDNA library construction, isolation of single or double stranded DNA, solid-phase DNA sequencing, hybridization procedures, charcoal trapping, sequence-specific magnetic particle probes, plasmid purification, and genomic DNA separation.

Biochemicals such as DNA, hormones, proteins, and ligands are also immobilized for diagnostics. DNA diagnosis uses DNA-carrying particles, composed of single stranded DNA, which subsequently binds to its complementary DNA or RNA. Research has shown some enhanced capabilities for 20-mer DNA on latex particles. These systems were capable of binding to complementary DNA faster than free DNA, presumably due to the restriction of dynamic motion of the chains (DNA attached to a particle is difficult to hybridize). The interactions between proteins, DNA, enzymes, antibodies, and substrates such as polymer particles have been an active area of research, driven by the desire for rapid and accurate diagnostics and for the development of ultrasensitive biosensors.

9.1.3. Polymeric Particles for In Vivo and In Vitro Analysis

Labeled polymer particles have been used to determine cardiac output and regional blood flow [266–284]. This has been achieved in mice by radioactively labeling the polymer particles and detecting the amount deposited by the blood into body tissues. Alternatives to this procedure that offer better safety included using polystyrene impregnated with dyes which could be measured with spectrometry, fluorescence labeling of the particles, and using air filled albumin particles that can be determined by ultrasound contrast. Some interesting trends on the effects of particle size on tissue distribution have been observed. Particles larger than 10 μm can be targeted to lung tissues and those smaller than a micrometer are typically engulfed by Kupffer cells in the liver.

A fascinating application of polymeric particles is their use in preoperative embolization. Such procedures can facilitate surgical removal of tumors by reducing their volume and vascularity as well as decreasing blood loss during surgery. Biodegradable particles composed of starch and poly(D,L) lactide have shown some success in emboluses. Other candidates come from thermosensitve polymers such as poly(N-isoproplyacrylamide) which precipitates out at certain temperatures and occludes capillary vessels.

Polymeric particles have also been utilized for the analysis of activity of phagocytes such as macrophages and leukocytes. These assessments were performed by using latex particles as inert invaders which the phagocytes would ultimately engulf. The latex particles were fluorescently labeled and were easily detectable inside of the phagocytes. The susceptibility of polymeric particles to phagocytosis is a crucial aspect to understand since drug delivery via these particles must reach its intended site. Research has mapped out a number of the influences of polymer particle size, composition, morphology, and surface chemistry.

9.2. Optical and Optoelectronic Applications

For many years, researchers in materials and photonics have been interested in the design and fabrication of structures that confine and manipulate electromagnetic fields on length scales comparable to optical wavelengths. The ultimate goal is an all-optical information processing and computation platform using photons in ways analogous to electrons in silicon devices on similar length scales. Specific focus areas such as wafer-scale integration, parallel processing, and frequency management (e.g., add-drop filters) on micro- or submicrometer length scales are active areas of photonics research. While a great deal of progress has been made in the burgeoning field of *microphotonics*, we are still a long way off from realizing important goals such as the optical transistor and all-optical integrated circuits [285].

One of the critical issues faced by researchers trying to engineer high-density photonic device and optical computing/information processing structures is the problem of "turning" the path of the photon. Waveguide structures work well as long as the path is straight; however, including turns with bend radii comparable to propagation wavelength is seriously problematic since the losses tend to be unacceptably high. Typically, minimum bend radii in such structures are on the order of several tens of micrometers (at least) to avoid scattering and retroreflection losses at the turn.

9.2.1. Photonic Molecules

A new strategy has recently emerged for confining and manipulating electromagnetic fields with precise frequency and spatial control. Based on coupled optical microcavities, these new photonic structures have been called photonic molecules (PMs) by virtue of the similarity between the field eigenmodes and electronic structure in real molecules [286]. In contrast with waveguides in photonic bandgap (PBG) crystals (fabricated by introducing line defects) where a broad range of frequencies are allowed to propagate within the band gap, PM structures permit transmission only at cavity resonance frequencies. Furthermore because the resonance Q's (energy storage factors) can be made quite high ($>10^4$), it is conceivable that these kinds of structures can function as amplifiers, switches, and add-drop filters.

A recent discovery that lends fascinating and interesting materials properties describes the use of a simple water-soluble polymer blend to generate a new kind of polymer microsphere-based structure which was called a photonic *polymer* [287]. In the course of screening different water-soluble polymer blends for high-density ordered microsphere array applications [288], it was discovered that particles made from polyethylene glycol ($\approx$10 k MW) and polyvinyl alcohol (14 k MW) in a 4:1 mass ratio had a tendency to stick together in clumps of two, three, or multiple particles. Under higher magnification, we observed that the "sticking" was in fact a partial merging of the particle surfaces shown in Figure 7. The particle binding was so robust that under high-precision particle focusing conditions, we were able to "stack" particles in nearly perfect columnar structures up to $\approx$20 particles high. Other types of two- and three-dimensional architectures were explored using an electric quadrupole and computer-controlled 2D translation stage for particle positioning.

One of the most surprising aspects of this work was the observation of sharp resonance features (distinct from "monomer" resonances) in fluorescence from dye doped
Figure 7. Electron micrograph of a photonic polymer structure made from merged polymer-blend microspheres [287]. There are about 30 individual spheres in the vertical chain that has folded near the top.

into the particles. Interestingly, the optical properties of merged-sphere systems were considered theoretically several years earlier by Videen and co-workers [289]. Resonance features in emission were also observed in transient merging-droplet experiments by Moon et al. [290]. What is surprising about the observation of shared optical resonances from merged spheres (especially with the large solid angle of intersection) is that a large segment of the dielectric boundary which confines the electromagnetic wave has been removed. Geometric optics calculations of long-lived trajectories in merged spheres show clearly that high-Q resonances are *not* supported for (plane) angles of intersection exceeding more than a few degrees. Calculations on bispheres of differing sizes have shown an interesting antinodal structure that includes an interaction between states with significantly different angular momenta, but with very low Q. Only in the special case where the contact angle is very small—similar to the physisorbed sphere case—are high-Q coupled resonances in the equatorial plane supported.

In the experimental case, typical plane angles of intersection can be more than 50 degrees; yet the structures clearly support high-Q resonances. Using a combination of three-dimensional ray optics and surface-of-section techniques [291], robust periodic trajectories that make a quasi-helical path around the particle chain axis have been demonstrated. These coupled resonances were highly robust with respect to overlap angle, deviations from collinearity, and size along the axis of the polymer structure.

9.2.2. Light Scattering Devices and Lenses

Light scattering by polymeric particles dispersed in different polymeric matrices can be used for the fabrication of a high efficiency back-light for liquid crystalline displays. Multimode scattering depends on the correlation length of the heterogeneous domains. The brightness of the back-light has been increased by a factor of 1.5 over conventional designs by using particles in a polymer film. Light diffusers, blinds, and shades can be developed if the polymer particles have a refractive index differing from the polymer matrix [292–294].

Lens effects have also been observed from polymer particles [292–294]. Amorphous polymer particles are generally transparent and the spherical texture can give a lens effect at the microscopic level. Polymer particles having a radial graded refractive index can be prepared by a dynamic seeded polymerization technique. These particles have a composition gradient decreasing toward the center of the particle which causes an increasing refractive index. Excellent light focusing properties have been observed. Other reports on lens effects of polymer particles have focused on using a close-packed structure of polystyrene microparticles on a glass slide. With this arrangement, standard optical microscopy was used to clearly view the insides of the particles.

9.2.3. Electroluminescent Devices

Organic electroluminescent devices based on polymer layers have attracted much attention because of low operating voltages, the ability to tune the color of the emitting light, and ease of fabrication. The phenomenon known as electroluminescence (EL) is caused by the emission of light generated from the recombination of electrons and holes electrically injected into a semiconductor. Traditionally most conventional and marketable electroluminescent devices have been inorganic semiconductors but developments dating back to the late 1990s have opened the door to a broad range of organic materials [295–306].

One of the most exciting developments in the field of conducting polymers occurred in the early 1990s with the discovery that conducting polymers such as poly(phenylene vinylene) (PPV) could be used as the emissive layer in light emitting diodes (LEDs). High-efficiency surface emission across the whole visible spectral range could be obtained relatively easily and researchers were able to achieve the emission of many different colors of light using these devices. The first polymer LEDs used PPV as the emitting layer [306]. Many different polymers have now been shown to emit light under the application of an electric field (EL). PPV and its derivatives are still the most commonly used materials, but *polythiophenes*, *polypyridines*, and *polyphenylenes* are now being tested for higher efficiency, longer lifetime, and lower power requirements.

Despite the extensive studies in this field, the quantum efficiency and brightness of polymeric LEDs still remain modest. In addition, one of the problems associated with such devices is that the lifetime of the cell is too short to use for many practical purposes, due to degradation of the cell caused by the gradual crystallization. Polymeric nanoparticles and nanoparticle composites may provide new possibilities for optimizing quantum efficiency and brightness as well as the LED lifetime [302]. Enhancement of current densities, radiances, and power efficiencies in polymer light emitting devices have been observed from using polymers mixed with oxide nanoparticles.

The semiconducting polymer PPV has attracted the most attention as an electroactive material. In general compounds with shorter conjugation lengths have a higher photoluminescence quantum yield. Precise control of the conjugated chain lengths could lead to very useful organic structures. Recently, research into semiconducting polymeric nanoparticles, in this case (poly[2-methoxy-5-(2′-ethyl-hexyloxy)-1,4-phenylene vinylene]) (MEH-PPV), has demonstrated the capability of possible control of the chain length and therefore the fluorescence emission spectra. This research is beginning to shed some light on the structural characteristics and luminescence properties which point toward many promising possibilities. An organic analog of inorganic quantum rods has been produced using droplet techniques and results indicate linearly polarized fluorescence with a narrow Gaussian-like emission spectra having a discrete distribution of center frequencies. The luminescence dynamics of these particles were found to be qualitatively similar to those of thin films but had a significantly higher photostability.

The luminescence properties of these newly discovered organic quantum rods might have important applications to biomedical imaging. For *in vitro* studies, a fluorescent microscope could be used to follow the time dependent activities of proteins, enzymes, or cells that have been tagged with organic quantum rods of different lengths. Rods that have different lengths are composed of polymer molecules that

include silicates, phosphates, flourides, humus, wool, proteins, cellulose, alumina, glass, and many others. The first industrial ion exchangers were inorganic aluminum silicates, used for softening water and treating sugar solutions. Later it was discovered that sulfonated coal was a relatively effective ion exchange material, but these types of materials are fragile and useful only under restricted operating conditions. Now nearly all ion exchange applications use synthetic polymer resins.

Ion exchange resins are polymers with electrically charged sites where ions may replace others [313]. These synthetic ion exchange resins are usually cast as porous beads with considerable external and pore surface where ions can attach. Absorption plays an important role whenever there is a large surface area and if a substance is adsorbed to an ion exchange resin, no ion is liberated.

Polystyrene-based ion exchange resins are the most common. These are generally insoluble spherical or irregular porous particles grafted with negatively (sulfonic or carboxylic) or positively (quarternary, tertiary, secondary, or primary amino) charged groups and the particles generally have excellent chemical, mechanical, and in most cases thermal stability. Typical applications of polymer particle-based ion exchange resins have included: water treatment, sugar refinement, preparation and purification of pharmaceuticals, catalysts, etc.

9.3.3. Calibration Standards and Chromatography

Polymer particles, in particular, polystyrene particles, which can be produced with quality size standards are often used for calibration of flow cytometers, particle and hematology analyzers, confocal laser scanning microscopes, and zeta-potential measuring instruments. In addition, monodisperse polymer particles provide advantages for support materials in high performance liquid chromatography [314–317]. By using precise sized polymer particles, uniform packing of the chromatographic columns can be achieved and allows operation under lower pressures with an associated high efficiency of separation capacity.

Another example of the advantage of using monodisperse polymer particles is in size exclusion chromatography. Size exclusion chromatography (SEC), is commonly used to obtain molecular weight distributions of polymers. Many biopolymers, including a large number of polysaccharides, have very large hydrodynamic sizes that may prevent an efficient use of SEC. By using macroporous, highly monodisperse polymer particles the range of molecular sizes accessible for aqueous SEC has been extended toward larger values.

9.4. Rheological Fluids

Viscosity control can be achieved by using particles whose volume changes with environmental conditions [318–333]. For example, the volume of carboxylated latex particles increases with increasing pH so that the viscosity of the dispersion increases [318]. Ethyl acrylate-methacacrylic acid copolymer latex is one of the most popular thickeners. Other variables used to influence viscosity have been temperature, poly(N-isopropylacrylamide) particles, and electric fields [318, 319].

9.4.1. Electrorhelogical Fluids

The use of electric fields to control viscosity of polymer particle-based fluids is known as electrorhelogical fluids [318]. These fluids are composed of particles from 1 to 100 μm in diameter that are suspended in a nonconducting liquid. The particles align themselves into structures along the direction of an applied electric field which dramatically changes its rheological properties. This is similar to a sol–gel transition but one that is controlled with an electric field. The extent of the alignment of polymeric particles has been found to depend mainly on the difference in dielectric constants of the liquid medium and the particle. Poly(methacrylic acid) particles in various media, paraffin oil, poly(dimethyl siloxane), chlorinated paraffin, and transformer oil, were also found to give increasing yield stress as a function of increasing particle diameter up to 900 nm. Applications of these fluids are expected to be mainly in the area of mechanical devices such as novel switches, actuators, clutches, etc.

9.4.2. Magnetorheological Fluids

Magnetorheological (MR) fluids are considerably less well known than electrorheological (ER) fluids. Both fluids are noncolloidal suspensions of polarizable particles having a size on the order of a few micrometers that respond to external MR or ER fields with a change in rheological behavior [318–333]. Typically, this change is manifested by the development of a yield stress that monotonically increases with applied field. Interest in magnetorheological fluids originates from their ability to provide simple, quiet, rapid-response interfaces between electronic controls and mechanical systems [318–333]. Many researchers believe magnetorheological fluids have the potential to radically change the way electromechanical devices are designed and operated.

The magnetorheological response of MR fluids results from the polarization induced in the suspended particles by application of an external field. The interaction between the resulting induced dipoles causes the particles to form columnar structures, parallel to the applied field. These chainlike structures restrict the motion of the fluid, thereby increasing the viscous characteristics of the suspension. The mechanical energy needed to yield these chainlike structures increases as the applied field increases resulting in a field dependent yield stress. In the absence of an applied field, MR fluids exhibit Newtonian-like behavior.

While the commercial success of ER fluids has remained relatively elusive, MR fluids have seen an increasing commercial success. A number of MR fluids and various MR fluid-based systems have been commercialized including an MR fluid brake for use in the exercise industry (stationary bikes), a controllable MR fluid damper for use in truck seat suspensions, and an MR fluid shock absorber for oval track automobile racing.

10. POLYMER PARTICLE PATENT REVIEW

There has been a relatively large number of patents on production methods and applications of polymer micro- and nanoparticles (on the order of 400 from 1996 to 2002).

A similar trend has been witnessed in the dendrimer and hyperbranched polymer area: approx. 433 patents issued during 1996–2000 on uses and production of dendrimers with an incredible growth rate giving a projection of well over 1000 patents before 2005. Such vibrant activity is clear evidence of the importance and applicability these materials to a broad range of fields. We provide a brief overview of some relevant patents in the area of polymer particles. The purpose is to give a brief overview of the various types of patent disclosures issued, not to discuss all of the various patents. Intricate details of the patents we discuss can best be obtained from the actual patent disclosures and supporting literature contained therein.

A continuous process for the preparation of inorganic and organic bead polymers using a static micromixer was disclosed by Eisenbeiss et al. [334]. According to this invention the bead polymers obtainable by the process have a very uniform particle size distribution, which can be set in a range of between 0.1 and 300 μm. The process is based on the mixing of liquid streams of suitable, usually immiscible component solutions in a micromixer, giving spherical particles in a continuous procedure with extremely improved volume yield, large particle yield with particle size range which can be set to a specific value, simplified temperature program, and reduced consumption of chemicals.

A composite paramagnetic particle and method for production was recently disclosed [335]. In one aspect of the invention, a particle comprised of a multitude of submicrometer polymer bead aggregates covalently cross-linked to each other to form larger diameter particles is presented. Distributed throughout the composite paramagnetic particle are vacuous cavities. Each submicrometer polymer bead has distributed throughout its interior and surface submicrometer magnetite crystals. In another aspect of the invention, composite particles are produced by using high energy ultrasound during polymerization of one or more vinyl monomers. In one embodiment, high energy ultrasound is used during an emulsification step and during the early stages of the polymerization process to produce micrometer sized composite paramagnetic particles. The particles according to the invention exhibit a high percent magnetite incorporation and water and organic solvent stability.

A method reported for the preparation of polymer particles includes: (a) forming an organic phase by dissolving a polymer material in a solvent; (b) dispersing the organic phase in an aqueous phase comprising a particulate stabilizer and homogenizing the resultant dispersion, thereby forming spherical particles having a selected particle and uniform particle size distribution; (c) following the homogenizing, adding a particle shape-modifying surface active material to the spherical particles; and (d) removing the solvent, thereby producing irregularly shaped polymer particles having mainly the same selected particle size and distribution as the spherical particles [336].

A process has been reported for the preparation of polyvinylarene polymer particles by suspension polymerization, where (a) vinylarene monomers are suspended in an aqueous medium to yield a suspension; (b) the temperature of the suspension is adjusted to a temperature above 50 °C, at which temperature an initiator is added; (c) subsequently, the reaction temperature is increased by 5 to 30 °C

per hour until a temperature of at least 120 °C is reached; and (d) the temperature is retained at least 120 °C until the polymerization is complete [337].

Wu describes polymer particles made from copolymers of multifunctional (meth)acrylate monomer and multifunctional aromatics [338]. He also described methods of improving the compression characteristics of (meth)acrylate polymer particles by copolymerizing with a multifunctional (meth)acrylate monomer a multifunctional aromatic monomer. The particles are of a size, are of a uniformity, and contain physical characteristics that make them ideally suitable for use as spacers in liquid crystal display devices.

Particles of a copolymer of a vinyl arene and a copolymerizable compound containing a polar moiety and a vinyl moiety containing water may be prepared by forming a mixture of monomers and small amounts of water and polymerizing under agitation to 20 to 70% conversion and then suspending the mass in water and finishing the polymerization. The resulting polymer beads contain finely dispersed water which is useful as an environmentally acceptable blowing agent [339].

An aqueous microemulsion polymerization procedure is described in which very small colloidal polymer particles are produced from tetrafluoroethylene monomer. The polymerization procedure involves adding a free radical initiator to a mixture of a microemulsion of at least one liquid saturated organic compound, and tetrafluoroalkyl ethylene [340].

A composition that includes a plurality of microcapsules each with one to five particles in a liquid droplet, and a complex coacervation induced shell encapsulating the liquid droplet and the one to five particles, has been reported [341]. There is also a composition comprised of a plurality of microcapsules each including a single particle in a liquid droplet, and a complex coacervation induced shell encapsulating the liquid droplet and the single particle. The authors also describe an encapsulation process [342] that includes (a) forming an emulsion composed of a continuous phase comprising a liquid, a cationic material, and an anionic material, and a disperse phase composed of a plurality of droplets of a second liquid, wherein a number of the droplets includes therein one to five particles; and (b) inducing complex coacervation of the cationic material and the anionic material.

A polymer packing material suitable for liquid chromatography and a method for producing it was described by Kimura et al. [343]. The polymer packing material was based on polymer particles with a styrene skeleton and had a monodispersed particle distribution that could be obtained by hydrophilic treatment of an inner surface of a micropore existing in a fine pore of the polymer packing material, or subsequent introduction of a hydrophobic group into the inner hydrophilic surface by chemical modification. A method for producing the polymer packing material suitable for liquid chromatography includes the step of polymerizing glycerol dimethacrylate as a cross-linking agent and 2-ethylhexl methacrylate as a monomer according to a two-step swelling polymerization process. Alternatively, the producing method includes the step of cross-linking and polymerizing only glycerol dimethacrylate to form a polymer and introducing the hydrophobic group into the polymer by

chemical modification to form a shell around each of the droplets [343].

An inorganic dispersant having a high specific surface area and a high surface activity which comprises a calcium phosphate type compound having a specific particle composition, particle shape, particle size and dispersibility, and specific surface area was recently disclosed. When used as a suspension polymerization stabilizer, it provides polymer particles having a uniform and sharp particle size distribution, and when the polymer particles are contained in an unsaturated polyester resin composition and a toner composition, the obtained compositions have excellent quality [344].

A seeded microemulsion polymerization procedure in which colloidal polymer particles are produced from tetrafluoroethylene or tetrafluoroethylene/comonomer or other polymerizable monomers was described by Wu. The particles have an average diameter between 1 to 100 nm. A microemulsion is formed of a liquid monomer in water and a gaseous monomer is added either before or after polymerization is initiated [345].

An efficient method was disclosed for obtaining polymer particles by evaporating an organic solvent while maintaining a solution of a polymer in the organic solvent in contact with polymer particles, using a simple apparatus and a simple procedure. The polymer particles (powder) produced by the method have a small particle diameter, a high bulk density, and a small amount of residual solvent. The method includes introducing the organic solvent solution of the polymer into a particle producing zone which does not substantially contain steam, wherein an atmosphere is maintained in which the organic solvent is vaporizable and the particles are stirred. The organic solvent is evaporated, while maintaining the solution in contact with the polymer particles [346].

A phase inversion process for preparing nanoparticles and microparticles has been reported. The process involves forming a mixture of a polymer and a solvent, wherein the solvent is present in a continuous phase, and introducing the mixture into an effective amount of a nonsolvent to cause the spontaneous formation of microparticles [347].

Microspheres have been prepared by providing a solution of the polymer and of the active principal in a water-immiscible solvent which is more volatile than water and mixing with an aqueous solution of the surface-active agent, followed by evaporation of the solvent [348]. Biocompatible microspheres containing one or more active principals, a biodegradable and biocompatible polymer and a surface-active agent which is also biodegradable and biocompatible, contain less than 10 ppm of heavy metals.

A method of making polymeric particles having a predetermined and controlled size and size distribution is described by M. Nair, Z. R. Pierce, and C. Sreekumar (U.S. Patent 4, 833, 060, 1989). This disclosure describes a process which comprises dissolving a polymer in a solvent immiscible in water to form a solution, forming a suspension of small droplets of said solution in water containing a promoter which is water soluble and silica particles having an average particle size of from 0.001 to 1 μm by high shear agitation. The promoter affects the hydrophilic/hydrophobic balance of the silica particles in the water suspension, removing the

solvent from the droplets and separating the solidified polymer particles from the water.

Otaigbe et al. [349] described a method for making polymer microparticles, such as spherical powder and whiskers (a whisker is defined here as a polymer microfiber of <100 μm in length and with a diameter of <10 μm). The method involves melting a polymer under conditions that avoid thermal degradation of the polymer, atomizing the melt in a special gas atomization nozzle assembly in a manner to form atomized droplets, and cooling the droplets to form polymer microparticles. The gas atomization parameters can be controlled to produce polymer microparticles with desired particle shape, size, and distribution.

Handyside and Morgan [350] used rotary, two-fluid, or ultrasonic wave melt atomization processes to prepare thermosetting polymer powder compositions suitable for powder coating processes. The thermosetting resin may consist of polyester or epoxy polymer containing a curing agent and one or more coloring agents. The melt-atomized powder is characterized by improved particle size distribution and by a generally rounded particle shape.

Noid et al. [351] used a new device called a microdroplets-on-demand generator (MODG) to produce polymer micro- and nanoparticles from solution. The proof of concept was demonstrated using poly(ethylene glycol) microparticles generated with the MODG and captured in a microparticle levitation device. The potential application of the MODG in materials science and technology was eluded to in the previous sections. There are several key advantages to this method for polymeric particle production: (1) It is relatively simple to produce particles of nearly any size and composition, including composites and novel blends. Many of these compositions are not obtainable by more conventional methods. (2) The technique lends itself to clean and efficient operation. There are no synthetic procedures requiring specialized knowledge or experience and there are generally no chemical by-products. (3) The technique is very controllable and arrays of particles or even intricate nanostructures can be quickly produced on any surface. (4) Encapsulation of chemicals, drugs, or other particles into a polymer particle is also relatively straightforward.

Aoki et al. [352] developed a method for making aqueous dispersions of ultrafine cross-linked diallyl phthalate polymer particles with average diameter 10–300 nm by polymerizing aqueous solutions containing up to 15% diallyl phthalates in the presence of 7–30% (on diallyl phthalate) water-soluble polymerization initiators without the presence of surfactants. The dispersions are useful as modifiers for rubbers and plastics. Organic monomers such as MMA or oligomers, optionally containing polymerization initiators, can be sublimed into reactors *in vacuo* in inert atmospheres and irradiated with ultraviolet (UV) light to give ultrafine PMMA particles (3000 to 5000 Å particle sizes) with good purity [353].

A method for manufacturing spherical and uniform-size polyolefin ultrafine particles is reported by Yamazaki and Takebe [354]. In this method, the ultrafine particles (approximately 1.5 μm particle size), useful for supports of absorbents, antiblocking agents, etc., are prepared by blending polyolefins in liquid organic compounds, melting the

blends, cooling to form spherical polyolefin particles, and removing the organic compounds by extraction.

In another method [355], electrically conductive polymer ultrafine particles (0.5 to 10 μm particle size) are prepared by mixing an organic solvent solution of a metal salt with another organic solvent solution of a thermoplastic polymer, cooling or pouring this mixed solution into water or a poor solvent of the thermoplastic polymer to separate the metal salt-containing thermoplastic polymer particles, and conducting the precipitation of metal from the metal salt by the difference of ionization or by the addition of a reducing agent. Powdered poly(tetrafluoroethylene) (PTFE) with a specific surface area of 2 to 4 m^2/g and a low pressure molding coefficient of 20–150 is ultrasonically ground to give powdered PTFE that has a specific surface area of 4 to 9 m^2/g and a low pressure molding coefficient of <20 [356]. The PTFE powders are useful for moldings having high density (e.g., 2.1872) and good surface smoothness.

Polymeric ultrafine particle-adsorbed structures with antistatic, low-friction, and abrasion-resistant properties were prepared by Akaishi et al. [357]. The structures are comprised of various substrates laminated with charged polymeric thin films on which charged polymer ultrafine particles, prepared by a macromonomer method, are adsorbed. The structures are manufactured by immersing charged polymeric thin-film-laminated substrates into a solution containing dispersed charged polymeric ultrafine particles prepared by the macromonomer method to adsorb the particles on the thin films. As an example of this invention by Akaishi et al. [357], a quartz oscillator microbalance as a substrate was alternately immersed 10 times into solutions of polyallylamine hydrochloride and Na styrenesulfonate homopolymer to form multilayer films having the homopolymer layer as the outermost layer. This was immersed in a solution containing dispersed N-vinylacetamide-grafted styrene polymer ultrafine particles in the presence of NaCl to give a polymeric particle-adsorbed structure in which the adsorption of particles depended on the concentration of NaCl. For a review of the macromonomer method for preparing polymer particles, the reader is referred to the classic, elegant review by Ito and Seigou [358, 359]. Printing inks and products made from them employ polymer and inorganic ultrafine particles. In one method, Yamada [360] mixed UV-curable resins with ultrafine Fe-based strong magnetic powders to give ink that could be printed on flexible films, fabrics, or paper to form electromagnetic shields. Polyester acrylate, epoxy acrylate, or urethane acrylate resins were used as the UV-curable binder and the ultrafine magnetic powder was mixed at 80–100 vol% (based on the binder resins) [360]. In a second method, Suwabe et al. [361] prepared aqueous inkjet inks, with good anticlogging ability and smudge prevention, by mixing aqueous dispersion of non-film-forming ultrafine inorganic or synthetic polymer particles (e.g., PMMA particles) with pigments and film-forming resin fine particles. In a third method, Uraki et al. [362, 363] prepared inkjet aqueous dispersion inks containing dispersed colored resin particles with an average diameter of 50–300 nm that were prepared by kneading organic pigments with water-soluble inorganic salts and water-soluble solvents in water and mixing with aqueous dispersions containing fine resin particles. The inks were easily

filtered through a 0.45-μm membrane to form ink showing good discharge ability and transparency.

Composite structures consisting of metallic nanoparticles coated with organic polymers or organic polymer blend nanoparticles have been reported [364–369]. Funaki et al. [364] prepared a metal–organic polymer composite (especially porous) structure composed of a microphase-separated structure from a block copolymer in which a metalphilic polymer chain and a metalphobic polymer chain are bonded together at each end, and ultrafine metal particles (<10 nm) were contained in the metalphilic polymer phase of the microphase-separated structure. Preferred polymers are a poly(2-vinylpyridine) and 2-vinylpyridineisoprene block copolymer. The composite structures just mentioned are useful as functional material (e.g., catalyst) in heterogeneous catalysis. Ehrat and Watriner [365] prepared thermoplastic polyolefin or olefin copolymer powders with average particle size of 80 to120 μm by grinding in an impact mill together with fillers, such as Al, Mg, and/or Ca hydroxides, carbonates, or oxides. The composite mixtures are useful as highly filled molding compositions for battery electrodes or as powder coatings. Tamura [366] developed anisotropic magnetic-permeable composites. The composite contains ultrafine particles of ferromagnetic Fe oxide that are smaller than single domain sizes dispersed in a solid organic polymer as oriented in the domain direction of the particles and substantially separated from each other. The composites are prepared by dispersing the particles in a monomer and polymerizing the monomer in a magnetic field. Far-infrared (IR) radiation-emitting bodies from polymer microparticles and inorganic compounds have been reported [367]. The bodies are prepared from polymer particles with ultrafine inorganic particles (e.g., Al$_2$O$_3$ or SiO$_2$) bonded to their surfaces. The bodies are useful for accelerating fermentation, preserving fresh food, and promoting plant growth. A typical method for producing the radiation-emitting bodies involves mixing an aqueous dispersion of PVC particles (2 μm) with AlCl$_3$ and NH$_4$OH to give polyvinylchloride (PVC) particles with adhering alumina hydrate particles (0.01 μm). The product can be extruded to give a film that is capable of far-IR radiation emission. The preparation of composite ultrafine organic polymer mixture particles has been reported by Kagawa [368]. The composite particles were prepared by dissolving two different organic polymers in a solvent with a boiling point higher than the melting point of the polymers and collision crushing with pressure to give particles with diameter <0.05 μm. The composite particles have good film-forming property (e.g., formed 5–10 μm film on Al foil that can be readily peeled off from the foil). Ultrafine polystyrene particles and their composites with other materials can be prepared by adding dropwise polystyrene (weight-average molecular weight 3,840,000) solution (approximately 0.0002% in C$_6$H$_6$) to the surface of H$_2$O and the solvent evaporated to give a thin layer of ultrafine particles which could be collected by moving barriers. The particles are cumulated on a chrome plate at a surface pressure of 1 to 50 dyne/cm^2 to give composite materials having area occupied with the particles ranging from 11 to 90%.

Hayashi et al. [370] and Suda et al. [371] developed low-temperature, glass coloring agents containing ultrafine

noble metal particle—polymer composite and ultrafine colored polymer particles, respectively. The former coloring agents contain a composite of ultrafine Au, Pt, Pd, Rh, or Ag particles dispersed in a polymer without coagulation, an organometallic compound for fixing the ultrafine particles in glass, a printing binder, glass powder, and an organic solvent [370]. The low-coloring temperature decreases strain in the colored glass and improves its cutting property. The ultrafine colored polymer particles developed by Suda et al. [371] are useful for electrostatic photographic image developing agents or cosmetics. The particles are prepared by mixing the pigments with COOH (or ester)-containing polyolefins and nonaqueous solvents and precipitating. Stirring the pigment-coated carbon black, Zn naphthenate, and saponified EVA polymer in organic solvents, evaporating, and precipitating resulted in particles with a median diameter of 1.564 μm.

Superparamagnetic composites have been developed by Tamura [372]. The superparamagnetic composite material consists of ultrafine particles of ferromagnetic Fe oxide smaller than sizes of single domain structures dispersed as substantially separated in an organic polymer and prepared by dispersing the particles in a monomer and polymerizing the monomer. An aqueous dispersion of the ultrafine particles is prepared by a chemical reaction, hydrophobic coating of the particles by adding a surfactant to the dispersion, separating the particles, and adding the mixture to the monomer. The resulting composite has an extremely low residual magnetization and coercive force [372].

Ultrafine polymer particles can be prepared from vinyl polymers [373, 374], polyisocyanates and acrylates [375], polystyrene [376], and polyacrylates [377–379] by graft copolymerization [373], spreading and curing [375], dispersion polymerization [376], and emulsion polymerization [374–379]. The resulting particles are useful for water-resistant coatings and films [373, 375, 377], adhesives [376, 378, 379], and freeze–thaw cycle resistant films [374]. Ultrafine particle polymer latex is obtained by emulsion polymerization using a redox-type polymerization initiator in the presence of a compound serving as polymerization inhibitor solution in the monomer [380]. Coagulation of rubber-modified polymer latexes has been reported by Kitayama et al. [381]. In [381], a 30% acrylonitrile-butadiene-Me methacrylate-styrene graft copolymer (melting temperature 90 °C) latex was coagulated with an aqueous solution of CaCl$_2$ (11 mmol/L) at a concentration of 12 mmol/L and 95 °C, separated, water washed, dewatered, and dried to form a powdered polymer without any particles. Ultrafine, particulate polymer latex based on unsaturated monomers with an average size <100 nm, a cross-linked structure, and glass transition temperature lower than that calculated by weight fraction method can be used to give a film excellent transparency, smoothness, tack, water resistance, and mechanical strength [382]. The polymer particle properties are dependent on the surfactant used. The latex is useful as a component in paints, adhesives, binder, additive for hydraulic inorganic material, fiber processing, reinforcement for optical glass fiber, electroconductive film, paper making, and photosensitive compositions [382]. Stable, aqueous colorants, useful in cosmetics, writing inks, and textiles, are prepared by encapsulating ultrafine, primary particles with

polymers which are not substantially altered in the process [383].

Artificial stone compositions for high-gloss products resistant to chemicals, water, and weathering can be prepared by mixing: (1) hydraulic inorganic material, (2) SiO^2-based by ash with an average particle size 1–20 μm, (3) water-dispersible ultrafine granular acrylic polymer with an average particle size 50–2000 nm, and (4) pigment [384]. The ultrafine granular acrylic polymer was prepared by emulsion polymerization.

Ultrafine particles can be dispersed in organic polymers to form composites that exhibit good transparency and stability, making the composites useful for selective wavelength-shielding optical filters and nonlinear optical materials [385, 386]. Yao and Hayashi [385] prepared ultrafine particle-dispersing polymer compositions from the reaction (which forms ultrafine particles) of metal compounds and chalcogenation agents in an organic solution of polymer bearing pyrrolidone groups and stabilizer, followed by removal of the solvent. A typical preparation of the ultrafine particle-dispersing polymer compositions consists of injecting 0.5 ml H$_2$S (g) into a tube containing 3.08 mg Cd(NO$_3$)$\cdot$2.4H$_2$O and 0.01 g polyvinylpyrrolidone in 5 ml MeOH. Displacing the H$_2$S with nitrogen gave a product containing dispersed CdS with size 60 Å, which showed absorbency at 510 nm. In another patent, Yao and Hayashi [386] reported cuprous halide-dispersed polymer compositions and manufacture of polymer compositions dispersed with ultrafine cuprous halide powders to give a transparent film containing ultrafine CuBr particles with average diameter of 8.5 nm.

Giannelis et al. [387] have published a comprehensive review covering recent references on polymer–silicate nanocomposites. Recently, considerable attention has been paid to this type of nanocomposite to afford model systems to study confined polymers or polymer brushes and because of various applications in technical and biomedical fields.

11. CONCLUSIONS

In this chapter, we have reviewed recent progress and discussed new insights into generating, characterizing, and modeling polymer micro- and nanoparticles. A wide range of electronic, optical, physical, chemical, and mechanical properties of single and multicomponent polymer particles have been used to fulfill needs for a broad spectrum of applications. Even with the large amount of work done in the past and currently occurring, there still remains tremendous potential in the future development of multicomponent polymer particles with tailored properties and particles for controlled release and delivery of pharmaceuticals.

One exciting area is in the observation that polymer particle structures suggest the capability of manipulation of optical waves in a wide variety of 2D and 3D photonic wire structures that can be tailored to a particular application. We anticipate a number of interesting applications of these type of structures including 3D conductive vertical wires/supports and sensor technologies. By tuning the particle intersection (via adjustment of polymer blend composition), one can turn on (or off) coupling between orthogonal particle chain segments where the bend radius is close to the particle radius

(e.g., 1 to 4 μm). Losses should be comparable to single (linear) chain coupling which has already been shown to be low. From a purely scientific point of view, photonic molecules represent a new field of study that incorporates a variety of disciplines including materials science, optics, and electronic structure. A number of challenges remain, however. Most polymeric materials are strongly absorbing at near infrared (i.e., telecommunications) frequencies so it remains a nontrivial task to find polymer-blend systems that are transmissive in this important frequency range but also retain the material properties similar to the PEG:PVA blend used in the studies summarized here. Further challenges include engineering an optical (or electronic) interface to the photonic molecule or polymer structure with specific frequency input–output requirements. This new class of structures may ultimately complement photonic bandgap crystal technology and add a new component to the toolbox for microphotonics.

Another developing and extremely important area that can benefit enormously from polymeric particle technology is that of drug delivery. More than 80% of all drugs are currently delivered in a powder format. Although tablets and capsules clearly play key roles in drug delivery, they can often be quite unsuitable for effective processing and delivery of macromolecules, especially proteins, peptides, monoclonal antibodies, antisense drugs, interleukins, cytokines, enzymes, and gene medicines. Preparation of fine powders of these types of macromolecules presents a significant problem to drug manufacturers since formation directly by precipitation from solution can cause numerous difficulties in filtering and drying the minute particles. Currently processors harvest larger particles from crystallizers and then dry and mill them to the desired size. This frequently damages the structure and surface of the drug and can also generate highly charged particles that stick to each other, making further processing very difficult. These types of difficulties in using conventional manufacturing processes to prepare fine particles with specific, preferred characteristics could also significantly constrain the design of new, promising drug delivery systems. Use of polymeric particles and the associated production technology can offer solutions to many of these current difficulties. In addition, the unique capabilities of nanoparticle delivery systems to protect drugs from degradation, prolong their residence time, withstand heat sterilization, have better storage life, remain stable in harsh conditions, and provide controlled release make this technology very attractive. It is clear that micro- and nanoparticulate systems have the potential to have a revolutionary impact on drug delivery and several other areas in the biomedical field. Already proof-of-concept studies have yielded some very encouraging results but further improvements are needed in order to employ a larger range of the available therapeutic macromolecules (gene therapy agents and sensitive proteins).

Other biomedical applications that may depend/benefit on new advances in polymer particle technology are medical imaging, bioassays, and biosensors. The incorporation of functional nanoparticles can be highly advantageous for the performance of numerous bioassays. The tremendous increase in surface area offers the ultimate ability for binding to target molecules such as proteins and enzymes. These same particles offer complementary advantages for the production of highly sensitive biosensors. In addition, polymer particles can be produced out of conjugated molecules that fluoresce. With future advances in the functionalization of these so-called organic quantum rods, noninvasive biomedical imaging could be substantially improved.

Finally, in the ultimate search for new and improved materials, polymeric particles offer the unique possibility of producing new alloys of polymers that do not typically mix. This capability opens the door to a nearly unlimited number of polymer blend and composite molecular systems of which the properties and dynamic behavior remain to be explored.

GLOSSARY

Biomedical engineering An integration of physical, chemical, mathematical, and computational sciences and engineering principles to study biology, medicine, behavior and health.

Catalysis A substance that increases the rate of a chemical reaction without being consumed.

Colloidal dispersion A system in which particles (solid, liquid, or gas) of colloidal size are dispersed in a *continuous phase* of a different composition or state.

Drug delivery The method and route used for administration of medicinal therapeutics.

Electroluminescence The nonthermal conversion of electrical energy into light in a liquid or solid substance.

Emulsion A system in which liquid droplets and/or liquid crystals are dispersed in a liquid.

Fluorescence The emission of light or other electromagnetic radiation of longer wavelengths by a substance as a result of the absorption of some other radiation of shorter wavelength. Fluorescent emission continues only as long as the stimulus producing it is maintained.

Immunoassay A process that measures and identifies a specific biological substance such as an antigen.

Latex An emulsion or sol in which each colloidal particle contains a number of macromolecules.

Molecular modeling Computational methods used to simulate and model simple and complex systems.

Nanoparticle A particle that has size dimensions on the nanometer scale.

Optoelectronic Any device that functions as an electrical-to-optical or optical-to-electrical transducer.

Photonics The technology of generating and harnessing light and other forms of radiant energy whose quantum unit is the photon.

Polyelectrolytes A polymeric substance which, on dissolving in an ionizing solvent, dissociates to give *polyions* together with an equivalent amount of ions of small charge and opposite sign.

Polymer Long-chain molecules of high molecular weight consisting of many repeating monomer units.

Polymerization A synthetic technique for producing polymers.

Semiconducting polymers   Polymers that are semiconductors (typically having conductivities in the range of 10^{-7} to 10^{-3} S/cm).

Suspension   A system in which solid particles are dispersed in a liquid.

Supercritical fluid   Substances that are above their critical temperature and pressure.
