Near-Field Optical Properties of Nanostructures

Nicolas Richard

Thomson Tubes and Displays, Genlis, France

CONTENTS

1. INTRODUCTION

During these last years, scanning near-field optical microscopy (SNOM) has become an extremely powerful technique for the analysis of surface structures with a resolution far beyond the diffraction limit [1, 2]. The role of the incident polarization associated with the incoming light is important for the understanding of optical images under the condition of total internal reflection in the near-field optics using a photon scanning tunneling microscope (so-called PSTM or STOM) [3–8] or under the illumination in normal incidence (SNOM configuration) [9]. These techniques tend to elucidate the optical properties of mesoscopic and nanoscopic particles in the near-field.

The mesoscopic regime corresponds to optical properties of the system where the size of the objects is of the order of the incident wavelength. For the visible range, it means that the object has a lateral size between 100 nm and 1000 nm. The nanoscopic regime corresponds to structures smaller than 100 nm. On the other hand, when the size of the object is much greater compared to the incident wavelength, one usually speaks of the macroscopic regime. Geometrical optics and Kirchhoff diffraction can be treated on a macroscopic scale.

Near-field optics deals with behaviors occurring with evanescent electromagnetic waves which become important when the size of the object is of the order or lower compared to the incident wavelength. The actual theory well describes the interaction between objects and light in the microscopic or in the macroscopic regimes. A numerical approach based on Maxwell equations is needed to know the optical response of such systems in the mesoscopic range.

Many approaches were realized to model optical microscopy in the near-field optics for objects deposited on perfectly flat and rough surfaces [10–12]. Different experimental devices were used for the study of near-field optical microscopy according to the properties in transmission [13]. To understand the optical properties of mesoscopic and nanoscopic objects, many studies were performed on periodic structures in the near-field optics [14]. Main problems come from the understanding of tip detection for the electromagnetic field at a given distance from the surface and many theroretical models try to understand the basic properties of an optical microscope [15].

Optical contrasts produced by nanoscopic or mesoscopic dielectric objects according to the incident polarization associated with the incoming light for nanoscopic or mesoscopic dielectric objects are presented. First, we will describe the notion of depolarization for nanoscopic objects in the near-field optics and the impact of the object size and of the wavelength in the optical images. Second, the impact of the polarization in the near-field optics will be discussed showing optical images under several conditions of illumination and detection.

The incident polarization is chosen rectilinear under the condition of total internal reflection and in the air [16]. Circular polarization is also chosen to see the optical behaviors in normal incidence [17]. These two configurations will show effects related to the impact of the incident polarization on the optical response of the dielectric object in the near-field optics.

In both configurations (PSTM and SNOM), the probe is the main tool for the detection of the electromagnetic field or the illumination of the sample at the nanometer scale. In near-field optical microscopy, the local detection of the optical signal relies on the use of nanometer-sized probes. In the SNOM configuration, the probe acts as a local source

of evanescent optical fields whereas in the PSTM setup, the probe behaves as a local detector of light. In these devices, SNOM and PSTM tips are usually coated with a thin metal layer in order to achieve a narrow localization of the incident light on the sample (SNOM configuration) or to improve the resolution in detection for the PSTM configuration. However, Al-coated tips showed limited improvement due to the degradation of the signal-to-noise ratio related to the very low transmission through such coating in the PSTM configuration.

The scattering effects are the main problems which occur strongly in the near-field optics because these waves damage the resolution of the optical images. Scattering of the electromagnetic waves by a sphere (Mie theory) and an ellipsoid has been extensively studied in both microscopic and mesoscopic regimes [18–23]. This problem has a known solution in an analytical way. More complicated shapes involving objects with sharp edges could not be solved analytically. Far-field expressions were detailed to understand the scattering cross-section behaviors but analytical near-field expressions could not be given in the same way. Mainly, backward and forward scattering were found in the different scattering diagrams according to the size of the sphere and to the refractive index of the material.

In order to eliminate the scattering behaviors which occur in the near-field optics, polarization studies are thus necessary to understand the scattered field behaviors in the analysis of near-field optical images. This outlines effects relative to the confinement of the electric field near the objects. Main problems are involved in the diffraction pattern of the forward and backward waves scattered by the objects. The study of the different components will reject this problem and only the objects' response is taken into account.

1.1. Green's Dyadic Technique

The calculations are based on the Green's dyadic technique using Lippmann–Schwinger and Dyson equations for all numerical computations [24, 25]. This method is proven to be an efficient computation technique for the typical parameters of near-field optics (size of the object, height of detection, wavelength, dielectric permittivity of materials). This numerical method is reliable to solve the Maxwell equations and it is based on the knowledge of the Green's dyadic associated with a reference system which is a flat surface or vacuum in our case. The procedure considers any object deposited on the surface or placed in the air as a perturbation discretized in direct space. The electric field is determined self-consistently inside the perturbations; a renormalization associated with the depolarization effect is taken into account for the self-interaction of each discretization cell. The Huygens–Fresnel principle uses the values of the field inside the perturbations to compute the electric field or the optical magnetic field elsewhere [26].

This method for the calculation of both optical electric and magnetic fields can treat any kind of nanoscopic and mesoscopic objects in the near-field optics. The shape and the dielectric constant of the particles can be arbitrarily taken. Moreover, this numerical technique can treat anisotropic objects in near-field and in far-field optics [27]. As the discretization is performed in direct space, this method can be thus extended to experimental samples using the topography of the surface, that is, any input geometry of the computations according to a given AFM (atomic force microscopy) data file recorded on the sample. This capability gives the opportunity to better understand the experimental images in the near-field optics.

1.2. Optical Initial Conditions in the Near-Field

We choose glass for the use of a dielectric material and we consider that the index of refraction of the glass, fixed to 1.5, does not depend on the incident wavelength. Other materials used for the optical properties in different wavelength ranges could be taken into account but the main physical principles are explained in the following sections. In the case of other materials, spectroscopic behaviors are important for the understanding of the near-field optical images in order to take into account resonance behaviors according to the optical response of a given structure [28–30].

Here, we will detail the case of dielectric particles deposited on a dielectric glass substrate or illuminated in the air. For the first case, the objects are bidimensional structures which are illuminated in the air. In the second case, these ones are tridimensional and illuminated under the condition of total internal reflection as in the PSTM configuration beyond the glass–air critical angle. For the circular polarization, the objects lying on a dielectric surface will be illuminated in normal incidence. We show numerical simulations which take account of the analysis for the intensity associated with the total electric field and with the optical magnetic field scattered by nanoscopic objects in transmission at constant height in the total internal reflection configuration.

In the case of a surface separating two dielectric media (glass–air interface), two modes of polarization are associated with the incoming light: TE and TM modes. The z-direction being perpendicular to the glass–air interface, as we chose the incident light to be linearly polarized, the TE mode (s polarization) corresponds to an incident electric field perpendicular to the plane of incidence (y-z plane). The TM mode (p polarization) corresponds to a field parallel to the plane of incidence. In the case of bidimensional objects, the direction of the incident light is perpendicular to the infinite z-direction of the structure. In both cases, the detection is performed in the x-y plane at a constant height in the case of the surface using three-dimensional structures.

2. DEPOLARIZATION EFFECTS IN THE NEAR-FIELD OPTICS

To understand the optical effects produced by subwavelength objects, it is important to introduce the notion of depolarization. In order to explain this behavior, one considers a bidimensional object which is illuminated along its smaller dimensions in the air; no surface is included for this model and the incident electric field is applied perpendicularly to the lateral sides of the particle. One can see that, for subwavelength objects, the negative contrast which occurs inside the object is a result of the depolarization effect which

is related to the conservation of the components normal to the object faces according to the displacement vector [31] (Fig. 1a).

Moreover, a higher intensity can thus be found around the lateral sides of the object close to its edges (Fig. 1a). This high-intensity effect borders the structure along the direction of the applied incident electric field (x-direction).

This depolarization effect is mostly related to the size of the object which belongs to the nanometer scale (100 nm) according to the incident wavelength (633 nm). One can observe that, when the size of the object is relatively small compared to the incident wavelength, which is the present case, the field intensity distribution around the object tends to reproduce its profile. This conclusion can be extended to any nanoscopic isolated objects in the near-field optics. We took the two-dimensional case; therefore, no depolarization effect appears along the infinite z-direction. In Section 3, we will show the importance of depolarization in different directions by using a tridimensional object deposited on a dielectric glass substrate.

2.1. Influence of the Particle Size on the Optical Image

Let us now consider a 200×200 nm^2 dielectric squared structure illuminated in the same conditions as in the previous section.

By doubling the object size, one can obtain an optical image including not only depolarization effects but also scattering waves near the structure because we switch from the nanoscopic regime (previous section) to the mesoscopic
range at the optical scale. One can see that a back reflected wave occurs in the optical image ($y < 0$) and also a forward scattering in the direction of the incident light ($y > 0$) (see Fig. 1b).

By this change, one can see the strong influence of the particle size on the resolution of the optical image. When we consider an object which has a size compared to the incident wavelength, the structure has not only depolarization properties but also scattering effects around the particle; these optical waves degrade considerably the resolution of the optical image.

2.2. Influence of the Incident Wavelength

The results presented in this section are a consequence of the different effects found in the previous one. To understand the impact of the wavelength in the optical image, let us consider a squared dielectric particle (100×100 nm^2) illuminated as previously but with a different wavelength lower than 633 nm. If one turns to a wavelength dependence, the use of a particle size (100 nm) which can be compared to the wavelength of the incident light (400 nm) shows scattering effects in the optical image (see Fig. 1c).

One can see the similar behaviors shown in the previous section: backward and forward scattering can be clearly seen in the optical image as we turned to the mesoscopic regime. Consequently, these effects show the main differences between the nanoscopic regime and the mesoscopic one in the optical images when dealing with nanometric objects in the near-field and by only changing the wavelength in the visible range.

Therefore, one has to be aware that the illumination wavelength and the lateral size of the particle have a strong impact on the resolution of the optical images in the near-field optics for the visible range as one can switch from the nanoscopic regime to the mesoscopic one.

3. OPTICAL PROPERTIES OF SUBWAVELENGTH OBJECTS DEPOSITED ON A SURFACE

In this section, the influence of the polarization associated with the incident light on the object is shown. The index of refraction of the substrate as well as the refractive index of the object is fixed to 1.5. Depending on the size of the object and on the incident wavelength, such a protrusion can behave more or less as a obstacle to the propagation of the surface wave. For the condition of total internal reflection, the object is illuminated with an angle of incidence of 60° and the detection is performed in the near-field optics at constant height above the object. It is also important to see what the tridimensional case will bring to the optical image. As the object will become three-dimensional, the other direction will give more insight for the depolarization effect along this direction.

3.1. Optical Electric Field

For the condition of total internal reflection, the $100 \times 100 \times 40$ nm^2 dielectric object is illuminated with an angle of incidence of 60° and the detection is performed in the near-field

Figure 1. For $\lambda = 633$ nm, variation of the intensity associated with the total electric field for a glass squared rod of 100×100 nm^2 section (a) and of 200×200 nm^2 section (b). For $\lambda = 400$ nm, variation of the intensity associated with the total electric field for a glass squared rod of 100×100 nm^2 section (c). The object is illuminated along the y-direction and the incident polarization direction is along the x-axis.

optics at a constant height of 10 nm above the object (see Fig. 2a and b). When the detection of the electromagnetic field is closer to the objects, one can find the same basic optical properties explained in the previous sections. Consequently, the backward and forward scattering effects cannot be seen in the optical images for both modes of polarization.

The depolarization effect occurs in the lateral sides of the particle in the TE mode as we had previously (Fig. 2a). However, this effect happens at the top of the object in the TM mode. In this mode, the incident electric field is parallel to the plane of incidence. Therefore, this field has components in both directions: parallel (y-direction) and perpendicular to the surface (z-axis). The angle of incidence ($60°$) is taken in such a way that the component which is perpendicular to the surface is larger compared to the parallel one. Consequently, the depolarization effect occurs in the z-direction, which produces the bright contrast in the near-field optical image (Fig. 2b).

Moreover, an inverse contrast similar to the TE polarization cannot show up in the TM mode because at short distances the vertical z-component of the electric field dominates. The matching condition of the vertical component of the displacement vector leads to a confined optical electric field close to the upper face of the pad. Therefore, in the three-dimensional case, the depolarization effect in the near-field optics could occur in the three axis according to the direction of application of the incident electric field.

A striking difference of behavior was found depending on the polarization state of the traveling wave along the

Figure 2. For $\lambda = 633$ nm, variation of the intensity associated with the total electric field for the TE mode (a) and for the TM mode (b) at a constant height of 50 nm above the dielectric surface. Variation of the intensity associated with the total magnetic field for the TE mode (c) and for the TM mode (d) for a $100 \times 100 \times 40$ nm^3 glass pad at a height of 100 nm above the surface. The object is illuminated by the glass substrate under the condition of total internal reflection with an angle of incidence of $60°$.

surface. In the subwavelength range, the TM polarization mode allows to reproduce the shape of the objects, whereas a TE polarized wave can be used to extract information on the contours of the objects themselves.

3.2. Optical Magnetic Field

Tip detection is important according to the optical properties of the sample surfaces. In the PSTM configuration, the detection performed with dielectric tips or with dielectric tips covered by a thin noble metal film shows different optical images in the near-field. In the first case, one detects an intensity associated with the optical electric field and in the other case, one can detect a signal proportional to the optical magnetic field associated with the optical wave for wavelengths in the visible range. This behavior is mainly related to the surface plasmon effect occurring in the thin metal film which covers the dielectric tip. Therefore, this proves that the optical images depend strongly on the tip response. We will discuss later the optical image patterns obtained with the electric field associated with the optical wave and also those of the magnetic field obtained in the same conditions.

In order to achieve a better resolution in the optical images, dielectric tips coated by a thin gold film can be used. But the optical images obtained using such tips show inverted contrasts compared to the ones obtained with uncoated dielectric tips. These results indicated that the detected signal may reveal different physical behaviors according to the probe composition [32, 33].

While the dielectric tip always collects a signal proportional to the square modulus of the electric near-field, using the same initial conditions, the optical images obtained with a coated gold tip display the same patterns as the theoretical maps of the square modulus of the magnetic field associated with the optical near-field. These images can be obtained under several conditions: the use of a defined gold film thickness which corresponds to a given excitation wavelength has to be achieved to obtain a signal proportional to the optical magnetic field associated with the scattered light in transmission. These conditions have to sustain a plasmon resonance mode in the thin metal film which covers the dielectric tip.

These studies show another way to detect a signal proportional to the optical magnetic field for wavelengths corresponding to the visible range. In order to show this purpose, one can compute the optical magnetic field associated with the lightwave in transmission (Fig. 2c and d). The object is illuminated as in Section 2 under the condition of total internal reflection. The height of detection is chosen to be 60 nm above the top of the dielectric object.

One can see that the depolarization effects occur at the top of the object in the TE mode while these occur on the lateral sides of the structure in the TM polarization for the optical magnetic field images (see Fig. 2c and d). These results show different behaviors compared to those found for the electric field intensities in both modes of polarization. All the optical responses are inverted for the detection of the magnetic field compared to the electric field signals: the dark contrast in the TE mode for the signal associated with the electric field gives a bright one for the optical

Figure 3. For $\lambda = 633$ nm, variation of the intensity associated with the total electric field (a), the x-component (b), the y-component (c), and the z-component (d) for a $100 \times 100 \times 40$ nm^3 glass pad. The incident polarization direction is along the x-axis (TE or s mode). The object is illuminated under the same conditions described in Figure 2. The dectection is performed at a height of 100 nm above the surface.

magnetic field (Fig. 2c and Fig. 3a). Similarly, a bright contrast for the TM mode for the intensity associated with the electric field leads to a dark one for the optical magnetic field (Fig. 2d and Fig. 4a).

Figure 4. For $\lambda = 633$ nm, variation of the intensity associated with the total electric field (a), the x-component (b), the y-component (c), and the z-component (d) for a $100 \times 100 \times 40$ nm^3 glass pad. The incident polarization direction is along the y- and z-axis (TM or p mode). The object is illuminated under the same conditions described in Figure 3.

4. ANALYSIS OF THE POLARIZATION NEAR SUBWAVELENGTH OBJECTS

As shown previously, one can detect experimentally the optical magnetic field associated with the scattered light. Using crossed polarizers, one can detect the different cartesian components associated with the electric field or with the optical magnetic field using coated gold dielectric tips at the resonance of the thin metal film or out of resonance. Choosing a proper incident polarized wave, one can detect the scattered wave obtained by eliminating the incident wave using another crossed polarizer at the fiber exit.

This could give more information on the size and shapes of the objects as the behaviors are not the same when using nanometric or mesoscopic objects compared to the incident wavelength. The cartesian components could give more insight about the shape of the object rising on the surface.

4.1. Detection of the Different Cartesian Components in the TE Mode

The detection is not performed close to the objects in order to show scattering effects along the dielectric surface. The aim of the following section is to show the possibility to suppress these optical waves in the near-field optics.

We illuminate a dielectric glass object at a wavelength of 633 nm through a glass substrate under the condition of total internal reflection with an angle of incidence of 60°. The lateral size of the dielectric pad is 100 nm and its height is 40 nm, placing it in the nanoscopic regime. The detection of the electromagnetic field is performed at 60 nm above the pad of dielectric permittivity of 2.25 which is equal to the one of the substrate. This detection height involves scattering behaviors around the object in the near-field optics.

The computation of the total intensity associated with electric field and to each cartesian component is realized for the TE mode (Fig. 3). The intensities are normalized according to the incident light.

It is known that in the near-field optics, a strong z-component of the electric field exists since this one does not appear in reflectivity or in transmission for thin films in the far-field. Moreover, it is also important to see its evolution with the incident polarization; this will be shown for the TM mode in the next section.

In this polarization mode, the electric field associated with the incident light is perpendicular to the plane of incidence. As shown previously, the negative contrast above the object is the depolarization effect and this can be seen in the optical images for the intensity associated with the total electric field (Fig. 3a) and also according to the x-component (Fig. 3b) which corresponds to the direction of application for the incident electric field.

In this mode, one can see first that the intensity associated to the total electric field shows a confinement of the electric field close to the lateral sides of the pad along the x-direction (Fig. 3a) which is displayed by an increase of intensity in the optical image. Nevertheless, interference phenomena due to the backward scattering effects of the incident light on the object are more accentuated in the near-field optical image (Fig. 3a) for $y < 0$. Moreover, the forward scattering appears on the optical image for $y > 0$.

Second, we can see that the *x*-component of the electric field, which is the incident one, is major (Fig. 3b) compared to the others (*y*- and *z*-components in Fig. 3c and d) as expected. One can see in Figure 3c that the interferences on the images due to the backscattering reflected wave on the object disappeared and only the effects due to the confinement of the field around the object show up. These ones are related to the topography of the object on the surface.

The same behavior can be seen in Figure 3d for the *z*-component of the electric field which shows optical effects due to the topography of the object. However, the intensities are greater for this component (Fig. 3d) compared to the other one (Fig. 3c). This shows the predominance of the *z*-component of the electric field compared to the one parallel to the surface (*y*-component) in the near-field optical images.

The image associated with the total electric field shows a negative optical response (dark contrast) above the nanoscopic object (Fig. 3a). Moreover, the *y*-component shows an electric field which is well confined at the corners of the dielectric pad (Fig. 3c), whereas the *z*-component displays the same strong effects on the lateral sides of the pad along the *x*-direction (Fig. 3d). By these optical patterns, one can distinguish the *x*-component of the electric field from the parallel *y*-component.

4.2. Detection of the Different Cartesian Components in the TM Mode

In this mode, one can see first that the optical images for the intensity associated with the total electric field and for each cartesian component are different compared to the TE mode. Consequently, the polarization plays an important role when analyzing the effects in the near-field optics.

For this mode of polarization, we can see first that the intensity associated with the total electric field shows a confinement of the electric field above the upper side of the dielectric pad along the *z*-direction (Fig. 4a), as shown in Section 3.1.

As in the TE mode, interference phenomena on the surface due to the backward scattering effect of the incoming light on the dielectric object show up in the optical image (Fig. 4a). Second, the *y*-component and more particularly, the *z*-component of the electric field which are associated to the incident one are major (Fig. 4c and d) compared to the other one (*x*-component in Fig. 4b) because they are associated with the incident electric field. The *z*-component is the strongest in the near-field optics, as discussed previously.

We can see in Figure 4b that the interferences on the images due to the backscattering reflected wave on the object disappeared and only the effects due to the confinement of the field around the object show up in the optical images. These are related to the topography of the object on the surface as in the TE mode.

We also show in this case that the *z*-component of the electric field is stronger in the near-field optical images compared to the *y*-component. Moreover, the *x*-component shows an electric field which is well confined on lateral sides of the pad (along the *x*-direction) whereas the *y*-component and the *z*-component display both interferences due to the incident light and a confinement of the electric

field respectively on the lateral sides along the *y*-direction and on the top of the pad along the *z*-direction (Fig. 4c and d).

It is thus possible to distinguish these three components in the near-field optics. Moreover, the forward scattering (*y* > 0) shows up in the optical images (Fig. 4a, c, and d).

Thanks to this study, we show that the analysis of polarization in the near-field optics shows that one can eliminate interference behaviors on the surface. Moreover, this analysis also shows the weight of each cartesian component in the near-field optical images.

Similar effects can be found for any kind of material of real positive dielectric permittivity. The behaviors are thus accentuated as the dielectric permittivity increases raising the intensities associated with each component. Nevertheless, the intensity variations associated with the component which was not in the polarization of the incoming light (for the TE mode: *y*- and *z*-components; for the TM mode: *x*-component) can be detected experimentally under the condition of a good signal-to-noise ratio.

Other studies show that these intensities could get higher values using other materials. In this case, it is necessary to make spectroscopy computations by varying the incident wavelength in the visible range showing for which one the exaltation of the electric field in the near-field optics appears. This intensity enhancement is mainly due to the basic properties of matter from which the object is based [34].

4.3. Dealing with Different Objects

In order to complete the previous discussion, we use several structures of different sizes and shapes. The sizes are arbitrary, taken in order to create a group which belongs to the mesoscopic regime.

Using different object sizes, one can see that scattering waves occur in the image providing difficulties to see the confinement of the electric field around each object. The case of bidimensional objects is chosen.

Using different objects sizes and shapes, it is important to see the optical signal associated with the component which is not in the incident electric field. One can see that the electric field is well confined on the edges of the different structures although surrounded by interference behaviors (see Fig. 5a).

Using different sizes of the structures in the mesoscopic regime, backward and forward scattering can be clearly seen in the optical images. One is aware that these effects

(a)   (b)
Figure 5. For $\lambda = 633$ nm, variation of the intensity associated with the total electric field (a) and the *y*-component (b) for several dielectric bidimensional objects.

degrade strongly the resolution of the optical images in the near-field optics. The detection of the y-component shows that one can detect with a better accuracy the positions of the objects as the scattered waves are almost eliminated (see Fig. 5b).

This analysis shows a new technique to eliminate interference behaviors occurring in the near-field optics, bringing to the fore only optical effects relative to the topography of the objects on the surface.

4.4. Circular Polarization

The use of circular polarized light has been developed for the case of dichroism in order to understand the optical properties of magnetic materials at the microscopic level. Circularly polarized light emitted from a scanning tunneling microscope was observed when the sample surface of a ferromagnetic material was probed with a tungsten tip in a longitudinal configuration. (The applied magnetic field is parallel to both the surface plane and the plane of light detection [35].)

The theory of radiative transfer has been used to investigate the interaction between linear or circular polarized light waves and a multiple scattering medium (spheres) according to the sizes of the objects and their relative index of refraction [36–38]. This theory shows that the circular depolarization length exhibits a strong dependence on the relative refractive index, whereas the linear one does not.

Chiral and achiral molecules show optical activity which arises from the different interaction of chiral media with left- and right-hand circularly polarized light. This optical

activity and the circular difference effects can also occur in nonlinear optics for chiral or achiral structures and magnetic materials in the second-harmonic generation signals [39, 40].

In our case, using the same computation technique, it is interesting to see the impact of circular polarization on a dielectric structure in the nanoscopic regime. We took the same dielectric object used in the previous section and illuminated under the same conditions. The detection of the electromagnetic field is performed at a height of 60 nm above the dielectric object.

In the case where the object is illuminated in normal incidence with a circular polarization (x- and y-components exist in this case), one can find that each component of the electric field gives information about the shape of the object in both directions. Therefore, an asymmetrical shape of the object can be detected with such method of illumination as the depolarization effects occur in both directions (x in Fig. 6b and y in Fig. 6c) using this particular incident polarization associated with the incident light (see Fig. 6a).

This technique could give more information about the shape of the object and also of the optical confinement of the electric field around the different structures. The main problem occurs on the detection of scattering effects along the surface and of the optical patterns produced by the mesoscopic and nanoscopic structure.

5. CONCLUSION

We present an accurate analysis of the optical effects produced by nanoscopic and mesoscopic structures in the near-field optics. The importance of the incident wavelength and of the particle size is one of the most important points to get a better optical resolution in the near-field optics. The depolarization effects associated with a nanoscopic object and the scattering properties of the structures were clearly shown. The analysis of polarization shows the possibility to extract optical effects relative to nanoscopic and mesoscopic objects in the near-field optics.

GLOSSARY

Depolarization of light On a smaller scale, when light waves pass near a barrier, they tend to bend around that barrier and spread at oblique angles. This phenomenon is known as diffraction of light, and occurs when the light wave passes very close to the edge of an object or through a tiny opening such as a slit or aperture. The light that passes through the opening is partially redirected due to an interaction with the edges.

Mesoscopic regime The adjective mesoscopic is used to define the situations where the sizes of the structures are of the order of the incident wavelength. For visible light, it corresponds roughly to the length range between 0.1 and 1 micrometer. By nanoswpic, one usually means low-dimensional Structures smaller than 100 nm.

Near-fields optics Near-field optics studies the behavior of light fields in the vicinity of matter and deals with phenomena involving propagating and evanescent electromagnetic wave which become critically significant when the typical
Figure 6. For $\lambda = 633$ nm, variation of the intensity associated with the total electric field (a), the x-component (b), and the y-component (c) for a $100 \times 100 \times 40$ nm^3 glass pad. The incident polarization is circular and the object is illuminated in normal incidence by the substrate. The detection is performed at a height of 100 nm above the surface.

sizes of the object are of the order of the wavelength or smaller. Near-field optical microscopy is the straightforward application of near-field optics.

Polarization   A light wave is an electromagnetic wave which mvels through the vacuum of outer space. Light wave is produced by electric charges which vibrate in a multitude of directions. An electromagnetic wave is a transverse wave which has both an electric and a magnetic component. A light wave which is vibrating in more than one plane is referred to as unpolarized light. It is possible to transform unpolarized light into polarized light. Polarized light waves are light waves in which the vibrations occur in a single plane. The process of transforming unpolarized light into polarized light is known as polarization.

Surface plasmon resonance   Under the condition of total internal reflection, while incident light is totally reflected the electromagnetic filed component penetrates a short (tens of nanometers) distance into a medium of a lower refractive index creating an exponentially detenuating evanescent wave. If the interface between the media is coated with a thin layer of metal (gold), and light is monochromatic and p-polarized, the intensity of the reflected light is reduced at a specific incident angle producing a sharp shadow (called surface plasmon resonance) due to the resonance energy transfer between evanescent wave and surface plasmons, corresponding to a collective excitation of the electrons at the metal/lower refractive index medium interface. The resonance conditions are influenced by the material adsorbed onto the thin metal film.

TE (s-mode) and TM (p-mode)   In the case of a surface separating two dielectric media, two modes of polarization can be associated with the incoming light: TE and TM modes. The z direction being perpendicular to the glass-air interface, as the incident light is chosen to be linearly polarized, the TE mode (s polarization) corresponds to an incident electric field perpendicular to the plane of incidence (y-z plane). The TM mode (p polarization) corresponds to a field parallel to the plane of incidence.

Tip detection   In near-field optical microscopy, the local detection of the optical signal or the illumination of the sample relies on the use of nanometer-sized probes. In near-field optics, a tip is constituted by a pulled optical fiber which illuminates or collects the light from a sample surface. This tip can be coated with a thin metal film in order to achieve a narrow localization of the incident light on the sample or to improve the resolution in detection.

Total internal reflection   At an interface between two transparent media of different refractive index, light coming from the side of higher refractive index is partly reflected and partly refracted. Above a certain critical angle of incidence, no light is refracted across the interface, and total internal reflection is observed.

Noble Metal Nanoparticles

Yiwei Tan, Yongfang Li, Daoben Zhu

Chinese Academy of Sciences, Beijing, People's Republic of China

CONTENTS

1. INTRODUCTION

During the final decade of the 20th century, nanomaterials were the focus of research in the field of materials science, which is driven by the expectations concerning the application of nanomaterials as a forthcoming generation of functional materials for the new century. A large amount of knowledge about the synthesis and properties of various nanoparticles and nanocomposites was accumulated within such a short period, with numerous new insights and techniques emerging with each passing day. The physical and chemical properties of substances can be significantly altered when they are exhibited on a nanometer-length scale, and this phenomenon opens up a completely new perspective for materials design that benefits from the introduction of not only particle size, but also particle morphology as new, powerful parameters.

A brand new concept is arising in material science: to utilize nanoparticles as the building blocks to displace the conventional microdevices by nanodevices. This challenging innovation will give rise to a revolutionary development: a drastic reduction in the necessary amount of traditional materials, subsequently of the cost and pollution, and finally turning the modern manufacturing that is regarded as an industry of exhausted natural resources and environmental harm into "smart and green production."

The substances with one dimension shrinking down to 1–100 nm can be called nanoscale substances. The nanomaterials can display various geometrical morphologies, which include zero-dimensional nanoparticles with an aspect ratio approximately equal to 1, one-dimensional nanorods (aspect ratio > 1), nanowires, nanofibers, nanotubes, and nanoribbons or nanobelts [1, 2], two-dimensional nanosheets [3–5] and nanoscale diskettes [6], and three-dimensional nanocages [7, 8]. Nanoparticles are the most thermodynamically stable form with respect to the other geometrically morphological nanoscale materials because they have the least surface energy. Having sizes located between those of small molecules (<1 nm) and eukaryotic cells (∼1–50 μm), they bridge the microscopic and macroscopic world, and provide completely novel dimensions when it comes to physical and chemical processing. Therefore, immense successes will be in gestation in this ongoing frontier research field of nanomaterials. In this chapter, the topic that will be dealt with in the following is just confined to the highlights in recent progress of noble metal nanoparticles. Additionally, copper nanoparticles are also involved since element copper belongs to Group IB.

Nanoparticles usually refer to approximately spherical particles with diameters within the range of 1–100 nm. The term nanocluster or cluster tends to be restricted for the description of nanoparticles of diameter less than 4 nm [9]. As used interchangeably in the literature, the terms nanoparticle and colloid are not clearly distinguishable. Colloidal metal nanoparticles have been known since the end of the middle ages. At that time, gold colloids were uniformly dispersed in glass to form the so-called beautiful red-colored ruby glass. In 1857, Faraday defined the "finely dispersed metal" as colloidal solutions of metal [10]. He proposed that the beautiful color of gold colloids is ascribed to metallic gold in its colloidal form. Later, at the beginning of the last century, a theory of light absorption by small metal nanoparticles was developed by Mie through solving Maxwell's equations for the absorption and scattering of electromagnetic radiation by spherical metal particles [11]. However, the research on noble metal nanoparticles is undergoing an unprecedented boom nowadays. There are a number of reasons for the resurgence of interest in nanoparticles of inorganic solids. On the one hand, new and powerful tools, both theoretical and experimental, have become available that permit a deep understanding of those fascinating materials. On the other hand, the unusual properties arise from the

material dimensions that are on the order of the electron mean-free path, which motivate their diverse application potentialities unexplored before. Perhaps most important is the finding that these materials, particularly when capped, behave almost like molecules in terms of their solubility, and the manner in which they can be crystallized in superlattices. In addition, there is the possibility of covalently modifying nanoparticle surfaces, in very much the same manner as one might take with a molecule.

It was found that some properties of metal nanoparticles may be comparable to those of semiconductor particles. There are no basic differences between metal and semiconductor nanoparticles since many effects, for example, sensitization of photoreactions of other solutes, the ability to store excess electrons and positive holes, changes in electronic properties upon surface modification, and photoelectron emission, which have been observed for semiconductor particles, can be showed in the metal nanoparticles [12]. It is known that large noble metal nanoparticles (i.e., Ag, Au, Pd, Pt, Rh, Ir, etc.) with diameters more than 10 nm have a high chemical stability due to their chemical inertness, whereas when the size of noble metal nanoparticles decreases to 2–4 nm, they are much more easily oxidized than the corresponding bulk metals in air [9]. Other transition metal nanoparticles are generally sensitive toward oxygen so that all experiments must be carried out under anaerobic conditions.

2. SYNTHESIS

2.1. Approaches to Noble Metal Nanoparticles

The accurate synthesis of colloids is never straightforward since small changes in synthesis procedures can give completely different results. Furthermore, the chemical preparation of colloids can produce nanocrystals having a crystal structure never found in bulk materials. It is thought that colloid chemistry could produce alloys of elements well known as nonalloying systems in the bulk. Noble metal nanoparticles are able to be prepared by physically or chemically forming noble metal atoms in suitable solvents, followed by an aggregation process (dispersion and condensation methods) of the noble metal atoms in the presence or absence of protective agents such as polymers, surfactants, or strong coordination ligands. The preparation of size- and shape-selected noble metal nanoparticles is always a great goal of chemists and physicists pursuing the transformation of their potential applications into reality.

Control over both the size and the shape of precious metal nanoparticles is not only of theoretical significance in the field of nanomaterials, but also an important way to modulate the catalytic and some other properties of precious metal nanoparticles. Much research work has been directed toward the preparation of shape-controlled precious metal nanoparticles. In the reported chemical preparations, there are two kinds of methods to control the morphology of precious metal nanoparticles. One is template-directed preparation, in which metal ions or complexes are reduced and the nanoparticles grow within a template, and therefore the shape of resulting products is controlled by the morphology

of the template. The other is growth-directed preparation, by which shape-selective precious metal nanoparticles are prepared using suitable precious metal precursors, protective agents, reducing agents, and reducing methods. Tables 1 and 2 show a survey of recent research activities concerning the synthesis of noble metal nanoparticles.

2.1.1. Physical Methods: Condensation of Atomic Metal Vapor

The principle of physical preparative methods is the metal vapor cocondensation with organic vapors in aqueous or nonaqueous media. These methods include metal evaporation [13–18] and laser pyrolysis [19–27], of which the metal evaporation route has been known since the start of the last century and was extensively studied in the 1970s. The metal vapors are commonly generated at reduced pressure of relatively volatile metals from a resistively heated hearth or an electron-beam furnace, and subsequently condensed on the walls of the reactor together with the organic solvent vapors at low temperature. A colloidal dispersion of the metal is then obtained by warming the frozen metal/organic mixture. By this means, Klabunde and co-workers prepared various dispersions of Au and Pd nanoparticles with a wide size distribution of 5–30 nm [28–33]. The generated zerovalent nanoparticles can be stable for several months, but the size distribution is hard to control.

A recent aerosol route developed by Whetten and co-workers [34–36] gave rather uniform Ag nanoparticles with a diameter between 4 and 6 nm: elemental silver metal is evaporated at high temperatures ($\sim$1500 K) into a flowing, preheated atmosphere of ultrahigh-purity inert gas (Ar, He, N_2, etc.). The flow stream is cooled over a short distance (and flow time) to lower temperatures, stimulating the growth of nanoparticles in the desired size range, for example, ca. 4–6 nm. Then, growth is abruptly terminated by expansion through a conical funnel accompanied by dilution in a great excess of cool inert gas. Subsequent steps may include reheating (annealing) of the separated nanocrystals and etching and passivation by molecular vapors such as long-chain alkylthiols and alkylamines introduced downstream.

Laser ablation techniques as a typical example of a dispersion method allow one to conveniently and sanitarily fabricate various noble metal nanoparticles without introducing a reductant. Here, let us give a simple description of it: a metal plate immersed in a solution containing a stabilizer was irradiated with a laser beam focused by a lens; the metal atoms were evaporated, and then condensed at the action of laser energy. Figure 1 presents a schematic diagram of laser ablation for the preparation of metal nanoparticles. The size distribution of the nanoparticles tends to be broadened because the coagulation processes of atoms are difficult to be controlled.

2.1.2. Sonochemical, Photochemical, and Thermal Decomposition

High-intensity ultrasound is a powerful tool for the preparation of nanostructured materials because of ultrasonic cavitation caused by ultrasonic irradiation of a liquid. The acoustic cavitation comprises the formation, growth,

Table 1. Various synthetic routes for noble metal nanoparticles with the exception of chemical reduction.

Noble metal (dispersity)	Synthetic route	Ref.
Cu (5–100 nm)	laser ablation	[24]
Cu (20–100 nm)	γ-radiolysis	[65, 247, 248]
Cu (7.5 nm)	thermal decomposition	[224]
Cu (elongated)	sonochemical synthesis	[254]
Ag (4–40 nm)	laser ablation	[25]
Ag (4–6 nm)	metal evaporation	[34–36]
Ag (13–34 nm)	sonochemical synthesis	[43]
Ag (6.5–12.5 nm)	γ-radiolysis	[68]
Ag (2–120 nm)	γ-radiolysis (seed mediated)	[70, 71]
Ag (5–10 nm)	UV irradiation	[78]
Ag (10–20 nm)	UV irradiation	[81]
Ag ($\sim$4 nm)	UV irradiation	[85]
Ag (nanoprism)	fluorescent light irradiation	[263]
Au (1–10 nm)	laser ablation	[26]
Au (1.7–5.5 nm)	laser ablation	[27]
Au (10–30 nm)	metal evaporation	[28]
Au (7–15 nm)	metal evaporation	[30]
Au ($\sim$2 nm)	metal evaporation	[31]
Au (2–10 nm)	metal evaporation	[32]
Au (2–9, 60 ± 30 nm)	sonochemical synthesis	[44, 268]
Au (15–22 nm)	γ-radiolysis	[74]
Au (7.5–12.5 nm)	UV irradiation	[77]
Au (10–20 nm)	UV irradiation	[78]
Au ($\sim$6 nm)	UV irradiation	[85]
Au (0.2–5 nm)	UV irradiation	[89]
Au (triangle, hexagon)	UV irradiation	[76]
Au (platelets)	UV irradiation	[88]
Pt (1.7–3.5 nm)	sonochemical synthesis	[50]
Pt (1–10 nm)	sonochemical synthesis	[56]
Pt (1–3 nm)	γ-radiolysis	[69, 274]
Pt (1.1 nm)	UV irradiation	[82]
Pt (0–5 nm)	UV irradiation	[83, 84]
Pt (2–4 nm)	microwave irradiation	[91]
Pt (0.6–2.2 nm)	microwave irradiation	[92]
Pt (2.5–5.0 nm)	electrochemical reduction	[214]
Pd (8 nm)	metal evaporation	[29]
Pd (6–110 nm)	sonochemical synthesis	[46]
Pd (1–6 nm)	sonochemical synthesis	[56]
Pd (0.1–12 nm)	sonochemical synthesis	[59]
Pd (2.0–40 nm)	UV irradiation	[84]
Pd (0.6–3.0 nm)	microwave irradiation	[92]
Pd (1.4–4.8 nm)	electrochemical reduction	[213, 214]
Pd (8–10 nm)	thermal decomposition of Pd complex	[235, 236]
Ru (3.5 nm)	electrochemical reduction	[214]
Rh (2.5 nm)	electrochemical reduction	[214]
Os (2.0 nm)	electrochemical reduction	[214]
Ag$_{core}$Au$_{shell}$	γ-radiolysis	[72]
Au$_{core}$Ag$_{shell}$ (60 nm)	UV irradiation	[317]
Au$_{core}$Pt$_{shell}$	γ-radiolysis	[73]
Pt$_{core}$Au$_{shell}$	γ-radiolysis	[73]
Ag/Pt alloy	γ-radiolysis	[300]
Ag/Pd alloy (3–11 nm)	UV irradiation	[309]
Au/Pt alloy (1.6–13.6 nm)	γ-radiolysis	[301]
Pt/Cu alloy (2.5 nm)	electrochemical reduction	[214]
Pt/Pd alloy (3.5 nm)	electrochemical reduction	[214]
Pt/Rh alloy (2.5 nm)	electrochemical reduction	[214]
Pt/Sn alloy (3.0 nm)	electrochemical reduction	[214]
Pd/Ni alloy (2.5–3.5 nm)	electrochemical reduction	[311]

and implosive collapse of bubbles in a liquid. When the cavitation bubbles are violently collapsing, the temperature and pressure of the bubbles reach several thousands of degrees and hundreds of atmospheres, respectively, accompanied by shock-wave generation [37, 38]. The sonochemical synthesis of novel nanostructured materials is based on such extreme conditions. The sonochemical reduction of transition salts usually proceeds in three steps: the generation of the active species, the reduction of the metal, and the growth of the colloids. These three steps occur in different compartments: (1) in the gaseous phase into the cavitation bubbles where high temperature and pressure allow water pyrolysis to form $^{\bullet}$H and $^{\bullet}$OH, (2) at the interface between the cavitation bubbles and the solution, and finally, (3) in the solution. Henglein first revealed that $^{\bullet}$H and $^{\bullet}$OH formed in the course of sonolysis of water [39], and reported the reduction of $AuCl_4^-$ and Ag^+ in an aqueous solution by ultrasonic irradiation under Ar–H_2 conditions [40]. Subsequently, the synthesis of stable metal iron colloids by the sonochemical decomposition of iron-containing complexes such as $Fe(CO)_5$ was described [41, 42]. In the case of reduction of noble metal ions, the sonochemical process undergoes the sonolysis of water and organic additives, which produce $^{\bullet}$OH and $^{\bullet}$H, as well as the following $^{\bullet}$R and $^{\bullet}$H, respectively. For instance, a previous work by Nagata et al. [43] suggested that the reduction of Ag^+ ions to metallic Ag under the protection of Ar atmosphere proceeded via the formation of H atoms in the sonolysis of water, and the subsequent secondary reducing radicals generated from the abstraction reaction between organic additives and OH radicals and H atoms. Due to the low vapor pressure of the metallic salts, the reduction cannot happen in the gaseous phase. The reduction occurs mainly at the bubble/solution interface and in solution. By this means, several types of metal nanoparticles have been synthesized in the presence of protective agents [44–58] or support substrates [59].

During the past few decades, γ radiolysis of solutions of precious metal salts has been applied to prepare nanoparticles [60–67]. The reduction of the precious metal ions occurs here by the reducing species such as organic radicals [$(CH_3)_2C^{\bullet}(OH)$] which are generated in the radiolysis of the aqueous solvent (the solvated electrons or $^{\bullet}$H and $^{\bullet}$OH originating from water radiolysis can react with organic molecules to give new radicals to reduce metal salts). Under certain conditions, a large number of atoms are homogeneously and instantaneously produced in the course of the irradiation, thus promoting the generation of particles with a narrow size distribution. For example, by irradiating a solution of copper perchlorate ($Cu(ClO_4)_2$) containing sodium formate, Cu nanoparticles are formed through the reduction of Cu^{2+} by both solvated electrons and $CO_2^{\bullet-}$ generated during radiolysis [65]. The irradiation of a solution comprising $AgClO_4$, sodium citrate, 2–propanol, and nitrous oxide yields rather uniform cuboctahedra and icosahedra nanoparticles [68]. Intriguingly, in an original example of radiolytic Pt colloid synthesis [69], both the nanoparticles and the protective polymer are produced simultaneously by radiolysis of a solution containing the monomer (acrylamide) and the metal salts (H_2PtCl_6). In the presence of seeds, radiolytic reduction has also been applied to enlarge particles. Gold nanoparticles with diameters ranging from 2 to 120 nm

Table 2. Chemical reduction approaches to noble metal nanoparticles with different reducing and stabilizing agents.

| Noble metal (dispersity nm)	Reducing agent	Stabilizer	Ref.
Cu (<5 nm)	H_2	carbon nanotube (template and support)	[253]
Cu (4.8–15.0 nm)	$NaBH_4$	PVP, PVA, dextrin, amylopectin, cellulose	[160–162]
Cu (<1.8 nm)	$NaBH_4$	polyamidoamine	[167]
Cu (<5 nm)	$NaBH_4$	alkylxanthate	[245]
Cu (4.5–6.0 nm)	N_2H_4	polyamidoamine	[166]
Cu (6.6–22.7, 15.5–30.2 nm)	$N_2H_4 \cdot H_2O$	PVP	[197]
Cu (4–7, 6–9, 3–12 nm)	N_2H_4	AOT reverse micelles	[215, 217, 249]

Pt (0–15.0 nm)	H_2	SDS, dodecyltrimethylammonium chloride	[84]
Pt (5–10 nm)	H_2	sodium citrate, NaOH	[96]
Pt (cube, tetrahedron, icosohedron, cubic octahedron, irregular prism)	H_2	sodium polyacrylate	[93]
Pt (5–8 nm)	H_2	sodium polyacrylate, polyphosphate	[274]
Pt (1–3, 3–5 nm)	H_2	polyethyleneoxide–polyethyleneimine	[205]
Pt (3–10 nm) (cube)	H_2	oxalate	[272]
Pt (cube)	H_2	poly(N–isopropylacrylamide)	[273]
Pt (1.2, 1.5 nm)	CO	nitrocellulose, cellulose acetate	[279]
Pt (0.8–2.0 nm)	ethylene glycol	ethylene glycol	[107]
Pt (0–5.5 nm)	ethylene glycol	poly(N–sulfonatopropyl–p–benzamide)	[137]
Pt (2–12 nm)	ethylene glycol	PVP	[143]
Pt (0.25–3 nm)	formaldehyde, benzaldehyde	trioctylmethylammonium chloride, TOPO	[113]
Pt (1.3–2.2 nm)	KBH_4	polyelectrolytes	[127, 130]
Pt (3.3 nm)	KBH_4	polystyrene–b–poly(methacrylic acid)	[132]
Pt (2.2 nm)	KBH_4	polystyrene–b–poly(ethylene oxide)	[132]
Pt (0.25–4.5 nm)	$NaBH_4$	poly[(vinylamine)–co–(N-vinylisobutyramide)]	[133]
Pt (0.5–4.0 nm)	$NaBH_4$	polyamidoamine	[168, 170, 174]
Pt (3–10 nm) (cubic)	$NaBH_4$ (0 °C)		[269]
Pt (2–5 nm) (highly faceted)	$LiBH_4$, $LiB(C_2H_5)_3H$, $LiAlH_4$	nonionic surfactants	[271]
Pt (1.3 nm)	dimethylamineborane	polyamidoamine	[175]
Pt	$N_2H_4 \cdot H_2SO_4$	PVA	[146]
Pt (2.5–4.0 nm)	N_2H_4	cetyltrimethylammonium bromide	[147, 148]
Pt (2.5–3.5 nm)	N_2H_4	pentaethylene glycol dodecyl ether	[147, 148]
Pt (1–5 nm)	Li (or Na,K)[B(Et)₃H], H_2, LiH, BEt_3	tetraalkylammonium halide	[189–195]
Pt (1–3 nm)	Cu, Ag nanocluster	polyamidoamine	[103]
Pt (2.0–4.0 nm)	sodium citrate	sodium citrate	[208]
Pd (1.0, 3.4, 7.8 nm)	ethanol	polystyrene–b–poly(methacrylic acid)	[85, 132]
Pd (2.1, ~5, 6.8 nm)	ethanol	polystyrene–b–poly(ethylene oxide)	[85, 132]
Pd (1–4 nm)	alcohol (MeOH, EtOH, 1-PrOH)	PVA, PVP, poly(methyl vinyl ether)	[106, 120, 139, 144, 277]
Pd (7.5 nm)	methanol	PVP	[280]
Pd (1.5–7 nm)	ethanol	polyacids	[128]
Pd (10, 19 nm)	ethylene glycol	PVP	[143]
Pd (1–12 nm)	H_2	polyethyleneoxide–polyethyleneimine	[205]
Pd (1.7–3.7 nm)	H_2	PVP	[206, 277, 280]
Pd (1.0 nm)	CO	PVP	[278]
Pd (3.5 nm)	CO	nitrocellulose, cellulose acetate	[279]
Pd (5–15 nm)	N_2H_4	poly(acrylic acid)	[97]
Pd (5 nm)	N_2H_4	pentaethylene glycol dodecyl ether	[147]
Pd (2.7–10.7 nm)	N_2H_4	CTAB, SDS, polyoxyethylene isooctyl phenyl ether	[180, 275, 276]
Pd (3.3 nm)	N_2H_4	polystyrene–b–polyvinylpyridine	[201, 203]
Pd (6.5 nm)	N_2H_4	polystyrene–block–poly–m–vinyltriphenylphosphine	[207]
Pd (1.0–3.7 nm)	KBH_4	polyelectrolytes	[130]
Pd (1.3–2.1 nm)	KBH_4	polystyrene–b–poly(methacrylic acid)	[132]
Pd (1.7–3.6 nm)	KBH_4	polystyrene–b–poly(ethylene oxide)	[132]
Pd (1–3 nm)	$NaBH_4$	polyamidoamine	[168]
Pd (1–2.7 nm)	$NaBH_4$, $LiB(C_2H_5)_3H$	polystyrene–b–polyvinylpyridine	[201, 203, 204]
Pd (2.7–9.3 nm)	$NaBH_4$	CTAB, SDS, polyoxyethylene isooctyl phenyl ether	[275, 276]
Pd (1–2 nm)	$LiB(C_2H_5)_3H$	polystyrene–block–poly–m–vinyltriphenylphosphine	[207]
Pd (1–5 nm)	$NaBH_4$	alkanethiolate	[231]
Pd (1–6 nm)	Li (or Na,K)[B(Et)₃H], H_2, LiH, BEt_3	tetraalkylammonium halide	[190–195]

Table 2. Continued.

Noble metal (dispersity nm)	Reducing agent	Stabilizer	Ref.
Pd (1.8–2.5 nm)	NaH_2PO_2	polystyrene–b–poly(methacrylic acid)	[132]
Pd (1.8 nm)	NaH_2PO_2	polystyrene–b–poly(ethylene oxide)	[132]
Pd (50–200)	polyaniline	polyaniline	[116]
Pd (0.8–4 nm)	sodium formate	trioctylmethylammonium chloride	[179]
Pd (2.7–20 nm)	ascorbate	CTAB, SDS, polyoxyethylene isooctyl phenyl ether	[276]
Pd (1–3 nm)	Cu, Ag nanocluster	polyamidoamine	[103]
Ir (0–3 nm)	methanol	PVA, PVP, poly(methyl vinyl ether)	[120]
Ir (3 nm)	ethylene glycol	PVP	[143]
Ir (0.6–2.7 nm)	Li (or Na,K)[B(Et)$_3$H], H$_2$, LiH, BEt$_3$	tetraalkylammonium halide	[189–195]
Ir (2.5 nm)	H$_2$ (in the presence of catalyst: Al$_2$O$_3$/Pt(2%))	pentaethylene glycol dodecyl ether	[147]
Ir (1.4–3.0 nm)	H$_2$	Bu$_4$N$^+$/P$_2$W$_{15}$Nb$_3$O$_{62}^{9-}$	[154–157]
Ru (1.0–3.0 nm)	H$_2$	nitrocellulose, cellulose acetate	[279]
Ru (1.1 nm)	H$_2$	PVP, cellulose acetate	[280, 281]
Ru (2–3 nm)	H$_2$	alkylamines, alkylthiols	[281]
Ru (12–35, 80–100 nm) sponge-like	H$_2$	methanol/THF	[282]
Ru (0.7–2.2 nm)	ethylene glycol	ethylene glycol	[107]
Ru (2 nm)	ethylene glycol	PVP	[143]
Ru (1–2 nm)	Li (or Na,K)[B(Et)$_3$H], H$_2$, LiH, BEt$_3$	tetraalkylammonium halide	[189–195]
Rh (0.7–2.2 nm)	ethylene glycol	ethylene glycol	[107]
Rh (0.9–3.4 nm)	methanol	PVA, PVP, poly(methyl vinyl ether)	[119–121]
Rh (2.8 nm)	ethanol	cyclodextrine	[123]
Rh (2–3 nm)	H$_2$, NaBH$_4$	trisulfonate surfactant	[149, 150, 182, 183]
Rh (3 nm)	H$_2$	pentaethylene glycol dodecyl ether	[147]
Rh (2–3 nm)	H$_2$	trioctylmethylammonium chloride	[151–153]
Ru (2.4–6.1 nm)	H$_2$	Bu$_4$N$^+$/P$_2$W$_{15}$Nb$_3$O$_{62}^{9-}$	[158, 159]
Rh (1.3–4 nm)	Li (or Na,K)[B(Et)$_3$H], H$_2$, LiH, BEt$_3$	tetraalkylammonium halide	[189–195]
Os (<1 nm)	methanol	PVA, PVP, poly(methyl vinyl ether)	[120]
Os	Li (or Na,K)[B(Et)$_3$H], H$_2$, LiH, BEt$_3$	tetraalkylammonium halide	[189–195]
Cu/Pd alloy (1–4 nm)	ethylene glycol	PVP	[294–296]
Cu/Pd alloy (3.0–5.0 nm)	2–ethoxyethanol	PVP	[299]
Cu/Pt alloy (1–4.5 nm)	ethylene glycol	PVP	[294]
Cu/Au alloy (3.8 nm)	N$_2$H$_4$	AOT reverse micelles	[303]
Ag/Pt alloy (1.8–5.2 nm)	NaBH$_4$	PVP	[310]
Ag/Pd alloy (4–10 nm)	ethylene glycol	PVP	[292]
Au/Pt alloy (3–4.5 nm)	N$_2$H$_4$	AOT reverse micelles	[304]
Au/Pd alloy (0.5–3.0 nm)	ethanol	PVP	[288]
Au/Pd cluster-in-cluster (1.0–4.5 nm)	ethanol	PVP	[312]
Pt/Pd alloy (1–4 nm)	H$_2$	PVP	[287]
Pt/Pd alloy (0.5–3.0 nm)	ethanol	PVP	[284–286, 291]
Pt/Pd alloy (2–5 nm)	N$_2$H$_4$	pentaethylene glycol dodecyl ether	[302]
Pt/Ru alloy (1–4 nm)	Li (or Na,K)[B(Et)$_3$H], H$_2$, LiH, BEt$_3$	tetraalkylammonium halide	[189–195]
Pt/Ru alloy (1.1–1.4 nm)	H$_2$	PVP	[308]
Pt/Ru alloy (0.8–3.0 nm)	N(Oct)$_4$[BEt$_3$H]	tetraoctylammonium	[305, 306]
Pt/Rh alloy (2–7 nm)	ethanol	PVP	[289]
Pt/Fe alloy (6 nm)	1,2 hexadecanediol and thermolysis	oleic acid and oleyl amine	[320]
Pt$_3$Co alloy (1.5–7.2 nm)	1,2 hexadecanediol and thermolysis	1–adamantanecarboxylic acid	[225, 321]
Pt$_3$Co alloy (1.5–2.1 nm)	Co$_2$(CO)$_8$ (transmetalation reaction)	oleic acid	[322]
PtCoFe alloy (3.5 nm)	1,2 hexadecanediol and thermolysis	oleic acid and oleyl amine	[319]
Pd/Ni alloy (1.2–2.8 nm)	ethylene glycol	PVP	[297, 298]
Pt/Sn alloy (0.4–2.8 nm)	N(Oct)$_4$[BEt$_3$H]	tetraoctylammonium	[307]
Pd/Rh (Ru) alloy	methanol	PVP	[291]
Ag$_{core}$Pt$_{shell}$ (12 nm)	Co$_2$(CO)$_8$ (transmetalation reaction)	oleic acid and tridodecylamine	[313]
Au$_{core}$Ag$_{shell}$ (27–62 nm)	ascorbic acid	CTAB	[428]
Au$_{core}$Pt$_{shell}$ (1–7 nm)	N$_2$H$_4 \cdot$H$_2$O	AOT reverse micelles	[100]
Au$_{core}$Pt(Pd)$_{shell}$ (~35 nm)	NH$_2$OH·HCl	P(m–C$_6$H$_4$SO$_3$Na)$_3$, p–H$_2$NC$_6$H$_4$SO$_3$Na	[313]
Pd$_{core}$Pt$_{shell}$ (1.5–5.5 nm)	H$_2$	PVP	[316]
Pd$_{core}$Au$_{shell}$Ag$_{shell}$	H$_2$	sodium citrate	[95]
Co$_{core}$Pt$_{shell}$ (4.0–8.0 nm)	Co nanoparticle	C$_{12}$H$_{25}$NC	[322]

have been made by this technique [70, 71]. The amount of gold that is allowed to deposit onto the seed particles is any desired. This procedure can also be used to prepare bimetallic nanoparticles of the core–shell type. For instance, Au(CN)$_2^-$ was reduced on silver [72] and platinum [73] nanoparticles. In addition, the radiolytic preparation of transition metal nanoparticles is also possible in organized environments such as micelles or microemulsions [74].

A slow UV-reduction technique is a quite effective class of generation of nanoparticles with well-defined shapes, by which long Ag naonrods, beautiful Ag dendrites [75], and large, but thin, platelet-like Au nanoparticles with a triangular or hexagonal shape [76] are generated, respectively. Here, it should be mentioned that the concentration of noble metal ions and the amount of protective polymers is of paramount importance in the shape control. Other reports on the photolysis of metal salts include the UV–visible irradiation of Au [77–80], Ag [78–81], or Pt [82] salts in reverse microemulsions in the presence of surfactants or polymers to yield metallic nanoparticles. In the presence of micelles of a wide range of surfactants, Toshima et al. synthesized Pt [83, 84] and Pd [84] colloids by photolysis and hydrogen reduction. They found that the UV–visible irradiation technique gives smaller and better dispersed nanoparticles. Mayer and Esumi described the UV–visible photolytic synthesis of Au nanoparticles stabilized by block copolymers, polyelectrolytes [85–88], or dendrimers (polyamidoamine: PAMAM) [89]. Another aspect of utilizing the UV–visible irradiation technique is the encapsulation of Pt nanoparticles into polymerized vesicles [90]. The vesicle reticulation and the colloid formation occur simultaneously during irradiation. More recently, the microwave irradiation reduction technique has been developed to synthesize noble metal nanoparticles [91, 92]. In principle, microwave irradiation is alien to UV photolysis and γ-ray radiolysis. The generation of metal nanoparticles originates from the heating effect rather than the energy of the quantum of a microwave. Polar molecules can be heated quickly under the microwave irradiation, but nonpolar molecules cannot couple with microwaves, so that the polar reaction solution can be heated to a high temperature instantaneously and homogeneously by microwaving. In comparison with conventional heating, more uniform nucleation and a shorter crystallization time will be achieved for the formation of colloids.

2.1.3. Chemical Reduction of Noble Metal Salts

From an efficiency point of view, the chemical reduction of a precious metal salt in an organic or aqueous medium is preferred and economical, so that it has thus motivated a vast amount of work. A series of chemical reduction approaches have been employed to prepare precious metal nanoparticles, in which the reducing agents comprise various compounds, such as H$_2$ [93–96], NaBH$_4$, N$_2$H$_4$ [97–100], NH$_2$OH [101], (CH$_3$)$_2$NH·BH$_3$ [102], Cu or Ag (relatively active metals for metathesis reaction) [103], ethanol [104–106], ethylene glycol [107], citric acid and citrate [108–110], formamide [111], formaldehyde [112, 113], ascorbic acid [114, 115], polyaniline [116], *o*–anisidine [117], and potassium bitartrate [118]. In these preparative procedures, the formation of metal nanoparticles is strongly governed by the balance of nucleation rate and particle growth. The control of the size of nanoparticles can be realized by simply changing the ratio of the nucleation rate to the growth of particles. If the rate of particle growth is much smaller than that of nucleation, it will result in the production of a large number of small embryos, and then these embryos grow further to form tiny nanoparticles. The achievement of accurate control of the stability and reactivity of the quantum particles is also required to allow the attachment to the surface substrates or other particles without leading to coalescence, and hence losing their size-induced electronic properties.

The refluxing of alcohol and some noble metal salts will lead to the formation of nanoparticles in the presence of stabilizers. In this process, the alcohol acts both as a solvent and a reducing agent. In general, the alcohols contain α–hydrogen. Thus, methanol, ethanol, and isopropanol are good candidates as reducing agents, whereas *tert*–butyl alcohol is not effective. During the reduction, the alcohols are oxidized to the corresponding carbonyl compounds. The presence of water is often required to fulfill this reaction. Hirai, or more recently Delmas, have extensively used aqueous alcohols as reducing agents in the synthesis of colloids such as Rh, Pt, Pd, Os, and Ir [104, 119–125]. The effective stabilizers can be a series of polymer materials or oligomers, such as polyvinylic alcohol (PVA), poly(*N*–vinylpyrrolidinone) (PVP), polyvinylic ether (PVE), or cyclodextrine. Other types of polymers were also used for the stabilization of Au, Pd, and Pt colloids formed during the metallic salt reduction, such as various polyacids [126–129], polyelectrolytes [126, 127, 130, 131], block copolymers [85, 126, 127, 132, 133], poly(*N*–isopropylacrylamide) (PNIPAAm) [134–136], poly(*N*–sulfonatopropyl–*p*–benzamide) [137], and PVA/PVP copolymers [138]. The synthetic conditions, including the variation of stabilizer quantity [139–143], structure and quantity of alcohol [139–143], metallic precursor [142, 143], as well as the addition of a base [144] have

an impact on the particle size distribution. Several systematical studies revealed that the reduction of H_2PdCl_4 [139], H_2PtCl_6 [140], and $RhCl_3$ [141] leads to smaller particles when the alcohol used had a higher boiling point. In the same way, the addition of NaOH in the course of the reduction of H_2PtCl_6 or $PdCl_2$ with methanol is accessible to a decrease in the size of the particles formed [144]. In addition, heating has an effect on particle size at times. The quick heating by microwaves of an aqueous alcoholic solution of H_2PtCl_6 allows the formation of nearly monodispersed Pt nanoparticles [91].

The hydrogen reduction method is one of the most powerful tools providing access to a variety of noble metal nanoparticles. With PVA as the protecting agent, aqueous colloidal solutions of Au, Ag, Ir, Pt, Pd, Rh, and Ru were prepared by H_2 reduction of the corresponding chloride salts [145]. Accordingly, hydrazine polyacrilic acid-stabilized Pt nanoparticles were fabricated [146]. A hydrogen reduction protocol was also applied to synthesize diverse precious noble metal nanoparticles in microemulsions, by which the preparation of Rh, Pt, Pd, and Ir colloids was achieved [147, 148]. In other reports, Rh nanoparticles were synthesized by hydrogen reduction of an aqueous solution of $RhCl_3$ in the presence of a trisulfonated surfactant [149, 150]. The reduction of $RhCl_3$ by hydrogen in water containing trioctylamine followed by extraction into CH_2Cl_2 gave a stable dispersion of Rh nanoparticles [151–153]. Thus, surfactant-capped organosols were obtained by the extraction of the colloidal metal into an immiscible CH_2Cl_2 phase from a preformed hydrosol. Here, the use of trioctylamine introduced both the phase transfer agent and the stabilizer as a single reagent. Finke and co-workers [154–159] studied the reduction of Ir and Rh organometallic complexes by hydrogen. Zerovalent nanoparticles stabilized by a couple ammonium (Bu_4N^+)/polyoxoanion $(P_2W_{15}Nb_3O_{62}^{9-})$ generating electrostatic stabilization are formed. These nanoparticles have a great stability, and their size distributions were sufficiently narrow to be qualified as monodispersions.

The borohydrides ($NaBH_4$ or KBH_4) are very strong reducing agents, and can reduce most transition metal salts to elemental metal. With the borohydrides reduction method, extensive polymers (PVP, PVE, and PVA) and polysaccharides-stabilized Cu nanoparticles [160–162], PVP-stabilized Pt nanoparticles [163], and stabilizing polymers (cationic polyelectrolytes, polyacids, nonionic polymers, and block polymers)-protected Ag, Au, Pt, and Pd colloids in aqueous solution [85–88, 129, 130, 132, 164, 165] are widely investigated. Recently, borohydride reduction was used to obtain nearly monodispersed dendrimers (polyamidoamine or PAMAM)-protected Au, Ag, Pt, and Cu colloids [166–176]. The oleo-soluble dimethylamineborane has also been used to prepare Au organosol in the presence of hydrophobically modified PAMAM in toluene or chloroform [177]. Cationic, anionic, and nonionic surfactants are extensively applied to stabilize a noble metal colloidal aqueous solution prepared by borohydride reduction. By this means, the fabrication of Ru, Rh, Pd, Pt, Ag, and Au nanoparticles stabilized by quaternary ammonium, sulfates, or poly(ethylene glycol) is reported [178]. As effective stabilizers, aliquat 336 (trioctylmethylammonim chloride)

and CTAB (cetyltrimethylammonium bromide) or glycerol monooleate also show the stabilization for Pd [179, 180] or Cu [181] nanoparticles in water/oil microemulsions. In addition, aqueous solutions of colloidal Rh stabilized by a trisulfonated surfactant were obtained with the borohydride reduction method [182, 183]. The borohydride-reducing approach has been proven to be successful in the preparation of transition metal colloids in organic media. For instance, after reducing a metallic salt in aqueous phase by $NaBH_4$ and then evaporating the water, the solid obtained can be redispersed in an organic solvent [184]. A range of approaches to the phase transfer of nanoparticles has been developed, with most studies focusing on the transfer from aqueous to organic media [185–188]. A valuable trick of the production of metal organosols involves the utilization of tetraalkylammonium hydrotriorganoborates ($NR_4(BEt_3H)$) in THF solution to reduce a wide range of Group VIB, VIIB, VIII, and IB metal halide salts [189–195]. The particle size locates generally between 1 and 10 nm. If appropriately substituted tetraalkylammonium salts are used, the colloidal metal nanoparticles can be solubilized in organic media. This protocol provides the possibility of large-scale production of various metal nanoclusters. However, there is a lack of exact compositional characterization of the resultant colloidal materials. Indeed, it was found that the resulting colloids contain boron from the initial BEt_3H^- reductant as a 1–2% impurity [195]. The advantage of this preparation process lies in the coupling of both the stabilizing agent (the NR_4^- group) and the reducing group in the same reagent. A high local concentration of the stabilizer is present during the reduction process, thus limiting the growth of the particles. The alternative developed by Bönnemann consists of coupling the reducing agent with the transition metal salts $((NR_4)_mMX_nY_m)$. The reaction route can be denoted as

$$(NR_4)_mMX_nY_m + n\text{Red} \xrightarrow{\text{THF}} M_{\text{colloid}} + n\text{Red}X + mNR_4Y$$

M = Group VIB, VIIB, VIII, IB metals
X, Y = Cl, Br
R = alkyl, C_{4-12}
Red = H_2, LiH, Li (or Na,K)BEt_3H, BEt_3.   (1)
This novel compound is then reduced by hydrides (superhydride, lithium hydride) to yield colloidal metal nanoparticles, where the local concentration of the protective agent is also high, leading to the particle size being 1–10 nm. Recently, Caruso contributed a promising strategy for providing the spontaneous phase transfer of nanoparticles from organic to aqueous media. First, $HAuCl_4$ or Na_2PdCl_4 were reduced by $NaBH_4$ in the presence of tetraoctylammonium bromide in toluene, and then the rapid and complete transfer without signs of degradation or aggregation of the nanoparticles was performed by the addition of aqueous 4–(dimethylamino)–pyridine solution [196].

Hydrazine and sodium citrate find their unique applications in the preparation of metal colloids. Hydrazine can be used in all of its forms to reduce transition metals. It allows us to reduce Cu [197] in the presence of PVA and PVP or Pd [180] in the cationic water-in-oil microemulsions of water/CTAB/n–butanol/isooctane at 25 °C. Hydrazine hydrochloride [145] or sulfate [146] turned

out to be efficient in the preparation of colloidal metal. The results recently reported in the literature also comprise the reduction of $HAuCl_4$ by hydrazine in the presence of cationic or nonionic surfactants (cetyltrimethylammonium chloride (CTAC), sodium dodecyl sulfate (SDS), hexadecylpyridinium chloride, dodecylpyrridinium chloride) [198, 199], the production of hexagonal Ag nanoparticles in the presence of aniline [200], the synthesis of Au, Pd, Ag, and Rh nanoparticles stabilized by block copolymers such as polystyrene–*b*–polyvinylpyridine, polystyrene–*b*–poly–*m*–vinyltriphenylphosphine, or poly(ethylene oxide)–polyethyleneimine, in which several polymer-stabilized systems show high thermal stability and can be used in drastic conditions [88, 201–207].

Sodium citrate has been known for half a century as a frequently used reducing agent in the synthesis of colloidal noble metal. Turkevich et al. [108] pointed out that the citrate is not only a reductant, but also an ionic stabilizer in the process of the nucleation and growth of Au nanoparticles reduced by sodium citrate. The preparation of Pt [208] and Ir [209] nanoparticles has also been accessible by the citrate reduction route. However, citrate anion is a noninnocent ligand, and has one significant disadvantage because of the simultaneous formation of the intermediate acetone dicarboxylic acid, which results in compositionally ill-defined colloids in opposition to focused modern nanoparticles. Carbon monoxide is also a useful reducing agent in the synthesis of metallic colloids. Kopple et al. reduced $HAuCl_4$ in the presence of polyvinyl sulfate to obtain Au colloidal particles [210]. CO can also reduce PtO_2 to form Pt nanoparticles [211].

2.1.4. Electrochemical Reduction

The pioneer work in the electrochemical approach to noble metal nanoparticles was developed by Reetz and co-workers [212, 213]. This large-scale synthetic procedure can offer size-controlled nanoparticles. A sacrificial anode, which is oxidized in the presence of quaternary ammonium salt, is used as a metal source. The quaternary ammonium salt is not only an electrolyte, but also a stabilizing agent. The ions are then reduced at the cathode to yield the metallic nanoparticles. In this way, Reetz and co-workers synthesized Pd nanoparticles with various sizes dispersed in acetonitrile/THF. The formation mechanism can be divided into five steps: (1) dissolution of the anode to form metal ions (oxidation of Pd to Pd^{2+}), (2) migration of the metal ions to the cathode, (3) reduction of the metal ions at the surface of the cathode, (4) aggregation of the particles stabilized by the ammonium ions around the metal cores, and then (5) precipitation of the Pd nanoparticles. This method allows us to produce nanoparticles of well-controlled size by varying the current intensity (higher current intensity gives smaller particles), and to obtain high yields (>95%) [212]. This synthetic procedure can be applied to easily oxidized transition metals such as Ni and Cu. The solubility of the colloids obtained can be modulated from nonpolar solvents such as pentane to polar solvents such as water by changing the polarity of the protecting agent (tetraalkylammonium halide for apolar solvents or sulfobetaine for polar solvents) [214]. For less easily oxidized metals such as Pt, Rh,

and Ru, the anode and the cathode used are made of Pt, and the metallic precursor is a transition metal salt [214]. In this new process, the anode is no longer sacrificed, and the metallic precursor is reduced by electrolysis in the presence of a quaternary ammonium salt which is both the electrolyte and the stabilizing agent.

2.1.5. Size Control of Noble Metal Nanoparticles

The size of noble metal nanoparticles is greatly influenced by the kind and concentration of the reducing agent. An appropriate choice of the kind and concentration of the reducing agent is important in controlling the particle size because the reducing rate of noble metal salts to noble metal is greatly affected by those of the reducing agent. In general, an increase in the concentration of the reducing agent increases the reduction rate of noble metal ions, leading to the formation of smaller noble metal nanoparticles. In other words, the protective agents (i.e., capping agents or stabilizers), besides apparently stabilizing the noble metal nanoparticles by protecting them from aggregating, can remarkably perturb the growth of particles through the coordination of active atoms of protective agents to surface metal atoms of noble metal nanoparticles. Accordingly, the amount of protective agents added to the colloidal solutions is expected to affect the growth process for the noble metal nanoparticles. An increase in the ratio of protective agents to noble metal ions can intensively suppress the growth of noble metal particles within a shorter time, leading to smaller noble metal nanoparticles.

Alternatively, one design strategy that shows tremendous potential as a viable route by which to produce metal nanoparticles with improved size control and colloidal stability is to vary the particle growth medium. Examples of such a growth medium include a solvent, template (i.e., using micelles as the microreactor), and a specialized polymer matrix. Founded on this fact, a judicious choice of the reaction media to control the size and/or polydispersity of the particles opens new ways to such production, which is carried out using various colloidal systems such as reverse micelles [i.e., water-in-oil droplets (W/O) stabilized by a monolayer of surfactant (e.g., sodium bis(2–ethylhexyl)sulfosuccinate, usually called Na(AOT))] [99, 215–221], Langmuir–Blodgett films [222, 223], organometallic techniques [224–226], and simple single-phase or two-phase liquid–liquid systems [227–232].

One typical preparation of colloidal metals relying on reaction media is to utilize micelles or liposomes as a stabilizer containing either metal salts or a reductant, thereby acting as microreactors to control the size distribution of the noble metal particles produced. A series of morphologies that can be produced by this method have been described as "cherries" (one central metal particle), "raspberries" (multiple internal particles), "strawberries" (a layer of metal particles outside the micelle boundary), and "red currant" or "ginger root" (a dendritic type with strings of metal particles radiating away from the central micelle) [233].

The conventional strategies for the preparation of small precious metal nanoparticles in the presence of a protective agent have been greatly promoting the development

of metal colloid or nanoparticle chemistry. However stable, "unprotected" small precious metal nanoparticles in organic media with a reasonable metal concentration should be of great help for research in the active and prospective field of metal nanoparticle chemistry. "Unprotected" metal colloids do not mean that the metal nanoparticles are truly bare. In fact, they are stabilized by solvents or simple anions adsorbed on them, or by both. In the presence of protective agents, not only are the formed metal nanoparticles stabilized, but also the clustering processes are influenced by the protective agents. In the absence of protective agents, however, to effectively prepare stable "unprotected" metal nanoparticles with small size and narrow size distribution in organic media, a suitable solvent and an effective method for controlling the precious metal nanoparticle size have to be used. Up to now, some results of the preparation of nanoscopic metal colloids in organic media without traditional protective agents have been described [29, 234–238]; the products can be called "unprotected" metal colloids. The "unprotected" copper colloid in methanol was prepared by the reduction of copper (II) salts with hydrazine hydrate. The produced colloidal particles have a mean diameter of 13.3 nm [234]. The stable Pd colloids with average diameters of 6–8 nm in acetone or propanol are synthesized by using the atom clustering process [29]. These Pd colloidal particles are "living" in the sense that they can be used to produce metal film. Stable palladium colloids with average particles sizes of 8–10 nm were also prepared from thermal decomposition of palladium complexes in methyl isobutyl ketone [235, 236]. By the chemical reduction method, using polyol as the reductant as well as the protective solvent, fine powders of Cu, Ni, Co [237], and tiny noble metal nanoparticles (Pt, Rh, and Ru) with particle sizes less than 3 nm were prepared [107], respectively. In general, the species adsorbed on the "unprotected" metal nanoparticles, that is, solvent molecules and the simple anion, can easily be removed or replaced by various coordination ligands or protective agents. This characteristic makes the "unprotected" metal nanoparticles very attractive as a building block material to prepare various nanoscopic metal clusters with the same core size and demanding different modifying or protecting shells, as well as matrix materials.

2.2. Au Nanoparticles

Au nanoparticles are the most intensive and comprehensive research subject in metal nanoparticles. It is necessary to elucidate exclusively in detail. Gold sols are easily prepared, and are identified by the attractive color which can vary from ruby red through purple to blue. Although the history of the preparation of colloidal gold can be traced back to Faraday's times, the past several decades have witnessed the great development of the production of gold nanoparticles. Among these, two highlighted advances are the aqueous Turkevich method [108–110] and the "phase transfer catalyst" method [238], which yield uniform and very stable Au nanoparticles in an aqueous solution and an organic solvent, respectively. By the Turkevich method, gold nanoparticles are prepared quite easily by refluxing the dilute aqueous solution of $HAuCl_4$ with citric acid or trisodium

citrate. They are larger in size (∼12 nm) than the typical alkanethiol-stabilized nanoparticles (<4 nm) obtained by the "phase-transfer catalyst" method, but a very narrow size distribution can be obtained with standard deviation of 10% in the presence of trisodium citrate. The nanoparticles utilize ionic interactions on the nanoparticle surface to obtain solubility. The stabilizers stem from the corresponding oxidation/decarboxylation products of citrate (such as acetone dicarboxylic and itaconic acids) and the unreacted citrate. They agglomerate irreversibly on removal of the solvent. In combination with hydroxylamine [101] or ascorbic acid [114] reduction of gold salts, a seed-mediated step growth method can produce larger nanoparticles of the desired size. The initially produced Au nanoparticles are used as seeds, and simultaneously, the metal salts are reduced on the surfaces of seed Au particles for producing large particles. Afterwards, if this route is repeated step by step, larger and larger particles will be synthesized. Au nanoparticles of 20–100 nm in diameter that have relatively narrow size distributions (<20% relative standard deviation) are available. In this procedure, there is, however, some drawback that seeds catalyze additional nucleation to cause the polydispersity of particle size, although not dramatically.

When long-chain thiols were used both for stabilization and for derivatization during biphasic syntheses of small gold colloids, such Au colloids behave as "molecules" solution, and have several great advantages. The resultant colloidal materials are obtained not only as stable concentrated solutions, but also as powders that can be easily redispersed after the addition of organic solvents, where they still give stable solutions, even at the highest concentration. Meanwhile, the modified nanoparticles can be stored for quite long periods in both solution and the dry state. Furthermore, the alkanethiol-stabilized nanoparticles are readily synthesized in a variety of core and shell sizes, and are able to undergo thiol substitution reactions that facilitate their self-assembly in ordered nanostructures. Despite these advantages, the solubility of such nanoparticles is limited to organic solvents. Complementarily, $Ph_2P(m–C_6H_4SO_3Na)$ and better $P(m–C_6H_4SO_3Na)_3$-stabilized Au colloids behave as an aqueous solution of "molecules" [239, 240]. They can be isolated as solid materials, and then be redissolved in water in any concentration forming blood-red solutions.

An alternative simple procedure has also been developed to obtain thiol-derivatized particles in an organosol, where, in the presence of an agent for inducing phase transfer, metal nanoparticles of desired shape and size distribution preformed in a hydrosol are easily transferred to a nonpolar medium containing an alkanethiol [230]. These inducing phase-transfer agents include concentrated HCl, orthorphosphoric acid, NaH_2PO_4, NaCl, and so forth [187, 230, 241]. To a biphasic mixture, the addition of phase-transfer agents will result in a rapid movement of metal nanoparticles from a hydrosol to a hydrocarbon layer containing thoils. By employing such a procedure, what has been achieved is not only the preparation of thiol-derivatized Au nanoparticles in organic solvents, but also the preparation of spherical, thiol-derivatized nanoparticles of silver as well as platinum in organic solvents. This is particularly advantageous since many of the water-soluble reagents may be easily washed away. Besides, this method may provide a rather

unique way of replacing polymeric or ligand shells surrounding metal nanoparticles by thiol molecules.

Intriguingly, it has been shown that the size distribution of tholate-encapsulated Au nanocrystals can be greatly narrowed when refluxed with excess long-chain thoils ligand [227]. Further size fraction occurs by the slow lowering of the colloidal temperature, during which the excellent homogeneity in particle size of the top layer of Au nanoparticles is given. By adopting this digestive ripening process, the relative standard deviation can decrease to ~5%. Other experimental evidence illustrates the evolution of both size and shape of Au nanoparticles following heating treatment [242]. After an Au nanoparticle solution is subjected to reflux at 110 °C under reduced pressure, an increase in core size from 1.5–2.5 nm (80% populations) to 4.5–5.5 nm (>90% populations) is observed. The other striking feature is that the particle shapes evolve from irregular to a "hexagon" outline. In view of the molecular and crystal natures of such core–shell systems, the size and shape are inherently a dynamic process, and an evolution may occur as result of changes in the chemical potentials of the particles. The size and shape evolution of the encapsulated nanoparticles in the solution may involve a balance of chemical potentials via desorption and redesorption of the shell components and coalescence of the cores as the driving force for the eventual size and shape.

Besides the well-known citrate-stabilized gold nanoparticles, many studies also handle aqueous solution of gold nanoparticles. When the nanoparticles are stabilized by an alkanethiol terminating in either an ionic species or a carboxylic acid group, it can lead to water-soluble thiolate-coated gold nanoparticles. The aqueous solubility of these nanoparticles is often coupled to the pH of the solution, and the presence of functional groups that can participate in hydrogen bonding between nanoparticles will lead to particle agglomeration. Additionally, the presence of ions in the system enhances the interference during conductivity measurements and electron transport studies. Ionic effects are of particular concern in nanoelectronics applications, where they can accentuate threshold nonuniformities associated with background charges.

However, so far, few synthetic approaches adapted to directly preparing both water- and oil-soluble gold nanoparticles are available. The reduction of gold salts with o–anisidine as the reductant offers convenient access to gold nanoparticles in both aqueous and organic systems [117]. The suitable reducing environment such as in micelles and liposomes permits reduction at more moderate conditions, and results in higher colloid uniformity than usual methods. In the organic medium, polymer production (poly(o–anisidine) in its doping state) simultaneously occurs.

2.3. Cu and Ag Nanoparticles

Metallic Cu has shown the catalytic ability in the formation of aldehydes from the conversion of methanol and ethanol [243, 244]. For the nanoscale Cu entities, colloidal preparations have been the essential aspect. The preparation is generally performed under an inert atmosphere since copper nanoparticles comparatively suffer from oxidation relative to noble metal nanoparticles. A wide range of techniques, such as chemical reduction (strong reductants including hydrazine (N_2H_4) and sodium borohydride ($NaBH_4$)

can reduce copper salts to metal instantly) [197, 245], γ-radiolytic reduction [246–248], and the reduction of copper ions in supercritical fluids [249, 250], have been developed to synthesize spherical nanoparticles. Especially, Cu nanoparticles with rather narrow size distribution can be prepared by the clustering of acetone-solvated Cu atoms generated via metal vapor synthesis [251]. In addition, other than the Cu nanoparticles, the morphologies with the rod and fiber shapes, which were, respectively, achieved in the presence of soft template–Cu(AOT)$_2$–isooctane–salt–water colloidal assemblies and hard template–carbon nanotubes [reduction of copper salts with H$_2$ at high temperature (500 °C)], have been described [252, 253]. In the presence of soft template-surfactant (cetyltrimethylammonium p–toluene sulfonate), elongated copper nanoparticles of 500 nm length and 50 nm width were prepared by a pulse sonochemical method [254].

Ag nanoparticles are easily prepared by conventional chemical reduction methods. The citrate (Turkevich method) [229, 255, 256] and NaBH$_4$ [255, 257–259] reduction method are the two standard chemical preparation routes. The synthesis of silver nanoparticles in AOT reverse micelles by mixing AOT reverse micellar solutions at the same water content containing Ag(AOT) and N$_2$H$_4$ or NaBH$_4$ offers a stable Ag colloidal solution and facile control of particle size [260]. Following the treatment by a size-selected precipitation process, nearly monodispersed Ag nanoparticles are accessible [261, 262]. Shape-controllable synthesis is always a challenging subject in nanoparticle preparation. This is, without exception, for the synthesis of silver nanoparticles. An amazing result of the shape control of Ag nanoparticles was reported by Mirkin and co-workers recently [263]. In the presence of bis(p–sulfonatophenyl) phenyl–phosphine dihydrate dipotassium salt (BSPP) (as a stabilizing agent), they observed that large quantities of silver nanoprisms evolve from the initial spherical nanoparticles through the fluorescent light irradiation. The production of Ag nanoprisms lies in the light-induced ripening process in which the small nanoprisms act as seeds, and then grow as the small spherical nanocrystals are digested, as shown in Figure 2. Most recently, one arresting experiment shows that triangular Ag nanoprisms are obtained by boiling AgNO$_3$ in N,N–dimethyl formamide (a powerful reducing agent against Ag$^+$ ions) in the presence of PVP [264]. The optimal experimental conditions are chosen ([AgNO$_3$] = 0.022 M, [PVP] = 0.06 mM) so that a large population of (mainly) triangular, and in general polygonal, nanoprisms are formed in solution. Another attractive experiment shows that truncated triangular Ag nanoplates can be synthesized
Figure 2. Fluorescent light-induced shape transformation of Ag nanospheres into triangular nanoprisms. Reprinted with permission from [263], R. Jin et al., *Science* 294, 1901 (2001). © 2001, American Association for the Advancement of Science.

in large quantities through a seed-mediated growth (by reduction of Ag$^+$ ions with ascorbic acid on silver seeds in a basic solution) in the presence of highly concentrated micelles of CTAB [115, 265]. It is noticeable that, in these cases, the optical properties of Ag nanoprisms or triangular nanoplates varied in contrast to that of spheroidal Ag nanoparticles. An intensive in-plane dipole resonance absorption peaks at 550–675 nm, which gives a red- or blue-colored colloidal solution. Another breakthrough in the shape control of Ag nanoparticles was achieved by Xia and co-workers [266]. They fabricated monodisperse Ag nanocubes in large quantities by reducing silver nitrate with ethylene glycol in the presence of PVP. Here, the concentration of AgNO$_3$ was high enough (0.25 M), and the molar ratio between the repeating unit of PVP and AgNO$_3$ was kept at 1.5. Meanwhile, the presence of PVP and its molar ratio (in terms of repeating unit) relative to silver nitrate both played key roles in the determination of the geometric shape and size of the product. The generated single-crystalline Ag nanocubes were characterized by a slightly trunctated shape bounded by {100}, {110}, and {111} facets. Other techniques, including pulsed laser irradiation [21, 267], γ irradiation [68], pulsed sonoelectrochemistry [58, 268], and ultraviolet irradiation [117], have proven to be efficient methods to control the shapes of Ag nanoparticles.

2.4. Other Noble Metal Nanoparticles

Pt colloids are characterized by their brown color. An inimitable characteristic possessed by Pt nanoparticles is a forceful tendency for particles to form with highly faceted and irregular surfaces [93, 269–271]. Moreover, these nonspherical particles are generally single crystals. Pt colloids prepared by the reduction of Pt (II) and Pt (IV) compounds with hydrogen were described as early as 1941. This method is now experiencing a renaissance, especially in the preparation of shape-selective Pt nanoparticles. One of the elegant experiments was accomplished by changing the ratio of the concentration of the capping polymer material (sodium polyacrylate) to that of the platinum cations used in the reductive synthesis (with H$_2$ as the reducing agent) of Pt colloidal nanoparticles in solution at room temperature, where cubic (80%), tetrahedral (60%), and truncated octahedral (TO) nanoparticles have been prepared in high percentages, thus making it possible to study the catalytic activities of nanoparticles with different shapes and crystal facets [93].

Here, the shape distribution of platinum nanoparticles at different stages of their growth is a function of time. The small nanoparticles formed during the early stages of growth or at high polymer concentration displayed distributions with a dominance of shapes having stable {111} faces. As the growth continues or at a low polymer-to-Pt-complex concentration ratio, the tetrahedral nanoparticles are transformed into TO, and eventually into cubic shapes. The initially rapid reduction of Pt^{2+} produces an initial growth that gives very small nanoparticles having the expected stable {111} faces present in tetrahedral and TO. The competition between polymer capping and H$_2$ reduction of the Pt^{2+} complex occurring on the most catalytically active {111} surface determines the fate of these tetrahedral nanoparticles. If capping dominates, tetrahedral nanoparticles of small size

are formed. Otherwise, the rapid reduction of Pt^{2+} on the most active {111} surface leads to its disappearance and the formation of a {100} face due to the deposition of Pt atoms on it to give larger TO nanoparticles having both {100} and {111} faces. The TO nanoparticles continue to grow until transformed into cubic nanoparticles, which have all of their six faces of the {100} type. It also has been noticed that the polymer, acting both as a capping molecule and as a buffering agent, plays an important role in this competition.

Alternatively, a higher selectivity of cubic oxalate-stabilized Pt nanoparticles (>90%) are obtained through reducing K$_2$[Pt(C$_2$O$_4$)$_2$] with hydrogen [272]. Using thermosensitive poly(N–isopropylacryamide) as a capping polymer, it was found that the morphology of resultant Pt nanoparticles was affected by temperature, and the Pt nanoparticles prepared at temperatures above the critical solution temperature of the thermosensitive polymer had sharper size and shape distributions (68% of cubic nanoparticles) [273]. Besides organic polymers, polyphosphate [274], sodium citrate, and a mixture of sodium citrate and sodium hydroxide [96] were also adopted to stabilize Pt colloids prepared by reducing Pt (II) complexes with hydrogen. In all of these preparation examples, the resulting colloidal solutions usually contain Pt nanoparticles of different shapes, albeit one shape has a dominant distribution. However, up to now, few methods could really be applied to realize the production of nanoparticles with a single shape.

Palladium and ruthenium are the two key metals of catalytic activity. In principle, the synthetic routes are the same as for gold and platinum nanoparticles. For instance, the reduction of H$_2$PdCl$_4$ and RuCl$_3$, respectively, with citrate leads to characteristic brown-colored colloidal solutions. Many reports regarding the preparation of Pd nanoparticles have emerged in our line of vision [230, 237, 270]. More recently, Pal and co-workers [275, 276] described the synthesis of palladium particles produced in aqueous surfactant media. Their catalytic properties toward the reduction of a number of dyes in the presence of different reducing agents, such as NaBH$_4$, N$_2$H$_4$, and ascorbic acid, were investigated. The dyes used were methylene blue, phenosafranin, fluorescein, 2,7–dichlorofluorescein, eosin, and rose bengal. In fact, some zerovalent organometallic complexes can be converted into colloidal metal by reduction or ligands displacement. For example, Pd(dba)$_2$ [277] (dba = dibenzylidene acetone) and Pd$_2$(dba)$_3$ [278] dimer can be reduced by hydrogen at atmospheric pressure to obtain 2.5 nm Pd nanoparticles. The use of carbon monoxide also allows obtaining smaller particles of 2 nm diameter. Similarly, with this reducing agent, Pt(dba)$_2$ and Pd(dba)$_2$ can be reduced to generate nanoparticle organosols in the presence of PVP, cellulose acetate, or cellulose nitrate in THF [279, 280]. Nevertheless, the reports on the preparation of ruthenium nanoparticles are relatively scarce. Notable exceptions are outlined as follows: Ru nanoparticles of various sizes and shapes generated from the decomposition organometallic precursor of Ru (Ru(COD)(COT) COD = 1,5–cyclooctadiene; COT = 1,3,5–cyclooctatriene) at room temperature in the presence of polymer (PVP or cellulose acetate) or ligands (alkylthiols or alkylamines) [281]. Particularly, in the case of amine ligands, the particles display an elongated

morphology, and have a tendency to form worm- or rod-like structures at high amine concentration. Sponge-like Ru nanoparticles with a porous structure were prepared by the reaction of $[Ru(C_8H_{10})(C_8H_{12})]$ with H_2 in methanol or THF/methanol [282]. The particle size can be controlled in the range 15–100 nm by varying the MeOH/THF ratio. The particles catalyze benzene hydrogenation without modification of their size or structure. Their formation mechanism is proposed to occur in the droplets of a nanosized emulsion, which act as nanoreactors.

2.5. Bimetallic Nanoparticles

The interest in the synthesis of bimetallic and even trimetallic nanoparticles originates from the unique properties compared to monometallic colloids. These new properties can be ascribed to a synergy between the two metals forming particles. The synthesis of bimetallic colloids can be implemented either by simultaneous or successive reduction of two metallic precursors. Most of the synthetic procedures used to prepare monometallic particles can be suitable for the bimetallic particle synthesis.

2.5.1. Coreduction of Metallic Precursors

A wide range of synthetic protocols used for the monometallic particle preparation was tested to be efficient in the production of bimetallic colloids because the principles of these protocols are identical to those applied for bimetallic nanoparticles. Polymer-stabilized bimetallic nanoparticles in hydro alcoholic media can be prepared by the simultaneous reduction of two noble metal salts in refluxing alcohol. PVP-stabilized Pd/Pt bimetallic particles were produced by refluxing an aqueous/alcohol mixture containing $PdCl_2$ and H_2PtCl_6 [283–287]. Following the same procedure, colloidal Au/Pd [288], Pt/Rh [289], Pt/Ru [290], Pd/Ru [291], and Ag/Pd [292] stabilized by PVP were synthesized by coreduction in refluxing alcohol of the corresponding metal salts. Other polymer-protecting agents such as PNIPAAm [293] were also used. Easily oxidized metal colloids such as Cu or Ni are difficult to prepare in comparison with noble metal nanoparticles made of Rh, Pt, or Rh. However, Cu/Pd [294–296], Cu/Pt [294], or Pd/Ni [297, 298] bimetallic nanoparticles stabilized by PVP were obtained by coreduction of the corresponding metallic hydroxides in refluxing glycol. The thermal decomposition of palladium acetate and copper acetate in a reducing alcohol solvent with a high boiling point (2–ethoxyethanol) has also been used to prepare PVP-stabilized Pd/Cu bimetallic colloids [299]. Gamma irradiation can be efficient in the production of bimetallic particles. Delcourt and co-workers demonstrated the synthesis of PVA or polyacrilic acid (PAA)-stabilized Ag/Pt [300] colloids by irradiation of a solution containing Ag_2SO_4 and K_2PtCl_4. Nonionic surfactants-stabilized Au/Pt nanoparticles were fabricated with γ irradiation of a mixture of $NaAuCl_4$ and $NaPtCl_6$ [301]. The preparation of Pt/Pd, Cu/Au, and Au/Pt bimetallic nanoparticles has been conducted in water-in-oil microemulsions [302–304]. The application of tetraalkylammonium hydrotriorganoborates $(NR_4(BEt_3H))$ as a reducing agent was reported by Bönnemann and co-workers for the synthesis of a series of bimetallic colloidal particles [190, 191, 305–307]. Organometallic

complexes can also be used as precursors of bimetallic colloids. $Pt(dba)_2$ and $Ru(COD)(COT)$ in various proportions were reduced with hydrogen to obtain PVP-stabilized Pt/Ru nanoparticles [308]. Esumi and co-workers [309, 310] developed a procedure to synthesize Ag/Pd and Ag/Pt by photo or $NaBH_4$ reduction of silverbis(oxalato)palladate or silverbis(oxalato)platinate complexes. The electrochemical technique developed by Reetz also allows the preparation of bimetallic nanoparticles. To do so, two different sacrificial metallic anodes and a Pt cathode were immersed in an electrolyte in the presence of a stabilizing agent (tetraalkylammonium salt) [311]. The metallic ions were generated by current, and reduced at the cathode to give tetraalkylammonium stabilized bimetallic colloids.

2.5.2. Successive Reduction of Metallic Precursors

Core/shell structured bimetallic colloids are generally synthesized by the deposition of a second metal on a preformed metallic particle through successive reduction of metallic precursors. The second metal has to be deposited on the whole surface of the performed monometallic nanoparticles. A preliminary synthesis was achieved by Toshima and co-workers [312] to generate core/shell Au/Pd nanoparticles, conducted, in fact, to randomly distributed Au/Pd bimetallic nanoparticles. On the other hand, the fabrication of Au/Pd and Au/Pt nanoparticles stabilized by such water-soluble ligands as $P(m–C_6H_4SO_3Na)_3$ or $p–H_2NC_6H_4SO_3Na$ has been described by Schmid et al. [313, 314]. Henglein achieved the synthesis of bimetallic gold and platinum particles of the Pt/Au, Au/Pt core–shell type and bimetallic $Pd_{core}Au_{shell}$ nanoparticles with hydrogen reduction and radiolysis techniques, respectively [73]. Likewise, he synthesized citrate-stabilized trimetallic $Pd_{core}Au_{shell}Ag_{shell}$ particles in aqueous solution by radiolytic methods [95, 315]. Toshima designed an original synthetic route to core/shell bimetallic colloids, by which PVP-stabilized Pd/Pt bimetallic colloids with a Pd core were generated [316]. The principle of this method is that hydrogen can easily be adsorbed on a Pd surface to form a metal-H bond. This H atom is a good reducing agent, and the Pt ions added to the preformed Pd colloids are easily reduced by the adsorbed hydrogen atoms. The zerovalent Pt formed will deposit onto the Pd surface to generate a perfect core/shell structure. Additionally, Pal prepared bimetallic Au/Ag particles with a core–shell type structure by a UV-photoactivation technique [317].

The synthesis of magnetic bimetallic and even trimetallic nanoparticles [318, 319] has been addressed in many publications. Well-known ferromagnetic alloys consist of $3d$ ferromagnetic metals and noble metal elements of the platinum group. The synthesis of ordinary bimetallic nanoparticles can be considered from two aspects: the coreduction of two metal salts in solution for alloy nanoparticles, and covering the "seed" with a second metal during a second reduction step for core–shell metallic nanoparticles. Nevertheless, for the preparation of magnetic alloy nanocrystals, the cases are different. The key point in the synthesis is the simultaneous reduction of noble metal salts and thermolysis of organometallic precursors. According to this principle, monodispersed FePt [320] and $CoPt_3$ [321] nanoparticles

are, respectively, prepared by the concurrent reduction of $Pt(acac)_2$ (acac = acetylacetonate, $CH_3COCHCOCH_3$) with 1,2–diol and decomposition of $Fe(CO)_5$ or $Co(CO)_8$. Similarly, $Fe_xCo_yPt_{100-x-y}$ alloy nanoparticles with size focusing are prepared by the simultaneous reduction of $Co(acac)_2$ and $Pt(acac)_2$ and thermal decomposition of $Fe(CO)_5$ [319]. Recently, Cheon and co-workers [322] showed the first utilization of redox transmetalation reactions for the synthesis of two different types, solid solution and core–shell, of CoPt nanoalloys under 10 nm without the need for additional reducing reagents. Stoichiometry tuned solid-solution-type CoPt nanoalloys are synthesized by the reaction between $Co_2(CO)_8$ and $Pt(hfac)_2$ (hfac = hexafluoroacetylacetonate). Core–shell type nanoalloys in which Pt resides as a shell around a cobalt nanoparticle core are achieved by the reaction of $Pt(hfac)_2$ with cobalt nanoparticles. The obtained nanoalloys are moderately monodispersed ($<10\%$) without any further size selection process. These two distinct reaction routes can be, respectively, elucidated as

$$Co_2(CO)_8 \xrightarrow{\triangle} Co \text{ nanoparticles}$$
$$\xrightarrow[\triangle]{Pt(hfac)_2} Co_{core}Pt_{shell} + Co(hfac)_2 \qquad (2)$$

$$Co_2(CO)_8 \xrightarrow[\triangle]{Pt(hfac)_2} Co_xPt_y + Co(hfac)_2 + 8CO \qquad (3)$$
An $Ag_{core}Co_{shell}$ structure of bimetallic particles has been prepared using standard Schlenck techniques [323]. This method is based on the thermal decomposition of dicobalt octacarbonyl in combination with a transmetalation [322] reaction with water-free $AgClO_4$ using oleic acid and tridodecylamine as surfactants, following the overall reaction

$$Co_2(CO)_8 \xrightarrow{\triangle} Co \text{ nanoparticles}$$
$$\xrightarrow[\triangle]{2AgClO_4} (2Ag)_{core}Co_{shell} + 8CO + Co(ClO_4)_2 \qquad (4)$$
As a result, bimetallic Ag/Co nanoparticles were formed.

3. SPECTROSCOPIC CHARACTERIZATION

It appears that the skillful application of a wide range of different synthetic methods has catalyzed a fruitful and still growing interest in nanomaterials such as nanoparticles, nanotubes, nanorods, and nanowires. Nevertheless, one might have not imagined what the situation is in nanoscience without the coinage of various advanced physical methods to characterize these materials. We would even know little about the substance in this mesoscopic world up to now. The optimization of the analytical tools and their wide availability will contribute to a better understanding of these materials. As far as the characterization of nanoparticles is concerned, a series of spectroscopic measurement approaches have been established. Among these, transmission electron microscopy (TEM), X-ray diffraction (XRD), and dynamic light scattering (DLS) are the most efficient and extensively utilized characterization techniques.

3.1. TEM

Transmission electron microscopy is an indispensable tool in the identification of nanoparticle size and shape, particularly, when particle shape is more important. Although scanning tunneling microscopy (STM) and atomic force microscopy (AFM) can provide atomic-scale resolution images of large crystal surfaces, they are unable to clearly resolve the atomic lattices of nanoparticles as done by high resolution TEM (HRTEM) because of the surface coating and the wobbling of the nanocrystals under the scanning tip. Figure 3 presents a comparison of a TEM image of Ag nanodisks with their corresponding AFM image. It can be seen that, from the TEM image, the outlines of round circles can be unambiguously defined, while the AFM image shows vague outlines of Ag nanodisks. However, the advantage of using AFM as a tool for the characterization of nanoparticles is that it can provide a three-dimensional outline of an object rather than a two-dimensional projection of a three-dimensional object as given by TEM. HRTEM is very powerful in revealing the atom distributions on the nanocrystal surfaces, even if they are capped with a layer of stabilizing polymers and allow the determination of individual crystallite morphology with lattice contrast. Figure 4 shows the typical particle shapes observed by HRTEM,
Figure 3. Comparison of TEM images of Ag nanodisks with their AFM images. (a) TEM images of the silver nanodisks obtained after 4 h aging at 40 °C. The particles in *a* lie flat on the substrates, while those in *b* stack together. The arrows in *b* show the partially stacked particles, giving an ellipsoidal shape in projection. Figure 3. Continued.

in which atom rows or lattice fringes can be resolved clearly. The function of today's TEM is versatile, which offers not only the atomic-resolution lattice images, but also chemical information at a spatial resolution of 1 nm or better, and allows direct identification the chemical composition of a single nanocrystal [324–327]. With a finely focused electron probe, the structural characteristics of a single nanoparticle can be fully characterized. Moreover, TEM is unique for characterizing the *in-situ* structural evolution of nanocrystals resulting from annealing, electric field, or mechanical stress, such as imaging a single carbon nanotube when a mechanical or electrical measurement is being carried out *in-situ* [328].

A modern HRTEM is composed of an illumination system, a specimen stage, an objective lens system, the magnification system, the data recording systems, and the chemical analysis system. The electron gun is the heart of the illumination system, which typically uses an LaB_6 thermionic emission source or a field emission source. The LaB_6 gun gives a high illumination current, but the current density and the beam coherence are not as high as those of a field emission source. The field emission source is greatly advantageous for performing high coherence lattice imaging, electron holography, and high spatial resolution microanalysis. The objective lens is like the human eye, and is the core device of a TEM which determines the limit of image resolution. The magnification system consists of intermediate lenses and projection lenses, and it gives a magnification up to 1.5 million. The chemical analysis system includes energy-dispersive X-ray spectroscopy (EDS) and electron energy loss spectroscopy (EELS); both can be used complementarily to quantify the chemical composition of the specimen. EDS relies on the counting of X-rays emitted from the beam-illuminated specimen region as a function of the photon energy, and it is probably the most precise microanalysis technique in TEM. EELS analyzes the intensity distribution of the transmitted electrons as a function of their energy loss. It provides not only the chemical information on the specimen, but also its electronic structure. A complementary application of the diffraction, imaging, the spectroscopy techniques available in a TEM, is likely to give a more precise and reliable determination of the crystal structure.

In theory, the image formation is a complex process. The entrance surface of a thin foil specimen is illuminated by a parallel or nearly parallel electron beam. The electron beam is diffracted by the lattices of the crystal, forming the Bragg beams which are propagating along different directions. The electron–specimen interaction results in phase and amplitude changes in the electron wave. For a thin specimen

and high-energy electrons, the transmitted wave function $\Psi(x, y)$ at the exit face of the specimen can be assumed to be composed of a forward-scattered wave. The exit wave $\Psi(x, y)$ contains the full structural information on the specimen. The diffracted beams are focused in the back focal plane, where an objective aperture can be applied. Electron waves leaving the specimen in the same direction (or angle θ with the optical axis) are brought together at a point on the back focal plane, forming a diffraction pattern.

3.2. X-Ray Diffraction

Similar to the corresponding bulk material, nanocrystal structures can be determined by X-ray diffraction. As judged from the diffraction peaks, the structure of the nanocrystallites can have characteristic features either of matching the bulk material or of a unique structure. A powder X-ray diffraction pattern of a sample of nanocrystals, unlike TEM, probes a large number of crystallites that are statistically oriented. The XRD peaks of the nanocrystallites are considerably broadened compared to those of the corresponding bulk material because of the finite size of the crystallites. The average size of the nanocrystallites can be determined from the width of the reflection according to the Debye–Scherrer equation [329]:

$$D = \frac{0.9\lambda}{\beta \cos \theta} \qquad (5)$$

where β is the full width at half maximum (FWHM) of the peak, θ is the angle of diffraction, and λ is the wavelength of the X-ray radiation. For very broad diffraction lines, a previous deconvolution of the signals in two components of strongest reflections is essential to obtain a more accurate FWHM measurement. It can be concluded that the diffraction peaks become wider gradually with a continual decrease in nanoparticle size (estimated by the Debye–Scherrer equation). Figure 5 records the wide-angle X-ray diffraction patterns of the PVP-protected Pt nanoclusters with different size. It can be found that, for the smaller noble metal nanoparticles, only a broad (111) peak is discernible. A study reported by Leff et al. shows a similar result for the long-chain alkylthiol-passivated gold nanoparticles [330]. A dispersed peak is the particularity of the metal colloidal cluster for the very small size of the particles [188, 331, 332].

X-ray diffraction is powerful in refining the structure of nanoclusters, particularly those smaller than 2 nm in diameter. If the particles are oriented randomly so that the entire assembly can be treated as a "polycrystalline" specimen composed of nanocrystals with identical structure but random orientation, so that the scattering from each can be treated independently, the structure of the nanocrystals can be refined by a quantitative comparison of the theoretically calculated diffraction spectra for different nanocrystals models with the experimentally observed ones. This was recently performed by Cleveland et al. in the determination of decahedral Au nanocluster structures with 1.7–1.9 nm size [333, 334].

X-ray diffraction is also a unique tool in the study of the self-assembled nanocrystal superlattice structures.
Figure 5. X-ray diffraction patterns of PVP–Pt nanoparticles obtained at various initial concentration ratios of PVP/Pt. PVP (wt%)/Pt (mM)=(a) 0.5%/1.0, (b) 1.0%/1.0, (c) 2.0%/1.0, and (d) 4.0%/1.0.

The diffraction spectrum in the high-angle range is directly related to the atomic structure of the nanocrystals, while the spectrum in the small-angle region is directly associated with the ordered assembly of the nanocrystals [335, 336]. By examining the diffraction peaks that are missing from the spectrum, one may identify the crystallographic packing. This analysis is based on the assumption that each particle is identical in size, shape, and even orientation (i.e., the same X-ray scattering factor), so that the extinction rules derived from diffraction physics apply. In practice, however, a fluctuation in either the size, orientation, or shape can easily make this assumption untenable. This is the reason why a quantitative analysis of the low-angle diffraction spectrum is rather difficult. Therefore, caution must be exercised in the interpretation of the 3-D assembly using X-ray diffraction data. However, X-ray diffraction is still the most powerful technique for evaluating the average interparticle distance D_{XRD}, and is a unique technique for studying the *in-situ* pressure- and/or temperature-induced phase transformations in nanocrystals [337].

Sometimes, ordered packing is only in short range. Moreover, in the region where two layers overlap, the short-range order in each layer is overshadowed by the disordered component of the other layer. It appears that an ordered structure does not exist as the number of stacked layers is increased. This is owing to complications from the 2-D projection effect in TEM imaging. In this case, X-ray diffraction might show reasonably well-ordered structures. Although X-ray diffraction may indicate ordered packing in the assembled nanocrystals, the range of ordering is still unknown. This is similar to the X-ray diffraction spectrum of a polycrystalline specimen, in which analysis of the grain size from the diffraction spectrum is rather difficult because there are many factors, such as defects, dislocations, and structural imperfections at surfaces/interfaces, which can give rise to line broadening. In this case, TEM is effective for imaging particle packing.

3.3. Dynamic Light Scattering

Dynamic light scattering (DLS), also known as photon correlation spectroscopy (PCS), is an effective method to study the size of colloids (hydrodynamic radius), the kinetics of aggregation of colloids, and the structure of the aggregates formed. DLS measures the autocorrelation function $C(t)$ of the intensity of the scattering light [338]. $C(t)$ is defined as

$$C(t) = \langle I(0)I(t) \rangle \tag{6}$$

where $I(t)$ is the scattering intensity at time t. $\langle \cdots \rangle$ indicates averaging over the measuring time. For monodispersed particles, $C(t)$ is an exponential decay function:

$$C(t) = B + Ae^{-t/\tau_c} \tag{7}$$

where $B = \langle I \rangle^2$ is the background or noise level, $A = \langle I^2 \rangle - \langle I \rangle^2$ is the signal magnitude, and τ_c is the correlation time. Assuming spherical particles, the correlation time is related to the size of particles by

$$\tau_c = 3\pi\eta d/2k_B Tq^2 \tag{8}$$

where η is the viscosity of the solvent, d is the average diameter of the particles, k_B is the Boltzmann constant, T is the temperature of the colloid, and q is the magnitude of the scattering wavevector. By measuring the autocorrelation function $C(t)$ and fitting it with (7), the correlation time, and consequently, the particle size, can be found. However, the measurements of a colloidal system can sometimes be complicated by several other factors. First, the single exponential decay function for the correlation only applies to colloids with monodispersed particles. For colloids containing binary or tertiary structures with different sizes, extra exponential terms must be the following fitting function:

$$C(t) = B + A_1 e^{-t/\tau_{c1}} + A_2 e^{-t/\tau_{c2}} + A_3 e^{-t/\tau_{c3}} \tag{9}$$

where each exponential term corresponds to one component of tertiary structures. The scattering of light from colloidal particles scales as the sixth power of their size if their size is much smaller than the wavelength λ. Therefore, the coefficients A_i $(i = 1, 2, 3)$ in (9) rely heavily on the size and concentration of each component. In some cases, one or two terms in Eq. (9) might be dominant, and the contribution from others can be neglected. Secondly, strong absorption of some highly concentrated colloids induces local heating in the path of the laser beam, which in turn causes a change of the optical index of reflection of the medium and a divergence of the beam. This phenomenon, normally called thermal blooming or the thermal lensing effect [339–341], results in a faster decay of the correlation function than the exponential decay. A second cumulant term must be introduced in order to obtain the correct particle size from τ_c [342]. The correlation function for a strongly absorbing monodispersed colloid therefore is

$$C(t) = B + Ae^{-t/\tau_c - t2/\tau_f 2} \tag{10}$$

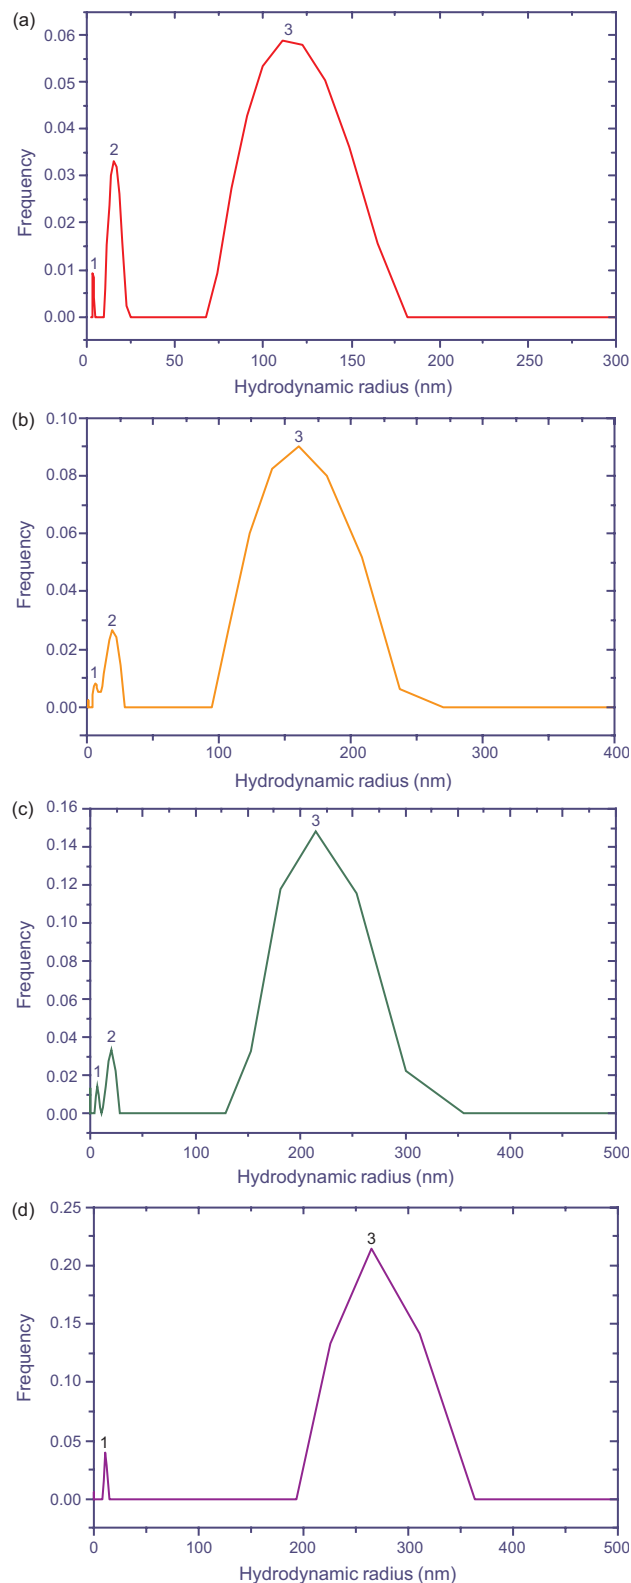
where the second cumulant τ_f depends on the intensity of the incident beam and the properties of the absorbing medium. As a representative example, shown in Figure 6


Figure 6. Plots of the hydrodynamic radius distribution of Ag colloids protected by 2–mercaptobenzimidazole in 50% aqueous solution at 25 °C, which were obtained by DLS after the sample being left for (a) 0 h, (b) 2 h, (c) 4 h, and (d) 6 h. are the hydrodynamic radii of Ag colloids measured by DLS after the sample was left for different periods. The distribution of the hydrodynamic radius of the scattering entity was calculated by the CONTIN method according to the autocorrelation function of the intensity of the scattering light.

4. PROPERTIES

4.1. Size- and Shape-Dependent Properties

The physical and chemical properties of nanoparticles have been addressed in many publications, which depend on several structural features of nanoparticles themselves, such as (1) the particle size and the size dispersity, (2) the structure of the particles, (3) the surface of the particles, (4) the shape of the particles, and (5) the organization of the particles into a nanomaterial and their dispensability. Monodispersed metal or semiconductor nanoparticles, which means uniformity in both size (the standard deviation is less than 10%) and shape, are paramount both for theoretical and practical reasons. Owing to their extremely small size, the characteristic of nanoparticles which makes them different from macroscopic solids or single atoms is mainly that the surface atoms have a very large percentage. A characteristic high surface-to-volume ratio provides sites for the efficient adsorption of reacting substrates, leading to unusual size-dependent chemical reactivity. Here, the role played by particle size is comparable, in some cases, to the particle chemical composition, thus adding another flexible parameter to the design and control of their behavior. Because of this characteristic, nanoparticles hold many novel physical and chemical properties that are size dependent, as described in many documents [11, 343–359]. Size-dependent physical properties were surveyed in a recent review article [360]. Size-dependent chemical properties of nanocrystals have been extensively discussed by Rao et al. in the other latest review [361]. These properties highlight several important aspects as follows: (1) electronic structure and properties (quantum size effects), (2) chemical reactivity, (3) self-assembly of nanocrystals, and (4) size-dependent structural and thermodynamic properties such as bond lengths, melting point, and specific heat.

Recent numerous findings added new dimensions to this subject. One representative example is that the nanoparticles with diameters usually smaller than 10 nm in size can be self-assembled. Moreover, it is in this range that many exciting and unusual physical properties are enhanced. Particularly, a decrease in the size of nanoparticles means an increase in reactivity, for example, for oxidation and a decrease of the Curie temperature of ferromagnetic materials [362]. A gigantic extensibility (elongation exceeds 50 times) without a stain-hardening effect was obtained after cold rolling of nanocrystalline copper at room temperature [363]. A size-induced transition from a positive to a negative temperature coefficient of electrical conductivity is observed by thin films of a series of (six) dodecanethiol-stabilized gold nanoparticle complexes with the Au core diameter progressively increasing from 1.7 to 7.2 nm [364]. The size of the Au core may influence both its intrinsic conductivity

and the charging energy barrier for tunneling to an adjacent monolayer-encapsulated cluster. The melting temperature of nanocrystals strongly depends on the crystal size, and is substantially lower than the bulk melting temperature. The melting points of sodium clusters consisting of 70–200 atoms are on the average 33% (120 K) lower than the sodium bulk value (371 K) [365]. A recent study shows that the electrooxidation rates of formic acid, formaldehyde, and methanol in acidic electrolyte on carbon-supported platinum nanoparticle films are changeable by varying the particle diameters [366]. The methanol electrooxidation rates on larger nanoparticles ($d > 4$ nm) are larger than those on Pt particles with diameters below 4 nm; formic acid electrooxidation shows a reverse behavior, while formaldehyde electrooxidation displays little sensitivity to Pt nanoparticle size. Otherwise, the shift of electron energy levels as a function of particle size causes the emission of photons with unique wavelengths, potentially useful for optoelectronics.

The shape of nanoparticles is another important variant to be considered in the design of nanomaterials. The particle shape determines the crystallographic structures of the particle surface since the different geometric nanoparticles are enveloped by different oriented planes in a different number. The {111}, {100}, and possibly {110} surfaces of face-centered cubic structured metal particles are different not only in surface atom densities, but also in the electronic structure, bonding, adsorption, and possibly chemical reactivity (catalysis properties). For instance, surface energies associated with different crystallographic planes are different, and a general sequence may hold: $\gamma_{\{111\}} < \gamma_{\{100\}} < \gamma_{\{110\}}$. Thus, the tetrahedral Pt nanoparticles enclosed mainly by {111} facets are more stable than the {100} faces enclosed cubic Pt nanocrystals [367]. For a spherical single-crystalline particle, its surface must contain high-index crystallographic planes, which probably result in a high surface energy. Therefore, facets tend to form on the particle surface to increase the portion of the low-index planes. For particles smaller than 10 nm, they usually have a faceted shape like a truncated octahedron [139, 368]. The sublimation activation energy of Au {110} faces has been found to be significantly lower than that of {100} and {111}, giving rise to the sublimation of Au atoms from the surface at temperatures as low as 220 °C, which is much lower than the melting point of bulk gold of 1063 °C [369]. A recent molecular dynamics calculation revealed that the melting process of Au clusters is punctuated by solid-to-solid structural transformations from low-temperature optimal structures, such as a truncated octahedral and a truncated decahedron, to icosahedral structures, which are believed to be the intrinsic thermodynamic precursors to the melting transition [370]. Well-known and studiously explored is the catalytic activity of nanoparticles with different morphology. Catalytic reactions take place on the surface of metal nanoparticles. Thus, it can, of course, be concluded that the different surfaces hardly exhibit the same reactivity due to the differences among different crystallographic planes, as mentioned above. Additionally, the strongly adsorbed species act as a poison to the reaction, thereby decreasing the rate of the reaction; therefore, the low-coordination-number vertex and edge atoms on the particle surfaces, whose numbers vary with the particle shape, have high catalytic activity.

4.2. Aggregation Stability

A large number of studies have been directed toward understanding the mechanisms of colloids aggregation and their relationship to the structure of the aggregates formed [371]. Generally, two limiting cases have been identified [372–374]. The first, termed slow or reaction-limited aggregation, refers to the case where only a small fraction of the collisions result in the two colloidal particles involved adhering to each other [372]. It has been found that the growth kinetics of reaction-limited aggregation are described by

$$R_h(t) = R_h(t_0) \exp(ct) \tag{11}$$

where $R_h(t_0)$ is the initial hydrodynamic radius of the aggregate, typically determined by dynamic light scattering, and c is a parameter characteristic of the experimental conditions. Related static light scattering experiments have established that the fractal dimension of such aggregates is 2.05.

The second case, termed fast or diffusion-limited aggregation, refers to the situation where each collision results in the two colloidal particles involved adhering to each other [373, 374]. It has been found that the growth kinetics of diffusion aggregation are described by

$$R_h(t) \propto t^{1/d_f} \tag{12}$$

where $R_h(t)$ is the hydrodynamic radius of the aggregate at some time t, determined by dynamic light scattering, and d_f is the fractal dimension which has a value of 1.75. The associated physical picture can be summarized as follows. In the reaction-limited regime, the particles have a low probability of adhering upon contact, sample many possible configurations, and form aggregates which are relatively dense, possibly local ordered, and have a fractal dimension of 2.05. In the diffusion-limited regime, the particles have a high probability of adhering upon contact, sample few possible configurations, and form relatively diffuse aggregates, probably locally branch-like, and so the particles which have a fractal dimension of 1.75.

The above description of particle aggregation assumes that nanoparticle motion is diffusive, and that particle–particle aggregation is homogeneous. Furthermore, it assumes that particle aggregation is irreversible with little subsequent reorganization of the aggregate structure. In practice, there are cases in which two particles have a high probability of adhering upon contact, and in which the kinetics of aggregation growth are diffusion limited, but the strength of the interaction between aggregated particles is sufficiently small that significant restructuring leads to a larger fractal dimension [375, 376].

The stability against aggregation of the noble metal nanoparticles is an important prerequisite for many potential applications. The general stabilization mechanisms of colloidal materials have been explained by the Derjaguin–Landau–Verwey–Overbeek (DLVO) theory [377]. Colloid stabilization is usually discussed in terms of two general categories: (1) charge stabilization, and (2) steric stabilization. Chemical functionalization of noble metal colloids performed in an aqueous or organic medium has often resulted in stability problems. In general, noble metal colloid aggregation is indicated by a red shift of the plasmon band. This problem is traditionally overcome by adding certain amounts of stabilizers that exhibit a high and specific affinity for the particle surface. Numerous stabilizers such as linear polymers (i.e., poly(N–vinyl–2–pyrrolidone [PVP]), cellulose acetate, and so on), macromolecules (highly branched dendrimer molecules [378, 379], π-conjugated poly(dithiafulvene) [380], and cyclodextrin [381]), ligands (alkanethiols [382–387], bi- and tri-functional thiols [118, 388, 389], acryldithiols and diisonitrile [390], dialkyl disulfides (RSSR′) [391], dialkyl sulfides (RSR′) [392–394], trioctylphosphine oxide (TOPO) [395, 396], and alkylamines [281, 397–400], surfactants [330, 401–403], tetraalkylammonium salts [404, 405], and heterogeneous supports [406–409] have been employed to prevent the nanoparticles from aggregation and allow one to isolate the nanoparticles. Based on these stabilizers, four types of stabilization mechanisms can be summarized: (1) the electrostatic stabilization by the surface adsorbed anions, (2) the steric stabilization by the presence of bulky groups, (3) the combination of these two kinds of stabilization with the electrosteric stabilization such as surfactants, and finally, (4) the stabilization with a ligand. The most common tools used for stabilizing nanoparticles so far have been polymers since the polymer-stabilized nanoparticles are able to be extensively used as catalysts in catalytic reactions, but they may not be useful in selected chemical or physical applications. For this reason, the use of ligands coordinated at the surface of the particles has been developed considerably in the past few years. Appropriate stabilizers play an overwhelming role in not only controlling the particle size and morphology, but also an aid to the functionalizing of the nanoparticles. For example, the incorporation of metal nanoparticles can enhance the conductivity of the π-conjugated polymers [410]. Nanocomposites consisting of conducting polymers and noble metal nanoparticles show the significance for catalytic applications [411].

However, stabilities at a large concentration can severely interfere with a subsequent surface functionalization due to the firm binding between stabilizer molecules and the surfaces of nanoparticles. One approach to the simultaneous solving of both the issues of colloidal stability and colloid derivatization consists of using functionalizable stabilizers such as hydrophilic polymers that are covalently grafted on the nanoparticle surfaces. For example, when biological molecules or environments are involved, the stabilizers should be compatible with biomedical requirements. As steric hindrance hampers the access to the colloid surface, the maximal amount of functional molecules that can be fixed is severely limited. Alternatively, a suitable solvent itself, such as methanol, acetone, propanol, ethylene glycol, and such, as the stabilizer has been applied to fabricate stable, "unprotected" metal nanoparticles with narrow size distribution [29, 106, 233–236]. By this means, the produced metal nanoparticles can be freely functionalized because the species adsorbed on the "unprotected" metal nanoparticles, that is, solvent molecules and the simple anions, will be easily removed or replaced by various coordination ligands or protective agents.

4.3. Electronic Properties

If a metal particle with bulk properties is reduced to a size of a few dozen or a few hundred atoms, the density of states in the valence band and the conduction band, respectively, decreases to such an extent that electronic properties change dramatically. In a metal, electrons are highly delocalized over a large space (i.e., least confined). This is a result of the fact that the separation between the valence and conduction bands vanishes, as shown in Figure 7(a), rendering the metal its conducting properties. As we decrease the size of the metal and confine its electronic motion, how do the electronic properties of a metal cluster have to be? The separation between the valence and the conduction bands becomes comparable to or larger than kT, and the metal becomes

a semiconductor, as illustrated in Figure 7(b). When more confinement increases the energy separation further, for example, as demonstrated in a cluster containing three metal atoms, energetically well-defined bonding and antibonding molecular orbitals are formed [see Fig. 7(c)]. The material becomes an insulator. In the size domain at which the metal–insulator transition occurs, new properties are expected to be observed which are possessed neither by the metal nor by the molecules or atoms forming the metal. Here, the quantum size effect dominates. In other words, if the number of electronic dimensions in a bulk system is decreased from three to two, a so-called quantum well is formed. While the one dimensionality of electrons induces a quantum wire, dimension zero effects result in a quantum dot which has a dimension of a particle consisting of hundreds or thousands of atoms.

An interesting aspect of clusters (metal clusters) is the coordinatively great unsaturation of the surface atoms. They interact only with atoms inside the particle, and have free valences outside. Therefore, their electronic contribution to the behavior of the particle is different from that of the inner atoms which are fully coordinated. Surface atoms will be even more distinguishable from inner ones if they are ligated. The smaller a metal particle becomes, the larger its fraction of surface atoms is. The distinction between the total number of metal atoms forming the complete cluster and the inner atoms (i.e., exclusively with other metal atoms as neighbors) is more significant the smaller a cluster is. For example, a close-packed cluster of 13 atoms has 12 surface atoms. A two-shell cluster containing 55 atoms has a "metallic" nucleus of 13 atoms, whereas the outer shell contains 42 atoms. In general, the nth shell includes $10n^2 + 2$ atoms. By increasing the size to a certain extent, a transition to bulk behavior will occur so that the inner metal atoms and not the total number of metal atoms should be considered.

In noble metals, the decrease in size below the electron mean-free path (the distance the electron travels between scattering collisions with the lattice centers) gives rise to intensive absorbance in the near UV–visible light. This results from the coherent oscillation of the free electrons from one surface of the particle to the other, and is called the surface plasmon absorption, which will be discussed in detail below. Noble metal nanoparticles are well known to have very efficient catalytic properties because of the large fraction of their atoms present on the surface. At this point, researchers in the high-vacuum surface science and electrochemistry fields have observed different catalytic efficiencies for the different metallic surfaces [412]. Atoms on different types of faces of a single metallic nanocrystal have different electronic structures, and thus promote different catalytic properties. The shift of the Fermi level manifests itself as a drastically increased sensitivity of the metal particles toward oxidation.

4.4. Optical Properties

Silver, gold, and copper colloids have been the major focus of interest because of their unique optical properties determined by the collective oscillations of electron density termed plasmons, which give rise to an intense absorption in the near UV–visible. Such strong absorption induces

the brilliant color of these metal nanoparticles in colloidal dispersion. It is produced by the strong coupling of nanoparticles to the electromagnetic radiation of incident light, leading to a collective excitation of all of the free electrons in the particles. As illustrated in Figure 8, the movement of the electrons under the influence of the electronic field vector of the incoming light leads to a dipole excitation across the particle sphere, the positive polarization charge acting as a restoring force, which makes the electrons oscillate. Thus, the electron density within a surface layer, the thickness of which is about equal to the screening length of a few angstroms, oscillates, whereas the density in the interior of the particle remains constant ["surface plasmon" (SP)]. From one up to three SP bands may be observed, corresponding to three polarizability axes of the metallic nanoparticles. A prerequisite for the formation of an intense plasmon absorption band is that ϵ_2 (the imaginary part of the dielectric constant of the metal) is not too large [11]. Silver particles have the unique property that the excitation of the collective oscillation (plasmon absorption, $\lambda = 380$ nm) and of the interband transitions ($\lambda = 320$ nm) occur in separate wavelength regimes. The plasmon resonances possessed by gold and copper are in the visible (Au 520 nm; Cu 570 nm), however, these resonances are superimposed by interband transitions.

In theory, the absorption spectra of metal particles smaller than the wavelength of incident light can be calculated on the basis of the Mie equation for nanoparticles whose metallic dielectric function is known and which are embedded in a medium of known dielectric constant [413–416]. The position and magnitude of the surface plasmon absorption band are intensively dependent on the size of the particles, the refractive index of the solvent, and the degree of aggregation. The surface plasmon resonance should shift slightly to high energy, and broaden

somewhat as the particle size is decreased; meanwhile, the intensity of absorption decreases remarkably until it is essentially unidentifiable for crystallites of less than 2 nm effective diameter [417, 418]. For example, a symmetric and comparatively narrow absorption peak at a shorter wavelength is usually indicative of relatively small, monodisperse, and spherical metal nanoparticles. However, it has been demonstrated both theoretically [419–422] and experimentally [423, 424] that the SP resonances of the coinage metal nanoparticles depend much more sensitively on the particle shapes than on the sizes. Typically, in the case of gold nanorods, the absorption spectra are characterized by the dominant SP_l band (at longer wavelength, ca. 620–900 nm), corresponding to longitudinal resonance and a much weaker transverse resonance than the SP_t band (at shorter wavelength, ca. 520 nm).

In general, for bimetallic Ag/Au nanoparticles, the absorption bands of alloys fall between the maxima of the respective constituent surface plasmon absorption bands, and core–shell structures manifest themselves in two distinct bands [413, 425]. Morphologies and absorption spectra of composite Ag/Au nanoparticles were, however, found to depend on the deposited metal atoms/surface ratio in a less than straightforward manner [426]. In contrast, several experimental results show that what is observed in the core–shell structured nanoparticles is only the plasmon absorption of pure metal of the core or shell constituent, probably due to particles deviating from the perfect core–shell model [427, 428]. The wavelength of the plasmon resonance of the nanoshells that are the other kind of colloidal particles, consisting of a small dielectric core covered by a thin metallic shell, can be tunable in the visible and near-infrared regions by varying the core/shell radii. This allows for the design of nanoshells with plasmon resonance across a spectral range from about 600 to 2500 nm [429]. The scattering from nanoshells adheres to the Mie scattering theory [429–431].

The efficiency for the absorption and scattering of light by metal nanoparticles can surpass that of any molecular chromophore. In addition, both absorption and scattering properties can be considerably altered by surface modification or by electronic coupling between individual nanoparticles. Together with an expectional resistance to photodegeneration, such favorable optical features are stimulating the development of new applications in analytical chemistry and in photophysics, making metal colloids attractive components for diagnostic, electronic, and photonic devices.

4.5. Magnetic Properties

Nanoscale magnetic materials show novel properties that are markedly different from those of the bulk due to their very small size and fundamental change in the coordination, symmetry, and confinement [432]. For magnetic nanoparticles, the intrinsic magnetic properties are strongly influenced by the particle size; meanwhile, they exhibit specific properties such as superparamagnetism and quantum tunneling of magnetization [433, 434], which are regarded as unique features of magnetic nanoparticles. When reducing the size of
Figure 8. Polarization of a spherical metal nanoparticle by the electric field vector of the incoming light.

magnetic particles, a transition from poly-domain to single-domain systems occurs. If the particles of ferro- or ferri-magnetic materials are smaller than the dimensions of a single domain (which for Fe and Co is ca. 20 nm), thermal fluctuations will supersede the Weiss anisotropy above the blocking temperature. Such particles are called superparamagnetic [435]. Naturally, magnetic particles smaller than 10 nm are usually superparamagnetic, and they do not aggregate because each particle is a single magnetic domain. A permanent magnetic moment has been observed in a self-assembled array of Co particles with sizes <8 nm by aligning them in a magnetic field during assembly.

The modification of the electronic band structure of nano-size magnetic particles, at the border of molecular and metallic states, induces unusual magnetic properties. As a consequence, an enhanced magnetic moment is predicted for nanoparticles of $3d$ ferromagnetic metals [436]. By applying molecular beam deflection measurements in high vacuum, such effects have been first demonstrated in the case of Fe, Co, and Ni metal nanoparticles containing fewer than 1000 atoms [437]. Bulk $4d$ metals do not display any ferromagnetic behavior; however, a spin polarization can be induced by a very small perturbation of the lattice parameter, by elaborating layered structures with a ferromagnetic material [438], and more efficiently by alloying with a $3d$ ferromagnetic metal [439, 440]. All of these fantastic phenomena motivate the preparation and characterization of magnetic nanoparticles.

Bimetallic nanoparticles in particular have raised a wide range of scientific interests because they may exhibit unique, synergistic properties, or combinations of properties, which go beyond those of single components. The investigation in the formation of alloy nanoparticles containing ferromagnetic $3d$ and noble metal elements of the platinum group becomes rather active with respect to the magnetic behavior of large magnetic moments and high magnetocrystalline anisotropy (i.e., FePt: $K_u \sim 6.6$–10×10^7 erg/cm^3) of these particles [441].

5. SELF-ASSEMBLY

Nonlithographic approaches based on thermodynamically driven self-organization processes are especially appealing because of their potential for low overhead in large-scale production. The spontaneous organization of monolayer-protected metal nanoparticles in periodic two-dimensional (2-D) arrays is archetypal of this approach, with many of these arrays demonstrating novel optical or electronic properties as a function of particle size or interparticle spacing. Hydrophobic compounds such as alkanethiols [34–36, 227, 238, 270] and alkylamines [224, 281, 399, 400] or cationic surfactants [404, 405] are often used to drive the nanoparticles toward self-organization at the air–aqueous interface (see Fig. 9). However, 2-D array formation by this method has mainly been successful only for small metal nanoparticles with diameters less than 10 nm, while a breakthrough, to some degree, has been achieved by the improvement of the largest unit size for a close-packed 2-D gold nanoparticle array from 18.5 to 170 nm [442]. Stabilized metal particles beyond this threshold of 10 nm become
(a)
(b)

Figure 9. Schematics showing self-assembled passivated nanocrystal superlattices of spherical (a) and faceted (b) particles. Apparently, long-chain thiol capping layers on the surfaces of nanoparticles are interdigitated.

increasingly prone to multilayer or three-dimensional aggregate formation, which can be attributed to the rapid increase in van der Waals attraction and the loss of surfactant chain mobility on the planer facets of the nanoparticles as a function of size.

Previously, Wang summarized that periodic arrays of nanocrystals are different from the 3-D packing of atoms

in several aspects [443]. First, to an excellent approximation, atoms or ions are spherical, while nanoparticles are faceted polyhedra; thus, the arrays of particles can be critically affected by their shape and size. Second, the atom or ion size is fixed, but the size of nanoparticles can vary slightly because their size distribution usually is within a certain range, even after size selection process. The degree of order within the close-packed domains suggests that the uniformity of arrays is determined largely by the size and shape dispersity [444] of the nanoparticles themselves. It should be noted that low size dispersity (5–10% relative standard deviation from the mean) is an important factor in the preparation of sterically stabilized colloidal crystals. Finally, atomic bonding occurs between outer shell (valence) electrons to form ionic, covalent, or metallic bonds, or mixtures of these. In most cases, the interatomic distance is fixed, while the bonding between nanoparticles is generated by a passivating surfactant whose length is variable; thus, the ratio of particle size to interparticle distance is adjustable. This is a parameter likely to determine the 3-D packing of the nanoparticles. The tunable internanocrystal spacing permits control over interparticle interactions, giving rise to novel tunable structural, optical, and transport properties.

Alternatively, a molecular recognition strategy for the self-assembly of nanoparticles has been systematically developed within the past few years. One recognition principle is to make possible the synthesis of receptor molecules, incorporating appropriately designed binding sites that are capable of recognizing and selectively binding molecular substrates in solution [259, 445, 446]. For example, the diaminopyridine moiety recognizes and selectively binds the uracil moiety in chloroform through the formation of three complementary hydrogen bonds in a way similar to the interactions between base pairs in DNA. Therefore, by incorporating a diaminopyridine moiety into a fraction of alkane molecules used as capping agents at the surface of a silver nanoparticle, the resultant assembly is expected to recognize and selectively bind another nanoparticle capped using alkane molecules modified by the incorporation of the uracil moiety. Generally, it is hoped that, by programming nanocrystals, the self-assembly of complex nanostructures in solution will prove possible. The other is the recognition-directed assembly of silver nanocrystals in solution via pseudorotaxane formation [446]. Specifically, a thiol modified dibenzo[24]crown-8 recognition motif was covalently linked to the surface of 7 nm diameter silver nanocrystals. Upon addition of bis–dibenzylammonium dication, an aggregation of nanocrystals was observed. The inhibition of the aggregation phenomenon by the addition of either an excess of dibeno[24]crown-8 or dibenzylammonium cation recognition motifs was further demonstrated.

To maintain a wetting layer on the surface so that nanocrystals can have a chance to self-assemble into large periodical structures, the evaporation rate of the solvent must be slowed. In analogy to molecular crystallization, it is quite reasonable to propose that better superlattices, larger and with fewer defects, are obtained when they form slowly. Once formed, these superlattices may be tough enough not to be perturbed when dewetting finally occurs. Excess low-volatile long-chain alkanethiol ligands turn out to be the ideal additive to slow the liquid droplet evaporation without introducing other impurities. With a dependence on particle concentration, the size of the domain with a remarkable degree of ordering is routinely greater than several microns in size by maintaining a long-lasting wetting layer. A sharp transition between the ordered monolayer regime and the bare substrate regime (such as amorphous carbon film) suggests that lateral diffusion in the wetting-liquid layer is mainly driven by the interaction between particles. A slight increase in size distribution near the edge of the monolayer domain occasionally takes place, indicating the size-selective process occurring simultaneously with the assembly process. The formation of well-ordered bilayers can be achieved by increasing the nanocrystal concentration while maintaining the concentration of the solvent mixture.

The formation of regular hexagonal close-packed 2-D supperlattices is frequently met in the precious metal nanoparticles with a narrow monomodal size distribution. However, what about the particles with bimodal size distributions? Two investigations give the intriguing answers [447, 448]. For alkanethiol-coated Au nanocrystals of two different well-defined size focusing, three types of ordered 2-D arrays that are primarily dependent on the local number and radius ratios of two components are observed, as shown in Figure 10 [447]: first, different-sized particles intimately mixed, forming an ordered bimodal self-organization [Fig. 10(a)], second, size-segregated regions, each containing hexagonal-close-packed monodispersed particles [Fig. 10(b)], and third, a structure in which particles of several different sizes occupy random positions in a pseudohexagonal lattice [Fig. 10c]. These different types of organization are closely related to the radius ratio of small particles to large particles. For two chemically different building blocks, such as thiol-passivated Ag and Au nanoparticles with bimodal particle sizes, they can spontaneously self-organize to true nanoscale colloidal alloy super-lattices [448].

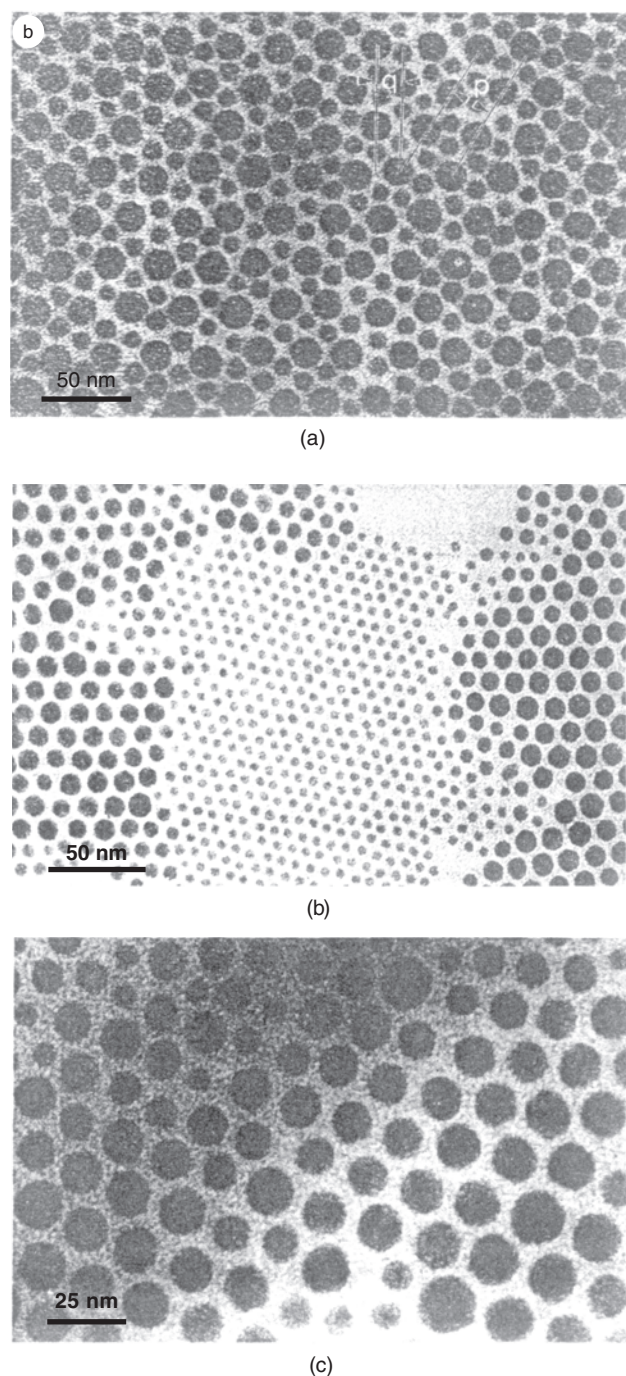
One (1-D)- and three-dimensional (3-D) arrays of nanoparticles are appealing. For the generation of low-dimension arrays, the use of templates supporting the arrangement of the particles is favorable. One-dimensional chains of Au nanoparticles linked with polypyrrole formed in porous anode oxidized alumina membranes [449]. As shown by Fitzmaurice and co-workers multiwalled carbon nanotubes can be used for supporting the 1-D arrays of Au nanoparticles up to 10 μm [450]. In particular, long-range 1-D chains of size-controlled Au nanoparticles in planar structured substrates (nanoscale ridge- and valley-structured carbon layers) are fabricated [451], where the Au nanoparticles are predominantly immobilized in valleys and partly on ridges. The other strategy is to utilize bifunctional linkers to form 1-D arrays. A representative example is demonstrated by dithiols with which nanoparticles are bridged to fabricate 1-D arrays of Au nanoparticles [449]. Another interesting experiment shows that the self-assembly of 2–mercaptobenzimidazole (MBMZ) molecules on Ag nanoparticles results in the formation of 1-D aggregates [452]. The length of the wire-like configurations ranges from 200 to 450 nm. Here, the hydrogen bonding (i.e., N–H$\cdots$N interactions) between MBMZ molecules on the surfaces of different Ag nanoparticles is believed to be the driving force for the formation of wire-like aggregates.


Figure 10. (a) Au nanocrystal superlattices comprising Au nano-particles of two distinct sizes with $R_B/R_A \approx 0.58$ (AB_2 structure, in analogy to AlB_2). (b) Organization of an approximately bimodal ensemble of particles for which $R_B/R_A \approx 0.47$ ($R_A = 9.6 \pm 1.5$ nm and $R_A = 4.5 \pm 0.7$ nm), where phase separation of $A + B$ mixture of Au nanoparticles in the superlattices takes place. (c) "Random alloy" of Au nanoparticles obtained for an R_B/R_A ratio greater than 0.85 (AB structure, in analogy to NaCl). Reprinted with permission from [447], C. J. 6. APPLICATIONS

Nanoscale metal particles hold great promise for use as advanced materials with new electronic, magnetic, optic, and thermal properties, as well as new catalytic properties. Recent and novel applications, such as building single-electron devices [453, 454], chemical sensors [455], luminescent probes [456, 457], drug delivery [458], medical diagnostics [459], and in high-density magnetic storage devices [319], are being found. For noble metal nanoparticles, the catalytic activities that they embody are ubiquitous as a side branch of this ongoing research in the field of nanotechnology. The noble metal nanoparticles provide new opportunities for catalysis for as much as they can serve as a bridge between homogeneous and heterogeneous catalysts. For instance, the colloidal metal particles of 1–3 nm mean diameter with narrow size distributions show high activity and selectivity for the hydrogenation of olefins and dienes [104, 343–345], the hydration of acrylonitrile [346], and light-induced hydrogen generation from water [347]. Furthermore, colloidal palladium nanoparticles serve as a good catalyst for Suzuki-, Heck-, and Stille-type coupling reactions for carbon–carbon bond formation [105, 460–462]. Platinum and gold nanoparticles catalyze the oxidation of L–sorbose and carbon monoxide, respectively [463–465].

Apart from the catalytic activity of silver [466–468], for example, poly(sodium acrylate)-protected Ag nanoclusters show high activity in catalyzing the oxidation of ethylene to ethylene oxide [468], the Ag nanoparticles play an important role in photographic processes [469–471] and in the substrate for surface-enhanced Raman spectroscopy (SERS) [472, 473]. In addition, due to their large effective scattering cross section and their nonbleaching properties, Ag nanoparticles hold great promise in the field of single molecule labeling-based biological assays [474] and as output signal enhancers in near-field optical microscopy applications [475]. Noble metal particles have also found application in protein–colloid conjugates, where they are used as markers and tracers in optical and electron microscopy to help locate and quantitate antibody–antigen binding sites in cells and tissues [476, 477].

Bimetallic particles find increasing interest not only in catalysis, but also as models for the study of the formation of alloys. Catalysts made of bimetallic nanoparticles are superior compared with those made of pure metals, in terms of activity, selectivity, stability, and resistance to poisoning [478]. The magic of bimetallic nanoparticles usually originates from their structures. Many investigations have shown that the structure–function relationship involving these nanoparticles holds the key to the understanding of catalytic processes. For instance, the catalytic mechanisms of monometallic nanoparticles and bimetallic nanoparticles in petroleum refining processes and multiwalled nanotube production are understood only after the structures of these catalysts have been examined [479, 480]. With extended X-ray absorption fine-structure (EXAFS) techniques, it has been found that Cu atoms concentrate in the surface of Cu/Ru bimetallic nanoparticles [479]. Such segregation helps reduce the rate of hydrogenolysis, which requires large patches of Ru atoms to function. Pd–Pt bimetallic nanoparticles are known to be more resistive to sulfur poisoning due to the special surface arrangement [478, 481, 482].

These results clearly demonstrate that special structures of bimetallic nanoparticles can lead to novel properties and enhancement of activities such as the catalytic function. In addition, bimetallic nanoparticles are preferred heterogeneous catalysts in petroleum reforming processes [479]. Large-diameter bimetallic nanoparticles have been used to catalyze the growth of carbon filaments [483]. Nanoscopic magnetic FePt, CoPt, and $Fe_xCo_yPt_{100-x-y}$ alloy particles received intensive attention due to their perpendicular magnetic anisotropy [484], high chemical stability [485], and potential applications for high-density magnetooptical recording media [486–490].

7. SUMMARY

This frontier of nanomaterial research follows great achievements, one after another, in the laboratory, so that it becomes more and more difficult to keep up to date with all new successes, and to derive the general trends that would be the main pathways to nanotechnology. So what would be the next logical step to take to envision the prospective functional materials? The development in nanosciences will motivate the advancement in future technology. Recently, large-scale production of monodispersed thiol-derivatized Au nanoparticles in gram scale have been successfully developed by Klabunde and co-workers using the solvated metal atom dispersion method [491]. Thus, it seems that this method lays the groundwork for the scaling up of known laboratory-scale syntheses into reliable, standard manufacturing procedures for nanomaterials with uniform size and monodispersed morphologies. Nevertheless, this alone is not enough since a nanoscale substance must have superior performance. Once available at low cost, the nanoparticles should have added functionality to a great extent by means of surface modification. If all of these problems have been tackled, the probable last step left that should be considered to make technological applications possible is the alignment and addressing of nanoparticles. This is necessary in nanodevices such as nanotransistors and nanocircuits.

The immense advancement in the synthetic ability of nanoparticles is partly attributed to the diverse analytic tools and characterization methods available, which contribute to a close examination of the morphologies and a profound understanding of the structures of the nanomaterials. For example, without the high-resolution transmission electron microscope and energy dispersive X-ray spectroscopy, we would know nothing about the structures and constituents of nanomaterials.

Although nanoparticles have numerous available properties for future applications as summarized in this chapter, nothing is ever omnipotent in the world. Therefore, the role of nanoparticles as well as other nanomaterials in future nanotechnology should hardly be overstated. We are looking forward to the day when we can abandon the old-fashioned manufacturing techniques and shrink them down to an economically and actually preferable nanoscale.

GLOSSARY

Colloid   System in which finely divided particles, which are approximately 1–1000 nm in size, are dispersed within a continuous medium in a manner that prevents them from being filtered easily or settled rapidly.

Dynamic light scattering (DLS)   Also known as **photon correlation spectroscopy (PCS)**. DLS measures the autocorrelation function of the intensity of the scattering light. It is an effective method to study the size of colloids (hydrodynamic radius), the kinetics of aggregation of the colloids, and the structure of the aggregates formed.

Energy-dispersive X-ray spectroscopy (EDS)   A precise microanalysis technique. It shows the counting of X-rays emitted from the beam-illuminated specimen region as a function of photon energy.

Noble metal   Metal or alloy, such as gold, that is highly resistant to oxidation and corrosion.

Plasmon absorption   Plasmons are the collective oscillations of the electron density in the metal nanoparticles of a colloid, which give rise to an intense absorption in the near UV–visible region. Plasmon absorption is produced by the strong coupling of nanoparticles to the electromagnetic radiation of incident light, leading to a collective excitation of all of the free electrons in the particles.

Poly(N–vinyl–2–pyrrolidone) (PVP)   A widely used stabilizer in the preparation of nanoparticles.

Stabilizer   Substance that renders or maintains a solution, mixture, suspension, or state resistant to chemical or physical change. In the field of nanoscience, a stabilizer is used to keep nanoparticles stable against aggregation.

Noble Metal Nanocolloids

Ichiro Okura

Tokyo Institute of Technology, Yokohama, Japan

CONTENTS

1. INTRODUCTION

Much attention has been paid to nanosized metal colloids, for their specific properties are different from those of bulk metal compounds. Nanosized metal colloids are usually synthesized by a *in-situ* reduction method from a suitable metal precursor, such as chemical reduction, photoreduction, electrochemical reduction, or thermal decomposition. Many small molecular ligands, surfactants, and polymers have been used to stabilize metal colloids. Some metal colloids exist stably for a long time without coagulation in a solvent. The methods for suppressing coagulation are needed to maintain the stability of metal colloids in a sol state. Additives that do not cause coagulation are steric stabilizers. Polymers such as polyvinyl alcohol and polyvinyl pyrrolidone and surfactants have frequently been used. The mechanism of the steric stabilization or suppression of the coagulation is illustrated in Figure 1, in which large adsorbed molecules that prevent coagulation can be seen. Recently many polymer-stabilized noble metal nanocolloids have been studied intensively. Stable noble metal colloids have also been obtained by a unique preparation method without a stabilizer. In this case the ionic groups on the surface of this metal colloid suppress the coagulation of metal particles by electric repulsion. The colloidal particles prepared by reduction with citrate, for example, are surrounded by an electrical double layer arising from adsorbed citrate and chloride ions and the cations that are attracted to them. This results in a Columbic repulsion decay with the interparticle distance; the net result is shown in Figure 2. Thus the metal particles are stabilized in the dispersing medium.

A counteraction can be achieved by the above two methods, electrostatic stabilization and steric stabilization. For historical details and an extensive survey of the properties of noble metal nanocolloids, the reader is referred to previous reviews [1–3].

2. PREPARATION AND CHARACTERIZATION OF NOBLE METAL NANOCOLLOIDS

Metal colloids can be prepared in two different ways: by dispersion of larger particles or by condensation of smaller units. Sols prepared by the dispersion method are rather unstable and consist of particles with a wide size distribution. To generate uniform particles it is necessary to use chemical methods such as the reduction of metal salts in solution.

2.1. Platinum Nanocolloid

Application of platinum colloid in catalysis is regarded as an active research field. Many colloidal nanocatalysts have been studied intensively, and nanosized platinum metal colloids exhibit special catalytic properties different from those of conventional heterogeneous and homogeneous platinum metal catalysts. Typical platinum nanocolloids are listed in Table 1. Particle size can be kept between 1.0 to 40 nm through control of the preparation conditions. Though most platinum colloids in the table are stabilized with polymers, platinum nanoparticles without stabilizer are also prepared. The platinum colloid with electrostatic stabilization is prepared by the reduction of chloroplatinic acid with sodium citrate [20]. The platinum colloid obtained by this method is very stable and does not coagulate for several months if kept in a refrigerator. The following three points are important in the preparation of the platinum colloid:

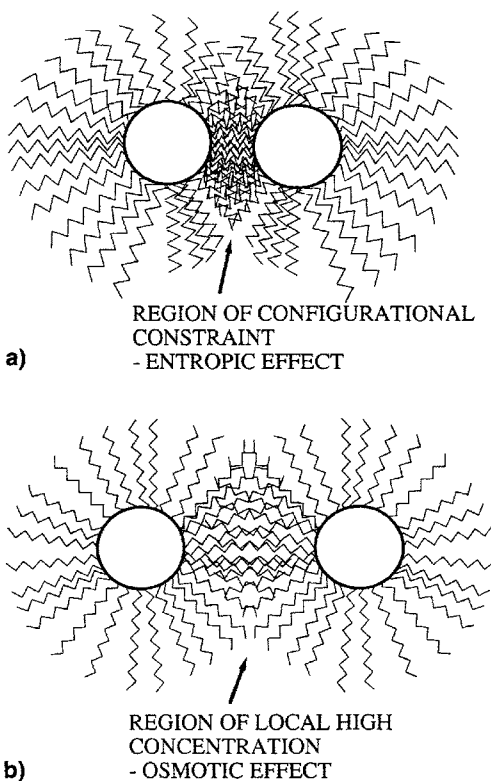
1. The flask must be carefully washed, preferably with aqua regia.
2. Attention must be paid to the water used. Double-distilled water is recommended.
3. The flask should always be sufficiently heated, and the solution must be kept boiling.
Figure 1. Steric stabilization of metal colloid particles by polymers or surfactant molecules. (a) In the interparticle space the configurational freedom of the polymer chains of two approaching particles is restricted, causing a lowering of entropy. (b) The local concentration of polymer chains between the approaching particles is raised and the resulting higher local activity is osmotically counteracted by solvation. Reprinted with permission from [1], G. Schmmid, "Clusters and Colloids." VCH, Weinheim, 1994, © 1994, Wiley-VCH.


Figure 2. Electrostatic stabilization of metal colloid particles. Attractive van der Waals forces are outweighed by repulsive electrostatic forces between adsorbed ions and associated counterions at moderate interparticle separation. Reprinted with permission from [1], G. Schmmid, "Clusters and Colloids." VCH, Weinheim, 1994, © 1994, Wiley-VCH.

Unreacted chloroplatinic acid and excess sodium citrate can be removed by passing the solution through a column with the ion exchange resin Amberlite MB-1.

Figure 3 shows the relationship between the particle size of the platinum colloid prepared by the above-mentioned method and the reflux time. The diameter of the platinum particles increases gradually with time and becomes constant at 32 Å. By this method, the particle size of the platinum colloid can be controlled just through control of the reflux time. The deviations in particle sizes are very small, and the particle size is homogeneous and almost uniform. From the results it seems that the number of colloid particles does not change during the growth process of the platinum colloid and that the particle size increases because of a gradual reduction in the amount of chloroplatinic acid adsorbed on the surface of the colloid.

2.2. Gold Nanocolloid

Gold nanocolloid is a typical historical particle. The gold colloids, ranging from 2 to 150 nm in diameter, are available and are typical hydrophobic particles (Table 2). The properties and applications of gold nanoparticles are summarized in [3] with historical details. The major objective in using colloidal gold is the *in-situ* localization of cellular macromolecules. This information is used to elucidate biochemical properties and functions of cellular compartments and components. The silver-enhanced colloidal gold method can be used for both light and electron microscopy. Colloidal gold as a marker meets many requirements necessary for precise ultrastructural localization, distribution, and quantitation of macromolecules in living or fixed cells and tissues. During the last decade, scientific literature involving the use of colloidal gold as an immunocytochemical marker has increased, and this trend is expected to continue. The different methods for the synthesis of colloidal gold are based on controlled reduction of an aqueous solution of tetrachloroauric acid, with different reducing agents under various conditions.

2.3. Other Noble Metal Nanocolloids

Other noble metal nanocolloids are also prepared as platinum and gold nanocolloids with electrostatic stabilization and steric stabilization. Nanocolloids of Rh, Pd, Ru, Ir, and Ag are shown in Tables 3–7.

2.4. Preparation and Characterization of Noble Bimetallic Nanocolloids

Bimetallic particles have been a focus of increasing interest not only in catalysis in the fuel industry, but also as models for the study of the formation of alloys. They can be divided into two classes: alloy-like colloids consist of a homogeneous mixture of two metals with colloidal distribution and colloids with an inner nucleus of one metal, which is covered by a layer of the second metal. In the metal evaporation method, two types of preparation procedures are used [62], for example:

(1) Half SMAD: A conventional catalyst was prepared, such as Pt/Al_2O_3, and this catalyst was treated with solvated Re atoms (in toluene). In this way the preformed Pt particles

Note: PVP, Polyvinyl pyrrolidone; PNIPAAm, poly(*N*-isopropylacrylamide); PVA, polyvinyl alcohol; PMP, poly(4-methyl-1-pentene); PTFE, poly(tetrafluoroethylene); PS-b-PMAA, polystyrene-b-poly(methacrylic acid); PS-b-PED, polystyrene-b-poly(ethyleneoxide); PNVF, poly(*N*-vinylformamide); PNVA, poly(*N*-vinylacetamide); PNVIBA, poly(*N*-vinylisobutylamide); PVPAA, poly(1-vinylpyrrolidone-*co*-acrylic acid).

would receive Re on their surface as a surface coating, but a homogeneous Pt-Re alloy should not form.

(2) Full SMAD: The two metals were evaporated simultaneously, and layered structures or homogeneous alloy particles could form. Some bimetallic nanocolloids are listed in Table 8. Platinum-gold alloy colloids can be prepared by a method similar to the above-described method for preparing a platinum colloid [61]. For the alloy colloid, a mixture of the gold chloride acid solution and the chloroplatinic acid solution (1 g Pt+Au/liter) at an arbitrary ratio is used.

The composition of the prepared alloy colloid corresponds to the composition of the starting material metal. Reduction with sodium citrate is completed within 4 h. This can be confirmed from a visible spectrum. Figure 4 shows a visible spectra of platinum, gold, and platinum-gold alloy colloids with various compositions. As the gold colloid has a characteristic absorption peak at 520 nm, the gold colloid does not appear to be included in the alloy colloid. The colloid thus prepared is an alloy, because the spectrum of the alloy colloid is not a summary of spectra of the pure metal

colloids. The color of the alloy colloid is brownish black, whereas the color of the gold colloid is red. Platinum-palladium alloy colloids are prepared by a method similar to the above-described method [67]. In the case of palladium, 15 h is needed to complete the reduction with sodium citrate. The visible spectra of platinum, palladium, and these alloy colloids show alloy formation by the higher absorbance. The color of the alloy colloid is brownish black. A platinum-palladium alloy colloid with arbitrary metallic composition can be prepared.

3. CATALYSES WITH NOBLE METAL NANOCOLLOIDS

The noble metal nanocolloids and alloy nanocolloids have been used in a sol state, in which the colloid is dispersed in the solvent, and in a gel state, in which the colloid is supported on the solid surface. Some examples of catalytic reactions in the sol state and the preparation and characterization of the noble metal nanocatalyst are described. Typical catalytic reactions with noble metal nanocolloids are listed in Table 9.

3.1. Hydrogenation

Hydrogenation reactions have been the most extensively studied for measuring the activity of colloids. The six platinum group metals (Ru, Os, Rh, Ir, Pd, and Pt) have been investigated as unsupported catalysts. Alcohol solutions of these metals are active catalysts with varying degrees of selectivity for the deuteration of 1,2- and 1,6-dimethylcyclohexenes. Both unsupported Pd and Pt colloids are active for selective hydrogenation of alkynes to alkenes.

3.2. Hydrogen Peroxide Decomposition

Ionic platinum is not active for hydrogen peroxide decomposition. It is known that the metallic state of platinum is active for hydrogen peroxide decomposition, though the platinum ion is inert. When the platinum colloid shows a metallic character, the reaction proceeds [75]. Thus, the hydrogen peroxide decomposition reaction is a suitable model reaction. Hydrogen peroxide decomposition was carried out with platinum colloids with different particle sizes. The decomposition is easily carried out as follows by kinetic measurement:

$$2H_2O_2 \longrightarrow 2H_2O + O_2$$
As oxygen is generated in this reaction by the following equation, kinetic study is possible by measurement of either oxygen formation or hydrogen peroxide consumption by titration with potassium permanganate. The reaction obeys a first-order kinetics and is expressed by the following equation:

$$\ln C_0/C = kt$$

where C_0 and C are the hydrogen peroxide concentrations at times 0 and t, respectively, and k is a rate constant.

Figure 5 shows the relationship between the rate constant k and the particle size of the platinum colloid. Although decomposition activity of hydrogen peroxide is not observed

when a colloid with a small particle size is used, the activity increases with increasing particle size. The activity increases remarkably at a particle size of about 16 Å. A platinum colloid with a particle size of 16 Å consists of crystalline particles that each contain 108 platinum atoms, and the platinum particles may be an amorphous cluster in a platinum colloid with a particle size of less than 16 Å, which is a precursor of the crystal. The number of active sites of platinum colloids can be determined by the poisoning method in which mercuric chloride ($HgCl_2$) is used as an inhibitor. The addition of $HgCl_2$ causes a remarkable decrease in activity. If one active site is inhibited by one $HgCl_2$ molecule, the amount of $HgCl_2$ obtained by the extrapolation corresponds to the
total active sites. For instance, in the case of platinum colloid prepared by reflex for 300 min, the number of active sites exposed on the surface is 4.2×10^{16}, and 37% of the platinum atoms are surface atoms. On the other hand, the activities of the hydrogen peroxide decomposition of platinum-gold and platinum-palladium alloys are strongly dependent on the alloy composition.

Gold colloid shows almost no activity. Even if up to 25% gold is added to platinum, the activity is almost the same as that of platinum alone. When 66% or more gold is added, the activity is almost lost. On the other hand, the activity decreases monotonously with the addition of palladium.

3.3. Photoinduced Hydrogen Evolution

Recently, hydrogen evolution by photolysis of water has been used to convert solar energy into chemical energy. The photoinduced hydrogen generation reaction and a homogeneous system can be outlined as follows:

where D is an electron donor, S is a photosensitizer, and V is an electron carrier.

In this reaction, the sensitizer is first photoexcited and reduces the electron carrier, and then the sensitizer is oxidized. The oxidized photosensitizer is reduced with the electron donor and returns to its former state. On the other hand, the reduced electron carrier gives an electron to the proton of water by the catalyst, resulting in the hydrogen evolution. The catalyst for the hydrogen evolution should be

highly active and should be soluble or able to be highly dispersed in the solvent. If a dispersed solid catalyst is used, the catalyst may prevent the light from reaching the photosensitizer, and the inefficient use of irradiation light would result in a lowering of the reaction efficiency. Widely used catalysts in this reaction are platinum colloid and the enzyme hydrogenase. These are highly active for the hydrogen evolution reaction and have little effect on irradiation light. The platinum colloid receives an electron from the electron carrier, serves as an electron pool, and gives the electron to the proton. The reaction pathway is shown in Figure 6. A comparison of the hydrogen evolution efficiencies for the platinum colloid and for other platinum catalysts shows that the hydrogen evolution efficiency is much higher for platinum colloid. This is an example of photoinduced hydrogen evolution when methyl viologen (electron carrier), ethylene-diamine-teraacetic acid (electron donor), and $Ru(bpy)_3^{2+}$ (photosensitizer) are used. When a semiconductor such as titania is used as the photosensitizer, water is completely decomposed. The following $RuO_2/TiO_2/Pt$ colloid has been synthesized for efficient photolysis of water (see Fig. 7), in which the charge separation proceeds and hydrogen and oxygen are obtained. The ruthenium oxide (catalyst for oxygen evolution) and the platinum (catalyst for hydrogen evolution) are supported on a colloidal semiconductor powder.

3.4. Immunochromatography with Au Colloid and Pt Colloid

Immunochromatography is a method for detecting an antigen by an antigen-antibody reaction as illustrated in Figure 8. A complex (conjugate) is used in this method. The conjugate is a compound that binds with the antibody and metallic colloid, and the bare surface (the antibody not being adsorbed) is coated by bovine serum albumin. In this method, the conjugate and the antigen in the sample are reacted in advance, and a conjugate-antigen complex is formed. The conjugate-antigen complex is developed on a supported nitrocellulose film. Since the conjugate-antigen complex binds metallic colloid particles through the antigen, metallic colloid particles accumulate. When a gold colloid is used, a purple gold colloid color is observed. The detection sensitivity is ~100 pg/ml. Sensitivity can be improved by platinum catalysis. For instance, a blue color appears when 3,3′,5,5′-tetramethylbenzidine is oxidized with a platinum catalyst. The detection sensitivity in this case is 8 pg/ml.

## 3.5. Preparation and Characterization of Supported Platinum and Alloy Catalysts

The metallic particles in a colloid are generally negatively charged. Therefore, the metallic particles are easily adsorbed to the carrier surface when the carrier contains polyvalent cations. Platinum and alloy colloids can be supported on an alumina plate as follows [20]. The hydrosol of the alumina plate is prepared as follows. Colloidal alumina is dispersed to aqueous acetic acid, and the hydrothermal reaction is allowed to proceed for 2.5 h at 200 °C. The obtained sol is deionized with the use of an ion-exchange resin (Amberlite MB-1). When the metal colloid is added to the alumina plate sol thus prepared, the metallic particles are immediately adsorbed to the alumina surface. The supported metal catalyst is obtained as a precipitate. As the adsorption of the metallic particles to the alumina surface is very fast, the metallic particles that adsorb to the surface are heterogeneous. To avoid this, the alumina plate sol is diluted 10 times and the metal colloid is dropped with vigorous stirring. The alumina plate with adsorbed metallic particles is obtained as a precipitate. This precipitate is separated by decantation and centrifugation. The precipitate is washed with clear water and dried at 105 °C.

Figure 9 shows an electron micrograph of a supported platinum catalyst prepared by the above-described method. The size of the platinum particles is the same as that of the sol, and the platinum particles are supported homogeneously on the alumina plate. The figure shows that 0.48 wt% platinum is supported on the alumina plate. The loading of the metal can easily be changed by changing the amount of metal colloid.

The platinum colloid supported on the alumina plate is active for hydrogenation of olefins and benzene and the H_2-D_2 exchange reaction, as is a platinum catalyst prepared by the usual method. The thus-prepared catalyst has platinum particles of uniform sizes that are homogeneously dispersed on the surface. Such a platinum catalyst is suitable for studying the turnover numbers and selectivity change, depending on particle size. An alloy catalyst prepared by the
Figure 8. Mechanism of immunochromatography with gold colloid.

usual method may be different from an alloy catalyst prepared from a colloid. In the case of a platinum-gold alloy catalyst, it is known that only an extreme alloy (0–17% Pt, 98–100% Pt) is prepared because an immiscibility area exists in a catalyst prepared by the usual method. In a platinum-gold alloy colloid, however, the metal composition in the bulk and that of the surface are almost the same. This has been confirmed by examination of visible spectra and by hydrogen peroxide decomposition reaction. When ethylene hydrogenation was carried out with the alloy colloid, the highest activity was observed when Pt/Au = 2 in the case of platinum-gold and at Pt/Pd = 1/2 in the case of platinum-palladium. The high activity is caused by an increase in the turnover number, not by the exposed metal atoms or the number of active sites. Colloidal alloy catalysts are expected to have excellent activity or selectivity because various metal combinations are possible.

4. CONCLUSION

The nanotechnology of noble metal colloids has been making rapid progress in recent decades, and tailor-made nanocolloids of specific particle sizes have now become available. Such advances are most evident with the nanocolloids of platinum and gold as mentioned. Gold nanocolloids have been used particularly as labeling compounds of various biological materials. Catalytic reactions with platinum nanocolloids such as hydrogenation, decomposition, and hydrogen evolution have been the most extensively studied in a sol state and in a gel state. For example, platinum nanocolloids with specific sizes and Stabilizers are available for various degrees of selectivity in hydrogenation of alkenes and alkynes. Very recently, the interest in bimetallic nanocolloids has increased remarkably because of their possible use as a multifunctional catalyst, such as a fuel cell catalyst. Tailor-made multifunctional nanocolloids are strongly desired.

GLOSSARY

Alloy A metal made by combining two or more metallic elements, especially to give greater strength or resistance to corrosion.

Coagulation   A flocculate or cause of flocculate by the addition of an electrolyte to an electrostatic colloid.

Hydrogenase   An enzyme that promotes the reduction of protonation or the oxidation of hydrogen.

Immunochromatography   A kind of chromatography that uses the affinity of an antibody for an antigen.

Stabilizer   Substance added to chemical compounds to prevent deterioration or the loss of desirable properties.

Turnover number   The number of times that a catalyst or enzyme catalyzes during a given period of time.

Nonlinear Optical Materials by Sol–Gel Method

Wenyan Li, Sudipta Seal

University of Central Florida, Orlando, Florida, USA

CONTENTS

1. INTRODUCTION

Current developments in optical telecommunications are leading to the demand in the near future for devices capable of ultrafast signal switching and routing. These functions are presently carried out mainly by electro-optical circuits and will be performed by a photonic technique, an emerging technology in which photos, instead of electrons, are used to acquire, store, transmit, and process information [1]. All-optical integrated devices, such as optical switching devices, are to be developed to achieve fast response times. In order to realize such devices, new optical materials, exhibiting strong nonlinear properties, need be developed.

Sol–gel optics has emerged over last 20 years, along with many other applications of sol–gel technology [2, 3]. Research has been moving along several directions, ranging from semiconductors and metals to polymers, from inorganic to organic materials, and from single phase materials to composites. In this chapter, a brief survey is provided for the sol–gel synthesis of the nanocomposites with nonlinear optical properties.

1.1. Optical Nonlinear Effect

This section describes general concepts of nonlinear optical effects [4, 5]. When an electron is pulled from an atom, the restoring force F, to a first approximation, is proportional to the displacement of the electron from its equilibrium position,

$$F = -kx \tag{1}$$

where k is the proportional constant, and this equation shows a linear effect.

When the force is related to the potential energy, V,

$$F = -\nabla V \tag{2}$$

where ∇ denotes the gradient ($\nabla = \partial/\partial x$ for the one-dimensional case), from Eqs. (1) and (2)

$$V = \frac{1}{2}kx^2 \tag{3}$$

This corresponds to a harmonic potential, and the potential energy is chosen to be zero at $x = 0$.

When an electric field (e.g., light) interacts with electrons in a material, the electron density can be provoked to be displaced. When the optical effect is linear, this leads to an induced dipole, or polarization, which is linearly proportional to the electric field,

$$p = \alpha E \tag{4}$$

where α is the linear polarizability.

So in a linear material the charges oscillate at the same frequency as the incident light. The oscillating charges either radiate light at that frequency or the energy is transferred into nonradiative modes, such as thermal or other energy form.

In most cases, the harmonic model is a good approximation, but closer examination indicates the importance of other terms in the potential. If the restoring force can be written as

$$F = -kx - \frac{1}{2}k'x^2 \tag{5}$$

this leads to the following potential energy:

$$V = \frac{1}{2}kx^2 + \frac{1}{6}k'x^3 \qquad (6)$$

As we can see, there is an additional anharmonic term, and it will give a V value which depends on the sign (or direction) of x. Similarly, the magnitude of polarization will depend on the direction of the electric field of the light. An example of such a material is one of an anisotropic charge distribution in the absence of an electric field, such as a noncentrosymmetric polar crystal. In this case, the electric field of light can displace the charge differently in different directions, resulting in nonlinear polarization. In a nonlinear optical material, or when the electric field is strong enough, the polarization can be written as a Taylor series expansion

$$p = \alpha E + \beta EE + \gamma EEE + \cdots \qquad (7)$$

where α is the linear polarizability, while β and γ are referred to as the first and second hyperpolarizabilities, respectively. In a nonlinear optical material, the induced polarization is not a pure sine wave at the frequency of light. It can be composed of the frequency (ν), and its harmonics ($2\nu, 3\nu, \dots$), as well as an offset, which is a dc component given by the static polarization. The hyperpolarizabilities give rise to the harmonics. The displacement of charge from its equilibrium value is a nonlinear function.

The macroscopic polarization P (i.e., the dipole moment density) can be described by

$$P = \chi^{(1)}E + \chi^{(2)}EE + \gamma^{(3)}EEE + \cdots \qquad (8)$$

where $\chi^{(n)}$ describes tensors of nth order, and $\chi^{(2)}$ and $\chi^{(3)}$ are the second- and third-order nonlinear optical susceptibilities. To have second-order nonlinear properties, there must be a preferred direction in the system, instead of an equivalent system. Most easily polar ordered dipole molecules fulfill this requirement. However, third-order nonlinear properties are nonzero for all materials, although they induced a weaker optical response.

1.2. Sol–Gel for Nonlinear Materials

The sol–gel method is suitable for the preparation of many nonlinear optical (NLO) materials, in the form of thin film, fibers, and even monoliths. Silica glass and other oxide glasses do not normally have high nonlinear optical parameters, but with their low optical losses and good mechanical properties, they serve as ideal matrix for nonlinear materials. Nanosized semiconductors, metal nanoclusters, and optically active organics can be introduced into the sol–gel derived transparent oxide glass and ceramic to form nanocomposites with nonlinear properties. A number of methods can be used to prepare NLO nanocomposites, which include the mixing of optically active organics into the sol–gel liquid solution, the impregnation of organics into the interconnecting pores of a stabilized oxide gel, and the direct chemical bonding of optically active organics and inorganics, metals, and semiconductors, to form NLO nanocomposites [6].

We will mainly introduce three types of NLO nanostructures made by the sol–gel process: semiconductor–glass, metal cluster–glass, and organics–glass nanocomposites. Metal or semiconductor nanoclusters dispersed in a glass matrix have high resonant-type $\chi^{(3)}$ [7–14]. Metal nanoclusters in glass matrix also exhibit picosecond switching and relaxation times, thermal and chemical stability, high laser damage threshold, low photon absorption, and optical tunability [15–18]. Organic polymer, such as paranitroaniline, diethylaminonitrostyrene, N-(4-nitrophenyl)-(L)-prolinol, and N-(3-hydroxy-4-nitrophenyl)-(L)-prolinol possess high second-order optical nonlinearity, after they have been oriented by electric field poling. Conjugated polymer, like polyphenylenevinylene has emerged as a class of important third-order nonlinear optical material [1]. The composites of sol–gel processed oxide/polymer offer promising nonlinear applications.

2. SEMICONDUCTOR–GLASS NANOCOMPOSITES

In 1983, Jain and Lind reported that some commercially available silicate glasses containing ultrafine crystals of CdS and CdSe had high values of third-order nonlinearities and fast switching times [19]. This so-called quantum confinement effect is now well known for a variety of semiconductors and semiconductor nanocrystal-doped glasses. These materials have emerged as potential candidates for nonlinear optical devices [13, 20–27]. If the dimension of the semiconductor clusters is of the order of or smaller than the Bohr exciton radius (about 20 Å for CdS), which indicates the effective separation of hole and electron in the first excited state of the semiconductor [28], the quantization of the energy levels due to size quantization can lead to a strong improvement of the nonlinear characteristics of the material itself [29, 30].

Research has initially concentrated on commercially available SDGs (semiconductor-doped glasses), commonly used as sharp-cut optical filters [31]. Though this first approach has been important for the understanding of some basic mechanisms of the nonlinear properties enhancement, these materials were not optimized either for integrated optical applications or for optimal performance in terms of nonlinear response [32, 33].

There are two problems associated with these materials. First was the size distribution of the clusters. The size range of early samples which were obtained by usual melting processes was too broad to obtain a sharp and strong enhancement of the nonlinearity [33]. The second problem was constituted by the darkening of the glasses when exposed to light beams (*photodarkening*). This phenomenon was probably due to photochemical reactions which take place at the boundary between the semiconductor and the glass matrix, caused by impurity at those locations. Photodarkening increases optical absorption and thus can harm light propagation.

To optimize the properties of SDGs, other processes have been explored, such as radio frequency sputtering deposition [34, 35] and sol–gel deposition, which offer better prospects especially for the control of size of the nanocrystals and the impurity in the material.

The easy control of the material composition in a sol–gel system also allows an increase in the dopant concentration,

which can further improve the special characteristics of such glasses.

Various semiconductors, such as CdS, CdSe, CdTe, PbTe, and ZnTe doped glasses with nonlinear properties, have been successfully developed by the sol–gel technique [20, 22, 36–41]. A few results are summarized in Table 1.

2.1. CdS-Doped Films

The semiconductor particles most studied were cadmium sulfide [28, 42]. The nonlinear properties of CdS incorporated in thin film prepared by the sol–gel method and in organically modified ceramics have been studied by Reisfeld [28, 43], Mackenzie [6], Nogami et al. [21, 44, 45], and many others. Most of the earlier work was based on SiO_2 matrix [44, 46, 47]. More recently, Takada et al. developed Na_2O–B_2O_3–SiO_2 glasses from gels and used it as the matrix material, since dense glasses could be obtained at temperature lower than 600 °C [36, 37]. CdS crystallites were prepared in glass matrix with diameters of 40 to 60 Å and concentrations up to 8 wt%. These glass nanocomposites exhibited excellent optical quality and on-resonance $\chi^{(3)}$ values up to 6×10^{-7} esu [48].

Besides inorganic glass systems, organically modified silicates (Ormosils) have also been evaluated as the matrix material for semiconductor nanocrystals, as they are less brittle than pure oxide gels [49]. A simple approach was to add cadmium salt, in the form of acetate or nitrate, to a TEOS (tetraethoxysilane)–PDMS (polydimethyl siloxane) liquid solution and allow an Ormosil to form. The cadmium salt was then converted to the oxide and then to the sulfide via H_2S treatment of the porous Ormosil. The resulting Ormosil was then densified to get transparent nanocomposite. The composite is then polished to achieve an excellent optical surface. Up to 20 wt% CdS nanocrystals of 30–60 Å can be dispersed in such a matrix. The off-resonance $\chi^{(3)}$ were of the order of 10^{-11} esu, and the on-resonance values around 10^{-8} esu. In these Ormosil-based NLO materials, photodarkening, a deleterious process due to prolonged radiation observed in traditional matrix made by fusion and "striking" process [19], was practically unobservable.

Different techniques can be applied to the process in order to effectively control the size of the clusters, obtaining narrower size distributions of the crystallites. For instance, particle size can be controlled by applying appropriate heat-treatment schedules [41, 50]. Thermal treatments for drying and densification, at temperatures usually lower than 500 °C, do not induce unwanted effects of growth of the nanocrystals and broadening of the size distribution. In contrast, it can be used to control the particle size distribution.

Two main processes are being investigated in order to efficiently control the size of the semiconductor clusters: the first one takes the advantage of the porosity of the sol–gel matrix to put an upper limit to the growth of the crystallites (*pore doping*), while the second one uses chemical agents to control the cluster surface and to terminate it by capping groups which prevent further aggregation and growth of the nanoclusters (*surface capping*) [51].

2.1.1. Pore Doping

Using pore size to control the particle growth inside the pore requires a well-controlled pore size in the matrix material. Wang and Herron studied the size dependence of nonresonant third-order nonlinear susceptibility in CdS clusters and found that, in their system, the value of $\chi^{(3)}$ reached maximum at a particle size of 60 Å [52]. It is to be noted that average size of the pores can be controlled by the pH of the starting solution [53]. They prepared porous silica glass starting from TEOS and introduced semiconductors into the pores. For the CdS system, Cd precursor can be added to the starting solution, and then the sol–gel product can be annealed in H_2S atmosphere to form CdS in the porous glass. In this case, the size of CdS cluster is also influenced by the annealing time; otherwise, Cd could be introduced into the porous glass by impregnation, soaking the substrate in a cadmium nitrate solution, and then obtaining CdS by carrying out a similar annealing process. The latter technique has the advantage of possible high density of semiconductor clusters in the glass pores but also poses difficulty in achieving a uniform dispersion throughout a large substrate. The impregnation approach was also followed by Choi and Shea [54], where Na_2S was used instead of H_2S for the sulphidation step.

Yeatman et al. [55] investigated thoroughly the influence of the sol–gel process on the pore size distribution and obtained CdS crystals with an average size of 4 nm by annealing a silica gel in an H_2S atmosphere where Cd had already been dispersed in the gel by adding cadmium acetate to the starting solution. They found that the higher the annealing temperature, the smaller the crystal obtained. Nonlinear m-line measurements using low and high intensities (0.76 and 8.41 μJ/pulse, respectively) were performed. The nonlinear refractive index at the wavelength of 0.532 μm was estimated to be $n_2 = -5.5 \times 10^{-9}$ $cm^2\,kW^{-1}$ [56]. However, the higher n_2 obtained for thinner films (e.g., 3.2×10^{-8} $cm^2\,kW^{-1}$ in [57]) suggests that substantial improvements are possible. Such values of nonlinear refractive index n_2 can be transformed into values of third-order nonlinear susceptibility [58], and the corresponding values of $\chi^{(3)}$ are 3.2×10^{-10} and 1.8×10^{-9} esu, respectively.

Using a similar technique, Minti et al. [59] obtained CdS clusters with sizes mostly in the range of 2–5 nm, and they can be as high as 20 nm. Despite the rather broad size distribution, third-harmonic generation signals were observed when the sample was laser irradiated at 1.06 μm and observed at 0.355 μm: the corresponding $\chi^{(3)}$ was evaluated to be 10^{-12} esu.

2.1.2. Surface Capping

While the pore doping method uses pore size as a physical limit of particle growth, surface capping introduces a terminating chemical agent to control the particle size. It is a molecule which attaches to the growing cluster surface and thus controls the size to which it can grow. Research efforts have been focused on the selection of the agent and the optimization of the process developing a synthetic methodology to prepare monodisperse nanoclusters is important not only for optical devices, but also for catalysis, chemical sensing, and novel magnetic devices [60].

Table 1. NLO and other related properties of some sol–gel semiconductor–glass nanocomposites.

S. No.	Matrix	Particle size	Dope concentration	Optical nonlinearity	Precursors	Ref.
CdS-doped Films						
1	SiO_2	2–5 nm	Cd/Si = 0.0077 to 0.12 (mol)		TMOS(TEOS) + H_2O + EtOH + H_2S + CdAc	[28]
2	SiO_2	3.5–4.5 nm	CdO/SiO_2 = 1, 2, 5, 10 wt% before reacting with H_2S	4.5×10^{-11} esu (CW laser) and 2.3×10^{-11} esu (pulse laser)		[78]
3	Na_2O–B_2O_3–SiO_2	4–6 nm	8 wt%	6×10^{-7} esu	TMOS + HCl + H_2O + $B(OEt)_3$ + NaOAc + $Cd(OAc)_2$	[6, 48]
4	ormosils	3–6 nm	20 wt%	10^{-11} esu (off-resonance) 10^{-8} esu (on-resonance)	CdAc or $Cd(NO_3)_2$ + TEOS + PDMS + H_2S	[49]
5	ZrO_2			4×10^{-1} esu		[79]
6	SiO_2–TiO_2	3.5 nm (heated at 300 °C) 5 nm (heat at 500 °C) surface capping agent: acetylacetone		$n_2 = -2.9 \times 10^{-7}$ cm²/kW, (resonant) corresponding to $\chi^{(3)}$ 1.6×10^{-8} esu	TEOS/methyltri-ethoxysilane (MTES) CdAc + methnoal + acetylacetone	[80, 81]
7	SiO_2–TiO_2		6% (molar)	-4.67×10^{-7} esu	TEOS + $Ti(OBu)_4$ + CdAc + H_2O + HCl ethanol + AcAcH + $SC(NH_2)_2$ or CH_3CSNH_2	[82]
8	SiO_2–TiO_2	2–20 nm surface capping agents: acetylacetone, 3-aminopropyltriethoxysilane, 3-aminopropyltrimethoxysilane, 3-mercaptopropyltrimethoxy-silane		$n_2 = -3 \times 10^{-9}$ cm²/kW	CdAc + thioacetamide (CH_3CSNH_2), TEOS + MTOS + EtOH + H_2O + HCl + $Ti(OBu)_4$	[83]
9	SiO_2	4 nm		$n_2 = -5.5 \times 10^{-9}$ cm²/kW, ($\chi^{(3)}$ 3.2×10^{-10} esu) for very thin film, $n_2 = 3.2 \times 10^{-8}$ cm²/kW, ($\chi^{(3)}$ 1.8×10^{-9} esu)	silica gel + CdAc + H_2S	[55]
10	SiO_2	2–5 nm, up to 20 nm		10^{-12} esu	CdS prepared in glass obtained from TMOS or TEOS	[59]
11	SiO_2	2.8 ± 0.9 nm surface capping agent: 3-aminopropyltriethoxysilane		10^{-6} esu	Silica gel + CdO + H_2S	[61]
CdSe-doped Films						
1	SiO_2	4–20 nm			TMOS + PrOH + H_2O + SeO_2 + CdAc + glycerol + methoxyethanol	[28, 73]
2	ormosil	3–5 nm	2% (wt)		CdSe was prepared inside reverse micelles in $AOT/H_2O/$ heptane ormosil was derived from 3-aminopropyl(trime-thoxy)silane	[74, 75]
CdTe-doped Films						
1	ZrO_2	6–20 nm		—	ZrO_2 sol + CdAc + TeO_2 + HCl + glycerol + methoxyethanol + $SnCl_2$ (or hydrazine)	[28, 77]
2	Na_2O–B_2O_3–SiO_2	2.4–8.5 nm			(a) immersing CdO doped gels in NaTe/MeOH (b) $Cd(NO_3)_2$ + H_6TeO_6, then reducing in H_2/N_2	[84]

Table 1. Continued

S. No.	Matrix	Particle size	Dope concentration	Optical nonlinearity	Precursors	Ref.
PbS-doped Films						
	ZrO_2	4.5 nm	5% to 30%	—	$Zr(OPr)_4$ + propanol PbAc + methoxymethanol	[28, 85]
	zirconia–ormosil	4.8 ± 0.8 nm surface capping agent: 3-mercaptopropyltrime-thoxysilane		the nonlinear refractive index $n_2 = 10^{-15}$ to 10^{-16} m^2/W	3-(trimethoxysilil)propylmetha-crylate + methacrylic acid + $Zr(OPr)4$, PbAc in methanol + thioacetamide	[86]
	SiO_2	4.5–5.0 nm	5% (molar)		TEOS + MEES + H_2O + HCl + EtOH PbAc + $SC(NH_2)_2$ + acetylacetone (acacH) + MeOH	[87]
	SiO_2–TiO_2	1.6–3.0 nm	5% (molar)		TEOS + MEES + H_2O + HCl + EtOH $Ti(OBu)_4$ + acacH PbAc + $SC(NH_2)_2$ + acacH + MeOH	[87]
	SiO_2–TiO_2	2.3–3.5 nm surface capping agent: 3-mercaptopropyltrime-thoxysilane	PbS/oxide molar ratio: 5% to 25%	$n_2 = 10^{-7}$–10^{-8} cm^2/kW nanosecond excitation $n_2 = 10^{-9}$–10^{-10} cm^2/kW picosecond excitations	MTES/TEOS + H_2O + HCl + EtOH PbAc + Ch_3CSNH_2	[80, 88, 89]

Takada and co-workers [61] developed CdS-doped glass samples by combining both techniques to control the cluster growth. They started producing a porous organically modified silica gel containing CdO clusters and carried out an annealing under H_2S atmosphere to obtain CdS clusters. By introducing 3-aminopropyltriethoxysilane as a ligand functional to the solution, a narrow distribution of the cluster size (2.8 ± 0.9 nm) was obtained. The ligand anchors the Cd to the gel–glass matrix, avoiding precipitation during the drying step, thus improving the homogeneity of the film. A huge nonlinearity, with $\chi^{(3)}$ of about 10^{-6} esu, was observed.

Another approach is to produce colloidal particles separately using a surface capping agent to control their size and then incorporate them in the sol–gel media [54, 59, 62, 63]. For example, Gacoin et al. [60] produced semiconductor nanoclusters capped with phenylthiol and then dispersed them in a sol–gel precursor solution.

Herron and Wang [53] also obtained CdS clusters of size up to 40 Å by using thiophenolate as a capping agent. In this case, the clusters were dispersed in acetonitrile solution and showed a $\chi^{(3)}$ of around 10^{-14} esu. Since the clusters are easily soluble in a wide range of solvents, the authors suggest either to produce pure CdS films by spray pyrolysis or to incorporate them in polymeric films like polymethyl-methacrylate (PMMA).

2.2. CdSe-Doped Films

CdSe nanoclusters are known to exhibit different colors at various particle sizes, from deep red to orange to yellow, due to the "blueshift" of the optical threshold, one of the quantum confinements.

Nanoparticles of CdSe have been prepared in colloidal solutions [64, 65] or embedded in solid and transparent media, such as zeolites [66], glasses [67, 68], and polymers [69]. Several studies showed an attempt to passivize the surface of colloidal nanoparticles by disordered organic capping [64, 70]. However, this leaves unsaturated bonds and sensitivity to photo-oxidation [65]. Other recent reports described the development of colloidal composite nanoparticles, containing a CdSe core, surrounded with another semiconductor shell [71, 72]. These can be viewed as epitaxial heterostructures of nanoparticles, enabling crystal matching and construction of electronically passivated surfaces. The solid media diminish the particles' surface reactivity, supply a stable chemical environment, and induce dielectric confinement [67].

CdSe nanoparticles films were prepared by chemical solution deposition and formation in a silica sol–gel matrix by Reisfeld. The silica film-dipped CdSe nanocrystals were obtained by adding the precursor solution of trimethoxyoxiorthosilane to a solution of selenium dioxide in monomethoxyethanol and cadmium nitrate [28].

Microscopic slides dipped into the solution allowed one to obtain homogeneous films which were then thermally treated [73]. X-ray powder diffraction and transmission electron microscope measurements confirmed a cubic crystalline structure of the nanoparticles, with mean diameter varying from 4 to 20 nm. The absorption and photoluminescence spectra of the smaller crystals were strongly blueshifted due to size quantization. The results indicate that the emission band involves the recombination between trapped electrons and holes presumably located on the surface states.

Nanosized, phenyl-capped CdSe quantum dots were prepared inside reversed micelles in AOT/H_2O/heptane [75, 76], and then isolated and redispersed in the amino-silicate ormosil (i.e., organically modified silicate) which was derived from 3-aminopropyl-(trimethoxy)silane by Ou and Seddon [74]. Doped ormosils were formed into films of a few micrometer thickness or small bulk samples. The ormosils

were structurally characterized by means of absorption spectroscopy in the visible and near-infrared ranges, and by [29]Si solid state nuclear magnetic resonance spectroscopy. The siloxane matrix of the amino-silicate ormosil was found to be 84% condensed and polymeric water molecules are hydrogen bonded into the matrix, presumably at silanol and amine sites. CdSe dots of apparently good monodispersity and radius 1.5 to 2.4 nm (going from yellow to red in visual appearance) were redispersed in the amino-silicate ormosil. Attempts to prepare larger dots resulted in flocculation of the CdSe. The maximum loading of CdSe dots in the amino-silicate matrix was measured to be 2.05 wt% $CdSe_{0.72}$, where the density of the amino-silicate host was around 0.5 to 0.7 of the density of a typical, melt-derived silicate glass.

2.3. CdTe-Doped Films

Cadmium telluride nanocrystallites were obtained by two synthetic methods in zirconia sol–gel films [77]. The nanoparticles were obtained by either chemical reduction of Te(IV) using a reducing agent (hydrazine) or tin chloride. Particle sizes ranging from 6 to 20 nm in diameter could be prepared by varying the experimental parameters. The size and crystalline structure of the particles were characterized by optical absorption, X-ray diffraction, transmission electron microscopy (TEM), and X-ray photoelectron spectroscopy. The film morphology was characterized by scanning force microscopy. The film obtained by the SnCl method is smooth and homogenous. A dense structure of CdTe nanoparticles of a few nanometers in diameter is revealed. The films prepared with hydrazine are porous as a result of evolution of the decomposition gaseous products during the reduction [77].

2.4. PbS-Doped Films

Lead sulfide (PbS) nanocrystals, embedded in amorphous zirconia sol–gel film with different PbS mol concentrations (5–30%), were prepared at temperatures ranging from 200 to 350 °C [28].

First, a zirconia solution is prepared. A 70% zirconium n-propoxide solution in 1-propanol was diluted to about 18% by n-propanol and stirred for 15 min. Then, glacial acetic acid was added and stirred for an additional 15 min. The solution was hydrolyzed with an acetic acid–water solution (1:1) under stirring for another 30 min, filtered, and stored in a refrigerator for 3–4 days. The solution was transparent, and its color was pale yellow. Then, to prepare the component solution, lead acetate trihydrate and ammonium thiocyanate were dissolved in 2-methoxymethanol at the boiling temperature of the solvent, 124.5 °C. An excess of sulfur, up to 50% was needed in order to bring the reaction to completion. Subsequently, the solution was stirred for 15 min, filtered, and cooled to room temperature. The solution was transparent and colorless. Finally, zirconia solution was diluted in n-propanol and component solution was added drop by drop. After an additional 30 min of stirring for homogenization, the final solution was transparent and pale yellow.

The films were prepared by dipping microscope glass slides or indium–tin oxide coated glass substrate into the final solution, followed by an annealing process, which completes the chemical reaction between lead and sulfur. The mol concentrations of the PbS nanocrystals within the zirconia films were 5, 15, 20, and 30%.

The size of PbS nanocrystals was determined by TEM and by blueshift of the absorption edge. The size increased with an increase in synthesis temperature and PbS mol concentration. The PbS nanocrystals have a nearly spherical shape, have an average size of 4.5 nm, and are homogeneously dispersed in an amorphous ZrO_2 thin film matrix.

3. METAL CLUSTER NANOCOMPOSITES

Optical properties of composites consisting of nanometer-sized metal particles dispersed in solid dielectric materials, such as glass, have been of increasing interest because of their optical applications. Colloidal gold and silver has been used in stain glass techniques since the medieval age, as their absorption spectrum exhibits an extinction band in the visible region and brings beautiful colors to the glasses [90]. Photochromic glasses containing silver and copper halides were developed by Corning in the early 1960s [91]. In the last two decades, noble metal nanoparticles embedded in a dielectric medium have been reported to exhibit some attractive optical properties, such as very high third nonlinear susceptibility $\chi^{(3)}$ of 10^{-9} to 10^{-8} esu [7, 92], ultrafast third nonlinear optical response [93–95], and surface plasma resonance absorption occurring in the near-ultraviolet (UV) or visible region [96, 97], which would have potential applications in nonlinear optics [92, 98, 99].

Noble metal clusters can be introduced into a glass matrix through different methods such as traditional melt quenching methods, ion implantation [100, 101], ion exchange [102, 103], and the sol–gel technique [92, 104, 105]. In recent years, sol–gel synthesis of nanocomposites containing ultrafine particles of noble metals in oxide matrices has been rapidly developed. Sol–gel technology is becoming one of the most useful and versatile methods of oxide film fabrication, due to the following advantages: the low processing temperature, homogeneity of coatings, easy control of metal concentration and coating thickness, as well as the possibility to add reducing and oxidizing agents in small concentrations [106, 107]. For preparing coating films containing dispersed fine metal particles, the sol–gel technique has advantages over the melt-quenching method. It gives much higher metal particle contents, which is important for obtaining a nonlinear optical material with high $\chi^{(3)}$ [93, 130].

Different metal particles were prepared in glassy matrices by the sol–gel method, such as gold [60, 108–115], silver, [104, 107, 108, 111, 112, 116–120], platinum [112, 114, 121], and copper [122, 123]. The matrices for dispersing metals include oxides, such as SiO_2 [124, 125], TiO_2 [126], ZrO_2 [127], AlOOH, and organic–inorganic hybrids [128]. Barium titanate thin film, with high dielectric constant and refractive indices, incorporated with noble metal nanoparticles, has also been studied as a potential nonlinear optical material [129–131].

Metal particles have been incorporated by dissolving metal salts in the precursor sols (including alkoxide, water,

and alcohol in most the cases) and reduction of the ions to metallic particles by thermal treatment in air or in a reducing atmosphere, or by irradiation with UV light or gamma rays [128]. The nonlinearities of some systems have been measured and many important results are summarized in Table 2.

3.1. Coating Films Containing Gold Colloids

During the last two decades, clusters of gold particles embedded in oxide glasses have been shown to exhibit very high values of $\chi^{(3)}$ of 10^{-9} to 10^{-8} esu [7, 92]. The sol–gel

Table 2. NLO and other related properties of some sol–gel derived metal–cluster nanocomposites.

S. No.	Matrix	Particle size	Dope concentration	Optical nonlinearity	Precursors (comments*)	Ref.
Au-doped Films

method has also been used to prepare such NLO nano-composites in thin film forms [124, 132]. Sodium tetra-chloraurate (NaAuCl$_2 \cdot$2H$_2$O) was reacted with TEOS in EtOH solution. The dip-formed films on SiO$_2$ substrates were heated in air up to 1000 °C. Micrographs of gold with radii of about 7 and 30 Å coexist in the glass film. The Au/Si atomic ratio was 0.01 and the $\chi^{(3)}$ was found to be 7.7×10^{-9} esu [133].

Matsuoka et al. [132, 133] showed that silica coating films that contain dispersed fine gold particles, from 7 to about 40 Å in size, were prepared by the sol–gel method using NaAuCl$_4 \cdot$2H$_2$O and TEOS as starting materials. Fine Au particles are precipitated when the film is heated at 300–400 °C in air. No special procedure for reducing Au^{3+} ions proved necessary. The glass film with an Au/Si atomic ratio of 0.01 to 0.04 was successfully prepared. The nonlin-ear susceptibility $\chi^{(3)}$ of the film was 7.7×10^{-9} esu. Sub-sequent heat treatment of the films at 1000 °C changed the absorption spectra and decreased the $\chi^{(3)}$ by a factor of two.

Kozuka and Sakka [124] obtained silica films that con-tained dispersed fine Au particles using Si(OC$_2$H$_5$)$_4$ and HAuCl$_4$ as precursors; films were formed through dip coat-ing. The Au content was 2.8 mol%. In as-coated films, gold is present as AuCl$_4^-$ ions. After heating at 200 °C in air, Au particles are precipitated. They are stabilized when the film is heated to 500 °C in air. It is found that some gold particles are present on the surface of the film and can be easily removed with tissue paper. The loss of gold is minimized when as-prepared coating films are exposed to monoethanolamine vapor before heating. It is assumed that the amine treatment promotes the formation of gel networks.

Partial substitution of CH$_3$Si(OC$_2$H$_5$)$_3$ (MTES) for Si(OC$_2$H$_5$)$_4$ (TEOS) in the solution for the silica film con-taining 4 mol% Au results in the reduction of the average size of Au particles [134]. The shape of particles is round at higher MTES contents and elongated at lower MTES con-tents. In addition, larger coating thickness (up to 0.5–0.7 μm in one coating step) can be obtained without cracks.

Kozuka et al. [114] employed TiO$_2$ as matrix for dispers-ing fine Au particles, using Ti(OC$_3$H$_7$)$_4$ and HAuCl$_4$ as pre-cursors (15 mol% Au). Films were formed by dip coating. Heating of the coating film at 500 °C in air produced spher-ical gold particles of 20–30 nm size. The crystalline phase of TiO$_2$ is anatase. The optical absorption peak due to the sur-face plasma resonance of gold particles in the film is located at around 640 nm, compared with 540 nm for the Au/SiO$_2$ system.

Kozuka et al. also prepared gold particles of 6–20 nm in boehmite gels of the composition AlOOH [135]. A coating sol was obtained by adding HAuCl$_4$ to a sol prepared from Al(OC$_4$H$_9$)$_3$–H$_2$O–HCl solution until Au content reached 2.5 mol%. A gel film was deposited on a slide glass by spin coating, dried at 120 °C, and then placed over a hydrazine in ethanol solution. Very thin coating films (20–25 nm) were obtained. It is assumed that the reduction of Au^{3+} ions by hydrazine causes precipitation of gold particles at room tem-perature and that the texture of boehmite matrix causes the shape and alignment of elongated gold particles. The sur-face plasma resonance absorption is found at 660 nm for

elongated particles, compared to 600 nm for spherical gold particles of similar size.

Barium titanate was also used as matrix for dispersing nanometal particles. Barium titanate thin films have high dielectric constants and high refractive indices, which could strongly influence the local fields around the metal parti-cles. The large third-order susceptibility $\chi^{(3)}$ of these films has been found to be dependent on local field enhance-ment near the surface plasmon resonance of the metal par-ticles by Hache et al. [92]. Recently, barium titanate thin films incorporated with noble metal nanoparticles, for exam-ple, Ag/BaTiO$_3$ [129] and Au/BaTiO$_3$ [130] nanocomposite films, have been investigated, but the concentration of metal particles dispersed in these films was low. In the work of Yang et al. [131], a larger volume fraction of Au nano-particles has been successfully incorporated into BaTiO$_3$ thin films, which exhibited high third nonlinear susceptibility and unique absorption redshift. Gold nanoparticle-dispersed BaTiO$_3$ films were prepared by a sol–gel route combined with a dip-coating method. First, BaTiO$_3$ precursor solu-tion was prepared through dissolving Ba(CHCOO)$_2$ in a mixed aqueous solution of acetic acid and 2-methoxyethanol. After stirring at room temperature, acetylacetone was added to stabilize the solution. This was followed by an addition of titanium butoxide. Then, HAuCl$_4$–ethanol solutions were prepared by dissolving HAuCl$_4 \cdot$4H$_2$O into ethanol. Finally, Au/BaTiO$_3$ composite precursor solution was prepared by injecting HAuCl$_4$–ethanol solutions into BaTiO$_3$ precursor solution slowly with a molar ratio of Au/Ba = 2:5. This com-posite solution was yellow and clear. Au-dispersed BaTiO$_3$ thin films were coated on glass slides by dip coating. As-prepared films were dried at 60 °C and successively heated to 200–600 °C in N$_2$ atmosphere. After heat treatment, the colors were light purplish blue.

As a result, Au nanoparticles were dispersed well in the BaTiO$_3$ matrix with an average size of 20 nm. The absorp-tion spectra of Au/BaTiO$_3$ films exhibited a large redshift of the absorption edge due to the dielectric constant increase of BaTiO$_3$ matrix with the increase of heat-treatment tem-perature. The nonlinear optical properties of these films were measured and the values of $\chi^{(3)}$ were calculated to be in the range of 10^{-8}–10^{-9} esu.

To understand the mechanism of the stability of Au nano-particles in glass systems, Matsuoka et al. [136] carried out a study to investigate the dependence of the maximum amount of Au microcrystals attainable in the sol–gel derived oxide films on the metal species in starting alkoxides. Au-microcrystal-doped TiO$_2$, ZrO$_2$, and Al$_2$O$_3$ films were made by a sol–gel dip-coating method using titanium isopropoxide [Ti(OC$_3$H$_7$)$_4$], zirconium n-propoxide [Zr(OC$_3$H$_7$)$_4$], and aluminum sec-butoxide [Al(OC$_4$H$_9$)$_3$] with HAuCl$_4 \cdot$4H$_2$O. At first, one of the alkoxide was diluted with anhydrous ethanol, and then the mixed solution of ethanol, water, HCl, and stabilizing agent (acetic acid) was added to form dip-coating solutions, followed by the addition of a different amount of HAuCl$_4 \cdot$4H$_2$O. The influence of the oxide matrix composition was studied to understand how it affected max-imum amount of the Au microcrystals that can be incor-porated in the oxide film. Some Au microcrystals were exhausted to the surface of Au microcrystal-doped oxide

films when an excess amount of $HAuCl_4 \cdot 4H_2O$ was dissolved in the coating solution. The maximum amount of Au that can be incorporated in the oxide film was found to increase with the increase of the pH point at zero charge (PZC) of the matrix oxide. This should be due to the fact that $AuCl_4^-$ ions are charged negatively and also Au microcrystals tend to charge negatively, so that the oxide gel with high PZC, which has a tendency to charge positively, may fix the ions and/or microcrystals to its interior. A maximum amount of Au microcrystals as high as 12.6 vol% was attained in an $Au:Al_2O_3$ film.

Besides inorganic oxides, inorganic–organic hybrids are also used as matrices. Compared with oxide, organic–inorganic hybrid materials (ormosils) have lower photostability and thermal resistance, but they do have several advantages over oxide matrices, such as easy formation of films, possible crack-free thick coatings, transparency, and high water durability.

Spanhel et al. [137] used coating solutions consisting of $HAuCl_4$, $NH_2[(CH_2)_2NH](CH_2)_3Si(OC_2H_5)_3$ (diamine silane), prehydrated methacryloxy-propyltrimethoxysilane, and H_2O, and the Au/Si mol ratio was 0.05. Coating films on commercial glass substrates were exposed to UV radiation. This treatment achieved both growth of the photo-induced gold metal particles and thermal curing of the film, that is, hybrid network formation, simultaneously. The resulting coating film had an absorption peak due to surface plasmon resonance at about 550 nm. Crack-free thick films up to 8 μm thick were obtained in a one-step coating. Spanhel et al. further stated that in this procedure diamine silanes act as ligands of gold particles, thereby preventing undesirable gold particle growth and at the same time modifying the optical properties of gold particles. If $NH_2[(CH_2)_2NH]_2(CH_2)_3Si(OC_2H_5)_3$ (triamine) was used as the gold colloid-stabilizing agent in place of diamine, photoirradiation was not required. Reduction of Au^{3+} is caused by organic materials and fine gold metal particles are spontaneously precipitated.

Tseng et al. [113] employed polydimethylsilane to prepare inorganic–organic hybrid coating films containing fine gold particles. Gold (up to 5%) and platinum (3%) cluster nanocomposites were prepared. A solution of silanol-terminated polydimethylsiloxane, $Si(OC_2H_5)_4$, i-C_3H_7OH, tetrahydrofuran, H_2O, and HCl was refluxed at 80 °C for 2 h and $HAuCl_4$ solution was added, in order to obtain a starting solution with 5 wt% gold. Gold particles were precipitated in the film heated at 100 to 300 °C or irradiated with UV, with a particle size, for example, of 2.5 nm for heating at 200 °C.

3.2. Coating Films Containing Silver Colloids

Silver particles have been incorporated by dissolving silver salts in the precursor sols and reduction of the silver ions to metallic particles by thermal treatment in air or in a hydrogen atmosphere, or by irradiation with UV light or gamma rays.

During the formation of Ag colloids in a thermal treatment, temperature is critical for the silver particle size and oxidation/reduction reaction of silver. It will affect the optical density and absorption wavelength of silver colloids.

While silver-containing sol–gel films and gels are heated, reversible darkening is observed in silver-containing sol–gel films and gels. Some suggest this darkening–bleaching effect occurs due to an aggregation–disaggregation of silver particles [138], while others attribute this to oxidation/reduction of silver colloids [139, 140]. The substrate being coated is also an important factor that influences the Ag colloid formation process. It seems that the silver colloids in a silica-based coating on the soda lime glass substrate have a greater tendency toward being oxidized than those on a silica substrate [139].

A simple way to form nano-silver-particle-containing silica films is through a sol–gel dip-coating method. The SiO_2–Ag sol was prepared using TEOS, C_2H_5OH, H_2O, HNO_3, and $AgNO_3$ as precursors. First, solution A is prepared by mixing TEOS and ethanol in equal volume. Then, solution B is prepared by adding distilled water, different amounts of silver nitrate ($AgNO_3$), and nitric acid (HNO_3) together. HNO_3 is added to adjust the pH to approximately 2. Finally, solution B was added to solution A drop by drop while stirring vigorously at room temperature. The final molar ratio is $TEOS:C_2H_5OH:H_2O:AgNO_3 = 1:3.825:3:x$, where x is the Ag/Si molar ratio in the glass coating. To stabilize the silver in the silica film, complete drying of the gel glass film is recommended right after the formation of the film, at about 450 °C. Without drying the film at an elevated temperature, the silver content can be lost through aggregation on the surface.

Following mixing of two solutions, the sol was left to age until the viscosity reached approximately 3 cP. It usually took two to four days for the sol to get ready, depending on the silver concentration, with sols with higher silver concentration taking less time. After the viscosity of the sol reached 3 cP, the coating was formed by dip coating at a pulling rate around 1 mm per second.

Mennig et al. [139] prepared coating films containing Ag colloids from solutions of $AgNO_3$, N-(2-aminoethyl)-3-aminopropyltrimethoxysilane (DIAMO), prehydrolyzed 3-glycidoxypropyltriethoxysilane, TEOS, C_2H_5OH, and HNO_3. The Ag content was 6.2 mol%. Films deposited on fused silica by dip coating and dried at 120 °C were yellow colored due to the presence of Ag colloids. Formation of Ag colloids was attributed to reduction of Ag^+ ions by organic materials in the coating films. DIAMO in the coating solution acts as a stabilizing agent for Ag particles. When coating films are heated at 120–600 °C in air for decomposition of organic materials and densification of the film, some of the Ag colloids were oxidized to Ag_xO_y. Heating of this film at 500 °C reduced silver oxide particles to Ag metal colloids of 8 nm average size. When a soda-lime–silica glass substrate was used, heating of the coating films at 400–600 °C oxidized all the Ag colloids to Ag_xO_y. Heating of these films at 500 °C in 90% N_2–10% H_2 atmosphere reduced Ag_xO_y to Ag colloids, producing an Ag colloid-containing film similar to that applied to the SiO_2 substrate.

The effect of heating temperature on the color intensity due to silver colloids at 410 nm has been studied with silica sol–gel glass doped with 0.05 mol% silver [138]. This glass was prepared by gelling $Si(OC_2H_5)_4$–$AgNO_3$–C_2H_5OH–HNO_3 solution at 60 °C and then densifying the

film at 600 °C. When a darkened sample is heated above 400 °C, reversible bleaching took place. This darkening–bleaching was attributed to aggregation–disaggregation of fine silver particles by Ritzer et al. [138]. Another explanation for this phenomenon is that Ag particles may be oxidized to Ag_xO_y above 400 °C (but below 600 °C), and reduced to Ag particles at 600 °C.

Kozuka et al. prepared TiO_2 coating films containing fine Ag particles by sol–gel processing using a $Ti(OC_3H_7)_4$, $NH(CH_2CH_2OH)_2$, i-C_3H_7OH, H_2O, and $AgNO_3$ precursor solution. The Ag content was 6.2 mol%. Exposure of a gel film to formaldehyde vapor at room temperature caused reduction of Ag^+ ions, forming Ag particles of 4–23 nm in size in the gel film. The gel film showed a sharp absorption peak at 441 nm due to surface plasma resonance (SPR) of Ag metal particles. Heat treatment of the gel films at 600–800 °C in air resulted in the formation of anatase or rutile polycrystalline films containing Ag particles 5–45 nm in size (5–25 nm for 600 °C and 13–45 nm for 800 °C). These films showed an absorption peak around 550 nm. The shift of the SPR absorption of Ag particles from 441 (room temperature) to 550 nm (600–800 °C) may be attributed to an increase in dielectric constant of the oxide matrix caused by its thermal densification and crystallization [120].

3.3. Coating Films Containing Platinum Colloids

Kozuka et al. [120] prepared TiO_2 coating films containing Pt colloid particles (7 mol% Pt) on silica substrate by the sol–gel processing. Precursor solution containing $Ti(OC_3H_7)_4$, H_2O, CH_3COOH, C_2H_5OH, and $H_2PtCl_4 \cdot H_2O$ solutions were used to produce coating films. Platinum fine particles were precipitated by heating at 800 °C in air.

Silica based ormosil coating films containing Pt colloids were prepared by Tseng et al. [113]. Pt^{4+} ion-doped gel films were prepared from coating solutions consisting of silanol terminated polydimethylsilane, H_2O, HCl, and $H_2PtCl_4 \cdot H_2O$. Thermal reduction by heating at 200 °C and photoreduction by exposure to a high pressure mercury lamp are used to produce hybrid coating films containing Pt colloids of 3–5 nm in size. The color of the film was light brown.

3.4. Coating Films Containing Palladium Colloids

Zhao et al. [141] prepared coating solutions from titanium isopropoxide, palladium(II) chloride, deionized water, ethanol, acetic acid, and hydrochloric acid to produce TiO_2 coating films containing 3 vol% Pd (7 mol%). A transparent red–brown solution resulted. Heating TiO_2 coating films at 600–900 °C in air produced PdO particles in the film. Reduction of this film by heating at 500 °C in a H_2/Ar atmosphere gave films containing dispersed metal particles. The average diameter of Pd is 15–30 nm. The films containing Pd particles are brownish grey, showing optical absorption due to surface plasmon resonance. Particle size was controlled by selecting the heating time at 800 °C. It should be noted that Pd metal particles are precipitated when TiO_2 coating films are heated at 1000 °C in air.

4. ORGANIC–INORGANIC HYBRID COMPOSITES

Many organic materials exhibit NLO properties either in the form of molecules, crystals, or polymers. NLO organic polymeric material has been an exciting area for the last two decades [151]. Following the early works [152–155] on their nonlinear properties, organic polymers have been studied extensively for nonlinear applications [156–171]. Among all nonlinear materials, organic polymeric systems provide the highest nonresonant nonlinearity [172] and therefore are very promising systems for achieving high speed. Glasses are ideal for use as a matrix for these organics, due to their highly cross-linked structures and good mechanical and chemical stability [173–193].

Through the sol–gel approach, organic/inorganic hybrid materials have rapidly become a fascinating new field of research in materials science [194–199].

The sol–gel process, based on inorganic polymerization reactions, is a synthesis method initially used for the preparation of inorganic materials, such as glasses and ceramics. Its low-temperature characteristic also provides unique opportunities to make organic/inorganic hybrid materials through the incorporation of low molecular weight and oligomeric polymeric organics with appropriate inorganics. There are several different synthetic techniques used to prepare hybrid materials [200]. The main methods for producing NLO hybrid are the following:

(1) By simply dissolving or dispersing the active organic into inorganic sol–gel precursor solution, organics can be impregnated or entrapped as a guest within inorganic gel matrix (as a host), on gelation.

(2) Hybrid networks can be synthesized by using low molecular weight organoalkoxysilanes as one or more of the precursors for the sol–gel reaction; as a result, organic groups are introduced into an inorganic network through the $\equiv$Si–C– bonds.

(3) Hybrid material can also be formed through the co-condensation of functionalized oligomers with metal alkoxides in which chemical bonding is established between inorganic and organic phases.

(4) A hybrid network can be formed by interpenetrating networks and simultaneous formation of inorganic and organic phases.

The properties of organic–inorganic nanocomposites depend on not only the organic and inorganic components, but also the interface between them. The precursor mixing in a homogenous solution allows organic and inorganic components to be associated at the molecular level. However, the chemical reactivities of organic and inorganic species are usually different and phase separation tends to occur. Chemical bonds have to be formed between organic and inorganic components in order to form molecular composites or organic–inorganic polymers. Hybrid materials are currently divided into two classes depending on whether the organic and inorganic phase share weak interactions such as van der Waals and hydrogen bonds (class I) or strong chemical bonds (class II). Some important optical applications of class II can be found in review articles authored by Sanchez and Lebeau [183, 201]. To accomplish superior

nonlinear optical properties in hybrid nanocomposites, it is important to have organic chromophores with high intrinsic nonlinearity, high chromophore concentration in the composites, good interfacial interaction between organic and inorganic components, and stability of the network structure. For second-order NLO composites, it is even more important to have strong bonding between the organic dye and the matrix. It is well known that second-order NLO effects cannot observed in centrosymmetric systems, but the NLO effects can occur after poling in order to orient the organic dyes within the sol–gel matrix. However, organic dyes tend to lose their induced orientation with time due to thermal relaxation processes. Both weak and strong interactions between the NLO dyes and the matrices are used to control the relaxation behavior of the NLO chromophores. This section gives a short review of the different hybrid organic–inorganic materials with NLO properties, especially second-order nonlinearities.

As we mentioned, different synthesis routes have been developed to synthesize NLO hybrid materials; both class I (host–guest) and class II (chromophore-linked) were prepared. Chaumel et al. [202] illustrated some important hybrid network structures and the routes to achieve them (Fig. 1).

4.1. Second-Order NLO Sol–Gel Hybrid Nanocomposites [201]

4.1.1. Guest–Host Hybrids Containing Embedded NLO Chromophores

Hybrid materials with embedded NLO dyes were synthesized in the early stage of sol–gel NLO hybrid material studies, due to the simplicity of the synthesis process [2, 203]. These composites are mostly class I composites, and the interactions between organic and inorganic components are weak interactions (van der Waals, hydrogen bonds, hydrophilic–hydrophobic behavior). Figure 2 shows some usual NLO dyes that have been embedded into sol–gel matrices.

Second-harmonic generation (SHG) (d_{33} coefficient) or electro-optic coefficients (r_{33}) have been measured in many sol–gel processed materials. Some results are shown in Table 3, along with those of other hybrid systems. Three different matrices were obtained by the sol–gel process, first, through hydrolysis of metal alkoxides $M(OH)_n$ M = Ti, Si, Zr, ...), written as MO_2; second, through hydrolysis of trialkoxysilanes $RSi(OR)_3$ (R = methyl, phenyl, etc.), written as $RSiOR_{1.5}$; third, through co-condensation between both precursors, which leads to $RSiOR_{1.5}/MO_2$ matrices.

In general, organic dye molecules embedded in those hybrids are randomly oriented, and electrical-field-induced orientation (poling) is needed for second harmonic response. There are few exceptions, due to the presence of microcrystallites of chromophores [204] or possible orientation preference of NLO molecules in the glass matrix via van der Waals interactions [205].

Griesmar et al. [206] and Toussaere et al. [207] first performed the orientation of organic chromophores in hybrid sol–gel matrices by using electrical-field-induced second-harmonic and corona electrical field poling techniques. These first attempts showed the potential of using poling

techniques in hybrid composites for the synthesis of second order NLO material. Unfortunately it also showed the general weakness of the guest–host system: the low efficiency and low stability of the optical nonlinearity, poor solubility

Note: Chromophores: NPP: *N*-(4-nitrophenyl)-(*s*)-prolinol, DR1: disperse red 1, DR19: disperse red 19, DANS: 4-(dimethylamino)-4′-nitrostylbene, SG-DANS: 4-[*N*,*N*-bis-(2-triethoxysilanoxyethylamino)]-4′-nitrostilbene, DNPA: 2,4-dinitrophenylamine, DR1: Disperse Red 1, DO3: Disperse Orange 3, ASF: aminosulphone, NA: 4-nitroaniline, TCVA: tricyanovinylaniline, SHG response stability %: final ratio SHG response/initial SHG response, *t*: time after field poling cutoff in hours. Systems: S-C—side-chain, M-C—main-chain [201].

of the chromophore in the matrix, and the fast relaxation of the poling-induced order, respectively [208].

To decrease the relaxation of poling-induced order, several research groups have started to use conventional metal-oxide-based sol–gel matrices (SiO$_2$, Al$_2$O$_3$, SiO$_2$–TiO$_2$) [173, 174, 209, 210], which exhibit high rigidity and mechanical properties. The conventional sol–gel matrix did achieve both high dye concentration and good temporal stability of the poling-induced order. The latter can be explained by the preferential interaction between the chromophore and the host matrix (hydrogen bonds and/or ionocovalent bonds) [173, 211]. However, the "conventional sol–gel matrices" also have their drawbacks. First, the type of films with good optical quality can only be obtained with thicknesses under 1 μm. Second, there is a concern about the porous and hydrophilic nature of the matrix. Water adsorption might promote the disruption of the hydrogen-bond

network, the cleavage of the ionocovalent dye–matrix bonds, and the loss of the SHG response as a result.

To suppress those drawbacks, hybrid organic–inorganic sol–gel matrix was used to deposit dense and hydrophobic thick films (1–20 μm) [212]. However, the problem of low chromophore concentration was not resolved in these systems.

4.1.2. NLO Chromophore Grafted to Sol–Gel Matrices

The best solution so far is hybrid organic–inorganic materials with NLO dyes grafted to the inorganic network [183, 201]. It allows easy optimization of the dye concentration and better control of chemical and processing parameters. The number of covalent bonds of the organic chromophore with the inorganic matrix classifies these hybrid materials into side-chain (one covalent bond) and main-chain (two or

more bonds) hybrid materials [200]. The most common way to introduce an organic group into a silica network is to use siloxane-based trifunctional organoalkoxysilane precursors, $R'Si(OR)_3$ (where R' is an NLO organic chromophore). Some of these precursors are presented in Figure 3.

The synthesis of a class II hybrid with second order NLO properties can be performed by hydrolysis and condensation of $R'Si(OR)_3$ carrying the NLO dyes or through hydrolysis and co-condensation between $R'Si(OR)_3$ and metal alkoxides $[Si(OR)_4, Zr(OR)_4, \text{etc.}]$.

Some important results of these class II NLO hybrids are shown in Table 3. Matrices obtained through hydrolysis of a trifunctional alcoxysilane $R'Si(OR)_3$ (R' being the NLO group) are denoted as $R'SiO_{1.5}$, while those prepared via hydrolysis and co-condensation between trifunctional alkoxysilanes $R'Si(OR)_3$ and metal alkoxides $M(OR)_4$ (M = Si, Zr, etc.) are written as $R'Si(OR)_3/MO_2$.

Class II Side-Chain Systems It has been shown that covalent coupling of the NLO chromophore to the lattice could improve chromophore loading and consequently NLO efficiency [173, 174, 217]. Compared to class I hybrids, the side-chain hybrid efficiency is better but still needs improvement.

Two strategies are used to improve the second-order NLO response of dye-grafted hybrid coatings. First is using chromophores with a higher intrinsic NLO response, such as *N*-(4-nitrophenyl)-L-prolinol or disperse red one (DR1) derivatives, which exhibit higher nonlinearities than nitroaniline. Second is to control the chromophore relaxation by increasing the matrix rigidity. The most common strategies to minimize relaxation is to increase the cross-linking in the network, through adding inorganic network builders

Figure 3. NLO chromophores functionalized with trialkoxysilanes. Reprinted with permission from [239], B. Lebeau et al., *Pure Appl. Opt.* 5, 689 (1996). © 1996, IOP Publishing.

$(MOR)_4$ or polymers with well known mechanical properties such as polymethylmethacrylates or polyimide.

For the class II side-chain systems, a promising result was obtained by Riehl et al. [180] ($d_{33} = 55$ pm V^{-1} at 1.064 μm) for an alkoxysilane–silica system functionalized with DR1. No NLO signal loss was observed at ambient temperatures 1 week after poling. The good temporal NLO response stability seems to be due to the two-step synthesis strategy. After the hydrolysis of precursors in an acidic medium, a base is added to enhance condensation reactions, therefore improving the formation of highly branched inorganic network.

Class II Main-Chain Systems To further increase the stability of the second-order NLO response of the hybrid composites, a main-chain system is used, with both ends of the chromophore anchored to the polymer backbone. Large second harmonic coefficient and high thermal stability can be achieved through this structure. By using a main-chain hybrid system, choosing organic dyes with a higher intrinsic NLO response (Red 17), and increasing cross-linking (adding SiO_2), one of the best results of sol–gel NLO hybrid so far was achieved by Lebeau et al. [222].

Further increasing the number of the bonds between the organic and inorganic component will help increase the stability of the poled structure, but it also makes it difficult to reach desired order during the polling process [223]. Because class II hybrid organic–inorganic materials allow better control of film thickness, film hydrophobicity, matrix rigidity and densification, and NLO chromophore concentrations, they become very promising in the field of quadratic NLO.

The sol–gel process is versatile, and yet it is also very complex. Many factors can be tuned in order to improve these new nanocomposites, such as the number and position of the alcoxysilyl groups, the amount and the nature of the cross-linking agent (TMOS) and catalysts, the hydrolysis ratio, the sequence of mixing, the nature of the solvent (which may influence nanophase separation), the aging time (which influence the complication of crosslinking), etc.

Poling protocol is also very important because these systems behave as thermosets or thermally hardened materials. The process must be optimized in such a way that desired noncentrosymmetric order can be introduced by electric field poling before the matrix hardening is completed.

4.2. Third-Order NLO Sol–Gel Hybrid Nanocomposites

Sol–gel hybrid nanocomposites for third-order NLO applications are not as well studied as second-order NLO hybrids. Prasad's group is one of the few that has been making continuing progress in developing those materials [226–229]. As we mentioned, polymer has high nonresonant third-order NLO properties. These studies are very meaningful for photonic application.

Most third-order NLO hybrid systems synthesized so far belong to guest–host hybrid materials, which are made through dissolving or dispersing the active organic into the inorganic solution. For example, poly-*p*-phenylene (PPV), a conjugated NLO polymer, was dispersed into a SiO_2 gel [226]. A $\chi^{(3)}$ value of 3×10^{-10} esu was obtained, using 400 femtosecond pulses from a Nd-YAG laser
pulse compressed amplified system at 602 nm. Two PPV derivatives, poly(2-bromo-5-methoxy-1,4-phenylene vinylene) and poly(2-butoxy-5-methoxy-1,4-phenylene vinylene), and poly(2,5-disubstituted-1,4-phenylene vinylene) were also incorporated into polymer/silica composites. The third-order nonlinear susceptibilities have been investigated for the polymers themselves and their sol–gel composites. Relatively large $\chi^{(3)}$ values (4×10^{-10} to 1×10^{-9} esu) with a subpicosecond response were observed [227].

In order to improve the optical quality, poly(thienylene vinylene)/silica composite was prepared by sol–gel, and its optical nonlinearity was determined. The soluble methoxy pendant poly(thienylene vinylene) (PTV) precursor and the silica sol were homogeneously mixed in tetrahydrofuran and converted to the final composite material by heat treatment. The blueshift of $\lambda_{\max}$ in the UV-visible spectra was observed which provides evidence of interaction between the PTV and the silica components. The third-order optical nonlinearities, $\chi^{(3)}$, were measured as 4×10^{-9} esu and 3×10^{-9} esu for the pure PTV and PTV/silica [228].

Prasad et al. have also investigated the nonlinear optical performance of new UV photostable dyes, didecyl and didecyloxy substituted para-polyphenyl heptamers, in sol–gel processed composite glass, using the techniques of degenerate four-wave mixing (DFWM) and optical Kerr gate [229].

There are other organic dyes incorporated into oxide gels by similar methods [230–234]. For instance, rhodamine-6G doped SiO_2–TiO_2 thin films were prepared using a dip coating method. Effects of the MTMS/TEOS ratio on the cracking of the thin films during the drying stage were studied. The cracking greatly decreased on increasing the MTMS/TEOS ratio. Crack-free thin films were obtained for samples with MTMS/TEOS > 0.75. The optical absorption and fluorescence spectra of the thin films were recorded. The refractive index increases linearly with increasing TiO_2 content (20, 40, 60 mol%). The third-order nonlinear susceptibility of the rhodamine-6G doped SiO_2–TiO_2 thin films is $\chi^{(3)}$ approximately $= 10^{-9}$ esu, measured by the DFWM technique [235]. Other matrix systems used include Al_2O_3 [236, 237] and V_2O_5 [238].

While third-order nonlinear hybrids do not have the same requirements for the SHG NLO hybrids, they still share many common ones, such as high transparence, good mechanical strength, stability of the structure, and high concentration of NLO dyes. So it may be helpful to find the possibilities of synthesizing THG hybrids materials through the well defined routes for SHG hybrid materials.

5. CONCLUSIONS

Sol–gel is an extremely versatile technique to produce inorganic–inorganic and inorganic–organic nanocomposites. Its may open many possibilities for the development of photonic devices. Using sol–gel derived ceramics as matrix, semiconductor, metal, and polymer are incorporated into various nanocomposites to achieve high nonlinear properties. Although further studies are still needed to improve the synthesis processes of those composites, through particle size control and/or enhancing chemical bonding, the sol–gel technique has been proved to be a very promising technique for developing various NLO materials.

GLOSSARY

Exciton Bohr radius   The optical properties of a material are usually determined by the nature of electrons and holes existing in it. Due to Coulomb interaction, the electrons and holes existing in a material are known to form excitons. The distance between the electron and the hole within an exciton is called Bohr radius of the exciton. Typical exciton Bohr radius of semiconductors is of a few nanometers (1 nanometer $= 10^{-9}$ meter).

Optical nonlinearity   Nonlinear effect is a general concept, and it refers to the nonlinear proportionality of the response to the input. When an electric field (e.g., light) interacts with electrons in a materials, the electron density can be provokes to be displaced. This is called polarization. In a nonlinear optical material, or when the electric field is strong enough, the polarization is a nonlinear response of the electronic field.

$$P = \chi^{(1)}E + \chi^{(2)}EE + \chi^{(3)}EEE + \cdots$$

Where $\chi^{(2)}$ and $\chi^{(3)}$ are the second and third order nonlinear susceptibilities, respectively.

Quantum dot   A Nanometer sized structure that is capable of trapping electrons in three dimensions. Quantum dots are made by creating an island of conductive material surrounded by insulating material. Electrons that enter the quantum dot will be confined because of the high potential required to escape.

Sol–gel process   A process that involves the evolution of inorganic networks through the formation of a colloidal suspension (sol) and gelation of the sol to form a network in a continuous liquid phase (gel).

Surface capping agent   A molecule which attached to the surface of a growing cluster surface to terminate its growth, thus control the particle size.

Surface plasmon resonance   Conduction electrons (−) and ionic cores (+) in a metal form a plasma state. When external electric fields (electro-magnetic waves, electron beams etc.) are applied to a metal, electrons move so as to screen perturbed charge distribution, further move beyond the neutral states, and again return to the neutral states and so on. This collective motion of electrons is called a "plasma oscillation." The surface plasmon resonance is a collective excitation mode of the plasma localized near the surface. Electrons confined in a nanoparticle conform the surface plasmon mode. The resonance frequency of the surface plasmon is different from an ordinary plasma frequency. The surface-plasmon mode arises from the electron confinement in the nanoparticle. Since the dielectric function tends to become continuous at the interface (surface), the oscillation mode shifts from the ordinary plasma resonance and exponentially decays along the depth from the surface.

CONTENTS

1. INTRODUCTION

Almost everyday we read the "nano" words (nanoscience, nanotechnology, nanoscale, nanometer, nanosecond, nanodevice, nanoelectronics, nano-optics, and so on) from television commercials, research journal papers, magazine articles, newspaper headlines, and conferences. Such excitement comes from the undisputed fact that scientists all over the world have begun to control materials at a nanometer scale resulting in a great many new techniques and skills which can be used to make new materials with unique and useful properties. Obviously, these extensive studies in nanoscience and nanotechnology have led to a range of commercial applications in electronics, photonics, spintronics, sensing, military uses, medicine, and so on. Certainly, the best and most exciting days of obtaining novel properties or other kinds of discovery in the nanoscience and nanotechnology are still ahead. In this chapter, we review the recent development of nonlinear optical (NLO) studies on fullerenes and carbon nanotubes. Before starting our review, we briefly introduce the theory of optical nonlinearity of a material and present the brief history of the new materials, called *fullerenes* and *carbon nanotubes*.

1.1. Nonlinear Optical Interactions

Nonlinear optics, focusing on the studies of NLO response of a material system to an applied optical field, plays an important role in many areas of science and technology [1–15]. To introduce the concept of optical nonlinearity one can express the field-induced dipole moment per unit volume, that is, the polarization $\mathbf{P}(t)$, in a power series of the strength of the applied optical field $\mathbf{E}(t)$ [9]. Assuming that this optical field vector can be represented as the discrete sum of a number of frequency components as the compact form [9]

$$\mathbf{E}(t) = \sum_n \mathbf{E}(\omega_n) e^{-i\omega_n t} \tag{1}$$

one can write the polarization $\mathbf{P}(t)$ as a function of $E_i(\omega_n)$ in the Gaussian system of units

$$\mathbf{P}(t) = \sum_{m=1} \sum_n \sum_{j=x,y,z} P_j^{(m)}(\omega_n) e^{-i\omega_n t} \tag{2}$$

with

$$P_j^{(1)}(\omega_n) = \sum_{i=x,y,z} \chi_{ji}^{(1)} E_i(\omega_n) \tag{3}$$

$$P_j^{(2)}(\omega_n) = \sum_{i,k=x,y,z} \sum_{(mo)} \chi_{jik}^{(2)}(\omega_n = \omega_m + \omega_o; \omega_m, \omega_o)$$

$$\times E_i(\omega_m) E_k(\omega_o) \qquad (4)$$

$$P_j^{(3)}(\omega_n) = \sum_{i,k,l=x,y,z} \sum_{(mop)} \chi_{jikl}^{(3)}$$

$$\times(\omega_n = \omega_m + \omega_o + \omega_p; \omega_m, \omega_o, \omega_p)$$

$$\times E_i(\omega_m) E_k(\omega_o) E_l(\omega_p) \qquad (5)$$

where the indices *ijkl* refer to the cartesian components of the applied optical field, and the notation (*mo*) or (*mop*) indicates that the sum $\omega_m + \omega_o$ or $\omega_m + \omega_o + \omega_p$ is to be held fixed in performing the summation over *m*, *o*, and *p*. The coefficients $\chi^{(1)}$, $\chi^{(2)}$, and $\chi^{(3)}$ are known as the linear optical, second-, and third-order nonlinear optical susceptibilities of the material system. Correspondingly, for atoms or molecules they are referred to as the linear polarizability α $(=\chi^{(1)}/\rho)$, the first-order hyperpolarizability β $(=\chi^{(2)}/\rho)$, and the second-order hyperpolarizability $\gamma(=\chi^{(3)}/\rho)$, respectively, where ρ is the number density of molecules in a material. Assuming that the molecule-field coupling system is initially prepared in the *g*th state (for example, ground state), we can derive α, β, and γ by using a perturbation theory [9]. The linear optical polarizability $\alpha(\omega_p)$ of a molecule at optical frequency ω_p can be [33]

$$\alpha_{ij}(\omega_p) = \hbar^{-1} \sum_m \left\{ \frac{U_{gm}^i U_{mg}^j}{\omega_{mg} - \omega_p} + \frac{U_{gm}^j U_{mg}^i}{\omega_{mg}^* + \omega_p} \right\} \qquad (6)$$

where U_{mn} is the transition-dipole matrix element between the *n*th and *m*th states and ω_{mn} is the corresponding transition frequency. The first and second terms in the above equation can be interpreted as the resonant and antiresonant contributions to the linear optical polarizability. $\beta(\omega_\sigma)$ of molecule at optical frequency $\omega_\sigma = \omega_q + \omega_p$ is given by [33]

$$\beta_{ijk}(\omega_\sigma; \omega_q, \omega_p)$$

$$= \hbar^{-2}\Theta \sum_{mn} \left\{ \frac{U_{gn}^i U_{nm}^j U_{mg}^k}{(\omega_{ng} - \omega_p - \omega_q)(\omega_{mg} - \omega_p)} \right.$$

$$+ \frac{U_{gn}^j U_{nm}^i U_{mg}^k}{(\omega_{ng}^* + \omega_q)(\omega_{mg} - \omega_p)}$$

$$\left. + \frac{U_{gn}^j U_{nm}^k U_{mg}^i}{(\omega_{ng}^* + \omega_q)(\omega_{mg}^* + \omega_p + \omega_q)} \right\} \qquad (7)$$

where Θ denotes the intrinsic permutation operator. (This operator tells us to average the expression that follows it over both permutations of frequencies ω_p and ω_q of the

applied field. The cartesian indices *j* and *k* should be permuted simultaneously.) The second-order hyperpolarizability $\gamma(\omega_\sigma)$ of molecule at $\omega_\sigma = \omega_r + \omega_q + \omega_p$ can be [33]

$$\gamma_{kjih}(\omega_\sigma; \omega_r, \omega_q, \omega_p)$$

$$= \hbar^{-3}\Theta \sum_{mno} \left\{ \frac{U_{go}^k U_{on}^j U_{nm}^i U_{mg}^h}{(\omega_{ng} - \omega_r - \omega_q - \omega_p)(\omega_{ng} - \omega_p - \omega_q)(\omega_{mg} - \omega_p)} \right.$$

$$+ \frac{U_{go}^j U_{on}^k U_{nm}^i U_{mg}^h}{(\omega_{og}^* + \omega_r)(\omega_{ng} - \omega_q - \omega_p)(\omega_{mg} - \omega_p)}$$

$$+ \frac{U_{go}^j U_{on}^i U_{nm}^k U_{mg}^h}{(\omega_{og}^* + \omega_r)(\omega_{ng}^* + \omega_r + \omega_q)(\omega_{mg} - \omega_p)}$$

$$\left. + \frac{U_{go}^j U_{on}^i U_{nm}^h U_{mg}^k}{(\omega_{og}^* + \omega_r)(\omega_{ng}^* + \omega_r + \omega_q)(\omega_{mg}^* + \omega_r + \omega_q + \omega_p)} \right\}$$

$$(8)$$

Available studies [1–4, 16] have shown that the second-order nonlinear optical interaction can occur only in noncentrosymmetric crystals which do not display inversion symmetry, while the third-order nonlinear optical interactions can occur for both centrosymmetric and noncentrosymmetric media. Assuming that the two input waves are at ω_o and ω_m, from Eq. (4) we have [33]

$$
\begin{array}{llll}
P^{(2)}(\omega_n = 2\omega) & \omega_o = \omega_m = \omega & \text{SHG} & \\
P^{(2)}(\omega_n = \omega_1 + \omega_2) & \omega_o = \omega_1, \omega_m = \omega_2 & \text{SFG} & \\
P^{(2)}(\omega_n = \omega_1 - \omega_2) & \omega_o = \omega_1, \omega_m = -\omega_2 & \text{DFG} & (9) \\
P^{(2)}(\omega_n = 0) & \omega_o = \omega_1, \omega_o = \omega = -\omega_m & \text{OR} &
\end{array}
$$

SHG, SFG, DFG, and OR denote second-harmonic generation, sum-frequency generation, difference-frequency generation, and optical rectification, respectively. If the nonlinear crystal used in a DFG process is placed inside an optical resonator, the frequency of the output signal or idler field can build up to large values resulting in the device of optical parametric oscillator (OPO) which is used primarily at infrared wavelengths where other sources of tunable radiation are not readily available. Since the nonlinear polarization can efficiently produce an output signal only if a certain phase-matching condition is satisfied and this condition cannot be satisfied for more than one frequency component of the nonlinear polarization, no more than one of these frequency components shown in Eq. (9) will be presented with any appreciable intensity in the radiation generated by the nonlinear optical interaction. Operationally, one often chooses which frequency component will be radiated by properly selecting the polarization of the input radiation and orientation of the nonlinear crystal. Based on Eq. (5), we can get third-harmonic generation (THG) if $\omega_m = \omega_o = \omega_p = \omega$. Other third-order polarization can be reached by varying the three frequencies. (For more details the reader is referred to standard textbooks about nonlinear optics, e.g., [1–15].) Here we briefly describe the process of degenerate four-wave mixing (DFWM). In the DFWM experiment, a polarization is induced in the sample by the interaction between three light waves and the electrons in the nonlinear

medium characterized by a third-order nonlinear optical susceptibility $\chi^{(3)}$ through Eq. (5), but two wave beams are incident at the same region on the sample and have equal and opposite wave vectors and the same frequency ω. The two wave beams from, for example, a He-Ne laser set up an interference grating, which interacts with the third light beam coming from the back side of a transparent sample. Then, the fourth beam, resulting from this interaction with wave vector equal and opposite to that of the third beam, is detected. So, if the frequency of the third wave is ω, the fourth wave will be generated with the same frequency ω but its complex amplitude everywhere will be the complex conjugate of the third wave.

1.2. Fullerenes and Carbon Nanotubes

Graphite is known as one stable and abundant solid form of pure carbon [17]. This form has three strong sp^2 trigonal bonds with an equal distance of 0.142 nm and weak π bonds perpendicular to successive sheets with an interplane distance of 0.34 nm [18]. Diamond, known as the hardest of all natural materials, is another slightly less stable and less abundant crystallographic form of pure carbon [17]. Each carbon atom in diamond is covalently bonded to four neighbors via sp^3 hybridization at the apexes of a regular tetrahedron. In 1985, Kroto et al. [19] synthesized the fascinating, truncated icosahedron molecule, named C_{60} [20] (see Fig. 1), which has 20 hexagonal and 12 pentagonal faces and 60 vertices (each vertice is at the intersection of two hexagonal and one pentagonal faces). This discovery brought us a new form of pure carbon, named fullerenes [21–26], which are made of an even number of three-coordinated sp^2 carbon atoms that arrange themselves into 12 pentagonal faces and any number (>1) of hexagonal faces. This kind of cage molecule can crystallize in a variety of three-dimensional structures [27, 28]. The macroscopic synthesis of a soot [27], which contains C_{60} and other fullerenes in large compounds, and the straightforward purification techniques of the soot, which make the pure fullerene materials available, have led to extensive studies on the structural, mechanical, electronic, magnetic, and optical properties of fullerenes [29–35]. Meanwhile, fullerenes can be doped in several different ways (e.g., endohedral, exohedral, and substitutional doping) because of their unique electronic properties [31]
Figure 2. Geometrical structures of two kinds of carbon nanotubes: (a) armchair carbon nanotube; (b) zigzag carbon nanotube.

(see Fig. 1). These doped fullerenes can be semiconducting, metallic, or even superconducting [31].

In addition to fullerenes, it is also possible to synthesize tubular fullerenes and nested concentric fullerenes. The new field of carbon nanotube research was greatly stimulated by the discovery of the existence of carbon tubules or nanotubes [36] and the subsequent report of conditions for the synthesis of large quantities of nanotubes [31, 37–57]. Theoretically, there are three major classifications of C_{60}-based tubules or nanotubes [31, 58–62]: armchair carbon nanotubes (see Fig. 2), zigzag carbon nanotubes (see Fig. 2), and chiral carbon nanotubes, depending on whether they are related to a fivefold, a threefold, or a twofold axis relative to the C_{60} molecule. Generally speaking, a single-walled carbon nanotube (SWNT) can be made if only one graphene sheet is rolled; while a multiwalled carbon nanotube (MWNT) can be obtained if a few stacked graphitic shells are built from perfectly concentric cylinders or a single graphene sheet is rolled as a scroll. Since 1991, carbon nanotubes have been extensively studied, both theoretically and experimentally, due to their unique geometric structures and remarkable mechanical, chemical, electronic, magnetic, and transport properties. The small diameter (at scale of nanometers) and the long length (at the order of microns) lead to such large aspect ratios that the carbon nanotubes act as ideal one-dimensional systems. Their rope crystallites offer host lattice for intercalation and storage. All these characteristics make carbon nanotubes the focus of extensive studies in nanoscale science and technology with potential applications in various materials and devices. Readers can find more details about the synthesis, physical and chemical properties, and technological applications of carbon nanotubes in recent books [31, 63–70] and review articles [71–77].

1.3. Conventions and Outline

In nonlinear optics, there are several different systems of units [9] that are commonly used in the community. In this chapter, we use the Gaussian system of units. In the Gaussian system, both the field **E** and polarization **P** have the same units, statvolt/cm. Thus, $\chi^{(1)}$ is dimensionless and the dimensions of $\chi^{(2)}$ and $\chi^{(3)}$ are given by

Figure 1. Geometrical structures of fullerenes: (a) C_{60}; (b) $C_{48}N_{12}$.

cm/statvolt ($\equiv$ esu $= 3.3354 \times 10^{-5}$ m/V) and cm^2/statvolt^2 ($\equiv$ esu $= 1.1125 \times 10^{-9}$ m^2/V^2), respectively. The units of $\chi^{(2)}$ and $\chi^{(3)}$ are not usually stated explicitly in the Gaussian system of units, but instead quote values simply in electrostatic units (esu). For other different systems of units, the reader may refer to Appendix A of Boyd's book [9]. In addition, there are different conventions for defining hyperpolarizabilities (for example, Taylor series, perturbation series, electric field induced SHG (EFISHG), phenomenological; see [78] for details). In this chapter, we use the convention of *Taylor series*.

In this chapter, we review recent studies on the second-order optical nonlinearities (characterized by the first-order hyperpolarizability β) of fullerenes and their derivatives in Section 2, and the third-order optical nonlinearities (characterized by the second-order hyperpolarizability γ) of fullerenes, fullerene derivatives, and carbon nanotubes in Section 3.

Many laser sources, for example, OPO, dye lasers, and Raman lasers, are widely used in many areas of science and technology. Naturally, a potential hazard for human eyes and other optical sensors arises because of the laser power. Hence, protecting all sensors and human eyes against the hazard is a very important task which stimulates many research groups all over the world to search for good optical limiters that should have high broadband linear transmittance for low input fluences and always keep the output energy below the damage threshold of all optical sensors and human eyes. This is one NLO application. In Section 4, we review recent developments of optical limiting studies of fullerenes, fullerene derivatives, and carbon nanotubes.

In Section 5, we end this chapter by giving some remarks and outlooks for further studies about the optical nonlinearities of fullerenes and carbon nanotubes.

2. SECOND-ORDER OPTICAL NONLINEARITIES OF FULLERENES

Second-order NLO measurements include techniques, for example, Maker Fringe method, EFISHG, hyper-Rayleigh scattering, and the second-order NLO processes mentioned before. The detailed descriptions of Maker Fringe method and hyper-Rayleigh scattering can be found in [1–15]. The EFISHG technique involves the mixing of three optical fields and one static field of parallel polarizations and details can be found in [79].

From a symmetry consideration, both C_{60} and C_{70} possess inversion symmetry. Thus, within a dipolar approximation, no SHG activity should be detected. However, several

groups [80–84] have observed SHG signal from vacuum-sublimed thin films on a glass or silica substrate. Some results of fullerenes and derivatives are summarized in Tables 1 and 2 and in Figures 3 and 4.

2.1. C_{60}

Hoshi et al. [80] were the first to investigate the NLO response of C_{60} film deposited on a silica substrate by impinging an unfocused polarized Nd:YAG laser (1064 nm) on the film and measuring the dependence of the SHG intensities on the polarization of light and on the angle of incidence in the transmission geometry. A polarization analyzer and a monochromator were used to detect the transmitted SHG (532 nm). No detectable SHG was emitted from the blank substrate. For convenience, we express the polarization state of incident light by $|I_i\rangle$ and that of the polarization analyzer by $|O_i\rangle$ ($i = x, y, z$. z-axis is the direction of the incident laser beam and x-axis the rotation axis). Hoshi et al. [80] noticed that no SHG is detected under $|I_x\rangle \otimes |O_x\rangle$ and $|I_y\rangle \otimes |O_x\rangle$, irrespective of the angle θ of incidence. For $|I_x\rangle \otimes |O_y\rangle$ or $|I_y\rangle \otimes |O_y\rangle$, SHG signal appears as the C_{60} film was rotated around x-axis to change the incident angle θ. Assuming that the normal axis (i.e., z-axis here) of the C_{60} film is a C_∞ symmetry, their observed results are due to a $C_{\infty v}$ symmetry if SHG comes from the electrical dipolar responses. If so, this implies that asymmetry exists along the z-axis direction. The presence of substrate is the only cause of the asymmetry. However, if SHG signal comes from an electrical quadrupolar response, either $C_{\infty v}$ or $C_{\infty h}$ symmetry is a consistent account for their observed results. Later on, Kajzar et al. [83] also observed the incidence angle dependence of SHG intensity from a sublimed C_{60} thin film: the maximum of the SHG signal is at $\theta = 55°$. Koopmans et al. [82] performed more systematic studies on SHG from thin C_{60} films by combining frequency-, rotational-, angular-, and film-thickness-dependent measurement and gave the first SHG spectrum of pure C_{60} films or C_{60} surfaces. They found C_{60} films to show a high SHG efficiency and a strong and sharp resonance at $2\hbar\omega = 3.60$ eV, which is close to an allowed optical transition. Meanwhile, Wang et al. [81] also found that the square root of SHG intensity of C_{60} film increases linearly with the film thickness and varies with the change of temperature (reaching a maximum at 415 K) showing a bulk second-order optical nonlinearity. All these experiments demonstrated that the SHG signal from sublimed C_{60} thin films comes from the bulk, and is not only an interface effect [85]. The large second-order NLO response

Table 1. Second-order optical nonlinearities of C_{60} and derivatives measured by different experimental techniques.

Fullerenes	β (10^{-30} esu)	$\chi^{(2)}$ (10^{-9} esu)	Method	State of material	Ref.
C_{60}	1.1	1.3	ATR	film	[88]
C_{60}/DEA	67 ± 20		EFISHG	solution	[103]

of C_{60} films is due to small amounts of impurities (such as C_{60} isomers, other fullerenes, or oxides which have noncentral symmetry), or electric quadrupole, or magnetic dipole contributions which are allowed in centrosymmetric materials.

Kuhnke et al. [84] presented a wide SHG spectrum of C_{60} films (see Fig. 3): three pronounced resonances at 1.18 eV (1046 nm), 1.82 eV (678 nm), and 2.02 eV (0.611 nm), and a weak one at 1.35 eV (914 nm). The resonance peak
Figure 4. SHG spectrum of C_{70} film. Reprinted with permission from [84], K. Kuhnke et al., *Chem. Phys. Lett.* 294, 241 (1998). © 1998, Elsevier Science.

observed at 1.82 eV by Kuhnke et al. [84] confirms the position and width of the resonance first observed by Koopmans et al. [82]. Kuhnke et al. [84] found a significant SHG signal at 1.165 eV (1059 nm), the energy of the study at fixed wavelength by Wilk et al. [86]. Later on, Janner [87] observed the resonance at 2.02 eV in a SHG spectrum. Using the experimental technique of electro-optically modulated ATR (attenuated total reflection) spectroscopy, Wang et al. [88] have measured the second-order NLO response of Langumir–Blodgett (LB) films of C_{60} by electro-optical (Pockels) characterization for the first time. Their observed electro-optical response was the Pockels effect, and the second-order NLO susceptibility $\chi^{(2)}$ of C_{60} film was determined to be 1.3×10^{-9} esu, in agreement with that of Wang et al. [81]. It should be noticed that although β is zero for isolated C_{60}, C_{60} film may exhibit nonzero value if it does not display centrosymmetry. Based on the work of Rashing et al. [89], the corresponding molecular hyperpolarizability β of the C_{60} molecule is about 1.1×10^{-30} esu [88]. Such large electro-optical response of C_{60} shows that it is a promising NLO material regardless of the molecular inversion symmetry.

Theoretically, Qin et al. [90] studied the dispersion relation of the quadrupole response for single C_{60} molecule. Two resonant peaks were at 1.09 eV and 1.86 eV, respectively. The peak at 1.09 eV is only about 0.1 eV lower than the lowest peak observed by Kuhnke et al. [84], while the one at 1.86 eV is in good agreement with experiment [84]. Although their calculated peak is of asymmetric shape, no separate feature appears around the energy 2 eV. Hence, their calculation showed that the peak observed at 2.02 eV by Kuhnke et al. [84] is not caused by the electric quadrupole transition. The sharp minimum [90] between the two peaks seems to be caused by a change of amplitude sign. In the SHG spectrum of Kuhnke et al. [84], a similarly sharp minimum at 1.57 eV was observed. Hence, their theoretical calculation is in overall agreement with experiment. Finally, it should be mentioned that no SHG peak is detected at the spin-forbidden excitation of the lowest triplet exciton at 1.55 eV (0.796 nm) [91].

The C_{60} film can be crystallized in a fcc structure at room temperature [92, 93], and is therefore centrosymmetric. As mentioned above, within the electric-dipole approximation, the C_{60} film would not show SHG signal so that only the surface contribution could be detected. Nevertheless, the experiment of Wang et al. [81] showed that the surface contribution to SHG should be very small. As discussed above, the origin of the SHG signal from a C_{60} film can only be an electric quadrupole, or a magnetic-dipole contribution, or from an impurity. The recent work by Koopmans et al. [94] has convincingly shown that a fullerene's SHG at 1.8 eV comes from a magnetic-dipole interaction. However, a recent study by Munn et al. [95] showed that although the SHG signal at 1.8 eV is dominated by the magnetic-dipole response, this is not the case at other frequencies. The theoretical study of Qin et al. [90] also demonstrated that the second-order quadrupole nonlinear contribution is large enough to explain the experimental results obtained by Wang et al. [81]. Liu et al. [96] have observed a change of the SHG signal of C_{60} film with the structural phase transition of C_{60} at 245 K. Since the impurity cannot display the

properties of C_{60}, their experimental results implied that the SHG in the fcc and sc phases was not induced simply by the impurity in the C_{60} material (or say, the SHG response of impurity in C_{60} films cannot explain the change in SHG at 245 K). Thus, the SHG signal from C_{60} films cannot be attributed solely to the impurity.

2.2. C_{70}

Kuhnke et al. [84] were the first to measure the SHG response of higher fullerene C_{70} and the SHG spectrum is presented in Figure 4. They observed a weak resonance peak at 1.26 eV (979 nm) and a steep signal at 1.85 eV (667 nm) showing a broad resonance feature without resolved structure. In a Ne matrix, Sassara et al. [97] assigned the lowest singlet (S_1) and triplet (T_1) excitons for isolated molecules to 1.93 eV and 1.56 eV, respectively. If a shift of about 0.1 eV between matrix isolated C_{70} and the solid exists, the lowest singlet exciton may correspond very well to the onset of the SHG intensity of C_{70} film. If so, the proximity of the next higher singlet exciton (S_2) and higher excitonic states may result in the broad resonance structure above 1.85 eV. However, the resonance peak at 1.26 eV is too low in energy to be assigned to the triplet exciton. The calculation of Shuai and Bredas [98] indicated that the SHG spectra for C_{70} come from the contribution of the electric quadrupole having a sharp peak at 1.2 eV and a broad resonance structure between 2.0 and 2.4 eV, which is in good agreement with the SHG spectrum of Kuhnke et al. [84].

C_{70} has a lower symmetry than C_{60}. Thus, the low-energy part of the absorption spectrum of the C_{70} solid may be rich in dipole-allowed transitions. However, only two features were observed in the SHG spectrum of C_{70} film; that is, many dipole-allowed transitions are absent. Anyhow, this and the agreement with theoretical calculation suggest that dipole-forbidden transitions in C_{70} may be observed most easily. Indeed, Kajzar et al. [83, 99] predicted a dipole-forbidden transition at 2.49 eV.

2.3. Fullerene Derivatives

Charge transfer is demonstrated to be the most effective mechanism to enhance the second-order optical nonlinearity of organic molecule [100, 101]. Since fullerenes are excellent electron acceptors [102], forming charge-transfer complexes with appropriate donors would break the centrosymmetry of C_{60} or C_{70} and thus induce significant second-order optical nonlinearity.

Wang and Cheng [103] measured the second-order NLO property of C_{60} charge-transfer complexes formed with N,N-diethylaniline (DEA), which is an electron donor well known to form charge-transfer complexes with various aromatic acceptor molecules [104], by using EFISHG technique [105, 106]. Indeed, the formation of charge-transfer complexes with DEA breaks the centrosymmetry in C_{60} and induces its second-order optical nonlinearity [103]. The value of β_μ in the dipolar direction for C_{60}/DEA is $(6.7 \pm 2) \times 10^{-29}$ esu. Based on the INDO/CI-SOS (intermediate neglect of differential overlap/configuration interaction plus sum-over-state approach) method [107–109],

Feng and his co-workers [110] calculated the second-order nonlinear optical susceptibilities β_{ijk} and β_μ of C_{60}/aniline (AN) (a theoretical model of the experimentally studied C_{60}/DEA [103]). The calculated value of β_μ at 1910 nm is 3.217×10^{-29} esu, which is in good agreement with experiment [103]. Later on, using this theory, Liu et al. [111] found that N-methyl-2-(2′-thiophene)-pyrrolo[3,4]C_{60} N-methyl-pyrrolo[3,4]C_{60} and its derivatives exhibit good second-order optical nonlinearities. Both theoretically demonstrated the polarization effects, induced by the charge-transfer interaction, on the large number of hyperpolarizable π electrons, which have significant contribution to the higher value of β_μ obtained by Wang and Cheng [103]. Fu et al. [112] found using INDO/CI-SOS that spiroannelated quinone-type methanofullerenes show enhanced second-order nonlinearity compared with C_{60}/AN.

Lamrani et al. [113] found experimentally that a combination of seemingly attractive carboranes and fullerene through an ethynyl π-system produced high β values. The β values found were 34.6×10^{-29}, 48.3×10^{-29}, and 118.9×10^{-29} esu for the three carborane-fullerene hybrids investigated.

The monofunctionized derivative C_{60}-($C_4H_8N_2$) has no centrosymmetry [114]. Gan et al. [115] have measured its SHG spectrum. The second-order nonlinear optical susceptibility $\chi^{(2)}$ and molecular hyperpolarizability β of C_{60}-($C_4H_8N_2$) are determined to be $(1.8 \pm 0.8) \times 10^{-7}$ esu and $(3.6 \pm 1.2) \times 10^{-29}$ esu, respectively [115].

Kajzar et al. [116] performed SHG measurements on C_{60}-based composites and multilayered charge-transfer structures with electron donors, 5,10,15,20-tetrapheny-21H, 23H-porphine (TPP) and 5,6,11,12-tetraphenylnaphthacene (rubrene) (TPN). In thin films that contain C_{60} molecule, only the SHG signal is observed, and a significant enhancement in SHG signals is observed in the multilayered structures. The enhancement is due to a ground-state permanent electron transfer from the electron-donating molecules to C_{60} [116].

The charge separation in substituted C_{60} leading to enhancement of the second-order nonlinear optical susceptibility was also demonstrated theoretically [117, 118]. Further charge transfer can take place during the excitation process from the ground state to the excited state [118]. This kind of strong intramolecular charge transfer causes large second-order nonlinear optical susceptibility in the substituted fullerene. Among C_{60}, C_{60}/DEA, C_{60}/AN, and $C_{59}X$ (X = B, N), C_{60} has the smallest β value and $C_{59}X$ has the largest one [117, 118]. As discussed later, enhanced β value is also obtained for Si-substituted C_{60}. This means that substitute doping is a good means to achieving a large second-order nonlinear optical susceptibility of pure C_{60}.

The crown ether modified C_{60} will be typical supramolecules which combine the unique properties of C_{60} and crown ethers together. Surely, the solubility and amphipathy of C_{60} can be improved because of the good hydrophilic properties of the crown ether moiety. This makes crowned C_{60} a kind of competitive compound to form structurally ordered fullerene thin films and may find practical applications as active surface layers in microsensors or optoelectronic devices. Several kinds of crowned fullerene

derivatives were synthesized [119], based on which Langmuir and Langmuir–Blodgett (LB) films [120] were made. Guo et al. [121, 122] investigated macroscopic SHG of a LB film of a novel crowned [60]fullero-pyrrolidine (CFP). They observed a strong SHG signal whose intensity depends linearly on the number of film layers, implying that the LB films of CFP are a promising material for SHG. The second-order molecular susceptibility $\chi^{(2)}$ and hyperpolarizability β were determined to be 3.2×10^{-8} esu and 8.3×10^{-29} esu, respectively. The mechanism is still the intramolecular electron transfer.

The second-order nonlinearity of C_{60} endohedral doped with Li, Li@C_{60}, has been investigated both theoretically and experimentally by Campbell et al. [123]. They found, theoretically, that displacement of the Li off the idealized molecular center can induce a large first hyperpolarizability. An enhanced nonlinear response was also found experimentally by considering the SHG from thin films containing ~30% Li@C_{60}. From the results it was suggested that $\chi^{(2)}$ of Li@C_{60} would be one or two orders of magnitude larger than the magnetically induced $\chi^{(2)}$ of pristine C_{60}.

Rustagi et al. [124] studied the first- and second-order hyperpolarizability of fullerene substitutionally doped with one B or one N atom using a tight-binding method and found large enhancement of the nonlinearities in the doped fullerenes. Also, heterofullerenes substitutionally doped with silicon atoms [125] are of great interest in many aspects. One is the possibility to increase second-order optical susceptibility. Very recently, Fuks et al. [126] have shown, both theoretically and experimentally, that fullerene molecules, for example, C_{60}, can be modified by substituting fullerene with Si atoms to enhance the second-order photoinduced nonlinear optical properties. The experimental results are [126]: $\chi^{(2)}_{xxx} = 0.21$, 0.87 pm/V for $C_{59}Si$ and $C_{58}Si_2$, respectively; $\chi^{(2)}_{zzz} = 0.66$, 0.67 pm/V for $C_{59}Si$ and $C_{58}Si_2$, respectively. The substitution by two Si atoms does favor the larger second-order susceptibility in comparison with that for only one-atom substitution [126]. The indicatrice of the photoinduced second-order NLO susceptibilities for $C_{58}Si_2$ is more isotropic than that for $C_{59}Si$.

Lin et al. [127] successfully incorporated C_{60}/C_{70} molecules into inorganic optical glasses with high melting temperatures. Fullerene doping leads to changes in glass properties [127]. Considering that optical glass without fullerene doping has centrosymmetry supporting no second-order optical nonlinearities, Zeng et al. [128] have recently shown that fullerene dopants can form ordered structures in the vitreous glass matrix. The fullerene doping broke the centrosymmetry of glass leading to macroscopic second-order optical nonlinearities. Nearly two orders of magnitude enhancement for the SHG was observed near the self-assembled islands [128].

It is known that high values of the first hyperpolarizability β tensor components for a given molecule imply optical nonlinearities as the molecule responds to applied optical fields. The so-called donor-acceptor model shows one approach to search the structure-property relationships of β and design our needed NLO materials. Based on this model, electronic excitation would result in charge migration from the donor to the acceptor group showing a large dipole moment along the direction bounding the two groups. Indeed, many of

donor-acceptor systems exhibit high values of β. This has also been demonstrated theoretically for B,N-substituted C_{60} by Jensen et al. [129] and for push-pull derivatives of C_{60} by Fanti et al. [130] where also a relation between the conjugation path length and β was found.

The first hyperpolarizability is made up of its dipolar and octopolar contributions. It is possible to cancel the dipolar part by symmetry and enhance the octopolar part of the β tensor [131, 132]. This gives us another approach designing NLO materials by exploring octopolar architectures of a number of possible molecules [132]. Such octopolar-enhanced approach has two advantages [131]: preventing the molecules from losing their optical properties in bulk by dipole cancellation on antisymmetric crystallization and raising the possibility for the system to have more than one optical axis. Barbosa and Nascimento [133] have proposed a new approach, incorporating the octopolar-enhanced approach into the donor-acceptor model, for designing molecules with large hyperpolarizabilities. In their approach, a central acceptor unit with a high value of electron affinity is used and bounded to several donor groups maximizing either the dipolar or the octopolar components of the β tensor.

In the late 1990s, C_{36} fullerene [134, 135] has been synthesized. This molecule with D_{6h} and D_{2d} symmetries exhibits rich structural and electronic properties [136–146]. The crystal D_{6h} structure has a very high electron affinity (>3 eV) and many symmetry elements [133]. By adding two equivalent donor amino-ethylene (ME) groups to one of the three unique symmetric positions of the central acceptor group C_{36} fullerene, Barbosa and Nascimento [133] explored the second-order NLO properties of such system. The nuclear frameworks with C_{2h} point group cannot present second-order NLO properties. The framework with C_{2v} symmetry, as listed in Table 2, may exhibit high values of the $\beta_{(z)}$ component, more than 10 times larger than those for the p-nitroaniline [147]. Because of the symmetry, most of the components of the β tensor vanish. Their results showed that a symmetric positioning of a great number of donor groups is more important to enhance the octopolar component of β than an augmentation of chain length which only influences significantly the dipolar component. According to their proposed approach, some of the designed molecules can be good candidates for building second-order NLO materials.

3. THIRD-ORDER OPTICAL NONLINEARITIES OF FULLERENES AND CARBON NANOTUBES

Third-order optical susceptibility $\chi^{(3)}$ of a material can be measured by DFWM, THG, EFISHG, Z-scan, optical Kerr effect, optically heterodyned OKE (OHD-OKE), and coherent anti-Stokes Raman spectroscopy (CARS) vibrational lineshape analysis. The THG and DFWM techniques are mentioned in Section 1.1. The THG process occurs in every medium and, consequently, the harmonic intensity is a result of the superposition of harmonic fields generated in the separate media. The DFWM is a powerful tool for measuring $\chi^{(3)}$ of a material. From the strength of the signal,

Table 2. The first hyperpolarizability (β, in 10^{-32} esu) and dipole (μ, in 10^{-20} esu) for amino-ethylene (ME) substituted C_{36} fullerenes with C_{2v} symmetry.

N	Unique site	β_{xyz}	β_{yyz}	β_{zzz}	$\beta_{(z)}$	$\mu_{(z)}$	β^{oct}_{xyz}	β^{oct}_{yyz}	β^{oct}_{zzz}	β^{dip}_z
2	1	−1338	−686	−7468	−9492	2172	1681	3637	−1773	−5695
	2	−584	−693	21	−1256	1969				
	3	268	1756	4691	6715	−550	−3225	1234	662	4029
4	2	−28451	146	294	28011	2812	−68546	17244	17100	−16803
	3	11170	−5758	−234	5178	−3243	30403	−20381	−3341	3107

Note: N is the total ME number. C_{36} has three unique sites ($S = 1, 2, 3$). β^{opt} and β^{dip} denote the octopolar and dipole parts contributed to the β tensor. The z axis is collinear to the z axis of the unsubstituted D_{6h} C_{36} fullerene. The value $\beta_{(z)}$ corresponds to the sum over components in the z direction.
Source: Adapted from [133].

one can determine the magnitude of $\chi^{(3)}$. It should be mentioned that the time-dependent behavior of the DFWM signal is related to the development and persistence of the grating and therefore provides information on the ultrafast physics of the material. The Z-scan technique [148] measures the real and imaginary parts of $\chi^{(3)}$ simultaneously. This technique is based on the variation of transmitted radiation intensity by alteration of the geometrical parameters of the interaction region. This is achieved by gradually moving a sample along the Z-axis of propagation of a focused Gaussian beam through its focal plane and measuring the transmission of the sample for each Z position. As the sample experiences different electric field strength at different positions, the recording of the transmission as a function of the Z coordinate provides accurate information about the nonlinear effect present. In the ordinary OKE experiments the detected signal is proportional to the quadrate of $\chi^{(3)}$. One can only acquire the modulus of $\chi^{(3)}$ which should be related to the excitation light because the imaginary component of $\chi^{(3)}$ is determined by the absorption of the sample at the wavelength of the excitation light. In most cases, the real component of $\chi^{(3)}$ is, in fact, more concerned since it is a more important parameter for the application in photonic devices. OHD-OKE determines the magnitudes and signs of $\chi^{(3)}$ and this method greatly improves the signal-to-noise ratio of experimental data. In the CARS technique, one fits the dispersive lineshape caused by interference between the unknown nonlinearity and a Raman resonance of a standard like benzene. This CARS procedure is well accepted and has been shown to provide accurate values for γ. Details about CARS techniques can be found in [149].

Photonic applications, for example, data processing, eye and sensor protection, and all-optical switching, need molecules with large third-order optical nonlinearities [6–8, 10–15]. However, the $\chi^{(3)}$ or γ magnitudes of most materials are usually smaller than those needed for photonic devices. Hence, searching for potential third-order NLO materials with large NLO response has been an interesting and important issue in physics, chemistry, and material science.

Quantum dots and conjugated π-electron organic systems (e.g., polydiacetylenes, polyacetylenes, and polythiophenes) have been shown to have large third-order optical nonlinearities [6–8, 12, 14, 150–161]. However, because of the overtones of high-energy C—H and O—H vibrations, those organic materials show strong absorption in the near-infrared region. Obviously, this would limit the application of organic materials in the infrared region, for example,

telecommunication. The advent of the technology for production of bulk quantities of fullerenes [31, 19–25] provides us another class of completely conjugated materials having quantum dot nature, a large number of delocalized π electrons. Since fullerenes are uniquely composed of carbon atoms, there is no C—H or O—H bond present in fullerenes. This implies that no absorption would be observed in the infrared region. On the other hand, the HOMO-LUMO energy gaps in fullerenes are narrower [162] than those in conjugated polymers. (The HOMO-LUMO energy gaps in conjugated polymers are broadened because of the confirmations, polymer chain length distributions, and vibronic couplings to electronic levels.) Thus, fullerenes would exhibit narrower resonances. These novel features naturally make fullerenes appealing NLO materials for photonic applications and stimulate researchers all over the world to investigate the third-order optical nonlinearities of fullerenes. In the following, we review the experimental and theoretical studies on the third-order optical nonlinearities of C_{60}, C_{70}, higher fullerenes, fullerene derivatives, and carbon nanotubes. The results are summarized in Tables 3–9. The NLO properties of doped carbon nanotubes are covered in our other chapter contributed to this edited book.

3.1. C_{60}

Blau et al. [163] were the first to measure the third-order optical nonlinearity of C_{60}. Although their measurement was found to have an error by more than three orders of magnitude for the final γ value [164, 165], their experiment did attract extensive studies of the third-order optical nonlinearities of C_{60}. As shown in Table 3 and Figure 5, which collect some of the reported optical susceptibilities $\chi^{(3)}_{xxxx}$ and hyperpolarizability γ of C_{60} at a few selected wavelengths measured by DFWM, THG, and electric-field-induced second-harmonic generation (EFISHG), their error was quite indicative of the later development for obtaining the value $\chi^{(3)}$ or γ of C_{60} [80, 103, 164–186]. From Table 3, we find that the third-order NLO responses are very sensitive to a great many experimental factors, for example, the incident laser power, pulse duration, the measurement techniques adopted, state of materials (sample preparation methods), and so on. Thus, it is very difficult for us to make a direct comparison of these experimental results obtained from different groups by different techniques. Surely, we see a reasonable agreement between the values measured by THG and EFISHG. From Figure 5, we

Table 3. Third-order optical nonlinearities of fullerenes (C_{60}, C_{70}, C_{76}, C_{78}, C_{84}, C_{86}, C_{90}, C_{94}, C_{96}) measured by different experimental techniques.

[83] within three-level model, and "•" denotes the experimental values of C_{60} films or solutions listed in Table 3.

model proposed Kajzar et al. [83] showed that the resonance observed at 1064 nm is a three-photon resonance with T_{1u} state of C_{60}. Since several states lie in the gap between 2.3 eV (537 nm) and 2.5 eV (494 nm), a one-photon transition is forbidden. Hence, the resonance observed at 1210 nm comes from a two-photon resonance [83]. The theoretical calculations of Kajzar et al. [83], as shown in Figure 5, agree very well with most of the experimental values. In spite of the obvious discrepancy for the $\chi^{(3)}$ or γ value of C_{60} in different experimental groups, most recent experiments have demonstrated that the third-order optical nonlinearity of C_{60} has a small value [187, 188]: the lower limit of γ is 3.7×10^{-35} esu measured by nondegenerate four-wave mixing [187], while the upper limit of γ is 9.0×10^{-35} esu determined by the femtosecond optical Kerr effect (OKE) [188]. The second hyperpolarizability γ of C_{60} has been studied extensively also by theoretical methods and the results are summarized in Table 4. As seen from Table 4 also among the theoretical results there is a large spread of the result. However, if one considers the first-principles methods, such as *ab initio* Hartree Fock and density functional theory, the results are more consistent. The low value of γ for C_{60} is confirmed by first-principles calculations [129, 181, 189, 190], although the experimental results tend in general to

be larger than the theoretical results. A direct comparison between experiments and theoretical predictions is difficult due to the presence of medium effects; that is, the experimental results refer to condensed phase whereas the theoretical results usually are for the gas phase. Luo et al. [191] showed that by carefully considering the intermolecular interaction and local-field corrections on the nonlinear optical properties of C_{60}, a good agreement with experiment could be obtained if care was taken to select experimental results without significant resonant contributions. Also, the vibrational contributions to the nonlinear optical properties of isolated C_{60} have been studied and shown to be significant for certain processes [192]. In Section 3.2, we shall see that a strong enhancement on third-order optical nonlinearity, for example, an increase from several tens to 100 times on the γ value, was even observed as C_{60} was chemically modified to form a charge-transfer complex [103, 188] or was chemically reduced to anions [210, 211].

3.2. C_{70} and Higher Fullerenes

Compared with the C_{60} molecule, higher fullerenes have attracted less attention on their third-order optical nonlinearities. One reason is that large amounts of higher fullerenes are not available. That is also why the synthesis and isolation of higher fullerenes is still an active research field. Theoretical calculations [178, 179, 181, 212–228] and a few experimental results [103, 174–176, 180, 182, 185, 229, 230] have shown that higher fullerenes possess larger third-order optical nonlinearity than C_{60}. C_{70}, the most easily purified higher fullerene, was experimentally proven to have a γ

magnitude of 1.6 to 3 times that of C_{60} [103, 174–176, 180, 182, 185]. Tables 3 and 5 list the third-order nonlinear optical susceptibilities $\chi^{(3)}$ of C_{70} and higher fullerenes studied by different experimental or theoretical techniques. In the following, we briefly review recent theoretical and experimental studies on the third-order optical nonlinearities of higher fullerenes. Other reviews on the nonlinear optical properties of fullerene (mainly C_{60} and C_{70} molecules) are also available in the literature; see Nalwa [13], Xie [33], Kajzar et al. [83], Rustagi et al. [231], and Belousov et al. [232].
Figure 6. Wavelength dependence of the third-order nonlinear optical susceptibility $\chi^{(3)}(-3\omega; \omega, \omega, \omega)$ in C_{70}. Solid line is the calculated results of Kajzar et al. [83, 99] within three-level model, and "•" denotes the experimental values of C_{70} films or solutions listed in Table 3.

3.2.1. Experimental Measurements

Neher et al. [174] measured the optical susceptibilities $\chi^{(3)}$ of C_{70} at 1064 nm, 1500 nm, and 2000 nm by THG in a toluene solution. Compared with C_{60}, C_{70} exhibits enhanced third-order optical nonlinearity. In particular, a strong effect with γ exceeding 5×10^{-32} esu was observed in the three-photon resonant regime, and a negative real hyperpolarizability in C_{70} and a positive γ for C_{60} were found in the nonresonant measurements. Later on, Kajzar et al. [83, 99] reported a broad THG spectrum for C_{70}. The overall THG spectrum shows a broad resonance enhancement in $\chi^{(3)}$ with a maximum value of $\chi^{(3)} = (0.9 \pm 0.1) \times 10^{-10}$ esu located at 1420 nm and a dramatic decrease at short wavelengths [83, 99].

Yang et al. [175] measured for the first time the third-order NLO susceptibility of C_{70} in a toluene solution by the DWFM technique using 10-ns laser pulses at 1064 nm. The third-order nonlinear optical susceptibility $\chi^{(3)}$ is determined to be 5.6×10^{-12} esu for a C_{70} toluene solution at a concentration of 0.476 g/l. Later on, Flom et al. [176], Lindle et al. [182], and Rosker et al. [180] performed time-resolved DFWM measurement on the third-order optical nonlinearities of C_{70} film using a picosecond laser pulse. C_{70} was found to exhibit a two-photon resonantly enhanced third-order optical response [182]. The dynamics of C_{70} shows wavelength and fluence dependence [176]. To our interest, at high laser intensities, their experiment showed a fifth-order component to the NLO signal due to a two-photon excited-state transient grating [182].

Wang and Cheng [103] determined the optical susceptibility $\chi^{(3)}$ of C_{70} by EFISHG measurements with 1910-nm radiation. The optical nonlinearities of C_{70} are comparable to those of linearly conjugated organics with due consideration to molecular size [103].

In Figure 6, we show the wavelength dependence of $\chi^{(3)}$ for C_{70}. Similar to C_{60}, the C_{70} spectrum exhibits several interesting features: (i) a sharp decrease of χ^3 at shorter wavelength; (ii) strong resonance enhancement in $\chi^{(3)}$ at 1410 nm; (iii) a shoulder around 1064 nm. Based on the three-level model proposed by Kajzar et al. [83, 99], the

observed resonance at 1410 nm is caused by a three-photon resonance with a one-photon allowed transition lying at 470 nm, while the shoulder at 1064 nm is due to a two-photon resonance.

Sun et al. [185] were the first to measure the third-order optical nonlinearity of C_{84} by using the time-resolved OKE technique with 150-fs laser pulse at 647 nm. A large instantaneous NLO response was observed for C_{84}. In comparison with C_{60} and C_{70}, the γ value of C_{84} is enhanced a little. Such small accretion of the optical Kerr response of C_{84} is due to the sample impurity. The experiment of Huang et al. [229] indicated that a purity of C_{84} is higher than 85%, but the impurities include C_{78}, C_{82}, C_{86}, and C_{90}.

Recently, Yang and his co-workers [229] have made DFWM measurements on the third-order optical nonlinearities of C_{90} (>97% purity) at 532 nm. The second-order hyperpolarizability γ of C_{90} is determined to be $(1.8 \pm 0.6) \times 10^{-30}$ esu, while the γ value of C_{60} was $(2.2 \pm 0.6) \times 10^{-31}$ esu. This shows the enhanced third-order optical nonlinearity of C_{90}, which is actually expected since there are more highly delocalized π-conjugated electrons over the spherical-like surface in C_{90} compared to C_{60}. Moreover, Yang and his co-workers [230] have systematically studied the third-order NLO response of other higher fullerenes including C_{76}, C_{78}, C_{84}, C_{86}, C_{94}, and C_{96} by using 70-ps laser pulses at 532 nm under optimized experimental conditions. The experimental γ or $\chi^{(3)}$ are listed in Table 3. In general, the eightfold increase in the γ values from C_{60} to C_{96} is consistent with the trend predicted by theory [220–227]. But the theoretical predicted increase trend is somewhat lower than the measured one. This implies that the existence of other important factors (e.g., geometrical structure, π-π overlap discussed above, resonance enhancement, etc.) contributed to the increased γ values for higher fullerenes.

3.2.2. Theoretical Calculations

Shuai and Bredas [218, 219] used the valence-effective-Hamiltonian (VEH) method to investigate the electronic structures of C_{60} and C_{70} and applied the VEH sum-over-state (SOS) approach to study the third-order NLO response of C_{60} and C_{70}. Their calculations are fully consistent with the EFISHG [103], THG [103], and DFWM [165, 170] measurements, but about three to four orders of magnitude lower than the data reported by Blau et al. [163] and Yang et al. [175]. The lowest two-photon and three-photon resonances in C_{70} were observed at almost the same frequencies for C_{60} due to the symmetry [218, 219].

Extensive theoretical studies have shown that the second-order hyperpolarizabilities γ of higher fullerenes scale with the mass of the all-carbon molecule [212, 216, 220–227]. The free-electron gas model proposed by Knize [212] showed that the γ value of higher fullerene increases as the cube of the number of carbon atoms [212]. Using the SOS-INDO/CI approach [220] or sum-over-molecular-orbitals (SOMO) approach, Fanti et al. [220, 221] found that the second-order hyperpolarizabilities of fullerenes are a nonlinear function of the number of carbon atoms. Later on, the extended Su–Schrieffer–Heeger model proposed by Xie and his co-workers [222, 223] indicated that the static γ values of armchair and zigzag tubular fullerenes of small size

scale with about three power of the number of carbon atoms. Using the SOS method, Harigaya [224–227] predicted that the off-resonant third-order NLO susceptibilities of higher fullerenes are nearly proportional to the fourth power of the carbon number when the on-site Coulomb repulsion is $2t$ or $4t$, t being the nearest-neighbor hopping integral. The work of both Xie et al. [222, 223] and Harigaya [224–227] has demonstrated the important roles of Coulomb interactions in higher fullerenes. Luo [216] pointed out that if C_{60} is excluded, a perfect power law dependence of the γ value on the number N of carbon atoms can be observed [216]: $\gamma = 1.1 \times 10^{-4} N^{2.4}$ for the data of Fanti et al. [221], and $\gamma = 3.2 \times 10^{-2} N^{0.75}$ for the data of Jonsson et al. [181]. Luo's work [216] reflected one important issue that C_{60} has the most exceptional electron localization among all fullerenes.

The C_{78} molecule has five topologically distinct structures: two with C_{2v} symmetry, two with D_{3h} symmetry, and one with D_3 symmetry. Using the SOS method, Wan et al. [233] demonstrated numerically that molecular symmetry and the arrangement of atoms have great effect on the γ values of five isomers of C_{78}. From a geometric point of view, Moore et al. [217, 228] analyzed the static γ values of C_{60}, C_{70}, five isomers of C_{78}, and two isomers of C_{84} in terms of the geometry symmetry (characterized by the molecular group order), aromaticity (characterized by the selection of six-member rings determined from the analysis of bond lengths), and molecular size (characterized by maximum interatomic distance and surface areas) by using the finite field method (FF), a semiempirical Hamiltonian, and molecular structures obtained from density functional theory calculations. The γ value is affected by a combination of the number of aromatic rings, length, and group order, in decreasing importance.

Based on the random phase approximation (RPA), Jonsson et al. [181] calculated the static γ values of C_{60}, C_{70}, and C_{84}, which are determined to be 55.0, 75.4, and 82.4×10^{-36} esu, respectively.

An important factor governing the optical nonlinearity is the extended delocalized π-electron cloud along the effective conjugation length or sphere of the π-conjugated system. Recently, Lin et al. [235] have demonstrated the crucial role of π-π overlap in determining the second-order hyperpolarizability γ in the π-conjugated framework, for example, by taking the semiempirical Austin model 1 (AM1) quantum chemical calculations on various isomers of higher fullerenes. For different isomers of the same mass of fullerene, different curvatures are exhibited and indicate that the π-π overlaps are different among the isomeric fullerenes. Table 6 summarizes the orientationally averaged second-order hyperpolarizability $\bar{\gamma}$ and the averaged pyramidalization angle $\overline{\theta_p}$ which describes the deviation from the planar sp^2 carbon and is defined as $\theta_{\sigma\pi} - \pi/2$ ($\theta_{\sigma\pi} = \pi/2$ for planar sp^2 carbons and 0.608π for tetrahedral sp^3 centers). For isometric fullerenes of the same mass, they found an excellent correlation between $\bar{\gamma}$ and $\overline{\theta_p}$: $\bar{\gamma}$ decreases with the increase of $\overline{\theta_p}$. Hence, a minor change of average π-π overlaps in fullerenes has a large effect on the average second-order hyperpolarizability.

Table 5 collects the static γ values of some fullerenes calculated by different theoretical techniques. A direct comparison between these theoretical results shows significant

Table 6. The averaged second-order hyperpolarizability ($\bar{\gamma} = (\gamma_{xxxx} + \gamma_{yyyy} + \gamma_{zzzz} + 2(\gamma_{xxyy} + \gamma_{xxzz} + \gamma_{yyzz}))/5$, in 10^{-36} esu) and the averaged pyramidalization angle $\overline{\theta_p} = \sum \theta_p/n$, where n is the total number of carbon atoms, for the isolated-pentagon rule isomers of higher fullerenes.

Fullerene	Symmetry	$\bar{\gamma}$ (10^{-36} esu)	$\overline{\theta_p}$

Source: Adapted from [235].

differences. All of the SOS approaches give a second-order hyperpolarizability, which is about an order of magnitude larger than that predicted by the *ab initio* calculations. This discrepancy arises from the truncation of the expansion in excited states in the explicit summation of contributions to γ in SOS calculations [181]. In contrast, the γ values obtained in the FF methods [179, 217] are of the same order of magnitude. The described problems are absent in the analytical RPA approach [181]. On the other hand, all above theoretical studies do not consider the screening effect induced by electron-electron interaction (in time-dependent density functional theory this is to some extent taken into account). Actually, the screening effect should be considered since the polarization of the electron cloud can modify the charge density and therefore the self-consistent potential seen by each electron. Detailed analysis of the screen effect is expected.

3.3. Fullerene Derivatives

Fullerenes, for example, C_{60}, C_{70}, and C_{82}, are well-known electron acceptors and thus they easily form charge-transfer complexes, or say, fullerene derivatives, with other organic groups or metal, for example, complex formed by C_{60} and polymers matrix, or trapping metal to C_{82}. Over the past 10 years, third-order optical nonlinearities of fullerene derivatives have been studied by different research groups and different experimental techniques, for example, coherent anti-Stokes Raman spectroscopy (CARS) analysis technique, optical Kerr effect (OKE), THG, DFWM, z-scan, optically heterodyned OKE (OHD-OKE). It has been demonstrated that fullerene derivatives, due to the charge transfer, do exhibit enhanced third-order optical nonlinearities at nanosecond or picosecond scales [188, 210, 211, 237–252]. The third-order optical nonlinearities of some representative fullerene derivatives are summarized in Table 7. It is seen that the chemical-modified fullerenes all exhibit enhancement on their third-order optical nonlinearities compared to small host fullerene molecules. The enhancement is greatly influenced by the measuring wavelength and pulse duration. The negative or positive $\chi^{(3)}$ or γ can be understood as follows. There are two terms in the sum-over-states representation of the nonlinearity γ_{ijkl} [253]: the first one representing

four-wave mixing pathways which involve two-photon transitions to or between excited electronic states, and the second one describing pathways which involve transitions that return to the ground state. The final value of $\chi^{(3)}$ or γ depends on the interference between the two terms. If the first term dominates, $\chi^{(3)}$ or γ will be positive; they will be negative if the second term dominates.

Lascola and Wright [210, 211] determined the second-order molecular hyperpolarizability γ for the charged species, C_{60}^-, C_{60}^{2-}, and C_{60}^{3-}, by using CARS vibrational lineshape analysis. Their measured γ values for those charged molecules are larger than that of the neutral C_{60} and are comparable to values of highly conjugated organic polymers, for example, polydiacetylene. Heflin et al. [237], Gu et al. [239], Campbell et al. [242], Mavritsky et al. [254], Qian et al. [247], and Huang et al. [245] have reported $\chi^{(3)}$ measurement of metal-containing endohedral or exohedral fullerenes, for example, $Er_2@C_{82}$ [237] by DFWM at 1064 nm, DyC_{82} by DFWM at 532 nm, LiC_{60} by z-scan DFWM at 497 nm, $(Ph_3P)_2PtC_{60}$ [254] by time-resolved z-scan technique at 527.5 nm, $C_{60}M_2$ (M = Pd, Pt, Sm) by OHD-OKE at 647 nm, and $CuPc-C_{60}$ by OKE at 830 nm all obtaining enhanced third-order optical nonlinearity compared to that of pristine fullerene. Recently, Wang et al. [251] have investigated the third-order optical nonlinearities of iron(III) and ruthenium(III) derivatives of organofullerene with ultrafast optical Kerr gate technique at 830 nm indicating that the electron-deficient metal ion iron(III) blocked charge transfer from the organic group to C_{60} and reduced the optical nonlinearity, while a ruthenium(III) compound, due to the chloro-bridge built by the remaining un-coordinate orbits of ruthenium ions, showed strongly enhanced optical nonlinearity. These measured results suggested that increased charge on the cage, and not asymmetric charge distribution due to metal-cage interactions, is the primary reason for increased nonlinearity, encouraging implications for the use of charge transfer and endohedral or exohedral fullerene complexes in future photonic devices.

The serial work of Gong's group [188, 243, 248, 250] showed the following order of the nonresonant γ value for C_{60}- or C_{70}-derived molecules: $C_{60} < C_{60}(NH_2CN)_5 < C_{60}((NH_2)_2CNCN)_5$ and $C_{70} < C_{70}(NH_2CN)_5 < C_{70}((NH_2)_2CNCN)_5$. This trend indicates that the enhancement of the third-order optical nonlinearity is proportional to the increase of charge-transfer strength. This is a very important rule for us to design and synthesize new molecules for third-order optical nonlinear applications.

The fabrication of stable and efficient NLO molecules is an interesting challenge because of a large class of possible applications of these molecules. Controlled transfer multilayered structures do offer an alternative solution, well argued by the controlled fabrication and expected enhancement stability. The work of Kajzar et al. [240], Gong et al. [238], and Koudoumas et al. [249] confirmed this point by measuring the nonlinear optical properties of C_{60}-based composites and multilayered charge-transfer structures with 5,10,20-tetraphenyl-21*H*,23*H*-porphine (TPP) and 5,6,11,12-tetraphenylnaphthacene (rubrene) (TPN), poly tetrahydrofurfuryl methacrylate (PTHFMA), and

polystyrene *n*-arm star polymers $(PS)_n$ ($n = 3, 6$) with molecular weights of 900, 17800, and 4800 Da.

Konstantaki et al. [244] examined the third-order NLO response of the water-soluble inclusion complex C_{60}/γ-cyclodextrin by using z-scan technique at 532 nm. Since ageing of this complex solution results in the formation of aggregates, enhanced γ values were obtained (see Table 7).

Theoretical investigations of the third-order optical non-linearities of fullerene derivatives have so far only been done for the substitute doped fullerenes [129, 124, 255–261]. Rustagi et al. [124] were the first to consider the second hyperpolarizability of C_{60} substitutionally doped with one B or one N atom. They used a tight-binding method for calculating the second hyperpolarizability and found a large enhancement in the doped fullerenes, especially for C_{59}N. Later, Dong, Jiang, Xing, and co-workers used the Su–Schrieffer–Heeger (SSH) model for calculating the second hyperpolarizability of $C_{60-n}X_n$ ($n = 1, 2$) where X = B or N [255, 256] and also found enhanced nonlinearities

compared with C_{60}, especially for the doubly substituted fullerenes. However, for the mono-substituted fullerenes they showed that by including Coulomb interactions in the SSH model they found a much smaller second hyperpolarizability [257]. Xie found, by using an SSH model with the Coulomb interactions included, enhanced third-order nonlinearity of C_{70} mono-substituted with either B or N [258]. Recently, the static second hyperpolarizability of the double substitute-doped fullerenes C_{58}NN, C_{58}BB, and C_{58}BN has been investigated by Jensen et al. [129] using time-dependent density functional theory. They found only small changes in the second hyperpolarizability for C_{58}NN and C_{58}BB, but an enhanced second hyperpolarizability was found for the donor-accepted doped fullerene C_{58}BN. Also, using the same method, Xie et al. [259, 260] investigated the second hyperpolarizability of the heterofullerene $C_{48}N_{12}$ and $C_{48}B_{12}$ and found an enhanced second hyperpolarizability, especially for $C_{48}B_{12}$ for which the average second hyperpolarizability was 180% larger than that of C_{60}. Cheng et al.

[261] studied the frequency-dependent second-order hyperpolarizability of the $C_{59}Si$ and $C_{58}Si_2$ heterofullerenes using the INDO/CI-SOS method. Using the results for the second-order hyperpolarizability of $C_{59}Si$ and $C_{58}Si_2$, they estimated the third-order susceptibility for the DFWM optical process for Si-doped films to be about 10^{-10} esu at the first excited state and 10^{-11} esu at the ground state.

A main direction for searching organic materials which have enhanced third-order optical nonlinearities has focused on adding π-conjugated bonds, for example, $-C{=}C{-}C{=}C{-}$. This leads to decrease of the transparency because of narrowing of HOMO-LUMO gaps. Very recently, Fuks-Janczarek et al. [252] have reported DFWM measurements on the third-order NLO responses of a novel dyad of C_{60}-TTF with saturated ($-C{-}C{-}C$) chemical bonds at 532 nm in picosecond time. The main importance of their work lies in their obtained results that the increase of the third-order optical nonlinearity is not connected with the increasing number of conjugated bonds (which increase the UV-vis transparency), but is due to the increasing number of saturated ($-C{-}C{-}C{-}$) bonds without a decrease of the effective HOMO-LUMO gap. It should be pointed out that those C_{60}-derived compounds have large optical limiting coefficients which imply an interesting application in optical limiting systems.

Organic materials have two advantages: being optimized at the molecular engineering level for a specific application (e.g., photorefractivity [262], holographic memory [263], electro-optic modulation [264]) and combining chemical functionality with their optical properties. Apart from showing NLO properties with the inherent electron-transfer properties between donor and acceptor groups, one of these groups can have redox or proton-transfer capability [265]. This was exploited to demonstrate the reversible switching of the first-order hyperpolarizability of a donor-acceptor molecule [266]. Very recently, Asselberghs et al. [267] have investigated the proton-accepting capability of the dimethylamino electron-donor group on substituted 5,6-open azafulleroids [268], obtained through ring-opening aryl azide with C_{60} in toluene, to demonstrate reversible switching based on proton transfer. Their open azafulleroid exhibits a clear charge-transfer absorption band around 710 nm and the first-order hyperpolarizability was determined by using nanosecond hyper-Rayleigh scattering at 1064 nm in chloroform to be 1.4×10^{-28} esu, which is slightly resonantly enhanced because of the closeness of the charge-transfer absorption band to the second-harmonic wavelength. It should be mentioned that the side product, 6,6-closed aziridinofullerene, lacked the homoconjugation with the electron-accepting fullerene moiety and led to a lower hyperpolarizability. Their detailed studies demonstrated that the second-order NLO response was dramatically reduced upon protonation and completely restored after deprotonation. From the point of view of developing molecular photonic devices whose properties can be switched by modifying one of the component parts, the ability to switch the NLO response of a molecule "on" and "off" reversibly by a simple controllable perturbation would add significant value to the utility of NLO molecules.

Since C_{60} is not easy to mix homogeneously with organic-inorganic material, less work on the optical nonlinearity of C_{60} doped in a solid matrix is reported. Very recently, Yu et al. [269] have used sol–gel technique and synthesized the solid compounds of C_{60} attached by three $NH_2{-}(CH_2)_3{-}Si(OC_2H_5)_3$ groups. The nonresonant third-order optical susceptibilities measured by OKE gate technique at 820 nm are 1.4×10^{-13} esu and 1.6×10^{-13} esu for $C_{60}[NH_2{-}(CH_2)_3{-}Si(OC_2H_5)_3]_3$ sol and gel, respectively. This off-resonant NLO response is also mainly derived from the electron-transfer process. Their results suggest a potential application of C_{60} derivatives of solid state in ultrafast optical devices.

3.4. Carbon Nanotubes

Compared with the extensive NLO studies of fullerenes, less work [213–215, 222, 223, 270–283] has been done on the third-order optical nonlinearities (TOON) of carbon nanotubes. Xie et al. [213–215] were the first to study theoretically the NLO properties of SWNT, predicting that SWNT has a larger TOON which would have potential applications as an ultrafast optical switch. Empirical relations for the static second-order hyperpolarizabilities γ of both armchair and zigzag nanotubes are established [222, 223, 270]: $\gamma = (1 + 0.3n)^{2.98}\gamma_{C_{60}}$ for zigzag tube and $\gamma = (1 + 0.167n)^{3.15}\gamma_{C_{60}}$ for armchair tube, where $\gamma_{C_{60}}$ is the static γ value of C_{60}. The average contribution Γ of one carbon atom to the third-order optical nonlinearity of each chiral carbon nanotube, as listed in Table 8, is examined by Xie and Rao [271]. The chiral effect on the TOON is clearly shown. Their work demonstrated that the metallic tube favors larger γ values, and the smaller the diameter of a chiral carbon nanotube, the larger the average contribution Γ. Compared with that of a well-characterized polyenic polymer listed in Table 8, chiral carbon nanotubes can compete with the conducting polymer achieving a large γ value needed for photonic applications.

Liu et al. [272] and Xie et al. [273] were the first to investigate experimentally the third-order optical nonlinearities of carbon nanotubes by using the picosecond and nanosecond Nd:YAG laser and the technique of backward degenerate four-wave mixing (DFWM). Their results are listed in Table 9. They found enhancement of the TOON in the carbon nanotubes, in agreement with the theoretical predictions of Xie et al. [213–215, 222, 223, 270, 271]. The two-photon and one-photon processes, as demonstrated in the theoretical work of Xie et al., contribute to the TOON. The fast response process of the carbon nanotubes on the picosecond scale is an instantaneous electronic process due to the large polarizability arising mainly from the $\pi \rightarrow \pi^*$ virtual transition, while the slow process on the picosecond scale is associated with an excited-state population. On the nanosecond scale, similar results are obtained.

However, Liu et al. [272] did not obtain real solution for carbon nanotubes. Thus, a large absorption was observed in the infrared region. On the other hand, their DFWM technique had limited ability to distinguish the NLO contribution from the π-conjugated electrons. Shi and co-workers [274, 275] have performed NLO measurements on real SWNT solutions by using the femtosecond optical Kerr technique with a Ti:sapphire laser operating at 820 nm. Their results are listed in Table 9. The magnitude of Γ for each carbon atom in the SWNT is about 7.7×10^{-33} esu, which is

Table 8. The static γ value and average contribution Γ of 17 chiral carbon nanotubes and 7 well-characterized polyenic polymers.

Notes: S-SWNT$_{(p,q)}$ and M-SWNT$_{(p,q)}$ denote semiconducting and metallic SWNT, respectively. D and θ are the diameter and chiral angle of carbon nanotubes. N is the total number of carbon atoms in a given material. Γ is the average contribution of a carbon atom to the third-order optical nonlinearity of the material. ζ is the ratio between the Γ values of a material and C_{60}.
Source: Some data are adapted from [33].

about three orders larger than the value of carbon nanotube reported by Liu et al. [272]. To improve NLO performance of SWNTs, it would be of interest to test the optical nonlinearity of SWNTs of various lengths.

Very recently, using standard time-resolved pump-probe photomodulation technique with a 150-fs fiber laser at the wavelength 1550 nm, Chen et al. [276] have experimentally demonstrated that SWNTs have an exciton decay time of less than 1 ps and exhibit a high third-order optical nonlinearity. Similar experimental results from MWNTs or a SWNT/polyvinyl alcohol composite are also observed by them. Their experiment suggested that SWNT/polyimide composites have the potential to become an ultrafast waveguide switch and to develop high-quality subpicosecond all-optical switches.

4. OPTICAL LIMITING OF FULLERENES AND CARBON NANOTUBES

As addressed before, a currently important problem in today's science and technology is related to the task of protecting the human eye and the sensors of instruments detecting high-power light beams from radiation damage [284–287]. A solution to this problem is the use of passive optical limiters as protection devices. An ideal optical limiter exhibits linear transmission below a certain input light fluence (ILF) threshold W_{ILF}, but above the W_{ILF} value nonlinear transmission occurs and the output light fluence (OLF) will reach a saturated value W_{OLF} [284]. A good limiter should also be stable under ambient and photoirradiation conditions and efficient from a few picoseconds up to

Table 9. Third-order optical nonlinearities of MWNTs and SWNTs.

Notes: λ and τ are the wavelength and pulse duration of laser source. Γ is the averaged second-order hyperpolarizability γ contributed by one carbon atom in carbon nanotubes. PPCE denotes the mixing of polypyrrol and m-cresol with ethanol. DMF = dimethylformamide.

longer pulse durations from nanoseconds and milliseconds on a broad range of wavelengths (visible and near infrared). Thus, the transmitted pulse energy never exceeds the damage threshold for the optical sensor.

Optical limiting is obtained by exploiting different NLO processes [284–287]: coherent nonlinear optical absorption (reverse saturable absorption (RSA), two-, three-, or multi-photon absorption [288]), nonlinear scattering (solvent bubble formation and/or particle sublimation [289–291] or mismatched indices [292]), nonlinear refraction (electronic effects [9] or thermal lensing [293]), and so on. Among the nonlinear optical absorption, RSA is a primary mechanism for the nonlinear absorption optical limiting and is demonstrated to be one of the best processes to use for optical limiting because it reduces the total pulse energy rather than simply reducing the fluence or irradiance. It is generally accepted that RSA of a material system, for example, C_{60}, can be described by a five-level model [294–299]. As shown in Figure 7, if $\sigma_{sg} > \sigma_{se}$, the material is more transparent and becomes a saturable absorber. However, when the absorption cross sections of the singlet or the triplet excited states are larger than that of the ground state and the lifetime of the excited state is long enough, the total absorption of the NLO material increases and the material is then a reverse saturable absorber (i.e., a RSA process occurs). For longer laser pulses, significant intersystem crossing (ISC) to a triplet state occurs for some kinds of materials (e.g., an important feature of C_{60} is the fast and efficient ISC from the first singlet excited state to the first triplet excited state). In these cases, the excited-state absorption appears from the lowest triplet to higher excited triplet states, providing an increasing contribution to the total absorption of the system. It should be pointed out that the transition from the ground state to the first singlet electron state is forbidden because of the same parity, but becomes partially allowed due to vibronic interactions responsible for the weak absorption band in the visible region extending from 450 nm to 650 nm. In this RSA mechanism, significant parameters are the excited-state lifetimes and the ISC time, compared with the duration of the laser pulse, plus the values of the absorption cross sections.
Figure 7. The energy levels of singlet (S_{ij}) and triplet (T_{ij}) states of a system. The optical absorptions are related to the absorption cross sections (σ) of the states. The emissions are correlated to the relaxation time (τ_{ij} from the ith state to the jth state). S_{ij} or T_{ij} denotes the jth vibrational state of the ith electronic state. S_{00} is the ground state. S_{1j} and T_{10} are the first singlet and triplet electronic states, respectively. S_{2j} and T_{20} are the second singlet and triplet excited electronic states. σ_{sg}, σ_{se}, and σ_{te} are absorption cross sections for singlet ground and excited states and triplet excited state, respectively.

Typical reverse saturable absorbers are molecules with weak ground-state absorptions at the concerned wavelengths such as metallophthalocyanines [286, 300, 301], mixed metal complexes [302–305], and fullerenes [287]. In a more general RSA mechanism, the strongly absorbing electronic excited states can be populated by other incoherent processes, for example, internal conversion, energy transfer, and so on.

In the following, we review extensive studies of the optical limiting properties of fullerenes, fullerene-derived materials, and carbon nanotubes (see our other review chapter about the optical limiting of doped carbon nanotubes). Most of these results for fullerenes are attributed to the RSA processes, while nonlinear scattering plays an important role in the optical limiting performances of carbon nanotubes. Some important results for those materials and others are summarized in Table 10.

4.1. Fullerenes

Tutt and Kost [306] were the first to observe the optical limiting performance in C_{60} solution. As listed in Table 10, C_{60} exhibits optical limiting behavior with saturation threshold lower than those reported for C_{70} and other materials currently in use. RSA is the dominant mechanism: there exist allowed broadband transitions from the first excited singlet and triplet to the higher excited states and this results in absorption in the visible and near-infrared range that is much stronger than the absorption from the ground state, leading to RSA. Because the higher ground-state absorption cross section for C_{70} leads to a smaller ratio of excited-state to ground-state cross sections, a higher threshold for optical limiting in C_{70} is observed [306, 307]. In comparison with the C_{60}-toluene system, a reduction of the saturated threshold by a factor of 3 to 5 is obtained by Belousov et al. [308] in a C_{60}-CCl_4 system (see Table 10). Results similar to those of the C_{60}-CCl_4 system are obtained in a C_{60}-decalin solution [308]. Solutions of C_{60} in methylene chloride give results similar to those of C_{60}-toluene system [306]. Sun et al. [309] have shown that the picosecond optical limiting threshold of C_{60} is higher than that of the nanosecond one. Further experiments [310] show that the optical limiting performance of C_{60} in room temperature solution toward nanosecond laser pulses at 532 nm strongly depends on the fullerene solution concentrations (see Table 10), which give significant optical limiting contribution. The optical limiting performance of the more concentrated C_{60} solution is in general stronger than that of dilute ones. For example, the C_{60} solution in toluene of 8.2×10^{-4} M concentration displays strong optical limiting, whereas in toluene of 1.6×10^{-4} M it gives a higher saturated value. In summary, RSA for excitation of C_{60} solution with picosecond duration laser pulses is due to absorption from the first singlet excited state since the population in the first triplet excited state is negligible, while for excitation with laser pulses having durations of a few nanoseconds the dominant contribution to RSA comes from absorption from the first triplet excited state. RSA is stronger for nanosecond laser pulses than for picosecond laser pulses for wavelength between 620 nm and 810 nm.

Sun et al. [311] found that the saturated threshold values of the mixture C_{60}/C_{70} solution (see Table 10) are higher

Note: W_{ILF} denotes the ILF threshold. W_{OLF} is OLF saturation threshold. τ and λ are the duration and wavelength of the laser light. P_t is the percentage of transmitting sample. The TCNEO-C$_{60}$/PC ratio for PCC1, PCC2, PCC3, PCC4, PCC5 and PCC6 are 1.02, 1.06, 1.01, 1.96, 3.05, 5.03 wt%. K_m (in 10^{-4} M) is the solution concentration. DMF = dimethylformamide. TBM(60)CO = *tert*-buty methano-C$_{60}$ carboxylate. C$_{70}$-Π = (η^2-C$_{70}$)Mo(CO)$_2$(o-phen)(DBM). PMMA = poly(methyl methacrylate). PPEI = poly(propionylethyleneimine). PPEI-EI = poly(propionylethyleneimine-co-ethyleneimine). PVDF = poly(vinylidenefluoride). OC = octadecylamine.

than that of C$_{60}$ solution but lower than that of C$_{70}$ solution, which is actually due to the lower triplet state quantum yield and stronger absorption in the visible wavelength for C$_{70}$ than C$_{60}$. Since the triplet state of C$_{60}$ [312] with lifetime 330 ± 25 ns and C$_{70}$ [313] with lifetime 730 ± 50 ns can be quenched by $^3O_2$, the existence of $^3O_2$ in the solution will influence the RSA process and the optical limiting behavior. Sun et al. [311] found that no argon-degassed solution of the mixture C$_{60}$/C$_{70}$ has a higher ILF threshold and a higher saturated threshold than the argon-degassed solution (see Table 10).

Optical limiting performance was also observed in a mixture of higher fullerenes C$_{76}$ and C$_{84}$ at $\lambda = 1064$ nm for $\tau = 10$ ns [308]. Their saturated threshold value is, however, higher than that of C$_{60}$-toluene in the visible region. Again, this is determined by the low quantum yield into the triplet state for the higher fullerenes.

All nonradiative relaxation processes lead to heating of the solvent. Justus et al. [293, 314] pointed out that RSA increases absorption and enhances thermal defocusing which shows additional contribution to the observed optical limiting performances in C$_{60}$ solution. Negative thermal lensing in C$_{60}$ is clearly reflected in z-scan studies of Mishra et al.

[315]. The thermal origin of negative lensing was also established on the optical limiting for different solvents [315]. C$_{60}$ in carbon disulfide, which has the largest thermal figure of merit, exhibits stronger optical limiting behavior [315]. A different kind of solvent dependence was also observed by Sun and Riggs [287]: the optical limiting response of C$_{60}$ solutions in electron-donating solvents, for example, diethylamine and dimethylamine, was much weaker than that in toluene solution. This can be understood: (i) upon photoexcitation of C$_{60}$, the dominant photogenerated transient species are C$_{60}$ anion and diethylamine or dimethylamine cation; (ii) since absorption from the C$_{60}$ anion is weaker than that from the triplet C$_{60}$, the optical limiting performance is degraded. It should be mentioned, however, that thermal refraction contributes to the optical limiting behavior of nanosecond laser pulses but not of picosecond laser pulses [316].

The work of Mishra et al. [317, 318] showed the significant contribution of nonlinear scattering to the observed optical limiting performance in C$_{60}$ solution. In their limiter geometry, the transmission could decrease at higher fluences only due to RSA or aberrations which come from the nonlinear lens. Their observed reduction in the transmission at higher

fluences was larger than that expected from a theoretical analysis including RSA and nonlinear refraction, where the difference is from the nonlinear scattering.

In addition, the work of Riggs and Sun [287, 310] showed us that RSA in C_{60} also has some contributions from singlet and triplet excimer-like states formed due to bimolecular processes involving C_{60} molecules in the triplet state.

4.2. Fullerene Derivatives

A category of metal-fullerene complexes [319–323] was synthesized in the laboratory. Their charge-transfer nature qualifies them to be promising group of excited-state absorption optical limiting materials. (Indeed, enhanced optical limiting performance of a molybdenum complex of fullerene $(\eta^2\text{-}C_{60})\text{Mo(CO)}_2(\text{o-phen})(\text{DBM})$ (DBM = dibutyl maleate; o-phen = 1,10-phenanthroline) [322]) was observed. Recently, Liu et al. [307] have also observed enhanced optical limiting performance of a novel molybdenum complex of fullerene $(\eta^2\text{-}C_{70})\text{Mo(CO)}_2(\text{o-phen})(\text{DBM})$ relative to fullerene C_{70} with nanosecond laser pulses (see Fig. 8). This is attributed to the increment on the triplet-state absorption because of intramolecular charge transfer.

Copper (II) phthalocyanines (CuPc) and C_{60} have been used to construct practical optical limiters due to their good optical limiting properties. As far as the solubilities and aggregations of these optical limiting molecules are concerned, combining phthalocyanine and fullerene in one compound through Diels–Alder reaction has many advantages, for example, combining the optical limiting properties of both molecules, improving the solubility and stability, and avoiding the phase separation problems exciting in the mixture of various materials. Recently, Zhu et al. [324] have demonstrated that in a higher-concentration solution, CuPc-C_{60} shows similar optical limiting behavior to CuPc, while in a lower-concentration solution, the CuPc-C_{60} shows similar optical limiting behavior to C_{60} at low input fluence (<0.2 J/cm^2) and to that of CuPc at higher input fluence (>0.2 J/cm^2). In this kind of combined molecule, there are two separated conjugation systems both of which independently contribute to the RSA.

The fullerene-metal nanocomposites remain as a relatively unexplored area [325, 326]. Recently, Sun et al. [327] have prepared a novel [60]fullerene-Ag nanocomposite

(DTC$_{60}$-Ag) by the *in-situ* reduction of silver ions encapsulated in a new mono-functionalized methano-[60]fullerene derivative (DTC$_{60}$) with reverse micelle-like structure. As listed in Table 10 and shown in Figure 9, their experimental measurements demonstrated that the optical limiting behavior of DTC$_{60}$-Ag is better than that of both C_{60} and DTC$_{60}$, even better than the results obtained with novel materials such as silver-dendrimer nanocomposite [328], the AF-380 dye [329], and single-walled carbon nanotube suspensions [330]. Similar results (see Fig. 10) [331] have been obtained for a new C_{60} hexamalonic derivative nanocomposite (HDTC$_{60}$-Ag) which is a better optical power limiter compared with the parent HDTC$_{60}$ and DT-Ag. Recently, gold nanoparticles have attracted considerable attention due to their potential applications as promising optical devices and nanoelectronic devices because of their higher surface-to-volume ratios and small size effects [332, 333]. However, less work has been done for optical nonlinearities of these nanostructural materials, especially for those with zerovalent metal nanoparticles [334]. Very recently, Fang et al. [335] have synthesized two novel C_{60}-derived nanoparticles containing bi-pyridye (BPY) and tri-pyridle (TPY) groups. The optical limiting responses of C_{60}BPY, C_{60}TPY, C_{60}BPY-Au, and C_{60}TPY-Au nanoparticles in chloroform were measured by using a Nd:YAG laser at both picosecond and nanosecond scales and 532 nm. Their measured results are listed in Table 10 and shown in Figure 11. The difference between the optical limiting properties of both C_{60}BPY and C_{60}TPY is little. However, the optical limiting performance of C_{60}TPY-Au at both picosecond and nanosecond scales was much better than that of C_{60}BPY-Au. Their further

Z-scan measurements indicate that nonlinear absorption (e.g., excited-state and the surface plasmon absorptions) and nonlinear scattering contribute a great deal to the optical limiting performance of C$_{60}$TPY-Au, while there is no nonlinear scattering for C$_{60}$BPY-Au. All these are caused by the excited-state interaction between the C$_{60}$ and silver or gold nanoparticles, showing the strong nonlinear refraction (or say, self-focusing effect), as well as the interband transition due to the surface plasmon resonance.

Suo et al. [336] explored the influence on the optical limiting performance of C$_{60}$ by attaching two strong pulling electron groups (-CN), that is, dicyanodihydrofullerene C$_{60}$(CN)$_2$. This molecule has an optical limiting performance for nanosecond laser similar to that of pristine C$_{60}$ (see Fig. 12). Although this molecule has an extinction coefficient of the excited triplet state larger than that of C$_{60}$, its low quantum yield leads to a lower triplet-state population and thus the optical limiting behavior similar to that of C$_{60}$. As mentioned before, there are generally two kinds of mechanisms for optical limiting performance because of the nonlinear absorption: dual photon absorption and RSA. Compared with the pristine C$_{60}$ (see Fig. 13), the picosecond optical limiting performance of C$_{60}$(CN)$_2$ is power independent but assigned to the RSA of the excited singlet state [336].

The incorporation of fullerene moieties into polymer systems such as polycarbonate (PC) is a hot recent topic due to the interesting optical and electronic properties that the combined materials exhibit. The work of Li et al. [337, 338] indicated that increasing the electron-accepting ability of fullerene derivatives leads to stronger intramolecular action between TCNEO-C$_{60}$ moiety and PC unit and thus TCNEO-C$_{60}$-PCs (e.g., PCC1, PCC3) (see Fig. 14 and Table 10 for different TCNEO-C$_{60}$/PC feed ratio; TC-NEO = tetracyanomethanoxymethano) show much better optical limiting properties than C$_{60}$-PCs. It should be pointed out that the optical limiting characteristics of TCNEO-C$_{60}$-PC can be described by the Golovlev model [339].

Fullerene compounds are very hydrophobic. Thus, most of the related physical and chemical studies about their structure, properties, and reaction have been performed in nonpolar solvents such as toluene or benzene. However, if the fullerenes are embedded in a suitable water-soluble

Figure 15. Optical limiting of two C_{60}/γ-cyclodextrin water solutions (0.15 and 0.3 mM) and a pure C_{60}-toluene solution (0.3 mM) at 532 nm. The transmitted energy is normalized (T = 100%) with respect to the linear transmission. Reprinted with permission from [341], M. Konstantaki et al., *Chem. Phys. Lett.* 318, 488 (2000). © 2000, Elsevier Science.

molecule, water solubility can be achieved. γ-Cyclodextrin has been proved to be a rather suitable candidate for producing a water-soluble complex which has a stoichiometry of one C_{60} for two γ-cyclodextrins [340]. Using 532-nm, 10-ns laser pulses, Konstantaki et al. [341] observed significant optical limiting action of C_{60}/γ-cyclodextrin complex (see Fig. 15), the effect being slightly lower than that of the pristine C_{60}. However, ageing of the C_{60}/γ-cyclodextrin-water solution leads to the formation of aggregates which can enhance the optical limiting action by a factor of almost 2 [341].

It has been shown that appropriate fullerene functionalization increases the solubility in polar solvent and allows the preparation of solid materials via sol–gel method [342, 343]. Signorini et al. [343] have compared the optical limiting

Figure 14. Optical limiting of (a) TCNEO-C_{60}-PCs and (b) MPYLD-C_{60}-PC with 8-ns, 10-Hz laser pulse at 532 nm with linear transmittance 70%. Reprinted with permission from [337], Y. Li et al., *Chem. Phys. Lett.* 337, 403 (2001). © 2001, Elsevier Science.

behavior of a pyrrolidino-fullerene derivative (FULP) solution with a FULP doped sol–gel sample. Compared to the green spectral region (532 nm) for both C_{60} and FULP in solution, enhanced optical limiting efficiency is demonstrated in the red spectral region (690 nm), that is, it shows better optical limiting performances than pristine fullerene. The inclusion in the sol–gel matrix does not influence the optical limiting performances of the fullerene derivative. The RSA is still the predominant mechanism for the observed optical limiting behavior.

Several groups have shown that the optical limiting performance of fullerenes in solid matrix, for example, in a poly(methyl methacrylate) (PMMA) matrix, is rather different from that in solution [344–346]. The dramatic difference should be contributed to mechanisms other than the RSA since the ground-state and triplet-triplet transient absorption spectra of C_{60} in PMMA polymers film are similar to those in room-temperature toluene solution [346]. Riggs and Sun [310] have investigated systematically the optical limiting properties of *tert*-butyl methano-C_{60} carboxylate (TBM[60]CO) in room-temperature toluene solutions of different concentrations, in PMMA polymers films, and in highly viscous solvent-polymer blends. Similar to C_{60}, optical limiting performance of TBM[60]CO strongly depends on the fullerene solution concentrations due to bimolecular excited-state processes of the fullerenes. Riggs and Sun [347] have studied a series of mono- and multiple functionalized fullerene derivatives [348] at different solution concentrations giving a generalized understanding of the concentration-dependent optical limiting in fullerene solutions. The medium viscosity is shown to contribute to effects on the optical limiting contribution that are also associated with excited triplet-state bimolecular processes (in particular self-quenching and triplet-triplet annihilation), resulting in weaker optical limiting performance in highly viscous solvent-polymer blends [310]. For example, for the highly viscous solution (i.e., the presence of large quantities of PMMA polymer in toluene) of TMB[60]CO at 71% linear transmittance, the fluence saturation threshold value

is about 0.17 J/cm^2, which is about 20% higher than that for TMB[60]CO in room-temperature toluene solution of the same linear transmittance [310]. For another example, at 69% linear transmittance, the fluence saturation threshold value for TBM[60]CO in a highly viscous blend of poly(propionylethyleneimine) (PPEI) polymer chloroform solution is significantly higher than in room-temperature chloroform solution [310]. Optical limiting properties of TBM[60]CO are found to be essentially film thickness independent. (Lacking meaning molecular diffusion in polymer films may explain why TBM[60]CO in both thin and thick PMMA films exhibited a poorer optical limiting behavior than that in room-temperature). Based on the modified RSA model including both unimolecular and bimolecular excited-state processes, Riggs and Sun [310] indicated that the fullerene solution concentration affects the efficiency of the bimolecular excited-state processes, whereas the medium viscosity influences the bimolecular rate constants through changes in the molecular diffusivity.

4.3. Carbon Nanotubes

The optical limiting properties of MWNTs [349–354] and SWNTs [352, 354–362] have been recently studied. Some of the results are listed in Table 10. Compared to C$_{60}$ and carbon black suspension (CBS), carbon nanotubes are also good candidates for optical limiting applications.

Sun and co-workers [349, 350] were the first to measure the energy-dependent transmission of MWNTs suspended in distilled water [349] and ethanol [350], or MWNTs embedded in PMMA films [349] in the visible and infrared spectral regions (e.g., 532 nm, 700 nm, and 1064 nm) with 7-ns laser pulses. For MWNTs in ethanol, the limiting threshold η, defined as the value of the input fluence at which the transmittance falls to half of the linear transmittance, is about 1.0 J/cm^2 at 532 nm (lower than those of C$_{60}$ and CBS), and 6 J/cm^2 at 1064 nm (lower than that of CBS). Optical limiting phenomena totally vanish for C$_{60}$ toluene solution. For MWNTs in water, $\eta \approx 1.0, 5.5, 13$ J/cm^2 at 532 nm, 700 nm, 1064 nm, respectively. For MWNT in PMMA, $\eta \approx 3.1, 4.1, 8.0$ J/cm^2 at 532 nm, 700 nm, 1064 nm, respectively. For MWNT and carbon particles in PMMA, the η values at 532 nm, 700 nm, 1064 nm are almost the same as those for MWNT in PMMA. Clearly, MWNTs, unlike C$_{60}$ which has no limiting response at 1064 nm, are a broadband limiter up to 1064 nm. Since carbon nanotubes with a lower work function, lower electron binding energy, and stronger plasma excitation have no ground-state absorption at 532 nm and 1064 nm, the broadband limiting response should result from another mechanism. Recently, the energy-dependent transmission of MWNT suspension measured with picosecond and nanosecond laser pulses has shown a strong optical limiting action on the nanosecond time scales but does not display any limiting behavior in the picosecond regime even with an input fluence as high as 3 J/cm^2 [351], which is different from that of C$_{60}$ but similar to that of CBS. Picosecond time-resolved pump-probe experiment of Sun et al. [351] indicated that it took about 0.5 ns for the nonlinear transmission to appear for both MWNT and CBS. Especially, the smaller the external diameters of MWNT, the faster and larger are the changes of the

transmission. The nonlinear scattering experiments of Sun et al. [351] with nanosecond laser pulses at 532 nm confirmed that nonlinear scattering exists in MWNT suspension since the observed limiting behavior of MWNT is similar to that in CBS. Thus, the optical limiting action in the MWNT suspension comes from a mechanism similar to that in CBS.

Vivien et al. [354–359, 361] were the first to report the NLO transmittance of SWNT in a water suspension [354–356, 359, 361] or in chloroform [354, 356–359, 361] for pulse durations ranging from 3 to 100 ns and for wavelengths from 430 nm to 1064 nm. Their results are summarized in Table 11. For SWNT in water [355, 356, 359, 361], $\eta = 3.8 \times 10^{-6}$ J/cm^2 (a bit higher than that of CBS) for 7-ns Nd:YAG laser pulse at 532 nm, and 2.6×10^{-5} J/cm^2 (lower than that of CBS) for 7-ns Nd:YAG laser pulse at 1064 nm. Obviously, the detailed studies of Vivien et al. [355–361] demonstrated that SWNTs are also efficient limiters over a broad wavelength range. Also, their results clearly show the wavelength effect [359] (this effect is attributed to the larger absorption cross sections of the suspensions at shorter wavelength and to the larger scattering cross sections of the laser-induced scattering centers [356]): the shorter the wavelength, the lower the limiting threshold η and the better the limiting efficiency. Their experimental measurements show that the pulse-duration effects reflecting two different mechanisms, that is, vapor-bubble growth and sublimation of carbon nanotubes, contributed to the optical limiting performance: for example, only the sublimation effect at 1064 nm for 5-ns Nd:YAG laser pulse, and both mechanisms at 1000 nm for 80-ns Ti:sapphire laser pulse. The limiting performances observed with 5-ns Nd:YAG laser pulse at 532 nm are considerably better than those obtained with 2-ns Nd:YAG laser pulse at 532 nm. Such strong pulse-duration dependence of

Table 11. Optical limiting threshold η of SWNT suspended in chloroform or in water using different laser source with different wavelength λ and pulse duration τ.

Solvent	Laser source	τ [ns]	λ [nm]	η [J/cm^2]
Water	Nd:YAG	7	532	3.8×10^{-6}
	Nd:YAG	7	1064	2.6×10^{-5}
	Ti:sapphire	25	700	1
	Ti:sapphire	15	800	0.3
	Ti:sapphire	30	900	1.1

Source: Adapted from the experimental work of Vivien et al. [354–359, 361].

the limiting performance can be explained by the fact that the maximum size of the scattering centers in the nanosecond regime is reached only after the end of the incident pulses [354]. That is also why optical limiting is not observed at all in the picosecond range, but appears in the nanosecond and longer pulses. Moreover, the solvent effects [358, 359] demonstrated that MWNTs in chloroform exhibit better limiting performance than MWNTs in water because of two main reasons [359]: (i) since the absorption cross sections of the particles are slightly larger in chloroform than in water, chloroform exhibits lower thermal conductivity and diffusivity; (ii) with longer pulses from Ti:sapphire laser, chloroform has a very low heat of vaporization, surface tension and, viscosity, which lead to faster solvent-bubble growth. Nonlinear scattering and nonlinear refraction are the dominant mechanisms [357].

Meanwhile, Mishra et al. [362] carried out a detailed study on the optical limiting behavior of SWNT suspensions in different host liquids, for example, ethanol, water, and ethylene glycol. Their results are listed in Table 10 and demonstrated that optical limiting behavior in SWNT suspension appears mainly because of absorption-induced scattering in the suspension [362]. Especially, the extent of nonlinear scattering for good limiting performance in carbon nanotubes strongly depends on the host liquid. For example, optical limiting in the ethanol suspension was the strongest among the three suspensions: water, ethylene glycol, and ethanol (see Table 10).

Riggs et al. [352] and Jin et al. [353] have investigated the size-dependent optical limiting behaviors of SWNTs and MWNTs. Their results are listed in Table 10. These experimental measurements show that carbon nanotubes of large aspect ratio (or say long nanotube) possess stronger optical limiting properties. Apparently, the carbon nanotubes exhibit significantly weaker optical limiting response in homogeneous solution than in suspensions, reflecting that the optical limiting properties of the suspended versus solubilized carbon nanotubes represent dominating contributions by a nonlinear scattering mechanism versus a nonlinear absorption mechanism [352].

Preliminary experimental results of Riggs et al. [352] pointed out that the optical limiting results of carbon nanotube suspensions of the same linear transmittance, similar to those of CBS, are independent of nanotube concentrations, whereas the solubilized carbon nanotubes, similar to fullerenes in solution discussed above, show significant solution-concentration-dependent optical limiting behaviors.

The above reviewed carbon nanotubes were suspended in liquids because of their poor solubility in most solvents. Those suspensions are unstable at high concentration. So it is necessary to get stable solutions of carbon nanotubes. Jin et al. [363] studied the optical limiting performance of several polymer-coated and polymer-grafted MWNTs (which form stable solution in DMF) using 532-nm, 7-ns Nd:YAG laser pulses. The poly(ethylene oxide)/MWNT, poly(4-vinylpyridine)/MWNT, poly(2-vinylpyridine)/MWNT, and poly(4-vinyl-phenol)/MWNT all exhibited optical limiting behaviors similar to that of MWNT suspension in DMF: the η values for all samples are about 1 J/cm^2. Considering that there is no optical limiting effect in all polymer-DMF solutions, their observed optical limiting behaviors of

polymer/MWNT composites are obviously due to the components of MWNTs. Hence, the polymer does not change the NLO properties of MWNTs, and a large variety of polymers can be used as the matrix of carbon nanotubes for the limiting applications. Since carbon nanotubes are broadband optical limiters, the polymer/MWNT composites are also broadband limiters. The important thing is that their polymer/MWNT solutions are very stable towards air and laser radiation [363].

Doped carbon nanotubes, for example, boron- or nitrogen-doped ones, can also exhibit good optical limiting performances. More details can be found in our other chapter contributed to this encyclopedia.

5. CONCLUSIONS

The advantage of the type of chromophore proposed by Asselberghs et al. [267] is that the switchability can be addressed by two different ways: proton transfer and redox switchabilities. As we know, electro-optical (EO) modulation is the main application for second-order NLO materials. In EO modulators, an applied electric field changes the refractive index of the NLO material through the EO coefficient. Based on the work of Asselberghs et al. [267], embedding the chromophore with the first-order hyperpolarizability, which can be switched by proton transfer in a matrix with such a photoaddressable proton donor, can make an EO modulator which can be controlled by light, that is, "on" state without light and "off" state with light. On the other hand, the combination of a second-order NLO chromophore with a photoaddressable proton donor would constitute a composite third-order optical material since the second-order NLO polarizability of a molecule would be influenced by light. This may allow for all-optical data manipulation, and the composite materials may provide for a new driving force in the field of third-order NLO materials.

As shown before, the less is the π-π overlap in the three-dimensional conjugated spheres, the isomeric fullerenes, the higher is the barrier for the π-conjugated electron flow and thus the lowering of the second-order hyperpolarizability. Such concepts can be extended to explain the γ values of one-dimensional and two-dimensional π-conjugated systems, for example, *trans*-1,3-butadiene, *trans*-1,3,5-hexatriene, styrene, biphenyl, and 2,2-bithiophene.

C_{36} fullerene is much more reactive than C_{60} and C_{70}. It has been shown that the ground state of C_{36} is of diradical nature and the crystal C_{36} is formed through covalent bonds among C_{36} units. Obviously, this is contrasted with C_{60} and C_{70}. On the other hand, bounding the electron donor groups to C_{36} would remove the strong diradical character and stabilize the entire system, showing the possibility of synthesizing these molecules. Hence it is expected for the C_{36} chemistry to be further explored, studying the possibility of using C_{36} derivatives for building NLO materials.

The improvement of the optical limiting performance observed in the molybdenum complex of C_{60} or C_{70}, which is attributed to the increment on the triplet-state absorption by intramolecular charge transfer, shows that the charge-transfer nature would make metal-fullerene complexes good candidates for optical limiting applications and leads to a

new means for significantly improving the performance of fullerenes.

The solubility of C_{60} can be improved by combining it with an alkyl group of substituted CuPc through the Diels–Alder reaction. The combined molecules exhibit good optical limiting performance. Hence, based on the combination of various optical limiting molecules through covalent bonds, broadband optical limiting materials may be designed and phase separation problems, which exist in the mixture of various materials, can also be avoided.

The large optical limiting performance observed from the novel nanocomposites DTC_{60}-Ag or $HDTC_{60}$-Ag at 532 nm is due to the combination effort from the C_{60} derivative and silver nanoparticles. Thus, these kinds of novel nanocomposites would lead to novel optoelectronics as well as catalytic properties assembled by fullerene and metals. Surely, much work needs to be done to understand the interesting photophysical phenomena observed in these systems.

The attachment of two cyano groups to C_{60} reduces its quantum yield, increases the absorption of the excited triplet state, and leads to $C_{60}(CN)_2$ which has a similar optical limiting behavior to C_{60} for nanosecond laser at 532 nm. Since the differential absorption between the excited triplet state and the ground state in $C_{60}(CN)_2$ is larger in the near-infrared region, we expect that this molecule may also have better optical limiting performance in the near-infrared region than at 532 nm.

GLOSSARY

Degenerate four-wave mixing (DFWM) A powerful tool for measuring a third-order nonlinear optical susceptibility by using two wave beams that are incident at the same region on the sample and have equal and opposite wave vectors and the same frequency.

Fullerene A cage molecule made of 12 pentagonal faces and any number of hexagonal faces.

Multiwalled carbon nanotube (MWNT) MWNT is obtained if a few stacked graphitic shells are built from perfectly concentric cylinders or a single graphene sheet is rolled as a scroll.

Nonlinear optics (NLO) The study of phenomena that occur as a consequence of the modification of the optical properties of a material system by the presence of light.

Optical Kerr effect (OKE) A useful technique that shows the detected signal which is proportional to the quadrate of the third-order optical susceptibility.

Optical limiter A protection device for human eye and instrument sensors and exhibits linear transmission below a certain input light fluence threshold, but above this threshold the output light fluence reaches a saturated value.

Second-harmonic generation (SHG) A nonlinear optical interaction in which all of the power in the incident radiation at frequency w is converted to radiation at the second-harmonic frequency $2w$.

Single-walled carbon nanotube (SWNT) SWNT is made if only one graphene sheet is rolled.

Third-harmonic generation (THG) A nonlinear optical interaction in which all of the power in the incident radiation at frequency w is converted to radiation at the third-harmonic frequency $3w$.

Z-scan A technique that measures the real and imaginary parts of the third-order optical susceptibility simultaneously.

1. INTRODUCTION

In the past 10 years, the scientific activity of the synthesis and study of so-called "nanoparticles" [1–17], indicating particles with diameter in the range of 1 to 20 nm, has became a major interdisciplinary area [18–21] of research in the world. As the sizes of the particle become smaller, the ratio of the surface atoms to those in the interior increases, thereafter leading those kinds of particles to play an important role in the properties of novel functional material. Those significant properties, such as chemical, electronic, mechanical, and optical properties, of nanoparticles obviously distinguish them from those of the corresponding "bulk" material. In particular, one of those significant properties is the nonlinear optical (NLO) response of nanoparticles, which is enhanced remarkably with respect to the relative "bulk" materials, due not only to their atomic scale structures but also their interface and surface structures [22]. Materials with large third-order optical nonlinearity and fast response time are essential for future optical device applications [16, 17]. Thanks to such a high nonlinear optical

response of these NLO materials, they are thought to be good candidates for use in fiber-optic communication systems, such as all-optical switching [23], routing units, digital signal restoration, and multiplexing and demultiplexing, as well as optical storage media and optical limitter applications [17]. Therefore, intensive investigations on NLO of nanoparticles have recently been carried out.

In the meantime, nanocomposites [24–28] formed by metal or semiconductor nanocrystals embedded in dielectric hosts have been intensively studied as these materials might also become an attractive alternative for the development of all-optical switching devices in waveguides [29]. Strong optical nonlinearities observed due to dielectric or quantum confinement effects, such as nonlinear optical absorption and second and third optical nonlinearities, can be studied for making optical limiters, optical modulators, and laser second and third harmonic generators [16, 17].

In this chapter, we briefly highlight and review the current advances and achievements in studying the NLO properties of nanoparticles and nanocomposites in Sections 2 and 3, respectively. Remarks and outlooks are given in Section 4.

2. NONLINEAR OPTICS OF NANOPARTICLES

2.1. Theoretical Explanation

The first experimental study of nonlinear optical properties of metal nanoparticle colloids was reported by Ricard et al. [30]. Later, Hache et al. [31] gave a theoretical model calculating the electric-dipole third-order susceptibility of conduction electrons in a metal sphere. They ascribed that

the large effective third-order nonlinear susceptibility, $\chi^{(3)}$, of metal nanoparticle colloids is substantially enhanced by a resonance that is due to the effective medium, the surface plasma resonance: collective oscillation of the conduction electrons of the metal under the influence of an applied electromagnetic wave, as expected by direct extension of the Maxwell–Garnett theory. The enhancement of the local electric field, which occurs in the particles at frequencies close to the surface plasmon resonance, is responsible for the amplification of their NLO properties as compared with those of bulk metal. For the large third-order nonlinear susceptibility of semiconductor nanoparticles, Chemla and Miller [32] identified that the enhancement of nonlinearity is due to the combination of local field effects from dielectric confinement and saturable excitonic resonance. In addition, they predicted that these effects would be greatly enhanced since the particles are so small that they also exhibit quantum confinement. Many other authors also have predicted enhanced optical nonlinearities, resulting from quantum confinement effects, with respect to the corresponding bulk materials [33–35]. Hanamura [36] analyzed theoretically the oscillator strength and the third-order optical polarizability $\chi^{(3)}$ due to excitons in semiconductor microcrystallites. The NLO polarizability is shown to be greatly enhanced for an assembly of such microcrystallites as the exciton is quantized due to the confinement effect and the excitons in a single microcrystallite interact strongly enough to make the excitons deviate from idea harmonic oscillators. Cotter et al. [35] have found that three-dimensional quantum confinement can alter radically the nonlinear optical properties of semiconductors in transparency region. This discovery that introducing quantum confinement can enhance this ratio has opened new opportunities for practical exploitation of the quantum-size effect in NLO devices.

Schwarze et al. [37] have developed a new model that combines the interaction between two physical mechanisms responsible for bulk third-order optical nonlinearity. The two physical mechanisms are:

  (i) saturable absorption, due to quantum confinement in nanoparticles,
  (ii) electrostriction, causing particles to migrate in the fluid host.

Schwarze et al. [37] have shown that enhanced optical nonlinearities are predicted to result from local field coupling and those oscillations can occur under certain conditions. In such a computationally feasible theoretical model, which describes the interaction between two nonlinear optical mechanisms, particles are free to move and cluster in the presence of optical field gradients, modifying the local electric field, which in turn modifies the effective permittivity of each nanoparticle. The coupling together of these phenomena can lead to significantly enhanced $\chi^{(3)}$ coefficients, and we have shown that oscillatory behavior can occur under certain conditions. The numerical simulations based on this model have shown the change in the bulk refractive index as a function of the particle size, concentration, and incident intensity. The model also has implications for designing some novel switching devices, which are optimal in the sense that particle sizes and concentrations can be

chosen to maximize the magnitude of the third-order optical susceptibility, $\chi^{(3)}$.

Very recently, Prot et al. [38] have initially applied a recursive transfer matrix method to calculate the electromagnetic field response for three-dimensional systems of scattering spheres to the study of nanocomposite material. Their calculations have shown that mutual interactions between nanoparticles are responsible for large local field enhancements as compared with fields inside isolated particles. According to the experimental study to measure the third-order nonlinear susceptibility of $Au:SiO_2$, they discovered that the imaginary part of $\chi^{(3)}$ values diverges from the theoretical predictions and does not vary linearly with the metal concentration. This discrepancy, attributed to the large enhancement of the local field, proves the qualitative agreement between the local field calculations and experimental nonlinear measurement.

2.2. Experimental Techniques

In the study of optical nonlinearity of nanoparticles, there are huge research works concerning the measurements of third-order nonlinear susceptibility, $\chi^{(3)}$. In these works, experimental technique plays a very important role in carrying out the NLO measurement of $\chi^{(3)}$. In our review of the NLO of nanoparticles, it is necessary to introduce several primary measurement approaches to obtain $\chi^{(3)}$. The most powerful or popular methods to measure the third-order nonlinear susceptibility $\chi^{(3)}$ may be degenerate four-wave mixing experiments (DFWM) and the Z-scan technique [17]. DFWM is a nonlinear optical technique that produces a coherent signal by nonlinear interaction of light with the samples in the beam-crossing region. The coherent signal obtained with such a nonlinear technique is in the form of a laser beam that is coherent and directional. It can be spatially separated and spectrally filtered to reject the intense luminosity in many application fields. DFWM showed a great promise for sensitive measurements of transient species.

DFWM involves the interactions of three beams incident on a sample. The three beams are arranged in such a way that two of the beams (pump beams) are counterpropagating each other and the third beam acts as a probe. The fourth beam, which constitutes the conjugate beam, retraces exactly the path of the probe beam. Three input beams of nearly equal power are divided by the beamsplitters. Two of the input beams have the translation stages so that the arrival time at the sample can be varied. The beam spot size in the sample is approximately 0.5 mm in diameter. The beam geometry is shown in Figure 1. The three input beams are labeled 1, 2, and 3, and 4 is the output beam, which is generated by the input beams through $\chi^{(3)}$. Beam 2 is time advanced or delayed relative to beams 1 and 3 (which are coincident in time), providing the temporal response of $\chi^{(3)}$. The angle between beams 1 and 3 in the sample is about 1 degree. This geometry permits the generated beam, 4, to be spatially separated from the more intense incident pulses and gives a high signal-to-noise ratio. This is important for DFWM experiments because all the beams have the same frequency. The signal beam, 4, is directed to the entrance slit of a spectrometer, recorded, and then analyzed by using
Figure 1. The beam geometry of DFWM techniques. The three input beams are labeled 1, 2, and 3. The output beam is labeled 4.

a photomultiplier and a boxcar interfaced to a microcomputer. Three beams were polarized parallel to the Y-axis. The tensor component $\chi_{1111}^{(3)}$ is measured, and the value of $\chi_{1111}^{(3)}$ can be expressed as a function of beam energies by using the four-wave mixing model described in [39],

$$\chi_{1111}^{(3)} \approx \frac{cn^2}{32\pi^2}\left(\frac{\lambda_0\omega_0^2}{2\tau l}\right)\left[\frac{45E_4}{8E_1E_2E_3}\right]^{1/2}\frac{l\alpha\ \exp(l\alpha/2)}{1-\exp(-l\alpha)} \quad (1)$$

where c is the speed of light in vacuum, n is the index of refraction of the sample, E_i is the pulse energy of the ith beam, ω_0 is the laser beam waist at the focus, τ is the pulse width, l is the sample length, and α is the sample absorption coefficient at the incident wavelength λ_0.

Z-scan [40–42] is also a simple, sensitive technique which relies on the transformation of nonlinear phase shifts into far-field amplitude deflections to obtain the complex nonlinear refractive index $n_2 = n_2' + in_2''$. However, the Z-scan technique has great advantages compared to the DFWM method, which consists of its ability to separate the imaginary and real parts of $\chi^{(3)}$ and, additionally, to determine the signs of the two components. It is essentially a derivative of the ubiquitous single-beam-power-in versus power-out transmission measurement [43] but attains greater efficiency by focusing the beam and translating the sample. The technique involves the measurement of the transmittance through an aperture placed in the far field as the sample is translated through the focus of a Gaussian beam. For a sufficiently small aperture, this procedure provides a measurement of the real part of the nonlinear refractive index n_2'. If the aperture is fully opened so that the detector collects all the light, then the Z-scan provides a measurement of the imaginary part of the nonlinear refractive index n_2'' or, alternatively, the nonlinear absorption coefficient β. If $\beta > 0$, then the Z-scan will result in a trough, indicative of an induced absorption. If $\beta < 0$, then the Z-scan will produce a peak, indicating an induced transparency. Since all the flux from the sample is collected at the detector, the transmitted power may be calculated without having to perform the free-space Fresnel propagation to the aperture. The normalized transmittance may be expressed as [44]

$$T(z) = \sum_{m=0}^{\infty}(m+1)^{-3/2}\left(\frac{-\beta I_0 L_{\mathrm{eff}}}{1+z^2/z_0^2}\right)^2 \quad (2)$$

where z is the longitudinal displacement of the sample from the focus, β is the nonlinear absorption coefficient, I_0 is the

on-axis peak intensity at the focus, L_{eff} is the effective interaction length, z_0 is the Rayleigh diffraction length, and the temporal profile of the pulse has been assumed to be Gaussian. Typically, if the series converge, only the first few terms are needed for numerical evaluation. Hence, the coefficient β may be determined from a fit of this expression to the empirical data.

Femtosecond optical kerr effect (OKE) [45–48] and transient grating scattering [49–51] techniques are also available approaches to measure nonresonant third-order optical nonlinearity of nanoparticles. Both techniques rely on an impulsive stimulated scattering [52–54]. Both the fundamental and the (anti)stokes frequency involved in this process are supplied by the ultrashort laser pulses. For 50 fs pulses the nuclear motions between 0 and 300 cm are probed.

2.3. Third-Order Nonlinear Optical Response

Pincon et al. [55] have studied the third-order NLO response of Au:SiO$_2$ thin films, under the influence of gold nanoparticle concentration and morphologic parameters. Based on their result, we find that, as the metal concentration reaches a few percent, the mutual electromagnetic interactions between particles greatly enlarge the nonlinear optical response of the material and cannot be neglected in the theoretical analysis. Moreover, the thermal treatment leads, for a given concentration, to a significant increase of the nonlinear response, which is ascribed to a modification of the material morphology. They finally point out that the material nonlinear properties are very sensitive to the incident wavelength through the local field enhancement phenomenon. In their study, the nonlinear optical measurements are performed by using the Z-scan technique. Vales of Im $\chi^{(3)}$ range from $-(0.049 \pm 0.009) \times 10^{-6}$ to $-(6.4 \pm 1.2) \times 10^{-6}$ esu as a function of the variation of metal concentrations before the thermal treatment. After anneal, it gives values from $-(0.69 \pm 0.06) \times 10^{-6}$ to $-(6.0 \pm 0.6) \times 10^{-6}$ esu. Smith et al. [56] also used the Z-scan technique at a wavelength (532 nm) near the transmission window of bulk gold to measure the nonlinear absorption coefficient of continuous approximately 50-Å-thick gold films, deposited onto surface-modified quartz substrates. They have fulfilled both open- and closed-aperture Z-scans to determine either the real or imaginary part of the third-order susceptibility that requires a measurement of both nonlinear absorption and nonlinear refraction. Closed-aperture Z-scans did not yield a sufficient signal for the determination of the nonlinear refraction. However, open-aperture Z-scans yielded values ranging from 51.931023 to 5.331023 cm/W in good agreement with predictions, which ascribe the nonlinear response to a Fermi smearing mechanism [31]. It should be mentioned that the sign of the optical nonlinearity is reversed from that of gold nanoparticle composites, in accordance with the predictions of mean field theories.

For the other metal nanoparticles, Takeda et al. [57] have applied a negative Cu ion-implantation technology to obtain the nanoparticle on the silica glass substrate. The DFWM method was performed to measure the $\chi^{(3)}$ at 532 nm with a second harmonic generation (SHG) light of Nd:YAG lasers and 561 nm with a SHG-pumped dye laser. As a standard

sample, CS_2 was used to evaluate absolute values of $\chi^{(3)}$. Nonlinear optical susceptibility $\chi^{(3)}$ of Cu implanted silica exhibits values of $(2.0 \times 10^{-9}) \pm (2.0 \times 10^{-8})$ esu near the peak of the plasma resonance. The estimated value of $\chi^{(3)}$ for the Cu nanoparticles is (9.0×10^{-9})–(8.0×10^{-8}) esu.

For semiconductor nanoparticles, the most studied is cadmium sulfide [58, 59]. The others, like InP, CdSe, CdTe, ZnS, ZnSe, Pbs, and PbSe, were reported in lots of studies. Those nanomaterials with large third-order optical nonlinearity and fast response time are essential for optical device applications in optical computing, real time holography, optical correlators, and phase conjugators [60]. Therefore, CdS and Pbs semiconductor nanoparticles as "quantum dot" materials are of interest for their large third-order NLO response and have been extensively investigated [61–64]. In works of Liu et al. [65], they use the Z-scan technique with 150-fs laser pulses at 780-nm wavelength to carry out the third-order susceptibility measurement of Pbs-coated CdS nanoparticles. The ion displacement technique was used in their work to obtain the Pbs-coated CdS nanocomposites. In such a technique, semiconductor material (Pbs) grows on a seed of CdS in microemulsion media. Their experimental result of high third-order refractive nonlinearity of confined semiconductor nanoparticles in the transparent region is in agreement with the prediction of Cotter et al. [66], who confirmed that the optical Stark effect makes a dominant contribution to the third-order refractive nonlinearity in this case when the absorptive nonlinearity can be negligible.

Other types of nanoparticles, such as magnetic nanoparticles, can be found, for example, in the review paper of Aktsipetrov [67]. In summary, three aspects of nonlinear magneto-optics of magnetic nanoparticles are considered:

(a) Correlation between GMR and NOMOKE has been experimentally approved [68].
(b) Magnetization-induced hyper-Rayleigh scattering has been observed [69].
(c) An internal homodyne mechanism for weakly nonlinear processes is suggested [69, 70].

Most recently, Pan et al. [71] have investigated the third-order optical nonlinearity of nanopolyacetylene using a femtosecond OKE technique at wavelengths from 790 to 860 nm. The ultrafast nonresonant effective second-order hyperpolarizibility for single polyacetylene nanoparticles was estimated to be as large as 1.0×10^{-27} esu, which corresponds to a single carbon atom contribution equal to 5.0×10^{-33} esu. We ascribe such observations to the highly ordered structure of nanopolyacetylene and suppose that the delocalization of the π electrons along the conjugated chains is responsible for such properties.

For convenience, Table 1 summarizes some results of the third-order optical nonlinearities of nanoparticles.

3. NONLINEAR OPTICS OF NANOCOMPOSITES

3.1. Metal Nanocomposites

We consider nanometric metal spheres dispersed in a thin dielectric film. The optical constants of the nonlinear medium are intensity dependent and can be written as

$$n' = n + \gamma \mathbf{I} \tag{3}$$

$$\alpha' = \alpha + \beta \mathbf{I} \tag{4}$$

where n, α, and $\mathbf{I}$ are linear refractive index, linear absorption coefficient, and the instantaneous light intensity, respectively. The nonlinear absorption coefficient β and nonlinear refraction coefficient γ are proportional to the imaginary or real parts of the third-order optical susceptibility $\chi^{(3)}$ as

$$\gamma = 3\Re(\chi^{(3)})/(4\epsilon_0 c n^2) \tag{5}$$

$$\beta = 3k\Im(\chi^{(3)})/(2\epsilon_0 c n^2) \tag{6}$$

where k is the modulus of the wave vector in vacuum and c is the speed of light in vacuum. The experimentally measured optical susceptibility $\chi^{(3)}$ of the composite material is

Table 1. Third-order optical nonlinearities of nanoparticles measured by different experimental techniques.

Nanoparticles	λ (nm)	τ	$\chi^{(3)}$ (10^{-10} esu)	Method	State of material	Ref.
Au:SiO$_2$ as deposited	532	7 ns	−490 to −64,000	Z-scan	film	[55]
Au:SiO$_2$ as annealed	532	7 ns	−6900 to 60,000	Z-scan	film	[55]
Au@CdS	800	100 fs	0.724±0.140	OKE	film	[108]
Cu	532		90 to 800	DFWM	film	[57]
Polyacetylene	790–860	120 fs	0.001	OKE	solution	[71]
Au:BaTiO$_3$	800	100 fs	0.066	OKE	film	[108]
CdS:BaTiO$_3$	800	100 fs	0.158	OKE	film	[108]
Au:TiO$_2$	780	130 fs	2300	OKE	film	[109]
Rh:BaTiO$_3$	308	17 ns	5710	Z-scan	film	[110]
Si-nc	813	60 fs	4 to 28	Z-scan	film	[111]
Au doped in aluminum	532		3.2 to 9.0	DFWM	film	[112]
Ad doped in aluminum	532		1.9 to 2.5	DFWM	film	[112]
ZnTe	532	5 ns	27,000	DFWM	film	[113]
PbS by PVB	595	25 ns	106,000	DFWM	film	[114]
CdS	470	400 fs	11000	DFWM	solution	[115]
Au:BaTiO$_3$	800	120 fs	100 to 10	OKE	film	[116]

Note: λ and τ are the wavelength and pulse duration of the laser source, respectively.

related to the intrinsic NLO third-order susceptibility $\chi_m^{(3)}$ of metal crystal [72]

$$\chi^{(3)} = pf^2 \mid f^2 \mid \chi_m^{(3)} \tag{7}$$

$$f = 3\epsilon_0/(\epsilon + 2\epsilon_0) \tag{8}$$

where p is the volume fraction of metal nanocrystal, f is the local field effect, and ϵ_0 and ϵ are the dielectric constants of the matrix and metal, respectively. Near the surface plasmon resonance ($\epsilon + 2\epsilon_0 = 0$), f becomes resonant and $\chi^{(3)}$ is thus enhanced by local field effects.

Metal nanocomposites can be synthesized by several techniques, such as sol–gel [73], sputtering [74], ion implantation [75], and pulsed laser deposition [76]. These nanocomposites normally present linear optical absorption due to both surface-plasmon resonance and strong third-order nonlinear optical susceptibility. The spatial confinement of the metallic electrons by the insulating host produces an enhanced electromagnetic field due to the large dipole moment induced by an optical field. Furthermore, for very small nanocrystals, the confinement of the electronic wave functions in either the initial or final states to a volume, which is much smaller than their bulk mean free path, produces an additional contribution to the electric susceptibility.

Sella et al. [77, 78] have synthesized Au:SiO$_2$ nanocomposites by radio frequency sputtering techniques. The metal concentration varies from 8% to 35%. Several characterization techniques such as transmission electron microscopy and small angle x-ray scattering have shown that the metal particles are spherical and randomly dispersed, the mean particle size varying from 2.6 to 4.8 nm as a function of the metal concentration. The Z-scan technique [79], as described in Section 2, is a simple and useful method to measure the third-order nonlinear properties of materials. This method enables us to measure both the real and the imaginary parts of $\chi^{(3)}$, proportional to the nonlinear refractive index and nonlinear absorption coefficient, respectively. Sella et al. [77, 78] have measured the optical nonlinearities of these Au:SiO2 films with a metal volume fraction of 20% using a Q-switched Nd:YAG laser frequency doubled at 532 nm and characterized by a pulse duration of 7 ns at a repetition rate of 10 Hz. Open aperture measurement exhibits a maximum close to the waist of light, which reveals a large negative coefficient. They derived $\text{Im}\,\chi^{(3)} = -(3.0 \pm 0.5) \times 10^{-6}$ esu. The absolute value for the real part is smaller than 3×10^{-9} cm^2/W.

Liao et al. [80] also investigated the optical nonlinearity within Au:SiO$_2$ films in the picosecond range at 532 nm by the DFWM method. They found that the third-order susceptibility increases quickly and reaches a maximum value of 2.5×10^{-6} esu at 40% Au. For 20% Au, their work led to $|\chi^{(3)}| = 2.0 \times 10^{-7}$ esu, much smaller than the result of Z-scans in the nanosecond range. This is due to the fact that the third-order optical susceptibility $\chi^{(3)}$ contains two components: a fast component and a slow one [81]. When a picosecond laser is used, the slower component would not have enough time to respond. Thus, the $\chi^{(3)}$ signal measured by picosecond pulses could be much smaller than that measured by nanosecond pulses.

Ballesteros et al. [82] have successfully deposited Cu nanocomposite films comprising Cu nanocrystals embedded in an amorphous Al$_2$O$_3$ matrix by a pulsed laser deposition (PLD) technique. The mean diameter of Cu nanocrystals ranges from 3 to 6 nm. The third-order susceptibility $\chi^{(3)}$ of the films was determined by means of a Z-scan technique using a cavity-dumped synchronously pumped, mode-locked rhodamine 6G laser tuned at 590 nm (slightly off the SPR at 578 nm) and providing 30 ps laser pulses at a repetition rate of 400 kHz. They have investigated metal size dependence of the third-order nonlinearity within Cu:Al$_2$O$_3$ thin films. Both thermal effect and electronic components were found to contribute to the nonlinear refractive index. The thermal contribution goes up with the increase of the metal size. This is understandable because the increase of metal diameter is accompanied by an increase of absorption of the film near the SPR; thus the thermal load of the medium also increases. It was observed that the electronic contribution to nonlinear refractive index increases from 8×10^{-10} to 1.4×10^{-9} cm^2/W when the nanocrystal is decreased. From the nanocrystal size dependence, the authors clearly demonstrated that the nonlinearity is caused by quantum confinement effects whose large contribution is associated to intraband electronic transitions.

The large nonlinear refractive index and $\chi^{(3)}$ have led many authors to suggest potential applications for the metal nanocomposites in optoelectronics. However, some difficulties remain to be addressed before these types of device application will be realized. Flytzanis et al. [83] define a figure of merit for strongly absorbing nonlinear optical materials to be $\chi^{(3)}/\alpha\tau$, where τ is a relaxation time. We can get metal nanocomposites with high values of $\chi^{(3)}$, but both $\chi^{(3)}$ and α have a peak near the same wavelength (surface plasmon resonance wavelength). The high value of α and the long thermal relaxation time τ of the insulating matrix decrease the figure of merit, particularly for laser excitation lasting longer than a few picoseconds. Recently work has been aimed at finding methods of maintaining a high $\chi^{(3)}$ while decreasing the surface plasmon absorption. One way to accomplish this is to get a narrow size distribution of extremely small crystals.

Because there exists the difficulty of producing a suitably narrow size distribution, some researchers have aimed at forming bimetallic core–shell nanoparticles [84]. Changes in the electronic properties across the core–shell boundary add an additional degree of freedom for the reduction of α and for increasing $\chi^{(3)}$. Recently, some researchers [85] have synthesized transparent Ag nanocomposite films by incorporating surface-modified silver nanoparticles into polystyrene through solution mixing and static casting. The Ag nanoparticles could be redispersed well in the polymer matrix. By time-resolved femtosecond OKE experiments at 830 nm, they found that the $\chi^{(3)}$ increases with increasing the particle size.

3.2. Semiconductor Nanocomposites

The effects of particle size on optical properties are more pronounced in semiconductor nanoparticles. In metals, the Fermi level is in the center of the conduction band where the energy levels are closely spaced, whereas in semiconductors, the band edges control the optoelectronic behavior. As the average particle size decreased, the optical

absorption onset shifted to higher energies [86]. This is one example of quantum confinement induced shift in semiconductor nanocrystals. Semiconductor nanocrystals have been proposed as light-emitting diodes [87] and single-electron transistors [88]. They have potential applications in optical limiting, optical computing, real time holography, optical correlators, and phase conjugators because of their high optical nonlinearity. Semiconductor nanocrystals embedded in glass may be synthesized by co-sputtering and thermal annealing. Other techniques for producing nanocomposites include direct chemical reaction in aqueous or organic solution [89] or inverse microemulsion techniques [90]. Among them, more attention has been paid on the sol–gel process in recent years due to the very low temperature involved in preparing this kind of NLO material.

The third-order NLO susceptibility $\chi^{(3)}$ can be measured by four-wave mixing or the Z-scan technique. The experiments normally were performed with a low power continuous wave, Ar ion, and high power Nd:YAG lasers operating at different laser wavelengths and pulse duration. The origin of the third-order optical nonlinearity may come from nonlinear refraction and nonlinear absorption. Normally, the optical nonlinearity is composed of an electric component (short time response) and thermal part (long time response); these can be separated by different measurements. The second-order nonlinear optical susceptibility $\chi^{(2)}$ can be measured by second harmonic generation or Maker fringes. The optical limiting effect is easily observed in nonlinear optical materials. The need to protect optical sensors and human eyes from the damage induced by the high fluences of pulsed lasers has led to increased attention for optical limiting materials [17].

Oak et al. [91] reported earlier the intensity-dependent transmission of CdS_xSe_{1-x} and $CdSe_xTe_{1-x}$ particle doped glasses at wavelengths of 1054 nm employing a mode-locked Nd:glass laser with a pulse width of 6 ps. They found that the transmission for the samples dropped down when the input energy increased. The linear absorption is negligible; the main mechanism of energy loss is from two-photon absorption. However, at higher intensities additional absorption induced by the laser-generated electron–hole pairs was observed.

By a modified inverse microemulsion technique, Han et al. [90] synthesized Ag_2S coated CdS nanoparticles (about 10 nm in diameter). They measured by the Z-scan technique the nonlinear absorption in the Ag_2S/CdS nanocomposites at 532 nm with both 25 ps and 7 ns pulses from two frequency-doubled Nd:YAG lasers. Enhanced nonlinear absorption in the nanocomposites was observed in comparison with the CdS nanoparticles, due to photo-excited free carriers. The relaxation times of the free carriers in the Ag_2S/CdS nanocomposites were determined to be a few nanoseconds. Furthermore, optical nonlinearities in the nanocomposites depend on the ratio of Cd^{2+} and Ag^+, which enables us to optimize and synthesize desired optical materials. Wu et al. [92] investigated the optical nonlinearity of nanosized CdO–organosol. Two samples, CdO–CTAB (cetyltrimethyl ammonium bromide) and CdO–DBS (dodecylbenzene sulfonate) organosols, were measured by using the Z-scan technique with an 85 fs pulse of a Ti:sapphire

laser operating at a wavelength of 800 nm with a repetition rate of 82 MHz. Nonlinear absorption and refraction from the samples were observed. The real and imaginary parts of $\chi^{(3)}$ at 800 nm have been determined to be -1.55×10^{-16} m²/W and 0.91 cm/GW for CdO–CTAB organosol, and -6.97×10^{-16} m²/W and 8.64 cm/GW for CdO–DBS organosol. The optical Stark effect and surface trapped states are the possible origins of the observed optical nonlinearity.

Liu et al. [93] prepared PbS–polymer (C1-PEO-C11-MA-40, NMA, AN, EGDMA, etc.) nanocomposites by polymerized bicontinuous microemulsions. The size of PbS nanocrystal is about 5 nm formed in aqueous domains embedded in the NMA/AN/C1-PEO-R-MA-40 copolymer network. They measured the nonlinearity of the nanocomposites at 780 nm using 150 fs pulses delivered by a mode-locked Ti/sapphire laser, operating at a repetition rate of 76 MHz. Its third-order nonlinear refractive index (γ) at 780 nm is -6.8×10^{-12} cm²/W, three orders higher than that of commercial bulk materials. Such a large optical nonlinearity might be due to the surface-induced large separation of charges between the delocalized electrons and localized holes.

Two-photon absorption generally involves a transition from the ground state of a system to a higher lying system by simultaneous absorption of two photons and leads to a fast optical limiting phenomena in semiconductors, such as ZnO, ZnSe, InSb, etc. [94], as well as in some organic materials. Recently, Sanz and Lbanez [95] synthesized sol–gel glasses doped with nanocrystals of stilbene 3. The organic–inorganic nanocomposite materials can be highly doped with active molecules through the control of nanometer-scale crystallization. In the nanosecond regime, nonlinear absorption was observed in the spectral range from 450 to 650 nm. The nonlinear absorption occurs in a two-step process, which is characterized by two-photon absorption and excited-state absorption spectroscopies. The two-photon absorption spectrum of stilbene 3 nanocrystals shows a resonance at 620 nm with a cross-section $\sigma_{TPA} = 3.3 \times 10^{-48}$ cm⁴ s/photon molecule. The excited state absorption spectrum of stilbene 3 nanocrystals, which was obtained by using a pump–probe ($\lambda = 355$ nm) geometry supercontinuum laser light with a 30 ps time resolution, exhibits a broad resonance with a maximum at 670 nm and a decrease of quasilinear absorption at blue wavelengths.

It is interesting to mention that Maciel et al. [96] reported nonlinear absorption experiments which were performed with a class of ferroelectric glass–ceramic samples. The samples were prepared by heat treatment of (in molar %) 35 SiO_2–31 Nb_2O_5–19 Na_2O–11 K_2O–2 CdO–2 B_2O_3 glass. A set of glass–ceramic samples with different volume fractions of sodium niobate ($NaNbO_3$) crystallites was obtained. The samples exhibit a large transparency window from the near infrared to the visible average, and the sizes of $NaNbO_3$ crystallites are around 10 nm. The optical transmission was measured by using a Q-switched Nd:YAG laser (532 nm, 1064 nm, 15 ns, 5 Hz). The energies of the incident and the transmitted pulses were simultaneously measured by using two large area photodetectors connected to a fast oscilloscope. The photodetector used to monitor the transmitted beam was placed in the far-field region and the light

intensity was totally collected to avoid misinterpretation of the data due to contributions of nonlinear refraction. They found that samples show a nonlinear absorption at 532 nm, and some of samples exhibit optical limiting depending on the bandgap of these samples. The nonlinear coefficients of two-photon and three-photon absorption were determined.

The approaches for increasing optical nonlinearity of nanocomposites materials are as follows:

(i) increasing particle concentration,
(ii) working at near-resonant wavelength,
(iii) adding the dielectric confinement effect beside the quantum confinement effect.

For example, the $\chi^{(3)}$ of 2% CdS doped glass was estimated to be 1.5×10^{-10} esu at 390 nm, while $\chi^{(3)}$ values increase to 6.3×10^{-7} esu after increasing the doping concentration of CdS up to 8% by the sol–gel process [97]. Optical nonlinearity can be enhanced by the dielectric confinement effect, which is a surface polarization effect induced by trapped state and atomic vacancy defects, as discussed. This includes two cases: (a) nanoparticles with high refractive index, such as SnO_2, CdS, and Pbs doped in a matrix with low refractive index, such as SiO_2 and PMMA; (b) nanoparticles with a high refractive index, coated with a low refractive index layer, such as stearic acid.

Very recently, Murugan and Varma [98] have fabricated glass nanocomposites in the system $(100-x)Li_2B_4O_{7-x} \cdot SrBi_2Ta_2O_9$ ($0 \leq x \leq 22.5$) by a melt quenching technique followed by heat treatment. They found that the optical transmission properties of these glass nanocomposites were composition dependent. The $\chi^{(3)}$ values of the system are higher for compositions containing higher $SrBi_2Ta_2O_9$ (SBT) content. The heat-treated samples could have larger $\chi^{(3)}$ values than as-quenched ones. The third-order nonlinear optical susceptibility $\chi^{(3)}$ for glass nanocomposites $x = 15$ is determined to be 3.046×10^{-21} cm^3. SHG was observed in the transparent glass nanocomposites. The dependence of second harmonic intensity on the angle of incidence is weak for the compositions with $x = 5$ and 15. However, an appreciable change in the SH intensity with the angle of incidence is observed for the composition corresponding to $x = 20$ possibly due to larger crystallites of SBT.

3.3. Other Nanocomposites

Zhang et al. [99] prepared well-crystallized SBT thin films by the PLD technique. The nonlinear optical measurements were performed by using a single-beam Z-scan method. A mode-locked Nd:YAG laser (1064 nm, 38 ps, 10 Hz) was used as the light source. They performed an open aperture Z-scan measurement and no nonlinear absorption was found. However, closed-aperture Z-scan experiments revealed a signal profile with a peak followed by a valley, indicating a negative (self-defocusing) optical nonlinearity. The calculated value of the nonlinear refractive index of the sample is 1.9×10^{-6} esu, which compares favorably with the nonlinearities of other representative third-order NLO materials, such as V_2O_5, high-density Au-dispersed SiO_2 and TiO_2 composites. This shows that SBT thin films are promising materials for applications in NLO devices. In

another recent work [100], Yang et al. have reported reflection results from SBT and $PbZr_xTi_{1-x}O_3$ (PZT, $x = 0.30$, 0.53, 0.8) samples employing laser pulses of 8 ns at 1064 nm. For the SBT sample, when the input energy is low, the output energy increases linearly with incident energy. However, in excess of 270 μJ/pulse, the output energy is nearly a constant value of 185.6 μJ/pulse. Saturation occurs for higher inputs and functionally appears as typical limiting behavior. They found that the output energy of the PZT sample also shows an optical nonlinearity, and the behavior depends on the atomic ratio of Zr and Ti. As to the mechanism, the bandgap of the sample is too wide to make any nonlinear absorption. The authors suggest that the nonlinearity may result from a scattering of the incident light by the ferroelectric domains in the films.

Recently, carbon nanotubes and their nanocomposites have been investigated [15–17]. Their third-order optical nonlinearity and optical limiting properties have been reported [15–17, 101–103]. Recently, Xu et al. [104] obtained another tube-shaped material, vanadium oxide (VO_x), by a sol–gel technique. These VO_x nanotubes are dispersed in water or embedded in PMMA films. Their nonlinear optical transmission was measured using 8 ns pulses from a Nd:YAG laser with an $f/40$ optical system. At 532 nm the transmittance of VO_x in water drops when input fluence increases. The behavior is similar with that of carbon nanotube suspensions. However, the phenomena of VO_x embedded in PMMA is much better than that of carbon nanotube–PMMA nanocomposites because the mechanism in VO_x nanocomposites is two-photon absorption, different from the nonlinear scattering that occurred in carbon nanotubes.

For convenience, Table 2 summarizes some results of the third-order optical nonlinearities of nanocomposites.

3.4. Optical Limiting Effect

A currently important problem in science and technology is related to the task of protecting the human eye and the sensors of instruments detecting high-power light beams from radiation damage [15, 17]. A solution to this problem is the use of passive optical limiters as protection devices. An ideal optical limiter is material or device that exhibits linear transmission at low incident fluence, but output light fluence will reach a saturated value when the incident light fluence is over one threshold due to the optical nonlinearity of materials. The possibility to fabricate an applicable optical limiter based on nanocomposites materials was widely investigated. optical limiting effects can be observed in several materials and with different mechanisms [15, 17, 105], such as reverse saturable absorption (RSA), two or three absorption, nonlinear scattering, or nonlinear refraction.

Among the nonlinear optical absorptions, RSA is a primary mechanism for some organic molecules and is demonstrated to be one of the best processes to use for optical limiting because it reduces the total pulse energy rather than simply reducing the fluence or irradiance [15, 17]. RSA occurs when a larger absorption from an excited state compared to that from the ground state is observed. For example, C_{60} and its derivatives represent such an interesting class

Table 2. Third-order optical nonlinearities of some nanocomposites measured by Z-scan (ZS), degenerate four-wave mixing (DFWM), nonlinear transmission (NLT), or Kerr experiment (Kerr), where λ and τ are laser wavelength and pulse width, respectively.

Material and state	λ (nm)	τ	$\|\chi^{(3)}\|$ (10^{-10} esu)	γ (10^{-20} m^2/W)	Method	Ref.

of molecules for optical limiting in visible range [17]. C$_{60}$ exhibits optical limiting behavior with a saturation threshold lower than other materials. RSA is its dominant mechanism [17]: there exist allowed broadband transitions from the first excited singlet and triplet to the higher excited states and this results in absorption in the visible and near infrared range that is much stronger than the absorption from the ground state, leading to RSA. In comparison with the C$_{60}$–toluene system, a reduction of the saturated threshold by a factor of 3 to 5 was obtained by Belousov et al. in a C$_{60}$–CCl$_4$ system [106]. Further experiments show that the optical limiting performance of C$_{60}$ in room temperature solution toward nanosecond laser pulses at 532 nm strongly depends on the fullerene solution concentrations.

Optical limiting from fullerenes in solid materials, such as SiO$_2$ matrix, was reported [17]. Measurements at 532 nm on samples with two C$_{60}$ concentrations exhibited RSA. The sample with a larger concentration shows a lower limiting fluence. The presence of thermal effects, scattering, and other effects besides RSA makes it difficult to get their relative contributions [17]. The fullerene–metal nanocomposites remain a relatively unexplored area [17]. Recently, Sun et al. [107] prepared a novel fullerene–Ag nanocomposite (DTC$_{60}$–Ag) by the *in-situ* reduction of silver ions encapsulated in a new monofunctionalized methano-[60] fullerene derivative (DTC$_{60}$) with reverse micellelike structure. Their experimental measurements demonstrated that the optical limiting behavior of DTC$_{60}$–Ag is better than that of both C$_{60}$ and DTC$_{60}$.

We have observed optical limiting effects in Ag–polymer nanocomposites. Here Ag can be nanoparticles with diameter from 2 to 10 nm or nanorods with length–diameter ratios of 2:1 to 8:1. Optical limiting at different wavelength was observed by adjusting the particle size or the length–diameter ratio of the Ag rod. The limiting comes from nonlinear scattering from the Ag due to the absorption of surface-plasmon resonance. Oak et al. [91] found optical limiting within CdS$_x$Se$_{1−x}$ doped glasses at 1054 nm in the range of 6 ps. They attributed the main mechanism of limiting to two-photon absorption. At higher input intensities, additional absorption due to laser-generated carriers was observed.

Recently, Sanz and Lbanez [95] synthesized sol–gel glasses doped with nanocrystals of stilbene 3. The organic–inorgnic nanocomposite materials can be highly doped with active molecules through the control of nanometer scale crystallization. For sample thickness and concentration to be 1 mm and 300 g/L, in a f/5 optical system, laser pulse 2.6 ns, at low energy ($<5\ \mu$J), the sample is transparent and the transmitted energy increases linearly with the incident energy. At higher incident energies, the output energy is damped below 20 μJ within the visible range due to two-photon absorption and excited state absorption.

4. CONCLUSIONS

We have not discussed the second-order optical nonlinearities of nanoparticles in this chapter. More details can be found in the work of Wang et al. [59].

As discussed, the novel properties of nanoparticles and nanocomposites are dominated by two major effects: surface effects and unique characteristics of electrons in confined systems. The increasing surface energy associated with the larger surface-to-volume ratio of small particles determines the physical and thermodynamic properties of the nanoparticles and nanocomposite, such as melting points. Surface effects and electron confinement combine to produce novel electronic properties that can be manifested in a wide range of effects, such as a large nonlinear optical susceptibility, etc.

For metal nanocomposites, people wish to have higher $\chi^{(3)}$ and lower linear absorption as higher linear absorption and the corresponding long thermal relaxation time of the insulating matrix decrease the figure of merit for these materials. $\chi^{(3)}$ varies as $1/r^3$. Thus, it would be the goal to produce extremely small particles with narrow size distribution and higher volume ratio of metal particles in the matrix.

For the ideal case of materials composed of linearly arranged particles, very large enhancements can be obtained provided that the particles are aligned in the polarization direction of the incident field. In this case, very high intensities are induced inside the particles at the center of the linear chain and the local field amplification is accompanied by a shift of the spectral location of the resonance.

Semiconductor nanoparticles and nanocomposites have also attracted much attention because they were shown to have large third-order optical nonlinear susceptibility. Basically, quantum size and interfacial effects are those we must consider when we want to increase the optical nonlinearity. For example, various chemical methods are developed to passivate the surface of nanoparticles. For the second case, various functional molecules are used to modify the surface of nanoparticles to form core–shell structure. Another factor to increase optical nonlinearity of nanocomposite materials is the dielectric confinement effect. This effect depends on the dielectric constant ratio, such as high refractive index nanoparticles doped in low refractive index matrix or coated with a low refractive index layer.

Finally, we would like to point out that the optical nonlinearity of nanoparticles and nanocomposites could be enhanced by the change of coupling between light and materials. We observed strong nonlinear absorption in VO_x nanotubes at 532 nm, but the nonlinear absorption vanishes when these nanotubes were unrolled into platelets. Another example is that a larger optical nonlinearity was observed in B, N doped carbon nanotubes compared to pure carbon nanotubes (see the chapter entitled "Doped Carbon Nanotubes" in this encyclopedia [15]). This means that the dimensional and electronic structures play important roles in the NLO properties of nanoparticles and nanocomposites.

GLOSSARY

DFWM The nonlinear interaction of three optical waves of the same frequency to generate a fourth, re-emitted wave is known as DFWM, and the method has provided a wealth of knowledge about the behavior of excitons in III–V semiconductors.

Gaussian beam Lowest divergence, smallest radius laser beam possible for a given oscillator. It is created when the laser is operating in the TEM00 mode.

Hyperpolarizabilities The coefficient of the higher than linear terms in the relation between the electric dipole moment of a molecule and the electric field which acts on the molecule.

Kerr effect A quadratic nonlinear electro-optic effect found in particular liquids and crystals that are capable of advancing or retarding the phase of the induced ordinary ray relative to the extraordinary ray when an electric current is applied. It varies as the square of the voltage.

Rayleigh scattering Scattering of radiation in the course of its passage through a medium containing particles, the sizes of which are small compared with the wavelength of the radiation. Method an OTDR uses.

Spectrometer A device used to measure radiant intensity or to determine the wavelengths of various radiations.

Surface plasmon resonance (SPR) phenomenon The collective oscillation of the conduction electrons of the metal under the influence of an applied electromagnetic (EM) wave.

Third-order nonlinear susceptibility Used to characterize the degree of third-order optical nonlinearity.

Transmittance The ratio of the radiant power transmitted by an object to the incident radiant power.

Z-scan technique Used to measure the sign and the magnitude of the refractive and the absorptive nonlinearities with single beam.

Nucleation Kinetics of Nanofilms

S. A. Kukushkin, A. V. Osipov

Russian Academy of Science, St. Petersburg, Russia

CONTENTS

1. INTRODUCTION

Progress in development of computer facilities, optoelectronics, and some other fields of engineering is, above all, associated with use of thin films as the ground of their elementary base. At present, a great interest is expressed in application of nanostructures and quantum dots as compared to use of continuous films [1–11]. There are reasons to suppose that application of nanostructures in optics, microelectronics, biology, or medicine can lead to a qualitative out-break in evolution of mankind.

Nanostructures can be prepared by various ways [1–5, 12, 14–18]. Here, we examine formation of nanoparticles on the surface of solid substrates. Particles whose sizes are not in excess of 100 nm are considered as nanoparticles. As for crystals of such sizes, they, in general, do not contain dislocations or some other linear defects. Films composed of such particles have a developed surface. This leads to formation of unique properties in the nanosystems, which are not observed in ordinary materials [2–9, 12, 13]. On the surface of solid substrates, nanoparticles can be prepared by deposition from liquid or solid phases [1–5, 12, 14–19]. In addition, they can be obtained by using sol–gel technology or electrodeposition [20, 21]. Nanocrystal formation processes represent typical first-order phase transitions. While the nanocrystals formed on the surface of substrates are not elastically stressed, their nucleation can be described by means of the classical nucleation theory. In the case where nanocrystals are elastically stressed and they are formed on crystal substrates, main approaches and methods of description of their nucleation remain unchanged; however, the mechanism of formation and growth of nanoparticles is of another physical nature. Therefore, we start with analysis of nucleation of unstressed nanostructures and then, in the next section, we present new approaches to description and examination of growth of coherent nanostructures. In literature, it is common to call the new phase nuclei as islands, whereas the island ensembles are named as island films. Here and elsewhere, we follow the above notations. This helps the reader to use the results outlined in our review for description not only of nanoparticles, but also of nuclei of any sizes. During growth of films containing islands of nanosizes, experimenters and engineers are forced to control a whole number of parameters, such as material and structure of the substrate, the temperature of the substrate, composition of vapor, and intensity of its inflow. To obtain the island size and composition needed, the parameters are selected, as a rule, empirically. In this case, it is necessary to know a terminal time of the growth process, in order that the size of islands does not fall outside the nanosize limits. It is already clear today that further development will be impossible without analysis of the complicated physical chemical phenomena which take place in the nucleation process [22–46]. The study of these phenomena began in the mid-1950s. Principal attention was paid to the new phase nucleation on the solid surfaces. Initially, the main theoretical analysis of new phase nucleation was carried out in the framework of the classical nucleation theory [23–25], disregarding the variation of supersaturation during condensation and, the more so, disregarding a possible change of growth mechanisms in individual islands. Hence, the comparison of experimental results on surface new phase nucleation with the classical

nucleation theory revealed a substantial difference between them. This led the researchers to an erroneous deduction for the impossibility of using the concepts of the classical theory of phase transitions in surface processes and the necessity of rejecting them. In particular, it was assumed that such quantity as the specific interphase energy could not be used at all in the description of the early stages of thin-film nucleation. That is why, in the early 1960s, the so-called discrete models appeared that described the new phase nucleation with the help of the methods of equilibrium statistical mechanics [29]. It should be noted that these theories could not describe the nucleation of strongly metastable and unstable systems in the same measure as the rejected classical model since they ignored the most important effect, namely, the increase of long-wave density fluctuations in the spinodal region [44, 46, 47]. To establish a correspondence between the theory and experiment, it was actually quite enough to allow for the variation of the supersaturation in time and the related possibility of changing growth mechanisms of individual islands [22, 23, 37]. Furthermore, most of the models were constructed for single-component films only, while a wide variety of experiments were carried out with multicomponent systems. The needs of engineering led, in the course of time, to the necessity of obtaining composite multicomponent films with prescribed properties and composition, and the above-mentioned models could, in no way, give answers to these problems. They rather "diverted" the researchers from the straight pathway. Meanwhile, fundamental studies of the kinetics of first-order phase transitions were being conducted in the same period. It is shown that the kinetics of first-order phase transitions is a complicated multistage process accompanied by various nonlinear phenomena [47–65]. Such stages typically include nucleation, the separate growth of new phase nuclei, coalescence, and the late stage, that is, Ostwald ripening (OR), where the growth of the larger islands proceeds at the expense of dissolution of the smaller ones. The indicated processes have widely different time scales. The most rapid stage is the nucleation, then goes the separate growth, and so on. This time hierarchy means that the fast processes have time to "keep up" with the slow ones [63]. Solution of the equations for fast processes provides, in fact, the initial conditions for the equations of slower processes. It turned out that the solution obtained in the framework classical theory was valid at the nucleation stage only. At later stages, it is necessary to take into account the equations of conservation of matter in a system and to solve the corresponding nonlinear problems. The extension of these ideas and methods to the nucleation process of islands, as well as the development of a consistent field approach [63] providing a unified standpoint for the description of condensation under any arbitrarily high supersaturations, offered quite a new view of the problems of the formation of nanofilms. The supersaturation values were found, for which it was necessary to employ the classical nucleation theory for the description of the nucleation of islands, and also the values, for which it was necessary to use the field approach [63]. All this made it possible to apply a unified approach to the description of condensation of multicomponent nanofilms, irrespective of the type of the initial phase (vapor, gas, liquid, etc.) and condensation conditions. It was shown that the surface brings appreciable diversity

to the phase transformation, although the basic stages stay unchanged.

2. THERMODYNAMICS OF AN ADSORBED LAYER

An important specific feature of the new phase nucleation on the substrate surface, as compared to homogeneous nucleation in the bulk, is the presence of various defects on the substrate. Defects are typically divided into point and linear ones; the latter include steps, surface dislocations, and scratches. No rigorous theory of heterogeneous new phase nucleation on a surface has yet been developed. The existing theories of new phase nucleation on solid surfaces proceed either from the classical nucleation theory [22–24, 43] modified for the two-dimensional case and allowing for the possible role of defects in nucleation, or from the atomistic model [29]. The surfaces of solid bodies can, in the general case, be both crystalline and amorphous. The modern concepts [22, 66] distinguish between atomically "smooth" and atomically "rough" surfaces. The former usually include singular and vicinal facets, while the latter include nonsingular ones. Singular surfaces are characterized by a local minimum in the surface tension σ and a discontinuity in the angular derivative $\partial\sigma/\partial\theta$ (here θ is the angle in the polar diagram [66]). Such features of σ and $\partial\sigma/\partial\theta$ behavior are typical for all directions described by rational Miller indices, the minima being sharpest and deepest in the directions normal to the close-packed planes (with minimum Miller indices). Vicinal planes have a small deviation from the alignment of close-packed facets [66]. To describe the atomic structure of vicinal facets, the TLK (terrace, ledge, kink) model [66] is most often used, which allows obtaining the binding energy of atoms that are in different positions. In terms of the TLK model, one can calculate both the number of ledges and the spacing between them and can also determine the concentration of atoms in each position, that is, in atomically smooth regions of the surface, on a step, in a ledge, etc. [66]. Thus, even ideal crystal surfaces having a slight deviation from a close-packed orientation are steplike; at $T > 0$, the steps are covered with ledges; the surfaces of real crystals are rough, contain surface vacancies, surface dislocations, intergrain boundaries, and other defects [8, 66–69]. They all essentially affect the parameters of the condensation and may serve as orienting centers for nucleation of nanoislands. Crystal surfaces of substrates for nanostructures could be exposed to thermal or chemical treatment [12, 14, 15, 18, 70–74]. After such a modification, crystal surfaces change their properties. The orientation and the number of free chemical bonds change in the process of the modification. Surface tension changes as well. So, the treatment of substrate surfaces allows the nucleation of nanoislands to be controlled.

The adsorption, desorption, and diffusion of atoms over the surface of a substrate have been rather well investigated [66, 75]. Adsorption is typically thought of as the first stage of film condensation [2, 4, 12, 14, 22, 23]. In condensation from a single-component vapor, monomolecular and dissociative adsorptions are most frequently distinguished [22] which, for small substrate occupation numbers, lead to a

uniform formation of adatoms over the entire nonoccupied substrate surface with a constant rate J

$$J = C_g P (2\pi M k_B T_v)^{-1/2} \qquad (1)$$

where P is the vapor pressure, T_v is the vapor temperature, M is the mass of one deposited molecule, k_B is the Boltzmann constant, and C_g is a geometric factor. The adsorbed atoms can either desorb back into vapor or jump over (diffuse) to one of the neighboring sites [29, 32, 66]. In the single-component case, the rate of desorption is described by the equation

$$\frac{dn_1}{dt} = -\frac{n_1}{\tau_r}, \quad \tau_r = \nu^{-1} \exp\frac{E_a}{k_B T} \qquad (2)$$

where n_1 is the surface adatom density, t is the time, dn_1/dt is the desorption rate, τ_r is the characteristic time of monomolecular desorption (re-evaporation time), E_a is the desorption activation energy, and ν is the frequency of tangential oscillations of an atom on the substrate surface [22, 66]. After establishing equilibrium between the surface and the surrounding initial phase, a two-dimensional "gas" of adatoms with surface density n_1 is formed on the surface of the solid body [22, 24, 29]. In the case of monomolecular desorption, this proceeds approximately within a time τ_r. A large number of papers is devoted to the study of the thermodynamic and kinetic characteristics of such an adsorbed "gas" [63, 75–77]. The most interesting and important for us are the thermodynamic stability, instability, and metastability of those systems, because it is these characteristics which are directly connected with the possibility of phase transformations in adsorbed layers. An expression for the state of an adsorbed gas on the substrate surface was derived in [63]. The equation is of the form

$$\frac{P}{k_B T_c} = \frac{T}{T_c} \ln\frac{1}{1-n} - 2n^2 \qquad (3)$$

where n is the density of atoms adsorbed on the surface and T_c is the critical temperature. For $T < T_c$, $P < P_c = (\ln 2 - 1/2)k_B T_c$, the $P(V)$ isotherms contain a characteristic van der Waals loop testifying to a first-order phase transition of gas-liquid type. In real systems such a transition occurs only in the interval $T_t < T < T_c$ between the triple and the critical points. The given model (the same as other models of this type) describes only the phase transition of gas-liquid type (amorphous state), that is, the amorphous film condensation and the first stage of the crystalline film condensation, which proceeds by the vapor-liquid-crystal mechanism. In spite of the simplifications made, this continual model satisfactorily describes many principal features of the behavior of the adatom system. From this equation the phase-equilibrium and spinodal curves can be obtained. The curves are plotted in Figure 1. where n_{1e} and n_{2e} are the equilibrium densities of the adsorbed gas and amorphous phase, respectively; n_{1es} and n_{2s} are the concentrations corresponding to the spinodal range. The region of metastable states, $n_{1e} < n < n_{1s}$, corresponds to a supersaturated vapor $\xi = n/n_{1e} - 1$, and the region $n_{2s} < n < n_{2e}$ to a superheated liquid. It is precisely in the region $n_{1e} < n < n_{1s}$ that the film condensation proceeds through nucleation, and for $n = n_{1s}$ the critical
Figure 1. Phase-equilibrium curve (1) and spinodal curve (2) respectively. The values of n_{1e}, n_{1s}, n_{2s}, and n_{2e} are shown for $T/T_c = 0.7$. Reprinted with permission from [22], S. A. Kukushkin and A. V. Osipov, *Usp. Fiz. Nauk* 168, 1083 (1998). [*Phys. Usp.* 41, 983 (1998)]. © 1998, S. A. Kukushkin and A. V. Osipov.

nucleus consists of only one particle. The quantity $\xi_{\max} = n_{1s}/n_{1e} - 1$ has the meaning of maximum possible supersaturation. For supersaturations exceeding $\xi_{\max}$, the adatom population becomes unstable and a spinodal decomposition begins in it [44–47, 63].

3. NANOFILM GROWTH REGIMES

The thin-film growth regimes are typically divided into layer-by-layer, island, and intermediate [29, 33]. Just the same regimes are realized during the growth of nanofilms. The layer-by-layer, or the Frank–van der Merwe, regime is realized in the case when the atoms of a deposited substance are bound with the substrate more strongly than with each other. Monatomic layers in this regime are occupied in turn; that is, two-dimensional nuclei (one atom thick) of a subsequent layer are formed on the upper part of the nuclei of the preceding layer after the latter is occupied. The equilibrium form of the nuclei is found by the Wulf theorem [66]. The theoretical description of the layer-by-layer growth is customarily given in the framework of the Kashchiev model [24] or its modifications [78, 79]. The island, or Volmer–Weber, regime is realized in the opposite case, that is, for the atoms of a deposited substance bound with each other more strongly than with the substrate. Island growth can only be realized under the condition [33]

$$\sigma_s < \sigma_d + \sigma_{s-d} - \text{const} \cdot k_B T \, \ln(\xi + 1) \qquad (4)$$

where σ_s is the free energy of a unit substrate surface, σ_d is the free energy of a unit adsorbate surface, and σ_{s-d} is the free energy of a unit substrate-adsorbate interface. Otherwise, the layer-by-layer regime holds. In the island regime, small nuclei are formed straight on the substrate surface and then grow, transforming into large islands of the condensed phase [33]. Thereupon, these islands merge to form a continuous film after the channels between them are filled [33]. In the intermediate, or Stranski–Krastanow, regime, the first to be realized is a layer-by-layer growth and then, after one or two layers are occupied, island growth begins. There may be several reasons for the change of the growth mechanisms [33]. The principal cause is that the lattice parameter cannot remain unchanged upon occupation of an immediate

layer. Its variation entails a strong increase of the adsorbate-intermediate layer interface energy, which provides fulfillment of the island regime criterion (4). A large number of examples illustrating all three thin-film growth conditions and experimental methods of their investigation are presented in reviews [29, 33]. It was shown in [80] that under certain conditions the faceting of cap-shaped clusters at the OR stage may lead to a replacement of the island mechanism by the layer-by-layer one. In this regime, condition (4) holds at first and then the change in the condensate symmetry causes its violation. Thus, the material of the substrate and the type of its surface determine the film growth regime. At present, investigators pay particular attention to the growth of films by the Stranski–Krastanow mechanism [1–5, 12, 14]. First of all, this is associated with requirements of optoelectronics in semiconductor structures based on quantum dots. During the growth of quantum dots, an elastic energy arising along the substrate-wetting layer interface is of great importance. The elastic energy is responsible for a substantial difference in the kinetics of nanostructure nucleation. Nevertheless, the basic equations describing the nucleation processes of nanoparticles coherently conjugated with a substrate and, accordingly, the methods for their solution are, in most cases, similar to the equations describing the growth of unstrained structures, from the mathematical point of view. Therefore, we start to analyze the nucleation of nanoislands without taking into account the elastic energy, that is, the islands forming and growing by the Volmer–Weber mechanism, whereas, then, we investigate the growth of coherent nanoparticles in Section 9.

4. NUCLEATION PROCESSES OF UNSTRESSED NANOPARTICLES

4.1. The Nucleation Processes of One-Component Nanoparticles

Let us discuss the methods used to describe the nucleation processes on the surface in the cases of single- and multi-component films. The most widely employed is the so-called capillary model [24, 25, 27, 31] first formulated by Volmer and Weber, Becker and Döring, and Zel'dovich. This model postulates the following. Positive free-energy fluctuations that lead to overcoming the activation barrier are necessary for the condensation of a new phase from a supersaturated vapor in the metastable state (i.e., over the region $n_{1e} < n_1 < n_{1s}$) [22, 24, 25, 27]. The presence of such a barrier is associated with the fact that the free energy of nucleation from a supersaturated vapor has a maximum at a certain critical point. Nuclei on a substrate may have various shapes [1, 2, 12, 22, 24] but theoretically they are most frequently assumed to look like a disc or a hemisphere according to the film growth mechanism [2], because many films grow by the vapor-liquid-crystal mechanism. The free energy F of the formation of disc-shaped clusters on an ideal substrate can be written in the form [23–25, 27]

$$F(i) = 2\sqrt{ai} - i\ln(\xi + 1) - \ln(n_0/n_1) \quad (5)$$

Here i is the number of particles in a nucleus, $a = (\sigma_{st}/k_B T)^2 \pi w/h$, σ_{st} is the effective interphase energy per

unit length of the disc boundary, h is the disc height, w is the volume occupied by one particle in the nucleus, n_0 is the number of adsorption sites on the substrate surface, $n_0 \sim 1/B^2$, where B is the substrate lattice constant, and F is expressed in $k_B T$ units. The first term in Eq. (5) is the energy of the surface tension, the second is the chemical potential difference between the new and the old phases, and the third is a statistical correction due to the distribution of n_1 atoms over n_0 lattice sites [22, 24]. The maximum of the free energy (5) is positioned at the point

$$i_c = a/\ln^2(\xi + 1) \quad (6)$$

and is equal to

$$F(i_c) = a/\ln(\xi + 1) - \ln(n_0/n_1) \quad (7)$$

The nucleus has to overcome just such a potential barrier of height $H(\xi) = F(i_c)$ owing to heterophase fluctuations in order that it might grow further regularly. According to the capillary model, an elementary act changing the nucleus size is either an attachment to it or, on the contrary, a loss of one molecule (the merging of nuclei is ignored). As regards sufficiently large nuclei containing $i \gg 1$ particles, this change is small, and therefore the evolution of large nuclei is described by the Fokker–Planck equation [22–24]

$$\frac{\partial g}{\partial t} = -\frac{\partial I}{\partial i}, \qquad I = -W(i)\left[\frac{\partial g}{\partial i} + g\frac{dF(i)}{di}\right] \quad (8)$$

where $g(i, t)$ is the distribution function of nuclei over the number of particles i in them, I is the nucleation rate (it vanishes for an equilibrium distribution $g = \text{const} \cdot \exp(-F(i))$, and $W(i)$ is the diffusion coefficient in the dimension space, which is equal to the number of molecules coming into the nucleus from the ensemble of adatoms per unit time. The stationary solution of this equation has the form [22–25, 27, 38, 40, 41]

$$g_s(i) = I\exp[-F(i)]\int_i^\infty W^{-1}(i')\exp F(i')\,di' \quad (9)$$

(the standard boundary condition $g_s \exp F(i) \to 0$ as $i \to \infty$ was taken into account here). The probability of fluctuations described by the second derivative of g with respect to i increases rapidly with decreasing size. Hence, the store of subcritical nuclei may be regarded as supplemented so rapidly owing to the fluctuations that their number remains in equilibrium in spite of the permanent outflow of the flux I. Consequently, the boundary condition to Eq. (8) takes the form $g_s(i) \to n_1 \exp[-F(i)]$ as $i \to 0$ and therefore from (9) we find

$$I = n_1\left[\int_0^\infty W^{-1}(i')\exp F(i')di'\right]^{-1} \quad (10)$$

The integrand in Eq. (10) has a sharp maximum at the point $i = i_c$, which allows us to calculate the integral using the Laplace method:

$$I = n_1\sqrt{-F''(i_c)/2\pi}\,W(i_c)\exp[-F(i_c)] \quad (11)$$

The square root in Eq. (11) is sometimes called a nonequilibrium Zel'dovich factor. Let us estimate the quantity $W(i_c)$, which is the frequency with which adatoms are attached to a critical nucleus. To this end we shall use the lattice model. Let R_c be the radius of the critical nucleus linear boundary, l_0 the length of diffusive jumps of adatoms, ν the desorption frequency, and E_d the activation energy of surface diffusion. Then we have

$$W(i_c) = 2\pi R_c n_1 \ell_0 (\nu_d/4) \exp(-E_d/k_B T) = 2\pi R_c n_1 D_a/\ell_0 \tag{12}$$

where $D_a = (\ell_0^2 \nu/4) \exp(-E_d/k_B T)$ is the diffusion coefficient of adatoms. From this, for disc-shaped nuclei we arrive at [23]

$$I(\xi) = C_1 n_{1e} n_0 D_a (\xi+1) \ln^{1/2}(\xi+1) \exp[-a/\ln(\xi+1)] \tag{13}$$

Similarly, for nuclei in the shape of a hemisphere we have

$$I(\xi) = C_2 n_{1e} n_0 D_a (\xi+1) \ln(\xi+1) \exp[-b/\ln^2(\xi+1)] \tag{14}$$

Here $C_1 = \sqrt{2w/h\ell_0^2}$, $C_2 = 2\sin\theta[\sqrt{3/2\pi}\ell_0^3 \times (1 - \cos\theta)^2 (2 + \cos\theta)/\omega]^{-1/3} b^{-1/2}$, $b = 4\pi(\sigma/k_B T)^3 \omega^3 (2 + \cos\theta)(1 - \cos\theta)^2/3$, σ is the interphase energy per unit area, and θ is the contact angle. The time t_s of setup of a stationary nucleation rate has been repeatedly evaluated by various authors, all the values being coincident in the order of magnitude [81, 82]. The mean value is as follows

$$t_s = \frac{1}{-F''(i_c) W(i_c)} \tag{15}$$

In thin-film condensation, this time is usually very short (10^{-4}–10^{-8} s) both for disc- and cap-shaped nuclei, and therefore, in practice it suffices only to calculate the stationary flow of nuclei I. The method of making allowance for nonstationary effects (necessary for the description of very fast processes) was proposed, for example, in [81–83].

4.2. The Nucleation Processes of Multicomponent Nanofilms

Multicomponent systems may be divided into two groups. One of them includes systems with solid solutions as islands [22, 23, 37], and the other involves systems with islands consisting of stoichiometric compounds [22, 23, 84–86]. We shall first discuss the nucleation of multicomponent stoichiometric islands and then pass over to an examination of nucleation processes in islands of solid solutions. According to [23], islands of stoichiometric compounds can be formed in the following ways:

1. The rate of the chemical reaction is much higher than the rate at which a new phase forms. In this case, molecules of the chemical compound are first formed, and then nucleation of the islands takes place.

2. The nucleation rate of the islands is much higher than the formation rate of a chemical compound on the substrate. In this case, islands of a mixture of chemical elements are formed due to heterogeneous fluctuations, and the chemical reactions then take place in the islands, producing a stoichiometric compound.

3. The rates of the chemical reaction and formation of the islands are comparable; the rate of the chemical reaction is nonlinear and the reaction product behaves as a catalyst of the reaction. In this case, self-induced oscillations in the number of the new phase nuclei and their self-organization are possible.

4. Growth of the islands proceeds as a result of the chemical reaction at their surface [23].

According to results obtained in [87, 88], the stationary flow of multicomponent stoichiometric disc-shaped islands of height h nucleating on the substrate surface is given by

$$I_s'(\xi) = \alpha_s' (\xi+1) \ln^{1/2}(\xi+1) \exp[-a^s/\ln(\xi+1)] \tag{16}$$

The flow of cap-shaped nuclei can be expressed by

$$I_s''(\xi) = \alpha_s'' (\xi+1) \ln(\xi+1) \exp[-b^s/\ln^2(\xi+1)] \tag{17}$$

In Eqs. (16) and (17), $\alpha_s' = A_{1s} n_0^2 D_s^0$; $\alpha_s'' = A_{2s} n_0^2 D_s^0$; $A_{1s} = (\omega_m^s/h)^{1/2}$; $A_{2s} = 2\sin\theta[\sqrt{3/2\pi}(1 - \cos\theta)^2 (2 + \cos\theta)/\omega_m^s]^{-1/3} (b^s)^{-1/2}$; $a^s = (\sigma_{st}/k_B T)^2 \pi \omega_m^s/h$; $b^s = 4\pi(\sigma/k_B T)^3 (\omega_m^s)^3 (2 + \cos\theta)(1 - \cos\theta)^2/3$; $\omega_m^s = \sum_{i=1}^{n^s} \nu_i \omega_i$ is the volume of a molecule of the chemical compound; ω_i is the volume of an atom of an ith component of the chemical compound; ν_i is a stoichiometric coefficient of an ith component; $n_{1e}^s = n_0 \prod_{i=1}^{n^s} \rho_{i0}^{\nu_i}$ is the equilibrium density of molecules of the chemical compound on substrate

$$D_s^0 = \left[\sum_{i=1}^{n^s} \frac{p_i^2 l_i}{D_{ai} \rho_{i0}} \right]^{-1} \tag{18}$$

is the generalized diffusion coefficient; ρ_{i0} is the equilibrium concentration; $p_i = \nu_i / \sum_{i=1}^{n^s} \nu_i$ are the reduced stoichiometric coefficients; D_{ai} is the diffusion coefficient of an ith component; l_i the length of diffusive jumps of an ith adatom. Supersaturation ξ in the case of multicomponent systems is

$$\xi = \frac{\prod_{i=1}^{n^s} \bar\rho_i^{\nu_i} - K_\infty^s}{K_\infty^s} \tag{19}$$

where $K_\infty^s = \prod_{i=1}^{n^s} \rho_{i0}^{\nu_i}$ is an equilibrium constant of the chemical reaction producing the chemical compound of composition s, and $\bar\rho_i$ is the concentrations on the surface of an ith component of the multicomponent system. As it follows from Eqs. (16) and (17), the formal expression of nucleation rates in multicomponent stoichiometric systems is similar to that for single-component ones. However, kinetic coefficients in the equations depend on the kinetic coefficients for each component. In the case of nucleation of multicomponent films of solid solution, the free energy of a nucleus depends on the number of particles of each component. Its calculation is a separate, fairly complicated problem [89]. Let a nucleus be involved in the new phase nuclei representing a mixture of different components, and let the mixture be a regular solid solution. Let m be the number of

vapor components, and $i_1, i_2, \ldots, i_m$ the number of particles of each component in a nucleus. Then the free nucleation energy F expressed in the thermal units $k_B T$ is equal to [22, 23, 89]

$$F(i_1, \ldots, i_m) = \sigma(i_1, \ldots, i_m)S$$
$$- \sum_{j=1}^{m} i_j \ln \frac{n_j}{n_{je}(i_1, \ldots, i_m)} - \ln\left[n_0 \Big/ \sum_{j=1}^{m} n_j\right] \quad (20)$$

where σ is the specific interphase energy, S is the area of the nucleus phase boundary, n_j is the surface concentration of the component j, n_{je} is the vapor concentration of the component j which is in equilibrium with the nucleus of this particular composition, and n_0 is the concentration of the lattice sites on which atoms are adsorbed. The nucleus composition is determined by the set of molar concentrations $\{\nu_k\}$ of each component, where

$$\nu_k = i_k \Big/ \sum_{j=1}^{m} i_j, \qquad \sum_{j=1}^{m} \nu_j = 1 \quad (21)$$

The dependence of σ and n_{je} on ν_k for a regular solid solution with a given heat of mixing of components is calculated within the thermodynamic theory of solutions [23, 89]. In particular, if a nucleus is an ideal solution, then

$$\sigma = \sum_{j=1}^{m} \sigma_j \nu_j, \qquad n_{je} = n_{je}^0 \, \nu_j \quad (22)$$

where σ_j and n_{je}^0 are the interphase energies and densities of a saturated vapor of pure components. Solution of the system of equations $\partial F / \partial i_j = 0$ gives the number of particles of each component $i_j c$ in the critical nucleus, after which one can readily calculate the height of the activation barrier $H = F(i_{1c}, \ldots, i_{mc})$. The equation $H^{-1}(n_1, \ldots, n_m) = 0$ specifies the surface that separates the regions of concentrations with and without nucleation. In the simplest case of an ideal solution with equal σ_j, this equation takes the form [89]

$$\sum_{j=1}^{m} \frac{n_j}{n_{je}^0} = 1 \quad (23)$$

Along with nuclei containing all m components, those involving a smaller number of components can be formed on the substrate, and therefore the whole range of concentration variation is divided into different phase regions with the help of $2^m - 1$ interfaces of the type $H^{-1}(n_j) = 0$, $H^{-1}(n_j, n_k) = 0$, etc. In particular, for $m = 2$, three dividing lines $H^{-1}(n_1) = 0$ $(n_1 = n_{1e}^0)$, $H^{-1}(n_2) = 0$ $(n_2 = n_{2e}^0)$, and $H^{-1}(n_1, n_2) = 0$ specify five phase regions; see Figure 2.

In region **a** no new phase formation is observed; in region **b** only two-component islands nucleate, in region **c** two-component islands and those of the atoms of the second component, nucleate in region **d** two-component islands and those of the atoms of the first component nucleate, and in region **e** two-component islands and islands of the atoms of each component nucleate (the nucleation rate for islands of a mixture is as a rule much higher than the single-component nucleation rate). In the newly formed islands of
Figure 2. Phase diagram of a binary system. Reprinted with permission from [22], S. A. Kukushkin and A. V. Osipov, *Usp. Fiz. Nauk* 168, 1083 (1998) [*Phys. Usp.* 41, 983 (1998)]. ©1998. S. A. Kukushkin and A. V. Osipov.

a new phase, a reaction begins among the components or (if the components cannot make up a chemical compound) a eutectic decay, or the formation of a solid solution takes place. The behavior of the system is determined by the type of the corresponding state diagram for a solid mixture. In particular, for a binary system there exist five main types of state diagrams for a solid mixture [23, 89]. All possible cases of condensation are accordingly divided into 25 variants. All of them are considered in detail in [89]. Systems with three or more components are analyzed similarly but with a significantly greater number of versions. The analysis of the behavior of an ensemble of adsorbed particles shows that all the versions of multicomponent film condensation make up a set of processes, each proceeding at a certain stage [89]. We shall point out the processes that play the key role:

1. chemical reaction in an adsorbed multicomponent gas with a simultaneous nucleation of the final product of the reaction;
2. formation of nuclei representing a mixture of components;
3. chemical reaction in such nuclei;
4. growth of islands of a new phase from a supersaturated adsorbed vapor;
5. separation of a eutectic mixture;
6. evaporation of nuclei.

The methods of description of processes 1–6 are presented in [23]. In the case of nucleation of islands from solid solution, the Fokker–Planck equation becomes multidimensional, and accordingly the boundary condition at the zero point becomes more complicated. The method of its solution is based on the simultaneous diagonalization of both the equation and the boundary condition by way of a linear change of variables [57]. Then, it turns out that the nucleation rate I can be estimated as

$$I = n_0 \left(\sum_{k=1}^{m} d_k\right) \exp(-H_0) \quad (24)$$

where d_k are the diffusion coefficients for each of the m components in the dimension space for $i = i_c$ [89], and $H_0 = H + \ln(n_0 / \sum_{k=1}^{m} n_{1k})$ is the nucleation barrier height without the entropy correction. It has been assumed above that the nucleation takes place on an ideal substrate, namely,

in a homogeneous way. However, various substrate defects often initiate nucleation by reducing the activation barrier height H. In particular, the work of heterogeneous nucleation at the step of a substrate has recently been found by Hirth and Pound. They shown that steps may substantially increase the nucleation rate [29]. This is confirmed by numerous experimental data [24, 29, 33, 36]. The activation barrier of nucleation on a step can be so small ($\sim k_B T$) that a nucleus consisting of two particles will already be supercritical, that is, $F(2) < F(1)$ (or $n_1 > n_{1s}$). In this case, as has already been mentioned, a new phase will be formed not through conventional nucleation, but through a spinodal decomposition, namely, an increase of the periodic fluctuations of substance concentration [46, 63]. At the same time, the size distribution of new phase islands on the step and their spatial distribution will already be different. Many modifications of the classical capillary model of nucleation on a substrate exist. We can point out several corrections to the height of the activation barrier, namely, the correction due to internal degrees of freedom of a cluster [22], the correction due to free-energy variation upon separation of a group of i molecules from a large ensemble [23, 24, 33], the correction due to cluster boundary smearing (see [63]), corrections due to cluster faceting [66] and nonisothermal effects [90], and so on. These corrections are, as a rule, relatively small and, moreover, have different signs. The most significant is obviously the correction due to the influence of nucleus surface curvature upon the interphase energy [63, 91]. It leads to a $10^2 \pm 10^6$-fold increase in the nucleation rate. We recall that the capillary model described above is only applicable for $i_c \gg 1$, because it is only in this case that the attachment and detachment of particles to and from critical nuclei can be described by the differential Fokker–Planck equation (8). An alternative to this model for $i_c < 10$ is the atomistic Walton model [29] exploiting the methods of equilibrium statistical mechanics. It allows I to be expressed in terms of i_c, but does not give the dependence of i_c on ξ. Moreover, it is invalid for $i_c = 1$ and $i_c = 2$, when the increase of long-wave density fluctuations is appreciable.

4.3. Effect of Medium Acidity on the Kinetics of Nucleation in Solutions

As it is mentioned previously, nanofilms of various materials can be prepared by deposition from ionic solutions [9, 19–21, 92–94]. In the course of film deposition, the acidity of a solution, that is, its pH, can be changed. The change in pH of the solution causes a change in equilibrium concentrations of components from which the film grows. This, in its turn, can alter supersaturation of the solution and, as a consequence, the rate of nucleation. The influence of pH on the kinetics of nucleation is examined in [95]. The investigation is performed by using as an example sedimentation of ionic compounds from liquid solutions. In [95], analytical expressions describing the nucleation rate–pH of a medium relationship are derived. The dependencies are obtained for two mechanisms of growth of nuclei. In the case where the growth of nuclei is controlled by diffusion of components

in solution, the expression for the nucleation rate is of the form

$$I_D(pH) = \frac{D N_a \rho_0 \xi(pH) \sqrt{k_B T}}{4\pi \omega \sqrt{\sigma}} \exp\left(-\frac{16\pi \sigma^3 \omega^2}{3\xi^2(pH)(k_B T)^3}\right),$$
(25)

where D is the diffusion coefficient of a matter dissolved in solution, ρ_0 is the equilibrium concentration of a material dissolved, N_a is the density of the molecules in the solution, $\xi(pH)$ is the dependencies of the supersaturation from the pH of solution (the specific form of this dependence can be found in [95]). In the case where the growth of nuclei is limited by the boundary kinetics, the nucleation rate depending on pH is of the form

$$I_{SK}(pH) = \frac{\beta\sqrt{\sigma}}{2\pi\sqrt{k_B T}} \exp\left(-\frac{16\pi\sigma^3\omega^2}{3\xi^2(pH)(k_B T)^3}\right)$$
(26)

where β is the specific boundary flow. Dependencies of the nucleation rate of $Pb(OH)_2$ and $CaCO_3$ in water solutions on the pH value calculated by Eqs. (25) and (26) are given in Figure 3.

5. GROWTH AND EVOLUTION OF ISOLATED NANOISLANDS

5.1. Growth Mechanisms

After the formation of nuclei of a new phase on the substrate surface, they start growing and interacting with atoms of the old phase of which they were formed. This latter phase may be a single- or multicomponent vapor, a single- or multicomponent solution-melt, an amorphous phase, a solid solution, etc. [22, 37]. Accordingly, the island growth mechanisms are changed substantially as well. Thus, the diffusion flux of atoms of the old phase towards the surface of the nuclei is responsible for their growth from vapor medium. Both the removal of the latent heat of phase transformations
Figure 3. Dependencies of the nucleation rate of $Pb(OH)_2$ and $CaCO_3$ in water solutions on the pH value; 1a—$I_D Ca(OH)_2$, 1b—$I_{SK} Ca(OH)_2$, 2a—$I_D Pb(OH)_2$, 2b—$I_{SK} Pb(OH)_2$, 3a—$I_D CaCO_3$, 3b—$I_{SK} CaCO_3$. Reprinted with permission from [95], S. A. Kukushkin and S. V. Nemna *Dokl. Akad. Nauk* 377, 792 (2001) [*Dokl. Phys. Chem.* 377, 117 (2001)] © 2001, S. A. Kukushkin and S. V. Nemna.

and the diffusion of atoms of the old phase are responsible for the island growth from solutions-melts and from an amorphous medium. If the film growth is due to decomposition of a supersaturated solid solution, the islands will grow via the presence of a diffusion flux of atoms of the old phase. In a case when the film growth proceeds in the course of another type of phase transformation, for instance, a film decay caused by elastic strains [14, 96] occurring at film-substrate interfaces, the islands grow owing to the diffusion atomic flux induced by elastic strains. The surface introduces an appreciable diversity into the nucleus growth mechanisms compared to the growth in the bulk of solids. According to contemporary concepts [22, 23, 37, 97], the following basic ways of atomic migration and energy, in particular, heat transfer over the surface, are distinguished as follows: three-dimensional or volume diffusion of atoms and three-dimensional heat removal; two-dimensional atomic diffusion over the substrate surface and two-dimensional heat removal; one-dimensional atomic diffusion along substrate steps, surface dislocations, and other linear defects. Islands may also grow owing to an immediate arrival of atoms from a vapor onto their surface. The ultimate goal of the study of island growth mechanisms is the determination of the islands growth rate as a function of their radius and the degree of supersaturation. With this purpose, the corresponding heat and mass transfer equations are solved [22, 23, 37]. Such problems are typically referred to as the Stefan problems [66]. They have been widely examined for three-dimensional systems [98], in particular, for crystal growth from single-component and binary melts. Similar calculations for the diffusion mechanism of island growth on surfaces have been made by Sigsbee and Chakraverty [99, 100] and others [14, 22–24]. But the authors of these papers analyzed only one of the possible mechanisms of island growth, namely, island growth due to surface diffusion of adatoms. It turned out that the island growth rate is notably governed by non-stationary effects induced by the nucleus boundary motion [23]. These effects become predominant for small values of $R/\sqrt{D_a\tau_r}$, where R is the island radius, and $\sqrt{D_a\tau_r}$ is the diffusion path length of adatoms. Below, we shall only consider the quasi-stationary approximation for the island growth rate, which holds for high values of $R/\sqrt{D_a\tau_r}$. The structure of diffusion fields in the bulk of a vapor phase, on a substrate surface, and with linear defects was investigated in detail and the expressions for the island growth rate v_R were found in [37, 86, 101]. Islands usually grow simultaneously through several atomic diffusion mechanisms. It is, however, more convenient to consider each mechanism of island growth separately. According to [37, 86, 101], the expression for the new phase island growth rate v_R can be written in the following general form for each of the mass transfer mechanisms:

$$v_R = -M^{2-d'} w \frac{J_{DR}\Psi(\theta)}{R^{3-d'}} \qquad (27)$$

Here w is the volume per atom in the islands of a new phase; d' is the dimension of the space in which the diffusion fluxes propagate: $d' = 3$ for mass transfer in the bulk of a phase, $d' = 2$ for mass transfer over the surface, and $d' = 1$ for one-dimensional atomic diffusion along substrate steps or other linear defects (in this formula $2 - d'$ is assumed

to take only nonnegative values); $J_D R$ is a diffusion flux of atoms onto the island surface, which is found from the corresponding diffusion equations (for more details see [23, 37, 86, 101]), and $\Psi(\theta)$ is the function taking into account the island geometry. For caplike islands we have $\Psi(\theta) = 2(2 - 3\cos\theta + \cos^3\theta)^{-1}(1 - \cos\theta)$ when the diffusion of atoms proceeds in the bulk of a gas phase, $\Psi(\theta) = 2\sin\theta/(2 - 3\cos\theta + \cos^3\theta)$ for the diffusion of atoms over the substrate surface, and $\Psi(\theta) = [2\pi(2 - 3\cos\theta + \cos^3\theta)]^{-1}$ for the one-dimensional atomic diffusion, and, finally, M is the number showing how many linear defects are crossed by an island during its growth. To find the atomic diffusion flux of atoms $J_D R$ to a nucleus, one has to solve the corresponding diffusion equations. The form of these equations, the boundary conditions on them, and the methods of their solution can be found in [23, 37, 86, 101]. The general expression for the new phase island growth rate has the form

$$v_R = \frac{K_p}{R^{p-1}}\left(\frac{R}{R_c} - 1\right) \qquad (28)$$

Here K_p is a constant involving the parameters which characterize the material of the island and the kinetic parameters of its growth (particular values of K_p in different cases can be found in [23, 37, 86, 101]), and the number p assumes the values 2, 3, 4 depending on the mass transfer mechanism. For our further purposes, it is convenient to express the number p in terms of the island dimension d and the growth index m, which takes the values 1, 3/2, 2, 3 depending on the island shape and the type of the limiting stage: $p = d/m + 1$. At the initial stages of phase transformation, the island radius is $R \gg R_c$, and therefore the unity in the right-hand side of Eq. (28) is customarily ignored as being negligibly small compared to R/R_c. Furthermore, it is convenient to write this equation not in terms of the radius growth rate but via the change of the number of atoms in the nucleus. Then, Eq. (28) will be rewritten in the form [23]

$$\frac{di}{dt} = m\frac{\xi}{t_0}i^{(m-1)/m} \qquad (29)$$

where ξ is supersaturation, and t_0 is a constant having the dimension of time and called the characteristic time of island growth. It is expressed through the constant K_p and the constants relating supersaturation to the critical radius [64]. It has been shown theoretically and experimentally that the new phase island growth is determined by two principal processes, namely, a substance transfer to the island, that is, diffusion proper, and the passage of atoms through the old phase–new phase interface, that is, the boundary kinetics. Having passed through the phase interface, an atom joins the island surface. The island surface, the same as the surface of any crystal (see Section 2.1), can be atomically rough, atomically smooth, or vicinal. The ways in which the atom joins the island surface are different and depend on the type of surface [37, 66]. So, phase interfaces rough at the atomic level grow by the normal mechanism of growth. Atomically smooth surfaces grow by way of two-dimensional nucleation on their facets. Vicinal surfaces grow either through the motion of already existing steps or through the use of screw dislocations appearing on their surfaces. Island growth by the two-dimensional nucleation, as well as the evolution of

an ensemble of such islands, was described in [102]. In [37, 80], a rigorous analysis of island growth due to the motion of dislocations over their surfaces was carried out and the conditions under which this growth mechanism is realized were found. The next stage represents incorporation of adatoms into a new phase island. The growth rate (28), namely, the constant K_p and the index p, are significantly influenced by which of the processes is limiting. The particular form of the constant K_p for each type of mass transfer mechanism can be found in [23, 37, 86, 101]. In the course of formation of multicomponent nanofilms, atoms arrive at the substrate surface and they may initiate islands of various chemical compounds. Many of the islands of these compounds represent an intermediate phase in the course of growth of other phases. Islands of a chemical compound will further on be referred to as the phase s. As in single-component systems, the growth of multicomponent islands is due to the same mass transfer mechanisms [23, 37, 86, 101]. However, there is one important difference in that the chemical components of which an island of phase s is formed, may diffuse towards it in different ways. One of the components may arrive at the island surface through surface diffusion, and another through gas diffusion. In this situation one usually has to find the component responsible for the limitation and by this component determine the main flow of substance towards the island. The growth rate of a multicomponent island of an arbitrary phase s will as before be described by Eq. (27) in which, however, instead of the product of the atomic flux J_{DR} by the volume w, there stands the sum of the products of an atomic flux from each component by their volume w_i, that is, $\sum_{i=1}^{n^s} w_i^s J_{iR}^s$, where the subscript i stands for the corresponding sort of atoms. Since the islands have a stoichiometric composition, it follows that on their surfaces, according to [23, 37, 86, 101], the stoichiometry condition $J_{iRr}^s/\nu_i^s = J_{i'Rr}^s/\nu_{i'}^s$ holds. This condition allows us to express the quantity $\sum_{i=1}^{n^s} w_i^s J_{iR}^s$ in terms of the product of the flux of one of the components i by the volume w_m^s of a molecule of the chemical compound of phase s, that is, $J_{iR}^s w_m^s/p_i^s$, where $w_m^s = \sum_{i=1}^{n^s} p_i^s w_i^s$ is the volume per molecule of phase s and $p_i^s = \nu_i^s/\sum_{i=1}^{n^s} \nu_i^s$. Thus, to calculate the growth rate of a multicomponent island, it suffices to find the flux J_{iR}^s of only one arbitrary component. In [23, 37, 86, 101], all possible mechanisms of substance transport in multicomponent systems were investigated and analytical expressions for any type fluxes J_{iR}^s were found. Their substitution into an equation of growth rate of the type (27) leads to an equation of motion for an island of phase s, which has the form (28), where the constant K_p is replaced by a generalized constant containing kinetic and some other coefficients of each component entering the phase s. The critical radius R_c in Eq. (28) is replaced by the critical radius R_c^s for a given phase. The exact calculation of the growth rate of solid-solution islands is much more sophisticated than that for stoichiometric compounds. If the diffusion processes inside the islands are slowed down compared to the same processes outside the islands, the island composition along their radii will be inhomogeneous. Only provided the diffusion rate inside the islands appreciably exceeds the rate of variation of their radius, the island composition may be thought of as homogeneous. To determine the island growth rate, it is necessary to know in what proportion the components are built in an island. This question can only be answered after the mixing entropy of the components is calculated [89]. The solution of this problem can be approached differently, namely, one may use the state diagram relating the composition of the old and the new phases [23, 37, 86, 101]. Solid-solution islands are formed as a rule from the vapor phase and melts. Any state diagrams of substances in which there are no chemical interactions can be represented in the form of one or other modification of the two simplest state diagrams, namely, the diagram describing melting crystallization of substances insoluble in each other when in solid state (Fig. 4a, the diagram with a eutectic point) and the diagram describing melting-crystallization (evaporation-condensation) of substances that form a continuous solid-solution series (Fig. 4b) [66]. Islands produced from systems of the first type are single-component substances of composition A or B, respectively. At a eutectic point (see Fig. 4b), there simultaneously appear islands of both A and B compositions. In [23, 37, 103] it was shown that whenever the volume diffusion in the island matrix was fast enough, the expression for the growth rate remained the same (27), but the flux J_{DR} already consisted of the difference of atomic fluxes of components A and B. The average composition of islands changed during their growth by a definite law (see Section 7.2). The examination of island growth from single-component melts has shown that the principal mechanisms of island growth are as follows: three-dimensional heat removal into the melt, three-dimensional heat removal into the substrate, and two-dimensional heat removal from the nucleus along the substrate. The limiting stages in this process are the thermal conductivity proper and the mechanism of atomic incorporation into an island, which depends on the crystalline structure of its surface. The general expression for the island growth rate for each heat transfer mechanism takes the form

$$v_R = w\frac{J_{TR}\Psi(\theta)}{qR^{3-d'}} \tag{30}$$

where q is the latent heat of phase transition per atom. Concrete expressions for the heat flows and the island growth rates can be found in [23, 37, 104]. Thus, the mechanism

of island growth defines its rate v_R which enters the main equations of film condensation kinetics and hence ultimately determines the structure and composition of the growing nanofilm, as will be shown later.

5.2. Morphological Stability of Nanoislands

The main problem of the theory of morphological stability is to find out whether a given particular form of a vapor-, solution-, or melt-grown island is stable under small distortions. The analysis of stability is carried out by the following scheme: one assumes the shape of an island or a crystal to be slightly distorted, and then finds out whether this distortion increases or disappears. The necessity of examining stability stems from the fact that crystals often grow in the form of dendrites. Dendrites, or treelike crystals, consist of a central trunk and primary, secondary, etc., branches off it. They are often observed in nature and in laboratory conditions in melt
Figure 5. Schematic sketch of the fundamental mechanisms of island growth: (a) growth of edged and nonedged islands, when the limiting stage is the surface diffusion of adatoms; (b) the limiting process is the diffusion of atoms in the vapor phase (evaporation-condensation), (c) growth of nonedged islands, when the process is controlled by the entry of atoms from the vapor phase, but the heat removal occurs over all their surfaces; (d) the same, but with the heat removal through the substrate only; (e) growth of islands through linear diffusion along the steps of the substrate: 1—substrate, 2—non edged island, 3—edged island, to the surface of which atoms join only in specific places, 4—the island at a substrate step, 5, 6, 7, 8—the atom in the vapor phase, on the substrate surface, on an island surface, and at a substrate step, respectively, 9—heat flow angle. Reprinted with permission from [22], S. A. Kukushkin and A. V. Osipov, *Usp. Fiz. Nauk* 168, 1083 (1998) [*Phys. Usp.* 41, 983 (1998)]. © 1998, S. A. Kukushkin and A. V. Osipov.

crystallization. A quantitative analysis of the stability of the form of the growing crystal was first carried out in the classic paper by Mullins and Sekerka [105]. Numerous experiments on film growth show that the form of nuclei on the surface changes as they grow. It either becomes edged or, on the contrary, unstable or dendrite-like [66, 98]. This fact significantly influences both the nucleation and the structure of nanofilms. The growth of islands on the surface from vapor medium differs noticeably from the melt growth of three-dimensional crystals. This is first of all associated with the fact that deposited atoms are permanently supplied to the substrate surface and, having a finite lifetime (see Section 2.1), leave the surface by evaporating. This introduces essential changes and thus has a crucial effect upon the physics of the process. The morphological stability of nanoparticles growing on the surface of solid substrates in examined in [106]. The stability of shape for a flat disc-shaped island of height H and radius R is analyzed there. It is assumed that the island grows due to diffusion of adatoms. A change in the island shape is induced by two forces. On the one hand, a ledge on the island surface appears to be in the region of higher concentration gradients of adatoms and must, therefore, increase in size. On the other hand, a ledge increases the curvature and thus raises the saturated vapor density at this point, which in turn slows down the growth rate of the ledge compared to the neighboring points of the nucleus boundary.

The analysis of the corresponding diffusion equation [106] has shown that the shape of nanoislands becomes unstable in the case where island radius R_0 lies within the range $R_1(\nu) < R_0 < R_2(\nu)$, where $R_1(\nu) = R_c$ for $R_c/\sqrt{D_a \tau_r} \ll 1$, R_c is the critical radius of a nanoparticle, $R_2(\nu) = [(\nu^2 - 1)/2]\sqrt{D_a \tau_r}$, ν are the integers corresponding to the order of modes arising in the course of an island shape change. Note that conditions needed for evolution of instability of the islands are substantially differnt from the conditions leading to formation of dendrites in the course of crystal growth from melts [66, 105]. A shape of the islands is more stable with respect to minor fluctuations as compared to the corresponding shape of three-dimensional crystals.

5.3. Structure of the Nanoparticle-Gas Interface

As it was noted before, the physical properties of nanoparticles differ significantly from the properties of volume materials. The reason for this is the influence of the surface of the particles on their properties. The problem of development of the rigorous model for the determination of the structure of interphase border nanoparticle-environment and the influence of surface active substances on the structure attracts attention of researchers (see, e.g., [24, 43, 47, 56, 57, 62, 107–109]).

The rigorous perturbation theory of the evolution of a small-sized cluster was developed in the framework of the density functional method in [110]. In this paper, for the first time, the size dependence of the surface tension for a cluster is defined and structure of the nanocluster-vapor phase interface is determined analytically. So, in the case of

clusters, the correction to the surface tension $\sigma(R)$ for the curvature is of the form

$$\sigma(R) = \frac{R}{R + (d-1)\delta} \tag{31}$$

where R is the nanocluster radius, d is the space dimension ($d = 3$ for a drop and $d = 2$ for a disc-shaped island in the growth of nanofilms), σ_0 is the surface tension of a solid material, which is calculated by the approach cited in [110], δ plays the role of a correction to the surface tension for the curvature; that is, δ the Tolman parameter, δ is strictly estimated within the framework of the perturbation theory [110], the $O(1/R^2)$ term denotes the corrections of higher orders within the framework of the perturbation theory. The density profile for a liquid cluster in the van der Waals three-dimensional gas at $T = 0.7T_c$ calculated in [110] is plotted in Figure 6. The temperature dependencies of the surface tension calculated [110] for the van der Waals three-dimensional gas and the two-dimensional lattice gas are displayed in Figure 7. This figure also shows experimental values of the surface tension for four gases, namely, methane, neon, argon, and krypton [110]. As is clearly seen, the theoretical results obtained for the surface tension of the van der Waals gases are in excellent agreement with experimental data. Figure 8 depicts the temperature dependence of the Tolman parameter for the van der Waals gas. It can easily be shown that, in the temperature range $0.5 < T/T_c < 1$, where T_c is the critical temperature, the Tolman parameter is of the order of $\delta \sim 0.1\sqrt[3]{\rho_c/m} \sim 0.5 \cdot 10^{-10}$ m. This will suffice to have a pronounced effect on the nucleation [111].

5.4. Surface Migration of Islands

Numerous experimental studies demonstrate that at the initial stages of crystal nanofilm condensation on foreign crystalline substrates, the nuclei of a new phase can rather rapidly transfer over the substrate surface [112–115]. This process serves as an important link in the nanofilm structure formation [113, 116]. Such migrations proceed under the action of various external forces: collisions with fast particles of the flow, the temperature gradient, the electric and
Figure 6. Density profile for a liquid cluster in the van der Waals gas at $T = 0.7T_c$. Here, T_c is the critical temperature, ρ is the density of the material at each point, ρ_c is the critical density of the material, r is the specific coordinates of a point of the medium, $\lambda = \sqrt[3]{m/\rho_c}$, m is the mass of one molecule. magnetic fields, the interaction with moving steps, etc. As concerns the mechanism of island migration, only two basic models describing the island transfer have been used up to now [112]. First, particle diffusion proceeds only across the island surface, and particles attached to the boundary surface remain immobile about it. Second, an island is assumed to slide over the substrate surface. Many specific mechanisms of the morphological change of the island and of the sliding process have been proposed, but all of them yield relatively low values for the migration velocity and the diffusion coefficient compared to those actually observed in some cases [113, 114]. In the models of the first type, this is associated with the low values of the coefficients of self-diffusion of adatoms which cannot provide sufficiently fast island migration. In models of the second type, this is caused by the high values of the sliding friction forces between the island and the substrate (i.e., the high activation energy of slide) particularly during epitaxial growth. We have recently proposed [117] an essentially different model of transfer of growing islands oriented over a foreign substrate. As is well known, under certain conditions mismatch dislocations are generated on the island-substrate interface. If the Burgers vector lies in the slip plane, the motion of the island can be provided by the motion of these dislocations (solitons) [117]. Such a mechanism looks preferable to the usual
Figure 8. Temperature dependence of the Tolman parameter for the van der Waals three-dimensional gas. Reprinted with permission from [110], P. V. Gordon et al., *Fiz. Tverd. Tela* 44, 2079 (2002) [*Phys. Solid State* 44, 2175 (2002)]. © 2002, P. V. Gordon, S. A. Kukushkin and A. V. Osipov.

sliding because during the motion of the dislocation at every instant of time almost all the atoms of the island remain immobile with respect to the substrate, and it is only a very small group of atoms that move. The passage of a dislocation (compression or rarefaction waves) from one end of an island to the other is equivalent to island displacement by one lattice constant of the substrate [117]. If the dislocation (soliton) velocity is much smaller than the velocity of sound in the material of the film, then the energy losses during its motion are very small; that is, in such displacement of an island there is almost no friction against the substrate. The estimate of the "effective" mass of an island migrating over a substrate owing to soliton motion takes the form [117]

$$M_{\text{eff}} = 4cM \ \ln \frac{1}{\epsilon - \epsilon_c} \tag{32}$$

where M is the island mass, c is the ratio of forces acting on an atom from the side of other atoms of the island to those from the side of the substrate, ϵ is the parameter of lattice mismatch between the film and substrate, and ϵ_c is the critical lattice mismatch parameter corresponding to the onset of generating mismatch dislocations.

6. KINETICS OF NANOFILM CONDENSATION AT THE INITIAL STAGE

Among the whole variety of processes accompanying film growth, the principal one is, undoubtedly, the new-phase nucleation of islands, that is, the first-order phase transition. It is at this initial stage of condensation that the number of islands of a new phase determines composition and structure of nanofilms.

6.1. Nanofilm Condensation at Low Supersaturations

The description of the real kinetics of new phase nucleation and the occupation of a condensation surface by the nuclei is one of the most important problems of the theory of first-order surface phase transitions. A large number of papers of both classical and nonclassical direction have been devoted to this issue [17, 22–29, 31–34, 36, 38, 40, 41, 50, 64, 118, 119]. The cornerstone of any theory is a correct account of the nonlinear feedback between supersaturation and the size distribution function of new-phase islands. Indeed, growing islands absorb adatoms and thus diminish the supersaturation which is responsible for the nucleation rate and the growth rate of the islands, that is, ultimately for the distribution function [64]. One of the first models describing film condensation kinetics was posed by Zinsmeister [120]. He was the first to investigate the influence of a supersaturation decrease due to cluster growth upon the nucleation kinetics. This model has at least three shortcomings. First, the cluster growth rate is thought to be independent of cluster size. Second, the number of particles in a critical nucleus is always assumed to be equal to unity and not to increase with falling supersaturation (the decay of all the clusters is ignored). Third, the nucleation rate I is assumed to be equal

to $\text{const} \cdot n_1^2$ over the entire nucleation stage (the possibility of a spinodal decomposition is neglected altogether). As a result, the island concentration given by the model is overestimated and increases infinitely in course of time. This model was further developed in many papers where the decay of all the clusters was also disregarded and it was assumed that $I \sim n_1^2$ over the entire film formation stage [23, 24]. Several papers have been devoted to the calculation of the maximum surface cluster concentration $N_{\max}$ by the equation

$$I(N_{\max}) = V_{\text{coal}} N_{\max}^2 \tag{33}$$

where V_{coal} is the rate of pair cluster coalescence (see Section 7) calculated from various geometric considerations [121], and I depends in a certain way on $N_{\max}$ through the supersaturation ξ. Such models typically ignore the fact that the limitation on the number of clusters is not only due to coalescence, but is largely due to the deterioration of supersaturation and the associated abrupt decrease of the nucleation rate I. An important step in the development of film condensation kinetics was the model of the rate equations [122]. It is based on the division of all nuclei into subcritical and supercritical and the use of averaged condensation characteristics, such as the average number of particles in supercritical nuclei, the average rate of particle trapping by supercritical nuclei, the average radius of particles, etc. This model is frequently employed in numerical computations, which determine various characteristics of condensation. The shortcomings of the model [122] also include the absence of analytical results, the absence of data on the size distribution function of nuclei, as well as a forced assumption of an identical rate of adatom consumption by growing clusters of various sizes.

We should specially mention the nonstandard Kikuchi model which represents the nucleation and thin-film growth as an irreducible cooperative process and exploits the so-called path probability method [123]. The method of path probabilities also determines the equation of state for a system of adatoms on a lattice.

The cluster model [26] describes the nucleation, growth, and coalescence of islands of a new phase using the microscopic stochastic equations reformulated in terms of "clusters." "Clusters" are defined as independent fluctuations of the local order parameter [26]. The division of all the variables into "relevant" and "irrelevant" ("irrelevant" properties induce random transitions in "relevant" coordinates, which are described by the Markov master equation) allows simplification of the kinetic equation. This equation is thoroughly examined in [26]. The stochastic models [124, 125] describe the film growth by various approximate stochastic equations. The characteristic feature of such models is the scaling behavior of various parameters of a growing film, for instance, its roughness.

The kinetic theory [64] yields analytical expressions for all the basic characteristics of film condensation at the initial stage using specially developed methods for an approximate account of the nonlinear feedback mentioned earlier. Finally, the continual model [63] represents thin-film condensation as the order-parameter field relaxation, the surface adatom density being the order parameter in this case. This approach is apparently the most general [63] because

it allows a description of film deposition in terms of both nucleation and spinodal decomposition, and for low supersaturations it becomes a standard kinetic model. Furthermore, there is an opinion that it is precisely this approach that will allow us to describe the appearance of the crystalline order during film growth from a vapor or melt.

6.2. Perturbation Theory

The variety of approaches to the description of thin-film growth is largely due to the impossibility of an exact analytical solution of the main system of equations of film formation in the opening stage, that is, the system consisting of the equation of conservation of matter on the substrate and the kinetic equation for the size distribution function of nuclei (this system is derived using the division of the whole size axis into three portions: subcritical, critical, and supercritical [64]).

Here, the set of equations is of the form [23, 64]

$$\frac{\xi_0}{\xi(t)} - 1 = \frac{(k+1)\tau_r}{n_{1e}t_0} \int_0^\infty \rho^k g(\rho, t)d\rho \tag{34}$$

$$\frac{\partial g}{\partial t} + \frac{\xi(t)}{t_0}\frac{\partial g}{\partial \rho} = 0 \tag{35}$$

$$g(0, t) = \frac{I(\xi(t))t_0}{\xi(t)}, \qquad g(\rho, 0) = 0 \tag{36}$$

where Eq. (34) describes the law of conservation of matter on the substrate, Eq. (35) is the kinetic equation describing evolution of the size distribution function for nanoparticles, Eq. (36) includes the initial and boundary conditions, and t_0 is the characteristic cluster growth time involved in the law of growth of stable islands (29), $g(\rho, t)$ is the size distribution function of stable clusters ρ $(\rho = i^{1/(k+1)})$, $I(\xi)$ is the nucleation rate, ξ_0 is the initial value of supersaturation, $k = m + 1$.

Practically all the above-mentioned models apply approximate methods for the solution of this system, which are based on some small parameter of the theory. From the physical point of view, the "principal" small parameter is the inverse number of particles in a critical nucleus (at the moment of maximal supersaturation). It is just this parameter that stands in the denominator of the nucleation rate exponent. Expanding all the quantities in power series of the small parameter directly, one obtains series that diverge for sufficiently long times, that is, not uniformly valid series. In order to provide convergence of the series, it is necessary to use a rigorous perturbation theory [126]. It should be noted that the presence of a small parameter does not always allow the solution to be represented in the form of a convergent series; that is, it is not always possible to provide a uniform validity of the series by way of a particular renormalization [126]. Therefore, it should be especially emphasized that the system of equations governing kinetics of the first-order phase transition in general and of thin-film condensation in particular admits an analytical solution in the form of a power series of the small parameter. The uniform convergence of this series is provided by the time renormalization procedure, that was made in [118, 119].

In the capillary nucleation model, the nucleation rate $I(\xi)$ entering Eq. (36) has the form [see Eqs. (14), (15)]

$$I(\xi) = P(\xi)e^{-H(\xi)} \tag{37}$$

where H is the nucleation barrier height, and P is the pre-exponential factor depending on supersaturation. The most important parameter Γ of the phenomenological theory is connected with the function H as follows [118]:

$$\Gamma = -\left. \xi_0 \frac{dH}{d\xi}\right|_{\xi=\xi_0} \tag{38}$$

For films growing from vapor medium and high values of ξ_0, we have $\Gamma \sim i_c \gg 1$, where i_c is the number of particles in critical nuclei at $\xi = \xi_0$. Consequently, the quantity

$$\varepsilon = 1/\Gamma \tag{39}$$

is the small parameter of the given problem. As a result of the analysis performed in [118], it was proved that all the unknown functions will be expressed here in terms of the auxiliary function $\varphi_k(x)$ specified by the equation

$$\frac{d\varphi_k}{dx} = \exp(-x^k\varphi_k), \qquad \varphi_k(0) = 0 \tag{40}$$

The dependence of φ_k on x is plotted in Figure 9. We shall only present the net result to the first approximation in powers of ε [118]:

$$\xi(t) = \frac{\xi_0}{1 + (1/\Gamma)T^k(t)\varphi_k(T(t))} \tag{41}$$

$$I(t) = I(\xi_0)\frac{\exp[-T^k(t)\,\varphi_k(T(t))]}{1 + (1/\Gamma)T^k(t)\varphi_k(T(t))} \tag{42}$$

$$N(t) = I(\xi_0)t_k\varphi_k(T(t)) \tag{43}$$

$$g(\rho, t) = \begin{cases} \dfrac{I(\xi_0)t_0}{\xi_0}\exp\left[-\left(T(t) - \dfrac{t_0\rho}{t_k\xi_0}\right)^k \varphi_k\left(T(t) - \dfrac{t_0\rho}{t_k\xi_0}\right)\right], \\ \qquad\qquad\qquad\qquad \rho \leqslant \xi_0\dfrac{t_k}{t_0}T(t) \\ 0, \qquad\qquad\qquad \rho > \xi_0\dfrac{t_k}{t_0}T(t) \end{cases} \tag{44}$$

$$T = \frac{t}{t_k} - \frac{1}{\Gamma}\int_0^T x^k\varphi_k(x)dx$$

$$t_k = \frac{t_0}{\xi_0}\left[\frac{n_{1e}\xi_0}{(k+1)\Gamma I(\xi_0)\tau}\right]^{1/(k+1)} \tag{45}$$
Figure 9. Dependence of the function $\varphi_k(x)$ on x: $1 - k = 0$; $2 - k = 1/2$; $3 - k = 1$; $4 - k = 2$. Reprinted with permission from [119], S. A. Kukushkin and A. V. Osipov, *Fiz. Tverd. Tela* 38, 443 (1996) [*Phys. Solid State* 38, 244 (1996)]. © 1996, S. A. Kukushkin and A. V. Osipov.

The time dependencies of the nucleation rate and the size distribution function of new-phase islands are illustrated in Figures 10 and 11.

The same method can be used to describe the growth of multicomponent films as well as inhomogeneity effects [118]. The perturbation theory technique [118] turned out to be rather effective. Application of the approach allows to describe the kinetics of phase transitions proceeding in various systems. Thus, for instance, in [127] the processes of nucleation of nanofilms from solutions or melts are described, whereas the phase transitions in ferroelectrics are investigated in [128].

The shortcoming of the small parameter technique is the impossibility of describing a phase transition for arbitrary τ_r, Γ, and t_0, which can only be done numerically by solving the equations of condensation kinetics (35)–(37).

6.3. Nucleation of Islands in Solutions Under Light Exposure

Precipitation of matter from photoactive solution is one of the methods of the island films formation. So, in [129, 130], a process of obtaining Ag, Au, Cu films on flat quartz substrates in solutions of photoactive chemical coordination compounds was experimentally investigated. The essence of this method consists in the following: supposing that one has a solution of coordination compound $[M^{z+}L_n]X_m$, where M^{z+} is the central metal atom ($z+$ is the degree of oxidation), L is inner-sphere ligands and X is outer-sphere counterions. If ligand-to-metal charge transfer ($L \to M$) occurs in this compound, then irradiation of the solution by light at wavelength $\lambda = \lambda_{L \to M}$ results in the reduction of metal atom. Under irradiation of a solution the one-electron reduction of a metal atom can be produced. Thus, we are able to write the following scheme of the entire process:

$$[M^{z+}L_n]X_m \xrightarrow{h\nu} M^0 + L^+ + X^-$$
One has to put the substrate to be deposited on the bottom of the vessel containing the solution. If we direct a light beam from above with its intensity decreased according to the Lambert–Buger–Behr law toward the substrate, then the beam is adsorbed on it. When a critical concentration of

metal on the substrate's surface is reached, the growth of new crystal metal phase starts.

In [129, 130] it has been noted that the essential feature of films which are obtained with the method described is the narrow size distribution of grains in the film.

The kinetics of the growth of thin metal films from solutions of photoactive chemical coordination compounds irradiated by light at certain wavelength has been theoretically investigated in [131]. In the framework of our mathematical model, the time dependencies of the basic characteristics of film growth process (size distribution function, density of nucleation, concentration of metal on surface) have been computed. Calculation of the characteristics is performed by the theory perturbation method mentioned earlier and described in [118]. These are according to experimental data. It is shown that the flux of metal (substance) from solution onto substrate's surface can be derived from stationary diffusion equation with added term taking into account the influence of photochemical substance source. It is concluded that the variation of light intensity, in wide range, saves the kinetics of the process of film deposition without drastic changes.

6.4. Nanofilm Condensation at High Supersaturation

If the external source of deposited particles has a large power such that a one-particle nucleus is energetically more advantageous than a two-particle nucleus, that is, $F(2) > F(1)$, then in the ensemble of adatoms a spinodal decomposition starts [44, 47, 63]. Any thermodynamic fluctuations increase in this case, the long-wave fluctuations increasing faster. A theory of spinodal decomposition in a system of adatoms was formulated in [63]. If the external source of deposited particles has such a power that in a metastable system it creates a supersaturation ξ close to ξ_{max}, which corresponds to approximately $i_c = 2 - 4$, then the character of the nucleation process radically changes. First, the correlation radius in the system may exceed the average cluster size (for $i_c = 1$ the correlation radius is equal to infinity). Second, the distribution of subcritical nuclei may be other than equilibrium, and, third, for small i_c the structure of critical nuclei and, therefore, the character of the interphase

energy significantly change. Hence, strongly metastable systems should be considered separately [132, 133]. It is appropriate to describe them in the framework of the continual theory [63], which represents a phase transition as a relaxation of the order-parameter field. The nucleation rate in this case depends on the supersaturation as

$$I(\xi) = I(\xi_{\max}) \exp[-\mathrm{const}(\xi_{\max} - \xi)^2] \qquad (46)$$

Thus, there exist three ways of relaxation of a supersaturated adatom population. The first is realized in weakly metastable systems where the supersaturation ξ is much lower than $\xi_{\max} = n_{1s}/n_{1e} - 1$. In this case the critical nucleus is so large ($i_c \gg 1$) that its fluctuations lead to a change of only the coordinate of its boundary, although it has a considerable thickness. The structure of the nucleus itself will remain unchanged. In this event it is convenient to apply the capillary model, in particular, formula (14). The second way of relaxation takes place for $\xi \le \xi_{\max}$. Here the critical nucleus contains only a few particles and is so small that its fluctuations affect not only the boundary, but the whole nucleus. In other words, the internal structure of the critical nucleus itself changes during fluctuations. Finally, the third way of relaxation lies through spinodal decomposition. It is realized for $\xi \ge \xi_{\max}$. In this event the system is unstable, $i_c = 1$, and thermal fluctuations generally destroy the structure of critical nuclei and lead to an increase of periodic fluctuations of substance concentration. This periodicity is a consequence of the fact that near a growing new-phase island no other islands are produced, and the whole ensemble of islands is strongly interacting [63].

7. KINETICS OF NANOFILM CONDENSATION AT THE LATE STAGE

The late stage of nanofilm growth is characterized by the fact that the new-phase islands generated earlier begin to interact. There exist three main types of cluster interaction. The first is cluster merging due to their migration over the surface (the migration mechanisms were briefly discussed in Section 5.4). The second is cluster merging due to their lateral growth [134]. The third is the growth of larger clusters at the expense of the evaporation of smaller ones (OR stage). The latter type of interaction is realized through the generalized diffusion or temperature field [37].

As a rule, cluster coalescence according to the first two types proceeds in a rather fast way. When merging, the islands are increased in their size. It can cause the size of islands to fall outside the limits of nanodimensions. However, investigation of the problem lies outside the scope of our chapter, and we do not discuss it here in detail. The readers interested in the phenomenon may refer to original paper [134] or reviews [22–24], where the problem is discussed more thoroughly. We only note that in preparation of nanostructures, it is necessary to avoid this process in coalescence.

The OR is a slow process. When changing such parameters as the substrate temperature, feed rate of components, and the substrate, one can effectively control the size and composition of nanoparticles. This process we shall discuss in more detail in the following subsections.

7.1. Ostwald Ripening Stage

The Ostwald ripening (OR) stage is the late stage of the phase transition. It begins only when the sources of evaporated adatoms are sufficiently weak and the supersaturation ξ on the substrate is small and tends to zero. No new islands are formed in this situation. The estimate of the starting point of this stage can be found in [23, 37, 84, 85, 118, 132]. The physical meaning of OR is as follows. At a late stage of evolution of an ensemble of islands, they begin to interact in a peculiar manner. This interaction is realized through a generalized self-consistent diffusion field. On a substrate, this field can be established by adatoms with a concentration $\bar{\rho}_a$, vapor atoms with a density $\bar{\rho}_r$ or, if the substrate surface contains linear defects, by adatoms ($\bar{\rho}_l$) adsorbed at the steps. This field depends on the size distribution function $f(R, t)$ of islands and is in equilibrium with islands of critical size R_c. Islands of size $R < R_c$ are dissolved in the diffusion field because near them the equilibrium concentration ρ_R of atoms exceeds the mean field concentration: $\rho_R > \bar{\rho}_a, \rho_R > \bar{\rho}_l$, or $\rho_R > \bar{\rho}_l$. Islands of size $R > R_c$ grow because for them $\rho_R < \bar{\rho}_a, \rho_R < \bar{\rho}_l$. The critical size R_c itself goes on increasing because the islands absorb the substance from the substrate, thus lowering the supersaturation.

For this interaction and, therefore, the OR stage to take place, it is necessary that the two-dimensional island density would satisfy the inequalities [23, 37]

$$[\pi(\bar{R} + \lambda_i)^2]^{-1} < N_s < (\pi \bar{R}^2)^{-1} \qquad (47)$$

where N_s is the two-dimensional island density, $\bar{R}$ is the mean island radius, $\lambda_i = \lambda_s$ for mass transfer over the substrate surface, and $\lambda_i = \lambda_l$ for mass transfer along the steps, λ_s and λ_l being respectively the mean free path along the substrate surface and along the steps. Otherwise, if $N_s \ge (\pi R^2)^{-1}$, the islands will "collide" and for $N_s \le [\pi(R + \lambda_i)]^{-1}$ the adatoms on the substrate will evaporate and will not participate in the OR process provided that $\lambda_i = \lambda_s$. When $\lambda_i = \lambda_l$, the adatoms can leave the step and will not participate in ripening of the ensemble of islands located at the step.

The OR of an ensemble of islands in thin films was first investigated by Chakraverty [100, 135]. He examined the evolution of an ensemble of single-component islands with the shape of a spherical segment and located on solid substrates in the regime of complete condensation and also in the presence of atoms sputtered onto the substrate. Chakraverty [100, 135] believed that mass transfer between islands is realized only through a surface diffusion of adatoms and that the island growth rate can be controlled both by the surface diffusion (heterodiffusion) of adatoms and by the rate of consumption and emission of atoms by the islands, that is, by boundary kinetics. He assumed that the emission and absorption (building-in) of atoms are realized not by the island contour, but by its whole surface. Such an assumption corresponds to the fact that self-diffusion flows along a free island surface must exceed the heterodiffusion flows on the substrate surface. This statement should have been additionally grounded. This problem was solved more exactly by Geguzin and Kaganovskii [136]. They studied the evolution of an ensemble of islands growing by the following mechanisms: surface diffusion of atoms, gas diffusion of

atoms, evaporation-condensation of atoms, one-dimensional atomic diffusion along steps, and surface dislocations on a substrate (see Section 5.1) with allowance for a possible island growth control by boundary kinetics.

Later, the OR stage of an ensemble of single-component islands with allowance made for all possible growth mechanisms and in the presence of atoms sputtered on the substrate was investigated by various authors (see reviews [23, 37]). The authors of these papers found the laws of variation of the critical radius, height (if the islands had the shape of a flat disc), the island density in time, as well as island size distribution to a zeroth approximation. The analysis has shown that these characteristics depend substantially on the island growth mechanism and the intensity of atomic supply onto the substrate. According to [22, 23, 37], if a flux of atoms coming onto a substrate has a power-law asymptotics: $g(t) \rightarrow ng_0 t^{n-1}$, where $n \geq 0$ and g_0 is the constant, then there exist only two types of sources, namely, weak with $n < d/p$ and strong with $d/p \leq n$.

The main idea of the OR analysis of such systems took root in the pioneering paper by Lifshitz and Slezov [137]. These authors showed that any disperse systems containing new-phase nuclei and old-phase atoms possess a whole number of common properties inherent only in disperse systems and apparent in the course of their evolutionary growth. From the thermodynamic point of view, this common property of disperse systems is their deviation from equilibrium state simultaneously in many parameters. One of the main signs showing that a disperse system resides in a nonequilibrium state is the presence of a fairly extended phase interface associated with an excess free energy. At heightened temperatures, when an appropriate diffusion mechanism becomes valid, some processes proceed in disperse systems that lead to a relaxation of the excess energy. These processes must be accompanied by a diffusive mass transfer which is responsible for the emergence of OR. This process was named after the German scientist W. Ostwald who, at the beginning of the century, examined this phenomenon experimentally during precipitation ripening. The principal system of equations describing this process has been presented in numerous works generalized in reviews and monographs [23, 37, 84, 85]. The basis for the analysis of the OR process is the Fokker–Planck equation (8) in which the term with the second derivative of the distribution function is omitted. When describing the non-isothermal ripening, we propose a more general system of equations, a particular case of which is the one given. The OR stage was also thoroughly investigated by Wagner [138], Ardell [139], Kahlweit [140], Oriani [141], Cahn [142], Voorhees and Cliksman [143, 144], Enomoto, Kawasaki, Tokuyama [145, 146] and many other authors [147–152, 154–156].

The general OR theory in non-isothermal conditions was constructed in [37, 101, 153, 157]. The OR processes in multicomponent systems are richer and more diverse than similar processes in single-component systems. In multicomponent systems, substance redistribution is a consequence of not only the Gibbs–Thomson effect, but also of the chemically nonequilibrium state. Islands of a chemical substance (phase s) may be stable from the point of view of the Gibbs–Thomson effect but unstable from the point of view of the thermodynamics of chemical reactions. At the OR stage in

multicomponent systems, when the component concentration is $\rho_j(0) \ll 1$ (here $\rho_j(0)$ is the concentration of the component j by the onset of OR), new islands are not formed and all the islands of the ensemble interact with each other through their generalized diffusion field. Islands of phase s with radius R smaller than the critical radius R_c^s are dissolved in the diffusion field, while islands with a radius exceeding the critical one grow. In a multiphase system, not only islands of the same phase, but also those of different phases will interact, and of all the stable phases only those for which the solution is supersaturated will be stable. For low component concentrations, when the law of mass action can be applied to the proceeding chemical reactions, this law can be written in the form

$$\sum_j \nu_j^s \mu_j^s = \ln \frac{\prod_{sj} (\rho_j(0))^{\nu_j^s}}{K_\infty^s} \geq 0 \qquad (48)$$

Here K_∞^s is the equilibrium constant of the sth chemical reaction, s^j is the number of the phase containing the j-component, and μ_j^s is the chemical potential of the j-component. If the islands generated in the system do not contain common components, condition (48) is necessary and sufficient since they will grow independently. Providing the islands contain common components, during their growth substance redistribution among the islands is possible and, although the solution was at first supersaturated in separate components, it may further appear to be unsaturated. In this case condition (48) is only necessary for a selection of islands capable of further competitive growth. In multicomponent systems, in the course of OR heat is liberated in chemical reactions, which affects the reaction constants. The thermal fields induced due to the heat liberation in chemical reactions affect the size distribution of islands in a nonlinear manner. The equilibrium concentration of the dissolved substance is not constant, but increases with temperature. The supersaturation will then tend to zero faster than in the isothermal case; however, the substance concentration gradient decreases in the process, which leads in turn to a decrease of the island growth rate. The amount of heat liberated in the course of phase transformation therewith decreases (if the system is conservative), which brings about stabilization of the equilibrium concentration; that is, the diffusion and thermal fields become self-consistent. Thus, the system temperature heightening may lead to a decay of some phases. A complete system of equations governing the evolution of an ensemble of multicomponent and multiphase islands at the OR stage looks like this [23, 37, 101, 153]:

$$\frac{\partial f^s(R,t)}{\partial t} + \frac{\partial}{\partial R}(f^s(R,t)v_R^s) = 0 \qquad (49)$$

$$\chi^s \sum_{s^j} \int_0^\infty f^s(R,t)R^{3-d}h^{3-d}J_{DR}^s \, dR = n_1|g_{D_j}|t^{n_1-1} \quad (50)$$

$$\prod_{j=1}^{n^s} (\rho_{jR}^s)^{\nu_j^s} = K_R^s(T_R) \qquad (51)$$

$$\frac{J_{jr}^s}{\nu_j^s} = \frac{J_{j'R}^s}{\nu_{j'}^s} \qquad (52)$$

$$\sum_{s=1}^{K} \chi^s q^s \int_0^\infty f^s(R,t) R^{d-1} h^{3-d} J_{T,R}^s \, dR = n_2 |g_T| t^{n_2-1} \quad (53)$$

$$q^s \sum_{j=1}^{n^s} \nu_j^s J_{jR}^s = J_{TR}^s \quad (54)$$

$$K_R^s = \varphi(T_R^s) \quad (55)$$

Here $f^s(R,t)$ is the size distribution function of islands of phase s, J_{jR}^s is the flux of atoms of the j-component onto an island of phase s, J_{TR}^s is the heat flux liberated during the growth of phase s, ρ_j is the mean concentration of the j-component on the substrate (or in a vapor), χ^s is the coefficient dependent on the island shape, q^s is the chemical reaction heat liberated during growth of islands of phase s per molecule of phase s, $|g_{D_j}|$ and $|g_T|$ are the intensities of the fluxes of j-component and heat, respectively, and, finally, n_1 and n_2 are damping exponents. A method for the solution of this type of system was developed in [23, 37, 101, 153]. This method allows reduction of the system of equations (49)–(55) to a single-component system [23, 37, 101, 153]. Further, this set of equations can be solved by the Lifshitz and Slezov approach [137]. However, not long ago, a rigorous asymptotic theory of OR was developed in [158]. According to the rigorous results obtained in [158], the asymptotic laws of variation of the critical radius, the height and the density of islands coincide with those of [137], whereas the asymptotic size distribution function differs from the functions obtained in the zeroth approximation. In accordance with the results obtained in [158], the asymptotic solution of the set of equations (49)–(55) for sources with $n < d/p$ are of the form

$$\bar{R}(t) = \text{const} \cdot R_c^s(t) \quad (56)$$

$$R_c(t) = \text{const} \cdot (A_{pd}^s t)^{1/p} \quad (57)$$

$$h(t) = \text{const} \cdot (A_{pd}^s t)^{1/p} \quad (58)$$

$$N(t) = \text{const} \cdot t^{n-d/p} \quad (59)$$

$$f(R,t) = \frac{N(t)}{R_c(t)} P_p\left(\frac{R}{R_c(t)}\right) \quad (60)$$

$$P_p(u) = \frac{u^p}{u^{p+1} - (p+1)u + p}$$
$$\times \exp\left[\frac{d - n(p+1)}{2} \int_u^{u_p} \frac{x^p \, dx}{x^{p+1} - (p+1)x + p}\right] \quad (61)$$

Here $P_p(u)$ is the distribution function normalized to unity, so that $\int_0^\infty P_p(u) \, du = 1$, and

$$v_p(u) = \frac{p^p (p-1)^{-(p-1)}(u-1) - u^p}{p \, u^{p-1}} \quad (62)$$

$u = (p-1)R/pR_c$, u_p are constants determined from the normalization condition $\int P_p \, du = 1$, $N(t)$ is the density of the islands of phase s, A_d^s is the kinetic coefficient of phase s depending on mass or heat transfer coefficients and on other constants of the deposited material. The values of these constants are given in [101, 153] for all the cases of heat and mass transfer which can be realized in the course of evolution of an ensemble of islands. As an example, we only present the value of A_{pd}^s for the case where the principal

mechanism is the surface diffusion of adatoms and the heat is transferred over the substrate surface. In this case, one can obtain

$$A_{pd}^s = \frac{27 D^{os} \sigma^s n_0 K_{sb} l T_0^s (w_0^s)^2 \psi_1(\theta)}{32 \left[D_s^{os} n_0 (q^s)^2 \ln(H/R_1^s) + K_{sb}\lambda_{\text{eff}} k_B (T_0^s)^2\right]} \quad (63)$$

where

$$D^{os} = \left(\sum_{j=1}^{n^s} \frac{(p_j)^2 \ln(\lambda_j/R_1^s)}{D_{aj}\rho_{j\infty}^s}\right)^{-1}$$

is a generalized surface diffusion coefficient for $\lambda_{sj} \gg R_1^s$; D_{aj} is the coefficient of Brownian motion of the adatoms of the j-component, $\psi_1(\theta) = 2(2 - 3\cos\theta + \cos^3\theta)^{-1}$, with θ as the contact angle, and the other designations were presented above.

In the case of atomic sources with $d/p \le n < d/(p-1)$, both for cap-shaped and disc-shaped islands the critical radius is also specified by Eq. (57) and the distribution function can be calculated within the kinetic nucleation model [see Eq. (44)].

The solution also showed [37, 153] that at the OR stage $N_{a,n} \sum_{s=1}^{K} q^s |g_D^s| = |g_T|$ and $n_1 = n_2$; that is, the powers of sources (sinks) of all the phases and heat are related to one another and vary in time by one and the same law. Otherwise, the ripening process is impaired. The equations allowing the determination of regions in the concentration and temperature space which demonstrate the coexistence of phases were obtained in [37, 101, 153]. In Section 8, an example of construction of the phase diagram, that is, the coexistence of phases for the system of GaN nanoislands, is considered.

Thus, in multicomponent systems the conditions of quasi-thermodynamic equilibrium are favorable to the distribution of the substance of components in a most advantageous way over phases and to the establishment of the regions of phase coexistence, while the action of the surface tension leads to a universal size distribution of islands of the existing phases. Notice that such a distribution is only possible for low component concentrations, when the law of mass action can be applied to the chemical reactions proceeding in the system.

We shall now turn to OR of solid-solution islands. Islands of such composition are mainly produced in the growth of films from melts which have a "cigar" type diagram of state (Fig. 3b). The theory of OR of islands growing from binary melts of this type was developed by a number of authors (see references in [23, 37, 157]). In particular, Voorhees [143, 144], independently of the authors of works [102, 103], described the ripening of new-phase nuclei in binary melts allowing for the fact that their growth is due to both the diffusion and the removal of the latent crystallization heat into the melt. Notice that the hypothesis of a non-isothermal OR was first suggested in [37, 157], where the system of equations governing the evolution of an ensemble of islands and determining the kinetic growth diagram was derived. In these papers it was also shown that generalized diffusion-thermal fields are induced in the course of OR in binary melts. Such fields result from crystallization heat removal during the growth of islands, which causes a temperature increase in the system. This leads in turn to a change of equilibrium concentrations and the diffusion coefficients of

atoms as well as to the appearance of an involved nonlinear relation between supersaturation and supercooling on the one hand, and the size distribution and the growth rate of islands on the other. The OR theory for islands growing from a eutectic melt (Fig. 3a) was formulated in [103]. It turned out that in the course of evolution of ensembles of nuclei growing from a eutectic solution-melt, the nucleus growth at the OR stage proceeds by the thermal OR mechanism [23, 37], that is, only due to a decrease of supercooling. The solution-melt supercooling becomes equal for islands of both components, and their critical sizes and the distribution functions appear to be interrelated and similar to each other. It has been established that among some substance constants (crystallization heat, surface tension), there hold simple relations allowing us to calculate the constants of one substance through those of the other.

7.2. Evolution of the Composition of Nanofilms

It is a well-known fact that the properties of films are mainly determined by their composition. It is precisely the composition that determines the majority of electrophysical, optical, strength, and other properties. To gain an insight into the evolution of film composition, so as to be able to control this composition during film growth, is one of the most important problems of thin-film physics. It was shown in [157] that at the OR stage the radius of solid-solution islands and their composition are in a one-to-one correspondence. Later, a rigorous theory describing the evolution of phase composition of ensembles of such islands at the OR stage was formulated in [159]. In particular, the composition distribution function of islands $\varphi(1/\chi_R, t)$ in the presence of substance sources with $0 \leq n < d/p$ has the form

$$\varphi(1/\chi_R, t) = N(t)\Delta(t)P_p(U) \tag{64}$$

The average film composition changes according to the law

$$\bar{\chi}(t) = \frac{2\sigma w \rho_{L0}(1+\gamma)}{k_B T (A_p^0 t)^{-1/p}} \tag{65}$$

Here σ is the specific interphase energy of the island-vapor boundary; ρ_{L0} is the equilibrium concentration of one of the components, for example, A (Fig. 3b) in the liquids line, that is, in the liquid or vapor phase; γ is the slope of the straight line joining the liquids and solidus lines (Fig. 3b).

7.3. Effect of Electromagnetic Radiation on the OR Stage

Electromagnetic radiation can markedly influence the evolution and nucleation of nanoparticles [160]. Influence of luminous radiation on the evolution of islands at the OR stage is studied in [161]. Here, we assume that a medium, where islands are present, is transparent and it does not absorb energy, whereas the islands absorb luminous radiation. In this case, the temperature of islands rises. The degree of heating of the islands is dependent on their size and thermal conductivity of the medium. As it is shown in [161], continuous influence of radiation leads to dissolution of islands.

The islands are dissolved due to increase of the equilibrium concentration in heating that causes supersaturation to fall. Under pulse action of the radiation on an island ensemble, evolution of the islands is substantially changed. It turned out that a certain critical size is established in such a system. In the case where a size of islands is less than the critical one, the islands are to dissolve, whereas in the case with a larger size they will grow. This fact makes it possible to control the size of islands efficiently, that is, to segregate the islands according to their size.

8. NUCLEATION AND EVOLUTION OF GaN NANOISLANDS

Processes of nucleation of GaN nanoislands prepared by the MBE and MOCVD methods are investigated in [87, 88]. The compound of GaN is a stoichiometric compound; therefore, analysis of nucleation processes is performed in parameters [87, 88] in the framework of the theory of island growth of stoichiometric compounds (see Eqs. (16)–(18)). The analysis shows that at the temperature of substrate (sapphire covered with a layer of AlN), $T = 480$ °C, the probability of nucleation of liquid Ga islands is higher than that of nucleation of islands of GaN compound. GaN particles are formed after the nucleation of islands of liquid Ga as a result of chemical reactions between gallium and nitrogen. At 750 °C $> T \geq 600$ °C, only GaN is nucleated. The physical cause for such behavior is following. Diffusion coefficients, lengths of diffusion jumps, and equilibrium concentrations of Ga and N included into the generalized coefficient of diffusion are highly dependent on the substrate temperature. At a low temperature, Ga atoms make a main contribution into diffusion mobility, therefore, the probability of nucleation of liquid GaN islands (at $T = 480$ °C gallium is present in a liquid phase) determined by formula (14) is higher than that of nucleation for islands of GaN compound estimated by expression (17). At higher temperatures, the mobility of N atoms, equilibrium concentration of Ga, rate of chemical reaction between gallium and nitrogen are increased. It leads to the fact that the probability of nucleation for islands of GaN compound becomes higher as compared to that of Ga nucleation. Mechanisms of growth for islands of GaN within the temperature range $T > 480$ °C and temperature conditions for a change in nanoisland growth mechanisms are described in [87, 88]. Dependencies of the nucleation rate and size distribution functions of nanoislands estimated by Eqs. (17) and (40)–(44) at the substrate temperature $T = 650$ °C are given in Figures 12 and 13. The OR of an ensemble of GaN nanoislands is examined in [88]. It proved that at the substrate temperature $T > 650$ °C, the process of OR of the ensemble is fairly subjected to the laws described by Eqs. (56)–(61) with subscript $p = 3$. Also, in [88] the kinetic phase diagram calculated by equations from [101] is plotted. The set of equations describing the phase diagram for GaN is of the form

$$Q_{0Ga} = \rho_{0Ga} + J^{Ga}$$
$$+ J^{GaN}$$
$$Q_{0N} = \rho_{0N} + J^{GaN}$$
Figure 12. Time dependence of the nucleation rate $I(t)$ GaN on the substrate surface at temperature $T = 650\,°C$. Reprinted with permission from [88], S. A. Kukushkin et al., *Fiz. Tverd. Tela*, 44, 2079 (2002) [*Phys. Solid State* 44, 1399 (2002)]. © 2002, S. A. Kukushkin, V. N. Bessolov, A. V. Osipov, and A. V. Luk'yanov.

$$(1 - \frac{1}{Q_{0N}}J^{GaN})(1 - \frac{1}{Q_{0Ga}}J^{GaN} - \frac{1}{Q_{0Ga}}J^{Ga}) = \frac{K_\infty^s}{Q_{0N}Q_{0Ga}}$$

$$\rho_{0Ga} = k^{Ga} \qquad (66)$$

where Q_{0N} and Q_{0Ga} are relative amounts of the total initial nitrogen and gallium on the substrate and in the new-phase nuclei at the start of the ripening stage; J^{Ga}, J^{GaN} are the total mass of the nuclei of liquid Ga and GaN at the end of the ripening stage; K_∞^s is the constant of GaN dissociation on the substrate surface; ρ_{0Ga} and ρ_{0N} are the equilibrium concentrations Ga and N on a substrate; k^{Ga} is a quantity equivalent to the chemical reaction constant for single-component substances. The GaN phase diagram calculated by Eq. (66) at three different temperatures is given in Figure 14.

9. NUCLEATION OF COHERENT NANOPARTICLES

The elastic energy released during the formation of nanoparticles coherently connected with matrix or substrate influences significantly the nucleation process [24, 98, 162–166]. This energy can lead to either the increase
Figure 13. Time dependence of the size distribution function, $f(R, t)$, where R is the radius of islands of GaN nuclei on the substrate surface at the nucleation stage at temperature $T = 650\,°C$. [1, 2, 4, 5, 14, 167–169] or the decrease [24, 98, 162, 163] of nucleation rate. In the process of formation of nanoparticles coherently connected with solid matrix, the formation work of nanoparticle increases by the value of an elastic energy which leads to the decrease of the nucleation rate. The elastic energy is the driving force of the nucleation process in case the nanoparticle forms on the surface of substrate from the elastically strained wetting layer. This particular process will be considered here in detail.

Let us start from the brief review of literature devoted to the analysis of growth of coherent nanoparticles. At present, the self-aligned Stranski–Krastanow growth of coherent semiconductor islands, which contain no lattice mismatch defects, is actively used for obtaining ordered structures with nanodimensional quantum dots (QDs) [1, 2]. The great interest in such structures is due to the prospects of their practical implementation in optoelectronics in relation to the localization of charge carriers in the vicinity of QDs [3]. In order to control the island shape during island growth, it is necessary to determine the driving force of nucleation. In Section 3 of this paper, we note that two principal mechanisms of nanofilm growth exist. According to the first mechanism described, the growth of nanoislands is due to a high density of adsorbed atoms on the wetting-layer surface. The islands grow in such a way by the Volmer–Weber mechanism, as a rule. In the case where there is close interaction between substrate and film materials in a film-substrate, the islands ought to grow due to the Stranski–Krastanow mechanism. In this case, the nonclassic nucleation from the atoms of the wetting layer itself proceeds under the effect of elastic energy [1, 2, 4, 5]. Thus, in the first case, the free energy

of the island decreases due to the difference in chemical potentials of the atoms in the two-dimensional adsorbate gas and in the island itself, whereas in the second case, the free energy decreases due to the difference between chemical potentials of the atoms in the wetting layer and in the island. Here, the chemical potential is determined by the difference between the elastic energy and the wetting energy. The island growth by the first mechanism occurs on a wetting layer of constant thickness. In the second case, the thickness of the wetting layer should decrease during the nucleation. The reason is that part of the atoms of the wetting layer transfer to islands in order to decrease an elastic energy [1]. A theory of growth of coherent nanoislands via the Stranski–Krastanow mechanism is outlined in [14, 96]. There, calculations and estimations are made taking the growth of Ge on (100) and (111) Si surfaces as an example. Experimental investigations to verify the extended theory are described in [96]. The Ge films were deposited by chemical vapor deposition in a vacuum chamber equipped with a spectroscopy ellipsometer and a mass-spectrometer. Digermane Ge_2H_6, which was diluted with pure He, was used as the precursor in the pressure range from 4 mbar. Depiction of coherent Ge islands on (100) surface of Si (see [96]) is given in Figure 15.

A growing-film model of the structure of Ge layers on Si surface used for ellipsometric measurements of the growth of Ge layers on (100) surface of Si (see [96]) is shown in Figure 16.

The following mechanism of the formation of coherent islands, which is based on our experimental data on the Ge on Si(100) growth, was considered in [96]. Initially, the layer-by-layer growth of the Ge film on the Si substrate occurs, since the Si surface energy is noticeably higher than the Ge surface energy, and wetting is favorable. However, Ge and Si have different lattice parameters, and the elastic energy increases with film growth (the elastic energy per atom is constant). The wetting energy per atom continuously decreases, since the Ge atoms are removed farther and farther apart from the substrate. At the instant when the elastic energy per atom is equalized to the wetting energy per atom for the upper atoms of the wetting layer, the layer itself is in equilibrium. However, the wetting layer continues to grow

Hess.

and becomes metastable, making it possible for the elastic energy to relax. One of the possible ways of relaxation is nuclei formation on the wetting-layer surface, since the higher clusters have a higher elastic energy compared with the lower clusters. This process sets in when the nucleation barrier becomes low enough. Due to this fact, the nuclei formed grow and reduce the elastic energy of the film, and the wetting layer becomes thinner, thus supplying the growing islands with atoms. After some time, the nucleation process will be completed, since a decrease in the wetting-layer thickness will lead to heightening of the nucleation barrier. As a result of the studies, the expression of free energy is derived. The free energy of the formation of the coherent island from the wetting layer is represented by three summands

$$F = \Delta F_{\text{surf}} - (\Delta F_{\text{elas}} - \Delta F_{\text{att}}) \qquad (67)$$

Here, ΔF_{surf} is the increase in the surface energy due to the formation of an additional surface of the film material, ΔF_{elas} is the decrease in the free energy due to the elastic energy relaxation within the island, and ΔF_{att} is the increase in the free energy due to weakening of the attraction (wetting) of the island atoms to the substrate. It is evident that the energy parenthesized in relationship (67) is the only driving force of this nucleation process. Each of the three quantities in relationship (67) depends not only on the number of atoms in the island but also on its shape. This is the distinction of this model from the theory of nucleation of incoherent islands. To calculate the ΔF_{surf}, ΔF_{elas}, ΔF_{att} quantities, the simplest island configuration is used. Specifically, we assume that a cuboid-shaped island with a square base L and height H lies on the wetting strained layer with a height h. For such an island configuration with two parameters L and H, all results are obtained in the analytical form. Calculations from [96] show that the coherent form of free energy (67) is as follows:

$$\frac{F(i, \beta, \xi)}{k_B T} = ai^{2/3}\beta^{1/3} + b\frac{i}{\beta} - c\xi i \qquad (68)$$

Here k_B is the Boltzmann constant, T is the temperature,

$$a = \frac{4\sigma_f (h_0 l_0^2)^{2/3}}{k_B T}, \qquad b = \frac{\varkappa}{6\pi}\frac{h_0}{l_0}, \qquad c = \varkappa\gamma \qquad (69)$$

$\varkappa = \lambda \varepsilon_0^2 h_0 l_0^2 / k_B T$ is the elastic-to-thermal energy ratio, $\gamma = \ln(\Phi_\infty / \lambda \varepsilon_0^2 h_0)$ is the constant characterizing the wetting-to-elastic force ratio, h_0 is the height of the monolayer film, l_0 is the average interatomic distance in the same layer, $\gamma = \ln(\Phi_\infty / \lambda \varepsilon_0^2 h_0)$ is the lattice mismatch between the film and a substrate, d_f is the lattice parameter for the film, d_s is the lattice parameter for the substrate, λ is the elastic modulus, and $\Phi_\infty = \sigma_s - \sigma_f - \sigma_{s\text{-}f}$, the surface tensions of the substrate, film, and interface between them. The expression derived for the free energy of a coherent nanoisland allows to describe the whole process of nucleation of the islands. Thus, the equations of nucleation rate, elastic energy relaxation rate time-density relations for the islands, and evolution laws of the thickness of a wetting layer in time were obtained.

Theoretical and experimental dependencies of the wetting layer thickness and the total Ge amount in the islands measured in monolayer units in relation to the depositions time are given in Figure 17.

As for theoretical time dependencies between the nucleation rate and surface concentration of Ge islands on (100) surface of Si, they are shown in Figure 18.

A model of self-limiting growth of coherent islands is constructed in [14]. It is shown that in the case where there is a barrier for addition of atoms on the boundary of an island and the barrier is dependent on the island size, the process of secondary nucleation is probable there. Accordingly, the size distribution function of nuclei becomes binodal. This is substantially different from the size distribution function of incoherent nanoislands, which has only one maximum in all cases. Dependencies of the nucleation rate-size distribution functions of coherent Ge islands on (100) surface of Si with the barrier for addition of atoms on the island boundary can be found in [14].
Figure 18. Time dependencies of the main characteristics of nanoislands nucleation Ge of surface Si (100), at $T = 550°C$. Reprinted with permission from [96], S. A. Kukushkin, et al., *Fiz. Tekh. 10. CONCLUSION

We have presented all the basic modern theoretical concepts describing both the nucleation of nanoparticles and the further evolution of nanoparticles. Our presentation was based on the general theory of the first-order phase transitions. This provides a general approach allowing a unified standpoint in the investigation of processes on the substrate surface and in the surrounding volume upon nanofilms deposition from the gaseous, liquid, amorphous, and solid phases. Due to application of the generalized approach, we could investigate the influence of various factors on nucleation of nanoparticles. In this review, we considered the effects of the free energy arising between substrates and nanoparticles, composition of an environment, temperature, electromagnetic radiation, and acidity of a medium upon the processes of nanoparticle nucleation. It was shown that application of the field approach to investigation of nucleation of nanoparticles allows to calculate the structure of an interface and dependence of surface tension upon the size of a nanoparticle. It should be mentioned that experimental studies are beyond the scope of this review, because the authors do not rank themselves as skilled experimenters. At present, there is a great deal of technical literature, where experimental plants and techniques for preparation of nanostructures are described, and for details the readers can address the literature.

Figure 17. Theoretical and experimental dependencies of the wetting layer thickness and the total Ge amount in the islands measured in monolayer units versus the deposition time for the Si (100). Reprinted with permission from [96], S. A. Kukushkin, et al., *Fiz. Tekh. Poluprov.* 36, 1177 (2002). [*Semiconductors*, 36, 1097 (2002)]. © 2002, S. A. Kukushkin, A. V. Osipov, F. Schmitt, and P. Hess.

The authors hope that the present publication will help the reader to gain insight into these processes and to better and more quickly comprehend the range of questions described.

GLOSSARY

Coalescence Interaction of nuclei of the new phase in the case of their direct contact. In the course of such a process the junction of nuclei in one particle can be realized.

Heterogeneous fluctuations Fluctuations of atoms or molecules in the volume of an old phase leading to the formation of the nuclei of the new phase.

Nucleation Formation of the nuclei of the new phase in the process of first-order phase transition.

Nucleation rate Number of the nuclei of the new phase formed in the unit volume (or on the unit surface) of an old phase per time unit during the process of phase transition.

Nuclei of the critical size Nuclei of the new phase which are in equilibrium with the initial phase under given supersaturation.

Ostwald ripening The late stage of first-order phase transitions on which the interaction of nuclei of the new phase with each other takes place by means of generalized diffusion, heat or another field. During such a process the bigger nuclei grow at the expense of the smaller ones.

pH The quantity characterizing the acidity of liquid media. *pH* is expressed by means of minus of the decimal logarithm of the concentration of hydrogen ions in a fluid (environment).

Spinodal curve The bounding curve of an area where phase is absolutely unstable with respect to arbitrarily small fluctuations.

Spinodal decomposition Non-barrier phase transition in the unstable (spinodal) region, that occurs by increasing of long-wave heterophase fluctuations.

CONTENTS

1. OVERVIEW

Bionanotechnology is an emerging field with great promise in molecular science. The field is so new that it has yet to be formally defined. However, it can be characterized as a primitive technology that takes advantage of the properties of highly evolved natural products like nucleic acids and proteins by attempting to harness them to achieve new and useful functionalities on the nanoscale.

It is appropriate to compare bionanotechnology to the technology of the paleolithic in which natural products like wood and stone were shaped into implements and devices. Much like the paleolithic technologists who used knowledge of their surroundings to identify components and processes used in tool-making, modern bionanotechnologists use knowledge of chemistry, biochemistry, and molecular biology to identify components and processes for the construction of self-assembling materials and devices. Paleolithic technology was limited by the basic properties of natural products like wood and stone. Wood and stone could be shaped and modified, but they could not be forced into the arbitrary *de novo* designs that can be attained with our modern understanding of wood composites and ceramics. In a like fashion, bionanotechnology is limited by the basic properties of biomolecules. The field will certainly mature in the near future, but this maturation will require, among other things, advances in our understanding of the nature of nucleic acid and protein folding so that arbitrary *de novo* design of such molecules can be contemplated.

Like other forms of nanotechnology, bionanotechnology seeks to define approaches to the fabrication of useful materials and devices. However, the construction principles utilized in the field often originate in biology and the goals are often biomemetic (e.g., the construction of biosensors [1]) or aimed at the solution of long-standing research problems (e.g., protein crystallization [2]. Nonbiological problems have also been approached in attempts at the construction of electronic circuitry using biomolecules [3] and the construction of a fuelled nanomechanical oscillator [4] and a nanomechanical switch [5]. At the heart of these approaches is the concept of self-assembly. Self-assembly of ordered elements is a defining property of living things. Moreover, the progressive increase in the complexity of the processes used by living things in self-assembly is a defining property of evolution. During the roughly 4.2 billion years of prebiotic and Darwinian evolution that have taken place on earth, an almost incomprehensible variety of molecular structures, functionalities, and associations have appeared. This evolutionary experience is stored in modern living systems. For this reason, modern living systems comprise a wealth of addressable macromolecular components. Of these, the nucleic acids and proteins are the most easily manipulated and the best understood. Thus, it is not surprising that they have been the first to be exploited to produce nucleoprotein-based addressing systems in nanobiotechnology [6–11] that attempt to exploit self-assembly and ordered proximity.

1.1. Creation of Biomolecular Machines by Directed Evolution

A machine is usually defined anthropomorphically as a device having a purpose [12]. A more general definition is as an assemblage of parts that transmit forces, motion, and energy one to another in a predetermined manner [13]. Such definitions are meant to encompass the spectrum of machines from the simple lever and wedge to the most complex networks of automata. In biology this definition encompasses an even broader spectrum of entities from the simplest biomolecular catalysts to the planetary biosphere. The central thesis in modern biology has been that the planetary biosphere arose spontaneously. Consequently an enormous amount of scientific research has been focused on

understanding how the earth underwent a transformation from an apparently lifeless state to the biosphere that it has now become.

A significant body of knowledge in support of this spontaneous transformation has now been accumulated in the field of prebiotic chemistry. This body of knowledge suggests pathways for the spontaneous production of each of the components of nucleic acids and proteins from conditions likely to have been present on the primitive earth [14, 15]. Most of this work has been aimed at constructing plausible routes to self-assembling chemical systems that would become subject to Darwinian natural selection. Working backward from apparent molecular fossils, the stated goal of these studies is to plausibly order the events that occurred on the prebiotic earth that gave rise to Darwinian evolution [16, 17].

The discovery of unifying principles in this area has been stimulated enormously by the discovery that nucleic acids themselves can serve as catalysts and must therefore be listed with peptides and proteins as the raw materials of simple biomachines. The current hypothesis is that the early stages of prebiotic evolution generated a series of supramolecular aggregates composed largely of RNA. These aggregates, sometimes termed metabolosomes [18], are postulated to have attained a high degree of complexity permitting them to carry out a complex series of chemical transformations. The level of complexity at which evolution by natural selection could take hold has been called the Darwinian threshold [17]. It is thought that the entity that crossed this threshold was a supramolecular aggregate that possessed the capacity for self-assembly, self-replication, and perhaps translation (i.e., the capacity to convert information stored in ribonucleic acid sequences into protein sequences [17]).

In efforts designed to recreate the basic designs for the postulated primitive nucleic acid machines, simple laboratory procedures for their construction have been developed using the principles of directed evolution *in vitro* [19–24]. Generally these techniques involve the production of a pool or library of nucleic acid sequences that are subjected to a selection process involving binding or catalysis. Those members of the library that can perform the binding or catalytic task dictated by the selection criterion are retained by the selective process. Initially, this represents only a tiny fraction of the initial library. This fraction is copied so as to increase the total number of copies of the selected species. After repeating this process many times, the resulting pool is thus reduced in complexity to a few representative molecules having the desired properties.

1.1.1. Aptamers

Aptamers represent perhaps the simplest class of molecular machine that has been produced by using bionanotechnology. The word aptamer is derived from the Greek word "aptus" meaning to fit, in this case, a molecule adapted to fit into another molecule. Under the first definition above [12], aptamers represent a class of molecular machine that can be considered to be devices having a specified purpose: binding to a ligand. Ligands that have been bound include organic dyes [23], proteins [25], other small molecules [26], and

other nucleic acids [27]. Aptamers have been produced from both DNA [25] and RNA [23]. Although most aptamers are essentially static machines, in the sense that a wedge is a static machine, more recently aptamers have been produced that exhibit behavior that can be regulated by a small molecule [28]. This suggests that the ligand either modifies the structure of the aptamer so that it fits into its target site properly or that the ligand forms part of a complex complementary to the targeted binding site. In short certain aptamers may be dynamic machines since they appear to move in order to bind.

1.1.2. Ribozymes

It is a short step from binding to catalysis because biological catalysts are selected so as to bind to and thereby stabilize transition states in a given reaction pathway. This property of catalytic biomolecules allows them to drive many organic reactions at ambient temperatures with reasonable efficiencies. RNAs with these properties are readily isolated by directed *in vitro* evolution techniques. *In vitro* selected ribozymes exhibit rate enhancements ranging from 10^3 to 10^5 over the uncatalyzed reactions. RNAs that have been isolated by these methods include those that catalyze carbon–carbon bond formation in a Diels–Alder reaction [29], phosphate bond cleavage in cleaving single-stranded DNA [22], phosphate bond formation during RNA polymerization [30], RNA ligation [31], carbon–nitrogen bond formation during self-alkylation [32], and carboxyl attack on phosphorous during amino acid activation.

1.1.3. Deoxyribozymes

Most secondary structure in nucleic acids involves hydrogen bonding. Since DNA lacks the $2'$ hydroxyl group on ribose that is present in RNA, it possesses a reduced potential for hydrogen bond formation and was initially thought to be less suitable for *in vitro* selection of aptamers and catalytic nucleic acids because it cannot adopt as many secondary structures as RNA (i.e., its conformation space [33] is restricted relative to RNA). This initial concern notwithstanding, catalytic DNAs of many types have also been selected by directed *in vitro* evolution. Porphyrin metallation [34], peroxidase activity [35], phosphoesterase activity [36], and DNA degrading activity [37] have all been documented, suggesting that the collection of accessible deoxyribozymes may be nearly as extensive as the collection of ribozymes.

1.1.4. Enzymes

Biologically occurring deoxyribozymes have not yet been observed. Biologically occurring ribozymes are rare, but several are known to exist. Catalytic proteins (enzymes), on the other hand, are the overwhelmingly predominant catalytic molecules in living things, with many thousands of different forms present in the average mammal, for example. Thus, by any measure, the collection of biologically occurring catalytic proteins (enzymes) is currently much larger than the collection of known catalytic nucleic acids since it encompasses the vast majority of the aggregate number of gene products contained in all species now present on earth. Even so, directed evolution techniques have been applied to the

development of new enzymes. Here, the methods are generally based on the selection of whole bacteria. In this process the bacteria develop previously unknown catalytic functions by recruiting proteins that are normally expressed in the bacteria for other purposes through a process of mutation and selection [38, 39]. For example, bacteria that are normally unable to use a certain sugar for growth are exposed to a DNA damaging agent that introduces random changes (mutations) in the genetic code of the organism. Most of these changes are deleterious and either cause the bacteria to die or grow more slowly than it would in its natural growth medium. However, if the mutated bacteria are forced to grow on the sugar that they are normally unable to use, a small fraction of them (perhaps 1 in 10^8) will be able to use the sugar in question for slow growth. Subsequent rounds of this mutagenesis and selection process yield new enzyme functionalities associated with absorbing and breaking down the sugar in question. Such *de novo* protein development completes the spectrum of currently known techniques for the *de novo* development of nanoscale components available for nanobioscience and nanobiotechnology.

Each of these *de novo* methods takes advantage of the almost incomprehensible conformation spaces available to proteins, RNAs and DNAs [33] as noted above. Given the hydrogen bonding capacities of each polymer and the number of commonly observed monomeric building blocks (4 each for nucleic acids and 20 for proteins), the number of available conformations is canonically ordered as follows: protein $\gg$ RNA > DNA when each oligomer contains the same number of monomers. It is worth noting that even the conformations available to the most restricted system (the DNAs) is 4^n (where n = sequence length in nucleotides) assuming only one conformation per sequence. It is clear that the vast collection of shapes available to oligmers of modest length ($n > 20$) offers an almost inexhaustible wealth of potential devices available for nanoscale assembly.

1.2. Modification of Existing Biomolecular Machines

Directed evolution has provided a productive route to the *de novo* selection of new nanoscale machines; however, with proteins, it has often been simpler to modify existing molecules for purposes related to their current function. This makes recombinant DNA technology among the most powerful tools in bionanotechnology. Recombinant DNA technology is generally used to place desired proteins under the control of specific DNA sequences, called promoters, that permit the production of large quantities of the desired material. This is generally coupled with the second tool, site-directed mutagenesis, which allows the modification of the protein itself. In site-directed mutagenesis, recombinant DNA techniques from molecular biology are used to alter the genetic code so as to modify the amino acid sequence of the protein. The resulting proteins have generally been redesigned so as to suit a particular application. In general these alterations improve stability or functionality of the protein in a given application.

These techniques have been used to optimize [40, 41] the capacity of the light harvesting protein bacteriorhodopsin to

cycle between two stable photochemical states so as to permit the construction of a three-dimensional memory device. In this device the modified protein is first immobilized in a matrix. A paging laser at 570–630 nm is used to cycle the engineered bacteriorodopsin from an all-*trans* state through a series of 13-*cis* retinal states to a light-adapted protonated all-*trans* retinal state. A full power write laser at 680 nm acting orthogonally through an active matrix liquid crystal light modulator is then used to convert volume elements of the protein-containing matrix from the light adapted all-*trans* retinal isomer to the 9-*cis* isomer to set the state of engineered protein in the matrix, thus creating a three-dimensional (3D) (volumetric) information storage pattern. The 570–630 nm paging laser is coupled with the 680 nm laser at low power to read the information by projecting the stored data onto a charge-coupled device. Bacteriorhodopsin is stable in this state and data stored in this manner are stable for decades in the absence of blue light or high temperatures. Erasure is accomplished with a 410–430 nm diode-pumped laser that converts the 9-*cis* to one of the all-*trans* states.

This working system integrates bionanotechnology (protein engineering and 3D immobilization techniques) with laser based input–output (IO) technology to achieve a storage device that is resistant to the high levels of radiation and shock required for satellite communications, while achieving a 1000-fold improvement in memory storage capacity over currently operational devices. The ultimate goal of bionanotechnology is to create devices based on biomolecules that achieve the even greater degree of complexity and miniaturization exhibited by living things.

2. SUPRAMOLECULAR ASSEMBLIES

A key step in the origin of life appears to have been the origin of translation [17, 18]. Translation is the process by which RNA sequence information is copied into peptide or protein sequence information. In general, this is assumed to have occurred at a time in prebiotic evolution when catalytic RNAs provided the only mechanism by which metabolic interconversion of chemical compounds could be accomplished. The appearance of translation is thought to have moved evolution to a new plane in which supramolecular aggregates (SMAs) appeared that had crossed the Darwinian threshold (i.e., the point at which the complexity of the aggregate permitted replication, self-assembly, and natural selection). This transition is thought to have been achieved by incorporating information storage and feedback to the storage mechanisms [17].

The modern ribosome is generally considered to be a molecular fossil representing a highly refined version of one of the key components of these supramolecular aggregates or SMAs. The more primitive SMAs that gave rise to them are generally thought of as metabolosomes in which nucleic acid scaffolds of RNA called organizing centers held catalytic RNAs in place by base-pairing between a short region of the nucleic acid scaffold and a short region of the catalytic RNA [18]. In this model, the alignment of sequestered catalytic RNAs was set by the sequence of the complementary RNA in the organizing center. This alignment and proximity is thought to have facilitated sequential reactions in the

metabolosome. The linear arrangement along the organizing center is thought to have been translated into the linear arrangement of amino acids, thus promoting the formation of peptides by ordering condensation reactions through appropriate juxtaposition of the amino acid adapters composed of RNAs. It is thought that these adapters ultimately evolved into modern transfer RNAs or tRNAs and that they continue to serve this purpose in modern living things. Bionanotechnological approaches to the construction of supramolecular aggregates have adapted many of these biological principles.

2.1. Creation of SMAs Using Base-Pairing in Complementary Nucleic Acids

Several nucleic acid scaffolds have been constructed using DNA complementarity. These scaffolds are assembled by annealing complementary DNAs followed by enzymatic ligation, or splicing, of the subsections of a larger entity. The scaffolds are defined by their connectivity. A cage having the edge connectivity of a cube [42] has been characterized, as well as a system with the connectivity of Borromean rings [43], the connectivity of a truncated octahedron [44], and the connectivity of a 2D lattice [45]. Thus, the topology available for the construction of supramolecular aggregates is quite elaborate. This topology has been used in the construction of a two-state switch that is actuated by changes in salt concentration [5] and in the construction of a DNA-fuelled oscillator [4] that is activated by the addition of oligodeoxynucleotides.

The two-state switch is based in the well-known transition of DNA from the right-handed B-form double helix seen at low salt to the left-handed Z-form double helix seen at high salt. In Z-DNA the phosphate backbone zigzags around the stacked base pairs instead of winding smoothly around them in a helical pattern as it does in B-form DNA [5]. This conformational change twists the DNA from the right- to the left-handed form, and it is favored by sequences that are rich in guanine–cytosine base pairs. Interestingly, it was found that a double-crossover molecule could be made to stabilize two duplex strands of DNA into a side by side arrangement that appears to remain in the B-form at high salt. Double-crossover is a term from genetics used to explain genetic exchanges that often occur during the DNA-strand exchanges that characterize recombination in biology. Physically a system of this type comprises four strands of DNA intertwined so that two of the strands cross over from one of the double helices to the other and back again so as to constrain them to lie side by side. This rigid system resists conformational change as salt concentration is altered. When two double-crossover systems are connected by a short double-stranded region that is rich in guanine–cytosine base pairs, the two double-crossover regions at either end of the double-stranded region can be made to lie on the same side of the double-stranded region at low salt and on opposite sides of the region after the B to Z transition induced by high salt. Resonant intramolecular energy transfer from chromophores placed at the ends of the double-crossover strands that lie near the linking region can be used to detect the change in proximity induced by the

increase in salt concentration. In effect, the system becomes a biosensor that can detect changes in salt concentration [5].

The DNA-fuelled oscillator likewise induces nanomechanical motion in a supramolecular assembly formed from DNA [4]. Here again, resonant intramolecular energy transfer is used to detect the close approach of two chromophores during the formation of a duplex waste product from the sequential addition of two complementary fuel strands. The system essentially makes use of strand displacement in DNA. Here a chromophore and a fluorescence quencher are placed at each end of a short DNA strand during synthesis. This short strand is hybridized (annealed) to two strands that are complementary to the ends of the chromophore-containing strand, extend beyond the ends by several nucleotides, but do not cover the central nucleotides of the chromophore-bearing strand. In this state the duplex DNA region is extended by the stiff stacking interactions along the Z-axes of the two duplex regions, thus maintaining the ends of the strand containing the chromophore and the fluorescence quencher at a distance adequate to prevent quenching of the fluorescent signal. Once this state is achieved, a closing fuel strand is added that is complementary to the unpaired ends of each of the previously added strands but is longer than one of them so as to leave another unpaired region. Once annealed, this strand forces the chromophore-containing strand into a hairpinlike conformation that juxtaposes the chromophore and the quencher, extinguishing the fluorescence signal by resonant intramolecular energy transfer. The system remains in this conformation until an opening fuel strand is added that is completely complementary to the closing fuel strand added previously. Annealing between the two fuel strands begins at the short unpaired region and continues by strand displacement until the opening fuel strand that maintains the chromophore containing strand in the hairpin conformation is stripped away to relax the system and permit fluorescence to reappear [4].

2.2. Creation of SMAs Using Complementary Protein Domains

Multisubunit proteins can exhibit a form of complementarity between subunits that results in self-assembly of defined multimolecular protein aggregates. Protein–protein interaction is not easily predicted, as can be anticipated from the increased complexity intermolecular interactions possible between the 20 common amino acids compared to that of the 5 common bases that comprise the nucleic acids. However, as the number of known 3D protein structures has increased it has become possible to catalog numerous interactions between internal protein domains that can be reproduced with synthetic peptides. For example, the SH2 and SH3 domains of the Src tyrosine kinases are known to interact with phosphotyrosine and proline rich motifs to form internal associations that influence kinase activity. SH3 and SH2 are well characterized examples of protein domains whose natural folds are spontaneously adopted by recombinant peptides containing the native peptide sequence [46, 47]. Each isolated domain retains its affinity for phophotryosine (SH2) or proline rich peptides (SH3)

that interact with these domains to form complex associations involving the Src kinases.

In general, domain–domain interactions also govern the spontaneous association of multisubunit proteins. Dimeric proteins often associated with DNA-binding proteins [48] represent the simplest examples of these aggregates. In addition, the multimeric assemblies that form viral capsids [49] provide examples of the complexity that is achieved in biology with simple interactions of this type. The symmetry rules that govern the self-assembly of these subunits into complex multimers are well known [49, 50].

These advances in the understanding of protein domain structure have allowed the construction of fusion proteins (i.e., chimeric proteins constructed by recombinant DNA techniques that fuse disparate functional domains in to a single unit) with predictable subunit–subunit complementarity that have been used in the formation of a closed tetrahedron protein cage and an extended protein filament [51]. The closed protein cage was designed by searching a protein database for dimeric and trimeric protein structures that begin or end in an alpha helix. Molecular modeling was than used in computer-aided design of a fusion between domains thus identified. Once models were constructed, they were examined to determine whether or not they possessed appropriate symmetry for self-assembly into a closed geometric figure. One fusion between the trimeric bromoperoxidase of *Streptomyces aureofaciens* and the dimeric M1 matrix protein of the influenza virus was shown to be capable of the formation of a tetrahedral cage by molecular modeling. Molecular cloning techniques were used to express the designed fusion protein in *E. coli*. The purified fusion protein was shown to form the expected tetrahedral cage based on sedimentation velocity, light scattering, and electron microscopy experiments. Similar methods permitted the construction of an extended filament [51].

Biomolecular motors are also potential components of a variety of protein containing devices that have obvious potential in structuring or redirecting flow and mixing in nanofluidic systems. The F1-adenosine triphosphate synthase (F1-ATPase) provides a well-studied example of a molecular motor. It is also a naturally occurring supramolecular protein aggregate, comprising three alpha, three beta, and one gamma protein subunits. It is effectively a three-point stepper motor that generates ATP from ADP and inorganic phosphate by using rapid sequential conformational changes driven by a proton gradient. The conformational changes associated with the stepwise rotation of the protein rotor (i.e., the gamma subunit) between the surrounding sets of alpha and beta subunits cause the enzyme to catalyze the formation of ATP. This mechanism of action was deduced through studies of the biochemical kinetics of the system [52]. It was later supported by 3D structure determination [53] and unequivocally demonstrated by chemical means [54] and by direct real-time observation [55, 56] of the reverse reaction in which ATP is hydrolyzed. These advances in understanding of the system have permitted it to be modified using site-directed mutagenesis so that it could be mounted on an engineered substrate in order for it to be able to produce controlled rotation of synthetic arms. Rotation can be initiated by the addition of one compound (2 mM adenosine triphosphate) and halted by the addition

of another compound (sodium azide). With further protein modification, rotation could be halted by the addition of the metal ion Zn^{2+} and reinitiated by the addition of the metal ion chelator EDTA. In short, the rotation of this modified machine can now be controlled by changing its chemical environment [57–59].

2.3. Addressable Supramolecular Assemblies Based on Nucleic Acid Complementarity

As noted above the key feature postulated for metabolosomes is the ability of the nucleic acid scaffolds that formed the organizing centers to sequester and align nucleic acid adapters. Base-pairing between a short region of the nucleic acid scaffold and a short region of the adapter is thought to have generated the appropriate alignment of the adapters [18]. This concept has also been employed in several applications in bionanotechnology. See Figure 1.

For example gold nanoparticles can be linked to DNA by attaching alkanethiol groups to the ends of single-stranded DNA molecules [10, 11]. When the modified DNAs are
Figure 1. Addressable nucleoprotein assemblies. (a) Molecular addressing using nucleic acid complementarity. Here the central duplex is formed either by DNA • DNA interaction or by DNA • RNA interaction along a DNA or RNA organizing molecule. Short tethers of DNA are used to link thermostable moieties to which other molecules can be attached (e.g., gold or streptavadin molecules) indicated by the spheres [6, 11]. (b) Molecular addressing using protein–nucleic acid interaction. Here the central duplex contains 5FdC residues that form covalent complexes with DNA (cytosine-5) methyltransferase fusion proteins as they catalyze methylation of the DNA target. The fusion proteins are ordered along the DNA sequence based on the biospecificities of the cytosine methyltransferses of which more than 40 are known [8]. Each fusion protein can carry a different functionality indicated by the irregular shapes attached to each sphere. (c) Molecular addressing to a lattice. In this proposal [70] a lattice of DNA is ligated together so as to serve as a host for guest molecules (ovoid shaped objects). The purpose of this proposal is to drive crystallization so as to facilitate 3D structure determination. (d) Molecular addressing of silicon objects to a patterned DNA surface. In this proposal, DNA is patterned onto a surface (depicted here as a checkerboard). Silicon objects bearing complementary DNA strands on one of their surfaces are moved into the vicinity of their complementary strands on the surface pattern where they should attach biospecifically [9]. The attached object is linked to the DNA strands on the front left of the surface. Noncomplementary DNA states at the right rear of the surface are ignored.

exposed to a gold surface they adsorb by forming covalent bonds between the gold and sulfur atoms. Like other metal sulfur bonds the Au–S bond is very strong and can easily link a long DNA molecule tightly to the surface of the gold particle. The sequences of the attached DNA molecules can be chosen so as to be complementary to a linker strand. This permits the nanoparticles to spontaneously self-assemble into aggregates when mixed with the linker strand [10]. If they are complementary to a linear DNA strand, then they can be tethered to duplex DNA in an ordered fashion [11] around the screw axis of the B-DNA molecule (36°/base-pair). This approach can also be used to order the thermostable-protein streptavadin along the screw axis of a DNA helix [6]. Here biotinylated DNA is allowed to interact with streptavadin prior to nucleic acid hybridization. The steptavadin protein binds to the end of the DNA due to the innate capacity of streptavadin to bind extremely tightly to biotin. A DNA or an RNA organizing molecule is then used to sequester and align the tethered streptavadin molecules [6] much as originally envisioned by Gibson and Lamond [18] for the metabolosome. When DNA is used as the organizing molecule the streptavadin moieties should be arrayed in accordance with the screw axis of the B-DNA molecule (36°/base-pair). When RNA is used this orientation is expected to be in accordance with the screw axis of the RNA•DNA hybrid (30°/base-pair).

Both the gold and the streptavadin aggregates provide the opportunity for secondary assembly via the gold or streptavadin moiety. For example, the streptavidin molecule binds biotin with a stoichiometry of four biotin residues per protein moiety, leaving three unused sites on the DNA–streptavadin conjugate. These unused sites have been used to attach biotinylated antibodies to DNA-tethered streptavadin [6]. This permits the derivatization of microstructured surface arrays of DNA using the base-pairing complementarity of the array so as to convert it to a protein array of different antigen specificities [6]. Further, by adding biotin to both of the 5′ ends of complementary oligdeoxynucleotides it has been possible to form ring structures or networks of DNA linked by two, three, or four biotin contacts per streptavadin residue [60].

Biotinylated proteins can be linked to streptavadin and then targeted to DNA or RNA organizing molecules. Although high-fidelity annealing is generally only achieved at temperatures above 50 °C, annealing with bound proteins can be carried out at room temperature [61]. Alternatively, biotinylated proteins can be sequestered without regard to order along an organizing DNA or RNA molecule by incubating them at low temperature with streptavadin molecules tethered to DNA or RNA [62].

Using these methods, the effects of protein proximity have also been studied with this system. Here, the NAD(P)H/FMN oxidoreductase was placed adjacent to luciferase in order to improve the properties of light emission by the system that is normally coupled by these enzymes in their soluble form. Chemical biotinylation of proteins is not regioselective and can damage proteins. To avoid this problem, fusion proteins were prepared that contained a biotin acceptor region from the *E. coli* biotin carboxy carrier protein. This served as a biospecific attachment site for *E. coli* biotin ligase for the regiospecific attachment of biotin

to the luciferase and to the NAD(P)H/FMN oxidoreductase. Streptavadin-containing adapters were attached to the fusion proteins and annealed to a DNA-linker strand that linked the two enzymes either to the same or to different strands. The SMAs thus created were then deposited on a microplate surface again through a streptavadin–biotin linkage to the end of the carrier strand. A 2.0- to 2.5-fold rate enhancement was observed when the proteins were adjacent on a linear DNA compared to randomly placed on a surface [61].

Each of these systems results in a free (often soluble) nanoscale assembly. On a larger scale DNA sequences can be manipulated by electrophoresis in ways that immobilize them on the micro- and submicroscale [63]. Such arrays become templates for addressing silicon and gold components [9] as well as biotin linked antibodies and proteins [6, 61, 62].

2.4. Addressable Supramolecular Assembly Based on Protein-DNA Specificity

The feasibility of an approach to addressable self-assembly that enables the construction of ordered assemblies and devices has also been described [7, 8, 64–66]. The principal advance brought about by this work is the ability to place fusion proteins in preselected positions on a DNA scaffold under conditions that do not denature sensitive protein components. The protein–nucleic acid structures self-assemble at 5FdC [7, 8, 64] or dU substituted [66] recognition sites. Order is specified during the synthesis of the DNA by placing DNA methyltransferase recognition sites along the DNA. Two- and three-address assemblies are obtained in good yield [65], and fusion proteins have been constructed and targeted to preselected sites on linear [8] or branched targets [67].

One advantage of fusion protein-targeting over streptavadin protein-tethering is that a covalent linkage is established between the cytosine methyltransferase and the DNA that is heat stable. Thus, an array of ordered fusion proteins that might find application in a thermal cycling system could be constructed by this method without difficulty, whereas the streptavadin system would break down under repeated thermocycling not only at the level of nucleic acid but also at the streptavadin–biotin linkage. With the tethering system, one could imagine ligating the tethers in place after assembly had taken place at lower temperatures. However, streric problems would reduce yields in many cases and ligation would not solve the problems associated with the biotin–streptavadin linkage in this application.

An advantage of tethered assemblies like those ordered by streptavadin conjugation is that the length of the tether can be varied in order to accommodate proteins or other elements of unknown dimensions by trial and error. On the other hand, the use of methyltransferase fusion proteins in ordering elements on DNA or elements that contain DNA requires considerable effort in computer-aided design. This is because the structural imperatives that are imposed by such assemblies must be anticipated, insofar as is possible. As noted above for the construction of SMAs from fusion proteins [51] extensive use of the 3D structures of proteins

available in protein databases is made [7, 8, 64, 66] in developing potential fusions and SMAs based on this method. Once it is determined that the proposed design can assemble spontaneously, it is important to test these predictions in several ways. Several interesting phenomena have surfaced in producing these assemblies.

For example, as DNA is added to either side of the four base-pair binding site in a linear DNA molecule, it has been shown that the rate of the coupling reaction between methyltransferases and the targeted 5-fluorocytosine residues increases in an apparently sigmoid fashion [8]. The initial inflection point in this reaction rate occurs at about 25 to 30 bp of total length for two unrelated bacterial cytosine methyltransferases (M•*Hha*I and M•*Msp*I). This was interpreted as the kinetic footprint of the enzymes (i.e., the minimum space required for unhindered approach by a methyltransferase to its targeted recognition sequence). However, the 3D structure of M•*Hha*I bound to DNA shows that it only physically covers about 13 bp of DNA [68], suggesting that it could be made to decorate DNA recognition sites that are closer then the 25 bp inferred from the kinetic experiments. This inference from the 3D structure turns out to have been correct, since three-point assembly along a linear molecule has been achieved with center to center placements as close as 17 bp [65].

3. DESIGNS

Although a considerable number of technical and structural feats have been achieved in bionanotechnology, an even larger number of designs for devices and assemblies based on addressable assembly have been proposed. See Table 1. Of these, many continue to be biomemetic with antecedents in prebiotic evolution. Proposals for macromolecular carcerands [69] and host–guest systems [70, 71] containing DNA form an important set of examples, since the protective nature of these assemblies touches upon one of the long-standing problems in prebiotic evolution: understanding how DNA ultimately became intertwined with the postulated RNA world. Given the rules that have emerged defining the attributes of the entity that first crossed the Darwinian threshold, it would appear that DNA was not required for the initial evolution of primitive supramolecular aggregates or metabolosomes [17, 18]. Nevertheless, the best evidence suggests that DNA was recruited early on in the evolution of these SMAs [16].

Recent discoveries on the structure of the supramolecular aggregates present in the macronucleus in protozoans and the nucleolus in primitive eukaryotes suggest that these structures may make use of the cohesive ends of DNA produced by telomerase. Telomerase is a molecular fossil with a structure resembling that of a ribosome, in that it comprises several proteins assembled on a functional RNA. In this case, however, one of the protein moieties serves to complement the RNA moiety in such a way that the supramolecular assembly becomes a primitive reverse transcriptase capable of generating short (often hexameric) DNA repeats that are capable of forming strong associations based primarily on hoogsteen pairing between guanine residues. Many of these associations can survive even in boiling water and

Table 1.

Concept	Proposed	Achieved
DNA array addressing		[63]
DNA-adapter-linked protein ordering on linear DNA		[6]
Fusion protein ordering on linear DNA		[8]
Protein assembly on branched DNA		[67]
DNA-adapter-linked gold ordering on linear DNA		[11]
DNA directed gold particle aggregation to 2D lattice		[10]
DNA directed protein assembly on 3D lattice	[70]	
DNA directed silicon component addressing aggregation to 2D array	[9]	

thus can provide considerable integrity to a supramolecular structure. Moreover, in an RNA world, one can safely assume that competition between evolving supramolecular aggregates would involve the production of RNA degrading enzymes or ribozymes selected for their destructive power against competing metabolosomes. Thus, the evolution of a primitive ribonucleoprotein assemblage capable of generating a protective DNA cage or matrix that was impervious to RNA-degrading activities would offer an important selective advantage for such a system. In short, telomerase-like reverse transcriptases may have been both enveloped and protected by their DNA products in the distant past. This possibility is consistent with the association of the modern telomerases (as molecular fossils) with macronuclei [72, 73] and with the membraneless aggregate of nucleic acid and protein called the nucleolus [74, 75]. Of these the nucleoli of the lower eukaryotes (e.g., *D. Discodium* and *P. polycephalum*) [76, 77] may represent living molecular fossils that evoke the freestanding supramolecular aggregate postulated as the antecedent of modern living systems [16, 17]. The DNA contained in these nucleoli is a short linear element that ends in cohesive telomeric DNA and encodes the other important molecular fossil from the RNA world: the ribosomal RNA [77, 78]. As with other nucleoli these are membraneless structures that are enclosed in an apparently freestanding fashion by the nucleus. That DNA came to be associated with the RNA world in this fashion is also consistent with the findings of Ohno who pointed out that all modern genes appear to have evolved from iterated repetitive elements of the type produced by modern telomerases [79].

These systems form biomemetic models for nanoscale cages, carcerands, and extended 3D assemblies that can be constructed with the bionanotechnological tools for supramolecular assembly and addressing described above. The utility of such assemblies lies in their potential as devices that may some day acquire the complexity attributed to nanorobots that can be directed to perform complex tasks in a nanoscale environment [80]. Targeted drug delivery, selective cell destruction, selective cell remodeling, telemetered detection of cellular abnormalities [80], and the creation of new life forms [81] are often suggested as long-range goals for these technologies.

More immediate goals for these technologies revolve around their potential for contributing to understanding

biological molecules and their interactions. A key area here has been the desire to control solid state 3D assembly of macromolecules so as to permit structure determination by X-ray diffraction. To this end, designs for extended 3D crystals based on DNA cages with oriented guests [70, 71] have also been proposed in the hope that macromolecules that interact with DNA scaffolds could be forced to adopt regular crystalline arrays that would diffract to high resolution. These nucleic acid-based proposals are supplemented by proposals for the assembly of 3D crystals based on protein cages and extended structures [51]. As with the DNA technology described above, designs for cages and shells, double-layer rings, two-dimensional layers, and helical filaments have all been proposed based on the ordered assembly of protein domain fusions [51].

Designs for nucleoprotein cages have also been proposed [69]. Here closed structures take advantage of ordered placement of methyltransferase targeted protein donors (e.g., proline rich peptides) and methyltransferase targeted protein acceptors (SH3 domains). When donors are ordered along one set of branched or linear DNA scaffolds and acceptors are ordered along another set, self-assembly can be initiated by mixing the two sets of biostructures. Using this method, it should be possible to achieve assembly of relatively large DNA cages and extended assemblies akin to those that characterize the macronucleus and the nucleolus as noted above.

Ordered assembly using biomolecules on an even larger scale has also been proposed [9]. Here, one envisions a two-step process utilizing complementary oligodeoxynucleotides. In the first step a surface is decorated with single-stranded oligodeoxynucleotides in a predetermined pattern using well known techniques [63]. In the second step, etching techniques are applied to a separate silicon-on-insulator wafer. The wafer is etched with potassium hydroxide around elements protected on their surface by a mask of Au/Cr. These islands are then released from the silicon insulator layer with hydrofluoric acid and linked to thiols at the ends of synthetic oligodeoxynucleotides through interactions with the gold surface. The silicon elements can then to be moved in an electric field until they contact the complementary oligodeoxynucleotide in the previously prepared surface causing them to become fixed in a predetermined pattern [9]. In principle such a system would permit macroscale addressing for assembly of electronic devices.

Designs for ordering functional proteins so as to produce vectored chemical processes on the nanoscale have also been proposed [6–8, 82]. In this case, the implication is that ordered proximity for a set of enzymes or ribozymes performing a sequence biochemical reactions would produce advances in understanding the nature of vectored biological catalysis and its potential applications in signal amplification.

4. CONCLUSION

Bionanotechnology adapts not only the results (functional proteins and nucleic acids) but also the processes (e.g., directed evolution, supramolecular aggregate, and metabolosome construction) of molecular evolution. Molecular addressing systems, based on DNA complementarity and DNA–protein interaction selectivity, are now available for the ordered assembly of a variety of functional elements from biology. Molecular motors, DNA-based switches, DNA-based oscillators, enzymes, ribozymes, deoxyribozymes, gold particles, chromophores, fluorescence quenching agents, antibodies, aptamers, and nucleic acid binding proteins can all be ordered along nucleic acid scaffolds. The potential for construction of useful devices utilizing the extraordinary wealth of functionality made possible by ordering these elements is quite broad. Given the success of this paradigm it is reasonable to assume that clues from biology will continue to be applied to the construction of useful bionanotechnological devices. It is likely that the successful construction of these devices will shed new light on both the origin and nature of living things. Moreover, one can anticipate the possibility that one of these devices might itself cross the Darwinian threshold at some time in the future.

GLOSSARY

Aptamer A short nucleic acid composed of DNA or RNA that has been adapted by selection using directed evolution to fit into a molecular surface.

Biosensor A device designed to detect a specific biological molecule, system of biological molecules, or biologically produced signal.

Conformation space A three-dimensional vector space occupied by representations of the 3D shapes that can be assumed by a molecule.

Darwinian threshold The point at which a system can begin to evolve by self-replication variation and natural selection.

Deoxyribonucleic acid (DNA) A naturally occurring polymer composed of deoxy ribonucleotides. Although commonly found as a double-stranded, right-handed helix it can adopt one-, three-, and four-stranded forms having a variety of shapes.

Directed evolution The process by which molecules are selected from a replicable library. Multiple rounds of selection and replication generate a desired product.

F1 ATPase A naturally occurring multisubunit complex of proteins capable of synthesizing ATP in living systems.

Hydrogen bond A weak polar bond formed between two electron-rich atoms, one of which is covalently bonded to a hydrogen atom.

Macronucleus A large inclusion found in the cells of certain living things that contains multiple copies of genes that are in constant use by the organism.

Membraneless structure A substructure often present inside a living cell that is not bounded by a lipid bilayer membrane.

Metabolosome A nucleoprotein assembly that has been designed or selected for functionally carrying out a series of chemical reactions.

Molecular fossil A molecule that has been preserved by evolution over eons of geologic time stretching to or nearly to the dawn of life.

Molecular machine A machine comprising an assembly of a small number of molecules.

Molecular modeling   A computer-aided design process in which computational chemistry software programs are used to create models of macromolecules based on electronic structure, and molecular mechanics calculations coupled with 3D experimental data.

Mutation   A change in the information storage mechanism of an evolving system that alters the information it contains but may or not alter the form or function of the system.

Nucleolus   A substructure within the cell nucleus that is composed largely of the genes responsible for the production of ribosomal RNA.

Ribonucleic acid (RNA)   A naturally occurring polymer composed of ribonucleotides. Although commonly found in its single-stranded form, it can adopt two-, three-, and four-stranded forms having a variety of shapes.

Selection of whole bacteria   Directed evolution in which bacteria and not macromolecules are used as the substratum for growth.

Transition state   An intermediate and generally unstable state in a chemical reaction in which reactants are transformed into products resembling both states but identical to neither.

CONTENTS

1. INTRODUCTION

Within the last decade, nanoscience and nanotechnology [1–7] have reached the status of leading sciences with fundamental and applied research in all basic physical, life, and earth sciences as well as engineering and materials science [8–17]. An important feature of nanoscience is that it bridges the crucial dimensional gap between the atomic and molecular scale of fundamental sciences and the microstructural scale of engineering and manufacturing [18]. Accordingly, a vast amount of true multidisciplinary fundamental knowledge is to be explored and linked [19, 20]. It shall lead to a tremendous amount of in-depth understanding as well as to the fabrication of novel high technological devices in many fields of applications from electronics to medicine [21–24]. Therefore, it should improve tremendously the level of technological advance to a much greater rate than human history has ever experienced. As a result, the technological, educational, and societal implications [25] of nanoscience and nanotechnology are of immense importance, which are attested to by the tremendous interests, the major economic efforts, and the national initiatives of many countries around the world.

At the end of the 20th century, most efforts were dedicated to develop synthesis and characterization techniques to produce and probe smaller and smaller nanoparticles. Such studies were rewarded by the generation of a new class of materials called quantum dots [26] that are characterized by zero dimensionality (0D). Such materials have revealed fascinating size-induced physical and chemical properties due to quantum confinements and very high surface-to-volume ratio [27–33].

One-dimensional (1D) nanostructures, a new class of low dimensional nanomaterials, have emerged recently. These maintain one of their dimensions in the nanometer range, but with a much larger length scale, ranging from hundreds of nanometers to hundreds of microns and up to millimeters in certain cases [34–37]. Such dimensionality can give aspect ratios (length over diameter) of several thousands: for example, 10,000 for a 1D object of 10 nm in diameter and 0.1 mm in length. With no specific nomenclature, the shortest 1D nanomaterials are often called *nanorods* and the longest are called *nanowires* regardless of their diameter. Also, many straightforward names have been used to describe their morphology and appearance based on their microscale analogs. One may find them in the literature as *quantum wires, nanofibers, nanopillars*, *nanocables*, and *nanolines*. They are also referred to as *nanowhiskers* by analogy to their micrometer counterpart [38–57]. However, these names are essentially similar and all of them refer to 1D anisotropic nanoscale objects of circular cross-section. For the sake of clarity, *nanorod* will be used in this chapter for 1D anisotropic objects with length below 1 mm and *nanowire* will be used for length exceeding such dimension. Their diameter ranges from several nanometers to several hundreds of nanometers.

Such 1D objects can also be produced with a hollow interior and are referred to as *nanotubes* regardless of their length, inner, or outer diameters. Such porous anisotropic nanostructures show very large specific surface areas.

Very recently, a new class of 1D building blocks has been reported. Such novel objects are called *nanobelts* and *nanoribbon*s. Compared with nanowires and nanotubes, they have extended length (up to millimeter scale) and exhibit a rectangular cross-section.

A schematic representation of 1D nanostructures is displayed in Figure 1.

The basic goals have been to develop synthetic techniques to produce a large quantity of 1D building blocks in a controllable and fashionable way. The crucial challenge remaining for scientists and engineers is to develop
Figure 1. Schematic representation of 1D nanostructures. From top to bottom: nanowire, nanorod, nanotube, and nanobelt/nanoribbon.

the ability and competence to hierarchically order, connect, and integrate nanowires, nanotubes, and nanobelts in functional networks, thin film coatings, and three-dimensional (3D) arrays to generate and manufacture practical nanodevices. These future devices based on such building blocks should revolutionize materials science and engineering given that they possess the unique properties of nanoscale as well as the ability to connect the nanoworld to the microworld. Along with metal oxides, several classes of materials have already been produced as 1D nanostructures [58] such as metals (Ag, Al, Au, Bi, Co, Cu, Fe, Na, Ni, Pb, Pd, W, Zn, and Zr), semimetals (B, MgB_2, C_{60}, C_{70}, Ge, Se, Si, and Te), chalcogenides (Ag_2Se, CdSe, CuInSe, $NiSe_2$, MoSe, PbSe, Sb_2Se_3, Ag_2Te, Bi_2Te_3, $CoTe_2$, $FeTe_2$, ZnTe, Bi_2S_3, CdS, CuInS, $AgInS_2$, Cu_2S, PbS, $PbSnS_3$, Cu_3SnS_4, WS_2, and ZnS), nitrides (AlN, BN, GaN, InN, Si_3N_4, and Ge_3N_4), carbides (AlC, BC, Fe_3C, NbC, SiC, and TiC), phosphides (GaAsP, InAsP GaP, InP, and Sn_4P_3), and arsenides (GaAs, and InAs).

This chapter will focus exclusively on metal oxide compounds, which are the most common, most diverse, and richest class of materials in terms of electronic structure and physical, chemical, and structural properties. Such properties include, for instance, optical, optoelectronic, magnetic, electrical, thermal, photoelectrochemical, photovoltaic, mechanical, and catalytic ones. As a result, numerous applications of metal oxides such as ceramics, (chemical, gas, and bio-)sensors, actuators, lasers, waveguides, infrared and solar absorbers, pigments, photodetectors, optical switches, photochromics, refractories, electrochromics, (electro- and photo-)catalysts, and support for catalysts, insulators, semiconductors, superconductors, supercapacitors, transistors, varistors, resonators, dielectrics, piezoelectrics, pyroelectrics, ferroelectrics, magnets, transducers, thermistors, thermoelectrics, protective and anticorrosion coatings, fuel cells, alkaline and lithium batteries, and solar cells have been developed.

The diversity of such applications originates from the more complex crystal and electronic structures of metal oxides compared with these of other classes of materials. The main reasons are related to their variety of oxidation states, coordination number, symmetry, ligand–field stabilization, density, stoichiometry, and acid–base properties, which yield fascinating compounds exhibiting insulating, semiconducting, conducting, or magnetic behaviors with transitions among those states.

The combinations of such a variety of distinctive properties and applications with the unique effects of low dimensionality at nanoscale make the development of 1D metal oxide nanostructures an important challenge from both fundamental and industrial standpoints. The synthesis techniques leading to the formation of rational 3D assemblies of 1D metal oxide nanostructures as well as their achievements will be presented in this chapter.

2. SYNTHESIS TECHNIQUES

The general deposition of metal oxides onto substrates and the fabrication of coatings such as dense thin films or nano- to microparticulate thin films have been mastered for several decades and a plethora of physical and chemical processing techniques is available. Techniques such as molecular beam epitaxy (MBE) [59–125], oxygen–plasma assisted MBE [126], ion beam-assisted deposition (IBAD) [127], electron beam evaporation [128], laser-assisted catalytic growth [129], laser photolysis [130], pulsed laser deposition (PLD) [131–191], thermal evaporation [192], metal organic vapor phase epitaxy (MOVPE) [193], vapor–liquid–solid (VLS) catalytic growth [191–197], spray pyrolysis [198, 199], chemical vapor deposition (CVD) [200, 201], radiofrequency magnetron sputtering [202–204], liquid phase deposition (LPD) [205, 206], spin coating [207], dip coating [208], electrodeposition [209, 210], electrostatic self-assembly [211], and Langmuir–Blodgett (LB) [212–222] techniques are the most utilized by scientists and engineers.

Although many thin film processing techniques are available, there are very few methods that can generate ordered and oriented anisotropic 1D metal oxide nanostructures onto various substrates in a controllable way. Such techniques can be divided in two major categories: the gas phase and the (wet) chemical methods.

2.1. Gas Phase Methods

2.1.1. Chemical Vapor Deposition

The process of CVD involves a gas-phase chemical reaction that generates a thin solid film onto a substrate [200, 201, 223–226]. Vapors of the precursors are transported via a carrier gas onto a heated substrate (500–1000 °C) where they condense and form a thin film. Such substrates can be single crystalline and induce the oriented growth of the thin

film onto the substrate by epitaxy, which is called epitaxial CVD. When such precursors are alkoxides or metallo-organics (MO), the technique is referred to as MOCVD.

2.1.2. Thermal Oxidation Methods

Thermal oxidation is a simple gas-phase method to produce metal oxides onto substrates [227–229]. The synthesis involves the high temperature annealing of a metal sheet in the presence of oxygen at ambient or higher pressures. It has used successfully to generate oriented crystalline metal oxide nanowires from various metal substrates despite its apparent simplicity. The formation of anisotropic features is attributed to the relaxation of thermal expansion mismatch stresses between substrates and thin films [230]. Indeed, the oxidation of various metals produces metal oxides with anisotropic crystal structure and such anisotropy promotes oxygen diffusion along specific crystallographic planes. A large volume change is induced, which leads to large compressive stresses that are relaxed by the formation of anisotropic features (i.e., hillocks).

2.1.3. Vapor–Liquid–Solid Processes

The VLS technique [35, 129] was developed several decades ago for the growth of single crystalline whiskers [194–196], which are the microscale equivalent of nanowires and nanorods. The mechanism involved three steps: alloying, nucleation, and axial growth (Fig. 2). The anisotropic crystal growth is promoted by the presence of a liquid alloy/solid interface. By supplying vapors of the metal at high temperature and in presence of oxygen, the alloy reaches supersaturation and consequently nucleation of the metal oxide occurs followed by the anisotropic growth of the nanowire. If such a process is carried out in presence of a substrate, large arrays of highly oriented nanowires are obtained onto the substrates. To achieve better control of the alignment and orientation of the nanowires, epitaxial VLS (VLSE) can be utilized to produce the epitaxial growth of 3D arrays of well-aligned nanowires onto selected substrates [196].
2.2. Wet Chemical Methods

Solution chemistry-based and wet chemical techniques represent the most economical and simplest techniques to produce 3D arrays on a large scale. They will contribute significantly to the manufacturing of raw nanostructures and play a large part in the fabrication of practical nanodevices. Such methods are template-based synthesis, electrodeposition techniques, and aqueous chemical growth.

2.2.1. Membrane and Template Syntheses

The most common process to produce oriented anisotropic metal oxide materials (i.e., nanorod and nanotube) is the so-called *template-based synthesis* [231–233].

This method consists of growing materials within the cylindrical pore (template) of a membrane. Subsequently, the membrane is removed either by thermal decomposition or by chemical dissolution in concentrated basic solutions, yielding ordered arrays of 1D nanomaterials (Fig. 3). There are two types of available membranes: polymeric *track-etch* and *porous aluminum oxide membranes*. In addition, any porous nanostructure can also be used as a template.

Track-Etch Membrane The track-etch membranes are formed by bombardment of α particles on nonporous targets such as polycarbonate, polyester, mica, or silica glass [234]. The result is a membrane with randomly distributed *tracks* that are subsequently chemically *etched* to form a random array of uniform pores. The size of the pores is within the range of 10 nm to 1 μm with a typical maximum pore density of 10^9 cm^{-2}. The available thickness range is 6–20 μm. Such membranes are commercially available from Cyclopore, Millipore, Nucleopore, Osmonics, and Poretics as filtration membranes.

Anodic Aluminum Oxide Membrane Porous alumina membranes are obtained by anodic oxidation (anodization) of aluminum sheets in acidic medium such as sulfuric, oxalic,

Figure 2. Schematic representation of the major steps (alloying, nucleation, and growth) involved in the vapor–liquid–solid (VLS) catalytic growth of 1D nanowires (top) and 3D nanowire arrays (bottom).

Nanorods

Nanotubes
Figure 3. Schematic representation of the major steps involved in the fabrication of 3D arrays consisting of 1D nanostructures by the template-based synthesis method.

or phosphoric acid. The membranes consist of cylindrical pores of uniform diameter organized as hexagonal array with a porosity of 25–65% (Fig. 4). The dimension of the cylindrical pores is tunable from 4 to several hundred nanometers with a typical pore density of 10^9 to 10^{11} cm^{-2}. The available thickness range is 10 to 100 μm. Such membranes are easily fabricated and commercially available from Whatman Anapore and Anotech.

Other Templates   Theoretically, any nanostructure could act as a template for the growth of another nanostructure. Therefore, several types of nanostructured materials have been utilized for such purposes. The most frequently used alternative nanostructure template is the carbon nanotube [235].

The synthesis paths to elaborate materials within the templates can be summarized into two categories: electrochemical deposition and chemical deposition. The former [236] involves coating one side of the membrane with a conductive material and subsequently applying a potential between the membrane and a solution consisting of metal salts or complexes (Fig. 5).

Chemical depositions involve the use of a membrane as a chemical reactor in which the reaction is performed.
Figure 4. Scanning electron microscopy (SEM) photographs of a typical alumina membrane obtained by anodization of aluminum sheets.
Figure 5. Schematic representation of the experimental set-up involved in the fabrication of 3D arrays consisting of 1D nanostructures by template-assisted electrodeposition.

In most cases, the sol–gel synthesis method is carried out within the pores of the membranes. A subsequent dissolution of the membrane is performed to release the structure. Heat treatments usually follow to assure the formation of stoichiometric oxides.

2.2.2. Electrodeposition

Electrodeposition [237–266] is another simple and efficient synthesis method to produce metal oxide thin films with a certain degree of orientation. There are two different generic processes of electrodeposition yielding the formation of thin films on an electrode (cathode): the electrophoretic and electrolytic depositions.

Electrophoretic Deposition   Electrophoretic deposition is a process in which charged nanoparticles (in kinetically stable dispersions) migrate and accumulate onto the surface of an electrode under the influence of an applied electric field in a liquid medium at room temperature. No redox reaction happens at the electrode surface, and the oxide nanoparticles are deposited onto the surface at a rate of 1 to 1000 μm/min. The deposition rate depends on the applied electric field, suspension concentration, and electrophoretic mobility of the nanoparticles. The liquid media are usually organic solvents with low conductivity rather than water because the latter could easily evolve oxygen and hydrogen gases under the influence of an applied potential. Film thicknesses of 1 to 10^3 μm are commonly achieved and depend directly on the voltage, current density, and deposition time. The uniformity of the films depends on the size of the particle and the electric field.

Electrolytic Deposition   Electrolytic deposition is a process that produces metal oxide or hydroxide thin films from the hydrolysis–condensation of metal ions or complexes in solution by a redox reaction at the electrode that is the electrogeneration of a base from water. Nanoparticles of oxides nucleate at the interface at a rate of 10^{-3} to 1 μm/min. Such a process is governed by Faraday's law, which means that the amount of material deposited is monitored by the deposition time and current density. The liquid medium is usually

a mixing of water and organic solvent with high conductivity. Film thicknesses of 10^{-3} to 10 μm are commonly achieved. The uniformity of the films is excellent due to the use of molecular scale species.

Epitaxial Electrodeposition   A more advanced electrodeposition technique is the *epitaxial electrodeposition* [267–276] in which thin films are deposited in epitaxy onto a substrate; that is, the crystal structure and crystallographic lattice parameters of the substrate induce a crystal orientation of the thin film. This method has the ability to produce metal oxide nanoparticulate thin films with fairly large area, and many devices have been developed by such techniques.

2.2.3. Aqueous Chemical Growth

This novel technique has emerged recently as a simple and powerful tool to fabricate, at low cost and mild temperatures, large areas of metal oxide nano- to microparticulate thin films [277]. 3D arrays consisting of oriented anisotropic nanoparticles are easily generated with enhanced control over orientations and dimensions. The synthesis involves the controlled heteronucleation of metal oxides onto substrates from the hydrolysis–condensation of metal salts in aqueous solutions. The most pertinent parameter to control the nucleation and growth and therefore the overall design and architecture of a thin film is the interfacial free energy of the system [278].

Theoretical Concepts   The main idea here is to play on the thermodynamics and kinetics of nucleation, growth, and aging of the systems by controlling experimentally their interfacial tension [279]. The ability to segregate the nucleation and the growth stage enables control of the monodispersity of the system. Indeed, performing the aqueous precipitation far from the typical point of zero charge (PZC) of the metal oxide allows enhanced control of the nucleation, growth, and aging processes. According to the well-known acid–base surface properties of metal oxides, decreasing (or increasing) the pH of precipitation from the PZC will increase the surface charge density by adsorption of protons (or hydroxyl ions) and consequently reduce the interfacial tension of the system. In addition, a high ionic strength will also increase the surface charge density by screening the electrostatic repulsion at the interface, allowing more surface sites to develop a charge. The surface charge may therefore reach its maximum, which is directly related to the composition and structure of surface oxygen. This will contribute to a further lowering of the interfacial tension of the system. From then on, thermodynamic colloidal stability may thus be reached, resulting in a considerable lowering of the secondary aging processes and henceforth maintaining constant the size and shape of the nanoparticles as well as avoiding crystal phase (and morphological) transformations. By careful consideration of the parameters involved in the nucleation and growth processes, the free enthalpy of nucleation shows a maximum as a function of the particle size, which depends on the interfacial tension at the cubic power. Therefore, reducing the interfacial tension leads to an important lowering of the nucleation energy barrier, leading to the reduction of the particle size and its distribution [280].

The experimental verification on the aqueous precipitation of spinel iron oxide (i.e., magnetite Fe_3O_4) at room temperature [281] has clearly illustrated that the thermodynamic stability of metal oxide nanoparticles does exist. It also demonstrated that the average particle size may experimentally be monitored and empirically predicted over an order of magnitude in the nanometer range with narrow size distribution. The excellent agreement between theory and experiments has yielded strong evidence for efficient growth control of metal oxide nanoparticles under low interfacial tension conditions; it has also produced great expectations for future development of nanomaterials devices and the optimization of their physical properties. Moreover, when the thermodynamic stabilization is achieved, not only is the size tailored but also the shape as well as the crystallographic structure may be controlled. For instance, at low interfacial tension, the particle shape does not need to be spherical; indeed, very often nanoparticles are spherical to minimize the surface energy because the sphere represents the smallest surface for a given volume. However, if the synthesis or dispersion condition is suitable (i.e., yielding to the thermodynamic stabilization of the system), the shape of the crystallites will be driven by the symmetry of the crystal structure and an anisotropy may therefore be developed. Manipulating and controlling the interfacial tension enables one to grow nanoparticles with various sizes and shapes. Applying the appropriate solution chemistry (precipitation and dispersion media) to transition metal ions along with the natural crystal symmetry and anisotropy or forcing the material to grow along a certain crystal direction by controlling chemically the thermodynamics and kinetics of nucleation, growth, and aging phenomena, one can reach the ability to develop novel crystal morphologies. In addition to particle size and shape control, precipitating nanoparticles at "zero" interfacial tension allows stabilization of metastable crystal phases.

Crystal phase transition in solution usually operates through a dissolution–re-crystallisation process to minimize the surface energy of the system. Indeed, when a solid offers several allotropic phases, it is generally the one with the highest solubility and consequently the lowest stability (i.e., the crystallographic metastable phase that precipitates first). This is understood by considering the nucleation kinetics of the solid. At a given supersaturation ratio, the germ size is as small and the nucleation speed as fast as the interfacial tension of the system is low. Thus, because the solubility is inversely proportional to the interfacial tension, the precipitation of the most soluble phases and consequently the thermodynamically less stable phases is therefore kinetically promoted. Indeed, due to its solubility and metastability, this particular phase is more sensitive to secondary growth and aging that lead to crystallographically more stable phases essentially by heteronucleation. This is typically the case for aluminum hydroxide (boehmite to bayerite or gibbsite), titanium dioxide (anatase to rutile), and ferric oxyhydroxides (goethite, akaganeite, and lepidocrocite to hematite). Usually, the growth and aging processes are delicate to control and the phase transformation appears within a few hours to a few days in solution, resulting in an undesired mixing of various allotropic phases. However, by careful consideration of the precipitation conditions, such a phenomenon might

be avoided when systems are precipitated at low interfacial tension [278].

In summary, by adjusting the experimental conditions to obtain the thermodynamic stability conditions, the particle size, shape, and crystal structure may be tuned and optimized and shape anisotropy may be generated and/or maintained.

Thin-Film Processing By applying the above-mentioned thermodynamic concepts to the thin film processing technology, an inexpensive and effective aqueous growth technique at mild temperatures has been developed to produce functionalized coating of metal oxide materials onto various substrates [282]. Such a technique allows generation of advanced nano/microparticulate thin films without any template, membrane, surfactant, or specific requirements in substrate activation, thermal stability, or crystallinity. Given that the crystallites grow from the substrate, a large choice of thin film/substrate combinations is offered, which provides consequently better flexibility and a higher degree of materials engineering and design. To understand the possibility of growing nano- and microparticulate thin films from aqueous solution as well as the ability to grow and align anisotropic nanoparticles into large arrays on a substrate, one has to take into account the differences between homogeneous and heterogeneous nucleation phenomena. In most cases, homogeneous nucleation of solid phases from solution requires a higher activation energy barrier and therefore heteronucleation will be promoted and energetically more favorable. Indeed, the interfacial energy between two solids is usually smaller than the interfacial energy between a solid and a solution, and therefore nucleation may take place at a lower saturation ratio onto a substrate than in solution. Nuclei will appear onto the substrate and various morphologies and orientations can be reached depending on the chemical composition of the medium.

For instance, if the nucleation rate is controlled and the number of nuclei is limited by the precipitation conditions, the growth will take place according to the crystal symmetry and relative face velocities along the favorable direction of crystallization. A condensed phase of anisotropic single-crystalline nanorods parallel to each other and perpendicular to the substrate will be generated. However, if the number of nuclei is further limited and if the crystal symmetry allows it, the system will promote twinning. The preferential growth of the rods along the favorable axis from the same nuclei will induce a star-shape (or flower-shape) morphology. Finally, if the rate is enhanced by the precipitation conditions, the fast appearance of a large number of nuclei will result in 2D growth, promoting therefore, the formation of the anisotropic nanoparticles with a parallel orientation with respect to the substrate.

The ability to design materials with different orientations stimulates the study of the influence of such parameters on the physical properties of materials and gives further opportunities for materials design.

The aqueous chemical growth method consists of heating an aqueous solution of metal salts (or complexes) in the presence of a substrate at moderated temperatures (below 100 °C) in a closed vessel. Therefore, such technique does not require high-pressure containers and is also entirely recyclable, safe, and environment friendly because only water is used as solvent. Such a process avoids the safety hazards of organic solvents and their eventual evaporation and potential toxicity. In addition, because no organic solvents or surfactants are present, the purity of the materials is substantially improved. The residual salts are easily washed out by water due to their high solubility. In most cases, no additional heat or chemical treatments are necessary, which represents a significant improvement compared with surfactant-, template-, or membrane-based synthesis methods.

Full coverage of the substrate is obtained within a few hours provided that the heat capacity of water and surface coverage control are achieved by monitoring the synthesis time in the early stages of the thin film growth. Partial coverage is obtained within the first hours, which may be necessary for certain applications to adjust and tune the overall physical properties of devices (e.g., optical properties of multi-bandgap thin films). Such a technique is a multi-deposition technique and the growth of layer-by-layer of thin films is readily obtainable. The development of multilayer thin films of various morphologies and/or of various chemical compositions, that is, composite, multi-bandgap, and doped thin films, is reached. The complete thin film architecture may thus be modeled, designed, and monitored to match the application requirements. In most cases, it should improve the physical and chemical properties of the devices. It also gives the capacity to create novel and/or improved thin film integrated devices. Growing thin layers directly from the substrate does substantially improve the adherence and the mechanical stability of the thin film compared with the standard solution and colloidal deposition techniques such as spin and dip coating, chemical bathing, screen printing, or doctor blading. Moreover, given that such materials do precipitate in homogeneous solution from molecular scale compounds (i.e., condensed metal complex), they will grow on virtually any substrate. It goes without saying that the overall mechanical stability of the thin films does vary from substrate to substrate, but in most cases, strong adhesion is observed. Scale-up is potentially easily feasible, and this concept and synthesis method are theoretically applicable to all water-soluble metal ions likely to precipitate in solution. Large-scale manufacturing at low cost is therefore achievable with such a technique. In addition to all these industrial related advantages, such a technique is also potentially very interesting due to the compatibility of water and aqueous solution to biological compounds. For instance, 3D arrays of composite bionanomaterials have been obtained using the aqueous chemical growth. Such concepts and thin film processing technique have been applied successfully to basic oxides and oxyhydroxides of transition metals [283–289] (Figs. 6, 7, and 8).

3. 1D METAL OXIDE NANOSTRUCTURES

One-dimensional metal oxide nanostructures such as nanorods, nanowires, and nanotubes are defined by their aspect ratio, which is essentially the ratio of the (outer) diameter to their length (Fig. 9).

Nanorods and Nanowires A literature survey of the synthesis and investigations of nanorods and nanowires of metal oxides, hydroxides, and oxyhydroxides is given below (sorted by alphabetical order of chemical formula):

- Aluminum
  α-Al_2O_3 [290–292], γ-AlOOH, and γ-Al_2O_3 [293]
- Boron
  $Al_{18}B_9O_{33}$ and MgB_4O_7 [294]
- Cadmium
  CdO [295–297]
- Cobalt
  CoO [298] and Co_3O_4 [299]
- Chromium
  α-Cr_2O_3 [300] and $BaCrO_4$ [301]
- Copper
  CuO [302–305], $Cu(OH)_2$ [306], Cu_2O [303, 307, 308], $GdBa_2Cu_3O_{6.5}$ [309], and $YBaCu_3O_7$ [310]
- Europium
  Eu_2O_3 [311]
- Iron
  α-FeOOH [312, 313], β-FeOOH [285], α-Fe_2O_3 [314, 315], and Fe_3O_4 [316]
- Gallium
  β-Ga_2O_3 [317–329]
- Germanium
  GeO_2 [330–332]
- Indium
  In_2O_3 [296, 333–341] and $SnIn_2O_3$ [342]
- Iridium
  IrO_2 [343]
- Lanthanum
  $La(OH)_3$ [344]
- Magnesium
  MgO [345–351] and $Mg(OH)_2$ [349, 352]
- Manganese
  γ-MnOOH [353], α- and β-MnO_2 [354], δ-MnO_2 [355], $LaBaMnO_3$ [356], $LaCaMnO_3$ [357], $LaSrMnO_3$ [358], and Mn_3O_4 [359]
- Molybdenum
  MoO_2 [343] and α-MoO_3 [343, 360–362]
- Nickel
  NiO [363, 364] and α-$Ni(OH)_2$ [365]
- Lead
  PbO_2 [296, 338, 339]
- Ruthenium
  RuO_2 [343, 366]
- Antimony
  Sb_2O_3 [367], Sb_2O_4 [368], and Sb_2O_5 [343, 367]
- Silicon
  SiO_2 [300, 369–372]
- Tin
  SnO_2 [296, 373–377]
- Tantalum
  $NaTaO_3$ [378]
- Titanium
  TiO_2 [379–383] and $BaTiO_3$ [384]
- Vanadium
  VO_2 [385], LiV_2O_4 [386], and V_2O_5 [343, 387–389]
- Tungsten
  WO_x [390], WO_2 [391], WO_3 [343, 391–393], $BaWO_4$ [394], and $CdWO_4$ [395, 396]

- Zinc
  ZnO [193, 296, 397–415]
- Zirconium
  ZrO_2 [416, 417].

Nanotubes Hitherto, one may find in the literature the synthesis and experimental investigations of the following metal oxide nanotubes: α-Al_2O_3 [418], CeO_2 [419], Co_3O_4 [420, 421], $Dy(OH)_3$ and Dy_2O_3 [422], Er_2O_3 [423], Ho_2O_3 [422], Lu_2O_3[423], MgO [424], MoO_3 [343], RuO_2 [343], SiO_2 [336–338, 418, 425], SnO_2 [426], TiO_2 [382, 427–433], $H_2Ti_3O_7$ [434], VO_x [435–445], V_2O_5 [418], $Na_2V_3O_7$ [446], WO_3 [300], Y_2O_3 [447], Yb_2O_3 [423], ZnO [448, 449], and ZrO_2 [450].

Nanobelts and Nanoribbons The latest class of 1D nanostructures has emerged recently, which consists of ultra-long (up to millimeter) belt-like (or ribbons) nanostructured building blocks and are called nanobelts and nanoribbons. The specificity of such novel 1D nanostructures is that the cross-section is rectangular in contrast to cylindrical for nanowires and nanotubes. So far, nanobelts and nanoribbons of α-Al_2O_3 [291], $Cu(OH)_2$ [451], CdO [296, 410], β-Ga_2O_3 [296, 327, 410, 452–455], In_2O_3 [296, 410], NiO [456], $Mg_2Mn_5O_{12}$ [457], MgO [348, 350, 458–461], α-MoO_3 [361, 462, 463], SnO [464], SnO_2 [296, 410, 465–472], β-PbO_2 [410, 473], TiO_2 [474], $K_2Ti_8O_{17}$ [475], WO_3 [392], $CdWO_4$ [396], and ZnO [296, 404, 406, 410, 470, 471, 476–478] have been successfully synthesized and promising physical properties are currently being investigated.

A more important challenge in nanowire technology is to develop economical synthesis methods to produce ordered, oriented, and aligned 1D nanostructures onto various substrates. The following section consists of a literature survey of the major achievements of two- and three-dimensional ordering of 1D nanostructures. 2D arrays are developed to probe and optimize collective physical properties, mostly optical (nematic–smectic phases) and magnetic. The goal of generating 3D arrays is to develop practical devices such as chemical, gas, and bio sensors as well as optoelectronic devices such as lasers, photodetectors, optical switches, photovoltaics, and photocatalytic cells.
Figure 8. Electron micrographs of 1D nanowires; SEM images of ZnO (top) and TEM images of γ-MnOOH (bottom) synthesized by the aqueous chemical growth method.
Figure 9. Schematic representation of the dimensional characteristics of 1D nanostructures; length (L), diameter (D), inner diameter (ID), and outer diameter (OD).

3.1. 2D Arrays

Anisotropic nanoparticles and their collective optical and magnetic properties are of fundamental and industrial importance. However, besides a few examples based on spherical metal oxide nanoparticles of CoO [479, 480], γ-Fe$_2$O$_3$ [481], CoFe$_2$O$_4$ [482], Fe$_3$O$_4$ [481, 482], SiO$_2$ [483, 484], and TiO$_2$ [485, 486], reports of two-dimensional ordered arrays in general and of metal oxide 1D nanostructures in particular are very seldom in the literature. The lack of such nanostructure assemblies is most probably due to the limitations in available synthesis techniques. Indeed, basically a couple of generic methods to produce ordered 2D arrays exist: self-assembly by solvent evaporation on substrate [487, 488] and the LB technique. The LB technique is usually utilized to fabricate ultrathin and layer-by-layer thin films and several metal oxide thin films have been produced by such a technique [212–222, 489]. However, only a few ordered 2D arrays of anisotropic nanoparticles of metal oxides have been reported. They involve BaCrO$_4$ [490, 491], β-FeOOH [492], TiO$_2$ [485], and BaWO$_4$ [493].

3.2. 3D Arrays

Besides the low-cost synthesis of well-defined 1D nanostructures, the most crucial challenge is to develop the ability to order and orientate them in functional network and oriented 3D periodic arrays. Although a plethora of synthesis techniques is available to produce metal oxide 1D nanostructures, only a few among them can generate anisotropic and oriented 1D nanomaterials assembled as 3D arrays.

Table 1 summarizes the dimensions, synthesis methods, and type of oriented arrays of 1D nanostructures (nanorods, nanowires, and nanotubes) that have been produced so far. Many 3D arrays of 1D oxides have already been produced with various dimensions, ranging from a few nanometers to several hundreds of nanometers in diameter with length ranging from a few hundred nanometers to several tens of microns. Ordered 3D arrays of porous 1D nanostructures have also been produced with various metal oxides, ranging from basic unary oxides to more complex oxides. TiO$_2$ and ZnO are, by far, the most representative 1D nanomaterials produced to date due to their established importance as

Table 1. Literature survey of oriented 3D arrays consisting of 1D metal oxide nanostructures (sorted alphabetically by chemical formula and by ascending diameter).

Material	Morphology	Dimension (D * L)	Synthetic Method	Ref.
Monoxide				
CdO	Nanowire	60 nm * few μm	Alumina membrane	[494]
CuO		30–100 nm * 15 μm	Thermal oxidation	[495]
Cu_2O		25–45 nm * 3–5 μm 80–100 nm * 10 μm	Electrodeposition	[496]
ZnO	Nanorod	15–40 nm * 1 μm	Molecular beam epitaxy	[497]
		20 nm * 400 nm	Pulsed laser deposition	[498]
		25 nm * 800 nm	Metallorganic vapor-phase epitaxy	[499]
		45 nm * 200 nm 70 nm * 600 nm	Chemical vapor deposition	[500, 501]
		85–95 nm * 500 nm	Epitaxial electrodeposition	[502]
	Nanowire	55 nm * 2.6 μm 190 nm * 15 μm	Metal vapor deposition	[503]
		90 nm * 1 μm	Electrodeposition in alumina membrane	[504]
		150–250 nm * 2 μm	Electrodeposition	[505]
		100–200 nm several μm in length	Aqueous chemical growth	[405]
		10–200 nm * 2–20 μm 20–120 nm * 5–20 μm	Vapor–liquid–solid growth	[506, 507]
		15–90 nm * few m	Alumina membrane	[508]
		200 nm * 50 μm		[509]
	Nanotube	150 nm inner diameter 200 nm outer diameter 60 μm in length		[510]
	Microtube	1 μm inner diameter 2 μm outer diameter 10 μm in length	Aqueous chemical growth	[511]
Dioxide				
CeO_2	Nanowire	100 nm * 1 μm	Chemical vapor deposition	[512]
$LiCoO_2$		100 nm several μm in length	Alumina membrane	[513]
$LiNi_{0.5}Co_{0.5}O_2$				[514]
$LiNiO_2$		100 nm * 50 μm		[515]
α-MnO_2		200 nm * 50 μm		[516]
$LiMnO_2$		100 nm * 50 μm		[517]
$LiCo_{0.5}Mn_{0.5}O_2$	Nanorod	100 nm * 500 nm		[518]
PdO_2	Nanocone	40 nm * 500 nm	Thermal oxidation	[519]
		200 nm * 1.2 μm		
SiO_2	Nanowire	50 nm mm in length		[520]
		125–200 nm * 10 μm	Sol–gel electrophoresis in polycarbonate membrane	[521]
	Nanoflower	20–120 * 10–250 μm	Catalytic gas–solid reaction	[522]
	Nanotube	16–24 nm inner diameter 30 nm outer diameter 6 μm in length	Alumina membrane	[523]
SnO_2	Nanorod	70 nm several μm in length		[524]

Table 1. Continued.

Material	Morphology	Dimension (D * L)	Synthetic Method	Ref.
Dioxide				
TiO$_2$	Nanowire	10–40 nm * 2–10 μm	Electrodeposition in alumina membrane	[525]
		15 nm * 6 μm	Alumina membrane	[526]
	Nanorod	40–50 nm * 140 nm	Photoelectrochemical etching	[527]
	Nanowire	125–200 nm * 10 μm	Sol–gel electrophoresis in polycarbonate membrane	[521]
		200 nm * 2 μm 500 nm * 8 μm	Magnetron sputtering	[528]
		15 nm * 30 μm	Alumina membrane	[516]
	Nanotube	2.5–5 nm inner diameter 20–40 nm outer diameter 0.3–0.9 μm in length		[529]
		200 nm outer diameter 50 μm in length		[516]
		25–60 nm inner diameter 250 nm in length	Anodic oxidation	[530]
		50–70 nm inner diameter 120 nm outer diameter several μm in length	Electrodeposition in polymer-coated alumina membrane	[531]
		170–180 nm inner diameter 200–233 nm outer diameter 3 μm in length		[532]
ZrO$_2$		170 nm inner diameter 190 nm outer diameter 50 μm in length	Alumina membrane	[533]
		170 nm inner diameter 280 nm outer diameter several μm in length		[534]
Trioxide				
MoO$_3$	Nanotube	20–150 nm inner diameter 50–300 nm outer diameter 5–8 μm in length	Chemical vapor deposition	[535]
WO$_3$	Nanowire	200 nm * 50 μm	Alumina membrane	[536]
Sesquioxide				
Al$_2$O$_3$	Nanorod	5 nm * 860 nm 20–80 nm * 30–200 nm		[537]
	Nanotube	10–20 nm inner diameter 40 nm outer diameter 450 nm in length	Anodization	[538]
		12 nm inner diameter 35 nm outer diameter 650 nm in length		[539]
α-Fe$_2$O$_3$	Nanorod	5 * 500 nm Bundles of 50 nm	Aqueous chemical growth	[540]
In$_2$O$_3$	Nanowire	60 nm several μm in length	Electrodeposition in alumina membrane	[541, 542]
	Nanotube	100 nm inner diameter 200 nm outer diameter 50 μm in length	Alumina membrane	[543]
β-Ga$_2$O$_3$	Nanowire	20–100 nm * 10–100 μm	Microwave plasma	[544]
		60–150 nm several μm in length	Chemical vapor deposition	[545]
	Nanotube	100 nm inner diameter 200 nm outer diameter 50 μm in length	Alumina membrane	[543]

Table 1. Continued.

Material	Morphology	Dimension (D ∗ L)	Synthetic Method	Ref.
Perovskite oxide				
$BaTiO_3$	Nanowire	125–200 nm ∗ 10 μm	Sol–gel electrophoresis in polycarbonate membrane	[521]
PbTiO_3	Nanotube	200 nm outer diameter 60 μm in length	Alumina membrane	[546]
$PbZr_{0.52}Ti_{0.48}O_3$	Nanowire	125–200 nm ∗ 10 μm	Sol–gel electrophoresis in polycarbonate membrane	[521]
Spinel oxide				
$LiMn_2O_4$	Nanotube	100 nm inner diameter 200 nm outer diameter several μm in length	Alumina membrane	[547]
Co_3O_4	Nanowire	200 nm ∗ 50 μm		[516]
Pentoxide				
V_2O_5	Nanowire	300–600 nm several μm in length	Electrodeposition in polycarbonate membrane	[516]
Miscellanous				
β-FeOOH	Nanorod	5 nm ∗ 500 nm Bundles of 50 nm	Aqueous chemical growth	[540]
γ-MnOOH	Nanowire	100 nm several μm in length		[353]
$La_{0.7}Sr_{0.3}MnO_3$	Nanorod	100 nm ∗ 500 nm–1.5 μm	Pulsed laser deposition	[548]
$La_{0.8}Sr_{0.2}MnO_3$		25 nm ∗ 70 nm		[549]
$Sr_2Nb_2O_7$	Nanowire	125–200 nm ∗ 10 μm	Sol–gel electrophoresis in polycarbonate membrane	[521]
VO_x	Nanotube	5–50 nm inner diameter 15–150 outer diameter 1–15 μm in length	Ligand-assisted template	[550]
		15–45 nm inner diameter 50–100 outer diameter 0.8–3 μm in length		[551]
		20–35 nm inner diameter 70–140 outer diameter 2–12 μm in length		
WO_x	Nanorod	10–30 nm ∗ 300 nm	Electrochemical etching	[552]
		10–30 nm ∗ 500 nm–1.6 μm	Thermal oxidation	

basic materials for catalysis and large bandgap semiconducting properties.

Many applications of 1D metal oxides are currently under investigation. Because of the very recent development of ordered 3D arrays of oriented 1D nanostructures, only a very few applications have been demonstrated. Most of the research and development have focused on developing new synthesis techniques to order and align 1D nanostructures. However, applications in the field of optoelectronic and photoelectrochemistry have been reported and are briefly presented below.

Room temperature lasing properties have been demonstrated based on highly ordered ZnO nanowires grown by epitaxial VLS (see 2.1.2) on sapphire substrate. Such arrays consist of perpendicularly oriented nanowires of ZnO of 100 nm in diameter and a few microns in length. Such hexagonal nanowires are well crystalline and faceted and behave as a natural (Fabry–Perot) resonating optical cavity. When pumped by a laser, inversion of electronic population and ultraviolet (UV) lasing action are observed at room temperature and at a much lower threshold compared with conventional lasers [553–557].

Another successful application of oriented nanowire arrays is found in the fields of photoelectrochemistry and energy conversion. For instance, the design of photovoltaic or photocatalytic cells that can, respectively, generate a current or induce a chemical reaction under UV/visible illumination has been achieved. Such photoelectric effects are well

known, and many attempts to produce economical solar cells or to photo-oxidize water with sunlight have been made. Well-aligned single-crystalline nanorods with a typical diameter of 5 nm, self-assembled as bundles of about 50 nm in diameter, grown in fairly perpendicular fashion onto the substrate and arranged in very large uniform arrays have been tested for such purposes. The length of the nanorods, which essentially represents the thickness of the thin film, may be experimentally tailored to any required dimension of up to about 1 μm by varying the time or temperature of aging in solution. For instance, nanorods of 100 nm in length have been produced after 1 h at 100 °C. The aspect ratio is 1 to 20 for the nanorod bundles and 1 to 200 for the individual nanorods. Such quantum-size 1D rods arranged in oriented 3D bundles feature an oriented, direct, grain boundary-free electron pathway. In addition, as the diameter of a single nanorod matches the minority carrier diffusion length, fast electron-hole recombination is prevented, allowing fast generation, transfer, and collection of photogenerated electrons. Accordingly, a high photoefficiency was achieved; more than 50% of the incident photon was converted to electrons at a wavelength of 350 nm [558]. Such materials have also been tested as photocatalytic cells [559] for the photo-oxidation of water [560].

Besides optoelectronics and photoelectrochemistry, sensor technologies [561–574] will also benefit from such ordered arrays of 1D metal oxide nanostructures. Metal oxides are already well established as basic materials for chemical, gas, and bio-sensors and promising improvements in terms of detection threshold limit and sensitivity, selectivity, response time, and temperature of operation could be demonstrated with the use of such nanostructures.

In addition to applications, fundamental knowledge regarding the effects of anisotropy, ordering, and orientation on the physical properties and electronic structure of 1D metal oxides can be developed. A recent study was performed on II–VI semiconductor 3D arrays consisting of oriented ZnO rods. In addition to the strong anisotropic effects that are not observed in the isotropic (spherical) samples, researchers were able to probe and demonstrate the symmetry contribution of oxygen orbitals to the conduction band of ZnO by means of polarization dependent soft X-ray spectroscopy and first principle calculations [575]. Such fundamental knowledge is of great importance for understanding and consequently optimizing the existing optoelectronic devices.

The production of novel 1D nanostructures and their controlled assemblies in 2D and 3D arrays are evolving at such a rapid rate that many physical properties and forthcoming applications as well as fundamental understanding are foreseen with confidence.

4. CONCLUSIONS

As for many new fields and emerging technologies, most of the efforts have been focused on the exploration and development of synthesis techniques and manufacturing processes to produce a variety of 1D metal oxide nanomaterials in a simple and economical, yet reliable approach. Mass production of nanorods, nanowires, nanotubes, and the latest nanobelts and nanoribbons is soon to be accomplished

owing to the intensive efforts and dedication of scientists and engineers. However, much remains to be explored fundamentally to understand the unique effects of low dimensionality on the electronic structure and structural, physical, and chemical properties of such advanced materials. Such fundamental knowledge will in turn help the optimization of current devices and most certainly the creation of new ones based on one-dimensional nanostructures and their ordered two- and three dimensional assemblies. Many fields of applications in basic physical, life, and earth sciences are directly targeted and the outcome should truly impact our society and its level of technological advance.

GLOSSARY

Allotropic phases Solids of same elemental composition but with different atomic arrangements (i.e. crystal structure).

Anisotropic nanoparticles Nanoparticles with a shape defined by distinct longitudinal and lateral dimensions and thus an aspect ratio different from unity.

Array Arrangement of objects (e.g. nanoparticles) in orderly fashion.

Interfacial tension Variation of the surface free energy by unit surface area. The interfacial tension g is given in mJ/m^2 or mNm^{-1}.

Nucleation Formation within an unstable, supersaturated solution of the first object (nucleus) capable of spontaneous growth into larger crystals of a more stable solid phase.

Particulate thin film Polycrystalline thin film consisting of fine particles deposited or grown onto a substrate.

Point of zero charge (PZC) pH at which the electrostatic surface charge density (per unit area) equals to zero.

Template A form (mask, pattern, mold) used as a guide to generate a product of similar morphology.

Optical Fibers for Nanodevices

Jenny M. Tam, Sabine Szunerits,[1] David R. Walt

Tufts University, Medford, Massachusetts, USA

CONTENTS

1. INTRODUCTION

Optical fibers offer a unique platform for the fabrication of a variety of nanostructures and nanodevices. Nanotechnology applications incorporating optical fibers have grown during the past twenty years, and modified optical fibers have been increasingly used in the fabrication of nanodevices. For example, optical fibers have been used in microscopy tools, such as near-field scanning optical microscopy (NSOM), to examine the optical properties of nanostructures. Analyzing the optical properties of nanometer-sized structures has become difficult as measurements and resolution have become diffraction limited [1–3], but NSOM has overcome this hurdle. NSOM uses an optical fiber tapered to a nanometer-sized aperture to bypass the diffraction limit of light. Illuminating a NSOM fiber probe and placing it close to the sample surface can make it possible to examine optical characteristics at the nanometer scale. In addition, NSOM has spawned a variety of devices to tackle some of the limitations with current lithographic technologies for data storage.

Optical fibers have also been used as transducers in sensing devices capable of monitoring and detecting a variety of chemical and biological analytes in different environments (e.g., blood, water, food, waste water) [4, 5]. Intracellular

---

processes inside living cells are more complicated to measure, but optical fibers have been tapered to a nanometer-sized apex and inserted into living cells without damaging them in order to measure cellular responses. As a result, these sensors have been able to further elucidate complex intracellular processes.

The nanometer physical aspects of tapered fibers and bundles of tapered fibers have also been used as templates to fabricate a variety of nanostructures. With the direction of light at nanometer-sized tip apices, photopolymerization can be controlled to form nanometer-sized polymer spots [6]. The nanotips have also been immersed in a heated polymer film, indenting the surface and forming nanometer-sized wells. Fiber optic bundles have also been modified to form arrays of nanowells [7] that have been used as templates for nanofabrication. With the immersion of the nanowell array in a polymer solution, arrays of nanocones were produced.

Fundamental characteristics of fibers and fiber bundles will be examined, as well as how they can be modified for nanodevices. Applications incorporating modified fibers, such as nanotips and nanowells, will be described, as well as new approaches to utilize these devices to overcome limitations that face current technologies.

2. OPTICAL FIBERS

2.1. Fundamental Characteristics of Optical Fibers

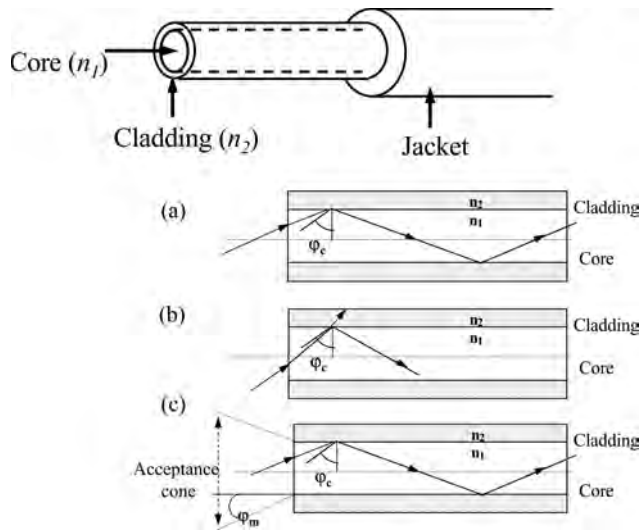
Optical fibers act as wave guides, efficiently transmitting light from one end of the fiber to the other. Optical fibers can be made out of glass or plastic, resulting in a strong, flexible, and durable component for a variety of applications. An optical fiber is composed of a core, with a refractive index n_1, surrounded by a cladding with a *lower* refractive index n_2 (Fig. 1). The refractive index mismatch results in total internal reflection at the core-clad interface, effectively acting like a mirror and confining the transmission of light to the fiber core with minimal attenuation. Several principles govern the light transmission through an optical fiber and are significant in their function in nanodevices.


Figure 1. Schematic diagram of an optical fiber with the core and clad structure. Propagation of light through an optical fiber occurs through total internal reflection. Total internal reflection occurs at the interface between the core (n_1) and the clad (n_2), where $n_1 > n_2$. (a) Total internal reflection occurs when the light angle is greater than the critical angle φ_c. (b) Light is partially reflected and partially refracted if the light angle is less than the critical angle φ_c. (c) Total internal reflection will occur only if the entering light angle is within the acceptance cone φ_m of the fiber.

2.1.1. The Critical Angle

The guiding principle for light in an optical wave guide is total internal reflection (Fig. 1). According to Snell's law of refraction

$$n_1 \times \sin \Theta_1 = n_2 \times \sin \Theta_2 \qquad (1)$$

For a step-index fiber, where $n_1 > n_2$, total internal reflection occurs when the incident angle Θ_1 meets the criterion $90° > \Theta_1 > \Theta_c$, where Θ_c is given by

$$\Theta_c = \sin^{-1}(n_2/n_1) \qquad (2)$$

The critical angle Θ_c depends on the indices of refraction between the core and the cladding. Provided that total internal reflection occurs at the core-clad interface, a ray of light propagates down the core as shown in Figure 1.

2.1.2. Acceptance Cone

High transmission efficiencies in optical fibers are achieved if the angle of the light entering the fiber is within the acceptance cone as shown in Figure 1c. The acceptance cone depends on the refractive indices of the core, clad, and the surrounding medium (n_o)

$$\sin \Theta_a = \frac{\sqrt{n_1^2 - n_2^2}}{n_o}$$

2.1.3. Numerical Aperture

The efficiency of the light collection of the fiber depends on the width of the acceptance cone and can be described in terms of its numerical aperture (NA)

$$\mathrm{NA} = n_o \sin \Theta_a$$

A wide acceptance cone can gather light more efficiently, symbolized by a high NA.

2.2. Types of Optical Fibers

Optical fibers are made from a variety of materials, but the most common material is silica. Pure silica has a refractive index of approximately 1.45, and doping it with various impurities will alter this value. For example, impurities that raise the refractive index include titania (TiO_2), alumina (Al_2O_3), and germania (GeO_2), whereas boria (B_2O_3) and fluorine (F_2) will lower it [8]. Fibers with silica cores surrounded by plastic cladding are also available, as are all-plastic fibers.

2.3. Optical Fiber Configurations

Optical fibers are produced in many different configurations, sizes, and formats. One type of optical fiber consists of a single core surrounded by a clad material. Fiber optics is mainly used in telecommunications applications, but it has also been incorporated into new applications such as microscopy and sensing. Recently, optical fibers have also been integrated into devices to analyze and create nanostructures. For some fiber-optic nanodevices, optical fibers with diameters ranging from 50 to 500 μm are tapered to a nanometer-sized tip for use in nanotechnology applications such as NSOM.

Fiber optic technology can go one step further—instead of using only one strand of fiber, thousands to tens of thousands of optical fibers can be bundled together and used for imaging applications. Single optical fibers cannot transmit images because the light signal mixes as it is carried from one end of the fiber to the other. Fiber optic bundles, on the other hand, are composed of thousands of individual fibers melted and drawn together coherently (Fig. 2), such that an
Figure 2. (a) Fiber-optic bundles are composed of thousands to tens of thousands of individual fibers that are coherently fused together. (b) Fiber bundles can be used for imaging purposes. Reprinted with permission from [7], P. Pantano and D. R. Walt, *Chem. Mater.* 8, 2832 (1996). © 1996, American Chemical Society.

image is carried and maintained throughout the length of the bundle. The spatial resolution of the bundle depends on the diameter of each fiber in the bundle. Fiber bundles have been used in devices such as medical endoscopes to transmit images from inaccessible parts of the body to a detector. Optical fiber bundles have also been incorporated into optical sensors and nanodevices [4, 5]. Similar to single core fibers, the surface of the fiber bundles can be mechanically or chemically modified to produce arrays of nanostructures such as nanotips and nanowells.

3. OPTICAL FIBER MODIFICATIONS FOR NANOSCALE APPLICATIONS

3.1. Optical Fibers as Probes in Near-Field Scanning Optical Microscopy

Conventional, far-field optical techniques have limited spatial resolution [9–11]. The typical rules of interference and diffraction are defined by the Abbe diffraction limit, in which the optical resolution is approximately $\lambda/2(NA)$, where λ is the wavelength and NA is the numerical aperture [9]. The rapid development of nanotechnology demands better spatial resolution and has led to the development of alternative microscopy techniques such as near-field optics (NFO) and NSOM. NSOM offers enhanced spatial resolution, bypassing the Abbe diffraction limit by using a small, subwavelength-sized light source that effectively focuses photons through an aperture that may be as small as $\lambda/50$ [9].

NSOM is a scanning technique that developed from principles derived from two other related scanning techniques, scanning tunneling microscopy (STM) and atomic force microscopy (AFM) [12–14]. In 1982, G. Binning and H. Rohrer at the IBM Research Center in Zürich showed that topographic pictures of surfaces on an atomic scale could be obtained by a method they called STM or scanning tunneling microscopy [12]. STM consists of two electrodes, the tip and the sample, and measures the tunneling current between the tip and surface. STM obtains information about both the topographical and electronic surface structure. STM led to the development of other types of microscopy, particularly AFM.

An atomic force microscope creates a topographical image of a surface through physical interactions between a nanometer-sized probe and the sample surface [13, 14]. The probe consists of a sharp tip attached to a cantilever, and an image is created based on the deflection of the tip as it rasters over the sample surface. As a result, each point in the image directly corresponds to the surface structure.

Unlike STM or AFM, NFO images sample through the interaction of light with the surface through simple refraction/reflection contrast or absorption and fluorescence. Introduced by U. During in 1986 [15], NSOM illuminates a specimen through a subwavelength-sized aperture, typically a tapered fiber probe, while keeping the specimen close to the probe, typically 100 Å to tens of nanometers from the fiber. NSOM picks up information contained in the optical field just above the surface of the illuminated sample called the near-field region, where the sample and the probe light closely interact [3]. Radiation emitted from the
Figure 3. Schematic of near-field optics.

nanometer-sized probe is highly collimated in the near-field regime, decaying exponentially as photons move away from the surface, as shown in Figure 3. In NSOM, the spatial resolution of a sample is no longer limited by the diffraction limit of light—it is independent of the wavelength of light used and depends only on the size of the aperture. As a result, the quality of NSOM measurements is fully dependent on optical tip parameters, and the resolution is directly related to the size of the probe aperture, which is typically 50–200 nm [16]. Betzig and Chichester have reported the development of one such probe that has an optimum spatial resolution of 12 nm [17]. A NSOM can also supply additional physical information about a sample such as spectroscopic properties, optical thickness, topography, lateral structure, transparency, as well as its chemical behavior. NSOM has been mainly used for analytical applications, but several new NSOM-based applications have been proposed recently for nanotechnology; these are described in Section 4.

The formation of nanometer-sized fiber probes for microscopy applications, such as NSOM, progressed rapidly during the 1980s and 1990s. In these applications, the formation and characterization of the tips are crucial to instrument performance and image interpretation [18]. Several methods have been used to scale micrometer-size optical fibers for nanotechnology applications.

3.1.1. Mechanical Pulling

One of the preferred methods for fabricating nanometer-sized probes is the mechanical pulling of heated fibers, with either a micropipette puller or a CO_2 laser [19–23]. In a micropipette puller, a small area of the fiber is situated in the center of a heating coil and then the tip of the fiber is pulled until it separates, leaving a long tip [23]. An apparatus used by Tan and co-workers [6] consists of a modified micropipette puller and a 25-W CO_2 infrared laser. The CO_2 laser replaces the heating coil. The laser beam is reflected off a mirror and directed to heat the optical fiber. Similar to the micropipette puller, the fiber is heated and then pulled until the fiber separates into two fibers, each with a long tip. To create nanometer-sized apertures, metal is coated along the length of the tapered fiber. To avoid metallizing and blocking the tip, the tip surface must be positioned essentially orthogonal to the pulled fiber wall [24]. The deposition angle also has to be carefully adapted to the tip geometry.

Mechanical pulling is fast compared with chemical etching (*vide infra*) and is quite controllable, since there is precise control over the heating and pulling parameters. Although transmission is low through pulled fibers, they have well-defined apertures, with diameters as small as 50 nm.

3.1.2. Chemical Etching

Chemical etching produces shorter tapers with larger cone angles, resulting in higher transmission efficiency (shown in Fig. 4) [18, 25–42]. Furthermore, chemical etching offers a simple and inexpensive fabrication method, especially compared with mechanical pulling. Depending on the composition of the glass, different acidic solutions are used. Silica fibers are chemically etched in a one-step procedure with a solution of hydrofluoric acid (HF) and ammonium fluoride (NH_4F) buffer. The etch rate depends on the dopant concentration in the fiber and the concentration of the acid solution. Single core optical fibers and fiber bundles can be etched to form either nanotips or nanowells. For example, in the fiber bundles used by Pantano and Walt [7, 43], the pure SiO_2 of the fiber cladding etches at a different rate than the GeO_2-doped SiO_2 of the core, and depending on the dopant concentration of the core and cladding, either nanotips or nanowells can be formed. Figures 5 and 6 show images of the nanotips and nanowells that can be fabricated. The chemical reaction of SiO_2 and GeO_2 with HF acid can be summarized by reactions (1)–(3) [44].

$$SiO_2 + 6HF \rightarrow H_2SiF_6 + 2H_2O \tag{1a}$$

$$GeO_2 + 6HF \rightarrow H_2GeF_6 + 2H_2O \tag{1b}$$
The fluorosilicic acid (H_2SiF_6) and the hexafluorogermanic acid (H_2GeF_6) are produced directly as outlined by reactions (1a) and (1b) but also can arise from

$$SiO_2 + 4HF \rightarrow SiF_4 + 2H_2O \tag{2a}$$

$$3SiF_4 + 2H_2O \rightarrow 2H_2SiF_6 + SiO_2(aq) \tag{2a}$$
$$GeO_2 + 4HF \rightarrow GeF_4 + 2H_2O \tag{2b}$$

$$3GeF_4 + 2H_2O \rightarrow 2H_2GeF_6 + GeO_2(aq) \tag{2b}$$
If an ammonium fluoride-buffered etching solution is used, there is a further possible dissolution step that arises from the involvement of ammonia ionized from the solution (reaction (3)).

$$H_2SiF_6 + 2NH_3 \rightarrow (NH_4)_2SiF_6 \tag{3a}$$

$$H_2GeF_6 + 2NH_3 \rightarrow (NH_4)_2GeF_6 \tag{3b}$$

The difference in solubility of the resultant $(NH_4)_2SiF_6$ and $(NH_4)_2GeF_6$ leads to different etching rates between the core and cladding. Therefore, the tip cone angle is a
Figure 5. Scanning electron micrograph of an array of nanotips formed by chemical etching of a fiber-optic bundle.

function of the concentration of etchant solution and the GeO_2 dopant level of the fiber core. Temperature can also influence the tip cone angle [18].

Etching parameters such as solvent type, acid concentration, etching time, and temperature are crucial for optical and geometrical characteristics (e.g., cone angle, aperture diameter, well size); Table 1 lists some of the conditions used in the literature. Recently, it was shown that a multiple-step etching process followed by application of an organic protecting layer improved optical characteristics of the fibers [37]. Stöckle developed a specific chemical etching method called tube etching. It involves etching fiber tips surrounded with an organic cladding where the acid first etches away the tip of the fiber without destroying the cladding [45]. The polymer cladding is thus acting as a wall, creating microcurrents in the acid, which, coupled with capillary action, cause the fiber to be etched into the shape of a cone with a large, smooth taper.

3.1.3. Fracturing

Fischer and co-workers [46, 47] fabricated tetrahedral tips for NSOM, using modified ultramicrotome glass blades. A rectangular slab of glass was cleaved twice at an angle. A tetrahedral tip consists of a pyramidal glass fragment, which is then coated with a gold film. The tetrahedral tip is mounted on the oblique end face of a glass support by an index matching glue. A beam of light incident at an angle of 45° can irradiate the tip.
Figure 6. Scanning electron micrograph of a nanowell array formed by chemical etching of a fiber-optic bundle. The doping concentration in the core and clad material determines whether nanotips or nanowells will be formed.

4. FIBER OPTIC-BASED NANODEVICES

4.1. NSOM-Based Applications in Nanotechnology

4.1.1. NSOM-Based Optical Storage

In addition to its use in analytical applications as well as in the detection of nanostructures ([48–50] and references therein), NSOM is also used for data storage applications. Data are written and read off of optical storage devices by using a focused laser beam on a storage medium [51]. The data density on optical storage disks is determined by the size of the focused laser spot, which is determined by the diffraction limit of light, approximately $\lambda/2$(NA). The diffraction limit can be overcome, however, by NFO

techniques, as discussed previously. Smaller spot sizes can increase the areal density over what is currently available on storage devices.

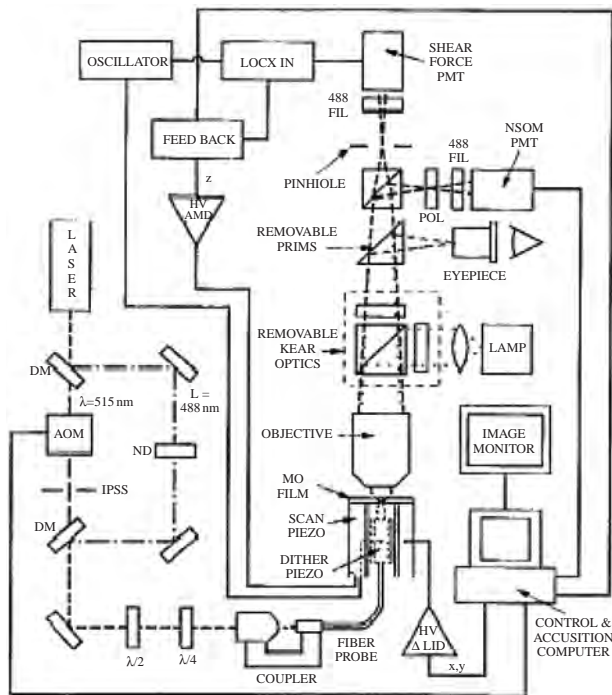
Near-field techniques were used to write and read data [52–60] domains as small as 60 nm in thin-film magneto-optic materials [61]. As shown in Figure 7, a dichroic mirror splits a beam from an Ar laser into two distinct wavelengths. One beam is used for reading, and another is used for writing. The beam used for reading is attenuated with a neutral-density filter, while the writing beam is controlled with an acousto-optic modulator. The beams are then recombined and coupled into an optical fiber NSOM probe. Half-wave ($\lambda/2$) and quarter-wave ($\lambda/4$) plates, positioned before the fiber coupler, adjust the polarization of the laser light to an almost purely linear state. The Faraday effect rotates


Figure 7. Schematic of system used for near-field magneto-optic imaging and recording. Reprinted with permission from [61], E. Betzig et al. *Appl. Phys. Lett.* 61, 142 (1992). © 1992, American Institute of Physics.

the polarization of the light slightly as it passes through the magneto-optical film. The direction of the rotation is determined by the orientation of the magnetization immediately under the probe. A conventional optical microscope then collects the light, and the image is viewed with a polarizer/photomultiplier tube combination.

The acousto-optical modulated laser beam writes data on the magneto-optical storage medium by heating the data region under the probe near the Curie temperature [61], magnetizing the domain in a direction opposite that of the surrounding medium. After writing, the data are then read with the lower power read beam. An example of written data is shown in Figure 8.

The data domains are approximately 100 nm in diameter with a 200-nm center-to-center spacing. The polarization of the aperture is rotated by approximately $+1°$ and $-1°$ (Fig. 9a and b, respectively). The pattern on the storage medium is imaged as it appears, composed of alternating contrast regions. Although high laser power may be required, the entire reading and writing process is straightforward.

4.1.2. NSOM Optical Lithography

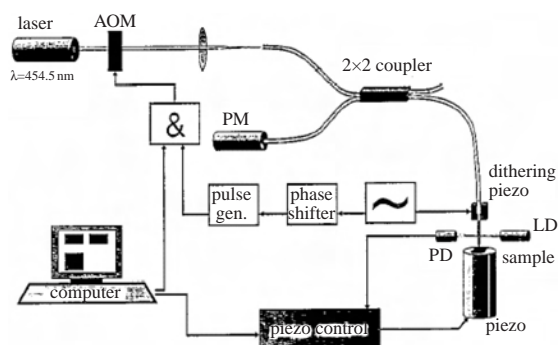
The smallest structures that can be achieved with conventional optical lithography are determined by the Abbe diffraction limit. Although shorter wavelengths (UV, X-rays) and particle beams have brought the feature sizes down to a few nanometers, the setups are costly. NFO lithography was investigated as a method to bypass the limitations faced in conventional optical lithography [62–64].

A near-field lithographic probe was fabricated by drawing an optical fiber while it was heated with a CO_2 laser. The tapered ends were subsequently coated with an approximately
Figure 8. (a–c) Near-field magneto-optic images of conventionally written domains at three different polarization states. Lett.* 61, 142 (1992). © 1992, American Institute of Physics.

100-nm layer of aluminum. Typical aperture sizes of about 50 nm were achieved.

As shown in Figure 10, a photoresist sample was mounted on a piezoelectric motor and was placed in proximity to the near-field probe, approximately 10 nm away. An Ar laser was coupled into the optical fiber that was connected to a fiber coupler. An acousto-optical modulator was placed in the laser beam to control the exposure of the laser light to the photoresist. Lines about 80 nm wide and 10 nm deep were written on the surface upon exposure to laser light emitted from the probe. The surface structures were analyzed with an AFM, as shown in Figure 11.

4.1.3. Near-Field Optical Array

Single probes in conventional NSOMs are limited in that they can only examine one particular region at a time [6, 65]. Pantano and Walt [7, 43] fabricated a NFO array
Figure 9. Written domains with ~100-nm diameters formed and imaged with near-field techniques. Two different polarization states are shown in (a) and (b). Reprinted with permission from [61], E. Betzig et al. *Appl. Phys. Lett.* 61, 142 (1992). © 1992, American Institute of Physics.


that can overcome this limitation. A 300-μm-diameter imaging fiber bundle, comprising approximately 6000 coherently fused optical fibers, was chemically etched in a buffered HF solution for 16 h, yielding an array of near-field tips (shown in Fig. 12).

To prevent light leakage from the sidewalls of each tip in the array, a gold layer coated the entire array. The entire array was crudely ground on a spinning mirror to create nanoapertures on each tip. Metal-coated tips with apertures as small as 300 nm were fabricated, and the height differences between near-neighbor tips were as small as approximately 20 nm, as shown in Figure 13. The optical properties of the array were also investigated by directing light through the proximal end of the fiber and imaging a small portion of the distal face through a microscope objective.

The major advantage of a near-field array is that it can scan a larger area of a sample. For example, in an equivalent period of time, an array of several thousand 100-nm-diameter near-field tips on the distal face of a 300-mm-diameter fiber bundle could scan over an area approximately three orders of magnitude larger than that of a single 100-nm-sized tip. In addition, commercial imaging fibers are available with up to 100,000 individually clad optical fibers such that very large regions can be imaged with subwavelength resolution.

4.2. Nanosensors

The resolution obtained in near-field microscopy has become useful for single molecule detection [66–69]. Nanoprobes have detected single dye and dye-labeled DNA molecules [48, 70]. The probes had a 100-nm resolution and were able to image labeled DNA molecules. Nanofibers can probe for specific chemicals in highly localized areas, capable of monitoring concentration gradients and spatial homogeneities in cellular environments. Kopelman et al. [6, 71] reported the first nanobiosensor to monitor the environment inside rat embryos. Measurements of Na^+ and Ca^{2+} were also analyzed [72]. These conventional sensors are based on the measurement of fluorescence intensity or on the measurement of luminescence decay time [73].

4.2.1. Nano-Bio-Optrodes

The recent drive in nanotechnology research has led to the development of the nano-bio-optrode, a device that is able to monitor biomolecular concentrations inside a single living cell, elucidating more about the complex intracellular processes that occur [6, 10, 74].

Nano-bio-optrodes are composed of optical fibers a few nanometers in diameter. The optical fiber initially has a diameter of a few micrometers before a modified micropipette puller heats and pulls it to form the bio-optrode.
Figure 13. High-magnification scanning electron micrographs of a gold-coated, chemically etched fiber before (A) and after (B) it was ground on a spinning mirror. The white bars denote a 0.5-μm distance. Reprinted with permission from [43], P. Pantano and D. R. Walt, *Rev. Sci. Instrum.* 68, 1357 (1997). © 1997, American Institute of Physics.

The distal tip of the tapered fiber typically has a diameter between 20 and 80 nm. Kopelman and co-workers [65] used this technique to fabricate nano-fiber-optic chemical sensors to monitor the pH inside living cells. A pH-sensitive dye was immobilized on the surface of the fiber tip in a polymer hydrogel to measure the pH changes.

An enzyme-based nano-bio-optrode was also used to measure nitric oxide content [75]. Fluorescently labeled cytochrome c' was immobilized on the tip of the fiber. In the presence of NO, cytochrome c' undergoes a conformational change. Nitric oxide concentration changes were correlated to changes in the energy transfer between cytochrome c' and the fluorescent dye.

Vo-Dinh and co-workers fabricated an antibody-based nano-bio-optrode to detect benzo[a]pyrenetetrol (BPT) [76–78]. The outer walls of the tapered end of a 200-nm to 300-nm fiber were coated with a thin silver, gold, or aluminum layer with the use of a vacuum evaporator as shown in Figure 14. A turning plate/motor device held and rotated the fiber in the deposition chamber. The fiber was held at an angle relative to the metal vapor, and as it rotated, the metal evenly coated the sides of the fiber while leaving the tip uncoated. The metal coating prevents light from leaking from the fiber walls and maximizes the light intensity at the fiber tip. The uncoated tip surface was then silanized to covalently attach anti-BPT antibodies.

Figure 15 shows how the nano-bio-optrode measured BPT concentrations inside a single living cell. The tapered end of the fiber was inserted at an angle inside a living cell and incubated for 5 min to allow the antibodies to bind the antigen (BPT). Laser light was transmitted through the fiber and excited the fluorescent BPT. Bound BPT molecules changed the fluorescence signal. The fiber was then removed from the cell, and the fluorescence signal obtained from the bound BPT was collected through a microscope objective and measured and analyzed with a photomultiplier tube.

Nano-bio-optrodes are advantageous over larger bio-optrodes in that they have higher sensitivities and faster response times. Nano-bio-optrodes could detect BPT concentrations as low as 300 zeptomoles.

4.2.2. Fiber Bundle-Based Nanotip pH Sensor

The desire to miniaturize analytical detectors such that data throughput can be increased while small volume samples are used has fueled the rapid development of nanobioanalytical techniques. Another desire in new imaging methodologies involves remote analysis of samples, without having to bring the sample to the microscope stage. A nanotip array, fabricated by chemically etching an imaging fiber bundle, was used to measure oxidative stress in biological cells [22].

Oxidative stress results in an overload of reactive oxygen species, such as hydrogen peroxide, and causes a pH change in cells. Oxidative stress is thought to be an important causative agent in a variety of pathologies such as aging, cardiovascular disease, some carcinogenesis, and possibly in AIDS. Conventional amperometric measurement techniques analyze oxidative stress by inserting the tip of a 5-μm carbon-fiber microelectrode into a biological cell. Analysis indicated that the hydrogen peroxide was generated as a direct result of the microelectrode insertion [79–82]. A nanotip array would improve conventional oxidative stress monitoring techniques because the nanometer dimensions of the tip would be less intrusive to the cell. A nanotip array should also increase measurement throughput by providing sampling through many probes instead of using only one, and the nanotip array's sensing layer can be readily modified to allow investigation of a variety of biologically relevant analytes.

A nanotip array was fabricated by chemically etching a fiber bundle with HF, as discussed in Section 4.1.3, and a chemical sensing layer was deposited across the array such that the nanotip architecture was retained. In addition to its remote sensing abilities and measurement throughput improvements, the small nanotip diameters (ca. 200 nm) of the nanotip array should more closely mimic the size scale of biological entities such as bacteria and viruses in comparison with a conventional 5-μm microelectrode tip.

Figure 14. Fabricating nano-bio-optrodes. (a) An optical fiber heated and then tapered to submicron dimensions. Metal is then thermally evaporated on the fiber sidewalls to prevent light leakage. The fiber is mounted on a rotating plate, evaporating an even coating while creating an aperture. Antibodies can be immobilized on the bare distal tip. Reprinted with permission from [77], T. Vo-Dinh et al., *Nat. Biotechnol.* 18, 264 (2000), © 2000, Nature Publishing Group; and [78], T. Vo-Dinh et al., *Sens. Actuators, B* 74, 2 (2001), © 2001, Elsevier Science.

4.3. Fiber Bundle-Based Photoimprint Lithography

Well-established methods such as electron beam, X-ray, and UV lithographic methods have been used to create nanostructures [83–86] (Sun, 2002 #152, 87). Dam and Pantano [88] created a nanotip array by chemically etching fiber-optic imaging bundles as described in the previous sections. An array of tips was produced as a lithographic template for surface patterning applications. As shown in Figure 16, two methods were used to pattern a polymer surface: photoimprint lithography and imprint lithography.

Both techniques produced arrays of picoliter-volume wells suitable for microanalytical applications. In photoimprint lithography, a patterned surface was created when the nanotip array was brought into contact with a photopolymerizable monomer film, and photoinitiation was directed through the array. With this method, an array of 1-μm wells was produced with a 4-μm center-to-center spacing. In imprint lithography, bringing the nanotip array into contact with a heated polystyrene-covered surface created a patterned surface. With this technique, an array of 0.8-μm-radii wells was produced with 3-μm cone depths and 25° cone angles, as shown in Figure 17.

4.4. Ordered Nanowell Arrays

Lithographic procedures such as microcontact printing [89], high-throughput imprint lithographic methods [90, 91], and nanochannel array glass materials [92] have been used to form ordered, periodic structures on a variety of materials. Arrays of nanowells were fabricated from fiber-optic bundles as another form of templating. Pantano and Walt [7, 43] produced arrays of nanowells with approximately 300-nm diameters, using an embossing template to create patterned polymeric films.

Fiber-optic imaging bundles were polished with a series of lapping films. The fiber bundle was then pulled with a standard micropipette puller and potted in epoxy such that the length of the imaging fiber's distal tip protruded from the polishing apparatus. Adjusting the length of the fiber
Figure 16. (a) Photoimprint lithography through a nanotip array. A PS802 polymer film is placed on a silicon glass surface. The nanotip array is then brought into contact with the film and glass surface, and light is directed through the fiber bundle, exposing the surface to light. The tip array is then removed, leaving a polymerized, patterned surface. (b) Imprint lithography with a nanotip array. An aluminum surface is coated with melted polystyrene. The nanotip array is then brought into contact with the warm polymer film. The array is then removed, leaving a patterned polystyrene surface. Reprinted with permission from [88], T. H. Dam and P. Pantano, *Rev. Sci. Instrum.* 70, 3982 (1999). © 1999, American Institute of Physics.

yielded the final, desired diameter of the tapered fiber. The fiber bundle was then chemically etched in a buffered HF solution, yielding an array of nanowells. Scanning electron microscopy and AFM were used to characterize the surface of the modified fiber bundle, as shown in Figure 18. Nanowells with diameters as small as 480 nm with 4.5-μm center-to-center spacings and 300-nm well depths (corresponding to $\sim$2 fL volumes) could be obtained. Such small wells could be used, in principle, as nanoreaction vials for molecule trapping.

The resulting nanowell arrays were used to emboss polymeric films with nanometer-sized structures. The nanowell array was dipped into a siloxane copolymer solution and allowed to cure. The polymer cured upon solvent evaporation, and the dip process was repeated five times. The polymer film was then peeled off of the fiber, resulting in a

hexagonally packed array with 600-nm tall cones, as shown in Figure 19.

5. CONCLUSIONS

A variety of techniques have been used to fabricate nanometer-sized optical fiber tips and arrays of nanotips and nanowells from optical fiber bundles. The nanoprobes and arrays of nanoprobes have been successfully applied in NSOM, near-field data storage, and near-field lithography. These systems overcome the diffraction limit, enabling one to study materials science and biomedical phenomena on the nanometer scale. Near-field methods have also been applied to data storage with the potential to create data densities higher than those currently available. NFO lithography can provide a potentially low-cost alternative to conventional lithographic techniques while improving the spatial resolution on substrates. With nanoprobes and arrays of nanoprobes, nanosensors for nitric oxide monitoring and oxidative stress monitoring can be created with higher temporal resolution, greater data throughput, and increased sensitivity. The large variety of nanoprobes will lead to new techniques and applications where progress has been limited by present technologies. In addition, arrays of nanowells have been fabricated for use as nanometer-sized templates for polymer films. As nanotechnology research advances, optical fibers will be further integrated with nanodevices, producing tools that will improve and enhance conventional tools used in scientific research and development.

GLOSSARY

Chemical etching Process of etching by a chemical reaction between a chemically reactive etching species and the material.

Near-field scanning optical microscopy (NSOM) [Also referred to as scanning near-field microscopy (SNOM)]. A scanning probe microscopy technique that analyzes the optical properties of a surface (e.g., fluorescence transmission, reflectance). The specimen is placed less than a wavelength away from the probe, and light is transmitted through a subwavelength-sized aperture as the surface is scanned.

Optical fiber Glass or plastic rod consisting of a core surrounded by a cladding material with a higher refractive index that results in total internal reflection light and confines light to the core. As a result, light is efficiently transmitted with minimal attenuation.

Optical Properties of Gallium Nitride Nanostructures

Annamraju Kasi Viswanath

Ministry of Information Technology, Pune, India

CONTENTS

1. INTRODUCTION

In the last decade, there have been dedicated efforts to develop the materials and solid-state devices based on III–V nitrides and other wide bandgap semiconductors [1–22]. The III–V nitrides belong to the general class of wide bandgap semiconductors. These semiconductors are particularly suitable to develop light-emitting diodes (LED), semiconductor lasers, ultraviolet (UV) detectors, field-effect transistors, etc. Short wavelength LEDs have very important applications in high-density optical storage, full-color display technology, color photocopy, digital video-disk, lighting, underwater communications. Nitride-based LEDs already are being used in traffic lights, automobile lights, home lighting, and entertainment. InN, GaN and AlN belong to the III–V nitride faimily. They have bandgaps in the range 1.9 to 6.2 eV, and, hence, it is possible to make ternary and quarternary alloys of these materials to obtain bandgaps in the red to UV energies. One can use the well-known semiconductor fabrication techniques such as molecular beam epitaxy (MBE) and metal organic chemical vapor deposition (MOCVD) to achieve various nanostructures of quantum wells and superlattices.

Figure 1 shows the schematic diagram of a LED [14]. It has a p-n junction of a semiconductor with a bandgap E_g.

When current is passed through the junction, electrons in the conduction band flow across the junction from the n-type semiconductor, while the holes in the valence band flow from the p-type semiconductor. A large number of electrons and holes recombine at the junction, giving rise to radiation that has the energy equivalent to the bandgap. In direct bandgap semiconductors, the luminescence radiation obeys the relation $h\nu = E_g$, where ν is the frequency of emitted radiation, h is the Planck's constant, and E_g is the bandgap of the semiconductor. The plot of bandgaps as a function of the lattice constant for some semiconductors is shown in Figure 2 [1]. The first LED was made in the red region of the visible spectrum by using a GaAsP direct bandgap semiconductor [16]. The emission wavelength of this red LED was 610 nm. Figure 3 shows the evolution of LED technology, the performance of LEDs has improved over the years [19]. As can be seen in the figure, several materials were used to achieve various colors. These semiconductors include GaAsP, GaP:Zn, O, AlGaAs/GaAs, AlGaInP/GaAs, etc. Figure 3 also shows the wavelengths that can be obtained from InGaN-based LEDs. These are in the blue and green region of the electromagnetic spectrum, which were very much wanted for a long time for a number of applications. Nakamura, at Nichia in Japan, made it possible to achieve this important breakthrough in solid-state display technology. Nakamura's team made several LEDs and semiconductor lasers in the pulsed and continuous wave (cw) mode. It also was shown that the InGaN-based LEDs have better luminous intensities than the SiC-based LEDs, which were the only commercially available blue-light-emitting devices before the GaN-based devices came onto the market. It also was shown that III–V nitride devices were useful for high-temperature and high-power electronics.

To develop blue- and green-light-emitting devices II–VI based semiconductor materials were investigated for a long time. An excellent review on optical properties of these materials was given by Morkoc et al. [2]. ZnSe is nearly lattice matched to GaAs, and, hence, integration of II–VI based technology with the well-established GaAs technology could be anticipated. Also, high-quality GaAs substrate
Figure 1. Schematic of a LED. Electrons injected across a p-n junction combine with holes to produce photons in radiative recombination. However, in nonradiative recombination photons are not produced. The wavelength of the emitted radiation depends on the bandgap of the semiconductor material.

can be easily obtained. It also is possible to make several quantum structures because ternary and quaternary compounds of II–VI materials can be made that will have different bandgap energies. In the ternary system of ZnCdSe, the wavelength could be tuned in the blue to green region by changing composition. The quaternary ZnMgSSe was used to make the cladding layers. However, the LEDs and lasers with these materials have a short lifetime because of crystal defects. Therefore, commercialization of these devices could not be made.

Figure 4 shows the schematic energy level diagram describing the optical processes in semiconductors. The recombination phenomena gives valuable information about excitons, donors, acceptors, phonon interactions, etc. Figure 5 shows the band diagrams of direct and indirect semiconductors. In a direct bandgap semiconductor, the electrons and holes combine directly without any need of momentum conservation, whereas, in the indirect bandgap semiconductors, phonon participation is required for momentum conservation.

In this review, we discuss the optical properties of nanostructured GaN and related materials and their applications in fabricating LEDs and semiconductor lasers. A large number of papers have been published on the growth and photoluminescence properties of GaN. A variety of commonly available substrates have been used to grow epitaxial GaN. A detailed discussion on this topic is out of the scope of the present review. The review chapters written by the author cover these topics [10]. The present chapter emphasizes the optical properties of nanostructures such as nanowires, nanodots, nanobelts, nanoparticles, nanorods, nanocrystals, etc. The properties of epitaxial thin films are given for comparison purposes. We also discuss in great detail the quantum well structures of InGaN that form the heart of LEDs and semiconductor lasers.

We will give a very brief introduction to quantum confinement in semiconductors. There are several special editions that deal with the development of the exciting field of semiconductor nanostructures [23–27]. The article by Weisbuch [28] gives a very comprehensive description of various quantum-confined semiconductor structures and their optical and electronic properties. Basically, the thin film quantum structures initially were developed at IBM and AT and T Bell laboratories. This was possible by the novel MBE technique by which atomic layers can be grown one on top of
Figure 4. Most common optical processes in semiconductors. (a) is absorption of photons that generates electron and hole pairs in the conduction and valence bands, followed by various recombinations, (b) is band-to-band recombination, (c) is donor to valence band, (d) is conduction band to acceptor, (e) is donor–acceptor pair recombination.
Figure 5. Band diagrams of direct and indirect band gap semiconductors. In a direct band gap semiconductor electron and hole combine directly producing a photon, where as in an indirect semiconductor conservation of momentum is required for recombination to occur.

the other. Esaki and Chang [29] were the first to observe the perpendicular differential conductance due to resonant electron tunneling across potential barriers. Soon after that Dingle et al. [30] showed in their optical experimental results, the quantization of energy levels. This has proved beyond a doubt that very thin semiconductor layers of small nanometer dimensions can be grown that behave like quantum mechanical objects. Quantum phenomena come into play when the actual size of the material is of the order of DeBroglie wavelengths. The simplest confined structure is a quantum well, which is a very thin semiconductor with a thickness of a few nanometers or less that is placed between two barrier layers having higher bandgap energies. These also are called quasi two-dimensional (2D) systems. The free motion of the carriers occurs in only two directions perpendicular to the growth direction, while the motion in the third direction, z, is restricted. Several solid-state devices were achieved by using the quantum phenomena in semiconductors. These include the quantum well lasers [31, 32], high-electron mobility transitiors, modulation-doped transistors [33–35], etc. Modulation-doped quantum wells also give us the opportunity to study very interesting physical phenomena such as Landau quantization, Fermi edge singularity, many body effects, etc. [36–41]. The nonlinear optical properties of the quantum wells were found to be useful in fabricating optical switches based on optical bistability [42].

Semiconductor structures with higher degrees of confinement of carriers have been achieved. A quantum wire is a one-dimensional electron system in which quantum confinement occurs in two dimensions and a quantum box or a quantum dot is a zero-dimensional system, and the confinement of electron motion occurs in all three directions. The method of tailoring the materials to custom design the structure and desired properties also is called bandgap engineering. Sakaki [43] has predicted that in a single-channel quantum wire, the electron scattering is minimal and the electron mobility will be extremely high. Arakawa et al. [44] have theoretically studied the use of quantum wires in semiconductor lasers. Quantum wires are expected to be suitable for high-gain and low-threshold current lasers

and for high-electron mobility transistors because the density of states is very high. Free-standing quantum whiskers of GaAs were grown for the first time by MOCVD at Hitachi Central Research Laboratory, and very intriguing aspects of surface and interface recombination were studied by the author and his collaborators [45–48]. Lieber and coworkers have written very interesting articles on the physics and chemistry of wirelike structures [49–61]. Confined movement of electrons in the crystal gives very unique properties. The study of dimensionality and its effects on the material properties is not at all new and has been known in the chemistry for several decades [62, 63]. For example, in bulk single crystals that contain square planar complexes of Ni, Pd, and Pt, which show the quasi one-dimensional behavior, the electron motion is confined in the z direction. The author and his collaborators at the University of Maine, have published a series of papers on the electronic structure, extended Huckel molecular orbital calculations, optical properties, and time-resolved phenomena in single crystal Ni, Pd, and Pt compounds that contain square planar configurations [64–71]. Very interesting observations that can be directly related to quasi one-dimensional behavior of electrons, such as energy transfer along the one-dimensional chains, energy migration and trapping, optical anisotropy, bandgap formation due to the orbital overlap along the one-dimensional chains, etc., were observed. These crystals may be called natural quantum wires. These are "natural" in the sense that no special efforts have to be made to fabricate them and the crystal structure offers the possibility of restricted motion of the electrons. These crystals also serve as the model systems to understand the more complicated bandgap engineered, semiconductor, low-dimensional nanostructures.

It is possible to further reduce the dimension of the semiconductor in such a way that the motions of the electrons are confined in all the three directions to obtain a quantum dot, which also is known as a quantum box, a nanocrystal, or a nanoparticle [72]. In this situation, the translational symmetry is completely removed, and the traditional band structure of the solid splits into a bunch of discrete energy levels. This kind of energy-level scheme has several implications in the design of a number of semiconductor devices. When the size of the nanocrystal becomes much smaller than the bulk Bohr radius, the confinement affects not only the center-of-mass motion but also the relative motion of an electron and a hole. So the excited electron–hole pair does not behave like a true exciton in the bulk. The quantum confinement effects of a system containing the nanocrystals has been observed as the blue shift in the absorption spectrum, which increases with the decrease of the crystal size [72]. In the strong confinement case, where the electrons and holes are completely confined in all the three directions, the electronic states can be described by molecular orbitals rather than the Bloch functions in momentum space. The author and his collaborators at the Korea Research Institute of Standards and Science have investigated the special properties of self-assembled quantum dots such as bandgap renormalization and screening of carriers by femtosecond laser spectroscopy [73].

There are two main approaches to making the nanostructures. First is the top-to-bottom approach. This generally is used by physicists and semiconductor technologists

and involves very complicated procedures such as MBE, metal organic chemical vapor deposition, masking, etching, lithography, etc. Second is the bottom-to-top approach, which is a very inexpensive and easy method used by chemists. In this method, nanostructures are made by wet chemical methods, LB film formation, etc.

2. GALLIUM NITRIDE (GaN) NANOSTRUCTURES

Among the III–V nitrides, most work has been done on GaN because its bandgap is very suitable for developing UV lasers. Several papers have been published on the growth and photoluminescence properties of GaN. A variety of commonly available substrates have been used to grow epitaxial GaN. Sapphire has excellent properties required for a substrate to grow epitaxial layers. Most of the work on GaN has been done by using sapphire as a substrate. It is very stable, even at high temperatures, and has good chemical stability. Dingle et al. [74], Monemar [75] and Pankove et al. [76] have done the early pioneering work on the optical properties of GaN. The development of GaN devices was hampered by the lack of good-quality single crystals. The major problems were the lack of suitable lattice-matching substrates, very-high background n-type carrier concentration, and the difficulty in achieving p-type material. Two Japanese research teams, led by Nakamura and by Amano and Akasaki, who have used GaN [78] and AlN [90] buffer layers on the top of the substrates just before growing the epitaxial layers, have solved these problems [77–104].

2.1. Optical Properties of Thin Films of GaN

The early work on GaN was on absorption and reflection. Generally, the donor- and acceptor-bound exciton emissions were observed only in the photoluminescence spectra. Free-exciton transitions were found very rarely in the luminescence. The observation of free-exciton transitions is an indication of the good quality of the sample. Also, it is better to understand valance-band physics based on the luminescence properties rather than on absorption or reflection, because optoelectronic devices like LEDs and semiconductor lasers are based on emission phenomena. Hence, it is absolutely necessary to carefully investigate the effects of crystal fields, spin-orbit coupling, strain-induced deformation potentials, etc., on degenerate valence bands and how these are manifested in photoluminescence spectra.

Photoluminescence studies of high quality GaN epilayers grown by rotating disk MOCVD were reported by Viswanath et al. [105]. They have deduced several important parameters, such as exciton energies, delocalization energies of donor- and acceptor-bound excitons, Varshni's coefficients, exciton–phonon interaction parameters, etc. Figure 6 shows the photoluminescence spectrum of a GaN epitaxial layer grown on (0001) sapphire substrate at 12 K. The dotted lines show the individual peaks obtained by a curve-fitting procedure that uses a Lorentzian line-shape function. Assignment of various transitions was made by considering the electronic and band structures of GaN. The lattice mismatch between GaN and sapphire substrate generates strain
Figure 6. Photoluminescence spectrum of a GaN epitaxial layer grown on a (0001) sapphire substrate at 12 K. FX(A): free-exciton A; FX(B): free-exciton B; DX: donor-bound exciton; AX: acceptor-bound exciton; FX(A)-LO: phonon-assisted free exciton transitions; DX-LO: phonon-assisted donor-bound exciton transition. The dotted lines show Lorentzian fitting to various peaks. A He–Cd laser is used for excitation. Reprinted with permission from [105], A. K. Viswanath et al., *J. Appl. Phys.* 84, 3848 (1998). © 1998, American Institute of Physics.

in the epilayers. When the strained layer epitaxy occurs along (0001), the corresponding strain keeps the wurtzite symmetry but alters the valence and conduction-band energies via strain-induced modifications of the chemical bonds. GaN conduction band (Γ_7^c) is mainly constructed from s states of gallium, whereas the valence band is mainly from the p states of nitrogen. When there is no perturbation, the valence band is a threefold degenerate. But the crystal fields of the hexagonal symmetry of the wurtzite crystal lift the threefold degeneracy partially into a doubly degenerate Γ_5 state and a lower-lying Γ_1 state. The degeneracy is further removed through the spin–orbit interaction, and, in this case, the top of the valence band consists of Γ_9^v, Γ_7^v, and Γ_7^v, where Γ_9^v is the highest level. These three levels also are called A, B, and C valence bands, respectively.

Viswanath et al. [105] have assigned the peak at 3.479 eV to free exciton A or FX(A), the 3.486 eV peak to free exciton B or FX(B), the peak at 3.472 eV to donor-bound exciton DX, and the peak at 3.454 eV to acceptor-bound exciton AX. Temperature-dependent photoluminescence studies were made to confirm these assignments.

Dingle et al. [74] reported the free exciton transitions for A, B, and C at 3.474, 3.481, and 3.501 eV, respectively, based on their polarized reflection experiments at 2 K. From the photoluminescence excitation spectroscopy studies, Monemar [75] has observed these exciton transitions at 3.4751, 3.481, and 3.493 eV, respectively. It is important to note that the exciton energy values reported by Dingle et al. [74] and Monemar [75] represent strains free values because they have used very thick GaN samples. In the case of thin epilayers, there is a large mismatch between the lattice constants

of the sapphire substrate and the GaN crystal. Also, there is a large difference in the thermal expansion coefficients, which gives rise to misfit strain, which, in turn, generates many crystal defects and dislocations. This strain has a significant effect on the optical and electrical properties and also on the bandgap. In the case of sapphire substrate, the compressive biaxial stress in the epitaxial layers increases the energy values of the excitonic transitions and also the separations between them. The strain decreases with an increase in the layer thickness. The relationship between the strain and epilayer thickness has been investigated by Akasaki and coworkers [100]. They have studied the donor-bound exciton transition in the Photoluminescence (PL) spectra. Deviation of free-exciton values in thin (<4 μm) epilayers from the values reported for thick samples was explained by the strain effects. The quality of the sample is estimated from the magnitude of the deviation.

Viswanath et al. [105] have also studied the free-exciton transitions at 12 K and room temperature over a wide energy range. The PL spectra are shown in Figure 7. At both the temperatures, the normally observed yellow band at 2.2 eV and the donor-acceptor pair recombination at 3.27 eV could not be observed. From this result, it was inferred that the quality of the sample was very good. The separation between the energy positions of FX(A) and FX(B) transitions, Δ_{AB}, was found to be 7 meV. Viswanath et al. [105] have

concluded that the strain in their samples due to lattice mismatch is small since the ΔE_{AB}, value of 7 meV they observed is close to that of the unstrained value of 6 meV.

The DX peak was found to be at 3.472 eV, which is shown in Figure 6 [105]. The exciton binding energy to the donor or the localization energy of the donor is 7 meV. The donor binding energy can be evaluated by considering the Haynes rule [109] for semiconductors, which states that the localization energy is αE_D, where E_D is the binding energy of the donor and α is a constant of proportionality generally taken as 0.2. Viswanath et al. [105] obtained the binding energy of donor as 35 meV. These shallow donors may be nitrogen vacancies or Ga interstitials. The peak at 3.454 eV was interpreted as due to AX. The binding energy between the acceptor and exciton is 25 meV. Considering the Haynes rule [109], a value of 250 meV for acceptor binding energy was estimated. In the case of acceptors, the constant of proportionality is 0.1.

Figure 8 shows the temperature dependence of the PL spectrum. As the temperature increases, FX(A) intensity increases at the expense of the DX peak. The donor-bound exciton dissociates into a free exciton and a neutral donor. The intensity ratio of the free exciton A peak to the donor-bound exciton peak, i.e., $I_{FX(A)}/I_{DX}$ is shown as a function

Figure 7. Photoluminescence spectrum of GaN showing the free-exciton transition at 12 K and room temperature. Note that there are no traces of yellow luminescence peaks and donor–acceptor transition due to background impurities or defects at both temperatures. Reprinted with permission from [105], A. K. Figure 8. Photoluminescence spectra at selected temperatures for GaN epitaxial layers on sapphire. The changes in the relative intensities of free-exciton A and the donor-bound exciton can be noticed. Reprinted with permission from [105], A. K. Viswanath et al., *J. Appl. Phys.* 84, 3848 (1998). © 1998, American Institute of Physics.

of temperature in Figure 9a, and we can see that the ratio increases. From this the authors have concluded that the donor-bound exciton dissociates into a free exciton and a neutral donor, DX → FX + D. The PL intensities of a donor-bound exciton are plotted as a function of $1/T$, as shown in Figure 9b. The thermal activation energy of donor was estimated as 6 meV. The PL peak positions were plotted as shown in Figure 10. The experimental points were fitted to the Varshni's equation for variation of the bandgap with temperature

$$E(T) = E(0) - [\alpha T^2/(\beta + T)] \tag{1}$$

In this equation, $E(T)$ is the transition energy at any temperature T, $E(0)$ is the corresponding energy at 0 K, and α and β are Varshni's thermal coefficients. The solid lines were obtained by least-square fitting. For FX(A), the best-fit values are $E(0) = 3.480$ eV, $\alpha = 5.0 \times 10^{-4}$ eV/K, and $\beta = 400$ K; and, for FX(B), $E(0) = 3.488$ eV, $\alpha = 5.2 \times 10^{-4}$ eV/K, and $\beta = 450$ K. In the case of GaAs, the β value is the same as the Debye temperature of the lattice. However, in the case of GaN, the exact relationship between β and the Debye temperature is not known yet. Figures 11a and b show the plots of PL peak energies as a function of $T^2/(\beta + T)$ for free excitons A and B, respectively. The authors have obtained a straight line in each case from which it was concluded that the excitons exist up to room temperature in GaN.

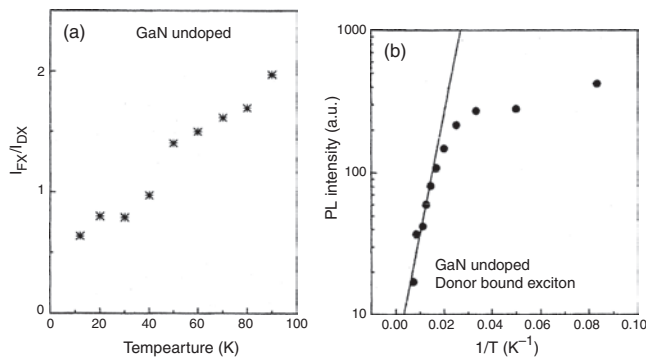
Based on the observation of excitons up to room temperature, it was proposed [105] that GaN can be used in fabricating nonlinear optical devices working at room temperature. These devices have applications in the area of nonlinear optical signal processing, digital optical switching, optical computing, and optical communication. The longitudinal optical (LO) phonon-assisted transitions of the donor-bound exciton, free exciton A, and free exciton B were observed at 3.383, 3.392, and 3.398 eV, respectively, as shown in Figure 12. The separations of these peaks from their zero-phonon peaks are 89, 87, and 87 meV, respectively. These energy separations are in the range of LO phonon


Figure 10. Temperature variation of the various transitions in the PL spectra of GaN/sapphire. The experimental points are represented by solid squares for free-exciton A, FX(A); solid triangles for free-exciton B, FX(B); and stars for the donor-bound exciton, DX. The solid lines are the theoretical fit curves following Varshni's equation for variation of the bandgap as a function of temperature. Reprinted with permission from [105], A. K. Viswanath et al., *J. Appl. Phys.* 84, 3848 (1998). © 1998, American Institute of Physics.

energy of GaN, which is 90 meV. The energy separation between FX(A)-LO and FX(B)-LO is 7 meV, while the separation between DX-LO and FX(A)-LO also is 7 meV. These energy separations agree with the corresponding energy differences of the zero-phonon transitions observed in the 12 K spectrum. The phonon replicas reveal that phonon-assisted exciton formation is very efficient in GaN. In polar semiconductors, Frohlich polar intraband scattering [110], which is the interaction between free excitons and LO phonons, is strong. Frohlich interactions were observed in other wide bandgap semiconductors [111–115].

Figure 13 shows the PL intensities of the free exciton A as a function of $1/T$. The activation energy of the free exciton was estimated as 26 meV [105]. Viswanath et al. [105] have estimated the bandgaps of GaN as 3.505 and 3.437 eV at 12 K and room temperature, respectively.

2.1.1. Exciton Phonon Interactions in GaN

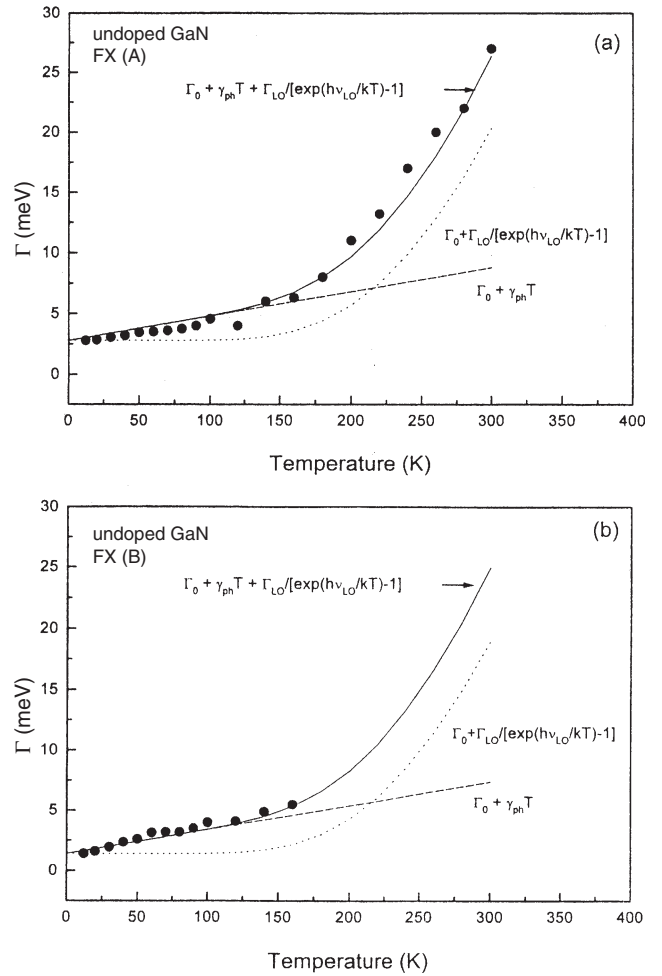
The lasing mechanism in GaN-based devices—excitonic versus band-to-band recombination—has not been understood so far. Viswanath et al. [106] have done the detailed analysis of exciton linewidths in the PL of GaN. Figures 14a and b show the temperature dependence of the linewidths of the free exciton A and B, respectively. Solid circles are experimental linewidths. The observed linewidths were fitted to a theoretical model. The basic formalism for phonon-assisted optical absorption and exciton lifetimes was developed by Toyozawa [116] and by Segall and Mahan [117]. Segall [118] applied it to describe absorption and emission in a number of materials. The temperature dependence of the width of the lowest 1S exciton in semiconductors initially was reported by Segall [119], and the most comprehensive
Figure 13. Photoluminescence intensities of the free-exciton A transition (shown as stars) as a function of $1/T$. The activation energy of free-exciton A is estimated as 26 meV from the slope of the straight line. Reprinted with permission from [105], A. K. Viswanath et al., *J. Appl. Phys.* 84, 3848 (1998). © 1998, American Institute of Physics.


Figure 14. Temperature dependence of the linewidths of (a) free exciton A and (b) free exciton B in GaN. Solid circles are the experimental points. Solid curve is the fitting of the experimental linewidths considering acoustic-phonon scattering and LO-phonon scattering. Dashed lines show the contribution from the acoustic-phonon scattering alone, and dotted lines show the contributions from the LO phonons only. In both the cases, inhomogeneous broadening was added. Adapted with permission from [106], A. K. Viswanath et al., *Phys. Rev. B* 58, 16333 (1998). © 1998, American Physical Society.

treatment was later given by Rudin et al. [120]. According to them, the exciton linewidth $\Gamma(T)$ at any temperature T can be written as

$$\Gamma(T) = \Gamma_0 + \gamma_{\mathrm{ph}}T + \Gamma_{\mathrm{LO}}N_{\mathrm{LO}}(T) \qquad (2)$$

In polar semiconductors, linewidth is dominated by LO-phonon broadening. Γ_0 is inhomogeneous broadening in the above equation. At very low temperatures, phonons are not active, and the contribution to the linewidth is mainly from inhomogeneous broadening. The second and third terms on the right-hand side of Eq. (2) are the homogeneous linewidths and are due to acoustic-phonon and LO-phonon scattering, respectively. The contribution due to acoustic phonons increases linearly with temperature T and is represented as $\gamma_{\mathrm{ph}}T$, where γ_{ph} is the exciton–acoustic-phonon coupling strength. The last term in Eq. (2) arises from interactions with LO phonons and is proportional to the Bose

function $N_{LO}(T)$ for LO-phonon occupation, which is equal to $1/[\exp(h\nu_{LO}/kT - 1)]$, where $h\nu_{LO}$ is the LO-phonon energy in GaN, and Γ_{LO} represents the strength of exciton–LO phonon coupling.

The solid lines in Figure 14 are the least-squares fitting considering acoustic-phonon scattering and LO-phonon scattering, in addition to inhomogeneous broadening. The LO-phonon energy was taken as 91.5 meV. The fitting parameters are $\Gamma_0 = 2.8$ meV, $\gamma_{ph} = 21$ μeV/k, and $\Gamma_{LO} = 525$ meV for FX(A), and $\Gamma_0 = 1.4$ meV, $\gamma_{ph} = 22$ μeV/k, and $\Gamma_{LO} = 495$ meV for FX(B).

In Figure 14, the dashed lines show the contribution from acoustic-phonon scattering and the dotted lines show the contribution from LO phonons to the linewidth. In all the cases, the inhomogeneous broadening also is added. The acoustic phonons contribute up to 120 K very significantly, but the contribution from LO phonons is negligible up to this temperature. From 120 K, the LO phonon contribution is very significant, and the linewidth increases sharply, because of the exponential factor. At 200 K, there is a crossover, and LO phonons dominate over the acoustic phonons.

The value of exciton–LO-phonon coupling parameter, Γ_{LO}, reported by Viswanath et al. [106] is very high. It indicates very strong interaction between excitons and LO-phonons. GaN is a polar material and has a very high Frohlich constant, which is responsible for the large Γ_{LO} value. The exciton–phonon interactions can be seen in the optical spectra in two ways. First is the line broadening of absorption or emission spectra. Second is the occurrence of phonon-assisted transitions in the absorption and emission spectra [105] as discussed in the previous sections.

It is necessary to have excitons that can exist up to room temperature, in order to realize room-temperature photonic devices. The existence of room-temperature excitons depends upon the delicate balance between two competing factors. The first is the excition–LO-phonon interaction parameter, and the second is the exciton binding energy. A very large value of Γ_{LO} will make the exciton line broaden, so much so that at high temperatures the line will vanish completely. But the larger binding energy of the exciton can resist the phonon interaction, and it is possible to observe room-temperature excitons. This is what actually happens in the case of GaN, which has a larger binding energy of 26 meV. Viswanath et al. [106] have suggested that to realize stable room-temperature devices, it is better to work with quantum-confined systems of GaN, which have higher binding energy and lower LO-phonon coupling as a direct consequence of quantum phenomena. Added to this, quantum wells have a much narrower emission due to smaller inhomogeneous broadening.

In the same publication Viswanath et al. [106] have reported the temperature dependence of the PL intensities of both free exciton A and B. These are shown in Figure 15. While the intensity of free exciton A decreases steadily with an increase in temperature, the intensity of free exciton B initially increases up to 40 K and then decreases. The initial increase in intensity was explained by the authors as due to the higher energy position of free exciton B compared with free exciton A.

2.1.2. Acceptors in GaN

The first LEDs made of GaN were based on the metal–insulator–semiconductor structure. These devices required very high operating voltages, and, hence, they were not useful in practical devices. Several acceptor impurities were tried to make p-GaN with Zn, Cd, Be, Mg, Hg, and Li. It was observed that all these impurities effectively compensate the electrons in GaN, leading to highly resistive material. Amano et al. [95] achieved p-GaN by low-energy electron-beam irradiation (LEEBI) of Mg doped GaN. They also demonstrated the p-n junction LED by using LEEBI treated Mg-doped GaN as the p-type material. Nakamura et al. [80] have successfully obtained p-type GaN by thermal annealing. Mg was recognized as the most suitable acceptor impurity.

Photoluminescence of Mg/GaN grown by MOCVD was reported by Viswanath et al. [121]. Energy levels of these acceptors were investigated by systematic photoluminescence measurements in the temperature range of 12–300 K. Mg concentration was varied from less than 1×10^{19} to higher than 5×10^{19} cm^{-3}. Figures 16, 17, 18, and 19 show the PL spectra for different Mg concentrations and for different annealing conditions. In the 12 K spectrum shown in Figure 16a, a strong line at 3.276 eV and satellites on the low-energy side at 3.184 and 3.092 eV were observed. The main line at 3.276 eV was attributed to zero-phonon donor–acceptor pair transition. The separation between two consecutive lines is about 92 meV. In the Raman spectra of undoped and Mg-doped GaN, the authors also observed the transitions due to the LO phonons with an energy of 91 meV. By this argument, the first satellite at 3.184 eV was assigned as the first phonon replica and the line at 3.092 eV as the second phonon replica of the donor–acceptor pair transition. The donors may be nitrogen vacancies. They have estimated the binding energy of the acceptor as 209 meV. Figure 13b shows the PL spectrum in the excitonic region at 12 K for the as-grown Mg-doped GaN with [Mg] less than 1×10^{19} cm^{-3}. The FX(A) is the free exciton A, FX(B) is the free exciton B, DX is the donor-bound exciton, and AX is the acceptor-bound exciton transition. The spectrum for the doped samples shown in Figure 16b has exactly the same features as those found in undoped GaN [105]. Figure 17 shows PL spectra at certain selected temperatures for the annealed samples of Mg-doped GaN with [Mg] less than 1×10^{19} cm^{-3}. The DA pair transitions were observed at low temperatures, which almost vanish at 120 K, and a new broad peak was seen at around 2.94 eV, which was attributed to conduction-band electron transition to a Mg acceptor.

2.1.3. Donors in GaN

The native defects were supposed to give high carrier concentrations in undoped GaN [10]. Nitrogen vacancy and oxygen impurities were considered as background donors.

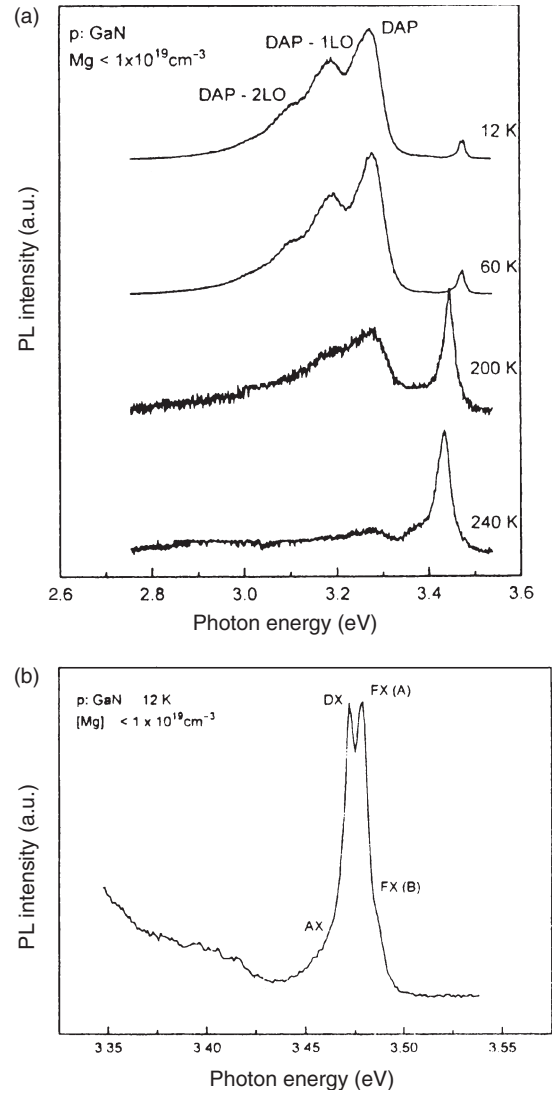
Photoluminescence studies of shallow donors in GaN were done by Viswanath et al. [108]. Ionized donor-bound excitons have been observed, in addition to donor-bound excitons, as shown in Figure 20. The donor-binding energy was deduced as 35 meV. Figure 21 shows the temperature dependence of the full width at half maximum (FWHM) of the neutral donor-bound exciton PL peak reported by


Figure 16. (a) Photoluminescence spectra at selected temperatures for magnesium-doped GaN, Magnesium concentration is less than 1×10^{19} cm^{-3}. Viswanath et al. [108]. The solid squares are the experimental points, and the straight line is the linear fit of the experimental points. The experimental linewidths may be described by

$$\Gamma(T)(\text{FWHM}) = \Gamma_0 + \gamma_{\text{ph}}T \tag{3}$$

Here $\Gamma(T)$ is the linewidth at temperature T; Γ_0 is the low-temperature limit of the linewidth and contains the contributions due to collision with other excitons, scattering by the crystal imperfections, or radiative recombination; and γ_{ph} is a measure of the exciton–acoustic-phonon coupling strength. From the linear increase of the linewidth with temperature, it was concluded by the authors that only acoustic phonons
Figure 17. Photoluminescence spectra at selected temperatures for the annealed samples of Mg-doped GaN. Magnesium concentration is less than 1×10^{19} cm^{-3}. The broad peak at 2.94 eV, which appears at higher temperatures is due to conduction band to acceptor transition. Reprinted with permission from [121], A. K. Viswanath et al., *J. Appl. Phys.* 83, 2272 (1998). © 1998, American Institute of Physics.

Figure 18. Temperature dependence of the PL spectra for as grown Mg:GaN. Magnesium concentration is in the range of $1-5 \times 10^{19}$ cm^{-3}. Reprinted with permission from [121], A. K. Viswanath et al., *J. Appl. Phys.* 83, 2272 (1998). © 1998, American Institute of Physics.

contribute to the homogeneous broadening. From the analysis of the linewidths, the following values were evaluated: $\Gamma_0 = 1.55$ meV and $\gamma_{ph} = 0.14$ meV/K.

Figure 22 illustrates the plot of the integrated emission intensity of the neutral donor-bound exciton as a function of $1/T$. The activation energy was reported as 9 meV. Figure 23 is a plot of the ratio of total intensity of free excitons to the total intensity of bound excitons, which includes both neutral and ionized donors, as a function of temperature. From the figure, it is clear that the bound excitons dissociate thermally, releasing free excitons and neutral donors as well as ionized donors. At 100 K, donor-bound excitons completely dissociate, forming free excitons and neutral donors. This temperature corresponds to the dissociation energy of the donor-bound exciton.

2.2. GaN Nanowires

Chen and Yeh [122] have reported the large scale production of GaN nanowires by a very simple method. They have reacted gallium and ammonia by using polycrystalline indium powder as a catalyst. The fiber-like semiconductors of GaAs, InP, etc. were grown by several groups by the vapor–liquid–solid crystal growth mechanism. The important ingredient in this method is the catalyst between the vapor and the solid at high temperatures that are normally required for the chemical vapor deposition technique.

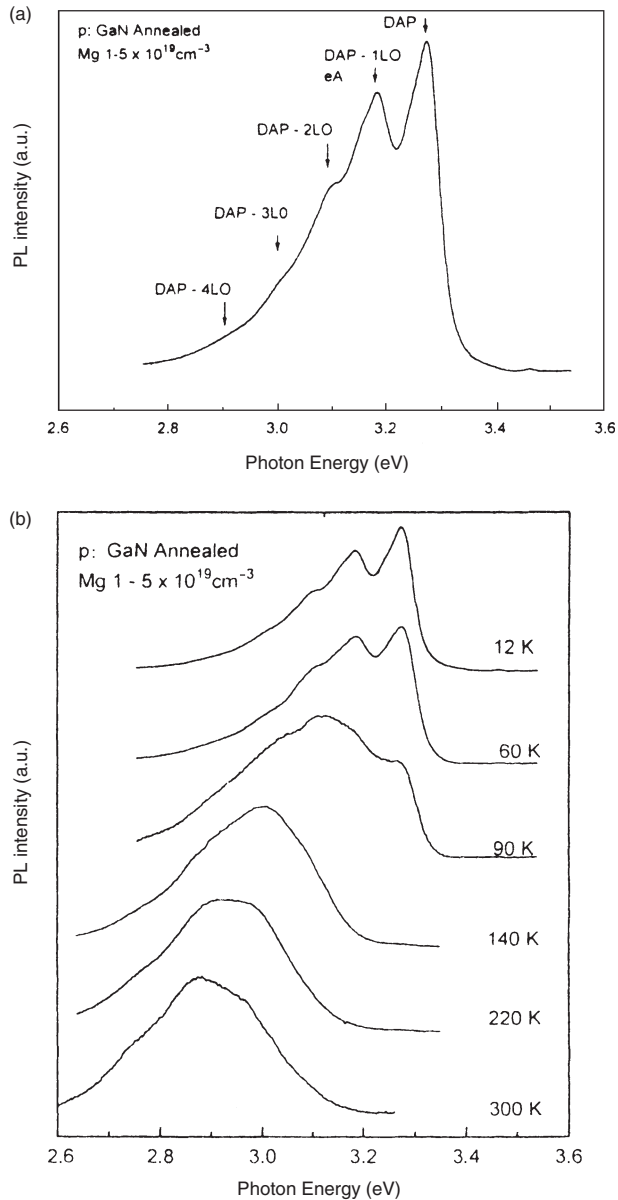
Generally, gold metal has been used as the catalyst for the wire-like structures of both III–V and II–VI semiconductors. Chen and Yeh have realized that elemental indium was better than gold as a catalyst. It was thought that very small In–Ga–N miscible droplets were formed during the heating process of the reaction, which act as nucleation sites in the VLS growth of GaN nanowires. However, the authors could not give any evidence for their mechanism. The diameters of the wires were estimated to be about 20 to 50 nm from the scanning electron microscopy results. Nanowires were found to be uniformly distributed over 95% of the substrate area, and the rest was filled with nanoparticles of GaN. Chen et al. [123] have examined the effect of various catalysts and reaction parameters on the size of the nanowires and their properties. In these trials, they have modified their experimental setup and tried to separate the residual gallium and bulk gallium nitride from resulting GaN nanowires after the catalysis reaction was complete. When the reaction was going on, several combinations of metals were tried to act as catalysts. To increase the yield and control the diameter of the nanowire, the parameters, which were varied, include the temperature of reaction, time, and heating rates. Figure 24 shows the scanning electron microscopy (SEM) images of GaN nanowires grown on a silicon substrate. It was noticed that when cobalt phthalocyanine or nickel phthalocyanine was used as a catalyst, the diameter of the nanowire was reduced to as low as 6 nm. Based on the experimentation with several metals and their compounds, it was concluded that the usage of metal complexes gives nanowires with very small diameter. Varying the reaction time has helped the authors to understand the growth mechanism.


Figure 19. Photoluminescence spectrum at 12 K for the annealed GaN doped with magnesium. Magnesium concentration is in the range of $1–5 \times 10^{19}$ cm^{-3}. The zero-phonon and various phonon-assisted donor–acceptor pair transitions can be seen. The eA is the conduction band to Mg acceptor transition, which overlaps with the first phonon replica of DA transition. (b) Temperature variation of the photoluminescence of GaN:Mg epilayers, which are annealed. (Mg):$1–5 \times 10^{19}$ cm^{-3}. Reprinted with permission from [121], A. K. Viswanath et al., *J. Appl. Phys.* 83, 2272 (1998). © 1998, American Institute of Physics.

It was concluded from these experiments that the total reaction time controls the diameter and the length of the wire. Figure 25 shows the SEM image of the sample that was heated for three hours. A large number of rodlike structures with diameters of several hundred nanometer were found. When the heating time was increased, the short, rodlike structures increased in length along the axial direction to form wirelike structures with the simultaneous reduction in their diameter. Based on these results, the authors have given the possible pathways of the vapor-liquid-solid (VLS)

growth of GaN nanowires as shown in Figure 26. The photoluminescence and Raman spectra of the GaN nanowires also were reported. In a later publication, the same group has reported the temperature dependence of the photoluminescence [124]. A very simple chemical route to prepare GaN nanowires and nanotubes, without using any catalyst or

a template was described by He et al. [125]. A direct reaction between Ga metal with flowing ammonia at a temperature of around 900 °C in a horizontal furnace was conducted. The diameters of the GaN nanowires thus obtained were in the range of 26 to 100 nm. The controlling parameters of the reaction were determined to be the temperature of reaction

Figure 26. Schematic illustration of two possible pathways of the VLS growth of GaN nanowires (a) At the beginning, the catalysts of metal powder gradually form catalyst–gallium–nitrogen alloys after gallium vapor transport to the catalysts on the substrate. Each alloy turns into a miscible liquid droplet and then spreads out, becoming many smaller droplets. Hence, after the concentration of gallium nitride reaches saturation in the droplet, the droplet can act as a nucleation site, and a GaN nanowire begins to grow in one direction. (b) At the initial heating stage, metal complexes are decomposed rapidly in the gas phase or on the substrate and sequentially generate many small metal clusters. These clusters form small Ga–N–catalyst liquid droplets and serve as nucleation sites after gallium and ammonium vapors are fed in. In comparison to pathway (a), the nanowires with smaller diameters could be obtained when the reaction goes through pathway (b). Reprinted with permission from [123], C. C. Chen et al., *J. Am. Chem. Soc.* 123, 2791 (2001). © 2001, American Chemical Society.

and the flow rate of ammonia. Nanoparticles of transition metal oxides such as NiO as catalysts were used by Chen et al. [126] to grow GaN nanowires of diameters of 10 to 40 nm. These nanowires, which were made without any template, were found to be straight and smooth compared to the twisted ones obtained by other workers from the confined reactions. In another approach, Ga and SiO_2 were reacted with ammonia in the presence of Fe_2O_3 catalyst to get GaN nanowires of diameters in the range of 10 to 50 nm [127]. The authors also have proposed a growth mechanism of the wires. Peng et al. [128] have used a hot filament in the chemical vapor deposition chamber and obtained GaN nanowires of the diameters of 5 to 22 nm and lengths of a few micrometers. Structural studies have shown them to be of a wurtzite structure. In this method, a mixture of Ga_2O_3 and C was placed above the hot filament and ammonia gas was passed at a pressure of 200 Torr. The temperature of the substrate was at 900 °C. A two-step reaction path was proposed for the growth of the nanowires. Duan and Lieber [129] have demonstrated a very novel method of laser-assisted catalytic growth to grow GaN nanowires. A laser is used to vaporize a solid target containing the desired material and a catalyst. Nanowires were supposed to grow by following the vapor–liquid–solid growth mechanism. The authors have stressed the importance of a rational approach in choosing the catalyst. The catalyst should form a miscible liquid phase with GaN but should not form a more stable solid phase under the nanowire growth conditions. According to this principle, Fe was chosen as the catalyst and quasi one-dimensional structures with diameters of 10 nm and lengths exceeding 1 mm were obtained. Figure 27 shows the growth
mechanism, and the SEM picture of these wires is shown in Figure 28. In a later study, Lieber and his group at Harvard have demonstrated the fabrication of several logic gates in which the basic building blocks were made by the bottom-up approach [130]. Kim et al. [131] have made use of the thermal chemical vapor deposition method to grow GaN nanowires with a wurtzite crystal structure. In this method, a Ni catalyst was used in a direct reaction between Ga metal and GaN powder in the presence of flowing ammonia at 1000 °C. InN nanowires were grown by a Taiwanese team on p-type silicon substrate that was patterned with gold [132a].

Soc.* 122, 188 (2000). © 2000, American Chemical Society.

Nanoscale structures also were made by using self-ordered nanochannel material that acts as a template. This is prepared by the anodization of Al in a suitable acid [132b–132d]. The anodic alumina membrane (AAM) contains a hexagonal-ordered porous structure with nanochannel diameters that lie in the range of 10 to 200 nm, and the channel density is in the range of 10^{10} to $10^{12}/cm^2$. The main advantage of these templates is that the aspect ratio of their channels, which is defined as the ratio of depth to width, is very high and that cannot be achieved by the conventional lithographic techniques. Several groups have made use of such templates and different nanowires were grown [132c–g]. Cheng et al. [132h] have grown GaN wires in the alumina template. Here, GaN was created by a reaction between Ga_2O_3 and ammonia gas. Zhang et al. [132i] have made highly ordered GaN wires in AAM templates. These workers have used indium nanoparticles as catalyst into the nanochannels of AAM through electrochemical deposition, instead of sputtering a layer of indium onto the side of AAM. The evidence for the catalytic activity of indium was found from the EDX analysis, which has shown that the nanoparticle on the tip contains In, Ga, and N. However, nanowire was found to consist of only Ga and N. The authors also have discussed the VLS mechanism for the formation of the nanowires that is similar to the proposals by Leiber. However, no quantum confinement effects were observed in the photoluminescence spectrum.

Yoshizawa et al. [132j] have grown nanocolumns of GaN on c-face sapphire by molecular-beam epitaxy. The SEM pictures of these nanostructures are shown in Figure 29. By controlling the Ga-cell temperature, the diameter of nanocolumn could be reduced to about 40 nm. These workers also have achieved GaN/AlGaN multiple quantum disks. Here nanostructures were grown by the self-organization process. Figure 30 shows the schematic of the multiple quantum structure and the SEM picture of the quantum disks. Quantum size effects were observed in the PL spectra.

2.3. Nanorods

Leiber's group at Harvard was the first to report a novel approach to synthesize nanoscale structures based on carbon nanotubes [133, 134]. In this method, the nanotubes were converted into carbide (MC) nanorods by reaction with a volatile oxide species. The reaction can be expressed as

$$MO\ (g) + C\ (nanotubes) \longrightarrow MC\ (nanorods) + CO.$$
Figure 29. (a) SEM photograph of GaN nanocolumn, in which AlN buffer was grown. Growth time of buffer is for 40 sec. (b) SEM photograph of GaN in which AlN buffer was grown. Growth time of buffer is for 10 sec. Reprinted with permission from [132j], M. Yoshizawa et al., *J. Cryst. Growth* 189–190, 138 (1998). © 1998, Elsevier Science.
Figure 30. (a) Schematic of GaN/AlGaN 10 disks MQD (b) Cross-sectional SEM photograph of MQD structure. Reprinted with permission from [132j], M. Yoshizawa et al., *J. Cryst. Growth* 189–190, 138 (1998). © 1998, Elsevier Science.

Where MO is a volatile metal or nonmetal oxide with a reasonably high vapor pressure at the reaction temperature. Han et al. [135] have adopted the similar procedure to prepare GaN nanorods. They have carried out the following reaction

$$MO\ (g) + C\ (nanotubes) + NH_3$$
$$\longrightarrow MN\ (nanorods) + H_2O + CO + H_2.$$
Here Ga_2O was taken for MO, which was prepared by the reaction of Ga and Ga_2O_3. Carbon nanotubes were made by metal catalyzed decomposition of ethylene and hydrogen in a chemical vapor deposition chamber. By this procedure, the research team could achieve the multishell carbon nanotubes with approximate diameters of 15 nm. The actural reaction in which GaN nanorods were prepared can be represented as

$$2Ga_2O\ (g) + C\ (nanotubes) + 4NH_3$$
$$\longrightarrow 4GaN\ (nanorods) + H_2O + CO + 5H_2.$$
The Ga_2O gas that was generated from the reaction of Ga and Ga_2O_3 powder reacts with ammonia gas to form the GaN. Transmission electron microscopy (TEM) results have shown that GaN rods of diameters in the range of 4 to 50 nm were formed. The GaN nanorods were solid, while the carbon nanotubes have a hollow-core structure. A strong broad band with a peak at 384 nm was observed in the photoluminescence spectrum at room temperature, in addition to the yellow band due to impurities. By using the methods similar to those described above, Han et al. [136–138] have made silicon nitride and boron nitride nanorods, boron nitride nanotubes with or without filling. Later, Han et al. [139] have prepared GaN–carbon composite nanotubes and GaN nanorods by arc discharge in nitrogen atmosphere. Ebbesen's special edition [140] on carbon nanotubes gives a complete discussion on the synthesis in the arc discharge of a variety of carbon nanostructures by using the high temperature of the plasma. Carbon whiskers [141], fullerenes [142], nanotubes [143], and carbon nanotubes filled with metals and nonmetals and their carbides and oxides [140, 144–150] were synthesized by arc discharge methods. Han

et al. [139] obtained the nanorods of GaN by dc arc discharge between a graphite anode filled with a mixture of GaN, graphite, and nicket powders, and a graphite cathode in a nitrogen atmosphere. The cathode was a graphite rod with a diameter of 12 mm. The nitrogen pressure was maintained at 400 to 500 Torr. The experiment could be completed in about 10 minutes. The authors also concluded that the nitrogen atmosphere played a very important role in synthesis of GaN nanorod fillings and also isolated GaN nanorods. For example, the experiments done in the helium atmosphere could not produce the nanostructures of GaN. Another observation by these workers was that Ni catalyst has yielded very high quantities of GaN nanomaterials. High-resolution transmission spectroscopy imaging has shown that the carbon tubes were filled with GaN nanorods and the isolated GaN rods with diameters of the order of 7 to 45 nm. The authors also have given a five-step process as the mechanism of growth of the nanostructures: (1) boiling GaN, Ni, and graphite powder in the anode; (2) plasma formation at the anode, (3) transport of Ga, N, Ni, and C ions toward the cathode, and formation of N radicals from the nitrogen atmosphere that goes along with the plasma processes; (4) crystalline growth of GaN nanorods that occurs as a result of reaction between Ga ions and surrounding N ions at the cathode; (5) agglomeration of carbon around the GaN rods that is catalyzed by Ni.

Tiginyanu et al. [151] have achieved columnar GaN nanostructures by electrochemical etching of GaN layers. In the micro-Raman spectroscopy of these samples, frequencies of Frohlich modes that lie between the LO and transverse optic phonon frequencies could be observed. It was argued that the nanotexturing will change the density of phonon states, induces surface-related vibrations, and spatially confines the bulk phonon modes. Kang's group in South Korea has demonstrated the growth of high-quality, well-aligned GaN nanorods by hydride vapor phase epitaxy [152]. The samples were grown on a sapphire substrate. The substrate temperature was kept at 480 °C in a horizontal reactor. The main advantage in this method is that the nanorods are straight and parallel to each other, unlike the ones made by other methods that have very irregular shapes, and, hence, they are very suitable for the device fabrication purpose. Quantum confinement effects also were observed in the luminescence spectra. Zettl's group at Berkeley has used a pyrolysis approach to synthesize GaN nanorods [153]. In this method, both the Ga and the catalyst come from organic sources. A two-stage furnace system fitted with temperature controllers was used for the pyrolysis. Gallium dimethylamide and ferrocene powders were mixed in a quartz tube, and the ammonia gas was passed through the tube throughout the reaction. The analysis of TEM revealed that the GaN nanorod is a single crystalline with a hexagonal structure, and the interface between the nanorod and the tip is polycrystalline. The energy dispersive spectra shows that the tip contains Ga, N, Fe, and O, whereas the nanorod contains only Ga and N in approximately a 1:1 ratio. Ferrocene was known to be a very good catalyst for the growth of nanotubes. The authors have found very firm evidence for the catalytic activity of ferrocene by doing the pyrolysis experiments with and without ferrocene. Nanotubes and nanorods could not be formed in the absence of ferrocene. The growth

process was thought to be by the vapor–liquid–solid mechanism. At high temperatures used in the pyrolysis experiment, ferrocene, gallium dimethylamide, and ammonia will decompose. The iron particles are surrounded by N, Ga, C, and other radicals, which leads to the increase in the size of the F clusters on the surface of the quartz tube. Later, Ga and N, in vapor phase, dissolve in the iron oxide clusters to form liquid catalyst centers. A supersaturated solution is created when Ga and N dissolve continuously. GaN nanorod growth takes place by precipitation from the supersaturated liquid of the catalyst centers. After cooling down the system, solid GaN nanorods are formed. In a recent report, Han and Zettl [160] have described the growth of GaN nanorods coated with insulating boron nitride.

2.4. Nanobelts and Nanoribbons

Nanobelts and nanoribbons of semiconducting oxides were first reported by Pan et al. [161]. These authors have described a chemical route synthesis of very novel nanostructures of oxides of zinc, tin, indium, cadmium, and gallium, which have a rectangular cross section, with widths in the range of 30 to 300 nm. Nanoribbons and nanoribbon rings of GaN were made by Chen's group by the reaction of Ga and ammonia in which silver particles were used as catalyst and with the sublimation of ball-milled GaN powders in the presence of ammonia flow [162, 163]. Bae et al. [164] have reported a synthesis of GaN nanobelts by the thermal CVD method. They have reacted a mixture of Ga and GaN with ammonia in the presence of boron oxide at 1100 °C.

2.5. Nanopillars

Pearton et al. [165] have discussed the application of reactive ion etching in the growth of nitrides. GaN pillar arrays were made by Grandjean and his coworkers in France [166–168]. First, 300-nm-thick GaN layers were grown along the [0001] direction on top of a 400-nm-thick AlN layer deposited on a sapphire substrate by molecular-beam epitaxy. Patterning was done by electron-beam lithography on poly-methlmethacrylate resist and then metallic mask was deposited by sputtering. Reactive ion etching was performed by using silicon tetrachloride at a pressure of 2 mT. The research team has done very detailed characterization of the pillars thus obtained. Seven pillars of different sizes, ranging from 5 μm, to 100 nm, spaced by 50 μm, were grown. Two unetched zones were used to compare the properties of the etched material with the grown material. Very large surface roughness was observed in the atomic force microscopy (AFM) pictures, which was attributed to the fact that the as-grown layer itself was very rough. In addition to this, ion etching leads to the surface roughness. The authors have measured the Raman and photoluminescence spectra of the GaN pillars.

2.6. Nanoparticles and Nanocrystals

Williams's group in Australia has reported a very novel method of preparation of GaN nanocrystalline powders by ball milling [169]. They have used high-purity elemental gallium ingot and high-purity ammonia gas as starting materials. Ga was milled in a specially designed laboratory ball

mill with perfect control of ball movement. In their design of the equipment, they also could control the temperature of heating. Ga metal was kept as a liquid by keeping the temperature at 100 °C. The TEM analysis has shown that the powder consists of small crystals of diameters ranging between 10 and 30 nm. There also are larger crystals with diameters of about 70 nm. It also was found that the nanocrystalline phase changes to polycrystalline GaN on thermal treatment.

Gladfelter's group has achieved the GaN nanocrystals by a molecular route [170]. The molecular precursor used for this purpose is cyclotrigalazane $[H_2GaNH_2]_3$, its molecular structure is shown in Figure 31. It should be noted that this compound does not have any carbon or organic substituents, which makes it a best candidate to prepare carbon-free GaN. Bulk GaN with a hexagonal structure has been chemically prepared by the following chemical reactions [171–173]:

$$Ga_2O_3 + 2NH_3 \longrightarrow 2GaN + 3H_2O$$

$$Ga + NH_3 \longrightarrow GaN + 3/2H_2$$

$$[NH_4]\{[GaF_6]\} + NH_3 \longrightarrow GaN + HF$$
GaN thin films also were made by different research groups according to the following chemical reactions [174–176]:

$$GaMe_3 + NH_3 \longrightarrow GaN + 3CH_4$$

$$GaMe_3 + N_2H_4 \longrightarrow GaN + CH_4$$

$$Ga\ (atoms) + N\ (atoms) \longrightarrow GaN$$
Nanocrystalline GaN was obtained by the pyrolysis of powdered samples of cyclotrigallazane under different conditions. From the TEM studies, the size of the nanocrystals was estimated to be 6 nm. In the initial products, both cubic and hexagonal phases of GaN were identified. If this mixture of nanocrystals is heated to 900 °C the nanocrystals convert to a pure hexagonal phase. The removal of hydrogen by a series of bimolecular reactions, followed by Ga–N bond formation, was thought to be the mechanism of formation of GaN from the original precursor molecule. The authors have argued that the cyclotrigallazane molecule has the correct formula, connectivity, and conformation so that solid-state polymerization takes place, which gives rise to a GaN crystalline state. Janik and Wells [177] have discovered a new polymeric precursor, gallium imide, with the formula $[Ga(NH)_{3/2}]$, which upon pyrolysis yielded nanocrystalline GaN. The authors have argued that the main advantage of

this precursor is that it does not contain any organic groups, and, hence, it is expected that relatively pure GaN without carbon content can be obtained. Also, it is easy to eliminate ammonia at low temperatures, through stepwise deamination. The preparation of the precursor also was described in the publication. Xie et al. [178] have discussed the preparation of nanocrystalline GaN by liquid–solid reaction,

$$GaCl_3 + Li_3N \xrightarrow{\text{(benzene)}} GaN + 3LiCl$$
This reaction was called the benzene thermal process, which is similar to the hydrothermal process. Here benzene is used instead of water.

A Chinese group has used the dc arc plasma method to prepare nanocrystals of GaN [179]. Bulk gallium was placed in a water-cooled copper crucible, which acts as an anode. A mixture of nitrogen and ammonia gases were sent into the chamber. The flow rates of the gases can be controlled, and, hence, the proportion of the two gases can be adjusted easily. The nitride reaction takes place when an arc plasma was generated with the mixture of nitrogen and ammonia as the discharge gas. The morphology of the nanocrystals was found to be hexagonal, with a particle size of about 20 to 200 nm. The authors have noted that it is very difficult to prepare GaN by using only nitrogen gas, because it is very stable up to very high temperatures. For this reason, ammonia is preferred as the the nitrogen source. However, if only ammonia is used, the generated plasma will be very unstable and so a mixture of nitrogen and ammonia has to be used. The larger nanoparticles were found to be due to the wurtzite phase GaN monocrystals from the diffraction patterns. A few nanoparticles grew into larger particles of several hundred nanometers as a result of collision and secondary nucleation. To study the thermal stability of the synthesized nanopowders, the research group has done annealing experiments. It was found that Ga_2O_3 oxide was formed when the GaN powder was heated in the temperature range of 200 to 900 °C. Benaissa et al. [180] have fabricated the composites of PMMA doped with GaN nanoparticles. First, the chemical reaction of $LiN(CH_3)_2$ with $GaCl_3$ in hexane was conducted at room temperature to obtain the precursor $Ga_2[NMe_2]_6$, which was decomposed under flowing ammonia gas for 4 h at 600 °C. The nano GaN thus obtained was reacted with methylmethacrylate and thermally polymerized at 72 °C for 50 minutes. It was observed that the GaN was highly dispersed in the polymer matrix, and the size of the GaN nanocrystals is around 5 nm.

Coffer et al. [181] have done a very detailed investigation on the effect of the precursor route on the photoluminescence of bulk and nanocrystalline GaN. They have experimented with two precursors namely gallium imide and cyclotrigallazane. This research team also has discovered a new chemical reaction to prepare cyclotrigallazane [182]. Nanocrystals of GaN with a diameter of about 12 nm were obtained after the pyrolysis of a gallium imide precursor at or above 500 °C in a vacuum or in the ammonia atmosphere. These samples have shown very low quantum efficiency and strong defect emission. The weak luminescence was thought to be due to the nonradiative centers at interfaces or in the interior of the sample. Very
Figure 31. Molecular structure of cyclotrigallazane. Reprinted with permission from [170], J. Hwang et al., *Chem. Mater.* 7, 517 (1995). © 1995, American Chemical Society.

strong luminescence was observed if the pyrolysis temperature was lowered or the reaction medium was changed. In the samples, which were obtained after the pyrolysis of a gallium imide precursor in ammonia atmosphere at a lower temperature of 300 °C, an intense defect luminescence with peak maximum at 560 nm was observed. From the temperature-dependent luminescence measurements, it was concluded that multiphonon-related nonradiative transitions take place, which have an identical character of the donor–acceptor transitions observed in nanocrystals of CdS [183]. Very strong luminescence in the blue with a peak at 460 nm was observed if the pyrolysis of the gallium imide was done in the refluxing N,N,N′,N′–tetramethyl–1, 6–hexane diamine. The variation in the luminescence for various conditions of preparation of GaN nanoparticles is shown in Figure 32. Experiments also were done to remove the surface defects on GaN nanoparticles by treating the samples with HF and HNO_3. Yamane et al. [184] have prepared GaN nanocrystals by using Na flux. Pyrolysis of $Ga_2[N(CH_3)_2]_6$ [185] and $[Ga(N_3)_3]_n$ [186] also yielded nanocrystalline GaN. Microwave-assisted nitridation of Ga_2O_3 [187] and also in combination with carbothermal reduction [188] were used successfully to prepare nanocrystals of GaN.

Fischer and his collaborators in Germany have used a very novel method of detonation chemistry to synthesize nanocrystals of GaN [189–191]. The main idea in using detonation for synthesis is that it acts like an arc discharge since very high temperatures and pressures are used for a very short time duration. The detonation chemistry of gallium azides was made use of to prepare nanosize GaN. It was proposed that the optimal mixing of Ga and N can be controlled at the molecular level. The molecular structure of gallium azide is shown in Figure 33. At very high temperatures, the nitrogen from the azide groups can be removed, and GaN can be formed. The sensitivity of the highly explosive triazidogallium unit $[Ga(N_3)_3]$ can be tuned by using the trialkylamine adducts (R_3N) $[Ga(N_3)_3]$ where $R_3N = Me_3N$, Et_3N, $Me_2C_8H_{17}N$ instead of the parent triazido compound.

taken, and the authors have observed blue luminescence and yellow luminescence due to defects. Gladfelter et al. [192] have described a solution–based route to nanosized GaN. They have isolated a polymeric intermediate in the conversion of cyclotrigallazane to GaN in supercritical ammonia. Initially, cyclotrigallazane $[H_2GaNH_2]_3$ was prepared, and then it was dissolved in liquid ammonia. This solution, upon heating, was converted to a product that was identified as polymeric hydridogallium imide $[HGaNH]_n$. Thermolysis of this compound for four hours at 600 °C under a flow of nitrogen produced nanocrystalline GaN.

Barry et al. [193a] have chemically prepared GaN particles with sizes in the micron large by using lithium as a nitrogen fixant. Such a procedure was used several decades ago by Grimmiess et al. [193b] to prepare bulk GaN crystal. They have used Li/Ga alloy and flowing ammonia. The alloy composition consists of an equal proportion of Li and Ga, and the temperatures used were in the range of 400 to 500 °C. Grimmiess et al. could obtain millimeter size GaN crystals with this method. The main intention of Barry et al. [193a] was to prepare very pure GaN microcrystalline powders, which should be white in color, by reacting a mixture of Li and Ga in the presence of ammonia. The reaction, which was originally proposed by Grimmiess, can be represented as

$$Ga/Li + NH_3 \longrightarrow GaN + LiNH_2$$
The mixture of GaN and lithium nitride was found to be white in color. This mixture was washed in water and aquaregia, and pure GaN without lithium metal contamination could be obtained easily. The earliest method by Grimmiess has produced GaN with a substantial amount of lithium as an impurity. Barry et al. [193a] also have developed a second method to produce GaN in which an alloy of Li and Ga were used instead of a physical mixture of Li and Ga. However, this method did not give pure GaN. Micic et al. [194] have obtained colloidal GaN nanoparticles. They have used the chemical procedures developed by Wells and coworkers to synthesize nanosize GaN by pyrolysis of $[Ga(NH)_{3/2}]$ [177, 181]. The $[Ga(NH)_{3/2}]$ was slowly heated in trioctylamine at 360 °C for over 24 h. The GaN nanoparticles were dispersed in a nonpolar solvent to get the colloidal solutions. The synthesis was conducted in an airfree and a water-free atmosphere. The authors also have found that using the mixture of trioctylamine and hexadecylamine has decreased the carbon adsorption on the quantum dot particles. The diameters of the nanoparticles were in the range of 2 to 4 nm. Photoluminescence of the colloidal GaN particles was recorded. Evidence for quantum confinement effects was obtained from the peak position of the luminescence peak. Coffer et al. [195] have done micro-Raman studies of nanocrystalline GaN and found that the spectra were dependent on the pyrolysis temperature used for the synthesis. For example, in the samples obtained with low pyrolysis temperature, many extra peaks were observed, which were very similar to those observed in the GaN samples ion implanted with Ar^+, P^+, C^+, and Ca^+. The Raman modes at 360, 420, and 670 cm^{-1} were thought to be due to the lattice damage by ion bombardment. It also was shown that these defect-related peaks can be removed by subsequent heating of GaN at 900 °C or higher temperatures.

These studies have proved the necessity of using relatively high temperatures in the preparation of GaN. Purdy [196] and Jegier et al. [197] have discussed the control of the coherent length of GaN powders derived from cyclotrigallazane [H_2GaNH_2]$_3$. They also have shown the conditions for achieving a zinc blend structure of GaN. The summary of their findings is given in Figure 36. Fischer's research team has followed the research work of Micic et al. [194] on colloidal GaN nanoparticles and has investigated the thermolysis of the molecular gallium azides [198]. The TEM images of GaN colloidal particles obtained from various precursors are shown in Figure 37. The particles sizes were estimated from the dynamic light-scattering experiments. The light scattering depends on the hydrodynamic radius of the particle. In the photoluminescence spectra of these samples, very broad peaks were observed. Diffraction patterns of these samples are not good, indicating that the sample quality is very poor. The researchers were of the opinion that the low temperatures at which the synthesis was made was the reason for the poor quality of the samples. Balkas and Davis [199] have studied the thermodynamics of several chemical reactions to

prepare GaN and concluded that nanosized particles can be made by using Ga metal, Ga$_2$O, and ammonia gas.

Wood et al. [200] have described the aerosol-assisted vapor phase synthesis (AAVS) [201, 202] of GaN particles with different sizes. These researchers have taken up this work encouraged by their earlier achievement of the submicron-sized h-BN [203] and AlN [204] by simply using inexpensive precursors such as aqueous solutions of boric acid and aluminum nitrate. To prepare GaN by the AAVS method, Ga metal or gallium oxides cannot be used. One has to use the soluble gallium salts, and the authors have used aqueous gallium nitrate and ammonia gas in a two-step AAVS nitridation chemistry. Figure 38 shows the SEM picture of the partially nitrided powder GaN$_x$O$_y$. As can be seen, the particles have a spherical structure with a cauliflower-like texture. The complete nitridation is achieved by heating the sample of GaN$_x$O$_y$ in ammonia atmosphere for about 5 h at a temperature of 1050 °C. The product was found to be a yellow powder, which was identified as pure h-GaN. The SEM picture of

these samples, displayed in Figure 39, shows that the particles are agglomerated. The sample contains many unagglomerated particles, also with sizes in the range of 20 to 50 nm. The agglomerated particles contain a range of crystals in the sizes 20 to 200 nm. Grocholl et al. [205] have synthesized a number of nanostructures of GaN, including nanoparticles and nanorods by solovothermal decomposition of azides. The decomposition of azides was done in superheated tolune or tetrahydrofuran. Figure 40 shows the

TEM and SEM images of GaN nanoparticles obtained from tolune and subjected to different annealing conditions. Li et al. [206] have investigated the resonant Raman scattering of GaN nanocrystals prepared by the arc plasma method. An enhancement in the intensities of the signals was observed when the exciting laser light coincided with the energy of the yellow band in GaN.

2.7. Nanoislands and Quantum Dots

Copel et al. [207] were the first to discuss the effect of surfactants on the crystal growth by MBE or any other epitaxial techniques. The technique developed by them is being widely used now in semiconductor technology to grow self-assembled quantum dots and nanoislands. They have pointed out that lattice strain and surface free energy are the ultimate determining factors to decide whether a film grows by layer-by-layer growth (Frank–Van der Merwe), islanding (Volmer–Weber), or layer-by-layer growth followed by islanding (Stranski–Krastanov [SK]).

Whether the epitaxial layer can wet the substrate or not is determined by the following inequality

$$\sigma_s > \sigma_f + \sigma_i$$

Here, σ_s is the free energy of the substrate surface, σ_i is the interface free energy, and σ_f is the surface free energy of the heteroepitaxial layer. When the above inequality is satisfied, Frank–Van der Merwe growth takes place, and, if the inequality has the opposite sign, then the Volmer–Weber growth will occur and there will not be any wetting of the substrate. The SK growth takes place when there is a wetting of the substrate but the overlayer strain is unfavorable or when there is interface mixing or surface reconstruction. Therefore, if element A can be grown on element B in Frank–Van der Merwe or SK mode, then B will grow on A in Volmer–Weber mode. In a situation like this, there will be problems in growing multiple layered structures such as multiple quantum wells or superlattices. For example, Ge grows on Si in SK mode, whereas Si grows on Ge in Volmer–Weber mode. In the attempts to grow Si/Ge/Si quantum well structures, the Si cap layer was found to contain islands. To solve this problem, Copel et al. [207] have passivated the Si surface by one monolayer (ML) of As prior to the growth. The unsatisfied dangling bonds on the Si surface are passivated by the one extra valence electron of As. By using the As-passivated surface as a stage for MBE growth, it was possible to change the growth mode of an epitaxial layer to induce wetting of the substrate. It should be noted that As itself will not be incorporated into the lattice since it segregates to the surface during growth. Therefore, the most important requirements for the surfactant are the following: (1) it should reduce the surface free energies of both the substrate and the overlayer and (2) it should be very mobile and segregate to the surface.

Self-assembled quantum dots of InGaAs, InAs, AlInAs, and various phosphides have been grown by a number of groups by the SK method [208–213]. Dmitriev et al. [214] were the first to make GaN quantum dots on SiC substrates by MOCVD. Aoyagi's group at RIKEN, Japan, have achieved the self-assembled GaN quantum dots on AlGaN

surface by using tetraethyl silane as a surfactant [215]. One of the aims in growing the GaN quantum dots is to develop ultraviolet (UV) LEDs and semiconductor lasers. At present, the threshold currents required for the nitride-based lasers are in the range of 9 kA/cm^2. Comparatively, these are much higher than those in other III–V lasers. The present nitride-based lasers use only the quantum well structures. On the other hand, if one uses the quantum wire or quantum dots as the active region, then the threshold currents are expected to be smaller, since the exciton-binding energy is very high in the case of quantum dots. Also, because of many-body effects, one may have lasing in the quantum dot systems due to biexcitons and other novel mechanisms. Aoyagi's group have grown multilayer structures with GaN quantum dots on Si faces of SiC substrate by MOCVD. They have used AlGaN as the cladding layer and also as the capping layer. A thin layer of AlN also was used as the buffer layer. After growing the atomically smooth AlGaN cladding layer, which was identified by AFM images, tetraethylsilane, with the hydrogen carrier gas, was sent into the reactor, followed by a short supply of trimethylgallium and ammonia gases. This has resulted in the growth of GaN quantum dots with an average width of 40 nm and a height of 6 nm. It should be noted that the surfactant was introduced to enhance the growth of GaN islands, and this is quite contrary to the use of surfactant in the growth of Si/Ge multiple quantum wells (MQW), in which case, the As surfactant was used to suppress the island formation. The exact role of the surfactant in the growth of GaN quantum dots is not known. The size of the quantum dots was controlled by the doping rate of TESi, the Al content in AlGaN, and the growth temperature. The photoluminescence spectrum revealed a strong peak at 3.55 eV with a FWHM of 60 meV. In a later publication, Aoyagi's group has reported the optically pumped lasing in a laser structure of GaN quantum dots [216]. The procedure to grow the dots is the same as discussed before. The structure consists of an $Al_{0.23}Ga_{0.77}N$ cladding layer (100 nm thick), an $Al_{0.09}Ga_{0.91}N$ barrier layer (100 nm thick), GaN quantum dots, an $Al_{0.12}Ga_{0.88}N$ barrier layer (300 nm thick), and an $Al_{0.20}Ga_{0.80}N$ cladding layer (600 nm thick). The optical pumping experiments were done with a nitrogen laser with an emission wavelength of 337.1 nm and a pulse width of 7 ns. Stimulated emission was observed at high-excitation densities. It also was noted that the laser emission has shown a red shift of about 50 meV, with peak at 3.49 eV. The threshold pump power density was estimated to be 0.75 MW/cm^2, which was thought to be somewhat high. The reasons for this are the following: the confinement of the carriers in GaN quantum dots is very poor, the absorption of the pump power in the AlGaN barrier lasers is rather small, and the Al mole fractions in each AlGaN layer also were too small to achieve high carrier and optical confinements.

Daudin et al. [217] have grown the GaN quantum dots in the SK mode by MBE by using lattice mismatched heterostructures. The occurrence of the SK mode was found to be dependent on the growth temperature. They have found that at low temperature, the growth was purely 2D. When three-dimensional (3D) islands were formed, further deposition of GaN resulted in the coalescence, followed by a plastic relaxation through misfit dislocation formation.

In-situ reflection high-energy electron diffraction (RHEED) was used to study the characteristics of the grown layers and surfaces. The results observed from the RHEED experiments were confirmed by the AFM images and high-resolution electron microscopy of the superlattices. AlN and GaN with wurtzite structures were grown on a sapphire substrate. Substrate temperature was varied, and three types of behavior were observed, corresponding to high T_s (>700 °C), low T_s (<620 °C), and intermediate T_s. In the intermediate T_s temperature range, a relaxation to island formation is followed by a decrease of the relaxation value corresponding to island coalescence. At high T_s, the relaxation rapidly reaches a plateau corresponding to 3D growth mode, and, at low T_s, the relaxation is small, correlated to 2D growth. After island coalescence, a gradual relaxation was observed for long deposition times. It should be noted that in this work, GaN quantum dots were achieved without using any surfactant and the 3D growth of islands occurs because of strain relaxation in the lattice mismatched heterostructures.

In a later publication, Daudin and coworkers have demonstrated the growth of a quantum dot superlattice [218]. They also have studied the various experimental conditions for the control of the size and the density of dots. The effect of substrate temperature was initially examined. The AFM pictures of GaN quantum dots grown at three different substrate temperatures, viz. 725 °C, 705 °C, and 685 °C were taken. It was shown that, as the substrate temperature increases, the dot density decreases. At 685 °C, many dots have coalesced, whereas they were isolated at 725 °C. The dependence of dot density on temperature was thought to be due to Ga surface diffusion. The ripening effects were investigated by studying the morphology of GaN quantum dots as a function of time under vacuum and under nitrogen plasma flux. GaN dots were grown at 700 °C by depositing 3 ML on an AlN surface. The dots were left either under vacuum at 700 °C before cooling under vacuum, or they were exposed to nitrogen plasma after growth and during cooling. The AFM pictures of GaN dots when the surface was exposed under vacuum and under nitrogen flux were taken. A ripening effect was noted when the dots were grown under vacuum. The dots were bigger in size and less dense compared to the other case of growth under nitrogen. Periodic, stacked layers of GaN quantum dots separated by AlN spacer also were fabricated. When the thickness of AlN was small, in the range of 8 nm, vertical correlation between the GaN dots also was observed in high-resolution electron microscopy pictures. The AFM studies were made to confirm the vertical correlation of the dots. Morphology of dots in a sample consisting of 20 layers of GaN quantum dots separated by 5-nm-thick AlN layers was investigated. The dot density was smaller compared to the case of no correlation. The authors have reported the photoluminescence and cathodoluminescence of these samples. Samuelson's group in Sweden has investigated the SEM and cathodoluminescence of GaN quantum dots and has shown the correlation between the actual position of the dots and the luminescence from these dots [219]. These samples were grown by Aoyagi's group in Japan. Very low intermixing between GaN and AlN layers was observed in the high-resolution TEM images

of MBE-grown samples containing self-assembled quantum dots of GaN [220].

Damilano et al. [221] have observed very intense room-temperature photoluminescence, from blue to orange, from the GaN quantum dots of various sizes. Also, white-light emission was observed by properly mixing quantum dots of various sizes. GaN and AlN layers were grown by MBE on a Si(111) surface. Ammonia was used as the nitrogen source. The native oxide on the silicon surface was removed by rapid thermal annealing at 900 °C. The quantum dots were obtained by strain induced 2D to 3D transition. The room temperature PL spectra of GaN/AlN quantum dots on Si were studied. The authors also have observed the PL of GaN dots from stacked planes, giving rise to white-light emission. Kuball et al. [222] have reported the resonanat Raman scattering of GaN quantum dots grown by MOCVD. The dots were grown on AlGaN by using tetraethylsilane as the surfactant. The Raman spectra were recorded for dots of different sizes by changing the excitation laser energy. It was noted that very little Si enters the GaN lattice, though it was used as the surfactant. Most of the Si was thought to remain on the AlGaN surface, where it was deposited before the growth of GaN. The authors have investigated the Raman spectra of sample A, which consists of GaN quantum dots on $Al_{0.15}Ga_{0.85}N$, and of sample B, which consists of GaN layer on $Al_{0.15}Ga_{0.85}N$, for various excitations of the laser. In resonant Raman scattering, the exciting laser light or the scattered light coincides in energy with an electronic transition of the material. In such a situation, the Raman spectra are dominated by the Frohlich scattering arising due to the longitudinal polar optical phonons. Therefore, it is possible to distinguish the lines arising from GaN and AlGaN. The fundamental transitions of GaN and $Al_{0.15}Ga_{0.85}N$ are at 3.42 and 3.66 eV, respectively. Both the spectra show Raman peaks at 736 and at 1474 cm^{-1}. The authors have assigned these transitions to first- and second-order Raman scattering from the A_1 LO phonons of GaN. These were supposed to be enhanced under UV excitation. The authors gave a detailed discussion on the effects of quantum confinement and the effects of Si, which was used as an antisurfactant. These workers have taken the Raman spectra of sample A, containing GaN quantum dots, and also sample B, containing the GaN layer, under 5.08 eV excitation. For this case, a shift of 9 cm^{-1} was observed for the GaN A_1 (LO) frequency of sample A toward lower wave numbers. Based on these results, the A_1 (LO) peak was assigned to the GaN quantum dots.

Daudin's group in France has done a very exhaustive investigation on the effects of surfactant on the growth of GaN quantum dots grown by MBE [223]. Ga was found to form a bilayer on the GaN surface during the growth in Ga-rich conditions. The study conducted dealt with the growth kinetics and relaxation mechanisms in the presence of a Ga film. The GaN dots were fabricated under various experimental conditions such as the V/III ratio, the substrate temperature, etc. The results were analyzed by using a set of important analytical techniques such as RHEED, AFM, TEM etc. When the Ga effusion cell temperature is $T_{Ga} =$ 1040 °C GaN, growth is nearly stochiometric and the SK growth mode takes place with the formation of GaN islands. If the Ga flux was increased above $T_{Ga} = 1040$ °C, the growth

conditions become Ga-rich and a Ga bilayer was formed because of excess Ga. In these conditions, no 2D to 3D transition occurs. However, when the Ga flux was in the intermediate range, a transition from 2D to 3D was observed. The GaN layer undergoes a lot of strain, leading to the formation of GaN pyramids, followed by the coalescence of grown islands and the formation of a smooth surface. As discussed before under Ga-rich conditions, there was no growth of GaN islands. However, it was observed that the 2D to 3D transition takes place under the N flux. It was noted in the AFM images that there is no difference between the quantum dots grown under N flux and those formed during the SK growth mode. When the substrate temperature was low, $T_s = 660\,°C$ formation of GaN platelets was observed. These dots were obtained with growth interruption under N after Ga-rich GaN growth on AlN. In these conditions, SK growth cannot occur since the 2D wetting layer was absent. The platelets were found to be flat islands with heights of around 4 ML (1 nm) and diameters of around 15 nm. In their very interesting paper, Daudin and coworkers also have made detailed discussion on the mechanisms related to the effect of surfactants on the SK growth mode. The inhibition of 2D to 3D transition was thought to be due to the surface stress caused by Ga adsorbate. It also was argued that under Ga-rich conditions, the adsorbed Ga layer is almost instantly formed without allowing the formation of GaN layers, and, hence, islanding of GaN never takes place.

Andreev and O'Reilly [224] have done the theoretical calculations on the radiative lifetimes in GaN/AlN self-assembled quantum dots. Gleize et al. [225] have measured the resonant Raman scattering of GaN dots in the MBE grown samples. They have changed the laser energies in the range 2.33 and 3.81 eV, which enabled them to select the quantum dots with specific size and energy. Resonance enhancement in the signals was observed. The Raman frequencies were related to the lattice mismatch strain between GaN and AlN. Multilayered superlattices of GaN quantum dots grown by MBE were characterized by Chamard et al. [226] by the technique of grazing incidence X-ray scattering. This method was shown to be complimentary to AFM and TEM.

Wolk et al. [227] at Berkeley, California, have demonstrated the growth of GaN nanocrystals by sequential ion implantation of Ga and N ions into a sapphire substrate. The TEM studies allowed the authors to identify the phase of GaN as wurtzite and the size of the quantum dots was found to be in the range of 1 to 5 nm. Photoluminescence experiments also were done on these samples. Bandedge luminescence and yellow peaks due to defects were recorded in the PL spectra. The main advantages of the ion implantation technique are the following. Firstly, it is possible to introduce a well-defined concentration of nanocrystals at a precalculated depth below the surface. Secondly, it is most suitable for integration into the standard semiconductor processing. Nanocrystals of GaN have been achieved by N implantation into GaAs [228]. Sequential ion implantation of Ga and As into sapphire and SiO_2 has been done to fabricate GaAs. [229]. The crystalline phase was found to be dependent on the dose of the N ions. In a later publication by Borcella et al. [230] ion implantation of Ga and N ions in a number of dielectrics such as crystalline quartz

or amorphous silica was reported to achieve GaN quantum dots. These authors have examined the influence of implantation conditions, the annealing procedures, and the role of substrate on the formation and morphology of GaN dots. Quantum confinement effects also were observed in the luminescence spectra. Morkoc's group has observed a drastic reduction in the dislocation density of GaN layers that were grown by using GaN buffer layers containing quantum dots [231].

Atomic layer epitaxy (ALE) was used for the first time by Daudin's group in France to grow GaN quantum dots on (0001) AlN [232]. This epitaxy also is called the migration enhanced epitaxy. Here, the growth proceeds by alternately exposing the surface to cation and anion fluxes. Another advantage of this method is that the layer thickness is independent of flux values and deposition time but depends on the number of growth cycles. When more than one ALE cycle was performed, GaN island formation was observed. The research group has done the optical characterization experiments on various samples. For the sample containing five quantum wells grown by one ALE cycle, an emission peak at a photon energy of 5.1 eV was recorded in the cathodoluminescence. In the samples with GaN quantum dots, the main emission peak was observed at 3.8 eV, which was found to be in agreement with the expected energy position of dots of the size 1.6 to 1.8 nm. In the sample made from four ALE cycles, another luminescence band was observed at around 3.2 eV, which was interpreted as the second mode of the island height distributions. This work has demonstrated the feasibility of using ALE to grow stable Ga film on the AlN surface, which was independent of the precise Ga flux between 0.2 and 0.8 ML/s at a substrate temperature of 740 °C.

Arakawa's group in Japan has grown the self-assembled GaN quantum dots on AlN by low-pressure MOCVD [233]. Trimethyl gallium and trimethylaluminum were used as the group III sources. an AlN layer of 110 nm thickness was grown on (0001) SiC at 1180 °C. After the growth of an AlN layer, the growth temperature was reduced to 960 to 990 °C to grow GaN quantum dots. The growth of GaN quantum dots was done at a very low V/III ratio. The research group has observed that the growth temperature and the V/III ratio are the most important factors to form quantum dots of GaN. These parameters will decide the migration and evaporation of Ga atoms on the GaN surface. The AFM pictures of GaN quantum dots, illustrating the dependence of dot density on the GaN coverage, which was changed systematically between 3.4 and 9.2 ML, were reported. It can be easily seen from the AFM images that the dots are formed only when the critical thickness of the GaN layer is around 4ML. After depositing over the critical thickness of GaN, quantum dots are immediately formed on the 2D GaN layer. It should be noted that such a sudden transition from 2D to 3D growth also was observed before in the literature in the case of InAs quantum dots grown by Petroff's group at the University of California, Santa Barbara California [234]. It can be observed in Figure 62 that no quantum dots were formed when the coverage was 3.4 ML, and the density of dots increases as the GaN coverage is higher. It also was observed that the density of dots saturated above the GaN coverage of 8 ML, which happens because of the increase in the size

of the dots. The AFM pictures of GaN quantum dots grown at different temperatures, e.g., 960, 975, and 990 °C were reported. The dots grown at 960 °C have smaller diameters and higher densities than those grown at 975 °C. Suppression of migration of Ga atoms as the growth temperature decreases is thought to be the reason for this observation. Tsong's group has grown the self-assembled GaN quantum dots by vapor–liquid–solid mechanism [235]. Daudin's group has demonstrated that Ga-covered GaN layers thicker than about 2.5 ML are stable against annealing under Ga flux but they transform into islands when the Ga layer is evaporated under vacuum at substrate temperature of 750 °C [236]. The AFM pictures of GaN quantum dots and the GaN 2D layer grown under different conditions were reported. Northrup et al. [237] have discussed, theoretically, the microscopic origin of the increased nucleation under different conditions of growth. They have performed the *ab inito* calculations on GaN surface structures. The interested readers should see references [238] and [239] for general reviews on quantum dots in semiconductors.

2.8. Quantum Wells

Morkoc's group has studied the optical properties of a Si-doped GaN/AlGaN quantum well [240]. The calculated confinement energies could be matched to the observed band-to-band transition, assuming a band offset of 67:33 and effective masses of 0.3 and 0.19 for the heavy hole and conduction electron, respectively. Time-resolved PL of GaN/AlGaN MQW indicated strong quantum confinement effects [241]. The researchers have compared these results with those of GaN epilayers and GaAs/GaAlAs MQW. The exciton-LO phonon interactions in AlGaN barriers were noted to be enhanced. Localized excitons at low temperatures and free excitons at higher temperatures were identified. An increase in the lifetime of an exciton up to 60 K was observed, which gave an indication of radiative recombination. In the photoluminescence spectrum of MBE grown MQW, A, B, and C excitons and their phonon replicas were observed [242]. From the intensity dependence of the luminescence, the assignments of the transitions were confirmed. The $n = 1$ band persists up to room temperature, whereas the extrinsic emission bands are ionized above 120 K. The thermal shift of the $n = 1$ band follows the thermal shift of the bulk GaN energy gap. Morkoc and coworkers have fabricated a 50 Å/50 Å GaN/Al$_x$Ga$_{1-x}$N ($x = 0.07$) MQW by the MBE technique [243]. Dry etching was used to pattern an array of microdisks of approximately 9 μm diameter and 50 μm spacing. Picosecond time-resolved spectroscopy was used to study the emission dynamics. A strong enhancement of the intrinsic exciton transition quantum efficiency was observed in the microdisk compared to MQW.

Radiative and nonradiative recombination dynamics were studied in GaN/AlGaN double heterostructures by using time-domain spectroscopy in picosecond scale [244]. The diffusion constant for the minority carriers in the AlGaN barrier layers was estimated. In another time-resolved study, the effects of well thickness and Si-doping on the optical properties of MQWs of GaN/AlGaN were identified [245]. Quantum confinement was observed in quantum wells of well thickness less than 40 Å. The exciton lifetimes in

MQWs with well thickness less than 40 Å increase linearly with temperature up to 60 K. It also was observed that the Si doping improves the quality of the crystals. Fabrication of GaN/AlGaN quantum wells by MBE was discussed by a French group [246]. The quantum well width could be controlled up to ML scale. The quantum well transition energy increases as the thickness decreases. Each quantum well exhibits a clearly resolved emission peak. This is due to relatively narrow PL linewidths, ranging between 20 and 30 meV. However, the luminescence from AlGaN barriers is not detected. This was thought to be due to strong capture of the excitons by the quantum wells. When the thickness of the well is decreased, the intensity of the quantum well emission vanishes. This was explained as due to thermal escape of carriers from the quantum well to the barrier due to insufficient confinement. In the time-resolved PL experiments of GaN/AlGaN MQW, a very high excitation was used [247]. This excitation condition will simulate the pumping powers required for lasing. It was found that under these conditions, the carrier distributions are characterized by plasma temperatures. Leroux et al. [248] have grown high-quality MQWs of GaN/AlGaN by MBE. They have examined the quantum confined Stark effect by temperature-dependent luminescence and reflectivity.

Picosecond time-resolved studies by Hangleiter's group enabled them to understand the piezoelectric fields in GaN/AlGaN quantum wells [249]. A reduction in oscillator strength was observed, which was attributed to piezoelectric fields. An increase in luminescence decay time, with increasing well width, was observed, along with a red shift of the emission peaks. Lefebvre et al. [250] have published a series of interesting papers on the recombination dynamics of free and localized excitons in MQWs of GaN/AlGaN. The decay times of excitons in both the wells and barriers was found to be ∼330 ps at 8 K. Spectral distribution of lifetimes was attributed to the localization of carriers by potential fluctuations that arise due to alloy disorder and well width and depth variations. The radiative lifetime of free excitons in the low-temperature limit was estimated as 2.4 ps, which is much smaller than that for GaAs/GaAlAs MQW. Grandjean et al. [251] have measured the PL of GaN quantum wells for different Al contents. Strong internal electric fields were found that have a linear relationship with Al content.

3. PHOTOLUMINESCENCE SPECTROSCOPY OF InGaN

The ternary compound InGaN is an active layer for both blue and green emission. The bandgap of this material can be changed from 1.95 to 3.4 eV by varying the concentration of In. In this section, we discuss the cw photoluminescence of InGaN epitaxial layers and quantum wells. Many papers were published on this topic [252–280]. Katsui et al. [252] at NTT were the first to propose the quartnary InGaAlN system in which a lattice-matched double heterostructure is possible for high-performance light-emitting devices. Nakamura and Mukai [255] have reported the PL of high-quality InGaN epilayers in which sharp band-edge emissions between 400 and 445 nm were observed, and the deep level emissions were barely observed at room temperature.

Multiple quantum wells of $In_{0.08}Ga_{0.92}N/GaN$ were grown by Amano and Akasaki [257]. In these samples, strong cathodoluminescence was measured compared to bulk material of InGaN. Chichibu et al. [258] have studied the emission mechanisms of InGaN SQW (SQW) and MQW structures. The electroluminescence (EL) from InGaN QWs was assigned to the recombination of excitons localized at certain potential minima in the QW plane. The blue shift of the EL caused by an increase of the driving current was explained by the combined effects of the quantum confinement Stark effect, screening of the piezoelectric field, and band filling of the localized states by excitons. Narukawa et al. [259] have proposed that the main radiative recombination was due to excitons localized at deep traps, which originate from the In-rich region in the wells, acting as quantum dots.

The compositional dependence of PL peak energy in InGaN-strained quantum wells was reported by a Japanese team [260]. When excitation intensity was increased, the PL peak energy was shown to be blue shifted. The well-width dependence of PL peak energies were calculated and found to agree with experiment. It was proposed that the quantum confined Stark effect occurs due to piezoelectric fields. Chichibu et al. [261] have attributed the emission from $In_xGa_{1-x}N$ to the recombination of excitons localized at the potential minima originating from large compositional fluctuations. Ploog's group has grown cubic $In_{0.17}Ga_{0.83}N$ by MBE, which has given blue luminescence [262]. Chichibu et al. [263] have investigated the exciton localization by spatially resolved CL mapping. The InN-rich quantum disks originating from compositional undulation in InGaN SQWs were identified. Shan et al. [264] have studied low-temperature photoluminescence in InGaN alloys as a function of pressure. The pressure coefficients for the direct Γ bandgaps of $In_{0.08}Ga_{0.92}N$ and $In_{0.14}Ga_{0.86}N$ have been estimated from the pressure dependencies of the radiative decay of the charge carriers localized in the tail states of the alloy fluctuations. Chichibu et al. [265] have reported the bandgap separation in $In_xGa_{1-x}N$ layers ($0.05 \leq x \leq 0.2$).

Self-assembled InGaN quantum dots were grown, and their PL was measured by Hirayama et al. [266]. Vertiko et al. [267] have demonstrated the applicability of near-field optical microscopy to study the influence of defects on the photoluminescence of InGaN. It was found that the pinholes do not have any effect on the radiative recombination in the epitaxial layers. McCluskey et al. [268, 269] have evaluated the bowing parameter as 3.5 eV for $In_xGa_{1-x}N$ ($x \leq 0.12$). Mitchel and Saxler [270] have proposed a hopping conduction model in InGaN/GaN multiple quantum wells.

PL studies of $In_{0.13}Ga_{0.87}N/GaN$ multiple quantum wells were made by Viswanath et al. [271]. The thickness of the quantum wells in these structures is 10 Å, and barriers have width of 50 Å. The MOCVD method was used to grow these samples, which were grown on (0001) sapphire substrate. Figure 41 shows cw photoluminescence spectrum of the InGaN MQW, recorded at 10 K. The dotted lines show the individual peaks obtained by the curve-fitting procedure by using Lorentzian line-shape function. The broad peak 3.134 eV is interpreted as due to the InGaN quantum well, and the narrow peak at 3.471 eV is due to the GaN barrier. The large blue shift was interpreted as due to strong
Figure 41. Photoluminescence spectrum at 10 K for InGaN/GaN MQW. It may be noted that the emission from GaN barrier is observed very clearly. Reprinted with permission from [271], A. K. Viswanath et al. (unpublished results).

quantum confinement effects in ultrathin quantum wells. At 10 K, the linewidth of the InGaN quantum well was estimated as 129 meV and was interpreted as due to inhomogeneous broadening. The origin of a solid-phase miscibility gap in nitrides was discussed by Ho and Stringfellow [272]. Localized excitons were considered to explain the luminescence. The observed PL linewidths were thought to be due to the effects of strong quantum confinement.

A display of photoluminescence spectra at different temperatures is shown in Figure 42. The PL peak positions were determined from the curve-fitting procedure. Figure 43 shows the temperature variation of PL peak energies of InGaN quantum wells and GaN barriers. From the temperature variation of the peak energies, it was inferred that the species involved in the luminescence of the InGaN quantum wells were localized excitons, which also were confirmed
Figure 42. Photoluminescence spectra of InGaN/GaN MQW at some selected temperatures. A He–Cd laser is used for excitation. Reprinted with permission from [271], A. K. Viswanath et al. (unpublished results).

by various techniques. The activation energy of 69 meV also gave an indication of the localized nature of the excitons. Band-filling effects were noted in the power dependence studies of photoluminescence, as shown in Figure 44. Chichibu et al. [274–276] recently have reported on the localization of excitons in a number of InGaN quantum wells emitting in various wavelengths.

Li et al. [277] have observed a blue shift in the InGaN/ GaN single quantum well bandgap energy, after
rapid thermal annealing in nitrogen atmosphere. This was explained as due to the flattening of the potential fluctuation as a result of spatial redistribution of atomic In and Ga in the InGaN quantum well. Luminescence from the phase-separated InGaN grown by MOCVD was reported by Li et al. [278]. The dominant peaks were observed around 2.9 and 2.8 eV. The low-energy peak at 2.8 eV was thought to be due to the phase-separated regions, which are rich in In content. They also have recorded very strong luminescence of the low-energy peak at room temperature. This was interpreted as due to quantum confinement enhancement in the form of nanostructures of quantum dots. Zhang et al. [279] have used a novel technique to improve the luminescence efficiency from the MQWs of InGaN/GaN. They have used a multilayer buffer on Si substrate. Hao et al. [280a] have reported the observation of electron-hole plasma emission from InGaN/GaN quantum wells. They have conducted the photoluminescence experiments at room temperature by using a He–Cd laser. Only exciton-related transitions were observed at low excitation powers. When the excitation power was increased, a peak has been observed on the low energy side of the exciton transition, which was interpreted as due to the electron plasma recombination. The assignment was also confirmed by the fact that the integrated PL intensity has shown a 1.9 power dependence.

Mishra's group at the University of California, Santa Barbara, California, have demonstrated that selective epitaxy of InGaN can done by MOCVD [280b]. They have used templates consisting of arrays of circular etched holes in SiO$_2$ mask layer, with pregrown GaN hexagonal pyramid structures. Figure 45 shows the SEM picture of GaN/InGaN pyramids. In the PL experiments, it was observed that the PL peak wavelength increased with an increase in mask opening spacing for a constant mask opening diameter (Fig. 46).

The same group also has achieved the InGaN nanoscale islands by MOCVD [280c]. A growth mode transition from step-flow into 3D spiral growth mode by predeposition of Si prior to InGaN was found to enhance the PL efficiency and the radiative recombination lifetimes. Figure 47 show the AFM images of GaN grown under different conditions.

Figure 44. Excitation power dependence of the PL spectra of InGaN/ GaN MQW. It may be noted that the emission energy of GaN barrier does not show any power dependence, while the InGaN quantum well emission shows a slight blue shift due to band filling. Oh et al. [280d] have investigated the effect of Si doping in the barriers of InGaN MQWs by PL spectroscopy. They have observed that the PL intensity was enhanced with Si doping under low-excitation conditions as shown in Figure 48. It also was shown that the blue shift with an increase in excitation intensity is larger for larger well width, and the blue shift for Si-doping is larger for lower-excitation density (Fig. 49). The increase in PL intensity with Si-doping was less pronounced at higher excitation densities, as shown in Figure 50.

4. TIME-DOMAIN PHOTOLUMINESCENCE OF InGaN

A number of research papers were published on the time-domain spectroscopy of InGaN [271, 273, 281–297]. The present author and his collaborators have done complete analysis of time-resolved photoluminescence of InGaN MQWs [271]. In the picosecond time-resolved spectroscopy experiments, a coherent synchronously pumped dye laser was used. This laser was pumped by a mode-locked Ar-ion laser, which has about 2 ps pulse width at 3.8 MHz repetition rate. The dye laser beam frequency was doubled by using a β-barium borate nonlinear optical crystal. The UV light thus generated was used to excite the sample. The PL

signal was dispersed by a McPherson monochromator and detected by a Hamamatsu photomultiplier tube. The time dependence of the decay was measured by a time-correlated single photon counting. The setup has a time resolution of 10 psec after deconvolution.

A display of spectra for different temperatures obtained in the time-resolved experiments is shown in Figure 51. At 10 K, the decay time was deduced as 720 psec. For reference, the lifetime of GaN epilayers also was measured, and it was found to be 100 psec at 10 K. The lifetimes of GaN and related materials are expected to be very short. This is because of the strong exciton-acoustic phonon interactions due to which fast energy relaxation of free excitons to the bottom of the exciton band takes place. But the lifetime observed in the InGaN MQW is about seven times that of the lifetime of free excitons in undoped GaN. This clearly shows that the excitons in InGaN are not in the free state. The slow down in the exciton relaxation in InGaN must be due to the trapping of excitons in potential fluctuations
Figure 51. Time-resolved photoluminescence decay curves of InGaN quantum well emission from InGaN/GaN MQW, at different temperatures. Reprinted with permission from [271], A. K. Viswanath et al. (unpublished results).

in the lattice. The lifetime was found to decrease with an increase in temperature. This shows that the nonradiative processes come into play as the temperature is increased. This should be considered very important, since the actual photonic devices like LEDs and semiconductor lasers are operated at high temperatures such as room temperature. The nonradiative relaxation has deleterious effects on the performance and efficiency of the semiconductor lasers. Time-resolved spectroscopy of $In_{0.20}Ga_{0.80}N$ (2.5 nm)/ $In_{0.05}Ga_{0.95}N$ (6.0 nm) MQW has revealed two peaks at 2.920 eV and 3.155 eV [273]. The main peak at 2.920 eV was attributed to localized excitons and the weak peak at 3.155 eV to free excitons. Satake et al. [287] have studied the exciton localization in $In_xGa_{1-x}N$ epitaxial layers. In the 2 K photoluminescence spectrum, they observed a Stokes shift from the absorption shoulder and broadening at the lower photon energy side. In ternary alloys, the spatial fluctuations due to composition fluctuations can localize excitons. The mobility edge was determined by site-selective experiments in which the excitation photon energy is changed and PL spectra are recorded for different excitation energies.

Picosecond studies of MQWs of $In_{0.20}Ga_{0.80}N$ (3 nm)/ $In_{0.05}Ga_{0.95}N$ (6 nm) and $In_{0.10}Ga_{0.90}N$ (3 nm)/$In_{0.02}Ga_{0.98}N$ (6 nm) have identified localized and delocalized excitons [292]. The decay times for different emission energies were studied. Decay times of localized excitons were found to be very long in the range of several nanoseconds. Photoluminescence and time-resolved spectroscopy of self-assembled InGaN quantum dots has been reported [293]. Lefebvre et al. [294] have studied the well-width dependence of luminescence and the PL lifetimes of InGaN quantum wells. In these samples, the In composition was kept constant. In the cw PL spectra, the FWHM was found to be constant for different well widths. The PL energies cover the entire visible range. In the PL time-resolved experiments, the decay times were found to increase with a decrease of peak energy. Lefebvre et al. [295] also have investigated the effects of the AlGaN barrier and of dimensionality on InGaN systems. Their studies have confirmed the carrier localization on potential fluctuations. Kuroda et al. [296] have performed the picosecond time-resolved experiments on $In_{0.12}Ga_{0.88}N/In_{0.03}Ga_{0.97}N$ MQWs. They investigated the excitation power dependence on the lifetimes and PL energy. The carrier recombination rate and the PL energy decreased nonlinearly with the decrease of carrier density. Ozgur et al. [297] have observed ultrafast carrier capture in InGaN MQWs by the four wave mixing experiments.

Kawakami et al. [297b] have described various time-resolved experiments carried out by them to understand the optical phenomena in GaN-based semiconductors. The experiments include time-resolved photoluminescence, time-resolved EL, transient grating, scanning near-field optical microscopy, pump-probe spectroscopy, etc. They also have given a model for the carrier dynamics in a localized system, which is shown in Figure 52.

5. LASER ACTION IN InGaN

Many laboratories in the world have studied the laser action in InGaN [287, 298–306]. Hangleiter and coworkers have measured the optical gain in InGaN/GaN heterostructures
Figure 52. Schematic of carrier dynamics in a localized system. α and $\alpha + \Delta\alpha$ denote absorption coefficient under low photoexcitation and under photo-pumping, respectively. Reprinted with permission from [297b], Y. Kawakami et al., *Phys. Status Solidi A* 183, 41 (2001). © 2001, John Wiley and Sons.

under optical pumping [289]. The measurements were made at room temperature. The stripe excitation method has been used to measure the gain in the system. Stimulated emission (SE) experiments on an epitaxial layer of InGaN were reported for different excitation powers [287]. When the laser power was greater than 10 μJ/cm^2, stimulated emission was observed. Above threshold, a superlinearly grown sharp emission band was recorded. The laser emission was just below the mobility edge. The SE has shown a red shift with the increase of excitation energy density. A multimode lasing spectrum was observed [300] in optically pumped lasing experiments on InGaN/GaN. A multimode lasing spectrum was observed for the input power density of 11 MW/cm^2. Stimulated emission in a number of samples of InGaN/GaN MQWs, with different well widths and barrier heights, revealed the dependence of the emission peak position on quantum-well thickness [301]. As the thickness of the quantum well decreased, the stimulated emission shifted to higher energies. The effective conduction and valence-band discontinuities also were estimated. In the samples used by Bidnyk et al. [304] for the optical pumping experiments, the GaN barriers were intentionally doped with Si. The concentration of Si was varied from 1×10^{17} to 3×10^{19} cm^{-3}. The threshold at room temperature was found to be 12 times as low as that of a high-quantity GaN epitaxial layer. Spectral narrowing was observed at higher excitation densities. The authors have interpreted the low SE threshold as due to large localization of excitons in quantum wells of InGaN. This research group has shown the applicability of InGaN MQWs for high-temperature laser operation by observing laser action up to 550 K. The threshold necessary at high temperatures is also high because nonradiative processes are very dominant at these temperatures. Laser action in the MOCVD-grown InGaN/GaN MQWs that have high In content also was studied by one research team [306]. The experiments were done at room temperature and 25 K. Annealing experiments have revealed that the potential fluctuations can be reduced.

6. LIGHT-EMITTING DIODES AND SEMICONDUCTOR LASERS BASED ON InGaN

There are several excellent reviews on LEDs and lasers based on InGaN [1, 307–311] Many research groups in universities and industry have fabricated the light-emitting devices of InGaN [312–356]. Nakamura et al. [313] have fabricated blue LEDs from a p-GaN/n-InGaN/n-GaN double heterostructure. The output power of this laser was twice that of the II–VI-based blue LEDs, at the same forward current. When a Zn-doped InGaN active layer was used, a candela class high-brightness blue LED could be achieved [315].

In a later work, Nakamura et al. [1] could increase the output power and lower the forward voltage. In the previous studies, electron-beam irradiation was performed instead of thermal annealing for as-grown InGaN/GaN epilayers to obtain a high-quality p-type GaN layer. In this case, the output power was not high since the entire p layer was not uniformly converted into a highly p-type GaN layer by electron irradiation. Thermal annealing could easily change the entire high-resistivity p-type GaN layer into a low-resistivity p-type GaN layer. The structure of the InGaN/AlGaN double heterostructure LED is shown in Figure 53.

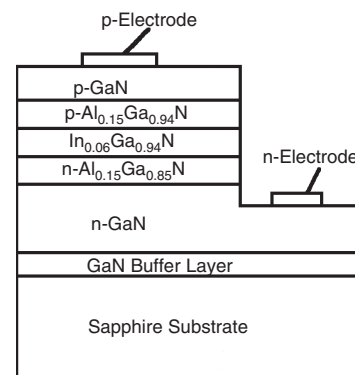
Blue-green LEDs were fabricated [314] with InGaN/AlGaN double heterostructure in which the In mole fraction was increased to 0.23. Also, the active layer of InGaN was co-doped with both Zn and Si. Donor–acceptor pair recombination was the recombination channel. The peak wavelength in the EL was 500 nm. High-brightness InGaN blue, green, and yellow LEDs with quantum well structure based III–V nitrides were grown on sapphire substrates [316]. The In mole fraction was varied from 0.2 to 0.7 to change the peak wavelength of the InGaN SQW LEDs from blue to yellow. Super bright green InGaN single quantum well structure, p-AlGaN/InGaN/n-GaN, with a luminous intensity of 12 cd were fabricated [317] in which the In$_{0.45}$Ga$_{0.55}$N active layer was undoped (Fig. 54). The luminous intensity of this LED was about 100 times higher than of conventional GaP LEDs. Amano and Akaskai's group have fabricated a double heterostructure of p-GaN/In$_{0.2}$Ga$_{0.8}$N/n-GaN by MBE,


Figure 53. The structure of the InGaN/AlGaN double-heterostructure LEDs. Reprinted with permission from [1], S. Nakamura and G. Fasol, "The Blue Laser Diode." © 1997, Springer-Verlag.

which has given violet emission upon current injection at room temperature [318].

Nakamura et al. [1, 317] have made breakthroughs in making white LEDs. There are several applications for white LEDs. They can be used in full-color liquid-crystal displays, fluorescent lamps, etc. White LEDs could be fabricated by exciting phosphors by using blue LEDs with high excitation energy. The structure of white LEDs is shown in Figure 55. The structure of this LED is almost the same as the blue LED chip except that a phosphor layer is used on top of the blue LED. When current is supplied to the single quantum well LED, blue light is emitted from the quantum well of InGaN. The phosphor is excited by this light and emits yellow luminescence. The mixture of blue light from InGaN and yellow light from phosphor gives white light.

Nakamura et al. [319] have fabricated InGaN MQW semiconductor lasers by MOCVD on (0001) sapphire substrate. Etching of III–V nitride films was done to get the mirror facets for the laser cavity. The active layer was a MQW consisting of 25 Å thick $In_{0.2}Ga_{0.8}N$ well layers and 50 Å thick $In_{0.05}Ga_{0.95}N$ barrier layers, with 26 periods. The n- and p-type $Al_{0.15}Ga_{0.85}N$ layers were cladding layers (Fig. 56). Under current injection, pulsed lasing was obtained at room temperature at a wavelength of 417 nm.

Figure 57 shows the room temperature EL, PV, and EA spectra of green, blue SQW LED, and MQW laser diode structures. The EL spectrum of the MQW laser diode was measured below the threshold density. The lasing emission
Figure 57. EL, PV, and EA (EA) spectra for InGaN green (510 nm) and blue (450 nm) SQW LED structures and a MQW laser structure, whose lasing wavelength is 406 nm. The EL spectrum of the MQW structure was measured below the threshold current. The In compositions in the InGaN quantum well for green, blue, and MQW LED are 0.45, 0.3, and 0.2, respectively. The structure in the EA spectra corresponds to the free exciton resonances. Reprinted with permission from [1], S. Nakamura and G. Fasol, "The Blue Laser Diode." © 1997, Springer-Verlag.

of this MQW LD appeared at 3.052 eV (406 nm). From these results, Nakamura's group has concluded that the EL emissions are from localized excitons in the quantum wells. In the MQW laser device, even the inhomogeneous column-like structures have shown lasing. From this observation, Nakamura et al. have concluded that the oscillator strength and gain at local potential minima are very large. The emissions were interpreted as due to inhomogeneity of InGaN layers, which are equivalent to quantum-dot-like states in InGaN quantum well layers. Figure 58 shows the surface morphology of InGaN well layers observed in AFM. The roughness of InGaN well layers was about 10 to 30 Å, with periods of about 1000 Å horizontally in the plane parallel to the junction. These islands-like structures were not found for layers thicker than 40 Å. It was thought that the In-rich regions in InGaN well layers can form potential minima to confine the carriers.

Nakamura et al. [325] has demonstrated the cw operation of a InGaN MQW semiconductor laser at room temperature, which has shown a single peak when the forward current was increased above the threshold current. Continuous-wave operation of InGaN MQW laser structure with a lifetime of 27 h [86] was demonstrated. The best method to reduce the number of threading dislocations is by using epitaxially overgrown GaN on sapphire [329, 330]. The GaN layer above the SiO_2 mask area surrounding the window, was found to have almost no dislocations. A high density of threading dislocations was observed in the window regions. InGaN MQW semiconductor lasers were fabricated on such GaN substrates. In these structures, $Al_{0.14}Ga_{0.86}N$–GaN modulation doped-strained-layer superlattice cladding layers were used. With these structures, operating lifetime of 10,000 hours was demonstrated in the cw mode at room temperature. Amber-[331] and violet-[332] color-emitting InGaN semiconductor lasers on a GaN substrate were reported by Nakamura's group. The semiconductor lasers with cleaved mirror facets have given much higher output powers [334, 336]. Kneissl et al. [338] have fabricated the mirrors by chemical-assisted ion-beam etching for their InGaN/GaN semiconductor lasers. From these lasers, emission was observed in the wavelength range of 419 to 423 nm in the pulsed current-injection conditions. Hofstetter et al. [339] have reported
the threshold current density of 16 kA/cm^2 in an electrically injected InGaN/GaN distributed feedback laser. The emission of this laser was at 403 nm and was found to be in a single longitudinal mode. Kneissl et al. [340] have characterized the mirrors made by chemical etching with the help of AFM and SEM. Bour et al. [341] have studied the dependence of threshold current density on the stripe width in the gain-guided InGaN MQW lasers. The lasing wavelength was 400 nm. The threshold current density was found to increase very rapidly as the stripe width was narrowed. The same group has later accomplished the room temperature cw operation of InGaN MQW semiconductor laser [342].

Low-threshold current operation is a desirable requisite for the utilization of semiconductor lasers for color printing and optical memory systems. To realize the low-threshold operation, it is essential that the injected carriers are confined. Generally, the injected electrons leak away from the quantum well region into the p-cladding layer, where they recombine with the holes. These electrons, which leak into the neighboring cladding layers, do not populate the quantum well active region, and, hence, they do not contribute to the stimulated emission. This results in the increase in threshold current and a decrease in the internal quantum efficiency. To prevent the leakage effects, Nakamura et al. [1] have used a thin, high bandgap, p-type AlGaN layer that is placed immediately after the quantum well layer. Bour et al. [343] have designed and studied the characteristics of InGaN MQW lasers with an asymmetric waveguide. The device structure is shown in Figure 59. The active region consists of five 35 Å $In_{0.1}Ga_{0.9}N$ QWs separated by 60 Å $In_{0.02}Ga_{0.98}N$:Si barriers. The cladding layers are 0.5-μm-thick $Al_{0.07}Ga_{0.93}N$. A room-temperature cw operation was achieved with this structure. Kneissl et al. [344] have examined the effects of compositional fluctuations on the optical gain characteristics in InGaN semiconductor lasers. Bour et al. [345] have demonstrated a cw operation of InGaN lasers with threshold current densities as low as 7 kA/cm^2 and an emission wavelength at 400 nm. Improvements in the

beam quality were observed when thick, superlattice, n-type cladding layer was used (Fig. 60). From theoretical considerations, it also was shown that thinning the sapphire substrate will give a better room-temperature cw operation of the laser. The cw operation was observed up to a temperature of 60 °C as shown in Figure 61. Bour et al. [348] have shown that polycrystalline LEDs of InGaN could be fabricated on quartz substrate. The active layer is an $In_{0.2}Ga_{0.8}N$ SQW with an emission wavelength of 430 nm. These polycrystalline LEDs were thought to be useful for large-area displays. Huh et al. [353] have described the fabrication and characterization of InGaN/GaN MQW LED by using a Pt thin film as a current spreading layer. The emission wavelength was at 453 nm and had a FWHM of 23 nm.

7. MECHANISM OF LASER ACTION IN InGaN

Lasing mechanisms in the InGaN epitaxial layer and quantum wells were discussed by several authors based on the optical experiments. However, it is still a controversial topic. Chichibu et al. [258] were the first who identified localized excitons in SQWs and MQWs of InGaN and proposed that they are responsible for the lasing in these materials. Later, Narukawa et al. [259] have demonstrated photo-pumped lasing from the locatized exciton states. Kuball et al. [283] suggested that the microscopic crystalline order influences the laser action. Satake et al. [287] have reported stimulated emission characteristics in InGaN epilayers. They were of the opinion that localized states can be easily filled by optical pumping, since the density of localized states in the band tail is lower than that of the extended states. If the optical gain from the filled localized states exceeds the losses due to light propagation, stimulated emission sets in. Similar phenomena have been very thoroughly investigated by Ding et al. [357] in the case of II–VI semiconducting quantum wells.

From the optical gain spectroscopy measurements, Frankowsky et al. [298] concluded that optical gain in GaN/GaN heterostructures is due to direct band-to-band transitions in an electron-hole plasma. The electron-hole plasma state under high optical excitation was also observed by Jiang et al. [302]. Song et al. [303] have performed
Figure 61. cw light-current characteristics of 2×500 μm^2 nitride diode with HR-coated mirrors. Reprinted with permission from [345], D. P. Bour et al., *Phys. Status Solidi A* 180, 139 (2000). © 2000, John Wiley and Sons.

the gain spectroscopy studies on InGaN/GaN quantum well lasers and concluded that the filling of localized band-edge states is a prerequisite for achieving lasing.

Viswanath et al. [106] have discussed the importance of the exciton binding energy in realizing the room-temperature semiconductor lasers based on GaN. Mohs et al. [358] have investigated the optical gain in Nichia company's InGaN blue LED. Experiments were conducted at room temperature by using the variable stripe-length method and nanosecond Nd:YAG laser. Plasma recombination from a quantum-confined level was thought to be the gain mechanism. Mohs et al. [359] have performed absorption and gain spectroscopy experiments and arrived at a conclusion that the conventional electron-hole plasma recombination model is valid to explain lasing in $In_{0.18}Ga_{0.82}N/In_{0.06}Ga_{0.94}N$ MQWs.

Mukai et al. [360] have studied the current and temperature dependence of EL in InGaN SQW lasers with different In compositions. For the lasers that emit shorter wavelengths (less than 375 nm), the emission was attributed to band-to-band recombination, while for the InGaN lasers with higher In composition, which emit in the longer wavelength region, lasing was due to the localized excitons.

8. CONCLUSIONS

Optical properties of GaN nanostructures and devices have been reviewed in this article. The discussion includes photoluminescence and time-resolved spectroscopy of these materials. Most of the work on material growth and device development has been done by using the MOCVD technique. However, other techniques, such as MBE, also were tried. To date, the MOCVD method has provided better materials and optoelectronic devices compared to MBE. Similarly, sapphire has been the most used substrate.

Now GaN and other III–V nitrides are realized as potential candidates in photonics. Light-emitting diodes and semiconductor lasers, which emit in a variety of wave lengths from blue to yellow, are now commercially available. They

are being used in full-color displays and traffic lights. By combining the three primary colors, white light LEDs also were developed. The LEDs emitting various colors also are substitutes for traditional fluorescent lamps and can be used in homes and shops. The market for this is very huge. Blue LEDs also find applications in laser printers and underwater optical communications. In conclusion, the future of nitrides looks extremely bright.

GLOSSARY

Laser Light amplification by stimulated emission of radiation.

Light-emitting diode This is the p-n junction of a semiconductor and emits light when current is passed through it.

Luminescence This is the phenomena of emission of radiation when the material is excited by suitable energy. If the excitation is caused by photons it is called photoluminescence and if the excitation is caused by electrons it is called as cathodoluminescence.

Quantum dot This is a zero-dimensional system in which the confinement of electron occurs in all the three directions.

Quantum well This is a very thin semiconductor with thickness of few nanometers or less and is placed between two barrier layers which have higher bandgap energies. In this case the free carrier motion occurs in two directions. Here quantum confinement occurs in one direction.

Quantum wire This is a one-dimensional electron system in which the quantum confinement occurs in two directions.

Semiconductor laser This is a solid state laser in which the active medium is a semiconductor.

Optical Properties of Oligophenylenevinylenes

Johannes Gierschner, Dieter Oelkrug

University of Tübingen, Tübingen, Germany

CONTENTS

1. INTRODUCTION

In the last 20 years, polyene-like organic molecules have attracted much attention as active components in organic light-emitting diodes (OLEDs), microlasing cavities, ultra-fast photoswitches and detectors, as well as organic field effect transistors (FETs) [1]. Among the varieties of materials, polyphenylenevinylene (PPV)-based materials are widely investigated due to their use in OLEDs [2]. In order to improve the optical and photophysical properties, that is, tunable emission wavelengths and high fluorescence quantum yields, the interplay of *intra*molecular effects (the effective conjugation length and band shifts by chemical substitution) and *inter*molecular interactions (mutual geometrical orientations, electronic and vibrational coupling between the chromophores) has to be understood. Oligophenylenevinylenes (OPVs, see Fig. 1) make possible the systematic study of these parameters, since the oligomers provide well-defined conjugation lengths, variable substitution patterns, and a variety of intermolecular orientations in the condensed phases.

OPVs have been studied since the 1960s as scintillators [3], laser dyes [4], and optical whiteners [5]. The photochemistry of stilbenoid compounds, especially the *trans–cis*

photo-isomerization of stilbene, has been extensively analyzed [6] and is still under investigation [7–12]. Since the early 1990s, with the synthesis of homologous series of soluble *t*-butyl-substituted OPVs by Schenk and co-workers [13], the oligomers have become a widely used model system for PPV. Since then, a great variety of substitution patterns has been established, allowing the tuning of the emission wavelength over the visible range [14, 15]. Quantum chemical investigations and theoretical modeling of the OPVs permit the precise prediction of the electronic transition energies and spectra of the oligomers in solution and extrapolation to the ideally conjugated polymer. Experimental and theoretical studies of intermolecular orientations in different model systems enlightened the correlation of structural and optical properties in the condensed phases and opened the opportunity to achieve full control of the photophysics of these systems. In the recent years, films, single crystals, dendrimer systems, and host–guest compounds of the OPVs have attracted growing attention for potential applications in optoelectronic devices due to their electroluminescent [16–23], lasing [24, 25], (photo) conductive [26–31], or photovoltaic properties [32, 33]. Substituted OPVs with large two-photon absorption cross sections are attractive materials for fluorescence microscopy, optical limiting, and optical data storage [34].

The article focuses on the photophysics of individual and condensed *para*-oligophenylenevinylenes and their correlation to *intra*- and *inter*molecular structural effects. In Section 2, an overview of the materials is given, including the variety of substitution patterns and the geometrical structures of the molecules. Section 3 discusses the features of the molecules in solution (absorption and fluorescence spectra, electronic transition energies, fluorescence quantum yields, and decay times) and the influence of mesomeric and inductive substituent effects, solvent shifts, and thermal effects. In Section 4, model compounds for the investigation of intermolecular interactions and their impact on the optical properties are discussed. In Section 5, the photophysics of condensed phases such as films, nanoparticles, and single crystals of OPVs are addressed.
Figure 1. Structure and notation of the atoms for oligophenylene-vinylenes (*n*PVs).

2. MATERIALS

2.1. Substitution Patterns

The homologous series of unsubstituted oligopheny-lenevinylenes, *n*PV, where *n* denotes the number of phenylenevinylene units (see Fig. 1 and Table 1), has been synthesized up to $n = 7$ [5, 27, 35, 36]. In order to enlarge the solubility of the oligomers, alkyl or alkoxy groups were introduced. The series of *t*-butyl-substituted oligomers (B*n*PV, see Table 2) with $n = 1$–6 was synthesized by Schenk et al. [13], and series of alkoxy-substituted OPVs were synthesized by Stalmach et al. (*n*POPVs with $n = 1$–11, see Table 3) [37] and Peeters et al. (*n*BOPVs, with $n = 1$–6, see Table 4) [38]. Recently, the syntheses of further homologous series with alkyl [39–42] and alkoxy [16, 40–43] substituents was reported. Finally, homologous series of donor–acceptor (DA)-substituted OPVs were synthesized, with D,A substituents either in the terminal 5,5′ positions (see Fig. 1, D,

dialkylamino, and A, cyano, carbonyl, nitro groups) [44] or in the vinylene units (1,1′ positions with D, dibutylamino, A, cyano) [45].

The substitution pattern was widely varied, especially on *para*-distyrylbenzene (2PV), including ring substitutions (Tables 5, 6) with alkyl [13, 26, 36, 39, 46–49], alkoxy [16, 26, 36–38, 43, 49–53], cyano [36, 49, 54–57], amino [34, 49, 58], nitro [26, 49], fluoro [59–61], bromo [49], carbonyl [62], carboxyl [49], sulfonyl [53], and silyl groups [63, 64] or push–pull systems [44, 53], as well as substitutions in the vinylene unit (Tables 7, 8) with sulfonyl [50, 65, 66] or cyano groups [48, 50, 66–71]. A systematic variation of cyanosubstitution was also performed on 4PV (Table 9) [72–75]. Thus, different substitution patterns with mesomeric ($\pm$M) and/or inductive ($\pm$I) groups, but also with varying sterical requirements, are now available. Recently, general procedures of OPV syntheses were reviewed [14].

2.2. Molecular Structure

According to X-ray studies on *trans*-stilbene (1PV) [76–79], 2PV [80], and 4PV [17], the unsubstituted OPVs are only slightly twisted, with torsional angles around the C_1–C_2 single bonds (Fig. 1) of $\phi \approx 5°$. A perfect planar structure (C_{2h} symmetry) of 1PV is found in the gas phase at low temperatures according to jet-cooled spectra [81–84]. The C_{2h} symmetry is also predicted by density functional (B3LYP) [8, 85–88] and semiempirical PM3 [89–92] quantum chemical

[a] EtHexO is 2-ethyl-hexyloxy.

calculations on 1PV. *Ab initio* Hartree–Fock (HF) [86, 87, 92–95] and semiempirical AM1 [89, 90, 92, 93, 96, 97] calculations yield a slightly nonplanar structure (C_2 symmetry) of 1PV; however, the ring-torsional potential is very flat for $\phi < 30°$. The bond lengths and angles of the *n*PVs, as determined by X-ray measurements [17, 76–80], are quite well reproduced by theory, resulting in pronounced bond alterations in the vinylene units [8–10, 87–94, 98–103]. In the gas phase at higher temperatures, the *average* geometrical structure, according to electron diffraction [104] and photoelectron studies [105, 106] of 1PV, is nonplanar, due to the low torsional barrier for rotations around the ethenyl–phenyl (C_1–C_2) single bonds [8, 85, 89–93, 95–97, 107].

Deviations from planarity in the solid state are observed in several substituted OPVs. According to quantum chemical calculations [69, 92, 93], the deviations from planarity depend sensitively on the kind and positions of substituents [93]. However, the torsional angles in most of the reported X-ray structures [17, 47, 60, 73, 74, 80, 108–114] do not exceed 11°–18°. Larger deviations from planarity are found for 2PV derivatives with cyanosubstituents in the vinylene moiety and additional alkyl substituents at the central phenyl ring (see Tables 7–9) [68].

2.3. Bridged Oligophenylenevinylenes

Oligophenylenevinylenes with defined mutual geometric alignment are represented by (i) hydrogen-bonded OPV pairs, introduced by Meijer and co-workers [115–117], and by (ii) covalently linked oligomers, which were synthesized by Schenk et al. [13], Anger et al. [11], Rau and Waldner [12], Bazan [118–129], and Song et al. [130–133]. The covalently linked OPVs cover dimeric stilbenoid cyclophanes with partial π–π overlap and different intermolecular orientations [13, 118–125, 134] (Fig. 2), stilbenophanes with perfect face-to-face alignment [11, 12, 135] (Fig. 2), tetrameric systems with tetrahedral OPV orientation [126–128, 136] (Fig. 3), and dendrimers [128, 136–141]. Dimeric OPVs were also prepared by Lewis and Letsinger using 1:1 mixtures of complementary oligonucleotides containing stilbene units [142–145].

2.4. Condensed Phases

Films of OPVs were prepared by vapor deposition from high vacuum [20, 28, 74, 146–155], by spin or drop coating from solution [21, 23, 156–158], and by the Langmuir–Blodgett technique [131, 159–170]. Nanoparticles were obtained by fast precipitation from solutions of the oligomers by addition of a poor solvent (i.e., water) and measured in suspension [38, 54, 116, 146, 148, 170–178]. The size of the nanoparticles (20–500 nm) can be controlled by the preparation conditions (concentration, solvent, temperature, mixing ratio). Nanoparticles were also prepared by cooling saturated solutions of the OPVs [62, 179–182]. General procedures for nanoparticle preparation were reviewed recently [183, 184]. Single crystals were grown from solution [60, 61, 68, 75–78, 108–112, 163, 185], melt [186], and gas phase [31, 79, 187, 188].
Figure 2. Structures of stilbenoid cyclophanes.

Host–guest compounds (HGCs), where the OPVs are incorporated in an inert host material such as γ-cyclodextrin [189] or channel-forming perhydrotriphenylene (PHTP) [55, 190, 191], were prepared by cocrystallization from solution. The cavities of the cyclodextrin HGCs permit the inclusion of cofacially oriented stilbene pairs. PHTP HGCs open the opportunity to investigate specific "head-to-tail" interactions of the oligomers.

3. OPTICAL AND PHOTOPHYSICAL PROPERTIES IN SOLUTION

3.1. Absorption and Fluorescence Spectra

At low temperatures ($T < 20$ K), the $S_0 \rightarrow S_1$ absorption and $S_1 \rightarrow S_0$ fluorescence spectra of 1PV [192] and the longer oligomers [91] show very small 0–0 bandgaps and the spectra are almost mirror symmetrical (Fig. 4). Thus, the frequencies and nuclear displacements of the totally symmetrical a_g vibrational modes which couple to the electronic transition must be very similar in S_0 and S_1, in agreement with *ab initio* quantum chemical calculations [91]. Detailed vibrational analyses of the electronic spectra were carried out on (substituted) *trans*-stilbenes under collision-free conditions [81–84, 193–196]. The fine structures of the experimental spectra are dominated by the progressions and combinations of a few prominent modes, which also becomes evident for the longer oligomers in solid solution
Figure 4. Fluorescence emission (left) and excitation (right) spectra of distyrylbenzene (2PV). (a) Experimental spectra in tetradecane at $T = 15$ K. (b) Calculated low temperature spectra (HF/RCIS 6–311G*) [91]. (c) Experimental spectra in dioxane at $T = 293$ K. (d) Simulated spectra, obtained by convolution of the experimental low temperature spectra with a Gaussian and an exponential distribution [91].

[91, 118, 179, 197, 198]. Theoretical calculations, obtained by a Franck–Condon approach [85, 91, 99, 100, 199, 200] from *ab initio* quantum chemical calculations, demonstrate that the nuclear displacements of the prominent modes essentially coincide with the geometrical changes upon the electronic transition. Among these modes, the low-frequency longitudinal in-plane deformation mode ($\nu = 204$ cm^{-1} for 1PV [193]) strongly decreases with n, resulting in $\nu \rightarrow 0$ for $n \rightarrow \infty$ [91], whereas the vinylene C_1–C_1' stretching mode around 1650 cm^{-1} [201–208] decreases only very little with n [96, 209–211]. The optical spectra of the nPVs were calculated at different levels of theory for 1PV [85, 99, 100, 212] and the longer oligomers [91, 200, 213], and good agreement with the experiment was obtained at the *ab initio* HF/restricted configuration interaction singles (RCIS) 6–311G* level, including the progressions and combinations of the complete sets of a_g modes (Fig. 4).

With increasing temperature, the mirror symmetry of absorption and fluorescence is lost and a 0–0 bandgap opens, which extends to 200 cm^{-1} at 77 K [173, 175, 214] and to 1000 cm^{-1} at room temperature (Fig. 4). The room temperature fluorescence spectra still exhibit distinct vibronic structure, whereas the absorption spectra are only slightly structured and asymmetrically shifted to the blue [91, 96, 146, 210, 214–219] (see Fig. 4). The differences in the spectral characteristics of fluorescence and absorption are due to the different torsional barriers of the ground and excited state structures. Compared to the S_0 state, the C_1–C_2 bond is rigidified in the S_1 state [8, 9, 89–91, 95, 100–103, 220], leading to a steeper potential of the torsional modes [8, 90, 91, 97, 212]. The torsional barrier can be investigated in the gas phase, where the low-frequency torsional mode of 1PV was determined to $\nu = 8$ cm^{-1} in the S_0 state and $\nu = 48$ cm^{-1} in the S_1 state [81]. Therefore, the room temperature absorption spectra arise from superimposed transitions of different nonplanar conformers of the molecules [91, 96, 146, 215, 216, 221], and the total band shapes are well described by a combination of a Gaussian-shaped and an exponential convolution of the low temperature spectra (Fig. 4). The Gaussian part accounts for inhomogeneities of the environment, and the exponential part accounts for the increase in the torsional potential in S_1 against S_0 [212]. Since the potential in S_1 is high against the thermal energy, the room temperature fluorescence spectra can be exclusively fitted by the Gaussian contribution to line broadening. In rigid environments, where the potential in S_0 is also high against the thermal energy, the absorption spectrum can also be reasonably fitted by a Gaussian convolution [178, 222].

3.2. Electronic Transition Energies

The energetic positions of the absorption spectra of the OPVs are strongly affected by the conjugation length and to a smaller extent also by the solvent and the temperature (Fig. 4) [36, 223] due to changes in the polarizability of the environment [224–226]. In nonpolar solvents, the polarizability shift becomes a linear function of the Onsager relation [224], which allows the extrapolation to the spectral positions *in vacuo* with a refractive index of $n_{solv} = 1$ [91]. The solvent red shift amounts to $\Delta\nu_R = 2500$ cm^{-1} compared to the values *in vacuo* (Fig. 4); thus solvent effects

should be considered if experimental transition energies are compared to calculated ones. Specific solvent interactions in polar solvents are observed for OPVs with electron withdrawing substituents like cyano, nitro, triflyl (SO_2CF_3), or fluoro groups [59, 75] and for donor–acceptor-substituted OPVs [225–227], resulting in unstructured, red-shifted fluorescence spectra and large Stokes shifts between the absorption and fluorescence maxima due to the contribution of charge separation not only in the S_1, but also in the S_0 state [228].

Vertical transition energies ν_{vert} for the $S_0 \rightarrow S_1$ transition were calculated at different levels of theory for 1PV [85, 88, 89, 99, 100, 229–233], substituted OPVs [8, 16, 55, 60, 67, 92, 119, 232–239], and the homologues series of the nPVs [91, 97, 101, 103, 107, 218, 234, 240–251]. The latter reproduce the experimental result of an inverse chain length dependence $1/N$ (with $N = 3n + 2$) of ν_{vert} [91, 96, 173, 216, 237, 247, 248]. However, the results obtained by semiempirical methods depend sensitively on the number of electron configurations considered in the calculations [89]. Time-dependent density functional (TDFT) methods tend to underestimate the vertical transition energies (Table 1) and to overestimate the slope of the $1/N$ dependence [245]. Reliable results were obtained by the *ab initio* RCIS/6–311G* method, where the vertical transition energies were calculated from adiabatic transition energies ν_{00} by addition of the equilibration energy [91] (see Table 1). In contrast, the direct calculation of the vertical transition energies by *ab initio* methods [246] yields unreasonably high values for ν_{vert} (see Table 1). For longer oligomers ($n > 4$), a deviation from the linear $1/N$ dependence is observed both experimentally [27, 37, 173, 175] and theoretically [234, 246, 247], which results in a faster convergence for $n \rightarrow \infty$. The experimental transition energies can be reasonably fitted by empirical functions [44, 246], within the extended Hückel Molecular Orbital [252] and free electron gas model [253] including bond alternation, Simpson's exciton model [254], or the classical oscillator approach by Kuhn [255]. The extrapolation to idealized PPV yields $\nu_{00} \approx 20{,}300$ cm^{-1} in solution (23,400 cm^{-1} *in vacuo*). The equilibration energy for PPV was calculated to $\nu_{vert} - \nu_{00} \approx 1750$ cm^{-1} [91].

The introduction of substituents in the *terminal* phenyl rings with +M effect (e.g., alkoxy [16, 215, 223, 256] or amino [34, 49, 58] groups), −M effect (e.g., carbonyl [62] or cyano [36, 49, 54–57] groups), or +I effect (e.g., alkyl groups [39, 96, 107, 175, 216, 218, 223, 257, 258]) shifts the $S_0 \rightarrow S_1$ transitions slightly to lower energies. The additional introduction of alkoxy substituents [18, 38, 43, 48, 51, 69, 173, 234, 237] in the *central* phenyl rings (nPOPVs, Table 3, nBOPVs, Table 4) leads to a splitting of the low energetic absorption band with a systematic bathochromic shift of the $S_0 \rightarrow S_1$ transition compared to that of the nPVs. According to quantum chemical calculations, this effect is ascribed to the interaction between carbon and oxygen π orbitals, destabilizing the highest occupied molecular orbital (HOMO) more strongly than the lowest unoccupied molecular orbital (LUMO) [238, 259]. In addition, a blue-shifted "RO band" appears, due to strong configuration interactions between the HOMO and phenyl orbital branches [234]. Extrapolation of the nBOPV spectral positions to $n \rightarrow \infty$ yields

$\nu_{00} \approx 17{,}600$ cm^{-1} for the idealized polymer (experimentally: ν_{00}(BOPPV) = 18,100 cm^{-1} [260]). The fluorescence and absorption spectra of OPVs with cyanosubstituents in the vinylene unit are strongly red-shifted against the unsubstituted ones (Tables 7–9), in agreement with quantum chemical calculations [238, 259, 261]. Terminal donor–acceptor substitution of 1PV, for example, 4-(dialkylamino)-4′-nitrostilbene [122, 225–227], causes a large bathochromic shift in the transition energies due to the intramolecular charge transfer (CT) character of the transition. These results are also well reproduced by quantum chemical calculations [239, 247]. With increasing chain length n, the extent of the CT character decreases [44, 239, 247]. Thus, for some donor–acceptor-substituted homologous series, the decrease in the CT character overcompensates the bathochromic shift induced by the increase in n, thus causing a hypsochromic shift with n [44].

According to polarized absorption [262] and fluorescence studies [148, 263, 264] in stretched polyethylene films and to the rotational resolved fluorescence excitation spectrum of 1PV under collision-free conditions [84], the $S_0 \rightarrow S_1$ transition moment μ of the nPVs is oriented approximately parallel to the long geometrical axes of the molecules (defined as the distance between the terminal carbon atoms $d_{\omega,\omega'}$). The experimental results are supported by quantum chemical calculations, [9, 218, 229, 265, 266], yielding for 2PV an angle of approximately 8° between $d_{\omega,\omega'}$ and μ [266]. The oscillator strengths increase roughly linearly with the chain length (Tables 2–4). The energetic positions, orientations, and oscillator strengths of the higher $S_0 \rightarrow S_n$ transitions of the OPVs were assigned by polarized absorption spectroscopy on 1PV [262, 263] and fluorescence excitation measurements (1PV [265, 267], BnPVs [218]) and correlated with quantum chemical calculations [9, 218, 229, 265, 272].

Two-photon absorption studies allowed the assignment of the weak $S_0 \rightarrow S_2$ transition in 1PV [267] and substituted OPVs [270, 268] (Table 5) located about 4000 cm^{-1} above the $S_0 \rightarrow S_1$ transition, in qualitative agreement with quantum chemical calculations [270, 97, 232, 269]. Substituted nPV derivatives with donor–donor, donor–acceptor–donor, and acceptor–donor–acceptor structural motifs exhibit large two-photon absorption cross sections, δ [34, 268, 270, 271], in combination with high fluorescence quantum yields (Table 5). According to quantum chemical calculations, the magnitude of δ can be correlated with the degree of intramolecular charge transfer from the terminal donor groups to the π bridge [34, 268] and the calculated δ values are in reasonable agreement with the experimental ones [34, 286, 271].

Triplet $T_1 \rightarrow T_n$ transitions of nPVs ($n = 1$ [273], $n = 2$ [221]) alkoxy OPVs [173, 274] and differently substituted 4PVs [275] were determined by photoinduced absorption spectroscopy and by pulse radiolysis, respectively. The transition energies decrease with increasing chain length [173, 257], in agreement with quantum chemical calculations [101, 103], whereby the decrease is somewhat stronger than the one in the $S_0 \rightarrow S_1$ transition [173]. The equilibration energies of the triplet transition decrease rapidly with chain length n [173] in agreement with theoretical results [101]. The triplet lifetimes at $T = 100$ K are in the range of 3–8 ms [173].

3.3. Fluorescence Quantum Yields and Decay Times

The fluorescence quantum yields Φ_F of the parent nPVs and their derivatives with substituents at the phenylene moieties are fairly high (Tables 2–6) [16, 36, 48, 54, 59, 60, 66, 69, 146, 175, 237, 276, 277]. An exception is 1PV (*trans*-stilbene) due to the crossing of the S_1 potential surface with the S_2 state in the twisted geometry, leading to efficient nonradiative decay and *trans–cis* photoisomerization [6, 278]. Consequently, Φ_F(1PV) strongly increases in highly viscous [279] or rigid environments [190], at low temperatures [279–281], and in stiffed *trans*-stilbenes [7, 279, 282], where the flexibility of 1PV is strongly reduced. The radiative rate constants k_r for the S_1 deactivation of the OPVs in solution (Tables 2–4) increase with increasing conjugation length n, saturating at $k_r^\infty = (1 \pm 0.3)10^9$ s^{-1} [146, 173]. The increase in the nonradiative rate constant with n is even stronger, due to the increase in torsional phonon state density with decreasing $S_1 \rightarrow S_0$ transition energy, leading to an overall decrease in Φ_F with n (Tables 2–4) [16, 173, 175, 283].

Compared to the alkyl- and alkoxy-substituted OPVs, the fluorescence quantum yields are significantly lowered for OPVs with cyanosubstituents in the vinylene unit. The reduction is a sensitive function of the additional substitution patterns (Table 7). Medium quantum yields ($\Phi_F = 0.3$–0.5) are observed if the central phenyl ring of 2PV is additionally substituted with alkoxy groups (molecules of Type A, see Table 7) [48, 50, 284]. Further alkoxy substitution at the terminal phenyl rings reduces Φ_F to 5–10% (Type B) [69, 146]. Finally, the oligomers become practically nonfluorescent if the central phenyl ring is substituted with alkyl groups (Type C) [146, 237]. Fluorescence quenching of these compounds is mainly a sterical effect. While molecules of Type A are almost planar [74], the structures of Type C molecules are far from planarity in the S_0 state [68], thus enhancing torsional induced nonradiative deactivation [146]. Rigid environments enforce planarization of the C-type molecules in the S_1 state; thus Φ_F increases by 2 orders of magnitude in EPA glass at 77 K [146] (see Table 7).

4. MODEL COMPOUNDS FOR OPV–OPV INTERACTION STUDIES

Intermolecular interactions between OPV chromophores and their impact on optical and photophysical properties can be studied on model compounds, which are formed of a small number of oligomers with defined intermolecular geometrical alignment. Simple tetrameric structures were obtained with 2PV derivatives, where the oligomers are covalently linked via a central sp^3 carbon atom or via adamantan (Fig. 3) [126–128]. One-dimensional head-to-tail alignments could be realized in channel-forming host–guest compounds [55, 190, 191, 285]. Since in these structures the OPV–OPV distances are large, the interactions between the oligomers are only of weak dipolar character. An increase in interactions is expected for arrangements with π–π overlap, represented by stilbenoid cyclophane compounds [11–13, 118–124, 134] and 1:1 mixtures of complementary oligonucleotides containing stilbene units [142–144].

4.1. Arrangements with Weak Dipolar Coupling

In order to investigate specific head-to-tail interactions, HGCs were prepared, where OPVs and their p,p′-substituted derivatives are incorporated in the channels of the pseudo-hexagonal host lattice of PHTP [55, 190, 191]. The intrachannel distances of the oligomers are given by the long axis dimensions and the van der Waals distances. The interchannel distances are in the order of $r_{a,b} \approx 1.5$ nm [190, 286], so that side-by-side interactions between the oligomers are suppressed. The fine structures and spectral positions of the fluorescence spectra are very similar to those observed in solution [55, 190, 191], thus indicating only small dipolar OPV–OPV interactions. The observed red shift of the spectra $\Delta\nu_R \approx 700$ cm^{-1} against solution is partly due to the high polarizability of the host lattice, and only a portion of $\Delta\nu_R \approx 300$ cm^{-1} can be attributed to OPV–OPV interactions [55, 191]. The intermolecular excitation transfer of energy (ET) in the HGCs was investigated by time-resolved fluorescence on doped systems [191]. The results were interpreted according to the Förster-type ET mechanism, considering homo- and heterotransfer as well as *intra*- and *inter*channel transfer steps [191, 287].

The spectral features of the OPV tetramers in Figure 3 are also comparable with those of solutions of the monomers [126–128]. The spectra remain structured and are red-shifted by $\Delta\nu_R \approx 350$ cm^{-1} against the monomers. This also indicates that in these compounds the interactions between the OPV units are only of weak dipolar character. However, very fast ET is observed. The monoexponential fluorescence anisotropy decay of **AdR**$_4$ can be reasonably fitted assuming a Förster-type energy transfer, again indicating a weak coupling of the OPV units [128]. For **CR**$_4$ a biexponential decay was observed, which may suggest the presence of short-range exchange (Dexter)-type interaction [128].

4.2. Arrangements with π–π Overlap

Stronger interactions are expected in OPV pairs with partial π–π electron overlap of the OPV units, as in cyclophanes [118–125]. For the "shifted" and "angled" arrangements of the 2PV cyclophanes (structures **2a**, **2b** in Fig. 2), a red shift of $\Delta\nu_R = 1100$ cm^{-1} against the spectra of the parent monomer unit (**2c** in Fig. 5) is observed [119, 121]. The intermolecular coupling is still of dipolar character, since the vibronic features of the room temperature spectra as well as the fluorescence quantum yields and decay times [119] are very similar to those of the monomer. A monomer-like emitting state was also predicted by theoretical calculations on the basis of the collective electronic oscillator (CEO) method [119]. However, differences between **2a** and the monomer become apparent at low temperatures. In contrast to the monomer, well-resolved phonon lines could not be observed in the fluorescence spectrum of **2a**, probably due to an increase in the Franck–Condon activity in low-frequency chain deformation modes [118].

Significant changes in the optical properties are observed if the relative extent of π–π overlap between the oligomers is enhanced. Thus, the shifted and angled arrangements of 1PV cyclophanes [119, 134] (structures **1a**, **1b** in Fig. 2)
Figure 5. Absorption and fluorescence spectra of stilbenoid cyclophanes. (Top) Spectra of compounds **1a**, **1b** (see Fig. 2) and of the parent monomer unit (**1c**). (Bottom) Spectra of compounds **2a**, **2b** (see Fig. 2) and of the parent monomer unit (**2c**). Reprinted with permission from [121], W. J. Oldham Jr. et al., *J. Am. Chem. Soc.* 120, 419 (1998). © 1998, American Chemical Society.

both show structureless, strongly red-shifted emission bands (Fig. 5) with low radiative rate constants [119], reminiscent of excimer emission. According to CEO calculations the emission of the 1PV cyclophanes occurs from a low-lying state with a significant contribution of the through-space delocalized paracyclophane core [119]. The main absorption band of **1b** shows a splitting of about 9700 cm^{-1}, in good agreement with CEO calculations, due to the "Davydov-like" splitting of the $S_0 \rightarrow S_1$ transitions of the monomer units in the angled arrangement [119]. An equivalent explanation accounts for the properties of the "crossed" 2PV cyclophane [120, 134] (structure **3** in Fig. 2), where the π–π overlap of the monomer units is increased against **2a** and **2b**, respectively.

Perfect face-to-face alignment in 1PV cyclophane dimers was realized in the dimers **4a** and **4b** of Figure 2. In contrast to the stilbenophane **4a**, which can form *ZZ*, *ZE*, and *EE* isomer pairs [11] due to the flexibility of the ethyl linkers, **4b** is unable to undergo *E–Z* isomerization [12]. The main absorption band of **4b** shows two components, an intense one at $\lambda_1 \approx 300$ nm, slightly blue-shifted against the monomer peak at $\lambda = 308$ nm, and a red-shifted weak one at $\lambda_2 \approx 350$ nm (Fig. 6). Due to the strong π–π overlap of the stilbene units, the fluorescence mimics excimer emission with an even stronger red-shifted emission spectrum than **1a** and **1b** and a fluorescence lifetime of $\tau_F = 11$ ns [12]. Similar
Figure 6. Absorption (dots), fluorescence excitation (solid line), and emission (dashed line) spectra of stilbenophane **4b**. Reprinted with permission from [12], H. Rau and I. Waldner, *Phys. Chem. Chem. Phys.* 4, 1776 (2002). © 2002, Royal Society of Chemistry.

features are also observed for 1:1 mixtures of complementary oligonucleotides containing stilbene units [142–144] and ternary complexes of 1PV/γ-cyclodextrin/cyclohexane [189].

The electronic properties of cofacial nPV dimers were theoretically treated by Cornil [242, 288–290] and by Tretiak and Mukamel [291] and Tretiak et al. [292] as a function of the interchain distance. For large interchain separations ($d \gtrsim 5$ Å), a symmetrical splitting of the first single chain transition into a dipole allowed higher energetic components and a forbidden lower one was calculated (H-type interaction), in agreement with Kasha's molecular exciton model [293, 294]. The excitation energy is still localized on a single chain. Below a critical distance of $d \approx 5$ Å the splitting becomes unsymmetrical due to second-order perturbations, inducing an additional stabilization of the both states [242]. The lower state is delocalized over both chromophores, whereas the upper state has small interchromophore coherence [292]. The splitting tends to decrease nonlinearly with the chain length of the oligomers [242, 288, 295–297], in contrast to the predictions of the molecular exciton model, which states that there is an increase with chain length [293]. The splitting for a cofacial 1PV dimer [242] at a distance of $d = 3.5$ Å, which roughly corresponds to the average interchromophore distance in **4b** [298], is $\Delta\nu = 5800$ cm^{-1} at the INDO/S-CI level, in reasonable agreement with experiments (see Fig. 6). Analogous to considerations on 2,2'-paracyclophane [299], the symmetrically forbidden lower excited electronic B_g state in **4b** may borrow intensity from the higher B_u state via an a_u vibrational mode. The weakly allowed B_g state is responsible for the low radiative rate constant of **4b**. The large red shift of the fluorescence spectra of **1a** and **1b** and particularly **4b** is mainly due to strong intermolecular vibronic coupling between the chromophore units: Quantum chemical calculations of 2,2'-paracyclophane [300] and **4b** [298] predict a strong decrease in the interring distance after $S_0 \rightarrow S_1$ excitation, which results in extremely high Franck–Condon activity of interring breathing modes [298].

5. OPTICAL AND PHOTOPHYSICAL PROPERTIES IN THE SOLID STATE

The optical and photophysical properties of OPVs in the solid state are extensively studied on vapor-deposited (VD) films. Many experimental data are available on the absorption and fluorescence spectra [20–22, 28, 51, 54, 55, 67, 110, 146–149, 153, 158, 237, 258, 301–304], fluorescence quantum yields [22, 54, 55, 237], and fluorescence decay kinetics [22, 54, 55, 110, 158, 237, 258]. However, in only a few cases were the geometrical arrangements of the oligomers in the films determined by atomic force microscopy [149] or by polarized absorption studies [148, 159, 169, 301]; thus structure–property correlations are often missing. On the other hand, the structures of several single crystals have been determined by X-ray measurements [17, 25, 47, 60, 61, 68, 73–80, 108–114, 163, 185, 305, 306], and in some samples the fluorescence properties were also investigated [80, 110, 163, 185–188, 306]. VD films, formed from the same molecules as the corresponding single crystals, are expected to form similar structures, but substrate-induced orientation effects and the formation of meta-stable phases cannot be excluded.

The model compounds of Section 4 demonstrated how the optical and photophysical properties of the individual molecules are changed by specific intermolecular electronic interactions and vibrational coupling. Similar interactions are expected in the solid state structures, but the extension to three dimensions will induce an increase in the total intermolecular coupling strength. Moreover, the photophysical properties in the solid state are influenced by additional effects, such as exciton diffusion, structural defects, and chemical impurities. However, most of the spectral characteristics in OPV condensed phases can be explained by (short-range) molecular ordering. A schematic matrix representation of nearest neighbor arrangements is given in Figure 7.

5.1. Unsubstituted Oligomers

5.1.1. Structure

In 4PV single crystals the molecules are oriented with their long axes parallel to each other, where the short axes of adjacent molecules are arranged in a T-shaped manner (Fig. 7.21) with a short-axis inclination angle of $\alpha \approx 71°$ [17]. The T-shaped short-axis arrangement of adjacent molecules is also found for 2PV [80]. The corresponding "herringbone" arrangement is also predicted for 7PV by force field calculations [307]. A different packing was observed for 1PV single crystals [76–79]. The unit cell contains two molecules that are oriented with their long axes almost perpendicular to each other. Nearest neighbor molecules are cofacially arranged with a slight shift in the x,z plane (Fig. 7.23).

On the other hand, T-shaped arrangements are also assumed for small aggregates of phospholipids with 1PV substituents [130–133]. The "unit" aggregate consists of a chiral tetramer "pinwheel," as determined by induced circular dichroism spectra [131, 133]. Analogous structures are assumed in self-organized nanoparticles [146, 148, 174–179] or VD films [20, 21, 28, 51, 146–148, 301] of unsubstituted nPVs ($n = 2$–4) as well as in Langmuir–Blodgett (LB) films
Figure 7. Schematic matrix representation of simple unit cells of oligophenylenevinylenes in the solid state.

of terminal-substituted nPVs ($n = 1$ [131, 159–164], 2 [165–169]), since the spectral and photophysical features are very similar for all of these systems. Especially, both LB [159, 169] and VD films [148, 301] exhibit strong optical linear dichroism, indicating a preferential parallel alignment of the transition dipole moments.

5.1.2. Absorption Spectra

The absorption characteristics can be well studied in systems with low optical density, such as VD films (film thickness <50 nm), small nanoparticles ($\varnothing < 100$ nm), or LB films. In thick films [21, 28, 51, 301, 308] or micro [51, 174, 309] or single crystals [80] the increase in the optical density masks most of the spectral characteristics by saturation effects.

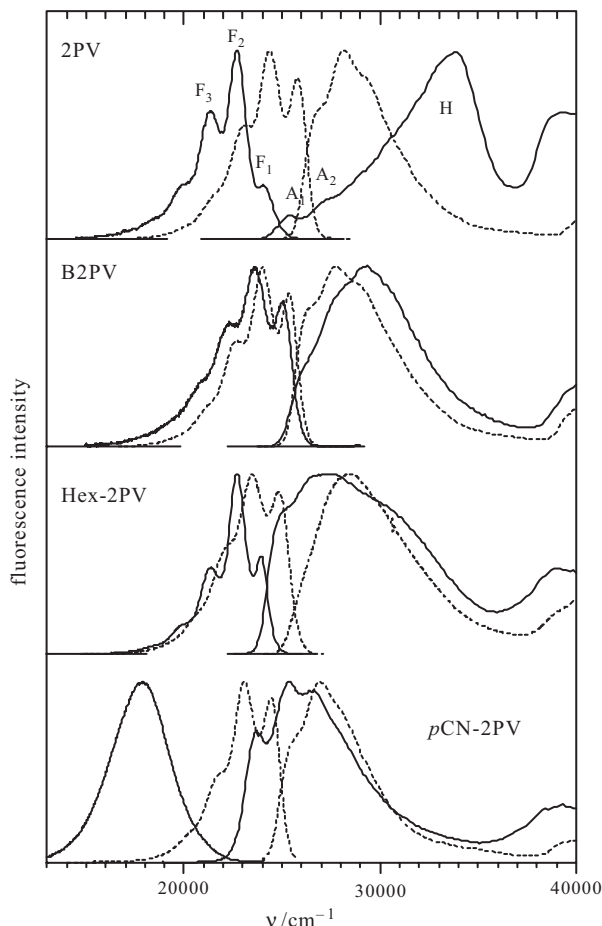
The absorption spectra of thin VD films and nanoparticles of unsubstituted nPVs consist of some weak bands (A_1, A_2) followed by the main maximum (H band, e.g., for 2PV [175] see Fig. 8), which is blue-shifted by $\Delta \nu \approx 6000$ cm^{-1} against the monomer spectrum. The blue shift is a consequence of exciton coupling of the transition dipole moments (H-type aggregation). According to the theoretical treatment by Spano [266, 310–314], the weak low energy peaks (A_1, A_2) of the spectrum are ascribed to vibrationally dressed excitons in pinwheels [266, 312] which may be present in the inhomogeneous distribution of different aggregate sizes [266]. The "noninteracting domains model" [313], which accounts for the distribution of molecular transition frequencies caused by disorder, reproduces the fine structure of the spectrum. The deviation from perfect parallel alignment of the transition dipoles was determined from the decrease in the time-resolved fluorescence anisotropy from the initial value $r_{F,0} = 0.4$ to the steady-state value of $r_F = 0.2$–0.3 [146, 148, 175–178], which yields a mean deviation angle of $\theta \approx 30°$ between the emitting species and the originally excited absorber. The forbidden lower exciton state (J band) is seen as a very weak shoulder at the low energy side of the spectrum [146, 313],


Figure 8. Fluorescence emission (left) and excitation (right) spectra of (substituted) distyrylbenzene (2PV) nanoparticles (solid lines) and spectra in solution (dashed lines).

where the energetic position in 2PV nanoparticles coincides well with the electronic origin ($\nu_{00} = 23,900$ cm^{-1}) observed in single crystals of 2PV [188]. The ν_{00} position is red shifted against solution by $\Delta\nu_R = 1800$ cm^{-1} and against vacuum by $\Delta\nu_R = 3800$ cm^{-1} due to the high optical polarizability of the solid samples in the direction of the long molecular axes. The anisotropic polarizability of 2PV nanoparticles was demonstrated by polarized light scattering measurements [176] and the spectral positions of the sensitized fluorescence of dopants [178].

5.1.3. Fluorescence Properties

The room temperature steady-state fluorescence spectra of the unsubstituted nPVs are very similar for VD films, LB films, and nanoparticles, whereas in thick films and microcrystals the high energy side of the emission spectra is suppressed by reabsorption [80, 146, 187]. The spectra reveal some vibronic structure (progression F_i, see Fig. 8) where the energy spacing of the subbands resembles the one in solution. Cooling of the films and nanoparticles does not significantly enhance the vibrational resolution of the spectra, which is due to the spatial inhomogeneity of these systems. Rich vibronic fine structure of the spectra was observed in

2PV single crystals [188] at low temperatures, clearly demonstrating that the vibronic progressions and intercombinations are very similar to those observed in the spectra of the isolated molecules. Thus the contribution of intermolecular vibrational modes is small. However, the electronic origins as well as the F_1 features (Fig. 8) are only of very weak intensity, in significant contrast to the solution spectra. According to the theoretical investigations by Spano [310–314] and Meskers et al. [158], this effect is ascribed to electronic interactions in the medium coupling regime. In the nanoparticles, the F_1 band shows varying intensities [174], which are caused by distributions of zero-order excited state energies [158] and/or distributions of interchain interactions [158, 310–314] due to (point) defects [312, 313]. The fluorescence lifetimes (2PV: $\tau_F \approx 2.5$ ns, Table 8) are considerably longer than those in solution (2PV: $\tau_F = 1.2$ ns), whereas the fluorescence quantum yields are reduced from $\Phi_F = 0.9$ in solution to $\Phi_F = 0.05$–0.1 in the films and nanoparticles. Thus the radiative rate constant k_F decreases against solution by 1 order of magnitude. At $T = 20$ K, Φ_F increases by a factor of 4–5 [54, 309], similar to PPV [258, 309], reaching the room temperature value of the 2PV single crystal ($\Phi_F = 0.65$ [80]). The increase in Φ_F is accompanied by an increase in τ_F of the same order [54, 146, 177]; thus in a first approximation k_F is independent of temperature.

Energy migration of the S_1 excitation energy in nPV films is due to a diffusion-enhanced Förster transfer process, as revealed from the bimolecular rate constant of S_1–S_1 annihilation [308]. The exciton diffusion (diffusion constant $D \approx 8 \cdot 10^{-4}$ cm^2 s^{-1}) [308] allows the deactivation via intrinsic or extrinsic traps. For 6BOPV (Table 4), which also forms H aggregates [38, 158, 173], a distribution of disorder-induced trap sites was deduced from time-resolved and site-selective fluorescence spectra [158]. With increasing excitation wavelength, the fluorescence decay becomes exponential on the time scale of the first nanoseconds [158]. However, on longer time scales, up to the ms regime [315], the fluorescence decay traces of the nPVs are strongly nonexponential [146, 148, 177]. This may be due to the recombination of bounded polaron pairs, whose generation was observed in a photoinduced absorption (PIA) study [308]. In this study evidence for fission of vibrationally hot S_1 states into triplet pairs was also found, a process which additionally reduces Φ_F. PIA studies on alkyloxy-substituted 4PV films (MeH4PV, see Table 9) [152–157, 316, 317] show that at low excitation densities, singlet excitons are formed as the only photoexcitations. At higher excitation densities, the singlet excitons are subject to bimolecular annihilation. In contrast to unsubstituted OPV, no evidence of exciton diffusion is found [153]. An additional contribution to the PIA at high excitation densities is ascribed to biexciton states that are stable in solution but dissociate into charged pairs in thin films [154]. The dissociation of singlet excitons into charged states is found to be a common process in conjugated polymers [157].

5.1.4. Doping with Acceptor Molecules for Electronic Excitation Transfer

Doping of the nPVs with suitable acceptor molecules, such as longer OPVs [146, 177], oligothiophenes [178], or acenes [186], leads to efficient energy transfer to these extrinsic

traps, resulting in sensitized fluorescence of the dopants. At doping ratios of $x_{dop} > 5 \cdot 10^{-4}$ the emission is almost completely dominated by the acceptor emission [146, 177, 178]. The appropriate choice of the acceptors allows tuning of the emission wavelength over the visible range. The acceptor molecules possess the same preferential orientation as the surrounding nPV molecules, as revealed from the constant fluorescence anisotropy over the whole emission range [177, 178]. The deactivation kinetics depend strongly on the choice of the dopant. OPVs as acceptors enhance the overall fluorescence quantum yield of doped 2PV nanoparticles up to $\Phi_{F,tot} = 0.6$ [146, 177]. Doping with oligothiophenes does not change $\Phi_{F,tot}$, which is probably a consequence of the competition between energy transfer and photoinduced electron transfer [178] from the HOMO of quinquethiophene to the HOMO of 2PV, which is approximately 1 eV lower in energy [150, 318]. The strong decrease in donor emission is not accompanied by a comparable decrease in fluorescence decay, thus indicating spatial inhomogeneities in these systems [146, 178].

5.2. Substituted Oligomers

5.2.1. t-Butyl-Substituted OPVs

Space-consuming substituents like tertiary butyl groups (BnPVs, see Table 2) hinder the coplanar or side-by-side alignments of adjacent molecules (Fig. 7.21, 7.22), since now these structures are energetically less favored than, for example, pairs with x,z-rotated axes (Fig. 7.31, 7.32). The lack of short-range parallel intermolecular orientation was demonstrated by the very fast complete fluorescence depolarization, occurring in the first ps after excitation [148, 176, 177]. Due to the different orientations of neighboring transition dipoles, the absorption spectra are very similar to those in solution [148, 176, 177] (see Fig. 8) and no indication of a blue-shifted H band can be observed. Also the energy spacings and relative intensities of the F_i bands in the fluorescence spectra are almost identical to the ones in solution. The small red shift of $\Delta\nu_R \approx 400$ cm^{-1} against solution is due to the high, approximately isotropic polarizability of the condensed material. The polarizability in the nonabsorbing region of B2PV nanoparticles was determined as isotropic by polarized light scattering measurements [176, 178]. The calculated isotropic value of the refractive index is in good agreement with the averaged value obtained from the polarizabilities of the constituting atoms and the one derived from the spectral positions of the sensitized fluorescence spectra of dopants [178]. The fluorescence quantum yields are low at room temperature (e.g., B2PV: $\Phi_F = 0.12$) [148], increasing by a factor of three at $T = 20$ K [258].

5.2.2. OPVs with Alkyl or Alkoxy Side Chains

Alkyl or alkoxy side chains (e.g., nPOPVs, nBOPVs, Tables 3, 4) destabilize T-shaped arrangements (Fig. 7.21) and favor partial π–π overlap. Thus in general cofacial arrangements, displaced in the x,z plane (Fig. 7.12, 7.13, 7.23), are observed. The 4PV oligomer with octyloxy side chains in the central phenyl ring (OctO-4PV, see Table 9) [24, 25, 74, 114, 305, 306] may serve as an example: The unit cell of the single crystal contains eight molecules, where

the conjugated backbones lie parallel to each other. Neighboring molecules are oriented in a cofacial arrangement, shifted in the x,z plane [305]. The highly anisotropic character of the cofacial arrangement becomes evident from the high degree of fluorescence polarization [114]. The crystal shift of the fluorescence spectrum against solution yields $\Delta\nu_R \approx 900$ cm^{-1} (Table 9). This value is significantly higher than that in isotropic solids (e.g., BnPVs) but much smaller than that in the herringbone-arranged unsubstituted 4PV sample ($\Delta\nu_R \approx 1800$ cm^{-1}, see Table 9). The smaller shift is due to the displacement of the OctO-4PV molecules in the x,z plane, but also to the decrease in the packing density by 11% compared to 4PV [17, 306]. The displacement gives rise to J aggregation with a well-structured, red-shifted absorption spectrum and high fluorescence quantum yields and decay rates [24, 306] (see Table 9). Similar considerations also apply for Oct-4PV [303] (Table 9) and Hex-2PV [54] (Fig. 8, Table 8), which all display well-structured fluorescence spectra similar to the ones in solution. No evidence for contributions of intermolecular vibrational modes to the fluorescence spectra is found for these systems.

On the other hand, microcrystals of hexyloxy-substituted 2PV (HexO-2PV, Table 8) show excimer-like emission [54], thus indicating a strong π–π overlap of the emitting adjacent molecules. The fluorescence is completely depolarized, which may be due to a random distribution of small π-stacked aggregates or to self-trapping of the excitation energy in excimer-like states [54].

5.2.3. Cyanosubstituted OPVs

The tendency to arrange in a π-stacked structure increases by introduction of cyanosubstituents. However, the crystal structure of cyanoderivatives depends sensitively on the substitution position. Thus cyanosubstitution at the *inner* position of the central vinyl moieties of octyloxy-4PV (OctO-4PV-CN$_i$, see Table 9) results in a cofacial x,z-shifted arrangement of neighboring molecules (Fig. 7.13) [73], where the displacement between the molecules is too large to allow intermolecular vibrational coupling. Concomitantly the fluorescence spectrum is structured and no excimer emission is observed [306].

On the other hand, cyanosubstitution at the *outer* positions of the central vinyl linkages (OctO-4PV-CN$_o$, see Table 9) results in a z shift of neighboring molecules (Fig. 7.12) by one phenylene unit [306]. The π–π overlap is now large and gives rise to high Franck–Condon activity of intermolecular vibrational modes, leading to excimer emission with a long fluorescence decay time of 8 ns, with a considerably high quantum yield of $\Phi_F = 0.5$ [306]. Excimer-like emission spectra are also observed for most of the cyanosubstituted 2PVs with additional hexyloxy substituents in the central phenyl ring (Table 8) [54, 57, 237]. However, it should be emphasized that the preparation conditions play a crucial role in the resulting arrangement of the molecules and hence, in the optical and photophysical properties. An illustrative example is p,p'-dicyanosubstituted 2PV (pCN-2PV). Depending on the preparation conditions (Table 8), H aggregates [319], J aggregates with well-structured emission spectra, or arrangements with excimer-like emission spectra (Fig. 8) [55] are observed (Table 8). In all these arrangements the molecules show a preferential parallel orientation

of the long molecular axes, as revealed from the high values of the fluorescence anisotropy, r_F (see Table 8). The differences in the absorption and fluorescence spectra of the systems indicate that small changes in the geometrical alignment may induce strong changes in the optical and photophysical properties of the materials.

Extended π–π stacks of adjacent molecules were observed for single crystals of various fluorosubstituted distyrylbenzenes [60] and binary cocrystals, containing pairs of unsubstituted and fluorinated nPVs, repectively [61, 109]. Nanoparticles and VD films of these materials exhibit H-type absorption spectra and excimer-like emission [321]. Excimer emission is also observed for single crystals of 3,5-dichloro-*trans*-stilbene (Fig. 1), which also crystallizes in a cofacial arrangement [185].

NOTE

Since the submission of the review chapter a number of new papers in the field of oligophenylenevinylenes have been published [322–363], which could not be included in the text, but should be brought to the attention of the reader. Further studies on the *trans–cis* photoisomerization of *trans*-stilbene (1PV) were published by several authors [322–324]. Room temperature Raman studies on 1PV suggest a distorted structure in solution [325]. In a theoretical paper, Møller-Plesset (MP2, MP3) calculations suggest a strictly planar geometry of 1PV in its absolute energy minimum [326]. Several papers described the preparation and spectroscopic characterization of new phenyl [327], alkyl [328], alkoxy [329–331], alkoxysilyl [332], amino [333, 334], bromo [335], and push-pull [336, 337] substituted OPVs. The effects of conformational [338, 339] and environmental disorder [338] on the optical properties were investigated both experimentally [338] and theoretically [338, 339]. A new method for the correlation of molecular shape and polarized luminescence, examined on OPVs, was introduced in Ref. [340]. The electronic transition energies of (substituted) OPVs were investigated at different quantum-chemical levels of theory [341–345], which *inter alia* allow the extrapolation for several ideally conjugated substituted PPV chains [341]. Two-photon properties of substituted OPVs were determined both experimentally [346] and theoretically [347, 348]. Molecular interactions in model compounds and their impact on the optical and photophysical properties were studied in OPV dimers with biphenyl linkage center [349], complementary oligonucleotides containing 1PV units [350], tetrahedral OPV structures [351], polystyrene bearing stilbenoid side chains [352], and supramolecular OPV ensembles [353]. Reference [354] shows that excimer formation of substituted OPVs might be used as strain sensors in polymer blends. Photo- [355–358] and electroluminescence [359–362] of films formed by substituted OPVs were investigated by a number of groups, addressing the influence of substituents [362], crystal structure [355] and morphology of the sample [356, 360]. OPVs have also been used as active material for energy transfer in gelation-assisted light harvesting [363] and for photoinduced electron transfer in TiO$_2$ hybrid materials [364]. Silver nanoparticles with OPV coating may act as ultrabright two-photon fluorescent nanobeacons [365].

GLOSSARY

Bridged oligomers Model systems of a defined number of chromophores whose conformational degrees of freedom are reduced by hydrogen or covalent bonds between the chromophores. These systems can be used to understand intermolecular interactions of adjacent molecules in the solid state and to build up supramolecular architectures, for example, dendrimers and helical self-organized structures.

Nanochannel-forming host–guest compounds Host–guest compounds (HGCs), in which chromophores are incorporated into the channels of inorganic (e.g., zeolites, nanoporous silica) or organic host materials (e.g., perhydrotriphenylene). HGCs provide ideal systems for studying weak dipolar interactions of chromophores and open up the opportunity to overcome the drawbacks of conventional condensed phase device structures for organic optoelectronic applications: Improved chemical stability by exclusion of oxygen, high fluorescence quantum yields by avoiding intermolecular aggregation, intrinsic polarization, high NLO efficiencies, and spatially directed energy transfer.

Nanoparticles Nanoparticles of organic chromophores are obtained by precipitation from solutions by addition of a poor solvent. Nanoparticles allow the investigation of substrate-free self-organized systems, easy color tuning by chemical doping with appropriate acceptor molecules, and preparation of optoelectronic devices.

Oligomer approach Oligomeric π-conjugated organic molecules provide well-defined conjugation lengths compared to polymers, variable substitution patterns, and defined intermolecular orientations in the condensed phase. Hence oligomers with variable conjugation lengths and substituents make possible the systematic study of the interplay of *intra*molecular (optical) properties and *inter*molecular interactions as well as the understanding of the properties of the polymers. These well-defined systems permit theoretical modeling of solid state properties for molecular engineering of optoelectronic devices.

Ordered Mesoporous Materials

Sebastian Polarz

Ruhr-University Bochum, Bochum, Germany

CONTENTS

1. INTRODUCTION

Ordered mesoporous materials are a subgroup of, or even prototypes, for so-called nanoporous materials. It is, therefore, necessary to give some comments on (nano)porous materials in general.

The most general definition of a porous material is a continuous and solid network material filled through and through with voids. The voids are of the order of ≈ 1–100 nm in the case of nanoporous materials. A material is obviously porous when the voids are filled with gas. However, the voids might be filled with a liquid or even a solid. Then, some authors prefer to label materials nanostructured instead of using the expression nanoporous. However, for this review, this not very exact distinction will not be made. Once a pore can possibly be emptied without destroying the material, the material is regarded as a porous material no matter what is momentarily in the pores.

The general definition given above already indicates that porous materials are actually a classical type of dispersion known for a long time in classical colloid science [1]. This is a solid foam. The voids show a translational repetition in three-dimensional space, while no regularity is necessary for a material to be termed porous. Correlating to this, the most common way is to consider a porous material showing gas-solid interfaces as the most dominant characteristic. This indicates that the creation of interfaces due to nucleation phenomena (in this case, nucleation of wholes), decreasing interface energy, and stabilization of interfaces is of elemental importance during the formation process of nanoporous materials [1]. Often, these factors are omitted because the final products are stable. Indeed, they are just metastable.

This metastability is gained by the rigid character of the void surrounding network that is covalently crosslinked in most cases. However, it should be noticed that most of the nanoporous materials reported in the literature or those that are of technical high relevance are not stable by thermodynamic means. As soon as activation-energy boundaries are overcome, materials start to break down. One example should elucidate this. Porous silica, for instance, is just metastable. As soon as temperature is raised and the melting point is reached, primary particles in the network begin to fuse and it comes to phase separation into a nonporous silica phase (and bulk air). Finally, at very high temperatures, the thermodynamic stable phase of SiO_2, quartz emerges. Control over interface energy and metastabilization of nanodimensional wholes becomes of special importance when the task is to produce nanoporous materials.

Ordered mesoporous materials exhibit some special features. These materials are characterized by pores of the order of 2 nm to 50 nm, the pores have a regular shape and a mutual correlation to each other, and the polydispersity of the pore radius is small (≈ 10–20%), sometimes less.

2. PREPARATION OF ORDERED MESOPOROUS MATERIALS

2.1. The Templating Concept

The most successful way to produce all sorts of nanoporous materials and ordered mesoporous materials, in particular, is the templating method as schematically shown in Figure 1.

An organic (or sometimes inorganic) compound acts as the placeholder, what later becomes the void space in the nanoporous material. The templating concept mainly allows the control of the criterium of pore size but also pore shape, obviously. At first, a suitable template structure has to be provided (see Fig. 1a). By suitable is meant that this template structure has to be compatible all the time with solvents involved in the process and the final network materials thoughout the whole process. In other words, the free interface energy between the template structure and the network material has to be smaller than kT, despite the huge created interface area. Otherwise, the material can rearrange or demix to more stable, unporous phases.
Figure 1. Schematical representation of the approach to obtain nanoporous materials by templating strategies. (a) shows a range of applicable templates beginning with single molecules (1) or amphiphiles (2), followed by assemblies of amphiphiles as micelles (3) or lyotropic phases (4), followed by polymeric spheres (5) or assemblies of spheres (6). These units are surrounded or bonded to the network precursor systems in the actual templating step (b). The created pore resembles the size, shape, and even functional characteristics of the template in an ideal case. Finally, the template is removed. Therefore, it is possible to tune the properties, and most importantly, the size and interconnectivity of the pore and pore system in the order (1)–(6).

The template structure can have sizes on many different length scales. The smallest pores are achieved for molecules as templates (Fig. 1a-1). The created pores have similar shape and size than the used molecules. The pores can be spatially uncorrelated to each other. In this case, one speaks about molecular imprinting [2–4]. Molecular imprinting is even successful for organic materials as network material and is, therefore, very often used for imprinting biomolecules to a matrix for biochemical applications [2, 4–8]. Highly ordered materials with pores that have a mutual correlation to each other are found for zeolitic materials. The template units for zeolites are also single molecules (primary amines and ammonium cations) and therefore, pore size normally does not exceed 2 nm. Zeolites are microporous solids.

Larger pores can be achieved by assemblies of molecules to form templates. Here, assemblies of amphiphiles (Fig. 1a-3) are ideal due to their self-organizing properties and their capability to lower interface energy. An amphiphilic molecule (Fig. 1a-2) has typically one hydrophilic and one hydrophobic part which tend to lead to microphase separation [1]. The resulting template structure are micelles or ultimately lyotropic phases with different possible symmetries (lamellar, hexagonal, or gyroid as depicted in Fig. 1a-3). Materials with pores of the order of 2–50 nm react with sometimes surprisingly high order. The structure of the liquid crystal, the pore size, and shape are imprinted into the solid materials. Therefore, the current review article focuses on these template structures derived from the amphiphilic organization of matter (underlayed in green in Fig. 1).

Alternatively, hydrophilic polymers can be adopted as templates which is not pursued further in this article [9–14]. Even larger pores are obtained when polymer spheres or colloidal crystals of these spheres are used as templates [15].

In conclusion, suitable central structures as well as network builders with the property of being able to surround and cast these structures on a scale smaller than the template, have to be available. This is of importance because if the network building blocks are (i) too large in size (then they create cavities by themselves just by packing effects and are not able to cast a template structure smaller than the cavities), and (ii) if there is a "wrong" interaction (zero interaction or repulsion) between the network building units and the template, no casting is possible. Instead, these two mistakes are often found in the literature when some authors claim that their materials are ordered mesoporous materials, just because they used a surfactant in the recipe. Instead, phase separation (isotropic distributions of the two phases but not mesoscopical ordering) could occur. Therefore, a certain degree of attraction is elemental.

2.1.1. Creation of Templates Through Amphiphilic Self-Assembly Processes

It is evident in the previous section that the formation of the template via amphiphiles is of extraordinary relevance. Therefore, this section briefly explains the formation of these templates.

Special structures in water (or other selective solvents) may emerge when molecules contain two parts in its architecture that are chemically very different. In most cases, one part is hydrophilic (ionic, hydroxy-, or polar groups) while the other part is hydrophobic (aliphatic, aromatic, or fluorinated groups). Molecules with these characteristics are called amphiphiles. Surfactants (special cases of amphiphiles) are characterized by a relatively short hydrophilic and hydrophobic block. The most striking feature of amphiphiles is their behavior at interfaces (see Fig. 2).

Due to the interface force pointing into the bulk phase (see Fig. 2), creation of additional interface requires energy. This force is given by the surface tension (force per length), which is defined via the free interface energy dG_i as $dG_i = \gamma\, dA$.
Figure 2. Schematic representation of the processes leading to self-assembly of amphiphilic molecules (the headgroup is printed in blue) in water. In the upper part of the figure, the behavior at interfaces is shown and how micelles and lyotropic phases are formed. The different symmetries of lyotropic liquid crystals are graphically demonstrated.

Due to their amphiphilic character, surfactant molecules are enriched on the air-water interface. This creates a new interface (the air-hydrophobic tail interface) and, consequently, the interface is energetically stabilized and surface tension decreases. When the concentration of the amphiphile is increased, the interface gets more and more enriched at the air-water interface until a monolayer of densely packed molecules is reached. Because all of the interface is now occupied, every additional amphiphile molecule has to be now located in continuous liquid phase. This state is not very favorable for the hydrophobic parts; thus, the aggregation to micellar structures is observed, where the hydrophobic chains are shielded from the water by the hydrophilic head groups. The structure of micelles is determined mainly by pure geometric factors of the amphiphile described by the so-called packing parameter N_s (with v = volume; l = length; a = area).

$$N_s = \frac{v_{tail}}{l_{tail} a_{head}} \tag{1}$$

For N_s up to 0.33 (wedge-shaped surfactants) spherical micelles, for $0.33 > N_s > 0.5$ cylindrical micelles, and for $0.5 > N_s > 1$, planar bilayers are the most favorable structures.

When the surfactant or amphiphile concentration is increased more and more, more and more micelles are also formed. A dense and ordered packing of micelles (cubic symmetry or others) is the consequence. At some point, the micelles come into contact with each other and fuse together. The formation of continuous structures, so-called lyotropic phases (liquid crystals), can be explained by this fusion [16]. First, hexagonal structures evolve which can be transformed at higher surfactant concentration to lamellar assemblies. It is possible to find bicontinuous gyroid structures in the region between the hexagonal and lamellar phases. For special amphiphile compositions, more exotic lyotropic structures can be obtained (see Fig. 2). Because the liquid crystals do not allow the penetration of the hydrophilic sol–gel precursors (for instance, silicic acid) into the continuous core of the amphiphile assembly, formation of SiO_2 in the hydrophobic domains is excluded and only allowed in the hydrophilic domains. This creates the pores.

2.2. Categorization of Ordered Mesoporous Materials

Directly from the range of possible amphiphilcally organized templates, one can conclude certain criteria for ordered mesoporous materials. First of all, the template determines the size of the pore. If larger templates are used, larger pores result. Although the mesopore size is defined by the International Union of Pure and Applied Chemistry (IUPAC) for 2–50 nm, the majority of ordered mesoporous materials are found in the size range 3–10 nm. Secondly, the template determines the shape of the pores and the mutual correlation of the pores to each other. Mainly independent from the template, as long as suitable interaction modes are present (as described before), is the composition of the void-surrounding network material.

2.2.1. Categorization by Dimensionality

As already expected from the possible template structures and the templating concept, different pore dimensionalities are possible. "Zero-dimensional" pores are obtained when spherical templates, for instance, micelles, are used (see Fig. 3a).

One-dimensional pores are realized for cylindrical pores as shown in Figure 3b. Three-dimensional pore systems are obtained when three dimensionally intertwined templates are applied as shown in Figure 3c.

2.2.2. Categorization by Network Material

One of the highest goals in the field of nanoporous materials is to achieve any possible chemical composition in the network materials "hosting" the pores. It makes sense to divide the materials into two categories:

1. inorganic materials
2. organic materials.

Among the inorganic materials, which is the larger group, we will find:

1a. Inorganic oxide-type materials. This is the field of the most commonly known ordered mesoporous: silica-, porous titania-, porous zirconia materials.
1b. A category of its own is given for nanoporous carbon materials. Contributed to this category are the highly important active carbons but also some examples for ordered mesoporous carbon materials.
1c. Other binary compounds such as sulfides, nitrides, etc. In this category fall also the famous $AlPO_4$ materials.
1d. There are already some examples in addition to carbon where just one element, for instance, a metal, could be prepared in a nanoporous state. The most prominent member of this class of materials is likely to be nanoporous silicon with its luminescent properties [17, 18].

There are far fewer examples for nanoporous organic materials as polymers, for instance [8]. Some of the known
Figure 3. TEM images demonstrating the possible shapes of pores: (a) spherical pores, (b) cylindrical but curved pores, and (c) highly curved, bicontinuous pores.

examples for ordered mesoporous polymers will be discussed in Section 4.3 and it will be explained what the limits are for the preparations of these materials.

3. ANALYSIS OF ORDERED MESOPOROUS MATERIALS

3.1. Gas Adsorption Methods

Gas sorption represents a widely used technique to characterize micro- and mesoporous materials and also provides porosity parameters such as pore size distributions, surface areas, and pore volumes. In the following, a brief description of classical methods to analyze sorption data is followed by an overview on recent advances in the interpretation of sorption experiments.

In a typical sorption experiment, the uptake of gases such as nitrogen, krypton, and CO_2 is measured as a function of relative pressures $p/p_0 < 1$ at constant temperature. p and p_0 are the equilibrium vapor pressures of the liquid in the pores and that of the bulk liquid, respectively. The interaction between the pore walls and the adsorbate is based on physisorption (van der Waals interaction) and leads to the formation of adsorbate layers at low p/p_0. Simplistically, the macroscopic laws of classical thermodynamics predict that the confinement of pores with radii on the nanometer scale leads to the condensation of gas inside the pores at a smaller pressure than p_0. In a typical sorption experiment, the adsorbed volume is plotted versus p/p_0, and this "sorption isotherm" is the superposition of different uptake mechanisms. At low p/p_0, adsorption in micropores takes place, which is supposed to be a process of volume filling rather than capillary condensation [19, 20]. The isotherms of microporous materials are characterized by a steep increase in the isotherm at low p/p_0, ending up in a plateau at larger p/p_0. In a mesoporous substrate, with increasing values of p/p_0, a liquid-like adsorbate film of statistical thickness $t(p/p_0)$ is formed on the pore walls. At a certain pressure, capillary condensation takes place filling the mesopores with liquid, which is apparent in isotherms as a pronounced increase of the adsorbed amount. The total pore volume ("porosity") is given by the overall uptake of adsorbate. Zsigmondy proposed the first explanation of the capillary condensation in a single, infinite cylindrical mesopore based on the macroscopic Kelvin equation:

$$\ln\left(\frac{p}{p_0}\right) = \frac{2\sigma V_L}{RTr_m}$$

where V_L and σ are the molal liquid volume and the liquid-gas surface tension at temperature T, respectively, and r_m is the mean radius of curvature of the liquid-gas interface (cylindrical for the condensation, spherical for desorption [21]). Based on the classical treatment of Cohan and the Kelvin equation [22], the condensation of a liquid in a nanoporous material at a certain p/p_0 can be related to the corresponding mesopore size, thus also providing a pore size distribution (PSD). Since the condensation starts at a relative pressure p/p_0, where the walls are covered by a film of thickness $t(p/p_0)$, in the so-called modified Kelvin equation, $2/r_m$ is replaced by $f/(r - t(p/p_0))$, where r is the

"true" mesopore radius and f the meniscus shape factor, which is 1 or 2 for the filling or emptying of the mesopore, respectively. This procedure represents the basis for the well-known "Barrett–Joyner–Halenda (BJH)" method, currently the most frequently used procedure to determine PSDs [23]. The dependence $t(p/p_0)$ can be described by the approach of Frenkel–Halsey–Hill describing the sorption on nonporous silica [24]. In addition, the pore geometry significantly affects thermodynamic properties of confined fluids and their adsorption behavior [25, 26]. The confinement is stronger in spherical pores compared to cylindrical pores of the same diameter leading to a shift of the capillary condensation to lower p/p_0; therefore the aforementioned procedures are restricted to cylindrical pores [27]. The progress in synthesizing ordered mesoporous materials (see Section 4) with well-defined pore morphologies in terms of uniform mesopore sizes and pore shapes allowed the testing, optimization, and further development of these classical approaches [28–30].

Furthermore, widely used methods to determine structural parameters are comparative plots such as the t-plot and α-plot methods [19, 31, 32]. Typically, the amount adsorbed on the porous solid under study is plotted as a function of the amount adsorbed on an ideally nonporous reference solid with similar surface characteristics, providing parameters such as the overall pore volume, specific surface area, and micropore volumes. This procedure has been used to determine microporosity in ordered mesoporous silicas [33–35]. It has turned out that the macroscopic, thermodynamics of the classical methods already described do not provide reliable descriptions of materials with mesopore sizes below about 4 nm for oxidic materials [36]. One of the main shortcomings of these approaches lies with the nonconsideration of fluid-wall interactions. Recent progress in understanding capillary condensation deals with molecular level models. The methods of the grand canonical Monte Carlo (GCMC) simulations [37], molecular dynamics [38], and density functional theory (DFT) [39, 40] allow direct modeling of capillary condensation/desorption phase transitions, and are capable of generating hysteresis loops of simple fluids sorbed in model pores. Neimark and Ravikovitch have shown that the nonlocal density functional theory (NLDFT) with properly chosen parameters of fluid-fluid and fluid-solid intermolecular interactions quantitatively predicts desorption branches of hysteretic isotherms of nitrogen and argon on reference mobil composition of matter (MCM)-41 samples with pore channels narrower than 5 nm [41–44]. This method was tested against Monte Carlo simulations and was shown to provide reliable pore sizes and wall thicknesses in MCM-41-type materials [34, 37, 44–46].

In spite of the recent progress in the theoretical understanding of sorption phenomena, certain issues of sorption are still unclear:

1. The nature of the hysteresis in ordered mesoporous materials is still subject to intensive theoretical and experimental research and not yet fully understood [14, 34, 47–49]. Recent NLDFT studies were able to shed some more light on the hysteresis phenomenon. It was concluded that in the range of pore sizes >5 nm, the experimental desorption branch corresponds to the

equilibrium evaporation, while the capillary condensation branch corresponds to the spontaneous (spinodal) condensation [34, 45].

2. The dependence $t(p/p_0)$ is still a matter of discussion due to the lack of independent techniques in determining film thicknesses, and usually reference data from nonporous materials are used [50]. An exact knowledge of $t(p/p_0)$ is needed for the determination of mesopore sizes by the classical methods, as well as for the testing of DFT models. Smarsly et al. have determined $t(p/p_0)$ by a combination of nitrogen sorption and small-angle neutron scattering [49].

3.2. Mercury Porosimetry

In mercury porosimetry (MP), gas is evacuated from the sample, which is then immersed into mercury, and an external pressure is applied to gradually force the nonwetting mercury into the sample. By monitoring the incremental volume of mercury intruded for each applied pressure, the pore size distribution of the sample can be estimated in terms of the volume of the pores intruded for a given diameter D. The evaluation of pore sizes from MP is based on the Washburn equation, quantifying the pressure p required to force a nonwetting fluid into a circular cross-section capillary of diameter D [51, 52]. Mercury porosimetry allows the determination of PSD between 3 nm and 200 nm and is, therefore, inappropriate for microporous materials, but more suitable for pore sizes above ca. 30 nm compared to nitrogen sorption. In addition, the total pore volume V_{tot} is accessible from the total intruded volume of mercury at the highest pressure determined, and the total pore surface S is calculated from

$$S = \frac{1}{\gamma|\cos\theta|} \int_0^{V_{tot}} p \, dV$$

Mercury porosimetry has inherent shortcuts in determining mesopore sizes, especially below 20 nm. During the measurement, high pressures to force mercury into small pores may compress the sample [53]. Damage or compression of highly porous silica has been reported previously [53, 54]. In addition, mercury porosimetry overestimates the volume of the smallest pores in case of ink-bottle shaped pores by the small openings [55].

3.3. Electron Microscopy

Electron microscopy (transmission electron microscopy (TEM) for micro- and mesoporous samples, and scanning electron microscopy (SEM) for macroporous samples) are a unrenouncable tool for the investigation of porous materials. The biggest advantage of these techniques is that they deliver an optical image of the samples. However, giving an overview above these techniques is definitely behind the scope of this review. Sakamoto et al. presented a method to obtain three-dimensional imaging of pores in a mesoporous system [56]. These authors use electron diffraction in a high-resolution electron microscope preserving phase information of the scattered electrons. The obtained two-dimensional scattering patterns equipped with this phase information allows the calculation of the three-dimensional spatial structure of the material by Fourier transformation.

3.4. Diffraction Techniques

Experiments using elastic X-ray and neutron scattering have turned out to be an invaluable tool for the characterization of various types of porous materials, providing quantitative parameters such as the pore size, surface area, and pore volume. In addition, diffraction techniques allow the determination of the shape and, in particular, the spatial distribution of the pores, both for highly ordered arrays such as in MCM-41 and a more disordered arrangement of pores, for instance, in activated carbons. In the early 1900's, Max von Laue, W. L. Bragg, and W. H. Bragg, and others laid the groundwork for X-ray crystallography, which has become a powerful method of visualizing complex inorganic and organic crystalline materials [57–59]. In spite of the variety of different diffraction techniques that are available nowadays, they all are based on the same physical phenomenon, namely, the scattering of X-rays and neutrons by the atoms through their electrons or nuclei, respectively. In the Fraunhofer approximation, the interaction of X-rays with the electrons leads to the superposition of the coherent scattering of the basic scattering centers (atoms, molecules, or pores), without changing the energy of the incoming X-rays ("elastic scattering"). The resulting coherent scattering pattern is directly related to the mutual position, size, and scattering power of these scattering units. For almost all types of ordered mesoporous materials, no single crystal diffraction data are obtainable. Therefore, these materials are studied in diffraction experiments as a polycrystalline powder. In this case, the powder diffraction raw data are obtained as one-dimensional plots of the coherent scattering intensity versus the scattering angle 2θ. Only in the case of thin porous films with an oriented alignment of the pores relative to the substrate, two-dimensional diffraction patterns can be obtained [60–63]. The main problem in analyzing scattering patterns of any kind of polycrystalline, nanoporous materials lies with the extraction of a maximum of structural information. Depending on the length scale of the pore size, two methods can be distinguished regarding both the experimental realization and the theoretical treatment. Basically, the characteristic length scale d, describing the pore system and the corresponding diffraction angle 2θ, are related by the Bragg equation

$$s = \frac{1}{d} = \frac{2\sin\theta}{\lambda}$$

where λ is the wavelength and s the corresponding scattering vector.

Several excellent textbooks are available on the general principles of diffraction theory and experiments [64–66]. Mesoporous materials with pores sizes above 1 nm are studied by so-called "small-angle scattering" (SAS), either using X-rays (SAXS) or neutrons (SANS). The evaluation of SAS data of porous materials is usually based on the approximation that the material can be regarded as a so-called "two-phase system": in case of X-ray scattering, basic theoretical considerations show that the SAS of such materials arises from the scattering at the void-solid interface and is related to the scattering contrast $(\delta_1 - \delta_2)^2$, where δ_1 is the average electron density of the voids ($\delta_1 = 0$) and δ_2 represents the *average* electron density of the solid. The SAS

of a sufficiently ordered nanoporous material with pores of a distinct shape is also given by Eq. (1), where the lattice factor Z has the same meaning as in wide-angle scattering, while the form factor F here corresponds to the shape of the mesopore/solid rather than the electron density of single atoms [67–69]. Polycrystalline-ordered mesoporous materials with a distinct pore shape and a well-defined two- or three-dimensional alignment, give rise to SAS patterns with a characteristic sequence of reflections ("peaks"). Therefore, the SAS patterns of the limited number of possible regular mesopore structures and space groups can serve as "fingerprints," allowing an almost unambiguous assignment of a certain mesopore lattice structure, if a sufficient number of reflection peaks is obtained. In combination with TEM, SAXS experiments turned out to be a powerful technique to determine the alignment and structure in a variety of ordered mesoporous materials and other structures [70]. As the main information, SAXS provides the crystallographic space group of the mesopore arrangement and the corresponding lattice parameter. While the three-dimensional alignment of the mesoporous can be obtained from the bare SAS peak positions, the determination of mesopore sizes from single-peak analyses involves substantial uncertainties, because both the peak profiles and intensities can be substantially superimposed by various factors such as smearing, incoherent background scattering, in the arrangement of the mesopores and background fluctuations, and the presence of additional intrawall micropores. In particular, no satisfactory approach has been developed so far to quantitatively simulate the influence of two- and three-dimensional disorder on SAS. Even highly ordered mesopore systems such as MCM-41 show a certain two-dimensional displacement of the cylindrical mesopores on the hexagonal lattice, which together with the polydispersity of the pores may result in a nonnegligible overlap of the peaks, thus severely aggravating a meaningful pore size analysis [71–73].

A different approach for the evaluation of SAS data, without assuming a specific model, was recently pursued by using the concept of the so-called "chord-length distribution" (CLD) $g(r)$. $g(r)$ is a statistical function describing the probability of finding a chord of length r, which is a connector of two points on the solid-void interface [74, 75]. The only preassumption of this concept is the formal description of the pore system as a two-phase system, but no assumptions about the pore shape and distribution are needed. Therefore, the CLD approach is most appropriate for disordered pore systems [14, 49].

3.5. Positron Annihilation

In the past 20 years, positron annihilation lifetime spectroscopy (PALS) has been developed as a powerful tool for the detection and quantification of defects on the atomic scale in various types of solids. Positron annihilation lifetime spectroscopy is sensitive to different kinds of defects such as dislocations and vacancies in metals or crystals, grain boundaries, as well as voids and pores. Similar to scattering techniques, PALS is a noninvasive technique and thereby allows the detection of inaccessible pores. In the area of micro- and mesoporous materials, Positron annihilation lifetime spectroscopy is predominantly applied to porous polymers and thin porous films. Positron annihilation lifetime spectroscopy is based on the decay of positrons into two gamma photons ("annihilation") and has been described in various publications [76–80]. Using ^{22}Na as the radioactive source, the formation of positrons (β^+) by radioactive decay is accompanied by the simultaneous emergence of a γ-quantum of 1.273 MeV, which defines the starting signal of the positron lifetime measurement. Entering the sample, the positrons lose their high energy by inelastic collisions with electrons. These "thermalized" positrons have energies on the order of few meV, form positroniums (Ps, the electron-positron-bound state) and diffuse through the solid until annihilation after their specific lifetime in the solid, which is measured as the time difference between the creation of the 1.273 MeV γ-quantum and the annihilation radiation (two 511 keV gamma rays). The natural lifetime of Ps of 142 ns is reduced by annihilation with electrons during collisions. The lifetimes, inverse of the annihilation reates, become longer when a positron or positronium is localized at spaces with lower electron density such as voids. Thus, positrons can be used as a probe to investigate average sizes of the free volume, size distribution, and the free volume concentration by measuring their lifetimes [81]. The raw data of PALS are plots of the annihilation radiation signal as a function of time. In case of not too high defect concentrations porosities, there will be at least two or three lifetime components τ_i in the spectra, which are usually analyzed as a sum of exponentials after background subtraction.

3.6. Homogeneity of Materials

The pore-size regime for nanoporous materials ranges from the 1 nm-region to 1000 nm = 1 mμ. According to IUPAC, three distinctions can be made [82, 83]:

- Microporous materials 0–2 nm pores
- Mesoporous materials 2–50 nm pores
- Macroporous materials >50 nm pores.

Especially in the field of mesoporous materials, the mistake is often made to mix up the terms mesoporous and ordered materials. When a sorption isotherm indicates that a material is mesoporous, it does not mean that it is ordered as well, nor does a single reflex in X-ray diffraction (XRD). Ordered mesoporous materials are judged to be much more interesting due to the control over pore sizes and pore shapes. Their disordered counterparts exhibit high polydispersity in pore sizes and the shapes of the pores are irregular (a good example of such a material can be found in [84]). Ordered porous materials seem to be much more homogeneous. But one has to be careful with this statement because it is often led by aesthetic arguments caused by the beauty of images. In many cases, a material possesses more than one porosity. These can be:

- For microporous materials: an additional meso- or macroporosity caused by random grain packing;
- For mesoporous materials: an additional macroporosity caused by random grain packing, or an additional microporosity in the continuous network;
- For macroporous materials: an additional meso- and microporosity.

These factors should be taken into consideration when materials are classified concerning their homogeneity. A material possessing just one type of pore even when they are disordered might be more homogenous than one having just a fraction of nicely ordered pores.

4. EXAMPLES FOR ORDERED MESOPOROUS MATERIALS

As previously described, mesoporous materials have pore sizes in the range between 2 nm and 50 nm. If a high porosity (larger than 50%) for materials can be achieved, porosity on the meso scale is always equivalent to high surface area. For instance, a material that has 80% of spherical 5 nm, voids can theoretically contribute 480 m^2/g mesopore surface area. However, there is one very important differentiation that has to be made, namely, if the pore system is ordered or not. The typical features of an ordered pore system is that the pores are monodisperse in size, have a specific shape and a mutual three-dimensional correlation between each other. When on the other hand, a template above its percolation threshold has been applied, disordered pore systems result. Both of these classes of materials (ordered or disordered) are highly important for practical applications as in sensing [85, 86], catalysis [87–89], dielectric coatings [90–92], and of course, typical molecular sieve applications [93–96]. The following section will focus on materials with ordered pore systems because it is believed that the properties of these materials can be designed to a very high degree.

4.1. Ordered Mesoporous Silica Materials

So far, the highest degree of perfections in materials design has been achieved for ordered mesoporous silica materials. As will be described in more detail later, ordered mesoporous silica materials can be obtained in a variety of pore sizes (2–80 nm), a variety of pore shapes (from spheres to lamellae), and a variety of surface properties. This makes ordered mesoporous silica materials a very active field of research. In 1992, Beck, Kresge et al. published their work about the first-ordered mesoporous silica material—the so-called mobile composition of matter (MCM)-41 [70, 97].

Before major achievements and the state-of-the-art in this field are presented, one might ask the more general question, "Why, especially for silica, these big improvements could be made?" There are three main reasons to mention:

1. Silica can be produced by sol–gel methods. The precursors used are not very reactive, despite other precursors for oxidic materials as titania, tin oxide, etc. This makes the silica sol–gel process very easy to control. Alkoxysilane compounds are used in most cases. The general process which is going on is given by the reaction scheme

$$Si(OR)_4 \xrightarrow{H_2O} [Si(OH)_4] \rightarrow SiO_2$$
Furthermore, there has been a great deal of investigation about the silica sol–gel process and nearly every detail is known. The description of the silica sol–gel

process is behind the scope of this article but very good presentations can be found in the books by Iler, Brinker, and Scherer [98–100].

2. The free energy of silica is very close to its most stable form crystalline quartz [101]. Furthermore, are the Si—O bonds so strong that the silica sol–gel process has highly irreversible character! Silica forms in its amorphous form and this amorphous silica is stable over a very high temperature range and period of time. This means that the shape of silica can be formed at room temperature and then be retained practically infinitely. Once more, this distinguishes silica from other oxidic materials where crystallization frequently leads to a restructuring in the network and therefore can destroy the mesostructure.

3. Finally, the interactions between surfactants and amphiphiles as surfactants or block copolymers can be tuned because silica units are available in anionic, neutral, or cationic form with dependence on the pH. Further, the charge density on these silica precursors matches the charge density of the surfactant head groups quite well. Silica precursors and amphiphiles are compatible.

4.1.1. The M41S Family

A description of morphologies of porous silica materials derived by supramolecular organic assemblies as structure-directing agents should begin with the pioneering work of Beck, Kresge et al. in 1992 [70, 97]. They termed their silica materials M41S family.

The "family" has three members, the most famous one MCM-41 with a hexagonal pore structure, MCM-48 with a bicontinous, gyroid structure, and MCM-50, which is lamellar. The preparation of MCM-41 itself has already been reported in 1971 but obviously Chiola et al. did not realize their important discovery [102].

Supposedly, Beck, Kresge et al. wanted to synthesize something similar to a zeolithe structure under the influence of the quite large surfactant hexadecyltrimethylammonium chloride/bromide (CTAB). They worked in a diluted solution of CTAB. The concentration of the surfactant was far away from the corresponding hexagonal lyotropic phase.

Most research interest in the field of ordered mesoporous silica materials focused on the preparation, investigation of formation, modification, and application of MCM-41. It was seen rapidly after the first publication in 1992 that the addition of alumina is negligible and pure SiO_2 MCM-41 can be obtained. Many silica sources such as tetraalkoxysilanes, sodium silicate, fumed silica, or Ludox worked out fine. In the original publication, only a fraction of the obtained silica materials was MCM-41. The yield and ordering was improved by various methods like the addition of acids [103–105], changing the pH-conditions [104, 106], the addition of fluoride anions [107, 108], modifications in the hydrothermal treatment [109–111], or changes in the electrolyte concentration [112]. The addition of cosolvents, on the other hand, decreased the order [113, 114]. Several scientists could influence the MCM-41 particle morphology as well [115–118]. An amazing example is given by Huo et al. in 1997 with their production of 1–3 mm-sized silica MCM-41

spheres [119]. Even the preparation of MCM-41 at room temperature is common in the meantime [106]. Already Beck, Kresge et al. studied the influence of surfactant chain length variations [97]. As expected, the pore diameter was adjusted from 1.5 nm (zeolite like) to 4 nm (MCM-41) in the row C_6- $\rightarrow$ C_{16}-surfactants. Well-ordered materials are obtained only for surfactant chains C_{14}-C_{16}, although Sayari and Wang reported the preparation of high-quality MCM-41 also for C_{12}-surfactants [120]. It was already pointed out by Beck, Kresge et al. in their original contribution that a change in the surfactant to a silica-source ratio leads to other structures than MCM-41 [70, 97]. The correct structure of MCM-48 was a point of discussion for quite a long time. First approximations assumed a cubic structure but in the meantime it is accepted to assign the minimal gyroid surface [113, 121]. The reason for the initial disorientation is nicely demonstrated by Anderson in his article "Simplified Description of MCM-48" [114] where he shows all different perspective modes of the complicated MCM-48 structure. An accurate synthesis procedure for MCM-48 was reported in 1993 [122]. When the surfactant-to-silica ratio exceeds the value 1, the main product of the M41S preparation is MCM-48 [123]. A systematic study of systems involving the corresponding surfactants was performed by Huo et al. in 1996 [124]. They also described the phase transitions between MCM-41 to MCM-48. It is seen that a key factor is the presence of ethanol which is suspected of suppressing the growth of one-dimensional cylinders (MCM-41) [121]. To provide easy and reproducible methods for the preparation of MCM-48 silica is still of interest as some recent reports indicate [121, 125, 126]. An interesting improvement was made by Schumacher et al. in 1999. They were able to prepare MCM-48 in the form of monodisperse spheres of approximately 500 nm size [127]. The last member of the M41S familiy is MCM-50. MCM-50 has a lamellar structure but it cannot be transferred to the porous state via surfactant removal by calcination. The pores collapse and the porosity is lost. Two models for the structure are discussed at the moment (i) ordinary silica sheets with intercalated surfactant or (ii) a special type of stacking of the surfactant rods to layers.

A common feature in the M41S family is that the cationic surfactant (S^+) is combined with the anionic silica species (I^-).

4.1.2. Other Examples for the S^+I^- Approach

McGrath et al. reported about the preparation of a new silica having a sponge-like L_3-phase [128, 129]. McGrath et al. claim that using a L_3-phase of cetylpyridinium chloride in 1:1 replication process, the corresponding silica is formed. The template phase consists of a surfactant bilayer system that is bent so strongly that a bicontinuous phase is created that divides the solvent (water) volume. Although the results are somewhat questionable, their characterization is not absolutely convincing; the preparation of a silica of this type is a real progress. The reasons are the following: According to McGrath et al., it is possible to adjust the pore size to any value between from 1 to 100 nm [128] simply by adding more water to the reaction system. Due to the fact that the pores

are filled with water and not with surfactant, as in other cases, the removal of the pore size directing agent is just drying. Furthermore, McGrath et al. claim that by removing the surfactant by calcination, an additional porosity appears.

Also, Huo et al. could show that completely new and unexpected morphologies could be reached via the S^+I^- route. Also, here the morphologies had no counterpart in the pure surfactant/water mixtures. Huo et al. presented a systematic study using the S^+I^- approach and a hole variety of cationic surfactants in 1996 [124]. They call their silica materials *S*anta *Ba*rbara (SBA) plus an additional number. SBA-1 was prepared in acidic media. The structure can be understood by assuming a densely packed cubic arrangement of spherical micelles (space group $Pm\bar{3}n$). Maybe even more interesting is the structure of SBA-2. Gemini surfactants $C_nH_{2n+1}N^+(CH_3)_2(CH_2)_sN^+CH_3)_2C_mH_{2n+1}$ were used in the synthesis. As can be seen from the formula, the two cationic head groups are separated by an adjustable hydrocarbon spacer. The surfactant packing parameter N_s can, therefore, be adjusted to several different values. In this case, a dense packing of globular micelles in a hexagonal fashion leads to a bicontinuous, three-dimensional $P6_3/mmc$ structure [125]. The silica can be understood best as an analogue of zeolite cages just on a different pore size level and noncrystalline. The $P6_3/mmc$ symmetry has no counterpart for pure surfactant-micelle/aqueous systems. A two-dimensional silica with a centered rectangular symmetry (SBA-8), which has been achieved by using related bolaform surfactants $(CH_3)_3N^+(CH_2)_n$-O-Ph-Ph-O-$(CH_2)_nN^+(CH_3)_3$, also has no counterpart [130]. It only exists as the silica-surfactant hybrid. Its structure is related to MCM-41 (hexagonal) by elongation of the crystallographic b-axis (space group *cmm*).

However, the S^+I^- pathway is not the only possibility in obtaining ordered mesoporous materials via the synergistic coassembly mechanism. Every combination that results in an attraction between surfactant and silica source can be chosen in principle. There are also $S^-X^+I^-$ (counter-ion mediated) and $S^+X^-I^+$ (reverse charge matching) approaches [131–133]. But much more important and widely used is the neutral S^0X^0 approach, using nonionic template systems.

4.1.3. Neutral Interactions S^0I^0

The first ones to utilize neutral template assemblies were Pinnavaia and, independently, Goeltner. The S^0I^0 approach is governed by hydrogen bonding between the template and the inorganic matrix [132]. Pinnavaia and Tanev tried to avoid the problems that appear concerning the recovery of the template, and to grant access to the porosity avoiding calcination. For ionic interactions between the silica walls and the template, a liquid-liquid removal is very difficult (time-consuming ion-exchange processes) or sometimes impossible. Tanev and Pinnavaia solved the problem by using primary amines $C_{8-18}NH_2$ as the template with EtOH as co-solvent [134]. They found larger wall thicknesses and smaller domain sizes in their hexagonally ordered materials in comparison to MCM-41 [135, 136]. An additional textural porosity is created by this decrease in domain size. A similar approach with polyethylene oxide (PEO)-based surfactants (C_{11-15}-PEO) led them to the preparation of silica materials with 2–6 nm pores [137]. The pore structure was not

so well ordered in this case. They found a bicontinuous "worm-type" morphology. Bagshaw et al. described already in this work the use of nonionic block copolymers Plyronics (PEO-PPO-PEO) as templates [137]. Later, they figured out that one further difference between the S^0I^0 and the ionic strategies is that the best-ordered materials are obtained at ambient temperature, while well-ordered MCM-41 required hydrothermal conditions [135]. Kim et al. also thought about the costs involved in the preparation of orderd mesoporous silica materials due to the use of silica tetra-alkoxysilanes. They extended the nonionic S^0I^0 approach to water soluble silicates as precursors [138].

Independently, Goeltner and Attard used poly(ethylene glycol) alkyl ethers like $C_{12/16}(EO)_8$ for the production of hexagonally ordered silica materials [139]. Their invention was to work with high-concentrated surfactant/water phases, namely, at concentrations where the lyotropic phase already exists. This allowed a 1:1 cast of the lyotropic template phase into the silica and was the beginning of the so called "nano-casting" [140, 141]. Then Goeltner et al. switched over to amphiphilic block copolymer systems to obtain larger pore materials [142, 143]. With poly(styrene) poly(ethyleneoxide), block copolymers worm-type pore systems with diameters from 4.5–10 nm were obtained. In the meantime, the structure of those silica is known in great detail. Large spherical mesopores are interconnected by smaller "bottleneck" channels. As all silicas that are derived by the use of amphilic block copolymers feature an additional microporosity created by the PEO chains. Even larger and beautiful morphologies were obtained with poly(butadiene)-poly(ethylene oxide) (PB-PEO) block copolymers [144, 145]. For these templates, the nanocasting (1:1 copy) could be nicely demonstrated and a phase transition between hexagonal cylinders and the lamellar phase was depicted. First, a lyotropic phase was prepared. Because the hydrophobic block of the copolymer contained polymerizable groups, treatment with γ-radiation led to crosslinking. The lyotropic phase was fixed this way and, therefore, accessible for TEM investigations. A comparison of this pure organic phase with the resulting silica revealed a match of 100% which means that the exact imprint could be shown. Also, ionic block copolymer systems have been used like poly(ethylene)-poly(styrenesulfonate) (anionic) or poly(butadiene)-poly(vinylpyridinium) (cationic). They produced casts of differently sized micelles and could even observe a micelle-lamella phase transition via the nanocasting [146].

At the same time (1998), Zhao et al. used a similar approach which led to various ordered mesoporous materials as $C_{16}(EO)_{10}$ (SBA-11; cubic $Pm\bar{3}n$), $C_{18}(EO)_{10}$ (SBA-12; hexagonal $P6_3/mmc$), and Pluronics [147] PEO-PPO-PEO (SBA-15; hexagonal and SBA-16; cubic $Im\bar{3}m$) [148]. Much of the later work of Melosh et al. was devoted to SBA-15, which is in the meantime well known and used by many other groups as the prototype of a block copolymer-derived, ordered mesoporous silica material. In 1999, they presented the preparation of a SBA-15 monolith that was dry indeed but still template-containing (no accessible pores) [149]. For the first time, Kim et al. tried to give a mechanistic interpretation of the nanocasting process using amphiphilic block copolymers. They gave an explanation for the microporous character of the mesoporous silicas and performed ^{29}Si nuclear magnetic resonance (NMR) studies to explain the state of the PEO chains in the silica walls. The order of the silica phase can be increased by the addition of a small amount of fluoride ions F^- [150].

A new way to create interesting silica structures as vesicles and others was recently discovered by Jung et al. They use organogel systems as templates. With crown-appended cholesterol derivatives, large multilayer vesicles were obtained [151]. Chiral amide gelators connected to a cyclohexane ring directed the silica growth to helical fibers [152], modified cholesterol organogelators too [153], and sugar-derived gelators to a lotus shape [154]. Even organic crystals of dl-tartaric acid were used as a template by Mann et al. for the creation of hollow fibers with rectangular shape [155].

4.1.4. Mechanistic Considerations

Figure 4 shows the formation mechanism of ordered mesoporous silica materials. There are two different pathways: The synergistic coassembly mechanism (a), and the nanocasting or true-liquid crystal mechanism (b). The surfactant (hexadecytrimethylammonium bromide, CTAB, for instance) concentration that was used for the preparation

Figure 4. Schematic representation of the mechanisms involved in formation of hexagonally ordered porous materials within the scope of templating strategies. One pathway is characterized by an interaction of amphiphile and network precursor leading to the nanostructured composite phase (synergistic coassembly). In the other case, a template structure is formed at first, and imprinted precisely into a solid mold.

of MCM-41 was way behind the critical micelle concentration [1] and extremely far away from the lyotropic phase regime. It was, therefore, quite surprising in the beginning that MCM-41, with its hexagonal pore system mimicking a hexagonal liquid crystal, had formed. In the meantime, it is accepted that the first step in the formation of MCM-41 is an interaction between the cationic surfactant head group and an anionic silica species (shown as black cubes in Fig. 4). This special interaction between silica species and surfactant is generally denoted as S^+I^-. If one considers the packing parameter (see Eq. 1) [1], one realizes that bonding of the silica species to the surfactant will modify the headgroup region. In principle, this creates a new, silica-organic hybrid surfactant with a different packing parameter and, therefore, also a different phase behavior. The morphology of the MCM-41 pores caused the assumption that a hexagonal arrangement of surfactant cylinders (a lyotropic phase) acted as the template for the formation of the final material. The silica could be formed by a direct solidification of this phase. But it was instantaneously clear that this could not be the truth because MCM-41 can be produced in concentration regimes below the critical micelle concentration (cmc) up to true liquid crystalline phases [156]. Consequently, Beck et al. proposed two general mechanistic ways [97]. One pathway involves the silica condensation in the hydrophilic domains of a preorganized liquid crystal and the other alternative suggests a cooperative interaction between the cationic surfactant and the anionic silica species. These two models were named *liquid crystal templating* (LCT) mechanism. More than one model was published to explain the final emergence of MCM-41 within the LCT. Chen et al. argued via ^{14}NMR spectroscopy that at first, two to three layers of silica preliminary stages are deposited on isolated cylindrical surfactant micelles [157]. Via crosslinking of the isolated silica-surfactant composites, ordering and the final MCM-41 occurs. This model was supported by electron paramagnetic resonance (EPR) measurements [158]. On the other hand, Steel et al. founded on the same technique a formation of silica layers with intercalated surfactant rods [159]. By aging, the layers are bent and finally result in MCM-41 (puckering layer model). This model was further supported by TEM [159] and ^{29}Si-NMR [160]. Monnier et al. introduced a related model, but they also considered charge density matching between the surfactant and silica [122]. The oligomeric silicate polyanions act as multidendate ligands which are connected to the surfactant. This leads to a lamellar silica-surfactant phase. The silica precursors now polycondensate primarily in these interface regions which reduces the negative charge. To obey the rules of charge density matching (the cationic charge of the surfactant head groups have to be compensated), the silica sheets have to bend. This phase transformation leads to MCM-41. Therefore, the formation of MCM-41 is a cooperative process. Although this process leads to the highly defined porous material MCM-41, a pre-determination of the pore morphology is not possible via this route.

It would be possible if a pre-existing template is casted into the silica by a 1:1 copy process. When the materials derived by block copolymer nanocasting are analyzed not only are the expected mesopores found but also a significant ratio of smaller pores. The micropores can contribute as much as 80% to the total surface area in some cases [14]. In the meantime, it is accepted that the microporosity is caused by the PEO chain imbedded in the network matrix during nanocasting [14, 149, 161–163]. The hydrophilic PEO domains of the template are dispersed in the water/silicic acid mixture during the casting process and remain there when the network solidifies. When the materials are calcined, these imbedded, single polymer chains lead to micropores.

Further investigations of this fact showed that the micropores, which are responsible for approximately 70–80% of the total inner surface area, are caused by PEO chains dispersed in the silica wall [14]. A "one-phase" situation within the template, where the hydrophobic and hydrophilic blocks fully contribute to the mesopore volume, is excluded (see Fig. 5a).

A situation depicted in Figure 5b, where the two blocks of the amphiphile are strongly microphase separated (the PEO is now fully dispersed in the hydrophilic silica/water phase), was also excluded in a recent work by Smarsly et al. [163]. In this work it was found that the size of the mesopores D_c for materials prepared with Brij (alkyl- poly(ethylene oxide) surfactants) depends on the length of the hydrophobic as well as on the length of the hydrophilic block. Smarsly et al. assumed that only a fraction of the PEO chains are dispersed in the silica wall while a significant amount is located in the mesopore volume next to the hydrophobic core of the alkyl chains (see Fig. 5c). One empirical and a physically reasonable relationship was derived which allowed to predict the pore size dependant on the length of the blocks in the amphiphiles. They could also show that every pore size between two boarders given by the "parent" template systems can be reached simply mixing different ratios of two amphiphilic block copolymers of different length together in the templating mixture. Obviously, the nanocasting allows the gathering of inside views into self-assembly processes of soft matter by investigating the pore structure of the corresponding ordered porous material. Besides the production of the porous materials, the analysis of the pore
Figure 5. Schematic representation of the three different phase models related to the nanocasting mechanism. (a) one-phase model, (b) two-phase model, and (c) three-phase model. The organization of the template units (amphiphiles) is indicated as well.

structure itself led to the proposed "three-phase model." Because only weak interactions between the template and the network phase are given within the nanocasting concept, nearly all structures occurring in the aqueous phase can be analyzed using this procedure. Polarz et al. demonstrated this by elucidating the proposed but unknown structures for cyclodextrins in water [164]. Cyclodextrins, cyclic oligo-saccharides, self-assemble to "worm-type" aggregates which can be depicted by transferring this structures into the solid silica replica.

When trimethylbenzene (TMB) is added to the lyotropic phase to increase the pore size by swelling, mesocellular foams are obtained at a certain ratio as Lettow et al. and Kim et al. pointed out independently [165, 166]. The ideal hexagonal structure of SBA-15 is maintained only for relatively low concentrations of TMB. When the oil to polymer ratio is 0.2–0.3, the silica walls begin to buckle forming nodes accompanied by an increase in the pore size. If the amount of oil is increased further, the nodes undergo a transition to spherical pores ($d \approx 20$ nm)—the so-called mesocellular foam. The explanation for this phase transition lies in the reaction of the lyotropic phase due to a change in the surfactant parameter by adding a hydrophobic solvent [167–169]. The TMB is located in the hydrophilic poly(propylene oxide) (PPO) regions of the amphiphilic assemblies, which changes the packing parameter of the surfactant and finally leads to the transition of micelles to microemulsions [165]. That emulsions could indeed act as templates was shown in 1997 by Imhof and Pine [170].

While the synergistic coassembly (MCM route) naturally leads to powder-like materials, or in best cases, larger particles [127], the nanocasting allows the production of monoliths or thin films. For the first time, this allows one to divide a macroscopic volume into well-defined, nanometer-sized compartments. A crucial problem in maintaining the macroscopical and microscopical integrity of the materials is the removal of the template and drying of the samples. Calcination fails for the production of crack-free monolithic samples. Fortunately, the templates can be removed by liquid-liquid extraction. However, capillary stress due to evaporation [171] can very easily lead to cracks. Capillary pressures generated by a phase transition of the pore fluid to the gas state can be avoided by supercritical drying [172]. Cracks can be further avoided by adding silica fibers to the sol which is used for the nanocasting process.

4.1.5. Adjustment of and Understanding of Pore Sizes

One blemish of the chemistry involved in the preparation of mesoporous materials is that most of the obtained silica structures were not discovered by planning but more by trying. Some work has been devoted to gain more knowledge regarding the silica morphologies (pore shape and size). Especially in the field of influencing the pore size, success was reached. Roughly, this was already shown in the previous section. Here, these different strategies should be summarized in a more general way.

Navrotsky et al. were able to show that there is, in principle, no limitation for accessible pore sizes in amorphous silica materials [101]. They demonstrated that the amorphous

silica in materials like MCM-41 is unsignificantly less stable than the most stable form of SiO_2, crystalline quartz. This means that only suitable experimental pathways have to be found to reach a certain pore size. Then the materials are absolutely stable.

To determine the pore size, three independent methods exist:

- variation of the amphiphile size (especially the hydrophobic part);
- swelling of the lyotropic phase by addition of selective solvents;
- change in reaction parameters like temperature or electrolyte concentration [173].

All these methods include the problem that their application changes the packing parameter of the amphiphile and can, therefore, change the desired lyotropic phase (phase transitions). For a modification of the hydrophobic block length, this is obvious as N_s directly depends on this parameter. Swelling of the lyotropic phase changes the volume of the hydrophobic chain which also appears in equation [165, 167–169]. One way to change pore sizes is to vary the temperature during preparation of the material [174, 175]. The higher the temperature, the larger the pores get and also the electrolyte concentration is an important factor [173]. A change in the electrolyte concentration (which also means the addition of electrolytes) changes the physical character of the aqueous phase, and due to interactions of the ions, with the ionic head of the surfactant the head group area.

The dependence of the pore size on the length of the hydrophobic chain was already demonstrateted by the first works of Beck, Vartuli et al. [70, 97, 176]. An investigation in our group on Brij surfactants $C_x(EO)_y$ showed that this dependency is true as well for nonionic approaches, but that in this case the length of the hydrophilic chain influences the pore size as well [163]. Expanding pore sizes by addition of selective solvents can also be used for S^+I^- [177, 178] and S^0I^0 [165]. Preparation conditions or post-treatment [179, 180] are also important for both systems. So far, the most comprehensive study on the nanocasting process and the creation of micropores was published by Smarsly et al. [163]. A quantitative relation between the size of the mesopore D_c and the composition of the used block copolymer (length of hydrophobic and hydrophilic block) was derived. This dependence $D_c \propto N_{hydrophobic}^{0.4} N_{hydrophilic}^{0.25}$ is described in more detail in [163]. It was shown in this article [163] that quantitatively the size of a pore depends in principle just on the average number of monomer units in the amphiphile. This average number can be simply varied if one uses mixtures of amphiphiles (for instance, a small and a large surfactant) in different amounts. Besides the prediction of pore sizes from the molecular composition of pore sizes, it now becomes possible to achieve a fine tuning of pore sizes by using mixtures of amphiphiles as templates. With the most commonly available amphiphiles (even pluronics), it is now possible to achieve every pore size between 1.5 to 10 nm.

4.1.6. Chemistry with Ordered Mesoporous Silica Materials

Certain fractions of other elements than silicon can be imbedded into materials mostly of the MCM-41 type. These materials can be obtained when a source for this metal is added directly to the precursor sols. The most prominent example, which was already prepared in the original work by Kresge, Beck et al. [70, 97], is Al-MCM-41, a MCM-41 where some Si atoms are substituted by Al. Through the incorporation of aluminum, the material obtains Lewis acidity. Therefore, Al-MCM-41 has been used for the catalytic cracking of various organic compounds [181–183]. The performance of the competing zeolites is often better [182], although sometimes higher product selectivities with mesoporous materials were observed. Other catalytic materials with acidic functions are Ni-MCM-41 and Mo-MCM-41 [184]. These materials have some importance for the removal of sulfur from raw oil hydrodesulfuration (HDS) process [185–187]. The latter cases (hydrocracking and HDS) are examples for the reasons why some major oil companies are even today quite interested in ordered mesoporous materials [188–191]. The acidic forms of MCM-41 have also been used for some classical organic synthesis catalyst such as Friedel–Crafts reactions and others [192–197]. The big advantage of ordered mesoporous materials in comparison to zeolites is that MCM can also be used for large and bulky molecules even when the reactivity is not so high. Basic forms of MCM-41 have also been prepared but here silica-organic hybrid materials are much more important and will be discussed later. Just Cs-MCM-41 has some importance as a catalyst for Knoevenagel reactions [198–200]. Another modified MCM-41, Ti-MCM-41, has been used for a variety of redox catalysis [201]. Other examples for MCM-41 redox catalysts are Ti-, Fe-, Cr-, V-, B-, Al-, and Mn-MCM-41 materials [202], but also Sn- [203–205], Zr- [206], or Ru-MCM-41 [207] have been invented.

A different way to enrich silica MCM-41 with catalytic properties is to deposit metal or oxidic nanoparticles inside the mesoporous framework. It was shown recently that the size of the resulting nanoparticles can be fine tuned by the size of the pore restriction and that the wall properties are of major significance [208].

It is possible to create noble metals particles which resemble exactly the size of the hosting mesopore after reduction of suitable precursors. If the same process is applied to a material that is able to interact with these precursors (in the case shown, a silanol-rich silica monolith interacts with $[PdCl_4]^{2-}$ ions), the created metal particles are bound to the pore surface and Ostwald-ripening is suppressed. Just subnanometer large particles are created [208]—not visible in TEM images. One is, therefore, able to create ordered silica materials carrying a great variety of nanoparticles, semiconductor nanoparticles, or even oxide nanoparticles [209–219]. Therefore, much of the work has been devoted to prepare semiconductor nanoparticles this route. Examples are gallium nitride [217], cadmium selenide [212], cadmium sulfide [220], silicon [221, 222], titanium dioxide [223], germanium [224], galliumarsenide [225], zinc sulfide [226], and indium phosphide [227]. Since then, preparation of colloidal particles inside mesoporous hosts has become a versatile

tool to produce different kinds of nanostructures [228]. One ideal example can be found in the work of Huang et al. where silver nanowires were produced inside MCM-41 [210]. Similarily, metal nanowires have also been produced with Pd [229, 230], and Pt [213].

The last work already indicated that it is possible to transform the whole pore system of a material into a new material which would not be accessible otherwise. The ordered mesopores act as a template again for new materials which is released by removal of SiO_2 via HF etching. For instance, when an ordered mesoporous material is filled with a suitable precursors for carbon, depending on the pore morphology particle-like carbon [231], or nanoporous carbons (for instance, with the *Ia3d* structure of MCM-48) have been prepared [47, 232–234]. Similar results can be obtained by preparing a replica of the pore structure with platinum. These results are extraordinary because the new material now resembles the structure of the organic liquid crystal, which was originally used as a template for the production of the ordered mesoporous silica materials. Having an "artificial carbon liquid crystal" in hand could be very beneficial because carbon is stable to very high temperatures. The mesostructured carbon might, therefore, be taken as a new template for many materials that are not accessible with organic templates.

It should be mentioned that many of the host-guest compounds with ordered mesoporous materials are not of the inorganic-inorganic type. In many cases, organic compounds as dyes or polymers have been immobilized in the porous framework preferentially of MCM-41 [235]. Polymers like polymethyl-methacrylate were directly created inside the pores and it was shown that the spatial confinement had some impact on the physical properties of the polymers [236]. Kageyama et al. reported about a titanocene containing MCM-41 material, which was used as a solid-state catalyst for the preparation of a unique, high molecular weight poly(ethylene) [237]. Very important in this respect are also ordered mesoporous silica materials containing conductive polymers as found, for instance, in the work of Gangopadhyay and De [238] and Wu and Bein for poly(aniline). The created organic-inorganic hybrid materials have often unique properties. One example for such unique features are new ordered mesoporous laser materials. Generally, an active laser dye is brought into a porous environment and its laser activity is studied. It was envisioned by Marlow et al. that a whole laser could be produced by using the self-assembly laws [240]. They could prepare a silica-surfactant laser dye (Rhodamine 6G) hybrid material which had a fibrous morphology. The laser dye is located in the hydrophobic domains of the lyotropic template phase. The fiber was pumped perpendicular to the fiber direction and above a certain threshold laser activity was detected. Wirnsberger and Stucky et al. extended their works [241, 242] and recently they prepared impressive waveguides by a combination of self-assembly and soft litography techniques [243]. Mesoporous silica (template removed) was deposited on silicon and as the third layer, there were the waveguides containing the dye-doped-ordered mesoporous silica [242]. The cylindrical channels were aligned throughout the whole waveguides and even the dye seemed to be oriented in the template phase.

In all of the preceding cases was the organic part of the material just immobilized inside the pore system of the ordered mesoporous silica material. An alternative is to covalently link organic groups to the silica network and change the material properties this way. After calcination, ordered mesoporous silica still possesses a certain amount of active silanol groups Si-OH [244]. These groups can be reacted with a variety of organically modified sol–gel (ORMOSIL) precursors which have the general formula R-Si(OR′)$_3$. The attachment of a terminal organic group in a post-modification procedure leads to new, mesostructured silica-organic hybrids. However, the organic groups loom into the pore volume and not every pore surface Si-group gets modified this way. These are two clear disadvantages of the post-functionalization method. In most cases, amino functions have been introduced this way to ordered mesoporous silica materials [245–248]. But also materials containing ephidrine for asymmetric catalysis [249, 250] or organometallic complexes were invented [87]. As was pointed out, it would be quite desirable if the pore wall itself is modified, instead having the organic groups located in the pore volume. Therefore, materials scientists tried with some success to add the ORMOSIL precursors directly to the synthesis mixture. This approach has two problems. The Si—O—R bond is not stable enough under most commonly needed synthesis conditions (high or low pH) and the organic group can negatively influence the interface energy, which is important when the amphiphile microphase separates and, thus, structures the material. Burkett et al. could show that this pathway is successful for octyl- and phenyl-groups [251], later also thiols, amines, epoxides, imidazoles, and other alkyl-groups [252], when the ORMOSIL precursors with Si-C motives are used. The template can now just be removed by liquid-liquid extraction due to the presence of the organic groups. Therefore, and due to the effect of the organic ligand on the condensation rates, one obtains not fully condensed, quite weak, or collapsed materials. Still, the amount of organic groups that can be incorporated in the materials remains with 25% quite low. If higher amounts of ORMOSIL precursor are taken, the structuring of the material via self-assembly is not successful.

A big improvement was made by MacLachlan, Asefa et al., when they used bridging ligands (Si-R-Si) to modify the pore wall [253, 254]. These groups are truly incorporated in the material; they even seem to cover the pore walls. Now it was possible to use 100% of the organically modified sol–gel precursor for the synthesis, the materials are stable, and the pore walls are 100% covered with different organic groups as ethylene or benzene [253–258].

4.1.7. Conclusions

It has been shown in this section that ordered mesoporous materials have become "designer" materials. They can be prepared with a great variety of or properties as pore size, pore shape, organic groups on pore walls, organic groups in pore volume, and any desired macroscopic shape of the materials. Next, it is considered if the structure principles that work for silica can be extended to other inorganic network materials (Section 3.2.3).

4.2. Other Inorganic-Ordered Mesoporous Materials

It was already suspected in 1993, briefly after the invention of MCM-41, that one would be able to create mesoporous materials of different compositions than silica by surfactant templating routes, because similar interactions between the network precursor and the amphiphile might be created [131]. However, creating other network sources than silica always involves two general problems. The precursors for these networks are much more reactive which makes the whole process less controllable. Secondly, most other networks tend to exist in the crystallized rather than amorphous form. The crystallization can result in major restructuring processes in the material and, therefore, might destroy the mesostructure. Most frameworks begin to crystallize at higher temperatures, when the surfactant is removed by calcination. This makes it often difficult to remove the template.

The first nonsiliceous example for a comparable material followed in 1994 about tungsten oxide, molybdenum oxide, antimony oxide, or vanadium oxide related materials, but it was not possible at that time to remove the organic template because lamellar structures were obtained [259–263]. Ying and Antonelli [264] were the first ones to obtain transition metal oxides with similar structures than MCM-41. For instance, a mesoporous titania material TiO$_2$ was obtained when the reactivity of the precursors was decreased by the addition of a complexing ligand as acac. Later, nicely structured niobium oxide and tantalum oxdide materials were obtained by tuning the interaction of the amphiphile with the precursors (ligand-assisted route) for the inorganic framework [265–267].

4.2.1. Transition Metal Oxides

Due to their high relevance in many areas of catalysis and their variable redox and magnetic properties, much work was devoted to the creation of stable-ordered mesoporous, transition metal oxides. In the meantime, many compositions with Ti, Zr [268–273], V [270, 274], Nb [265, 267, 270, 275, 276], Ta [266, 270, 277], Mo [278, 279], W [278, 280, 281], Mn [282, 283], and Y [284, 285], as the central element have been introduced. In comparison, most of the work has focused on ordered mesoporous titania because of its potential use in solar cells [286, 287] and electrochromic devices [288]. Ordered mesoporous titania is a quite representative example for transition, metal-based materials. The reactivity of titania precursors goes in the order TiCl$_4$ > Ti(iOPr)$_4$ > Ti(OBu)$_4$ > Ti(OEt)$_4$ [289, 290]. These precursors all react rapidly with moisture and form TiO$_2$. In order to control the growth of a titania network around a template phase, the reactivity has to be decreased. The most frequently used approach is to take TiCl$_4$ as a titania source and react it with anhydrous ethanolic solutions of the template (surfactant or block copolymer) [270, 291]. The reaction between TiCl$_4$ and EtOH releases high amounts of HCl. High concentrations of HCl stabilize titania nanoclusters and, therefore, prevent uncontrolled condensation. Additionally, one deals with an anhydrous solvent. The water needed for the self-organization of the amphiphile and for the condensation of the titania is provided exclusively by the atmospherical

humidity. The humidity is the crucial point in these preparations and it should be around 50%. It is also interesting to note that the water seems unable to diffuse from the top of a deposited film into the material, presumably due to densely packed surfactant hydrophobic chains on this surface. Diffusion of water and ordering of the material begins at cracks and propagates from there. As prepared, the materials have amorphous framework which is often undesired for many applications. Crystallization of titania occurs at temperatures above 400 °C, which might also disrupt the mesostructure and leads just to 3 nm large crystallites. As a possible solution, titania nanocrystals were proposed as the starting material for ordered mesoporous titania as well [292].

4.2.2. Metal Sulfides

Tohver, Osenar, Braun et al. used a true liquid crystal approach to prepare various mesostructured metal sulfide materials [293–295]. A lyotropic block copolymer phase is swollen by an inorganic salt solution as Cd^{2+} salts and then treatment with H_2S vapor follows. A nanocrystalline, ordered, mesoporous CdS material is the result. Soon, a ZnS material followed [296]. Similar to the work, where titania nanoclusters have been used for the preparation of mesostructured titania [297], several groups prepared ordered mesostructured germanium sulfide materials with Ge_4S_{10} clusters in the initial state [86, 298–300].

4.2.3. AlPO$_4$

Due to the similarity between silica molecular sieves (zeolites) and aluminium phosphates (ALPOs), there have been many attempts to synthesize MCM-41 analogous ALPO materials. In most of these cases, nonstable materials are obtained or the pore systems are quite different from MCM-41 [301, 302]. Kimura et al. reported a nicely ordered hexagonal ALPO material in 1999 [303] and Holland et al. reported on an interesting approach using an Al_{13} Keggin species as the source for aluminum [304].

4.2.4. Silicon Nitride

Similar to ALPOs, one could suspect that it will be possible to produce ordered, mesostructured silicon nitride because the NH unit as in imides or amines is isoelectronic to oxygen, which would allow a similar sol–gel chemistry as for silica. There have been attempts to synthesize these compounds with silicon amines, ammonia, and nonaqueous solvents and surfactant [305].

4.2.5. Al$_2$O$_3$

Ordered mesoporous alumina would also be a very interested material due to its high relevance in catalysis. The classic way of preparing mesoporous alumina is by electrolytic etching (anodized alumina) and the obtained results are impressive for the production of thin films [306]. This technique is restricted to surfaces. Therefore, preparing ordered mesoporous alumina via templating routes should be very promising. It was found that it was very difficult for alumina to achieve highly ordered materials and to achieve control over pore size although some examples exist [270, 307]. It seems that the S^0X^0 pathway is appropriate for alumina.

4.2.6. Metals

Attard and Goltner succeeded in the preparation of hexagonally ordered metal sponges via templating techniques [308]. This technique is very similar to the described approaches although the network is now formed by reduction of noble metal precursors.

4.3. Ordered Mesoporous Organic Materials

The templating concept introduced in Section 2 can be extended towards pure organic or polymeric compositions of materials. Similarly, an organic monomer is polymerized around a prefabricated template structure. The chemical and physical parameters of the obtained polymer differ very much from the monomer species if one compares it to the sol–gel process of inorganic oxides. Often, restructuring processes occur during polymerization which can lead to partial or complete phase separation. Therefore one has to distinguish:

- Transcriptive synthesis: The pore structure is a 1:1 imprint of the template structure.
- Reconstructive synthesis: The polymerization takes place under the spatial confinement imposed by the template and morphological rearrangements lead to the final material.
- Synergistic synthesis: The monomer itself self-organizes.

Similar to all the approached previously discussed, the interactions between the template phase and the network builder (or in other words, charge density matching considerations) are of crucial importance. Additionally, entropic forces, such as restriction of polymer segment mobility due to spatial restrictions, can become important. These factors determine whether a synthesis is transcriptive or reconstructive. One problem that also remains is that the porous materials are just metastable. In the case of polymeric materials, this fact becomes much more important than for most inorganic networks. Due to the swelling of polymers and their high flexibility, polymer systems might be unable to retain the porous structure in the long run.

One important field is the transcriptive translation of molecules into pores designed on a molecular level which is also known as molecular imprinting [309]. The synthesis pathway is similar to a key lock or antibody/antigene mechanism. The template molecules (often amino acids [310, 311], sugars [312], peptides [313], or steroids [314, 315]) exhibit a certain pattern of distinct, spatially distributed functional groups. Suitable functional groups in the monomer systems interact with these patterns and this leads to an imprint of the shape and functional structure. Finally, the template molecules are removed by extraction or chemical cleavage. Typical monomers that have been used are methacrylic acid and ethylene glycol dimethacrylate. More detailed reviews about molecular imprinting to obtain porous polymers can be found in the recent literature [316–319].

The second type for a clear transcriptive synthesis of porous, organic polymer materials are found when colloidaly crystals (opals) are used as templates [320, 321]. Large mesopore materials or macroporous structures are obtained. Possible polymer compositions involve polyurethane [322, 323],

poly(acrylate-methacrylates) [324], poly(divinylbenzene)-co-poly(ethyleneglycoldimethacrylate) [325], polystyrene and poly(methyl methacrylate) [326], and polypyrrole [327].

Already, when micelles are used as templates, a clear transcription to pores is questionable. Styrene/divinylbenzene polymers with spherical pores of 10–20 nm were obtained by templating with water swollen AOT (sodium bis(2ethylhexyl) sulfosuccinate) micelles [328, 329]. The pore size appears to be too large to be caused even by swollen AOT micelles. In a similar work, water swollen AOT micelles were used for the preparation of ethylene trimethacrylate polymers in supercritical CO_2 with 20 nm pores [330–332]. When supercritical CO_2 was omitted, pores of 100 nm were obtained indicating the reconstructive character of the synthesis.

The micelles in the previous cases were already swollen with a polar solvent as water, while the continuous phase contained the hydrophobic monomer. The next logical step is to use microemulsions as templates for the production of porous polymers. Microemulsions are thermodynamically stable systems with droplet sizes in the range of 10–100 nm [1]. Of particular interest for this application are bicontinuous microemulsions.

It was seen in all reported cases that the pore morphology was no longer directly related to the structure of the microemulsion. Very often just latex particles were obtained [333, 334]. However, when hydrophilic (as acrylic acid) and hydrophobic (as methylmethacrylate) are copolymerized in the presence of a microemulsion, true porous materials have been obtained [335]. The final product was, as mentioned, very different as expected from the morphology of the microemulsion. Therefore, one has to conclude a reconstructive synthesis pathway. The transformation from a microemulsion to the final porous system for such a system was studied and not less than four phase transitions have been observed during the polymerization reaction [336].

The next level of complexity is reached when lyotropic phases are used as templates for porous polymers. First attempts to imprint a lyotropic structure into a polymer failed due to demixing [337, 338]. However, it was possible to get nicely ordered, reconstructed morphologies this way [338, 339].

It can be concluded that a variety of nanoporous polymer materials can be obtained. But due to thermodynamic factors during the polymerization, demixing processes lead to the formation of different materials than was planned. Also, nonequilibrium conditions might play an important role. Although the prepared structures are very interesting and might have applications, it seems hard to synthesize designed nanoporous polymers. Furthermore, it seems that there are currently restrictions to just a few polymer systems.

5. CONCLUSIONS

It was shown in this review that the field of mesoporous materials is very interdisciplinary. It ranges from a variety of network compositions (inorganic, organic, and metallo-organic), different pore shapes (disordered, spherical, cylindrical, lamellar), different pores sizes (from 2 nm to several tenths of nanometers), and last but not least, different pore-surface properties.

This high level of knowledge for these types of materials creates several new challenges which would fill pages if one considers all the different classes of materials in the mesoporous materials family. However, some relevant future directions should be mentioned.

During the next few years, scientists are going to achieve compositions as much as possible for this class of materials. It is also somewhat surprising that so far, no significant application has been established for ordered mesoporous materials. It can be envisioned that the more it is possible to create materials with designer properties as electronic, magnetic, or mechanical properties, applications will be found. One interesting application could be photocatalysis. It is still unanswered if the narrow pore size distribution and the regularity in shapes of the pore channels has some special effects on processes in pores. Therefore, these effects will have to be studied on a more fundamental basis.

All porous materials presented so far have some kind of static character. This means that once the materials have been prepared, they don't change their properties any longer. Smart porous materials, that is, materials changing their properties in dependence on outer stimuli (for instance, pH or electric fields), are a very interesting goal. As a first problem one might address changing pore sizes due to a chemical stimulus. However, it cannot be overlooked that mesoporous materials are just metastable once the template is removed. This metastability has to be retained whatever smart or intelligent materials are to be created. Therefore, it seems that neither pure inorganic nor pure organic materials are able to fulfill this task. Inorganic-organic composites might be able to have these desired properties once the complexity of the materials has been increased.

Much progress can also be expected from the field of colloidal crystals (which also can create mesoporous materials) and photonic materials. Ideally, several disciplines—chemistry physics, and engineering—will fuse to predict and realize materials and device properties. The future will tell if the next computer generation will run with light.

GLOSSARY

Amphiphile Molecules containing hydrophilic and hydrophobic parts.

Cetlyltrimethylammoniumbromide (CTAB) A cationic surfactant.

MCM-41 The first ordered mesoporous material with hexagonally aligned cylindrical pores.

Mesoporous materials Materials with pores between 2–50 nm.

Micropores Pores below 2 nm in size.

Self-assembly Process due to weak intermolecular forces which leads to higher organized structures.

Template A central structure which acts as some kind of a place-holder.

CONTENTS

1. INTRODUCTION

Porous materials are of scientific and technological interest because of their potential for applications in separation processes, catalysts, chromatography, the controlled release of drugs, low dielectric constant fillers, pigments, microelectronics, electro-optics, and other emerging nanotechnologies [1–4].

Based on the IUPAC (International Union of Pure and Applied Chemistry) definition, the pores of materials are classified according to size: pore sizes in the range of 2 nm and below are defined as micropores, those in the range of 2 nm to 50 nm, as mesopores, and those above 50 nm, as macropores [5]. A direct relationship exists between the distribution of sizes, shapes, and volumes of the void spaces in porous materials and their ability to perform the desired function in a particular application. Hence, a need exists to create uniformity within a pore size, shape, and volume, since such properties can lead to superior applications. For example, a material with uniform micropores could be used to separate molecules on the basis of their size by selectively adsorbing a small molecule from a mixture containing molecules that are too large to enter its pores [1]. In another example, the controllability of pore size as well as the morphology of a material are important in the development of size-selective filters and selective optical cavities. The wavelength of the optical mode in a cavity is dependent on cavity size and the bandgap of optical crystals depends on the crystal periodicity, typically denoted as a photonic crystal [6].

In 1988, the first report of a crystalline microporous material, aluminophosphate ($AlPO_4$; VPI-5), with uniform pores of 1.2 nm was reported [7]. Following the discovery of VPI-5, numerous extra-large pore materials were synthesized. In 1992, Mobil researchers disclosed the first family of highly ordered mesoporous molecular sieves M41S (pore size in the range 2–10 nm) where surfactants were used as the template or pore forming agents during a hydrothermal sol–gel synthesis [8, 9]. The use of appropriate starting materials and synthesis conditions permitted the preparation of different mesoporous silica oxides with ordered structures in hexagonal form (denoted as MCM-41), cubic form (denoted as MCM-48), and lamellar form (denoted as MCM-50). Several reviews dealing with microporous and mesoporous materials have appeared [1, 2]. In 1997, the first ordered macroporous materials produced via a template were reported [10]. A variety of macroporous ceramics, metals, semiconductors, and polymers with well-defined pore sizes in the submicrometer range have been successfully synthesized using self-assembled templates of a colloid as well as self-assembled templates of emulsion [10, 11]. Several reviews on the subject of macroporous materials have appeared in the literature [3, 4]. The above methods for preparing ordered porous materials have, thus far, resulted in irregular shapes and/or thin-film shapes. However, for practical applications, ordered porous materials must have the shape of a usable object. It would be desirable, for example, to produce ordered porous materials having a particular form.

Reviews of previous methods used in the preparation of well-ordered porous particles are described here with the following main subjects: (1) synthesis, (2) characterization, and (3) properties.

2. SYNTHESIS

The preparation of ordered nanoporous particles was carried out in several ways as shown in Table 1. Surfactants, which function as templates for forming ordered porous materials, were typically used, particularly for the preparation of ordered microporous and mesoporous particles. A colloidal templating procedure was also used for the preparation of ordered macroporous particles. For the materials, silica was typically used in this process.

2.1. Emulsion Templating

Schacht et al. [12] reported on the preparation of the mesostructured and macroscopically structured ordered porous particles by interfacial reactions conducted in oil/water emulsions. The use of emulsion biphase chemistry offers the possibility of simultaneously controlling shape on the micrometer to centimeter scale and the ordered mesostructure at the molecular scale. The cetyltrimethylammonium bromide (CATB), or other related surfactants as the pore structure directing agent, was used as surfactant. The surfactant was dissolved in water and an aqueous solution of HCl was then added to the solution. To this solution a mixture of the auxiliary (typically mesitylene) and tetraethoxysilane (TEOS) was added slowly with stirring at room temperature, resulting in the formation of an emulsion. The morphology of the final product can be controlled by the simple tuning of the stirring speed in the synthesis mixture. A flat mesoporous silica film, mesoporous silica fibers, and hollow porous silica particles form can be produced by appropriate control of the stirring speed.

Huo et al. [13] extended this general emulsion-based approach to the preparation of mesoporous particles with a diameter of 0.1–2.0 mm. A similar synthesis method was employed, using CTAB as a surfactant. NaOH, as an optional source of basic catalyst, was added to the CTAB solution. To this solution, tetrabutyl orthosilicate (TBOS) was added with stirring. The resulting product, a collection of hard spheres, was filtered, and air-dried at room temperature. They reported that the size of the silica spheres can be controlled by varying the reaction conditions and the volume.

2.2. Biomimetic Templating

Tanev and Pinnavaia [14] condensed silica in the interlayer regions of multilamellar vesicles, a biomimetic templating approach, to form roughly spherical particles. The procedure is based on the hydrolysis and cross-linking of a neutral silicon alkoxide precursor in the interlayered regions of multilamellar vesicles formed from a neutral diamine bola-amphiphile. Unlike surfactant templating approaches, this method produces porous lamellar silicas with vesicular particle morphology. In a typical preparation, TEOS as the silica source was added to a 1,12-diaminododecane (DDAD) template in ethanol and deionized water. The reaction mixture was vigorously stirred at ambient temperature to give the templated lamellar product with a vesicular morphology. The crystalline product was recovered by filtration, washed with deionized water, and air-dried. The template was removed either by calcination in air or by solvent extraction. Complete cross-linking of the structure of the ethanol-extracted product was accomplished by subsequent calcination in air.

The use of 1-alkylamine as a templating agent in the synthesis of mesoporous silica particles has also been reported by Kosuge and Singh [15]. In a typical preparation, TEOS was mixed with dilute aqueous HCl and stirred at a constant speed. To this solution, 1-alkylamine (designated by using carbon numbers such as C_6, C_8, C_{10}, or C_{12}) was added and the solution was then stirred. The resulting mesoporous silica particles were collected by centrifugation, dried, and calcined. Appropriate control of the synthesis conditions led to the production of various morphologies of mesoporous silica particles.

2.3. Liquid-Phase Surfactant Templates

2.3.1. Preparation under Acidic Conditions

Ozin and co-workers [16] reported on the preparation of mesoporous silicates particles using an extremely dilute aqueous acidic solution using cetyltrimethylammonium chloride (CTACl) as cationic surfactant template and TEOS as silica precursor. The prepared particles show the co-presence of various morphologies, for example, toroidal, disklike, spiral, and spheroidal shapes.

Table 1. Synthesis method for the fabrication of ordered nanoporous particles.

Synthesis method	Template	Materials	Porous structure	Ref.
Oil–water interface emulsion templating	Surfactants	Silica	Mesoporous	[12, 13]
Biomimetic templating	Diamines	Silica	Micro- and mesoporous	[14]
Liquid-phase surfactant templating under acidic and basic condition	Surfactants	Silica	Mesoporous	[16–18]
Liquid-phase surfactant templating with modification of Stöber method	Surfactants	Silica, composite	Mesoporous	[19, 20, 22–25]
Aerosol spray surfactant templating	Surfactants	Silica	Mesoporous	[26, 27]
Aerosol spray colloidal templating	Latex	Silica	Macroporous	[30, 31]
Aerosol spray surfactant and colloidal templating	Surfactant and latex	Silica	Meso- and macroporous	[32]
Micromolding in inverted polymer opals	Surfactant and latex	Silica	Mesoporous	[32]
Air–oil interface colloidal templating	Latex	Silica, titania	Macroporous	[34]
Double templating	Polystyrene latex, silica spheres	Silica, titania	Macroporous	[35]

This synthesis method was extended by Qi et al. [17] to the synthesis of micrometer-sized mesoporous silica spheres by mixed cationic-nonionic surfactant templating. The mixed surfactants used were cetyltrimethylammonium bromide (CTAB) and decaethylene glycol monohexadecyl ether ($C_{16}EO_{10}$). In a typical synthesis, CTAB and $C_{16}EO_{10}$ were dissolved in HCl aqueous solution. To this solution, TEOS was added at room temperature with stirring. After the complete addition of TEOS, the mixture was allowed to age either without stirring or with additional stirring. The white precipitate was then recovered by filtration, washed with water, and dried. Finally, the product was calcined in air to remove the surfactants.

2.3.2. Preparation under Basic Conditions

Chai et al. [18] reported on the preparation of mesoporous particles using a dilute aqueous basic medium. Silica particles with several morphologies were prepared. In this study, CTAB was used as a cationic surfactant, while TEOS served as the silica source. Aqueous sodium hydroxide or ammonia was used as the catalyst. The synthetic conditions, both stirring speed and surfactant concentration, were varied so as to control the morphologies and size of the prepared particles. Typically, a solution of CTAB, TEOS, NaOH, and water, in a known ratio, was mixed at different stirring speeds. The resulting product was filtered, washed, dried, and then subjected to calcination.

2.3.3. Modification of Stöber Method

Unger and co-workers [19, 20] first reported the synthesis of spherical silica particles featuring a hexagonal (MCM-41) mesoporous structure, using a modification of the Stöber synthesis [21] by adding surfactants to the reaction mixture during particle formation. The synthesis was carried out in an alcohol-water-ammonia system. Porosity was created by adding two different types of pore structure directing agents to the starting solution: one was an n-alkyltrialkoxysilane which was covalently bonded to the silica framework, while the other was an n-alkylamine which acted as a nonionic template. Water hydrolyzes the tetraethoxysilane (TEOS) to silicic acid which further condenses to oligomers, and these primary particles agglomerate to the final silica spheres in sizes up to 1.5 mm. Ethanol acts as a cosolvent to produce a homogeneous solution, and ammonia acts as a morphological catalyst. The particle size can be adjusted by the ratio of water, alcohol, ammonia, and silane. After removal of the solvent, the product was calcined to remove the porogen and to form porous silica particles.

In another paper [22], they extended this method to the preparation of submicrometer-sized solid core/mesoporous shell (SCMS) silica particles. The particles were nearly perfectly spherical in shape, with the pores being randomly distributed over the silica shell, whereas the core was composed of dense silica. The formation of the pore structure of the shell was studied as a function of the amount of n-octadecyltrimethoxysilane (C_{18}-TMS) as the porogen in the starting solution during the growth process.

Yoon et al. [23] extended this approach to the production of mesoporous carbon hollow spheres. In this synthesis, silica (or aluminosilicate) spheres with SCMS structures were used as template materials and an *in-situ* polymerized phenol-resin or poly(divinylbenzene) as carbon source. Aluminum was incorporated into the silicate framework via an impregnation method to generate strongly acidic catalytic sites for the polymerization of phenol and formaldehyde. Phenol and formaldehyde were incorporated into the mesopores of SCMS aluminosilicate, and further carbonized to obtain carbon/aluminosilicate nanocomposite. The dissolution of the aluminosilicate template using either NaOH or HF solutions generated HCMS carbon capsules.

Schumacher et al. [24] reported a similar synthesis route for the formation of submicrometer- to micrometer-sized particles with a three-dimensional cubic structured (MCM-48) pore system. n-Hexadecyltrimethylammonium bromide was used as template. Aluminum-, chromium-, gallium-, niobium-, and vanadium-MCM-48 were also synthesized using this general procedure by using different metallic precursors (e.g., $Al_2(SO_4)_3 \cdot 18\ H_2O$ and V_2O_5).

2.3.4. Mesoporous Nanocomposite Particles

The preparation of monodisperse spherical mesoporous silica/gold nanocomposites consisting of mesoporous silica and a single gold particle approximately 60 nm in diameter using a liquid-phase self-assembly process was reported by Nooney et al. [25]. To prepare gold vitreophilic, a bifunctional ligand, mercaptopropyl trimethoxysilane (MPTS) was bound to the surface of the gold. Following this, an organic mesopores template and tetraethylorthosilicate (TEOS) were added using a Stöber method. The template used in this work was a quaternary ammonium salt, cetyltrimethylammonium bromide (CTAB). In an aqueous solution this surfactant forms an ordered hexagonal micellar array, which serves as a template for the polymerization of silicate, and the length of the carbon chain controls the radius of the mesopores. After 2 h of growth at room temperature, the sample was filtered and washed.

2.4. Aerosol Spray Method

2.4.1. Surfactant Templating

Bruinsma et al. [26] first used an aerosol spray method (spray drying) to prepare mesoporous powders by the rapid evaporation of hydrolyzed silicon alkoxide-surfactant in an acidic alcohol/water mixture. During solvent drying, the silica and surfactant, cetyltrimethylammonium chloride, self-assemble to form a hexagonally ordered mesophase structure and all of the nonvolatile components (silica, polymer, and surfactant) are incorporated into the mesophase. Spray-dried particles, consisting of hollow particles with mesoporous shells, were produced.

Lu and co-workers [27, 28] extended this method to the preparation of spherical well-ordered mesoporous particles via the self-assembly of surfactant templates. The synthesis process starts by using a homogeneous solution of soluble silica plus a surfactant prepared in an ethanol/water solvent. The solution was generated in the form of an aerosol dispersion within a tubular reactor (Fig. 1). In a continuous process, the aerosol particles are dried, heated, and collected on a filter. Preferential alcohol evaporation during drying enriches the particles in the surfactant, water, and silica,
Figure 1. Schematic for the preparation of ordered mesoporous particles via a surfactant template using aerosol spray method.

inducing micelle formation and the successive co-assembly of silica–surfactant micellar species into liquid-crystalline mesophases. Typically, particles produced by this method are solid, with highly ordered hexagonal, cubic, or vesicular mesostructures. Rao et al. [29] extended this method to the preparation of mesoporous particles with diameters in the range of 5 to 10 μm.

2.4.2. Colloidal Templating

The production of spherical-shaped porous particles with a nanoscale ordering porosity by means of an aerosol spray method via a colloidal crystal template has been reported by Iskandar et al. [30, 31] The synthesis via colloid crystallization permits pore sizes to be controlled in the range of nanometers to micrometers. Figure 2 depicts the schematic for the preparation of such ordered porous particles. Colloidal silica nanoparticles were mixed with polystyrene (PS) latex, in a certain fraction in water, which was then atomized to generate droplets. The size of the silica particles varied from 5 nm to 25 nm and the PS latex from 42 nm to 178 nm. The reactor consisted of two heating zones: the first was used to evaporate the solvent in the droplet and the second was used to evaporate the PS latex particles, resulting in the formation of porous silica particles. This method is rapid and relatively simple. A large amount of porous particles can be produced in just several seconds. The production rate can be easily controlled by the appropriate control of the rate of flow of the nitrogen carrier gas. This method is an *in-situ* process. No post treatment is required to produce porous particles. Particle size can be controlled by altering the droplet size as well as the concentration of primary particles in the precursor, which represents additional advantages of this method.
2.4.3. Combining of Surfactant and Colloidal Templating

The synthesis of hierarchical porous silica nanoparticles with well-defined pore sizes (or cells) templated by combining colloidal particles with surfactants, or microemulsions, through an aerosol process has been reported by Fan et al. [32]. Adjustable meso- or macroporosity nanoporous silica particles could be produced using a soft microemulsion and solid polystyrene beads as templates.

The synthesis process starts by using a homogeneous solution of polystyrene spheres/silica, polystyrene spheres/surfactant/silica, or microemulsions/silica. The method for preparing the porous silica particles was similar to that used for the preparation described in Figures 1 and 2. After removal of surfactants and polymer spheres, the resulting materials exhibited a controlled meso- and macroporosity.

2.5. Micromolding in Inverted Polymer Opals

The synthesis of silica spheres composed of the hexagonal symmetry form of mesoporous silica using micromolding in inverted polymer opals (MIPO) was reported by Yang et al. [33]. MIPO begins with the synthesis of a polystyrene micromold having the structure of an inverted opal (Fig. 3). This is achieved by the radical polymerization of styrene monomer within the void spaces of a silica opal that had been grown and sintered followed by removal of the silica opal by fluoride-based etching. The polystyrene micrometer-scale structure is well ordered and within each spherical void regular arrangements of smaller holes that originate from the necking points between silica spheres in the sintered fcc opal template can be observed. The polystyrene inverted opal is subsequently infiltrated with a silicatropic liquid crystal composed of a nonionic surfactant $C_{12}H_{25}(OCH_2CH_2)_{10}OH$, water, hydrochloric acid, and TEOS, which slowly undergoes hydrolytic polycondensation to a monolithic periodic mesoporous silica. Removal of the polystyrene mold either by solvent extraction or by calcination in air leaves behind

Figure 2. Schematic for the preparation of ordered macroporous particles via a colloidal template using aerosol spray method.
Figure 3. Schematic for the preparation of ordered mesoporous particles via a surfactant template using micromolding in inverted polymer opals. Reprinted with permission from [33], S. M. Yang et al., *Adv. Mater.* 12, 1940 (2000). © 2000, Wiley-VCH.

a well-ordered opal replica in which the individual particles are composed of periodic mesoporous silica.

2.6. Air–Oil Interface Colloidal Templating

Ordered macroporous particles of silica and titania fabricated by colloidal templating in aqueous droplets straddling an air–oil interface have been investigated by Yi et al. [34]. The procedures involve the initial preparation of spherical colloidal crystalline particles of polystyrene latex spheres followed by infusion with metal precursor solutions that form silica or titania in the interstices (Fig. 4). Finally, calcination is employed to decompose the polystyrene latex spheres, leaving macropores at their sites. The shape of the template can be controlled by the presence of added surfactant or by the action of an applied electric field. Specifically, spherical, concaved disklike, and ellipsoidal colloidal crystals were successfully prepared and used as templates in the fabrication of ordered macroporous particles.

An electric field can be applied to the droplet-template colloidal crystallization cell with electrodes that are connected to an alternating current (ac) electric power supply. The suspension droplet of the monodisperse PS latex spheres straddles the air–oil interface, but most of the suspension droplet is immersed in the oil phase. If necessary, an ac electric field can be applied to deform the suspension droplets. During the evaporation of the drop-phase liquid (i.e., water in the present case), the PS latex spheres in the suspension droplets begin to order into a macrocrystalline structure. In the presence of an applied electric field, the suspension droplets are deformed into spheroids. A viscous silicone oil or a partially fluorine-substituted silicone oil was used as the continuous oil phase.

The suspension droplets underwent shrinkage during incubation. Finally, the oil that had infiltrated into the macrocrystalline structure was extracted with hexane and drying gave supraparticle assemblies having various shapes.

The prepared macrocrystalline particles were soaked in a solution of a metal alkoxide precursor, which penetrated the interstices between the PS latex spheres by capillary force.
The macrocrystalline spheres into which the precursor had fully infiltrated were removed and then exposed to air. The metal oxide precursor was then hydrolyzed by moisture in the air. It is especially noteworthy that before the hydrolysis reaction proceeded, the residual alkoxide precursor remaining on the surface of spherical colloidal assemblies must be removed. Otherwise, a thick skin is formed on the ordered macroporous sphere. Skin formation can be avoided by removing the precursor solution on the surface of colloidal assemblies in a moisture-free space or by treatment with n-propanol. Finally, the polystyrene latex spheres constituting the organic-inorganic composite microstructured particles were removed by calcination, leaving ordered spherical air voids at their sites in a matrix of titanium oxide or silicon oxide.

2.7. Double Templating

Yi et al. [35] reported on a fabrication method for preparing an array of uniform micron-sized ceramic spheres with ordered macropores by double templating. The synthetic method for preparing the macroporous particles is a two-step template-assisted fabrication process, as illustrated in Figure 5. Micrometer-sized silica particles are initially assembled into a close-packed colloidal crystalline array and are then encapsulated by polymerizing a polymer in the interstices. The silica spheres are then removed by selective chemical etching, leaving behind micrometer-sized air cavities. The polymer latex particles are then injected into the spherical air cavities inside the polymer matrix. The polymeric particles assemble within the voids to form an ordered close-packed structure. Finally, an inorganic precursor is infiltrated into the interstices between the latex particles and gelled to capture the ordered structure. A key feature of the polymer template is that the macropores are interconnected with windows sufficiently large for small polystyrene latex with size of about 500 nm to pass through.

3. CHARACTERIZATION

Characterization of the morphology and porous structure of prepared particles usually involves the use of scanning electron microscopy (SEM), transmission electron microscopy (TEM), X-ray diffraction (XRD), and adsorption analysis. In this section, the characterization of the prepared particles will be described from the following points of view: (1) microscopy observation, (2) X-ray diffraction, and (3) adsorption analysis. Table 2 shows some data relative to the characterization of ordered nanoporous particles.

3.1. Microscopy Observation

Using SEM and TEM observation techniques, the morphology, size distribution, and porous structure of the prepared particles can be observed. In the following subsections, the microscopy characterization of the prepared particles will be summarized according to the synthesis method used.

3.1.1. Emulsion Templating

In the preparation of ordered porous particles via oil–water interface emulsion templates, Schacht et al. [12] reported that the final product morphology can be controlled by the stirring speed used in the synthesis (see Section 2.1). Stirring is one mechanism for controlling emulsion properties through modification of long-range hydrodynamic forces and is crucial in the formation of the secondary morphology. Under low stirring speed, a fiber type morphology was observed. By increasing the stirring speed, more spherical particles were formed and the fiber morphology disappeared. The spherical particle size decreased with increasing stirring speed. However, the size distribution was broad and some of the particles were agglomerated. By carefully controlling the synthesis conditions, a relatively narrow

size distribution of spherical particles was obtained. From other SEM images, these particles were shown to be hollow and most were crushed after the organic phase had been removed. Silica particles in the form of fibers have a size of 50–1000 μm in length, and in the hollow spherical form have a diameter of 10 to 500 μm.

Using a similar method, Huo et al. [13] reported that by combining different surfactants and basic catalysts, the prepared particles have a solid and spherical morphology, where the stirring speed influences the condition of the particles. A low stirring speed resulted in the formation of soft gel particles, a medium stirring speed give millimeter-sized particles, and high stirring speeds resulted in smaller particle sizes. The size of the silica particles was uniform and could be controlled in the range of 0.1 to 2 μm. TEM images suggest that the particles exhibit a small pore size in the nanometer range (1–5 nm) and a preferentially ordered hexagonal form (MCM-41), while other areas show pores that appear to have a narrow size distribution but with a random orientation.

3.1.2. Biomimetic Templating

In the preparation of ordered porous particles via diamine templating, elliptical well-ordered multilamellar regions near the vesicles of 300 to 800 nm were observed, as evidenced by TEM and SEM observations [14]. The multilamellar regions near the vesicle surface are populated by a dense inorganic phase. This structural feature is indicative of biomimetic nucleation and the growth of lamellar silica material, as the self-assembly process occurs in the interlayered regions of the multilamellar bola-amphiphile vesicles. Tanev and Pinnavaia postulated that the formation of vesicular materials occurs in a manner reminiscent of natural biomineralization processes.

Table 2. Characterization data of ordered nanoporous particles.

Preparation method	Morphology	Ordered type	Size [μm]	Pore size [nm]	Specific surface area [m^2/g]	Specific pore volume [cm^3/g]	Ref.
Oil–water interface emulsion templating	Fibers, spherical solid and hollow	Hexagonal	1–2000	1.4–10	~1100	0.24 ~ 0.61	[12, 13]
Biomimetic templating	Spherical hollow	Vesicle	0.3–0.8	0.6, 1.2	~984	0.47 ~ 0.56	[14]
Liquid–phase surfactant templating under acidic/basic condition	Toroidal, disklike, spiral, spherical	Hexagonal	2–20	2.5 ~ 5	~1042	0.70	[16–18]
Liquid–phase surfactant templating with modification of Stöber method	Spherical	Hexagonal, cubic	0.4–2.3	2.10–11.2	~1600	0.49 ~ 1.2	[19, 20, 22–25]
Aerosol spray surfactant templating	Spherical	Hexagonal, cubic, vesicular	0.05–0.5	1.8–9.2	~1770	—	[26, 27]
Aerosol spray colloidal templating	Spherical, doughnut-like	Hexagonal	0.3	42–178	—	—	[30, 31]
Aerosol spray surfactant and colloidal templating	Spherical	Hexagonal	0.1	4.0–100	~480	0.53–0.88	[32]
Micromolding in inverted polymer opals	Spherical	Hexagonal	0.28 ~ 0.36	4.1	~560	—	[32]
Air–oil interface colloidal templating	Spherical, concave disklike, ellipsoidal	Hexagonal	2000	190–275	—	—	[34]
Double templating	Spherical	Hexagonal	60	500	—	—	[35]

In the preparation of ordered porous particles via diamine templating, various types of spherical morphologies of spirals, hollow and solid mesoporous silica with submicrometer-sized diameters were obtained [15]. By changing the mixing order of the reactants used in the synthesis, mesoporous solid particles of several tens of micrometers in size were obtained. The morphologies of the particles produced and their porous properties are strongly influenced by the alkyl chain length of the 1-alkylamine template and the concentration and volume of the acidic aqueous solution used in the synthesis mixture. A longer alkyl chain (C_{10}, C_{12}) leads to production of a flaky, ultrathin lamina morphology, while a short alkyl chain (C_6, C_8) produces a spherical morphology, C_6 templating produces hard mesoporous silica spheres, and C_8 templating, spiral or hollow spheres. With a very long alkyl chain (above C_{12}) or a short alkyl chain (below C_6), the amorphous qualities significantly increase, indicating instability or incomplete solubility of the 1-alkylamine.

3.1.3. Liquid-Phase Surfactant Templating under Acidic and Basic Conditions

Mesoporous particles prepared by this method have spherical and curved morphologies including toroidal, disklike, spiral, and spheroidal shapes [16–18]. In the case of the use of a cationic surfactant under acidic conditions, SEM images reveal that the morphologies are extraordinary in terms of their diverse and remarkable shapes and impressive range of curvature [16]. However, for the use of cationic-nonionic surfactants, SEM images reveal the production of entirely spherical particles, although some agglomeration is evident. The size of these silica spheres ranges from 2 to 6 μm. In the case where a cationic-nonionic surfactant is used, the exterior surface of the particles is very smooth, in contrast to the faceted and corrugated surfaces exhibited by the mesoporous silica bodies synthesized by cationic surfactant templating. TEM images of the basic morphologies clearly show the presence of hexagonally close-packed channels with a center-to-center spacing of ∼5 nm.

3.1.4. Liquid-Phase Surfactant Templating: Modification of Stöber Method

The morphologies of particles prepared by the Stöber method using the CTAB surfactant as a template were almost spherical with a size range from 400 to 1100 nm. In the case where n-alkylamines were employed as templates, spherical particles in a wide range of sizes, from 0.5 to 2.3 μm, were obtained. The particles are nearly completely dispersed although some agglomeration was visible.

3.1.5. Aerosol Spray Surfactant Templating

In the preparation of particles by aerosol spray surfactant templating, particles with ordered mesoporous structures and a spherical morphology were obtained. Different surfactant templates, that is, CTAB, Brij-58, Brij-56, or P123, exhibited different structural mesopores of the prepared particles. The use of the CTAB surfactant gave particles that exhibit a highly ordered hexagonal mesophase (Fig. 6a). Many of the particles adopted a polyhedral shape that is hexagonal in cross section. The use of nonionic surfactants (Brij-56/58) commonly resulted in vesicular mesostructures,
Figure 6. Representative TEM micrographs of mesostructured silica particles. (a) Faceted, calcined particles with hexagonal mesophases. The sol was prepared using 5 wt% CTAB as the surfactant template. (b) Calcined particles showing a cubic mesostructure. The sol was prepared using 4.2 wt% Brij-58. (c) Calcined particles showing a vesicular mesophase. The sol was prepared using 5% P123. (d) Uncalcined silica particles showing the "growth" of ordered vesicular domains from the liquid–vapor interface. The sol was prepared using 2.5% Brij-56. Reprinted with permission from [27], Y. Lu et al., *Nature* 398, 223 (1999). © 1999, Macmillan Magazines Ltd.

but cubic and hexagonal mesostructures could also be produced (Fig. 6b and d). The use of the P123 surfactant as the triblock copolymer template typically resulted in a vesicular mesophase (Fig. 6c).

Evaporation during aerosol processing creates a radial gradient in surfactant concentration within each droplet that steepens with time and maintains a maximum concentration at the droplet surface. Starting with an initially homogeneous solution, the surfactant critical micelle concentration is exceeded first at the surface of the droplet, and, as evaporation proceeds, is progressively exceeded throughout the droplet. This surfactant enrichment induces a silica–surfactant self-assembly into the micelles and further organization into liquid-crystalline mesophases. The radial concentration gradient and the presence of a liquid–vapor interface causes the rapid inward growth of ordered silica–surfactant liquid-crystalline domains (Fig. 6d) rather than in the outward direction from a seed.

Unlike films—which have flat liquid–vapor interfaces and show a progressive change in mesostructure (disordered → hexagonal → cubic → lamellar) with increasing surfactant concentration, particles prepared with comparable CTAB concentrations show only disordered or hexagonal mesophases. The reason for this is because the liquid–vapor interface serves as a nucleating surface for liquid-crystal growth; the high curvature imposed by this interface alters the generally observed relationship between the surfactant packing parameter and the resulting mesostructure.

Although the use of CTAB typically leads to the formation of lamellar mesophases in bulk and thin-film samples, it appears that this molecule cannot pack into a cone that is truncated by surfaces of high and opposite curvature, as is required to direct the vesicular mesostructure. Only surfactants containing ethylene oxide (EO) blocks consistently gave vesicular mesophases.

3.1.6. Aerosol Spray Colloidal Templating

In the preparation of particles by aerosol spray colloidal templating, ordered macroporous particles were obtained. The resulting powders are almost spherical (Fig. 7a). Ordered pores with a close-packed hexagonal arrangement are clearly observed on their surfaces, indicating that a self-organization of the PSL particles occurred spontaneously during the evaporation process. The area of organization (arrangement) increased with an increase in powder particle size, which was obtained using a larger-sized droplet. TEM images reveal that the pore arrangement persists throughout the entire volume of the particles (Fig. 7b). The pore sizes are similar to the PS latex particle sizes. This suggests that the pore size can be easily controlled by appropriately altering the size of the PS latex particles (Fig. 7c and d). There is an optimum fraction of PS latex and primary silica particles to result in the formation of spherical particles with an organized pore arrangement.

3.1.7. Micromolding in Inverted Polymer Opals

SEM images of prepared porous particles using this method showed that the morphology of particles was spherical (Fig. 8). The diameter of the product of mesoporous silica
Figure 7. (a) Typical SEM image of ordered macroporous silica particles synthesized by templating spherical colloidal 178-nm PS particles using a spray drying method. Iskandar et al., *Nano Lett.* 2, 389 (2002). © 2002, American Chemical Society.
Figure 8. Microscope images of mesoporous silica particles prepared by micromolding in inverted polymer opals. (a) SEM image of calcined mesoporous spheres, (b) a triplet coalescence defect, and (c) TEM image of a microtomed thin section. Reprinted with permission from [33], S. M. Yang et al., *Adv. Mater.* 12, 1940 (2000). © 2000, Wiley-VCH.

depends on the colloidal template (silica microspheres) size used. In the case where a silica microspheres size of 460 nm is used, the diameter of the air microspheres in the inverted mold is ca. 460 nm. The mesoporous silica opal showed that the size of the as-synthesized mesoporous silica microspheres is ca. 420 nm and this observed shrinkage is due to the condensation of silicate to silica (Fig. 8a). The mesoporous silica particles further shrink to ca. 390 nm after calcination because of further condensation polymerization of Si-OH groups on the surface of the mesoscale channels (Fig. 8c). In the case where a silica opal consisting of smaller ca. 360 nm microspheres is used, the diameter of the as-synthesized mesoporous silica microspheres is ca. 280 nm. The monodisperse mesoporous silica microspheres are packed in a regular fcc array. In addition, intriguing coalescence defect structures are observed, as depicted in Figure 8b. These structures are most pronounced when templating the mesoporous silica opal with smaller microspheres. TEM images of a thin microtomed section show hexagonally ordered mesoscale pores with a diameter ca. 5 nm.

3.1.8. Air–Oil Interface Colloidal Templating

The shape of the prepared colloidal crystals was either spherical or nonspherical (oblate or prolate spheroids) and could be successfully controlled by applying an ac electric field or by adding a surfactant. Specifically, spherical, concaved disklike, and ellipsoidal colloidal crystal were successfully prepared and used as a template in the fabrication of ordered macroporous particles. The SEM images of the prepared macroporous particles showed that the pores were interconnected and ordered into a hexagonal arrangement. The sizes of the pores ranged from 190 to 275 nm, depending on the colloidal template size. All samples underwent shrinkage during calcination. Nevertheless, the spherical shapes of the colloidal crystals remained, as shown from a low-magnification image of an optical

microscope (Fig. 9a). The SEM images reproduced in Figure 9b showed that calcined samples of titanium oxides were highly ordered in three dimensions over the entire range, resembling a cubic close packing of cages. However, the cubic close packing structure can clearly be seen from the two-dimensional Fourier transforms (FFTs) of the corresponding SEM images (see the insets in Fig. 9b). The resulting spot pattern indicates that the image plane is close to the (111) plane of an fcc lattice. The void spaces were interconnected in three dimensions through windows, the diameters of which typically exceeded 40 nm, and the wall thickness was about 40 nm (Fig. 9c).

3.1.9. Double Templating

SEM images of mesoporous silica particles prepared by the double templating method are shown in Figure 10. Figure 10a shows several millimeter-sized polymer skeletons filled with small latex particles. After the large pores were filled with the polymer particles and the remaining water was removed by drying, the metal alkoxide precursor of silica or titania was infiltrated into the interstices formed between the latex particles (Fig. 10b), after the organic polymer matrix and latex particles were removed. Figure 10c shows that photonic balls with ordered spherical macropores were successfully produced. The size distribution of the photonic balls was determined by the size of the silica particles that were used in the original templating process. The inset of Figure 10c shows that the internal structure of each photonic ball is highly ordered.

3.2. X-Ray Diffraction

X-ray diffraction techniques are frequently used to characterize the porous structure of ordered nanoporous particles. XRD patterns of hexagonal ordered mesoporous materials

usually exhibit three or five reflections, or Bragg peaks, between $2\theta = 2°$ and 6°. Figure 11 shows XRD patterns of dried and calcined fibers prepared by an aerosol spray surfactant templating method [26]. The reflections are due to the ordered hexagonal array of pores and can be indexed assuming a hexagonal unit cell as (100), (110), (200), and (210) after calcination.

The XRD pattern of lamellar mesoporous materials typically shows one intense peak between $2\theta = 2°$ and 6°, along with a broad weak shoulder [14]. However, samples with only one distinct reflection have also been reported to contain substantial amounts of hexagonal structure [16]. The XRD patterns of cubic structure mesoporous materials typically exhibit three or five Bragg peaks, between $2\theta = 2°$ and
Figure 11. XRD patterns of mesoporous silica fibers: (A) air-dried fibers; (B) calcined fibers. Reprinted with permission from [26], P. J. Bruinsma et al., *Chem. Mater.* 9, 2507 (1997). © 1997, American Chemical Society.

6°. The reflections can be indexed assuming a cubic unit cell as (211), (220), (421), (332), and (431) [24].

Since the materials are not crystalline at the atomic level, no reflections at higher angles are observed. Moreover, these reflections would only be very weak in any case, owing to the strong decrease of the structure factor at high angles. It is not possible to quantify the purity of the materials by means of XRD. Samples with only one distinct reflection have also been found to contain substantial amounts of hexagonal materials. Using XRD patterns, the pore center-to-center diameter, or d-spacing, can be calculated.

A small-angle X-ray scattering (SAXS) was also used to characterize the porous structure of the particles [27]. Figure 12 shows small-angle X-ray scattering (SAXS) patterns for silica particles prepared by aerosol spray surfactant templating method and different surfactants. The main peak is indexed as the [100] reflection of the hexagonal (A, prepared using CTAB surfactant) and vesicular mesophases (B and C).

3.3. Adsorption Analysis

Adsorption analysis has been widely used to determine surface area and to characterize the pore-size distribution of ordered nanoporous particles. N_2, O_2, and Ar gases are typically used to characterize the porosity of mesoporous materials [36–38]. Figure 13 shows the adsorption-desorption isotherm of N_2 for ordered nanoporous particles [13].

To determine the pore-size distribution, several methods based on geometrical considerations [39], thermodynamics [40], or a statistical thermodynamic approach have been used [41]. In addition, freezing point depression can be used, as well as nuclear magnetic resonance (NMR) [42]. A method for analyzing in the mesopores range is the Barret–Joyner–Halenda (BJH) method [43, 44] which is

based on the Kelvin equation. Figure 14 show a sample of a BJH pore-size distribution plot from the adsorption branch of the sample shown in Figure 13 [13].

4. PROPERTIES

4.1. Pore Size and Surface Area

Ordered nanoporous materials are used technically as adsorbents, catalysts and catalysts supports, and separation materials due to their high surface area and well-ordered pore size. The extremely high surface areas are conducive to high catalytic activity. From Table 2, it was found that mesoporous particles prepared using an aerosol spray surfactant template had the highest surface area, 1770 m^2/g [26]. Well-ordered mesoporous materials also offer interesting potential for use in separation and adsorption [45].

4.2. Thermal Properties

Thermal stability by annealing nanoporous silica particles has been investigated [24, 31]. By annealing particles below 750 °C, the porous structure of silica particles (mesoporous

Figure 12. Small-angle X-ray scattering (SAXS) patterns of silica particles with (A) hexagonal or (B and C) vesicular mesophase. Reprinted with permission from [27], Y. Lu et al., *Nature* 398, 223 (1999). © 1999, Macmillan Magazines Ltd.

[24] and macroporous [31]) remains stable. At higher temperatures in the vicinity of 1000 °C, the XRD patterns of materials show that several peaks disappear. From SEM images, by annealing at 1200 °C, some silica nanoparticles collapse from the pore wall and give rise to smaller pore sizes inside the particles. The morphology of the powder becomes smoother and smaller, due to the sintering of silica, which occurs at this temperature. When the annealing temperature reaches 1500 °C, the pores collapse and, finally, solid spherical silica particles are obtained. The difference in powder particle volume before and after annealing determines the porosity of the powder [31].

4.3. Optical Properties

Chang and Okuyama [46] reported on the optical properties of ordered macroporous particles prepared by an aerosol spray colloidal surfactant method. Light scattering by solid and macroporous silica particles was investigated using a laser particle counter (LPC) coupled with a pulse height analyzer. The measured partial scattering cross section of solid and macroporous silica particles with same diameter showed significant differences. The effective relative indices of solid and macroporous silica particles were computed by the best fitting of the scattering intensity measurements. The result showed that the macroporous silica particles have a low effective refractive index, 1.147 (for solid silica particles, the effective refractive index was 1.46). By changing the porosity of the porous particles, the refractive index could be easily controlled.

5. SUMMARY

Ordered nanoporous particles have been synthesized by several methods, in the liquid process as well as in the aerosol phase using a surfactant and/or colloidal templates. The morphology of prepared particles, the pore size, and the porous structure are typically influenced by the template types, the synthesis method, and the synthesis procedures. The use of a surfactant template led to the formation of micro- and/or mesoscaled structured porous particles. The use of a colloidal template gave particles with macroscale ordered pores. A high surface area and well-ordered nanoporous particles would be potentially useful as catalyst, adsorbent, separation materials, and low refractive index materials. Research in the preparation of particles that contain ordered nanopores (microporous, mesoporous, and macroporous) with a controlled morphology is in its infancy. It remains to be seen if these systems can be developed for other applications such as low dielectric constant, microelectronics, and electro-optics.

GLOSSARY

Aerosol A substance composed of solid or liquid particles that are small but larger than most molecules in gas phase.

Aerosol spray method A method for material processing by spraying the droplets containing precursor in gas phase.

Biomimetic Biomimetic refers to human-made processes, substances, devices, or systems that imitate nature.

Colloid A substance composed of particles that are small but larger than most molecules. The particles in a colloid do not actually dissolve but remain suspended in a suitable liquid or solid. Among the colloids are polymers, such as rubber, plastics, and synthetic fibers.

Emulsion A stable dispersion of one liquid in a second immiscible liquid, such as milk (oil dispersed in water).

Macroporous materials Materials which have pore size above 50 nm.

Mobil oil composite of matter (MCM) Silicate-surfactant composite structures that posses mesoscopic order which have attracted large interest since the pioneering work of the Mobil Oil group published in 1992.

Mesoporous materials Materials which have pore size between 2 and 50 nm.

Microporous materials Materials which have pore size below 2 nm.

Scanning electron microscopy (SEM) The use of a stream of electrons controlled by electric or magnetic fields to obtain the profile materials surface. The examined object is scanned with a focused beam of accelerated electrons in a vacuum cannon. Under the influence of the bombardment the object emits various sorts of radiations that can be captured by fluorescence screen or film.

Transmission electron microscopy (TEM) A fine electron beam passes through the specimen, which must therefore be sliced extremely thinly. The transmission electron may be thrown on a fluorescent screen or may be photographed to produce specimen image.

Organic Nanofilm Growth

Serkan Zorba, Yongli Gao

University of Rochester, Rochester, New York, USA

CONTENTS

1. INTRODUCTION

The last couple of decades have seen the emergence of organic or "plastic" electronics, a term that would probably have sounded peculiar to scientists half a century ago, to take its deserved place among today's scientific and technological endeavors. It all started with the discovery of the conducting polymers by Shirakawa et al. and Adam in the mid 1970's [1, 2]. Organic electronics has been a hot and prolific field of science and technology since then. With important discoveries made recently, scientists became even more excited and encouraged about the feasibility of plastic circuitry. Among these recent discoveries are relatively high electron and hole mobilities, and high on/off current ratios observed in single crystals of simple conjugated molecules such as pentacene, perylene, and sexithiophene, etc., when used in thin-film transistor (TFT) applications [3–8]. These achieved results rival those of conventional hydrogenated amorphous silicon. This is by no means suggesting that organic electronics will supersede the inorganic electronics in its high performance and high device density. Rather, the former presents a host of new possibilities like flat panel displays, smart cards, and identification tags with numerous advantages, such as ease of fabrication, reduced cost and power, mechanical flexibility, and other desirable features [3–10].

It has been shown by many research groups in the field that there is a strong relationship between the microstructure and the charge-carrier mobility in organic nanofilms [11–16]. In this article, we will review the recent progress made in organic semiconductor nanofilms as they are used in thin-film field-effect transistors (OTETs) and organic light-emitting diodes (OLEDs). We will outline the basic modes of organic thin-film growth with selected examples and discuss the effect of morphology on charge transport. It seems that molecular ordering is of crucial importance. Charge carriers can hop easily from one molecule to another if there is ordering between them. However, lack of molecular ordering and presence of grain boundaries can be the greatest bottlenecks to charge transport in polycrystalline organic semiconductor nanofilms [11–18]. We will also deal with organic thin-film growth from kinetic roughening considerations, and examine pentacene and perylene more extensively as two model organic semiconductor materials, as they are among the most favorable material due to their relatively high electron and hole mobilities [6, 19, 20].

A direct and easy way of measuring conductance and morphology, and charge injection barrier in organic nanofilms is an effective and desirable way of learning about transport characteristics and potential hurdles to charge transport in these films. To this end, new, reliable, and very powerful scanning probe microscopy (SPM)-based techniques of measurements, such as conducting probe atomic force microscopy (CP-AFM) [7, 8, 12, 16–18, 21–25], and height versus potential (z-V) scanning tunneling microscopy (STM) measurements [26–28] on organic semiconductor nanofilm interfaces, are described. These versatile tools let us investigate the structure, structure-transport relationship, charge-carrier transport characteristics, and potential hurdles to charge transport in organic semiconductor nanofilms and interfaces with nanometer-scale spatial resolution.

This review consists of two main parts: structure and morphology aspects, and their effects on the application aspects of organic semiconductor nanofilms. In the first part (Sections 1–4), we will briefly summarize the fundamental principles of organic thin-film growth, and give some background as to the growth dynamics of thin films. We will finish the first section by reviewing the recent works done on some of the selected organic semiconducting materials from

a growth and morphology perspective. In the second part (Section 5), some of the recent results on the applications of organic semiconductor nanofilms will be reviewed, elaborating more on the organic thin-film transistor (OTFT) and OLED applications. The subject of organic semiconductor thin films is such a broad topic that reviewing all the work done in this area so far would require extensive discussion and space. We will, therefore, focus more on the morphology and morphology-transport correlation, and leave the rest to be outside the scope of this article.

2. GROWTH MODES

Organic molecules (Chart 1 displays typical chemical structures of some of the promising organic materials), when deposited onto an inorganic substrate, can result in three different growth modes (see Fig. 1), depending on the relative strengths of the adsorbate-adsorbate and adsorbate-substrate interactions [20, 29, 30]. First, if the substrate is chemically inert, the adsorbate-substrate interaction will be very small having almost no influence on the growth of the organic film. This will enable the organic molecules to move freely on the surface and form large, separated islands of crystals after adsorption. This type of growth is known as Volmer–Weber or three-dimensional island growth. Second, if the substrate has highly reactive bonds, the adsorbate-substrate interaction will be very large, and as soon as the organic molecules hit the surface they will be bound strongly to the substrate. This will prevent a self-ordering mechanism of the organic molecules, which is of crucial importance for ordered growth; hence, result in disorder. This mode of growth is known as Frank–van der Merwe or layer-by-layer growth. The third type of growth is a moderate combination of the first two scenarios. That is, the adsorbate-substrate interaction is neither too strong, nor too weak. It is such that the substrate has strong enough influence on the deposited particles to impose its crystallinity to the grown organic film, and the deposited particles have enough mobility to self-order themselves. This type of growth goes by the name of Stranski–Krastanov mode or layer island growth.

Producing very thin defect-free organic nanofilms with high structural order and well-controlled interfaces is a prerequisite for improving charge-carrier speed in electronic device applications. One way to accomplish that is to use organic molecular beam epitaxy (OMBE). Due to the fact that the lattice spacing of organic materials are much larger than that of inorganic ones, it is a difficult task to obtain true epitaxial organic layers. However, well-defined crystal orientations of organic nanofilms are obtained in spite of the absence of lattice matching. This phenomenon is known as quasi-epitaxy. Over the last few years, researchers have tried a number of substrates that might be suitable for epitaxial growth. Noble metals such as gold and silver, therefore, provide the necessary conditions for making highly ordered monolayers with large and defect-free domains. Fenter et al. and Umbach et al. succeeded in fabricating quasi-epitaxial layers of perylene-tetracarboxylicacid-dianhydride (PTCDA), one of the most favorable and intensely studied molecules used in getting highly ordered organic films, on gold [31] and silver [32] substrates, respectively. In their study of the fundamentals of quasi-epitaxy
Chart 1. Chemical structures of some of the molecular semiconductors.

of PTCDA Kendrick and Kahn observed that this planar molecule reveals all of three possible growth modes mentioned at the outset of this section when deposited on Se-passivated GaAs (100) (2 × 1), graphite, and InAs (001) (4 × 2) substrates, respectively [29]. We will discuss more about PTCDA and other perylene derivatives later in this article.
Figure 1. Three different modes of nanofilm growth: (a) Volmer–Weber or three-dimensional island, the adsorbate-adsorbate interaction dominates and thus deposition results in multilayer islands. (b) Frank-van der Merwe or layer-by-layer, the adsorbate-substrate interaction dominates the adsorbate-adsorbate interaction and thus a new layer can begin to grow only after the previous one is completed. (c) Stranski–Krastanov or layer + island, after the formation of a couple complete layers, the adsorbate-substrate interaction becomes weaker and the adsorbate-adsorbate interaction dominates, forming islands on top of the complete layers.

3. MODELING THE NANOFILM GROWTH

Devices based on organic nanofilms, such as light-emitting diodes, field-effect transistors, and solar cells have been demonstrated in recent years [19, 33–39]. In spite of the fact that the performance of these devices has been shown to largely depend on the morphology of the organic thin films [11, 28, 30, 40], only recently has there been a growing interest in studying the growth properties of these films [41–44]. The roughness studies on polymer and small organic molecule films have shed some light on the way the organic interfaces nucleate and evolve to form the desired thin films. In what follows is a brief discussion on the theory of kinetic roughening. We will then review some of the recently published articles dealing with the growth dynamics of organic thin films.

In order to study the growth kinetics of a surface, one can use the qth-order height-height correlation function, which we can be defined as [45]:

$$C_q(r, t) = \left((1/N) \sum_{i=1}^{N} |h(r_i, t) - h(r_i + r, t)|^q \right)^{1/q}$$

where N is the number of sites with single-valued heights $h(r_i, t)$. By definition, the $q = 2$ case refers to the height-height correlation function, which is the rms fluctuation in the height difference between two surface points separated by a lateral distance r. It scales as follows according to the scaling hypothesis [46–48]:

$$C_2(r, t) \sim t^\beta g(r/\xi(t))$$

where r is the lateral separation, t is time, β is a scaling exponent, and g is a scaling function which depends on r and ξ, where ξ is the correlation length. The correlation length is the critical distance over which two heights are correlated. $C_2(r, t)$ takes the following asymptotic behavior:

$$C_2(r, t) \sim t^\beta$$

Namely, for distances much larger than the correlation length, $C_2(r, t)$ increases as a power of time. β in the above equation is called the growth exponent. It characterizes the time-dependant dynamics of the growth. For distances much

less than the correlation length ξ, $C_2(r, t)$ is independent of time for surfaces that obey the normal scaling law. It reads as

$$C_2(r, t) \sim \rho r^H$$

where ρ is the local slope of the interface, and H is a second scaling exponent called the Hurst exponent. The Hurst exponent H characterizes the roughness of the saturated interface. As for the local slope ρ, it is literally the approximate average slope of the local structure. Its value is related to the intersection of $C_2(r, t)$ with the vertical axis. For normal scaling, it does not depend on time [49, 50]. If ρ does depend on time, the scaling becomes anomalous. As one can see, to be able to characterize a growing interface, one needs the height-height correlation function $C_2(r, t)$, and more specifically, the critical exponent H and β.

Zhao et al. have shown in their study of roughness evolution of a simple polymer growth system, -(C$_8$H$_{10}$)-, called p-xylylene, that monomer bulk diffusion is the dominant growth mechanism in the formation of linear poly(p-xylylene) (PPX) (with the tradename Parylene®) via vapor deposition polymerization (VDP) [41]. Parylene® is a conformal protective polymer-coating material with high thermal stability and excellent electric and dielectric properties which is used for coating electronic components and insulating applications. In a VDP process, the monomer from the gas phase condenses on the substrate and reacts to form high molecular weight polymers. The monomer can take part in two chemical reactions: initiation and propagation. In initiation reactions, new polymer molecules are spawned, and in propagation reactions, existing polymer molecules are made longer by the addition of new monomers. When a monomer condenses on a substrate from the gas phase, the reaction can only occur at the ends of a polymer chain. This is contrary to what happens in the physical vapor deposition (PVD), where deposited atoms can attach to the nearest neighbors of nucleated sites making the film dense and compact. In PVD, the growth is affected by the surface dynamics, such as surface and edge diffusion, step barrier effects, etc. In VDP, on the other hand, surface diffusion, intermolecular interaction, and chain relaxation can occur during growth. The latter two processes are very different from the atomistic processes of PVD, and this gives rise to a distinct dynamic behavior for the VDP film morphology. In the case of Parylene®, this is realized as monomer bulk diffusion with the growth exponent $\beta = 0.25$, roughness exponent $\alpha = 0.72$, and dynamic exponent $1/z = 0.31$, where $z = \alpha/\beta$. This type of scaling behavior belongs to a novel universality class.

Other types of mechanisms might also be present in organic thin-film growth. Tsamouras et al., for example, have observed that the Kardar–Parisi–Zhang (KPZ) type of growth, in which desorption or vacancy formation are the dominant relaxation mechanisms, is the best model to describe roughening in the growth of Oligomer van der Waals thin films [44]. They based their conclusion on the fact that the height distribution was not Gaussian, and the Hurst exponent, H, was 0.45, the growth exponent, β, was 0.28. These observations agree with what the KPZ model predicts.

We have studied the growth dynamics of perylene on glass and Au substrates grown side-by-side by vapor deposition

using AFM. Higher order height-height correlation functions have been calculated for the perylene thin films on glass and Au substrates [51]. The results show a complex, multiaffine behavior on both substrates evidenced by order dependence of the Hurst exponent [45, 52], and point to a critical thickness value for both substrates that might have important implications regarding the film substrate interactions. We will discuss this issue later on in this article.

It is desirable to have high enough mobility in organic semiconductors for any kind of realistic device applications. The best mobilities can be obtained with single-crystal organic thin films in comparison to polycrystalline ones. The reason being the least amount of grain boundaries and discontinuities, the higher the structural order found in single-crystal films. However, it is not easy to obtain single-crystal semiconducting films as most semiconductor depositions result in polycrystalline structures. The grain size and continuity of polycrystalline thin films depend strongly on the substrate temperature, deposition rate, and substrate material itself. The underlying physical principles governing organic thin-film growth and crystallization are not as well understood as those of metal and inorganic semiconductor thin films, and very little has been done to relate the experimental findings to growth theories. By studying the growth dynamics of organic materials, we are exploring more about the structure of these materials, which has a substantial effect on their transport properties.

4. ORGANIC NANOFILM GROWTH AND INTERPLAY BETWEEN MORPHOLOGY AND CHARGE TRANSPORT

Among the organic semiconductor materials that are being used extensively by researchers worldwide in molecular device applications, pentacene has been one of the most promising material due to its relatively high hole mobility [3–6]. In fact, field effect mobility as large as 2.2 cm^2/Vs has been observed in OTFTs that use pentacene as the active layer [6]. Pentacene is an aromatic hydrocarbon molecule consisting of five linearly fused benzene rings. It is a p-type semiconductor. When deposited onto a SiO_2 substrate, as would be the case in a field-effect transistor application, pentacene initially grows in almost a layer-by-layer fashion (Frank–van der Merwe mode) over the substrate. After a while islands start forming, making it layer + island type of growth (Stranski–Krastanov). Figure 2 shows the tapping mode images of pentacene films on SiO_2 substrate [43]. In Figure 2(a), we can first see monolayer steps of pentacene developing and forming the dendritic grains of about 1 μm in size (Figs. 2(b), 2(c), and 2(d)). From X-ray diffraction experiments, it has been shown that this kind of dendritic growth of pentacene on SiO_2 has well-ordered crystalline structure [11]. The step size of the monolayer steps have been obtained from the line analysis to be about 15 Å, which is the length of one pentacene molecule. The mobility measurements have shown that pentacene films on SiO_2 with such dendritic grains have higher mobility than the ones with granular structure obtained by flash evaporation on the same kind of substrate. In fact, high mobility can only be obtained if
Figure 2. Tapping mode AFM images of different coverages of pentacene on SiO_2 substrate. (a) 7 Å, (b) 20 Å, (c) 50 Å, (d) 150 Å. Image sizes are 5×5 μm.

the pentacene film is highly ordered, making it easier for the charge carriers to hop from one molecule to another.

The ordered growth of pentacene thin films is a very peculiar one that involves many contrasting growth mechanisms. As can be seen in Figure 3, pentacene grains form mounded structures with diffusion limited aggregation (DLA)-type dendritic crystal growth. The mounded growth with well-established facets, such as we see in Figure 3, is predicted to be a result of step barrier effect [48]. This type of faceting may indicate the existence of a potential barrier, which is
Figure 3. A close-up image of 50 Å pentacene on SiO_2. One can see many growth mechanisms involved in the ordered pentacene nanofilm growth. Mounded growth, DLA-type growth, and dendritic growth are all copresent as is seen in the image.

also called a Schwoebel barrier, at the step edge of well-defined pentacene terraces. It can be shown that there exists a potential barrier at the edge of a step that generates a bias in the diffusion process. If a molecule diffuses towards an ascending step, it sticks to the molecules of the step. If it diffuses towards the edge of a descending step, it will most likely be reflected back from the step without jumping down the step due to the existing edge barrier. This asymmetry in the diffusion process will force molecules to move uphill on a stepped surface, producing an average upward current (see Fig. 4). If there is sufficient nucleation of islands on terraces, mounds will develop and with time they will get bigger and bigger, finally to coalesce and form one single big mound on the order of the size of the substrate [53]. Diffusion limited aggregation, which is another mode of growth observed in ordered pentacene, forms via diffusion of molecules through pure random walk and their sticking to a cluster to create irregularly branched and chaotic patterns. The striking thing is that, in addition to the mounded and DLA-type growth, there is also dendritic crystal formation, as was mentioned earlier. Dendritic crystals have regularly branched structure, such as observed in snowflakes [54]. One can see that DLA and dendritic growth are two competing mechanisms. This competition can result in one of the following three scenarios:

(i) DLA-like crystal growth occurs when random perturbation, such as roughness, is very strong or substrate lattice anisotropy is very weak;

(ii) dendritic crystal growth occurs when crystal anisotropy is very strong;
Figure 4. Molecule B may go to the left or right (top drawing). If it goes to the left, it will stick to the edge, as the energy is minimal at that spot. Going to the right to jump down the edge, however, there is no atom to the right of the edge to help molecule B to diffuse in that direction. This asymmetry in the lattice potential (bottom drawing) creates a higher probability of moving to the left than to the right. This bias in diffusion will generate an average uphill particle current.

(iii) a peaceful existence of both growth types when random perturbation and crystal anisotropy both contribute to the growth.

In the context of a SiO_2 substrate that is used in Figures 3 and 4, the adsorbate-substrate interaction must be such that pentacene molecules once deposited onto the SiO_2 have enough mobility to diffuse randomly on the surface to attach to the already formed clusters (DLA). Yet the substrate anisotropy must be strong enough to introduce dendritic crystal growth alongside DLA. As previously, this kind of interplay between the adsorbate-substrate and adsorbate-adsorbate interactions is found in the layer + island (Stranski–Krastanov) growth mode. Pentacene achieves high mobility only if it has formed the ordered thin-film structure that we have just discussed. In addition, the larger the size of those grains, the higher mobility one would get [42]. It is intriguing that there are so many mechanisms involved for the pentacene thin films to be ordered and to have a relatively high mobility.

Perylene is another favorite organic semiconductor molecule that has attracted a great deal of interest especially among the organic solar cell, and more recently, the organic thin-film transistor communities [19, 28]. It has been observed to not only have relatively high hole mobility, but also high electron mobility [28, 55, 56], which might enable it to be used in *n*-channel, as well as *p*-channel, device applications. This is very significant because most organic semiconductors are p-type, and hence only show p-channel conductivity. However, a broad variety of circuit designs call for the development of both types of materials.

We have, extensively investigated in our laboratory the growth morphology of perylene on glass and Au substrates as a function of the deposition rate. The shape and size of perylene single crystals varied from glass substrate to Au substrate (see Fig. 5). However, the single crystal size, in both substrates, increased as the deposition rate decreased. Perylene, for slower deposition rates, forms large-scale mounds that are almost of a regular size on the glass substrate but irregular on the Au substrate. This might indicate that the adsorbate-adsorbate interaction is stronger when perylene is deposited on Au rather than glass. This naturally results in the formation of large islands of single crystals. This growth scheme falls under the three-dimensional island (Volmer–Weber) growth scenario. Perylene on glass also forms islands, but the individual islands are well spread over the substrate, hinting at the fact that the adsorbate-substrate interaction is not negligible. For faster deposition rates, small perylene grains are formed and uniformly spread over both substrates.

We applied the kinetic roughening theory for the initial coverages of perylene crystals on these surfaces. The initial crystal sizes on both substrates were observed to be much smaller than the length scales we investigated. This allowed us to use the theory of kinetic roughening to investigate the evolution of the nucleation process of perylene thin-film interfaces [51]. The height-height correlation function and the Hurst exponent saturate once the nominal perylene film thickness reaches the critical value of 40 Å on glass, and 100 Å on Au substrates. Once these critical thickness values are reached, overhang structures develop and dynamic scaling analysis becomes inappropriate. This shows that there is
Figure 5. Tapping mode AFM images of 200 Å of perylene on glass ((a) and (b)) and Au ((c) and (d)) substrates. The deposition rate for the top images was about 0.1 Å/s, and for the bottom images about 10 Å/s. The image sizes are 10×10 μm.

Figure 6. Grayscale STM image of an ordered nanofilm of PTCDA molecules on HOPG surface. The film thickness is 30 Å and the size of the image is 500×500 Å. The image was taken in the constant current mode in air with a tip current of 300 pA and a voltage of 150 mV. PTCDA grows in a layer-by-layer fashion on HOPG.

a critical thickness for each substrate until which the organic semiconductor perylene develops nucleation sites during its initial growth. The critical thickness might be where the interaction between the incoming flux and the substrate weakens dramatically, even though the surface might not be altogether covered.

Wang et al. recently found that the interaction between aromatic molecules and substrate increases with the increase of aromatic rings in their investigation of pyrene and perylene on Cu(111) [57]. Derivatives of perylene, such as PTCDA—a symmetric planar stacking molecule have–also been investigated as potential players in molecular device technologies [28–32, 58, 59]. Our group at the University of Rochester has also studied the quasi-epitaxial growth of PTCDA on highly oriented pyrolitic graphite (HOPG) using STM in air. Perylene-tetracarboxylic acid-dianhydride formed highly ordered large domains on HOPG (see Fig. 6). The growth mode that it follows is layer-by-layer growth. It is remarkable that STM can obtain molecular resolution images, as seen in Figure 6, in air, a difficult environment to work with. In spite of the highly ordered structure of quasi-epitaxial PTCDA films, devices based on these films gave poor transport characteristics. The maximum mobilities reported were about 0.03 cm^2/Vs [60]. The poor mobility of PTCDA is explained partly by the morphology. The PTCDA molecules lie flat on the dielectric. Molecular planes are parallel to the transport direction in a TFT. Electrons move along this direction where π orbital overlap is minimal. Hole transport dominates in the direction normal to the molecular planes, where the π orbital overlap is maximal. However, this does not do any good as holes move in a direction perpendicular to that of transport in a TFT [59]. Another

setback for PTCDA, like much of the other n-type organic semiconductors, is that it is not stable in wet air. This is attributed to the fact that oxygen acts as trap centers for the electrons in such organic materials [9, 60].

More recently, Malenfant et al. reported mobilities up to 0.6 cm^2/Vs and current on/off ratios larger than 10^5 obtained with another perylene derivative, perylene tetracarboxylic diimide (PTCDI-C$_8$H), used as the active material in a TFT device [61]. They explain the observed good characteristics by highly ordered extended structures, which were formed by interdigitation of alkyl substituents.

Naphthalene tetracarboxylic dianhydride (NTCDA) is another symmetric and planar organic molecule. Like PTCDA, NTCDA also forms quasi-epitaxial layers on substrates such as HOPG [28]. Laquindanum and Katz et al. have studied naphthalene-based materials, such as NTCDA and naphthalene diimides [62, 63]. They measured higher mobilities when the substrate during deposition was held at elevated temperatures. More continuous films were obtained at higher temperatures. Their devices were unstable in air. Better air stability was achieved with tetracyanonaphthoquinodimethane (TCNNQ), another naphthalene-based substance. Furthermore, TCNNQ gave higher mobilites than its relative molecule tetracyanoquinodimethane (TCNQ) [64]. A short note on TCNQ: it is a strong electron acceptor, which is why it easily forms ionic salts with good electron donors such as tetrathiofulvalene (TTF). The donor-acceptor compounds such as TTF-TCNQ are also called charge-transfer compounds because their conductivity depends on the transfer of charge from the donor molecule to the acceptor molecule. Katz et al. also observed that changing the substitution in naphthalene diimides varied the transport characteristics drastically [63]. Fluorinated naphthalene diimides (NTCDI-C$_8$F, NTCDI-BnCF$_3$) showed high

mobilities in air. On the other hand, alkyl functionalized diimides (NTCDI-C_8H, NTCDI-C_{12}H, NTCDI-C_{18}H) revealed high mobilites under vacuum only.

C_{60} has also been explored as a potential player in organic electronic business. It has been used as the active material in OTFT applications. In fact, it is one of the few n-type materials that show very high mobilities [65]. In addition, contrary to other materials that require highly ordered morphology with peculiar shapes (e.g., pentacene), isotropic films of C_{60} provide good device characteristics. This might be due to its approximately spherical shape, as compared with the elongated and/or planar shape that other organic semiconductors have. However, there is an air-stability issue with C_{60} as well, that one has to deal with [9, 60].

Since the introduction of molecular crystals as TFT semiconductor active materials [36, 37], oligothiophenes have been investigated widely due to their favorable characteristics [7, 9, 10, 13–15]. They have been found forming highly ordered self-assembled thin films on Si/SiO_2 and S-treated Au substrates. As will be discussed later in the next section, Seshadri and Frisbie were able to obtain large enough sexithiophene (6T), an oligothiophene molecule, single crystals to achieve relatively high hole mobilities [8]. In their work on the mobility dependence of polycrystalline oligothiophene thin films, Horowitz and Hajlaoui found that the mobility increases roughly linearly with grain size [14]. They further observed that temperature dependence of mobility in these thin films changes drastically from small grains to larger grains. For small grains, they found that mobility is thermally activated, whereas for larger grains, mobility becomes practically temperature-independent. Recently, Hajlaoui et al. reported that heating the substrate during octithiophene (8T) film deposition enhances the molecular order and leads to large crystallites, which in turn, gives rise to high-charge carrier mobilities [15]. The carrier mobility was observed to rapidly increase once the substrate temperature exceeded 120 °C, reaching a value as high as 0.33 cm²/Vs.

Metallophthalocyanines (M-Pcs) have found applications in areas such as solar cells, optical limiters, photoconductors, OLEDs, and OTFTs [60–70]. Copper phthalocyanine (CuPc) has been an especially important molecule for improving OLED device stability when deposited between the anode and hole transport layer. Forsythe et al. showed that growth morphology of the hole transport layer, α-naphthylphenyl biphenyl diamine (NPB), is changed significantly by the interposing CuPc layer [69]. Without that interlayer, NPB grows on the anode in isolated islands (three-dimensional island mode). With the CuPc interlayer, NPB grows in layer-by-layer fashion (at least for relatively thinner coverages), making the interface much more smoother and thus resulting in improved adhesion as compared to NPB deposited directly on the anode substrate.

Bao et al. have explored a number of M-Pcs exhaustively for OTFT applications [66–68]. They reported that highly ordered M-Pcs can be obtained by heating the substrate during deposition. This way, they were able to get relatively high mobility and on/off ratios. However, they also observed that after some critical temperature value, the mobility starts decreasing even though the crystal size keeps getting larger. This is most likely due to the increasing gaps formed between very large, nonspace-filling crystals when the temperature is too high. Furthermore, their results show that there is a great difference in mobility with different metal coordinations even when the films are deposited under the same conditions. They obtained the optimal results with a perfluorinated phthalocyanine with M = Cu (F_{16} CuPc) and T = 125 °C. Electron-withdrawing groups are known to lower the highest occupied molecular orbital (HOMO) and the lowest occupied molecular orbital (LUMO) energy levels. The LUMO level of F_{16} MPc has been shown to drop by 1.6 eV. This opens up new possibilities of converting p-type materials to n-type materials by simply lowering the LUMO levels via substitution with strong electron-withdrawing groups. With such an option, fabrication of high-performance all-plastic complimentary circuits and ring oscillators become possible. In addition, these materials might be of great interest as n-channel semiconductors in photovoltaic devices and electron-transporting materials in OLED applications. Bao et al. also showed that these devices are very stable in air, and do not show any degradation for half a year.

In an effort to study the growth structure of thick evaporated CuPc layers on Si (111) surface by STM, Hiesgen et al. found that the CuPc molecules arrange themselves in a slipped stacking order rather than in the expected zig-zag orientation normally encountered in CuPc crystals [70]. This leads to polycrystalline film formation after initial coverages. The growth mode in this case resembles the layer + island mode (Stranski–Krastanov).

Last in this section, we would like to mention about solution-processable, organic semiconductor materials. The use of such materials has the potential to eliminate the costly lithography and reduce the need to use expensive and cumbersome high-temperature, vacuum deposition techniques. Poly (3-hexylthiophene) (P3HT) is among the widely used, soluble organic semiconductor materials. The solubility of this polymer increases with the addition of long insulating alkyl side-chains without any harm to the electrical properties of the polymer [71, 72]. Since its first use in an OTFT, the mobility of polythiophene materials has been improved dramatically from $\sim 10^{-5}$ through ~ 0.1 [71, 73]. Bao et al. reported that the solvent used effects the film quality and field-effect mobility strongly [74]. Solution-processed films of regioregular P3HT self-orient into well-ordered lamellar structures. Sirringhaus et al. showed that depending on the processing conditions the lamellae can adopt two different orientations—parallel and normal to the substrate [75]. The difference in mobility between these two orientations is more than two orders of magnitude. In the case where the lamellae are parallel to the substrate (π-π^* stacking direction perpendicular to the substrate), the mobility is minimal. On the other hand, for the case where the lamellae are normal to the substrate (π-π^* stacking direction parallel to the substrate), the mobility is maximal. This is very telling as far as the role that the structure plays in charge transport in such organic materials. Furthermore, this work indicates that a π-π^* stacking direction is very critical in determining the final mobility of organic semiconductor materials. Some of the other organic semiconductor materials that have enough solubility to allow them to be used by solution-processing techniques are oligothiophenes.

However, semiconductor materials with very poor solubility, such as pentacene, can also be processed via their soluble nonsemiconducting precursor molecules. Upon deposition of the precursor molecule, the sample is heated to convert back to the insoluble semiconducting molecule [76, 77].

In fact, there are plenty of organic semiconductor materials that need to be explored and exploited by the scientists, thanks to the infinite variety of organic materials. Understanding the growth mechanisms of these molecules is imperative in improving the charge-transport properties of such materials.

5. CHARACTERIZATION AND APPLICATION OF ORGANIC NANOFILMS

Organic semiconductor nanofilms find a broad range of applications among which are organic thin-film transistors, organic light-emitting diodes, solar cells, photo detectors, lasers, sensors, rectifiers, electro-optic switches, waveguides, and optical couplers, to name a few [9, 28]. Instead of treating all of these devices here, we will just focus on the thin-film transistor and light-emitting diode applications. In particular, we will review some of the new SPM-related techniques that have been developed to learn more about these devices and their characteristics.

Organic TFTs are perhaps one of the most exciting applications of plastic electronics. It is especially suitable for "all plastic" applications where every device element is designed to be organic [36, 37, 78–80]. Figure 7 shows a schematic diagram of a typical field effect transistor (FET). The transistor is said to be in "on" state when substantial current flows from source to drain at a given source-drain voltage, while it is in "off" state when little or no current flows between source and drain at that voltage. The switching between these two states is done by the application and removal of an electric field, respectively. In a typical FET characteristic measurements, the mobility can be determined using the following formula of a standard FET equation in the saturation regime [81]

$$I_{DS} = WC_i\mu/2L(V_G - V_T)^2$$

where I_{DS} is the drain saturation current, W is the channel width, L is the channel length, and C_i is the capacitance per unit area of the insulating dielectric layer. If the square root of I_{DS} is drawn versus V_G, the mobility can easily be derived from the slope of that plot.

Before we move further on to reviewing the recent findings on OTFTs, let us briefly describe a very powerful and versatile instrument that is being used in investigating these and other types of devices. Conducting probe-AFM (hereafter referred to as CP-AFM) has been proven to be an indispensable tool in studying and correlating morphological, electronic, and mechanical properties of organic molecules with high spatial resolution [7, 8, 12, 16–18, 20–24, 43]. Conducting probe-AFM is a scanning probe method that incorporates the standard AFM technique with point contact electrical measurements using a metal-coated tip that serves both as a movable electrode and force sensor (see Fig. 8). It is an ideal tool to quantify the effects of microstructure, such as grain boundaries and contacts on the performance of organic semiconductor devices.

Frisbie et al. have used the CP-AFM technique extensively to study the electrical transport properties, nanostructure-transport correlation, and possible bottlenecks to electrical transport in organic thin-film transistors based on 6T [7, 8, 12, 16–18, 22]. Field-effect conductance measurements made on a 6T-based transistor have shown no discernible dependence of the carrier mobility on thickness, even down to monolayer thickness. This suggests that much of the current is carried by the first monolayer next to the dielectric layer. This can be expected, as the field-induced carriers will be electrostatically confined to the organic-oxide interface. Hole mobility as large as 0.5 cm²/Vs has been observed for

Figure 7. Schematic diagram of a typical "bottom contact" FET, where the source and drain electrodes are fashioned directly on the gate dielectric and underneath the organic semiconductor material. There is also "top contact" geometry, where the source and drain electrodes are fashioned on top of the organic material. For more information about the variability of OTFT structures, please see [9].

Figure 8. Schematic diagram of CP-AFM. CP-AFM incorporates the standard AFM technique with point-contact electrical measurements using a metal-coated tip that serves both as a movable electrode and force sensor.

6T-based OTFTs. Electrical measurements done on polycrystalline 6T-based OTFTs show that grain boundaries (such as seen in Figure 4 for ordered pentacene) can be the primary hurdles to charge transport in such materials. As high as 10^{10} Ω resistance has been observed for a 1-μm boundary length. However, the grain boundary resistance is found to be gate voltage dependant. The device's turn-on voltage depends on the potential barrier that exists on the grain boundary. It cannot be turned on until this barrier is reduced to allow charge-carrier flow. Another important stumbling block to charge transport in organic molecular devices are the contacts. The potential profile across the channel of an operating 6T-based FET reveals that, for any given source-drain bias, most of the potential drops at the source and drain contacts. This means that the FET is contact limited. Moreover, the potential drop depends on the applied drain and gate voltages. In order to lessen the effects of contacts, researchers are resorting to various techniques, such as employment of self-assembled monolayers (SAMs), [82–85]. Choosing the right SAM would enable chemical bonding at the contacts, which would in turn minimize the contact resistance giving rise to higher mobility. It is quite clear that in order for OTFTs to be satisfactorily used in plastic electronic applications, these obstacles to transport need to be overcome.

Pentacene has also been widely used in OTFTs since they were first demonstrated [3, 4, 6, 10]. Gundlach et al. reported a mobility of 2.2 cm^2/Vs, and on/off current ratio of 10^8 for thermally evaporated pentacene-based OTFTs [6]. These values compare favorably with the conventional amorphous silicon-based TFT technology. In an effort to take the performance of small-molecular organic semiconductor-based OTFTs to even higher values, Gundlach et al. treated the dielectric substrate with octadecyltrichlorosilane (OTS) before deposition of the organic. This OTS pretreatment really did increase the device performance [86]. The predeposited OTS layer seems to increase the molecular order, which is beneficial for the transfer of charge carriers between molecules.

Another exciting application of plastic electronics is OLEDs, which was demonstrated during late 1980's by Kodak scientists [33] to be realistic candidates for display applications. Since then, the giants of the display industry have been eagerly investing a wealth of resources in this exciting field to acquire their shares of this growing market. Naturally, there are obstacles in this endeavor as well, such as device stability and efficiency, which need to be improved for high-end applications. These problems can be solved by developing new organic materials [87]. For this, one needs to have the necessary techniques to investigate possible candidates. One of the most challenging tasks in trying to find and investigate such materials is to understand and characterize the energy-level alignments of organic/metal, organic/organic interfaces that are involved in such devices. Substantial efforts worldwide have been made on the characterization of the alignment of the occupied and unoccupied states of those interfaces using different techniques [25–27, 88–97]. Scanning tunnel microscopy has long secured its position as a critical instrument to be used in the characterization of surfaces and interfaces [98–100]. Razafitrimo et al. [101] and Rasmusson et al. [102] have

employed STM and AFM to study the morphology of polymer films. Their study reveals nanometer-scale structures in polymeric LEDs caused by the substrate, polymer film, and top electrode. These nanostructures may significantly alter the local electric field and therefore profoundly affect the performance and lifetime of polymeric LEDs. Lidzey et al. used STM to induce electroluminescence on polymer films [103]. This might be very crucial for the realization of electrically pumped laser diodes. Electroluminescence can be generated by tunneling injection from an STM tip [104]. Electrons can tunnel from the tip directly into unoccupied states of polymer, and upon combination with holes injected from the anode, excitons are formed that can decay radiatively with the emission of light. Other SPM-related spectroscopy methods have also been used to study the organic and polymer semiconductors. Conventional scanning tunneling spectroscopy (STS) technique has helped researchers in getting the density of states (DOS) of materials [105, 106]. In STS, the feedback is turned off for the tip to scan at constant height. The bias voltage is then ramped, and the current is collected. One gets the DOS from the normalized conductance calculations. This way, energy as a function of the DOS is obtained. Scanning tunneling microscopy z-V spectroscopy, which is a relatively new technique [25–27, 107], on the other hand, probes the DOS via the voltage-dependant tip displacement at a constant tunneling current. It has the capability of providing direct access to molecular level alignments of the occupied and unoccupied states. This means that it is even possible to probe charge-carrier injection into optically forbidden electronic states. Figure 9 shows a schematic z-V spectrum of a thin film. Such a plot consists of three consecutive phases, indicated in Figure 9 as 1, 2, and 3. Under normal conditions, the tunneling resistance is much higher than the resistance of the organic layers. Charge-carrier injection takes place through the vacuum barrier into
Figure 9. Schematic drawing of an STM z-V curve (solid line). The dashed curve represents typical STM tip displacement measured for a clean metal substrate. E_{p-} and E_{p+} are the corresponding charge injection thresholds for electrons and holes, respectively, into polaronic states. E_{gsp} is the single-particle energy gap. Note that the slopes in region 2 are drawn depending on the polarity of the bias voltage. The above scheme represents a hole-conducting material, as the slope of z-V curve in the positive bias region is drawn to be higher than that in the negative bias region.

the organic material. This means that the applied bias voltage drops completely at the tunneling barrier. In phase 1, where each *z-V* run begins, the tip is biased at a potential difference high enough to ensure that the tip is above the surface of the organic film to avoid modifying or damaging the organic thin-film structure before the actual acquisition of data. As the magnitude of the bias voltage is decreased under constant current conditions, the tip moves toward the organic thin film until a characteristic threshold bias voltage is reached, at which point the tip makes an abrupt penetration into the film [107, 108]. This threshold voltage is approximately the LUMO level of the organic thin film. At this point, the Fermi level of the tip will be very close to the edge of the forbidden energy gap of the organic material. The tip will move down in a step-like fashion, by only one or two molecular spacings initially until full penetration (phase 2). The rate of penetration, dz/dV, is a measure of the mobilities of the electron and hole polarons. In fact, the average slope of *z-V* curves in phase 2 is directly proportional to the conductivity of the organic material which is being investigated. However, one should be prudent to note that the slope of the *z-V* curves can be influenced by different factors such as the potential drop within the organic material and the shape of the injection barrier and the sharpness of the tip. In addition, the charge-carrier mobility is a field-dependant quantity. As a result, the slope of a *z-V* curve could only be a qualitative measure of the local electron and hole polaron mobilities.

Another point to note is that the high electrical field across the organic layer causes band bending and the formation of a Schottky-like diode. The gradient of the electrical field strongly depends on the curvature of the injecting electrodes. Thus, the highest electrical field drop occurs at the STM tip apex. It will be the predominant site for charge-carrier injection into the organic thin film under ideal conditions. Finally, when the tunneling voltage is reduced to the value at which the Fermi level of the tip enters the forbidden energy gap at the interface with the metal electrode, the charge carriers are injected into the organic material (phase 3). The point at which this transition occurs determines the position of the lowest electron polaron state (E_{p-}) for negative bias voltages, or the highest polaron state (E_{p+}) for positive bias voltages.

Using STM *z-V* spectroscopy technique, Alvarado et al. were able to directly measure the electron and hole injection barriers [26], E_{p-} and E_{p+}, respectively, of some of the organic semiconductor materials, such as tris-(8-hydroxyquinoline) aluminum (Alq_3), phthalocyanine (CuPc), and (NPB), which are of potential use for OLED applications. From these measurements, together with the optical bandgap, they were able to calculate the single-particle energy gaps, E_{gsp}, and the exciton binding energies, E_b, of these materials. Furthermore, they were able to learn qualitatively about the local mobility of electrons and holes from the slopes of *z-V* curves.

We note that STM-based methods have been used extensively to study the organic semiconductor materials that are potential candidates to be used in OLEDs.

6. SUMMARY

In this article, we have described the principal growth modes of organic nanofilms on inorganic substrates with examples. We have shown that worldwide efforts are being made in trying to understand the growth dynamics of organic nanofilms. The application of scaling theories in understanding the mechanisms involved in the evolution of organic interfaces is especially noteworthy, considering the fact that the major efforts in applying such theories have been thus far focused on the study of the growth of inorganic thin films. We have seen that, generally, more than one growth mechanism is involved in organic nanofilm growth, which makes the topic at hand a challenging subject. However, encouraging and exciting results that are being obtained in improving the morphological, and hence, transport properties of organic nanofilms, are the impetus that derives this newly flourishing field.

Important and recent SPM-based characterization techniques, such as CP-AFM and *z-V* spectroscopy, have been discussed. These tools will contribute immensely to the investigation of organic materials by providing information about the structure, structure-transport, and electronic properties of these materials.

Many obstacles are on the road to fully utilizing the organic semiconductor nanofilms fully in organic device applications. Among these obstacles are charge-carrier speed—depending on how fast the device will operate—and the long-term device stability. Basic research of such issues will have potential benefits. In addition, organic electronics is an area closely intertwined with nanotechnology and molecular electronics, all of which might be the driving force for the next industrial revolution.

GLOSSARY

Atomic force microscope (AFM) A very high resolution microscope with a small stylus attached to a cantilever which in turn is attached to a piezoelectric scanner. As the cantilever is approached to the surface of a sample via the computer controlled piezoelectric scanner, it is bent due to the interatomic forces between the probe and the sample. The extent of the bending of the cantilever is detected via a laser that is being reflected off of the back of the cantilever, and is proportional to interatomic forces present. Appropriate mapping of these forces would give properties of the sample such as morphology, stiffness, viscoelasticity, etc., at very high resolution. Since AFM's operation principle involves interatomic forces, there is no restriction on the conductivity of the sample under investigation. It could be a conductor, semiconductor, or insulator.

Conducting-probe atomic force microscope (CP-AFM) If the probe used in AFM is a conducting one, then AFM can be used to perform electrical measurements. This system is known as conducting-probe AFM. It is also called conducting AFM.

Diffusion-limited aggregation (DLA) A famous cluster growth model. A seed particle is fixed in the center of the lattice, and another particle is released at some distant point traveling on the lattice in a random fashion. The meandering particle may either stick to the seed, or escape

to infinity. As more particles are released, the sticking probability will increase and an aggregate will start forming. The aggregate will have random branching due to the random nature of the process. This branching will prevent the newcoming particles to diffuse into the inner regions of the aggregate ending up with a wispy fractal structure.

Highly ordered pyrolytic graphite (HOPG) It is manufactured at around 3273 K. HOPG consists of highly oriented atomic layers of carbon. It is very smooth, easy to cleave, and non-polar. When used as substrate, it will provide favorable background with only carbon in the elemental signature. All of this makes HOPG a good candidate as a research material.

Kardar-Parisi-Zhang (KPZ) An nonlinear differential equation to describe a particular self-affine growth in which the growth direction is along the local surface normal.

Organic light emitting diode (OLED) A structure in which a hole transport layer and an electron transport layer are sandwiched between anode and cathode electrodes. Upon application of voltage across the terminals, the organic layer emits light. OLED, in comparison with its inorganic counterparts such as LED and liquid crystal display, has higher brightness, longer lifetimes, lower power consumption. Due to its organic nature, it is more robust, and can be made flexible as well.

Organic molecular beam epitaxy (OMBE) Deposition of highly ordered organic films by sublimating organic material from an oven. Contrary to the conventional inorganic MBE, organic MBE does not result in lattice-matched growth. Because organic lattice spacings are much larger than those of inorganic substrates. However, it is still possible to obtain well-ordered organic nanofilms by choosing the right substrate. This is known as quasi-epitaxial growth. The interaction between the substrate and the growing organic film must provide necessary mobility to the growing film and also have enough strength that the crystallinity of the substrate will be dictated into the growing film.

Organic thin film transistor (OTFT) A transistor whose active material is an organic semiconductor film the thickness of which is no more than about 5000 Å. It is crucial in implementing "all plastic electronics."

Physical vapor deposition (PVD) The particles are deposited by heating and evaporating the source material. The deposited particles can attach to the nearest neighbors of nucleated sites making the film dense and compact. In PVD, the growth is affected by the surface dynamics, such as surface and edge diffusion, step barrier effects, etc.

Scanning tunneling microscope (STM) A sharp metal tip is brought in close proximity of the conducting or semiconducting surface. When the tip is close enough to the surface but not yet touching, due to the quantum mechanical phenomenet of tunneling, there will be current flowing between the tip and the sample upon application of a small electrical potential. The magnitude of the current that will flow is exponentially dependent upon the distance between the tip and the sample surface. A very small change in the distance will produce significant change in the current. This in turn provides STM with remarkable sensitivity to the morphology of the sample. However, since the interaction parameter is current, only conducting and semiconducting materials can be studied with STM.

Vapor deposition polymerization (VDP) In a VDP process, the monomer from the gas phase condenses on the substrate and reacts to form high molecular weight polymer. Surface diffusion, intermolecular interaction, and chain relaxation can occur during growth.

Organic Polyradical Magnetic Nanoclusters

Andrzej Rajca

University of Nebraska, Lincoln, Nebraska, USA

CONTENTS

1. INTRODUCTION

In 1980, Lis reported Mn_{12} synthesis, structure, and magnetic susceptibility measurements for nanometer-sized $[Mn_{12}O_{12}(CH_3COO)_{16}(H_2O)_4]$ molecules [1]. Subsequent magnetic studies determined the $S = 10$ ground state ($S =$ total spin quantum number), primarily arising from uncompensated magnetic moment from antiferromagnetic interactions between eight $S = 2$ Mn^{III} and four $S = 3/2$ Mn^{IV} ions. (All spins of one valence point up and the remainder point down.) In 1993, a significant magnetic anisotropy barrier (ΔE_A) for reversal of magnetization ($\Delta E_A/k = 60$ K, $k =$ Boltzman constant), which manifested itself as magnetic hysteretic cycle at temperatures below 4 K, was found [2]. Because this hysteretic behavior is analogous to that for nanometer-sized magnetic particles or bulk magnets, except it is of purely molecular origin, the designation "single-molecule magnet" (SMM) was coined. Numerous organometallic molecules, based on Mn, Fe, Ni, Mo, W, etc., with large magnetic moments (S up to 5 1/2) were prepared but none of them had $\Delta E_A/k$ exceeding room temperature (or even 60 K for Lis' Mn_{12} cluster); also, selected nanoclusters showed non-negligible intermolecular interactions, which interfere with the SMM behavior [3, 4]. Thus,

significant obstacles remain in the development of molecule-based magnetic memories, based upon classical reversal of magnetization.

More recently, quantum effects in reversal of magnetization (tunneling of magnetization) were discovered for Lis' Mn_{12} and other related clusters; that is, steplike hysteretic cycles were found at temperatures below 4 K [5]. This quantum behavior, which is associated with greatly accelerated reversal of magnetization at certain applied magnetic fields, has attracted wide interest for both fundamental reasons and potential technological applications of SMMs in so-called quantum computing [6, 7].

The advances in transition metal ion based magnetic nanoclusters open an interesting question as to whether alternative sources of electron spin, such as organic radicals, could be used for SMMs. In this chapter, we will briefly summarize the selected aspects of magnetism of SMMs and then review two classes of organic radical-based nanometer-sized molecules: organometallic metal-radical nanoclusters and organic polyradicals.

2. PREREQUISITES FOR "SINGLE-MOLECULE MAGNET" BEHAVIOR

The magnetic anisotropy barrier (E_A) for inversion of magnetization (between up- and down-spin states) in a molecular cluster may be related to $S^2|D|$, where S is the total spin quantum number for the molecule and D is the axial zero-field splitting parameter for the molecule [8]. When E_A/k significantly exceeds the temperature (T) at which the experiment is carried out, the inversion of magnetization becomes slow on the experimental time scale; for example, for a relatively slow experiment, such as hysteretic cycle, $E_A/kT \approx 10$ is usually needed. Therefore, attaining relatively large values for E_A through optimization of S and D will be the primary goal. Furthermore, the energies associated with intermolecular interactions (E_{inter}) should be significantly

lower than thermal energies (i.e., $E_{inter} \ll kT$), to prevent bulk magnetic ordering interfering with the SMM behavior.

2.1. Total Spin Quantum Number *S*

Three generic coupling schemes for individual spins, associated with organic radicals and/or metal ions, and leading to large values of S are illustrated in Figure 1A. In the ferromagnetic scheme, all nearest neighbor pairs of individual spins are ferromagnetically coupled. Another coupling scheme relies on antiferromagnetic coupling of the nearest neighbor spins connected in such a way that the spins are not compensated, giving an overall value of $S > 1/2$. The third coupling scheme may be referred to as ferromagnetic (i.e., it relies on antiferromagnetic coupling of unequal spins). For all coupling schemes, the exchange coupling (ferromagnetic or antiferromagnetic) has to be sufficiently strong so the energy difference(s) between the high-spin ground state with the large value of S and the low-spin lowest energy excited states significantly exceeds the thermal energy (kT) at the temperature of the experiment.

Conceptually pairwise ferromagnetic and antiferromagnetic couplings may be visualized as transmitted through ferromagnetic coupling units (FCUs) and antiferromagnetic coupling units, respectively (Fig. 1B) [9, 10]. These coupling units may correspond to organic radical-metal linkage or, in polyradicals, the π-system bridging two nearest neighbor radical sites. For an $S = 1$ ground state diradical, such as a Schlenk hydrocarbon, a 1,3-phenylene FCU links two arylmethyl spin sites (Fig. 1B) [11]. A ferromagnetic coupling scheme may be implemented via connection in an alternating mode of the FCUs and the spin sites to provide polyradicals with $S = n/2$, where n is the number of spin sites [9, 10].

Ferromagnetic coupling is attained when the orbitals containing unpaired electron spins are orthogonal and coinciding in space [12, 13]. This situation is found in an $S = 1$ ground state diradical (Fig. 1B) with unpaired electron spins located in nearly degenerate, coinciding in space, and orthogonal molecular orbitals, which are characteristic of 1,3-phenylene moiety (an FCU). Other examples of strong and moderate ferromagnetic couplings are Cu^{II} (and Ni^{II}) complexes with *o*-semiquinone and Cu^{II} complexes with nitroxide in the axial position, respectively [14]. A ferromagnetic coupling scheme may be implemented via connection

in an alternating mode of the FCUs and the spin sites to provide polyradicals with $S = n/2$, where n is the number of spin sites [9, 10].

Antiferromagnetic coupling is associated with an effective overlap of nonorthogonal orbitals; thus, it may be viewed as a weak chemical bonding. This situation may be found in an $S = 0$ ground state diradical with 3,3'-biphenylene bridging two arylmethyl sites (Fig. 1B) [15]. Other examples of strong antiferromagnetic couplings are Mn^{II} complexes with nitroxides [14, 16, 17].

2.2. Zero-Field Splitting Parameter *D*

For a molecule with the ground state with $S \geq 1$, a splitting of its Zeeman energy levels in a zero applied magnetic field leads to anisotropy of magnetic properties, including a barrier for inversion of magnetization. Only states without first-order angular momentum will be considered; D is the axial zero-field splitting (ZFS) parameter, which is related to the principal value of the corresponding tensor **D**. There are two primary mechanisms for ZFS. The first mechanism involves coupling of the ground state with the excited states through spin–orbit coupling. The second mechanism involves magnetic dipole–dipole interactions. Of the two mechanisms, the spin–orbit coupling is capable of attaining much greater values of D than the magnetic dipole–dipole interactions. This is the situation found in selected transition metal ions, such as Mn^{III}, Ni^{II}, Cr^{III}, etc., in their numerous complexes [18, 19]. Jahn–Teller distortions may lead to large values of the parameter D for single ion. In derivatives of Mn_{12}, where single ion D is main contributor to the large value of D for the cluster, the relative phases of Jahn–Teller distortions for Mn^{III} have a large effect on the value of D of the cluster [20]. For a cluster, in which the exchange coupling is the dominant interaction between the ions, overall values of D for each state with a value of S can be derived from tensors **D** for single ions [14].

Because spin–orbit coupling is a relativistic effect, it is very small in the elements of organic molecules such as C, N, and O [18]. There are several methods for estimating values of D from classical magnetic dipole–dipole interactions [14]. Perhaps the most straightforward method involves indirect estimate of D through the shape anisotropy; this estimate is especially applicable to molecules or clusters with large numbers of approximately uniformly distributed and ferromagnetically coupled electron spins [21]. Such estimates may be applied to organic polyradicals [22].

3. MOLECULAR ORGANIC RADICAL-METAL NANOCLUSTERS

A plethora of organic radical-metal one-dimensional chains and extended networks, in which organic radicals act as bridging groups between the metal ions, leading to relatively large E_A and/or magnetic ordering are known. Organic radicals involved in such one-dimensional chains and networks are nitronyl nitroxides, [23, 24] di- and trinitroxides, [25] nitroxides with nitrogen base, [26] and pyridine-based photochemically generated carbenes [27–29].
Figure 1. (A) Coupling schemes leading to large net values of S. (B) Pairwise ferromagnetic and antiferromagnetic couplings in diradicals with $S = 1$ and $S = 0$ ground states, respectively.

Analogous molecular organic radical-metal nanoclusters, in which organic radicals act as bridging groups between the metal ions, are relatively scarce.

One of the pioneering examples of organic radical-metal nanoclusters is a macrocyclic $[Mn(hfac)_2NITPh]_6$ cluster with $S = 12$ ground state (hfac, hexafluoroacetyl acetonate; NITPh, 2-phenyl-4,4,5,5-tetramethyl-4,5-dihydro-1H-imidazolyl-1-oxy-3-oxide) [30]. In $[Mn(hfac)_2NITPh]_6$, the manganese(II) ions with $S = 5/2$ are antiferromagnetically coupled to $S = 1/2$ organic radicals (nitronyl nitroxides), resulting in an overall spin value of $6(5/2 - 1/2) = 12$. Both the oblate shape of the cluster and the small spin–orbit couplings associated with high-spin Mn^{II} (half-filled d-shell) and nitronyl nitroxide may contribute to its overall low magnetic anisotropy.

More recently, a $S = 7$ nanocluster, $[Fe_2(CN)_{12}Ni_3(IM-2Py)_6] \cdot 4H_2O$, in which two Fe^{III} and three Ni^{II} ions are bridged with cyanides and six organic radicals (IM-2py, 2-pyridyl substituted imino nitroxide), was reported [31]. The $S = 7$ value is accounted for by a weak ferromagnetic coupling between three high-spin $S = 2$ [Ni(IM-2-Py)$_2$] and two low-spin $S = 1/2$ [Fe(CN)$_6$] fragments. Below 1.2 K, magnetic hysteresis is observed, though magnetic relaxation studies reveal nonexponential time dependence and temperature dependence down to 0.05 K, precluding SMM behavior. Most likely, intercluster interactions are responsible for magnetic ordering.

[Mn$_{12}$] anion modified with organic radical cation, that is, salt of $[Mn_{12}O_{12}(PhCOO)_{16}(H_2O)_4]^-$ anion (Ph = phenyl) and $S = 1/2$ cation (*m-N*-methylpyridinium nitronylnitroxide), was found to undergo relatively fast inversion of magnetization; at 1.7 K, hysteresis was almost negligible compared to [Mn$_{12}$] anions with diamagnetic cations or the unmodified [Mn$_{12}$] [32]. Recent studies of analogous salts of [Mn$_{12}$] anion with $S = 1/2$ ferrocenium cation and related diamagnetic cations led to the conclusion that the counterion may have a direct influence on the E_A by affecting alignment of Jahn–Teller elongation axes of the eight Mn^{III} ions [33].

Synthesis of organic radical-metal ion clusters, and metal ion clusters in general, relies largely on finding the right mixture of the reagents that would produce a crystalline material suitable for X-ray crystallography. The development of self-assembly approaches to organic ligand-metal ion clusters provides hope for future rational syntheses of metal ion clusters of increasing size with predetermined magnetic properties [34].

4. NANOMETER-SIZED ORGANIC POLYRADICALS

Organic polyradicals (i.e., molecular organic radical-based nanoclusters) possess covalently linked organic radicals. Unlike metal-based nanoclusters, they are amenable to the rational stepwise syntheses, employing powerful methodologies of organic chemistry. Furthermore, powerful chromatographic techniques are available for fast purification of organic molecules; that is, those products and intermediates at each synthetic step, which are stable at ambient conditions, can be isolated and purified even from complex reaction mixtures. Such a rational synthetic approach

is especially important if clusters with specific values of S or particular shapes are sought. The major drawbacks of organic polyradicals include moderate, at best, stability of organic radicals. Also, single crystals for X-ray crystallography are relatively difficult to grow for large organic molecules (as opposed to metal-based clusters); the structural characterization of organic polyradicals is largely based upon spectroscopic (or scattering) techniques as applied to polyradicals and their synthetic intermediates.

From the viewpoint of magnetism, nanometer-sized organic polyradicals can be classified as possessing either weak or strong exchange coupling. The thermal energy at a readily accessible temperature of 2 K is designated as a relative measure of strength for exchange coupling. Thus, weak exchange coupling will imply that the $S = 1/2$ radicals are effectively noninteracting above a temperature of 2 K. The more interesting situation for the potential SMM behavior is the case of strong exchange coupling, implemented with one of the coupling schemes in Figure 1, leading to large values of S.

4.1. Nanometer-Sized Organic Polyradicals with Strong Exchange Coupling

Polyradicals with strong exchange coupling are primarily based upon a π-conjugated system mediating exchange coupling between the radicals. The majority of nanometer-sized π-conjugated polyradicals rely on the ferromagnetic coupling scheme, though the ferrimagnetic coupling scheme using unequal spins recently became important (Fig. 1) [35]. 1,3-Phenylene is by far the most dominant FCU. The most developed types of nanometer-sized organic polyradicals with strong exchange coupling are polyarylmethyls, polyphenylcarbenes, and polyphenoxyls.

4.1.1. Polyarylmethyls

Polyarylmethyls have long history dating to Gomberg's triphenylmethyl [36] and Schlenk and Brauns' hydrocarbon [11] reported in 1900 and 1915, respectively. In the 1990s, the first attempts at synthesis of nanometer-sized polyarylmethyls were made, using branched or dendritic connectivities of 1,3-phenylene FCUs and arylmethyls. However, values of S for such dendrimers with up to up to 31 arylmethyls did not exceed $S = 5$ [22, 37–39]. With increasing number of radicals per molecule, the generation of unpaired of electrons at the radical sites must approach perfection. Otherwise, even relatively small numbers of failures in generation of unpaired electrons (i.e., chemical defects) may disrupt π-conjugation, and consequently exchange coupling. The chemical defects may arise from incomplete oxidation of polycarbanion, protonation, or hydrogen transfer leading to Ar_3CH moieties, or reaction of radicals with excess of iodine giving Ar_3CI moieties [40, 41]. As illustrated for pentadecaradical **1** in Figure 2, a chemical defect at one of the inner radical sites will cut the π-conjugated system into noninteracting segments, with low values of S, for example, a mixture of $S = 3/2, 3/2, 8/2$ vs $S = 15/2$ for a "perfect" **3** with all 15 radicals intact and ferromagnetically coupled [22]. Another type of defect involves severe out-of-twisting of the π-conjugated system, which may lead to antiferromagnetic

coupling through the twisted linkage; such a defect in the inner part of **1** could severely reduce the overall value of S in the twisted conformation (Fig. 2) [35, 42, 43].

Another approach relied on dendrimers with macrocyclic cores, such as 24-radical **2** (Fig. 3) [44–47]. The macrocyclic core provides the second exchange pathway, preserving exchange coupling in the presence of one chemical defect located at one of the four inner radical sites. Overall, 24-radical **2** possess only four radical sites (those adjacent to biphenyl moieties), where a defect would interrupt exchange coupling. The ferromagnetic coupling scheme is implemented in 24-radical **2** using two types of FCU: 1,3-phenylene and 3,4′-biphenylene. Model studies showed that the pairwise ferromagnetic couplings mediated by 1,3-phenylenes (within the dendritic branches and the macrocyclic core) are significantly stronger than those mediated by four 3,4′-biphenylenes (between the branches and the core) [45, 48]. Therefore, 24-radical **2** may be viewed as a cluster of five component spins, 5/2, 5/2, 5/2, 5/2, 4/2, associated with the branches and the core. Magnetic studies corroborate this pentamer model, though the average value of $S = 10$ is below the expected $S = 12$ for a 24-radical with 24 ferromagnetically coupled unpaired electron spins. A small density of chemical defects may account for this discrepancy in the values of S [47]. Alternatively, the presence of conformations, in which one or two dendritic branches are significantly out-of-plane twisted at the biphenylene moieties, may decrease the overall value S too because of antiferromagnetic coupling between the twisted branch and the core.

Synthetic precursor to 24-radical **2** (i.e., polyether **3**) was employed to obtain the size and shape estimate (**2** is obtained from **3** by replacing 24 triarylmethyl ether, $Ar_3C–OCH_3$, groups with 24 triarylmethyl radicals, $Ar_3C•$, through a two-step sequence of chemical transformations) [47]. The fast atom bombardment mass spectrum shows the expected molecular fragment ion corresponding to the loss of one OCH_3 group; the isotopic multiplet fits well with the expected $C_{503}H_{589}O_{23}$ formula for the $[M–OCH_3]^+$ ion [47]. Small angle neutron scattering (SANS) for **3** in tetrahydrofuran-d$_8$ (THF-d$_8$) gives a radius of gyration $R_g = 1.38$ nm (Table 1). Preliminary numerical fitting of the SANS data using simulated annealing programs suggests an

approximately dumbell-like shape. Similar values of R_g and analogous shapes are found for hydrocarbon **4**, though carbopolyanion **5** has relatively large R_g, presumably due to increased solvation. Assuming similar shapes for 24-radical **2** and its derivatives **3–5**, and approximating them with a prolate spheroid with half-axes of 2 and 1 nm, shape anisotropy based $E_A/k \approx 0.06$ K is estimated for $S = 12$ (Fig. 3).

Further evolution of dendritic architecture is illustrated by 36-radical **6**, which possesses macrocyclic branches and a macrocyclic core; that is, five calix[4]arene macrocycles are linked with four bis(biphenylene)methyls (Fig. 4) [35, 49]. The macrocycles provide additional exchange pathways; 36-radical **6** has only four radical sites (those bridging biphenylene moieties), where a defect would interrupt exchange coupling. The exchange coupling within the π-system of **6** may be described in terms of strong 1,3-phenylene FCUs and weak 3,4′-biphenylene FCUs, which connect radical sites within macrocycles and outside macrocycles, respectively. Therefore, **6** may be viewed as a cluster of nine component spins, associated with the macrocyclic branches ($4 \times 7/2$), the linkers ($4 \times 1/2$), and the macrocyclic core (4/2) (Fig. 4). The component spins are exchange coupled through the weak 3,4′-biphenylene FCUs. Notably, the nearest neighbor component spins have significantly unequal values (i.e., component spins 1/2 are located between the

Figure 2. Polyarylmethyl dendritic pentadecaradical **1** and possible defects (D): missing unpaired electron (top) and large out-of-plane twisting (bottom).
Figure 3. Polyarylmethyl dendritic-macrocyclic 24-radical **2** and its diamagnetic derivatives.
Figure 4. Polyarylmethyl macrocyclic–macrocyclic 36–radical **6** and its diamagnetic derivative.

larger spins of 7/2 and 4/2). Consequently, large out-of-plane distortion at the biphenylene moieties, leading to antiferromagnetic coupling between component spins, could be expected to lower the overall value of S only moderately. Magnetic studies show an average $S \approx 13$ for **6**, below the expected $S = 18$ for a 36-radical with 36 ferromagnetically coupled unpaired electron spins [49].

SANS for a polyether **7** (synthetic precursor to 36-radical **6**) in THF-d_8 gives a radius of gyration $R_g = 1.81$ nm (Table 1). Assuming that the shape for 36-radical **6** is a prolate spheroid with $a/b = 2$, analogous to that in 24-radical **2**, shape anisotropy based $E_A/k \approx 0.09$ K is estimated for $S = 18$ (Fig. 4).

The alternating connectivity of unequal spins was applied to polyarylmethyl polymers **8** and **10** by linking calix[4]arene with bis(biphenyl)methyls (Fig. 5). Polymer **8** had an average value of $S \approx 18$ (Fig. 6). SANS and multiangle light scattering (MALS) studies showed that the corresponding polyether **9** had $R_g = 3.2$ nm and $M_w \approx 30$ kDa. Polymer **10** possessed even higher values of S that depended on the polymerization conditions leading to the corresponding polyether **11** (Fig. 5). The benzene soluble fractions of
Figure 5. Polyarylmethyl polymers **8** and **10** and their diamagnetic derivatives.

polyethers **11** with $M_w = 300$–500 kDa gave polymers **10** with average values of $S > 40$ [50]. SANS studies gave $R_g \approx 9$ nm for benzene-soluble polyethers **11**. The benzene insoluble fractions of polyethers **11**, which were polymerized for a long time beyond the gel point, gave polymers **10** with average values of $S \approx 5000$ (Fig. 6). Polymers **10** with $S \approx 5000$ showed the onset of magnetic ordering near the temperature of 10 K. The blocking behavior for the inversion of magnetization is analogous to that in insulating spin glasses and blocked superparamagnets but closer to spin glasses [51].

In conclusion for polyarylmethyls, polyradical **10** showed magnetic ordering and slow inversion of magnetization below a temperature of about 10 K. Whether this magnetic behavior is associated with single macromolecules is difficult to establish because of the insoluble network nature of **10**. For the soluble polyradicals **2**, **6**, and **8**, possessing $S = 10$–18, magnetic studies in the miliKelvin range would be needed to search for SMM behavior (slow inversion of magnetization) due to the shape anisotropy. The requirements for sample handling with present state-of-the-art microSQUID techniques would make such studies
Figure 6. Plot of reduced magnetization (M/M_{sat}) vs the ratio of applied magnetic field and temperature (H/T) for polymers **8** and **10** with an average $S \approx 18$ and $S \approx 5000$, respectively.

difficult because such polyarylmethyls decompose above 170 K and are sensitive to oxygen. Polyradicals with stability at ambient conditions, in which triarylmethyl radicals are replaced with more stable radicals such as nitroxides, would be desirable for such studies.

4.1.2. Polyphenylcarbenes and Other Organic Polyradicals with Significant Values of S

In addition to polyarylmethyls, very few organic polyradicals are known, in which significant values of S have been achieved. Those include polyphenylcarbenes, trimethylenemethanes, aminium-based polyradicals, and polyphenoxyls. Among those, polyphenoxyls stand out because of their size characterization by microscopy and relative thermal stability.

Iwamura and co-workers prepared numerous polyphenylcarbenes with large values of S; the leading example is the $S = 9$ nonacarbene **12**, which was prepared from the corresponding nona-diazo precursor **13** (Fig. 7) [52–56]. The solid state photolysis of the diazo precursors, such as **13**, is reported to proceed essentially quantitatively for molecules with up to nine diazo groups, providing polyphenylcarbenes with significant values of S, as shown in Figure 7. Attempts to prepare polyphenylcarbenes with more than nine carbene centers were not successful [56]. For **12** and the related polyphenylcarbenes, the ferromagnetic coupling scheme, using 1,3-phenylene and 1,3,5-phenylyne as FCUs, is implemented in the star-branched structure of nine $S = 1$ carbenes. Although the initial report on **12** suggested the possibility of slow inversion of magnetization below 5 K for **12** in 2-methyltetrahydrofuran (2-MeTHF), [53] it is most likely that slow interconversion between conformations with
different values of S is involved, as observed in organic diradicals in 2-MeTHF matrices [57, 58].

Polyphenylcarbenes, such as **12**, are extremely reactive and typically have to generated in frozen matrices below 77 K. Recently, more stable $S = 1$ carbenes were prepared; for example, **14** and **15** have a half-life of 16 s and 19 min in degassed benzene at room temperature, respectively (Fig. 8) [59, 60]. For **15**, this fair persistence may be derived from its triphenylmethyl-like structure. These values of half-life are several orders of magnitude longer than the half-life of 2 μs for the parent diphenylcarbene under the same conditions. Polycarbenes derived from those relatively stable carbenes are still rare. The leading example is the $S = 3$ tricarbene **16**, which is generated from the corresponding tris(diazo) derivative **17** and characterized by two-dimensional electron paramagnetic resonance (EPR) spectroscopy (Fig. 8) [61].

Dougherty and co-workers developed a so-called "bisTMM" (TMM = trimethylenemethane) approach to design and prepare numerous $S = 2$ tetraradicals [62–65]. Their ferromagnetic coupling scheme employs 1,3-phenylene, cyclobutane, or cyclopentane as FCU (Fig. 9). More recently, this approach is extended to an $S = 3$ hexaradical, with 1,3,5-phenylyne and cyclopentane as FCUs (Fig. 9). [66–68] In each case, the polyradical is prepared by ultraviolet photolysis of the corresponding bis- or tris-azoalkanes at cryogenic temperatures; typically, efficient and complete conversions are difficult to attain, resulting in mixtures of polyradicals from the successive loss of dinitrogen. The resultant mixtures of polyradicals are quite unstable requiring handling in frozen matrix at temperatures of 77 K or below. Magnetic characterization of these tetra- and hexaradicals is limited to EPR spectroscopy.

Bushby and co-workers prepared aminium based polyradicals; the leading example is polyradical **18** with an average value of $S \approx 4$ at temperatures below 10 K (Fig. 10) [69]. The ferromagnetic coupling scheme in **18** relies on the FCU composed of 1,3-phenylene and two 1,4-phenylene spacers; this rather long coupling pathway results in a relatively weak ferromagnetic coupling. Polyradical **18** was generated from the corresponding polyamine **19** with $M_w > 10$ kDa; no size measurements are reported [69].

Polymeric aminium-based polyradicals may be viewed as examples of the "polaronic" approach to organic polymers with large values of S, in which the source of electron spin is

relatively localized aminium radical cations [70]. Dougherty and co-workers examined various polymers and oligomers, in which short fragments of the π-system are linked together with 1,3-phenylene couplers. The studied π-systems include radical cations of polyacetylene, radical cations of aromatic heterocycles, and radical anions of fuchsone (Fig. 10). The variable values of S up to 3 were reported for such polymers [71, 72]. However, only electrochemically generated fuchsone-based radical anions (polymer **20** with $S \approx 2$) have significant concentration of electron spin (0.5 radical per repeat unit) [72]. Radical ion based polymers are generally stable at room temperature. Their main drawbacks are complicated ion multiplet equilibria and tendency for formation of diamagnetic aggregates [73–75].

Nishide and co-workers prepared many examples of polyphenoxyls with significant values of S (up to 5) (Fig. 11) [76–80]. The leading example is polyphenoxyl **21**, which possesses an average value of $S \approx 5$ at low temperatures below 10 K (Fig. 11) [80]. The ferromagnetic coupling scheme in **21** is implemented using phenoxyl pendants attached to the poly(1,2-phenylenevinylene) FCU. Polyphenoxyl **21** was obtained from the corresponding polyphenol **22** ($M_w \approx 32$ kDa, $M_w/M_n \approx 1.2$). Dichloromethane solutions of **21**

and **22** are transferred to a highly oriented pyrolitic graphite surface and examined with atomic force microscopy (AFM), followed by magnetic force microscopy (MFM). Notably, both AFM and MFM studies are carried out at ambient temperature (i.e., polyphenoxyl **21** has a value of $S = 1/2$, corresponding to an ensemble of a large number of independent $S = 1/2$ electron spins, at these conditions). AFM images for **21** and **22** are similar (i.e., the horizontal distance of 35 nm and the vertical distance of 0.6 nm are determined). The follow-up MFM images, using a tip coated with ferromagnetic CoCr film (magnetic moment of 10^{-13} emu), are observed only for paramagnetic **21**, with the 35-nm size analogous to the AFM images. The MFM contrast weakens and ultimately disappears following slow decomposition of paramagnetic polyphenoxyl **21** to the undetermined (perhaps diamagnetic) products after one day; however, the 35-nm sized image of the decomposition products remains visible in AFM even after one week [80]. The detection limits for MFM for small paramagnetic moments and the effects involved in magnetization of the tip in the opposite direction as found for this $S = 1/2$ paramagnet will need more detailed analysis. If confirmed, these preliminary MFM results may open the way for organic polyradical-based magnetic dots.

4.2. Nanometer-Sized Organic Polyradicals with Weak Exchange Coupling

In organic polyradicals with weak exchange coupling, the energy level splitting due to the exchange coupling is smaller than the thermal energy (RT) at the readily accessible temperatures down to 2 K. Such polyradicals possess a value of $S = 1/2$ above temperature of 2 K. The barrier for inversion of magnetization for $S = 1/2$ paramagnets will be very low if not absent [8].

The magnetic susceptibility for a paramagnetic polyradical with a large number (n) of $S = 1/2$ electron spins scales with n as approximately n^2 and n for the strong and the weak
Figure 12. Third generation of nitroxide-functionalized poly(propylene imine) dendrimer DAB-dendr-(PROXYL)$_{16}$ and sixth generation PAMAM dendrimer functionalized with 198 nitroxides (G-6-TEMPO-198).

ferromagnetic couplings, respectively. Therefore, even in the absence of large values of S, the magnetic susceptibility for an $S = 1/2$ polyradical with n weakly coupled (effectively independent) $S = 1/2$ electron spins will still be greater by a factor of n than that for a single $S = 1/2$ monoradical. This is the situation for polyphenoxyl **16**, which is weakly coupled at ambient temperature but still reported as detectable at ambient temperature by the current MFM technology [80].

The review of nanometer-sized weakly coupled polyradicals will be limited to well-defined dendrimers. Janssen and co-workers reported five generations of nitroxide-functionalized dendrimers, with up to 64 nitroxide radicals [81]. Poly(propylene imine) dendrimers were functionalized with 3-carboxy-2,2,5,5-tetramethyl-1-pyrrolidinyloxy radical (PROXYL) end groups [DAB-dendr-(PROXYL)$_n$] (Fig. 9). Because DAB-dendr-(PROXYL)$_n$ dendrimers are prepared via divergent synthetic routes, substantial contamination with nonseparable dendrimers with a smaller than nominal number of PROXYL end groups, especially for higher generations, is expected. Already for intermediate generations with $n = 8$ and $n = 16$ PROXYLs, the matrix-assisted laser desorption ionization time-of-flight (MALDI-TOF) mass spectra showed the impurity mass peaks corresponding to dendrimers with $n = 7$ and $n = 15$ PROXYLs. The EPR spectra in solution were consistent with the presence of a weak but detectable exchange coupling, as shown by the hyperfine splitting patterns for the lowest generations [81].

Few examples of poly(amidoamine) (PAMAM) dendrimers, functionalized with spin carrying end groups (radicals or radical ions), have been reported [82–84]. Because PAMAM dendrimers are prepared according to divergent synthetic routes, significant contamination with incompletely end-functionalized dendrimers is expected. In particular, the commercially available sixth generation PAMAM (G-6 PAMAM^{TM}) dendrimers possess oblate spheroidal shape with nominally 256 amine end groups on the surface of the macromolecule.

Miller and co-workers reported a conducting film formed from a PAMAM dendrimer that had been functionalized with naphthalene diimide radical anions [82]. The defects in these modified dendrimers prepared according to divergent synthetic routes were not estimated. The radical anions of this type are known to form conducting π-stacks, rendering the dendrimer effectively diamagnetic. In high humidity, the third generation dendrimer had conductivities in the 0.12–11 S cm^{-1} range depending on the content of radical anions vs nonreduced diimide moieties [82].

PAMAM dendrimers with relatively low densities of nitroxide radical end groups for their studies in vesicles are known. For example, the sixth generation dendrimer (G-6 PAMAM^{TM}, diameter of 7 nm from dynamic light scattering) was functionalized 2,2,6,6-tetramethylpiperidine-N-oxyl (TEMPO) with only 3% conversion of the amino end groups [83].

Much higher densities of radicals are reported in a polynitroxyl G-6 PAMAM^{TM} with 198 (G-6-TEMPO-198) or with 80 (G-6-TEMPO-80) TEMPO end groups for possible applications in EPR imaging [84]. MALDI-TOF mass spectra showed the expected mass averages for G-6-TEMPO-198 and G-6-TEMPO-80, with a difference of about 1 kDa between the number and weight averages for both dendrimers. One of the possible drawbacks for their application as intravenous contrast agents may be their affinity for aggregation in aqueous solution because of the relatively lipophilic surface for the nitroxyl labeled dendrimers. MALS analyses identify particles with an average molecular weights of 549 kDa (degree of aggregation $\approx$ 5.4, radius of gyration $\approx$ 19 nm) and 113 kDa (degree of aggregation $\approx$ 1.6, radius of gyration $<$ 10 nm) for G-6-TEMPO-198 and G-6-TEMPO-80, respectively [84].

Octaferrocenyl dendrimer (with ethylene silane backbone) was reported to undergo 8-electron oxidation to the corresponding dendrimer with eight ferrocenium radical cations. However, neither the exchange coupling between the radical cations nor the size of this relatively low molecular mass dendrimer were characterized [85].

5. SUMMARY

The development of rational synthetic methods for organic radical-metal ion nanoclusters may provide a new library of organometallic SMMs with predetermined magnetic properties. Through incorporation of di- and polyradicals into such nanoclusters, SMMs responsive to the external stimuli may be designed (e.g., photomagnetic SMMs).

The rational synthetic methods for the unstable organic polyradicals should be extended to the ambient stable organic polyradicals with large values of S and elongated

shapes. This will greatly facilitate the search for organic SMMs. Intriguing questions will be whether the magnetic anisotropy barrier arising from purely classical magnetic dipole–dipole interactions could be achieved and whether quantum tunneling of magnetization could be observed in such magnetic nanoclusters.

GLOSSARY

Exchange coupling or exchange interaction The interaction between electron spins that originates from a quantum exchange term of the Coulomb interaction between electrons. Although electrostatic in its origin, the exchange coupling is one of the key aspects of magnetism.

Magnetic nanocluster Nanometer-sized cluster of magnetic metals, metal ions, or other magnetic subunits.

Organic polyradical Organic molecule that possesses more than several unpaired electrons.

Single-molecule magnet (SMM) Individual molecule that functions as a nanoscale magnet, effectively a single domain magnetic particle that shows magnetic hysteresis below its blocking temperature.

Organic Thin Film Deposition Techniques

M. C. Petty

University of Durham, Durham, United Kingdom

CONTENTS

1. INTRODUCTION

The success of many nanotechnology ideas will depend on the ability to process and pattern ultrathin films (1–100 nm in thickness). Techniques such as spin-coating, thermal evaporation, and chemical vapor deposition are routinely used for the fabrication of electronic and optoelectronic components where the nanoscale is not yet critical [1–7]. Organic compounds are becoming increasingly useful to the electronics industry, although, for fast and efficient signal processing, it is unlikely that these materials will outperform inorganic semiconductors such as silicon and gallium arsenide in the foreseeable future. However, in niche areas, organic compounds can have significant advantages over their inorganic counterparts. Perhaps the best known example is the liquid crystal display. Organic and biological compounds are also being exploited in chemical sensors, light-emitting displays, photocopiers, and infrared detectors [8]. The field of plastic electronics is developing rapidly for the fabrication of low-cost electronic components for use where high-speed operation is not essential, for example, in smart cards.

In their bulk form, many organic materials are difficult to handle and single crystals can be extremely fragile. The ability to form high-quality thin layers of these materials can therefore present particular difficulties. Here, an overview of the methods that can be used is presented. Emphasis will be given to those techniques that can be used to build up thin films of organic molecules at the molecular level (i.e., film

thicknesses of a few nanometers). Such molecular engineering approaches offer much scope for the development of *molecular and nanoscale electronics* [8].

2. LANGMUIR–BLODGETT FILM DEPOSITION

A method that allows the manipulation of materials on the nanometer scale is the Langmuir–Blodgett (LB) technique [9–12]. Langmuir–Blodgett films are prepared by first depositing a small quantity of an amphiphilic compound (i.e., one incorporating both polar and nonpolar groups— the classical materials being long-chain fatty acids), dissolved in a volatile solvent, onto the surface of purified water, the subphase. When the solvent has evaporated, the organic molecules may be compressed to form a floating two-dimensional solid. Monolayer films can exhibit a multiplicity of phases during this compression; these are similar to the mesophases shown by liquid crystals.

The surface pressure Π of the floating organic film is defined as the reduction of the subphase surface tension by the film, that is,

$$\Pi = \gamma_0 - \gamma \qquad (1)$$

where γ_0 is the surface tension of the pure subphase and γ is the surface tension of the film-covered surface. In the case of a water subphase (almost all the work on LB films has involved a water subphase), values of Π of the order of mN m^{-1} are generally encountered; the maximum value of Π is 72.8 mN m^{-1} at 20 °C, the surface tension of pure water.

Figure 1 shows a surface pressure versus area isotherm (i.e., measurement at constant temperature) for a hypothetical long-chain organic material. This generic diagram is not meant to represent that observed for a particular substance, but shows most of the features observed for long-chain compounds. In the "gaseous" state (G in Fig. 1) the molecules are far enough apart on the water surface that they exert little force on one another. As the surface area of the monolayer is reduced, the hydrocarbon chains will begin to interact. The "liquid" state that is formed is generally called the expanded monolayer phase (E). The hydrocarbon chains
Figure 1. Surface pressure versus area isotherm for a long-chain fatty acid material.

Figure 2. Langmuir–Blodgett film deposition: (a) condensed monolayer on water surface; (b) transfer of monolayer on upstroke of solid substrate; (c) subsequent transfer on downstroke; (d) Y-type multilayer film.

of the molecules in such a film are in a random, rather than a regular orientation, with their polar groups in contact with the subphase. As the molecular area is progressively reduced, condensed (C) phases may appear; there may be more than one of these. In the condensed monolayer states, the molecules are closely packed and are oriented with the hydrocarbon chains pointing away from the water surface. The limiting area per molecule in such a state will be similar to the cross-sectional area of the hydrocarbon chain, that is, approximately 0.19 nm^2 molecule^{-1}.

If the surface pressure of the monolayer is held constant in one or more of the condensed phases, then the film may be transferred from the water surface onto a suitable solid substrate simply by raising and lowering the latter through the monolayer–air interface. Monolayer transfer speeds are usually of the order of a few millimeters per second. Several deposition modes are possible depending on the interactions between the polar and nonpolar parts of the molecules, and the nature of the bond between the first layer and the substrate surface. Figure 2 shows the most common form of LB film deposition. The substrate is hydrophilic and the first monolayer is transferred, like a carpet, as the substrate is raised through the water (Fig. 2b). Subsequently, a monolayer is deposited on each traversal of the monolayer–air interface (Fig. 2c). As shown, these stack in a head-to-head and tail-to-tail pattern; this deposition mode is called Y-type (Fig. 2d). Although this is the most frequently encountered situation, instances in which the floating monolayer is only transferred to the substrate as it is being inserted into the subphase, or only as it is being removed, are often observed. These deposition modes are called X-type (monolayer transfer on the downstroke only) and Z-type (transfer on the upstroke only); the molecular arrangements in Z-type and Y-type films are contrasted in Figure 3. Mixed deposition modes are sometimes observed and, for some materials, the deposition type can change as the LB film is built up. Film transfer is characterized by the measurement of a deposition, or transfer, ratio, τ. This is the decrease in the area occupied by the monolayer (held at constant pressure) on the water surface divided by the coated area of the solid substrate, that is,

$$\tau = \frac{A_L}{A_S} \quad (2)$$
where A_L is the decrease in the area occupied by the monolayer on the water surface and A_S is the coated area of the solid substrate. Transfer ratios significantly outside the range 0.95 to 1.05 suggest poor homogeneity. Fatty acid and fatty acid salt (obtained by the addition of metallic cations, such as Cd^{2+}, to the aqueous subphase) monolayers normally deposit as Y-type films. However, X-type deposition is possible with suitable changes in the dipping conditions; X-type deposition is favored by high pH values.
Figure 3. Molecular arrangements for LB molecular assemblies: (a) Z-type deposition; (b) Y-type deposition; (c) alternate-layer deposition.

It is possible to construct LB films using more than one type of molecular film. In the simplest case, condensed floating monolayers of two different amphiphilic materials are confined (using mechanical barriers) to different regions of the water surface. By lowering the solid substrate through the first layer of, say, material A, and raising it up through the other, material B, alternate layers of structure ABABAB... may be built up, Figure 3c. This permits the fabrication of organic superlattices with precisely defined symmetry properties. Such molecular assemblies can exhibit pyroelectric (electric charge generation on heating), piezoelectric (charge generation on the application of a mechanical stress), and second-order nonlinear optical phenomena (frequency doubling) [9, 10, 13].

The final molecular arrangement in an LB layer may not be always as depicted in the "molecular stick" diagrams. For fatty acids, early experiments using X-ray diffraction revealed that the spacings between the hydrophilic head groups was nearly the same, and equal to twice the length of the hydrocarbon chain, whether they were deposited as X-type or Y-type films. This suggests that the molecules in some LB films rearrange, during or shortly after deposition [9].

Although fatty acids and their salts are the "classical" materials for LB film formation, much activity has focused on the incorporation of electroactive groups into such long-chain compounds. Some examples are depicted in Figure 4. Charge-transfer materials, such as the N-octadecylpyridinium-Ni(dmit)$_2$ complex, are important organic conductors. These are formed from a variety of molecules, primarily aromatics that can behave as electron donors (D) and electron acceptors (A) [8]. Complete transfer of an electron from a donor to an acceptor molecule results in a system that is electrically insulating (e.g., the transfer of a valence electron in a Cl atom to a Na atom to form the compound NaCl). However, if the ratio of the number of donor molecules to the number of acceptor molecules differs from 1:1 (e.g., the stoichiometry is 1:2 or

2:3), or if there is incomplete transfer of an electron from a donor to an acceptor (say, six electrons in every ten donor atoms are transferred), then partially filled electron bands can be formed and electrical conduction is possible.

Well-known donor and acceptor molecules are tetrathiafulvalene (TTF) and tetracyanoquinodimethane (TCNQ), respectively. A 1:1 TCNQ:TTF salt exhibits a high room-temperature conductivity (5×10^4 S m^{-1}) and metallic behavior is observed as the temperature is reduced to 54 K (i.e., the conductivity increases with decreasing temperature). The molecules in such compounds are arranged in segregated stacks, in which donors and acceptors form separate donor stacks (DDDDD...) and acceptor stacks (AAAAA....). The possibility of imitating this structural arrangement in multilayer LB films has resulted in the synthesis of many amphiphilic derivatives of TTF and TCNQ and related compounds [14]. The organometallic Ni(dmit)$_2$ compound shown in Figure 4 is an electron acceptor. The long-chain pyridinium counterion allows this compound to form an insoluble layer at the air–water interface and to be built up as a multilayer structure using the LB technique [15]. Following iodine doping, a relatively high in-plane conductivity (10^2–10^3 S m^{-1}) is observed. Such thin films show electrical behavior associated with inorganic semiconductors and can be used as the basis of a field effect transistor (FET) device [16]. Although the carrier mobility (carrier velocity per unit applied electric field) is much lower in these devices than in single crystalline silicon or gallium arsenide, the values are comparable to those found in amorphous silicon and auger well for the development of devices that can be processed using low-cost methods. Metallic behavior (i.e., conductivity decreasing with increasing temperature) has also been reported in LB films based on the electronic molecule bis(ethylenedioxy)tetrathiafulvalene (BEDO-TTF) [17, 18]. The results of low-temperature conductance and magnetoconductance experiments have been interpreted in terms of a weakly localized two-dimensional electronic system formed in the conducting donor layers. Other relevant electroactive materials that can be manipulated by the LB technique have been based on fullerene derivatives [19] and on carbon nanotubes [20, 21]. In the latter case, the nanotubes were either mixed with surfactant molecules or grafted with poly(ethylene oxide) to form condensed floating films.

An intriguing possibility is that of observing molecular rectification using monolayer or multilayer films. This follows from the prediction of Aviram and Ratner [22] that an asymmetric organic molecule containing a donor and acceptor group separated by a short σ-bonded bridge (allowing quantum mechanical tunnelling) should exhibit diode type characteristics. There have been many attempts to obtain this effect in LB systems [9]. Asymmetric current versus voltage behavior has certainly been recorded for many metal–LB film–metal structures, although the results have often been open to several interpretations because of the asymmetry of the metallic electrodes and the presence of oxide layers. However, data obtained using gold for both electrodes suggests that molecular rectification can be observed using appropriate LB films of charge-transfer complexes [23, 24].

Hemicyanine dye

Polyaniline
Figure 4. Examples of amphiphilic organic compounds suitable for LB film deposition.

As noted above, an area of interest is the fabrication of asymmetric nanostructures that exhibit second-order nonlinear optical effects. The hemicyanine dye shown in Figure 4 is an example of a compound that has been extensively investigated in this respect. The molecule possesses both donor and acceptor groups separated by a conjugated π-electron system; the long hydrocarbon chain facilitates molecular alignment on a water surface. By alternating the hemicyanine dye with a "spacer" molecule (e.g., a simple fatty acid) or with a compound with a complementary donor–acceptor configuration (i.e., a similar compound, but with the donor moiety positioned adjacent to the hydrocarbon chain), an LB film may be assembled that exhibits significant second harmonic generation [25]. Some LB film materials may be built up to over a hundred layers in thickness, where they might be suitable for use in electro-optic devices [9, 26].

A further field of endeavor is that of chemical sensors [27–29]. Gas detectors with high sensitivity, reversibility, and appropriate selectivity continue to be sought for process control and environmental monitoring. For most gas sensors, advantages accrue by using the sensing element in thin film form (not least, the high surface-to-volume ratio). A simple sensor exploits the variation of electrical resistance of a thin layer of gas-sensitive material, for example, a phthalocyanine or conductive polymer. The conductivity of such organic semiconductors changes in the presence of oxidizing or reducing agents. The effect is analogous to the doping of an inorganic semiconductor, such as silicon, with acceptor or donor impurities. A problem associated with these chemiresistor devices is that the resistance of the organic layer is usually very high. Consequently, the output currents are low (typically picoamperes), requiring elaborate detection electronics and careful shielding and guarding of components. This difficulty may be overcome by incorporating the organic sensing layer into a diode or field effect transistor [29].

An optical transduction method that is often used with ultrathin films, such as LB films, is that of surface plasmon resonance [30, 31]. Surface plasma waves are collective oscillations of the free electrons at the boundary of a metal and a dielectric. These can be excited by means of evanescent electromagnetic waves. This excitation is associated with a minimum in the intensity of the radiation reflected from the thin film system, called surface plasmon resonance (SPR). The sensitivity of SPR is noteworthy, and changes in refractive index of 10^{-5} may be monitored; thus the technique compares favorably with ellipsometry. The method has been used with LB films to provide both gas detectors [29] and sensors for metal ions in solution [32].

One criticism that is often levelled at the LB approach is that the amphiphilic compounds necessary for film formation are not particularly stable. Long-chain fatty acid type materials possess relatively low melting points and have poor mechanical properties. Furthermore, the incorporation of a long hydrocarbon chain can "dilute" the electroactive part of the molecule. Certain LB film materials, however, such as phthalocyanines, other dyes, and polymers (see next paragraph), can be deposited without the need for long aliphatic chains [33, 34], although the molecules of such compounds may not possess a high degree of order when deposited as LB multilayers.

Improvements in film stability can be achieved by using polymeric materials. There are broadly two different methods available to produce polymeric multilayer structures [9]. First, a monomeric amphiphile, which can be deposited using the LB approach, can be used. The molecules in the LB film can then be cross-linked, for example by exposure to ultra-violet radiation. An alternative is to build up LB films from a polymeric monolayer, that is, a preformed polymer. In some cases, it is not necessary to use a "traditional" LB material, for example, a long chain with hydrophilic and hydrophobic terminal groups. Rod-type preformed polymers, based on porphyrins or phthalocyanines, can undergo self-organization on the water surface. During the LB transfer, the long axes of the rods are preferentially aligned parallel to the dipping direction so that oriented multilayers with nematic-like order are formed [9]. Figure 4 shows an example of the conductive polymer polyaniline that can be deposited in this way [35], although, as noted in the previous paragraph, the molecular order in such films is not always high [36]. Polyaniline possesses three reversible oxidation states, each with a distinct backbone structure composed of different proportions of quinoid and phenylene rings; the compound in Figure 4 represents a generic formula for this polymer. To form a multilayer film, polyaniline, in its emeraldine base form ($x = 0.5$ in Fig. 4), is mixed first with a small quantity of acetic acid; this improves spreading on the subphase surface. The mixture is then dissolved in 1-methyl-2-pyrrolidinone. Following spreading on a water surface and compression, electrically conductive Z-type LB films can then be deposited, up to 50 layers in thickness, on a solid substrate.

The LB technique may also be combined with solid-state chemistry methods to produce novel molecular architectures. For example, a network of conductive polypyrrole (molecular "wires") may be obtained in a fatty acid matrix [37, 38]. First, monolayers of the iron salt of a long-chain fatty acid (e.g., ferric palmitate) are assembled on an appropriate substrate. The multilayer film is then exposed to saturated HCl vapor at room temperature for several minutes. During this process, a chemical reaction transforms the fatty acid salt into layers of ferric chloride separated by layers of fatty acid. In the third and final step, the film is exposed to pyrrole vapor and a reaction occurs between the pyrrole and the ferric chloride, producing polypyrrole distributed within the multilayer assembly.

Highly ordered layers of nondispersive colloids may also be formed with the Langmuir–Blodgett technique [39]. The interest in such structures lies in the fact that it is possible to induce the particles to coalesce into a structure analogous to a close-packed crystal. It is possible to obtain repeat distances large enough so that radiation in the optical region can be diffracted, just as X-rays are diffracted in a ordinary crystal. Such photonic crystals may have many practical uses in optoelectronics.

Many biological molecules form condensed monolayers on a water surface [9, 10]. Phospholipids, chlorophyll a, the green pigment in higher plants, vitamins A, E, and K, and cholesterol are all examples. Biochemists and biophysicists have also been long aware that monomolecular films bear a close resemblance to naturally occurring biological membranes and many revealing experiments may be undertaken

with floating and transferred layers of biological compounds. The structurally similar proteins streptavidin and avidin have been the model system for protein binding studies. Each tightly binds biotin at four symmetrically located sites. Streptavidin in an aqueous subphase will bind to a biotin lipid at the air/water interface [40]. The resulting complex forms two-dimensional crystalline domains.

The vertical dipping LB process is not the only way to transfer a floating molecular film to a solid substrate or to build up multilayer films. Other methods are based on touching one edge of a hydrophilic substrate with the monolayer-covered subphase or lowering the substrate horizontally so that it contacts the ends of the floating molecules [9]. This is useful for the transfer of highly rigid monolayers to solid supports.

3. SELF-ASSEMBLY

In principle, self-assembly is a much simpler process than that of LB deposition [12]. Monomolecular layers are formed by the immersion of an appropriate substrate into a solution of the organic material, Figure 5. The best known examples of self-assembled systems are organosilicon on hydroxylated surfaces (SiO_2, Al_2O_3, glass, etc.) and alkanethiols on gold, silver, and copper. However, other combinations include dialkyl sulphides on gold; dialkyl disulphides on gold; alcohols and amines on platinum; and carboxylic acids on aluminum oxide and silver. The self-assembly process is driven by the interactions between the head group of the self-assembling molecule and the substrate, resulting in a strong chemical bond between the head group and a specific surface site, for example, a covalent Si—O bond for alkyltrichlorosilanes on hydroxylated surfaces. Molecules possessing one or more electroactive groups may be deposited by self-assembly. For example, the incorporation of an amphiphilic TTF unit into a metal-binding macrocyclic structure allows the resulting self-assembled monolayer to act as a sensor for metal ions [41]. The presence of the metal cation imposes an inductive effect on the polarizable TTF system, resulting in an anodic shift of the first oxidation potential as indicated by cyclic voltammetry experiments. Thus, self-assembled monolayers represent an attractive method for device fabrication, having the advantages of straightforward preparation and generally being very robust (stable to solvents, acids, and bases).

The self-assembly process is usually restricted to the deposition of a single molecular layer on a solid substrate. However, chemical means can be exploited to build up multilayer organic films. A method pioneered by Sagiv is based
on the successive absorption and interaction of appropriate molecules [42, 43]. The headgroups react with the substrate to give a permanent chemical attachment and each subsequent layer is chemically attached to the one before in a very similar way to that used in systems for supported synthesis of proteins.

Functionalized metallic nanoclusters represent a hybrid material that can combine the advantages of organic specificity with the robustness and processability of inorganic materials. Such nanoparticles can be chemically modified with a variety of terminal groups, including OH, CH_3, NH_2, and COOH [44] and combined with the self-assembly technique to provide selective coatings, for example, for chemical sensing.

4. LAYER-BY-LAYER ELECTROSTATIC DEPOSITION

In another method, shown in Figure 6, the ionic attraction between opposite charges is the driving force for the multilayer buildup [45, 46]. In contrast to the Sagiv technique, which requires a reaction yield of 100% to maintain surface functional density in each layer, no covalent bonds need to be formed. A solid substrate with a positively charged planar surface is immersed in the solution containing the anionic polyelectrolyte and a monolayer of the polyanion is adsorbed (Fig. 6a). Since the adsorption is carried out at relatively high concentrations of the polyelectrolyte, most ionic groups remain exposed to the interface with the solution and the surface charge is reversed. After rinsing in pure water, the substrate is immersed in the solution containing the cationic polyelectrolyte. Again, a monolayer is adsorbed but now the original surface charge is restored (Fig. 6b), resulting in the formation of multilayer assemblies of both polymers (Fig. 6c). This method has been used to build up layers of partially doped polyaniline and a polyanion, sulphonated polystyrene [47]. Biocompatible surfaces consisting of alternate layers of charged polysaccharides and oppositely charged synthetic polymers can also be deposited in this way [48].

Figure 5. Self-assembled monolayer film of an alkane-thiol on an Au-coated substrate.
Figure 6. Buildup of multilayer assemblies by consecutive adsorption of anionic and cationic polyelectrolytes: (a) substrate with a positively charged surface is immersed in an anionic polyelectrolye; (b) following monolayer adsorption and washing, the substrate is immersed in a cationic polyelectrolyte; (c) resulting multilayer assembly.

Bilayer films of poly(ethyleneimine) (positively charged) and poly(ethylene-co-maleic acid) have been used for chemical sensing [49]. The technique of surface plasmon resonance was used to monitor, *in-situ*, the deposition of these films. Subsequent exposure to aqueous solutions of metal acetate (metal = copper, nickel) resulted in a shift in position of the SPR curve. Phase-separated polyelectrolyte multilayer films that undergo a reversible pH-induced swelling transition have also been exploited for erasable nanoporous antireflection coatings, opening up applications for bioresponsive materials and membrane applications [50].

A related, but alternative, approach uses layer-by-layer adsorption driven by hydrogen-bonding interactions [51]. This has been accomplished with polyvinylpyrrolidone, polyvinyl alcohol, polyacrylamide, and polyethylene oxide. In the case of polyaniline, comparisons with films assembled via the electrostatic mechanism, using sulphonated polystyrene, indicate that the nonionic polymers adsorb onto polyaniline with a greater density of loops and tails and form highly interpenetrated bilayers with high polyaniline content.

5. SPIN-COATING

Spin-coating is a method that is extensively used by the microelectronics industry for depositing layers of photoresist, generally polyimides, onto silicon wafers [7, 52–54]. A quantity of a polymer solution is first placed on the semiconductor wafer, which is then rotated at a fixed speed of several thousand rpm (or the solution can be applied while the wafer is slowly rotating). The resist solution flows radially outwards, reducing the fluid layer thickness. Evaporation of the solvent results in a uniform thin film. The initial stage involves delivering a quantity of solution to the surface of the substrate. The substrate surface may be pretreated with an adhesion promoter, such as hexamethyldisilazane (HMDS), to improve wetting. This is often used when coating silicon wafers. The HMDS consists of six methyl groups and a Si_2NH group. This reacts with the thin layer of oxide on the silicon surface to form a new surface layer of hydrophobic methyl groups, allowing the organic solution to make intimate contact with the substrate.

The initial volume of the fluid dispensed onto the rotating disk and the rate of fluid delivery have a negligible effect on the final film thickness. In contrast, the resist viscosity (dependent on the concentration of the starting solution) and final film speed are both important process parameters. An increase in angular velocity decreases the film thickness; an inverse power-law relationship generally holds for the thickness dependence on the final spin speed. For a given speed, the film thickness decreases rapidly at first, but then slows considerably at longer times. A simple theory predicts the following relationship between the thickness of the spun film, d, the viscosity coefficient of the solution, η, its density, ρ, the angular velocity of the spinning, ω, and the spinning time, t [7]

$$d = \left(\frac{\eta}{4\pi\rho\omega^2}\right)^{1/2} t^{-1/2} \tag{3}$$

More sophisticated models have been developed to allow for changes in the resist resulting from solvent evaporation and

the non-Newtonian character of the rheological behavior of the photoresist [52–54].

Organic compounds that have been deposited successfully by spin-coating include electrically insulating polymers such as polyvinylidene fluoride, conductive polymers, and dyes developed for electroluminescent (EL) displays [55–62]. A selection of such compounds is shown in Figure 7. A key polymeric material for use in EL displays is poly p-phenylene vinylene) or PPV [59, 60]. This is a conjugated polymer that has the advantage of being readily processable to form thin films over large areas, which are stable over a wide temperature range and relatively cheap to manufacture. Changing the chemical structure of the polymer can alter the emission color and the electrical transport properties. Figure 7 shows the structure of one PPV derivative that has been extensively used—poly(2-methoxy-5-2'-ethyl-hexyloxy)-1,4-phenylene vinylene), MEH-PPV. Spin-coating can be used to prepare high-quality films of MEH-PPV of a few hundred nanometers in thickness [61, 62]. This polymer can also be processed into much thinner films using the LB technique [63].

Amorphous elastomeric polymers represent an important category of materials for the electronics industry that can be processed by spin-coating. Materials such as silicones

MEH-PPV

Poly(cyanopropylmethylsiloxane)

Tetrakis-arborol-TTF derivative
Figure 7. Examples of compounds suitable for spin-coating.

are used extensively as sealants and encapsulants [64], but are also finding use as nonconductive sensor coatings [29]. In the elastomeric phase (i.e., above the glass transition temperature), constant thermal motion of the polymer chains allows rapid vapor diffusion. Adsorption and desorption of a vapor leaves the material in the same state. The softness of elastomeric materials has an additional advantage for piezoelectric sensors such as surface acoustic wave devices that are sensitive to changes in material stiffness. An example of such materials is the family of polysiloxanes, which are characterized by a repeat unit (-RR′-Si-O-) where R and R′ are generic functional groups. By modifying the side chains, nonpolar, polar, and polarizable polymers can be obtained. One such example, poly(cyanopropylmethylsiloxane), is shown in Figure 7. Chemical vapor sensors based on a number of different transduction methods have been demonstrated with this polymer [65–67].

Figure 7 also shows the structure of a tetrakis-arboral-TTF derivative that can be processed by spin-coating to form potentially conductive nanowires [68]. The TTF inner core of these molecules self-assembles into supermolecular aggregates possessing a redox-active interior and a hydrophilic exterior sheath [69].

6. PHYSICAL VAPOR DEPOSITION

Solid materials vaporize when heated to sufficiently high temperatures; this process may proceed through the liquid phase. A thin film is obtained by the condensation of the vapor onto a colder substrate [4]. This thermal evaporation method is applied to deposit films of inorganic materials, such as metals and their alloys. However, the technique is being used increasingly for the formation of layers of low molecular weight organic compounds.

Because of collisions with ambient gas atoms, a fraction of the vapor atoms will be scattered. For a straight-line path between the evaporating material (source) and the substrate, it is necessary to use low pressures ($<10^{-4}$ mbar), where the mean free path of the gas atoms is much greater than the source–substrate distance. This allows the use of a shadow mask immediately in front of the substrate to define patterns. The low pressure also prevents contamination of the source material (e.g., by oxidation). A typical evaporation system, which can be made out of glass or metal, is evacuated to a pressure of 10^{-4}–10^{-6} mbar, normally with two types of vacuum pump operating in series (a rotary and diffusion pump).

Although commonly thought of as a single process, the deposition of thin films by thermal evaporation consists of several distinguishable steps: (i) transformation of the condensed phase, solid or liquid, into the gaseous state; (ii) vapor molecules traversing the space between the source and the substrate; and (iii) condensation of the vapor upon arrival on the substrate.

The first step requires the conversion of thermal to mechanical energy, which is achieved by a variety of physical methods. Resistive heating has been used to deposit fluorescent dyes, charge-transfer salts, and large macromolecules,

such as the phthalocyanines [70–74]; many of these compounds are finding use as the light-emitting layer or charge-transport layer in organic light-emitting devices [59, 60]. The molecular structures of some of these compounds are shown in Figure 8. Typical evaporation rates are 1–10 nm min^{-1}. Other techniques include arc evaporation; RF heating; or heating by electron bombardment. Deposition of polymer films by laser ablation is an area that offers some promise [75]. Laser pulsed methods have been used successfully for polyethylene, polycarbonate, polyimide, and polymethyl-methacrylate; typical film growth rates are 0.02–0.1 nm per laser pulse. As an alternative to traditional thermal evaporation or spin-coating, this method has also been used to deposit organic materials for organic electroluminescence [76]. An organic pellet target was ablated with two wavelengths, 532 nm and 355 nm, of a Q-switched Nd/YAG laser at a base pressure of 2×10^{-5} torr. Films deposited in this way were more amorphous than films fabricated by excimer lasers.

Materials that dissociate in the vapor phase may provide solid films with a stoichiometry that differs from that of the source. Therefore, special techniques have been devised. One approach is to use the method of "flash" evaporation. Rapid evaporation is achieved by continuously dropping fine particles of the materials onto a hot surface. Although fractionation occurs during the evaporation of each particle (the more volatile component evaporating first), at any time there will be several particles at different stages of fractionation. Consequently, the vapor phase will possess a similar
Figure 8. Examples of organic compounds suitable for thermal evaporation.

composition to that of the source material. A further technique is to evaporate from two or more sources, and control the vapor flux from each to obtain a vapor with the required composition. This has been used effectively to deposit thin films of doped organic charge-transfer salts [77]: one source is the charge-transfer salt, for example, tetrathiafulvalene, while the other is the dopant, for example, iodine. Laser co-ablation techniques can be used to deposit films of metal-polymer composite films [75].

The microstructure of an evaporated thin film depends on the evaporation rate, substrate temperature, and chemical and physical nature of the substrate surface. The size of the grains in a polycrystalline film will generally be larger for high source and substrate temperatures. However, if the kinetic energy of the incoming molecules is too high, the surface mobility of the adsorbed species is reduced because the vapor molecules will penetrate the condensed film. The effect of substrate temperature on grain size is greater for relatively thicker films. For a given material–substrate combination and under a fixed set of deposition conditions, the grain size increases as the film thickness increases. However, beyond a certain thickness, the grain size remains constant, suggesting that coherent growth with the underlying grains does not go on forever.

The physical nature of evaporated films can be changed by post-deposition heat treatment (annealing). This is usually associated with a change in the crystallinity of the film. For example, following thermal evaporation, the dc in-plane conductivity of thin films of the electron donor bis(ethylenedothio) tetrathiafulvalene (BEDT-TTF) can be increased by many orders of magnitude by doping with iodine and then annealing at 60 °C [78].

Molecular beam epitaxy (MBE) is, in principle, very similar to the method of vacuum evaporation described in the previous section [8]. However, an ultrahigh vacuum ($<10^{-9}$ mbar) is required to eliminate the scattering by residual gas molecules. The technique consists of directing controlled "beams" of the required molecules towards a heated substrate. Multiple sources, Knudsen cells, can be shuttered and used to create a superlattice structure on the substrate and control the molecular composition, orientation, and packing in two dimensions. Each Knudsen cell encloses an evaporating surface that is large compared to the orifice. The diameter of the orifice must be about one-tenth or less of the mean free path of the gas molecules, and the wall around the orifice must be vanishingly thin so that gas molecules leaving the enclosure are not scattered, adsorbed, and desorbed by the orifice wall. MBE has been used to produce ordered films of phthalocyanines and other molecular crystals on inorganic single-crystal substrates [8, 79, 80].

Sputtering is based on the momentum transfer exchange of accelerated ions incident on a target of source material [4]. The principle advantage of sputtering is that almost any material can be deposited. Since no heating is required, materials that are difficult to evaporate by thermal means are readily sputtered. The method has found application for the formation of thin films of certain organic polymers, for example, polytetrafluoroethylene, PTFE. However, a relatively large amount of the material is needed. This is not always practical for many novel organic compounds that may only be available in small quantities.

7. NANOPATTERNING

Planar microelectronic components are patterned using photolithography. A surface is covered first with a light-sensitive photoresist and then exposed to ultraviolet light through a mask. Either the exposed photoresist (positive resist) or the unexposed regions (negative resist) can be washed away subsequently to leave positive or negative image of the mask on the surface.

Conventional photolithography has feature sizes greater than about 100 nm. However, structures of less than 10 nm may be fabricated using techniques of shadowing and edge-step deposition [7]. Substrate steps with a square profile are first formed by ion-beam etching. Ion-etching the film-coated substrate at an angle then produces wires of triangular cross section, so that the wire is formed in the shadow of the step. Metal wires as narrow as 30 nm and as long as 0.5 mm have been fabricated in this way. Chemical approaches to the deposition of ultrathin organic films offer some control over the composition and structure of a surface [81]. Here, a substrate is patterned with gold and aluminum strips by conventional photolithography. The aluminum spontaneously oxidizes in air and presents aluminum oxide at the solid–vapor interface; in contrast, the gold remains "clean." Two adsorbates are then chosen (in this case an alkane thiol and a carboxylic acid) so that they adsorb strongly and selectively on the gold and alumina.

Brittain et al. describe a series of "soft" lithographic methods that may be suited to the patterning of organic layers [82]. A pattern-transfer element is formed by pouring a liquid polymer, such as poly(dimethylsiloxane), onto a "master" made from silicon. The polymer is allowed to cure to form an elastomer, which can then be removed from the master. This replica can be used subsequently as a stamp to transfer chemical ink, such as a solution of an alkanethiol, to a surface. Features with dimensions of 40–100 nm can be produced with the technique of near-field, phase-shift photolithography [82].

Scanning microscopy methods offer a powerful means of manipulating molecules and are able to reposition molecules, such as the fullerene C_{60}, on surfaces or to break up an individual molecule [83]. A further approach that has recently been developed is called dip-pen nanolithography (DPN) [84, 85]. This technique is able to deliver organic molecules in a positive printing mode. An atomic force microscope (AFM) tip is used to "write" alkanethiols on a gold thin film in a manner analogous to that of a fountain pen. Molecules flow from the AFM tip to a solid substrate ("paper"), making DPN a potentially useful tool for assembling nanoscale devices. A range of different materials can be used with the DPN process, including proteins [86] and magnetic nanoparticles [87]. The method has also been used to write organic patterns with sub–100-nm dimensions directly onto silicon and gallium arsenide surfaces [88].

The need to combine large area coatings with device patterning has resulted in the development of ink-jet printing [89, 90]. Although ink-jet printhead droplet ejection can be achieved with thermal (bubble-jet) and piezoelectric modes of operation, the majority of published literature on ink-jet printing as a tool for manufacturing organic devices has been the result of using piezoelectric actuated printers. Piezoelectric printhead technology is favored primarily because it

applies no thermal load to the organic "inks" and is compatible with the printing of digital images. The combination of solution-processable emissive polymers with ink-jet printing offers some promise in the development of low-cost, high-resolution displays [91]. The technique has also been applied to the manufacture of all-polymer transistor circuits [92].

GLOSSARY

Dip-pen nanolithography An atomic force microscope is used to transfer a chemical ink to a surface in a manner analogous to that of a fountain pen.

Ink-jet printing Ink droplet ejection from a reservoir to a surface using either thermal (bubble-jet) or piezoelectric means.

Langmuir–Blodgett (LB) film deposition Transfer of a condensed monomolecular film from a liquid subphase (usually water) surface to a solid substrate by raising and lowering the latter through the monolayer/air interface.

Layer-by-layer electrostatic deposition Formation of multilayers of organic compounds on a solid substrate by sequential immersion of the latter in solutions of positively and negatively charged polyelectrolytes.

Molecular beam epitaxy (MBE) A variation on physical vapor deposition. The technique consists of directing controlled "beams" of the required molecules towards a heated substrate. The deposition takes place in ultrahigh vacuum.

Molecular electronics Exploitation of organic compounds in electronic or optoelectronic devices.

Photolithography The method used to pattern microelectronic devices. A surface is covered first with a light-sensitive photoresist and then exposed to UV light through a mask. Either the exposed photoresist (positive resist) or the unexposed regions (negative resist) can be washed away subsequently to leave a positive or negative image of the mask on the surface.

Physical vapor deposition Thin film formation by vaporization under reduced vacuum followed by condensation of the vapor onto a solid surface.

Self-assembly Spontaneous formation of a monolayer on a surface by the immersion of an appropriate solid substrate (e.g., Au) into a solution of an organic compound (e.g., alkanethiol).

Soft lithography The pattern-transfer element is formed by pouring a liquid polymer onto a master made from silicon. This replica can be used as a stamp to transfer chemical ink, such as a solution of alkanethiol, to a surface.

Spin-coating Thin film formation by deposition of a solution onto a solid, which is then rotated at a speed of several thousand revolutions per minute.

Sputtering Thin film deposition technique based on the momentum transfer between accelerated ions and a target of source material. The process is undertaken at reduced pressure.

Surface plasmon/surface plasma wave Collective oscillations of the free electrons at the boundary between a metal (e.g., Ag, Au) and a dielectric (e.g., air, water).

Organic/Inorganic Nanocomposite Colloids

Elodie Bourgeat-Lami

Laboratoire de Chimie et Procédés de Polymérisation, CNRS–CPE, Villeurbanne, France

CONTENTS

1. INTRODUCTION

At the dawn of the 21st century, members of the U.S. Interagency Working Group on Nanoscience, Engineering and Technology (IWGN) wrote in a report to the National Science and Technology Council: "The emerging fields of nanoscience and nanoengineering are leading to unprecedented understanding and control over the fundamental building blocks of all physical things. This is likely to change the way almost everything—from vaccines to computers to automobile tires to objects not yet imagined—is designed and made" [1–3]. This futurist vision of nanomaterials construction from the bottom up (atom by atom) rather than the top down (via nanophysic ultraminiaturization fabrication methods) is shared by many scientists all other the world who aim to create new materials with the control of matter on the nanometer length scale [4]. As a matter of fact, it is now well established that the way molecules of various shapes and surface features organize into patterns on nanoscales determines important material properties including electronic, optical, and magnetic properties and mechanical strength [5]. So, by manipulating atoms and molecules, chemists are learning how to synthesize perfect nanosize objects with new sets of properties [6–8].

One important class of nanomaterials is organic/inorganic (O/I) hybrids and nanocomposites. These materials are nanostructured materials that combine the characteristics of organic and inorganic constituents at the nanoscale.

Nanocomposite materials can be elaborated as fibers, gels, thin films, or particles. By tailoring the structure of these materials at the nanometer length scale, it should be possible in principle to significantly change their properties at a larger scale. Applications are various and concern optics, electronics, catalysis, coatings, and biotechnologies [9–11]. Nanocomposite materials have gained intense interest in recent literature and a variety of significantly different preparation methods have been described and recently reviewed [12–17]. Among the various synthetic techniques, the so-called sol–gel methodology has been extensively investigated as a well-established wet chemical route for creating glassy and hybrid materials [18–23]. But despite the recent interest in nanotechnologies, it is to be underlined that nanoscaled materials are old products that have been produced for several years. Colloidal science [24–26], for instance, affords an extremely broad variety of such nanomaterials ranging from surfactant and macromolecular aggregates to polymer latexes [27–28] including metal colloids (Au, Ag) [29–33], semiconductor nanocrystallites [34–37], and metal oxide nanoparticles [38–43]. Colloidal particles constitute one of the major components of many industrial products such as food, ink, paint, adhesives, papers, and cosmetics. Some typical examples of colloidal particles with their respective range of particle sizes are reported in Figure 1. Since colloidal materials are an important class of products with applications in material science, chemistry, and biology, they have been the subject of extensive research for a long time, the most studied and best established examples being silica colloids and polymer latexes. However, it is only very recently that the combination of organic and inorganic components into colloidal nanocomposites has been considered with interest [44–48]. The earliest developments in this field were principally motivated by the coating industry and concerned the elaboration of polymer encapsulated pigments [49]. Surface modification of pigments is of major technological importance for ink and paint applications. Now, an extremely broad range of seemingly different materials is concerned with those developments.

We aim in this chapter to give an overview of the techniques recently developed for the elaboration of O/I
Figure 1. Particle size range of different types of colloidal systems.

nanocomposite colloids with diameters in the range of 10 up to several hundred nanometers. These systems are characterized by the fact that each particle of the colloidal suspension is a composite particle. Either *ex-situ* or *in-situ* techniques can be used for the elaboration of nanocomposite colloids. Figure 2 shows idealized spherical morphologies of the different types of organic/inorganic colloidal particles that can be produced through assembly, precipitation, organic polymerization, and/or inorganic polycondensation processes. Although in practice nanocomposite colloids can exhibit a variety of shapes and geometries, we have exclusively represented spherical and isotropic morphologies.

This chapter is divided into three parts. In the first part, physicochemical processes based on supramolecular assembly of preformed nanoparticles and/or macromolecules, including heterocoagulation and the sequential deposition of preformed colloids and polyelectrolytes onto latex seeds, are described. Such strategies enable us to associate a variety of polymeric and colloidal materials in one step or using multisequential procedures. In the second part, nanocomposite
Figure 2. Idealized morphologies of different types of O/I nanocomposite particles. Core–shell (1, 8), occluded (2), raspberrylike (3, 6), hairy (4), shell-cross-linked (5), multilayered (7), and hybrid interpenetrated organic/inorganic networks (9).

particles are produced *in-situ* giving rise to nanostructured colloids with various morphologies (core–shell, multicores, raspberrylike, hairy, and shell-cross-linked). In this synthetic strategy, preformed colloidal nanoparticles are used as seeds for polymer growth or inorganic condensation on their surface either in solution or in multiphase systems. Unusual colloidal materials, for instance vesicles or block copolymers, can also be used as host or templates as will be briefly discussed in a short section. The third part deals with the elaboration of hybrid colloids from the simultaneous reaction of organic and inorganic molecular precursors. The emphasis is put here on the unusual properties of the so-produced particles. Finally, the potential applications of nanocomposite colloids and nanocapsules will be briefly presented and illustrated by typical examples.

2. NANOCOMPOSITE COLLOIDS VIA SELF-ASSEMBLY TECHNIQUES

The development of self-assembly methodologies in the creation of new materials has veritably expanded the range of supramolecular structures that can be built up in the field of nanotechnology [50, 51]. Not only can organic molecules and block copolymers be assembled onto inorganic substrates but the assembly process can also take place between two types of colloidal particles or between colloids and macromolecules. The interaction of surfactants with pigments and inorganic particles, for instance, is a well established process and this will not be discussed here [52]. Similarly, a large range of polymeric materials such as dendrimers and block copolymers have demonstrated huge potentialities as unique nanoscale reactors, templates, or building blocks for higher order nanoscale construction. The elaboration of nanostructured colloidal materials (nanoparticles, nanocrystals, and clusters) by organic templating and the construction of higher hierarchical assemblies (for instance colloidal crystals) will not be covered in this chapter. These aspects have been discussed and reviewed in more detail elsewhere [53–58]. We are mainly interested, here, in the creation of complex nanoparticle structures through the assembly of binary colloidal materials. The assembly process is driven by weak interactions (e.g., steric, electrostatic, hydrophobic, and hydrogen bonding) or chemical and biomolecular recognition. This section describes the main synthetic strategies and briefly reports on the recent advances in this area.

2.1. Electrostatically Driven Self-Assembly

2.1.1. Heterocoagulation

Aggregation between particles of different characteristics (sizes, charges, and chemical composition) is generally known as heterocoagulation. This kind of process is commun in nature and frequently encountered in many industrial and biological processes. Due to its major technological implications, the fundamental aspects associated with the stability behavior of mixed colloidal dispersions, including the mechanisms and kinetics of the heterocoagulation process, have been extensively studied both experimentally and theoretically for a long time [59–61]. Systematic studies have been performed using different types of inorganic and polymer

colloids such as metal oxides and polymer latexes. By changing the pH, both the sign and the surface potential of the colloids can be finely tuned, making it possible to evaluate the effects of these determinant parameters on the interactions of unlike particles. In addition to these theoretical considerations, attractive interactions between positively charged particles and negatively charged colloids also provide a possible mechanism for the encapsulation of inorganic particles giving a core mineral surrounded by small heterocoagulated polymer particles. The interaction of preformed amphoteric latex particles with titanium dioxide pigments, for instance, has been studied by Kato et al. [62]. The latex particles were synthesized in the presence of a zwitterionic emulsifier, N, N'-dimethyl n-lauryl betaïne at pH 7.0 and showed an isoelectric point in the range of pH 7–8. Strong interactions were observed between pH 3 and 8, where the latexes were positively charged while titanium dioxide particles were negatively charged. As evidenced by turbidity measurements, the mixed heterocoagulated suspensions were destabilized upon addition of an increased number of latex particles due to the neutralization of the surface charge of the pigment, but restabilization occurred with further addition of the latexes. Similarly, the adsorption of cationic polystyrene latexes onto spherical rutile titanium dioxyde particles has been investigated by Marston and co-authors [63]. It was shown that the ionic strength of the suspension medium had a great influence on the adsorption behavior. More latex particles were heterocoagulated on the TiO$_2$ surface when the electrolyte concentration was increased due to the diminution of the electrostatic repulsion between neighboring adsorbed particles. Using the heterocoagulation technique, a large variety of O/I nanocomposite colloids can be successfully produced. Among them, magnetic colloids are important class of materials with potential applications in biotechnology and medicine including bioseparation, diagnostics, magnetic resonance imaging, therapy, and drug targeting. The elaboration of magnetic colloidal supports and their utilization in the biomedical field have been extensively described and reviewed in recent years, and only few typical examples will be reported here [64, 65]. Monodisperse hydrophilic magnetic polymer latexes have been synthesized for example using a two-step procedure. In the first step, magnetic iron oxide particles have been separetely obtained by procedures known for a long time [66], and adsorbed onto various cationic latexes [e.g., polystyrene, core–shell poly(styrene-N-isopropylacrylamide)(NIPAM), and poly(NIPAM)] via electrostatic interactions [67]. Figure 3 shows the rasberrylike morphology of the so-produced nanocomposite colloids. In the second step, the iron oxide-coated polymer latexes were encapsulated by poly(NIPAM) after separation of the excess free iron oxide particles in a magnetic field [68].

Trilayer composite microspheres containing small Fe$_2$O$_3$ or NiO–ZnO–Fe$_2$O$_3$ oxide particles in middle layer have been elaborated by a similar procedure [69, 70]. In the first step, the magnetic ultrafine powder was heterocoagulated on the surface of the core latex particles by adjusting the pH of the mixed dispersion to 2, 5. Then, sodium methyl acrylate [69] or sodium oleate [70] was added in order to improve the hydrophobicity of the heterocoagulates and to ensure the formation of a third polymer layer at the surface of the composite seed latexes. Under these conditions,
Figure 3. Scanning electron micrograph of polystyrene latex particles coated with iron oxide colloids. Reprinted with permission from [67], F. Sauzedde et al., *Colloid Polym. Sci.* 277, 846 (1999). © 1999, Springer-Verlag.

a polymer shell was obtained giving composites with a trilayer morphology (Fig. 4). In a related work by Lee and Senna, composite magnetic particles of the core–shell type were prepared by emulsion polymerization of styrene in the presence of polystyrene (PS) seed microspheres and ultrafine magnetite colloids coated with sodium oleate [71]. Small composite particles were produced in the continuous phase through emulsion polymerization. These nanoparticles were shown to adhere to the seed surface giving rise to the formation of large PS microspheres covered with a uniform layer of smaller nanocomposite particles.

2.1.2. Layer-by-Layer Assembly

A versatile technique that combines colloidal assembly and polymer adsorption strategies, first developed by Caruso and Möhwald's research group, has been extensively described in the last five years [72]. The general concept involves forming a sequential alternate layer-by-layer (LbL) deposition of polyelectrolytes [73–75] or polyelectrolytes and nanoparticles [76–79] through electrostatic self-assembly onto sacrificial polymeric colloidal templates. Removal of the organic core and the bridging polymer by chemical (dissolution, etching) or thermal treatments generates hollow polymeric or nanocomposite structures (Fig. 5) [80–85].

Due to their low density, large surface area, stability, and surface permeability, the resulting nanocapsules are of major technological and scientific interest. Hollow particles offer a lot of promising applications in various domains of advanced materials, especially in architectural coatings, optics, electronics, and biotechnologies. Hollow latex particles, for instance, are used as synthetic pigments in paper coating [86] and paint materials [87, 88]. By scattering light, the voids contribute to increase hiding and opacity, whereas microspheres with large voids (typically 10–100 μm in size) are inefficient in such processes. Nanometer-sized capsules are also very promising materials for encapsulation and controlled release of various substances—dyes, drugs, cosmetics, and inks—and are particularly suited for biological applications such as drug targeting, artificial cells, and diagnostics. By using the LbL technique, determinant parameters such as size, composition, geometry, wall thickness, and uniformity can be precisely controlled. A huge variety of such hollow spheres has been successfully produced over a wide range of micrometer and submicrometer inner diameters, and the thickness and permeability of the walls have been varied by proven formulation variations. The organic templates involved in these coating procedures were either melamine–formaldehyde resins [73–75] or PS latex particles [76–85]. Poly(allylamine hydrochloride) (PAH), poly(sodium 4-styrene sulfonate), and poly(diallyl dimethylammonium chloride) (PDADMAC) were used as the polyelectrolytes. Among the coating materials, silica [76, 77], titanium dioxide [84], clays [84], zeolites [78, 83], and iron oxide [79, 85] have been successively reported. As mentioned in the previous section, magnetic colloids are of particular interest in diagnostics and bioseparations where the particles can be selectively oriented and directed by application of an external magnetic field. Figure 6 shows the type of anisotropic orientation that can be obtained from latex particles coated with alternate layers of PDADMAC and iron oxide nanoparticles. In alternative procedures, inorganic precursors can be used instead of preformed nanoparticles [89, 90]. For example, water soluble titanium (IV) bis(ammonium lactado) dihydroxide was employed to uniformly coat PS templates with a thin titania layer. A regular and smooth coating was obtained by this approach. LbL nanoengineered capsules are versatile materials. They can be used for instance as microreactors for chemical reactions to be conducted inside the hollow spheres. Preformed hollow capsules are particularly well suited for such applications since they provide effective size limitations because of the compartmentalization of the precipitation chemistry [91]. Different species can be incorporated into the nanocapsules making them attractive for a wide range of applications from biotechnology to catalysis. For example, hollow polyelectrolyte shells have been used as microenvironments for the precipitation of inorganic salt and crystal deposition in the inner part of the capsules [92]. Nanoscale objects with controlled sizes and shapes have been successfully obtained by this technique. In a typical example, the spheres are first suspended in a solvent for the organic solid to be precipitated. The solubilized reactive compound then permeates the sphere wall and enters the nanocapsules. A nonmiscible solvent is subsequently slowly introduced into the suspension to initiate precipitation of the principal compound contained inside the hollow spheres by osmotically shifting the original solvent. Precipitation can be alternatively induced by change in pH or by addition of a trigger. The key limitation of the LbL technique, however, is the difficulty one may encounter to produce stable nonaggregated hollow spheres in large quantities without damaging the shell properties. For scaling-up procedures, the technology must be carefully optimized to reduce time scale experiments and limitate the amount of free polyelectrolyte that must be removed from the suspension. A complete description of these systems encompasses the goal of this chapter. More detailed information on the LbL concept

including the limitations and potential applications of the technique can be found elsewhere [93].

2.2. Nanosphere–Microsphere Assembly

Mixtures of organic and inorganic colloids of different sizes and number ratios can also arrange into supramolecular colloidal architectures by means of chemical or biological interactions. Fleming and co-workers have demonstrated for instance that polymer colloids, functionalized with amine groups, can be assembled onto glutaraldehyde-activated silica microspheres [94]. The assembled composite particles were subsequently heated above the glass transition temperature of the polymer nanospheres to produce uniform core–shell composite microparticles. Alternatively, the introduction of suitable biological functions on both parts, for instance avidin and biotin groups, allowed the two sets of particles to be assembled via a specific biomolecular recognition mechanism (Fig. 7). Assembly procedures of this type, based on both biological and nonbiological molecular recognition, have been largely reported in recent literature for binary dispersions of polymer colloids [95] and inorganic particles [96, 97], respectively. However, there are only few examples of supramolecular recognition-directed assembly of organic and inorganic nanoparticles.

Controlling the assembly of unlike colloidal particles in a binary suspension requires control over the surface properties of each of the two colloidal materials as illustrated in the example in Figure 7. However, systems can also be specifically designed to undergo self-colloidal organization by using a bifunctional mediating molecule bearing reactive groups on both ends capable of bonding particles together, as recently reported in our group for binary mixtures of silica and polymer colloids [98]. Biologically programmed assembly of nanoparticles was first described by Mirkin et al. [99] and Alivisatos et al. [100, 101]. They showed that complementary DNA antigens could be used to self-assemble nanoparticles. The concept was recently applied to gold colloids by Mann and co-workers who used antigen/antibody recognition assembly to induce the reversible aggregation of the inorganic nanoparticles and
produce a conjugated hybrid material with long-range interconnectivity [102]. Recent examples also include the elaboration of colloid/colloid [103], dendrimer/colloid [55], and polymer/colloid [104] composite superstructures. According to this general principle, we recently demonstrated that addition of a small amount (only $0.1 \text{ g} \cdot \text{L}^{-1}$) of a monomethylether monomethylmethacrylate poly(ethylene oxide) macromonomer allowed us to direct the self-assembly of nanometric polystyrene latex particles on the surface of submicronic silica particles through an *in-situ* nucleation and growth process (Fig. 8) [98]. The two sets of particles were assembled in a raspberrylike morphology via the formation of hydrogen bonds at the interface of the inorganic and organic colloids. The size and shape of the assembly can be easily controlled by varying the sizes and stoechiometries of the colloidal components. In a related work, hydrophilic poly(vinyl pyrrolidone) (PVP)-based macromonomers having styrene end groups were shown to be efficient compatibilizers during the coating reaction of large colloidal silica particles by dispersion polymerization of styrene into a mixture of ethanol and tetrahydrofuran (THF) [105]. The encapsulation was shown to take place via the copolymerization of styrene with the terminal group of the macromonomer adsorbed on the inorganic surface. A large variety of amphiphilic block copolymers and nonionic water soluble polymers like polystyrene-*b*-poly(ethylene oxide) (PS-*b*-PEO) and hydroxypropyl cellulose (HPC), respectively, can be used for this purpose. For example, it was found that HPC strongly adsorbed on silica and that the saturated amount of adsorption was dependent on temperature. The adsorption value (around 1.5 mg/m^2) at temperatures higher than the lower critical solution temperature (LCST) of the polymer was 1.5 times larger than the value obtained at room temperature. Furusawa et al. [106] described that the dense layer of HPC adsorbed at the LCST allowed synthesization of composite polystyrene latexes containing silica beads in their core through hydrophobic-mediated interactions. When the emulsion polymerization reaction was performed in presence of an anionic emulsifier at concentrations higher than the critical micellar concentration, nanocomposite colloids with a raspberry-like morphology

were produced by the spontaneous and controlled heterogeneous coagulation of the polymer particles formed in the continuous phase onto the hydrophobized silica surface. A similar behavior was observed by Long et al. during the seeded emulsion polymerization of methyl methacrylate in the presence of silica particles and hydropropyl methyl cellulose [107]. Such cooperative effects have been reported as well when using "adhesive" monomers, that is, monomers with strong interaction with the inorganic surface [108, 109]. 4-Vinylpyridine, aniline, and pyrrole are typical examples of such mediating monomers. The possibility to produce O/I nanocomposite colloids through acid/base chemistry will be discussed in the following section. Although the idea of colloidal nanocomposites construction via a building block approach is still in its infancy, it can be anticipated that the concept of bottom-up recognition-mediated multiscale ordering of dissimilar organic and inorganic nanoparticles will find extensive and innovative developments in the near future.

3. NANOCOMPOSITE COLLOIDS VIA POLYMERIZATION TECHNIQUES

The possibility to synthesize O/I nanocomposite colloids by direct polymerization techniques (i.e., solution, emulsion, miniemulsion, dispersion, and precipitation reactions) has gained much interest in recent years due to the large range of applications of those colloidal nanomaterials. Nanocomposite colloids are of major technological importance in the coating industry as well as in electronics, catalysis, optics, and medicine. Composite colloids are elaborated for a variety of reasons. The incorporation of, for instance, magnetic, optical, or catalytic functions enables us to produce multifunctional colloids, the properties of which can be finely tuned by controlling the proportions and spatial organizations of the inorganic and organic constituents. In addition, coating of minerals with a polymer layer can be of particular interest in order to protect the nanoparticles from chemical (oxidative, thermal, photochemical) and physical degradations and to improve their dispersion state. The coated surfaces have significantly different properties leading to increased durability or stability and better end-use performance. Nanocoating technologies have been extensively developed in recent years and reviewed [110–112]. In addition to the aforementioned interest, nanoengineering of particle surfaces also offers the possibility to control the shape of the resulting material by using templates of well defined sizes and characteristics. Since the coating can be done in a variety of ways, the nanocomposite particles can display a large range of morphologies as illustrated in Figure 2. Once the template is removed from the composite particles, replicas are formed that present interesting structural properties (Fig. 9).

3.1. Synthetic Strategies

In order to circumvent the inherent incompatibility of polymers and minerals, synthetic strategies need to be developed in order to establish a physicochemical or chemical link at the interface of the organic and inorganic constituents. The
Figure 9. Synthetic scheme for synthesis of hollow particles by colloidal templating.

affinity of polymers for inorganic substrates, in terms of wetting or adhesion, can be substantially increased for instance by the prior adsorption by hydrogen bonding or electrostatic interactions of suitable organic substances over the inorganic particle surface. If covalent bonding is required, organic or inorganic reactive groups need to be grafted onto the surface of the nanoparticles. The general synthetic approach to O/I colloids thus involves two successive steps: (1) synthesis of the core material with the desired surface group and chemical reactivity and (2) coating of the templating core with an organic, inorganic, or hybrid shell. Figure 10 illustrates the kind of surface modification that can be done with the purpose of compatibilizing the core and shell components. Among the different strategies, organic functionalization of metal oxide nanoparticles has been much described in recent years and a full description of these systems will not be attempted here [113–115]. Initiating, propagating, or terminating groups can be attached to the seed surface in order to promote in a subsequent step anchoring of the growing polymer chains [17, 44–48]. Electrostatic interactions also provide a driving force for noncovalent association of organic and inorganic constituents into colloidal nanocomposites as briefly discussed in the previous section. Finally, it can also be envisaged to perform polymerization reactions at the interface of inorganic colloids with water provided that some amphiphilic molecules have been previously adsorbed on the nanoparticle surface. Inversely, inorganic polycondensates and metallic nanoparticles can be grown on the surface of polymer latexes if care is taken to use inorganic precursor molecules (e.g., metal salts or organometallic compounds) with sufficient affinity for the organic templates. Only a few directions are given here. A more complete description of these strategies will be reported in the following section.

3.2. Organic Polymerization

3.2.1. Polymerization in Multiphase Systems

Polymer-Encapsulated Pigments Pigments are important class of solid materials that enter into the composition of a variety of industrial products such as inks, paints, papers, and cosmetics. They are used for instance as additives in the coloration of thermoplastic materials or in the pigmentation of resins and synthetic fibers. One major drawback of pigmented formulations, however, is that high energy and cost-productive milling operations are necessary in order to disperse the pigment into particles of pigmentary dimensions throughout the plastic mass. Pigment agglomeration is also of major inconvenience during film formation in water-based paint formulations. Pigment flocculation creates zones locally enriched in pigment particles with undesirable
Figure 10. Different reaction schemes for (a) the graft polymerization of vinyl monomers from functionalized oxide surfaces via initiation, propagation, or termination, and (b) the hydrophobization of mineral surfaces for compatibilization with hydrophobic polymers.

effects on the hiding power of the latex paints. To improve and stabilize a paint dispersion, it is common to use polymeric dispersants [116]. However, this is generally not sufficient and a lot of pigments need a surface treatment to maximize their efficiency. Among the various surface modification techniques (use of derivatives, coating with inorganic materials), *in-situ* polymerization offers interesting perspectives. The coating of pigments with a thin polymer layer enables one to control interparticle spacing and reach better paint performances (hiding power, titing strength, gloss, scrub resistance, stability, . . .). Since the paint properties are highly dependent on pigment dispersibility, various encapsulation techniques have been described so far in order to achieve an optimal disposition of the pigment particles within the polymeric film [117]. This section describes the main synthetic strategies and briefly reports on the recent advances in this area.

Owing to the major technological importance of pigments in industry, it is not very surprising to see that

most published works in this field are in the patent literature [49, 118–125]. Among the various solid particles to be coated, titanium dioxide pigments (TiO_2) have gained more and more interest since they constitute one of the major ingredients of water-borne coatings. Similarly, there have been a number of attempts to produce polymer encapsulated inorganic solids, but emulsion polymerization is by far the approach most frequently used [126]. In a typical procedure, the pigment particles are dispersed into water with the help of surfactant. High shear mixing is carried out to help dissociate the pigment agglomerates. Alternatively, fine pigment dispersions can also be produced by applying ultrasound as reported by Templeton-Knight [127–129]. A monomer or a mixture of monomers is then introduced into the suspension medium, and a water-soluble free radical initiator is subsequently added to start polymerization. The nature of the surfactant obviously plays an important role in the coating mechanism. It has been shown for instance that the presence of an amphipathic polymer in combination with a companion surfactant allows one to produce more uniform coverages and reach better coating efficiencies [124, 130]. Solc [120, 123] and Hasegawa et al. [131, 132] claimed the use of water-soluble anionic surfactants, while Martin [121, 125] recommended the use of nonionic oxyethylenic amphiphiles. In reality, the role of the surfactant is somewhat complex. It is generally admitted that the process begins with the adsorption of the surfactant molecules on the particle surface. Interaction takes place through the hydrophilic head group of the surfactant, the hydrophobic part being consequently directed toward the aqueous phase. A second layer of emulsifier molecules is then adsorbed on the first layer to provide an energetically stable arrangement. The net result is the formation of a surfactant bilayer that can solubilize monomer molecules in the hydrophobic interlayer and promote polymerization at the interface of the pigment particles with water (Fig. 11).

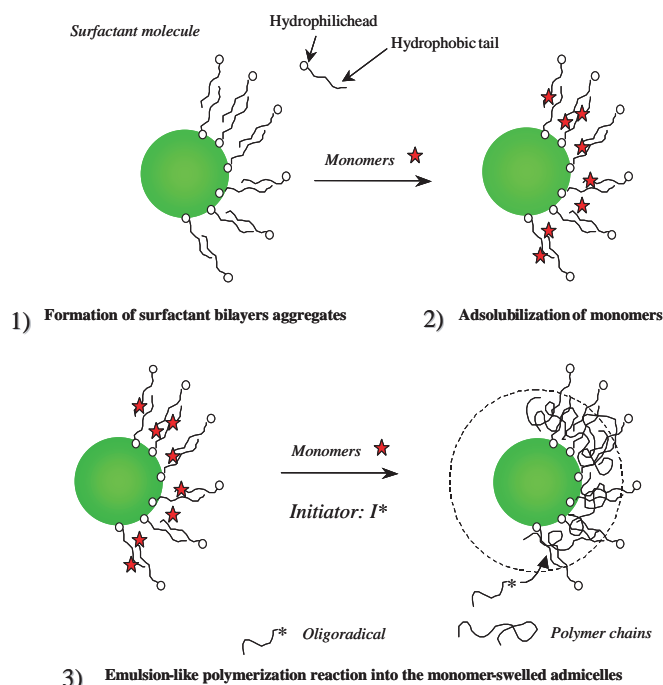
This process, also known as admicellization/adpolymerization, is of course highly dependent on the geometry of the bilayer structure and on the surfactant packing density, which in turn are functions of the nature and concentration of the soap. Too low emulsifier concentrations may lead to incomplete pigment coverage while a too large a concentration may result in the formation of free polymer particles that do not participate in the coating. Better results are usually obtained when the monomers are introduced under starved feed conditions. Various attempts have been made in the literature in order to achieve higher coating efficiencies. For example, Caris and co-workers used diisopropyl methacryl isostearoyl titanate molecules (Structure 1) to covalently attach polymer chains on the surface of TiO_2 pigments [133, 134]. Modification of the titanium dioxide pigments was carried out by suspending TiO_2 into an organic solution of the coupling agent and shaking for several hours. The authors recommended the use of aprotic solvents like diethylether or dichloromethane to avoid the rapid solvolysis of the titanates. When TiO_2 was modified in isopropanol, low levels of grafting were obtained in contrast to diethylether. The high sensitivity of the titanate bonding toward hydrolysis could be reduced by incorporating a small amount of another titanate coupling


Figure 11. Schematic illustration of pigment encapsulation through an emulsionlike polymerization reaction. The process involves (1) formation of surfactant bilayers, (2) solubilization of monomer, and (3) free radical polymerization.

agent bearing long hydrophobic chains which provided effective protection of the methacrylic acid ester groups against hydrolysis by steric hindrance. In a subsequent work, they determined the polymer content of the encapsulated pigments and found that the highest amount of surface polymer was obtained when the initiator was chemically bound or strongly attracted to the particle surface [135]. Similar results were obtained by Haga et al. who used a diazoic amidinium initiator to promote anchoring of the polymer chains onto TiO_2 pigments [136]. It is worthwhile to mention also the work of Janssen et al. [137], who used redox initiators to improve the efficiency of the encapsulation reaction of surface modified titanium dioxide pigments by PMMA and polystyrene. Although a real benefit was achieved with the nature of the initiator, in particular in the case of MMA, there was still competition between the formation of surface polymer and free latex particles in these systems. Another critical aspect of encapsulation reactions is the stability of the encapsulated powders. The occurrence of severe coagulation during the encapsulation process has been evidenced by several authors. The temporary decrease in the polymerization rate observed by Caris et al. during PMMA encapsulation of titanium dioxide pigments has been attributed to pigment agglomeration in the course of the coating reaction [138]. Hasegawa et al. [139] also described that $CaCO_3$ powders have a strong tendency to aggregate in a certain
range of SDS surfactant concentrations. The decrease in polymerization rates with increasing SDS concentration was found to follow the sedimentation curves of the inorganic pigment which supported the fact that aggregated rather than individual pigments had been encapsulated. Such instability appeared to be even more pronounced in the case of titanium dioxide pigments for which it was described that coagulation can take place under certain experimental conditions. In order to prevent the formation of agglomerates or coagulum during encapsulation reactions, the evolution of the surfactant concentration has been controlled by Janssen and co-authors using on-line conductivity measurements [140, 141]. It was found that the critical micellar concentration (CMC) of the soap determined in the presence of monomer and initiator, the so-called apparent CMC (CMC_{app}), was significantly lower than the CMC measured in pure water. On the other hand, CMC_{app} increased with increasing amount of pigment since more and more surfactant molecules were adsorbed on the mineral surface. By measuring the conductivity signal of the suspension, it was thus possible to follow the surfactant concentration evolution during the encapsulation reaction. Of course, an increase in the total surface area, due to polymer particle growth or renucleation, leads to a decrease in the conductivity because surfactant is adsorbed from the continuous phase (CMC_{app} is increased). On the contrary, when coagulation takes place, surfactant is released from the agglomerated particles due to a decrease in the surface area and thus the conductivity is increased. The occurrence of severe coagulation during batch encapsulation reactions was then clearly manifested on the conductivity curves by one maximum in the conductivity signal. In order to prevent coagulation, extra surfactant must be introduced in the course of the coating reaction. On-line conductivity measurements were shown to provide an effective way to optimize the surfactant addition profile in order to obtain the best efficiency with maximum stability.

As mentioned previously, polymer-encapsulated pigments are of major implication in the coating industry and, consequently, a variety of monomers have been used to produce the shell, including vinyl acetate as well as combinations of vinyl acetate, isobutyl acrylate, styrene, *n*-butyl acrylate, methyl methacrylate, acrylonitrile, and isobutyl vinyl ether. In principle, a huge number of inorganic solids including metal powders, such as iron, steel, titanium, cobalt, nickel, gold, platinium, or copper, metal oxides (CuO, ZnO, Al_2O_3, CeO_2, ...), and various fillers, such as talc, mica, barytes, calcium carbonate, china clay, and dolomite, can be covered with polymers according to the general synthetic procedure described previously. However, in practice, the synthesis needs to be adapted to every individual situation. Metallic surfaces do not display for instance the same reactivity as metal oxides or carbonates and sulfates, and specific strategies need to be developed. Similarly, it is clear that the surface properties of metal oxides may suffer significant changes from one oxide to another depending on the pH of the suspension, the ionic strength, as well as the acidic or basic character of the surface. Batzilla and Tulke described for instance the encapsulation reaction of commercial aluminum pigments through an emulsionlike polymerization process [142]. They reported the use

$$((H_3C)_2HCO)_2Ti \begin{cases} OCOCH_2C_{16}H_{33} \\ \\ OCOC(CH_3)=CH_2 \end{cases} \quad \textbf{KR7}$$

Structure 1. Diisopropyl methacryl isostearoyl titanate.

of phosphorous-containing protecting agents to provide a good dispersion of the Al pigment and control its reactivity. They also recommended using monomers with strong adhesion with the metal surface (e.g., carboxylic acid derivatives). In a related work, silver nanoparticles have been recovered with a thin polymer layer via emulsion polymerization of styrene and MMA monomers in presence of oleic acid [143]. The fatty acid derivative was shown to be essential to achieve pigment encapsulation. Yu et al. recently reported the preparation of $CaCO_3$/polystyrene composite particles using a polymerizable silane derivative previously attached on the mineral surface [144]. The pretreated $CaCO_3$ particles were shown to act as comonomers during the emulsion polymerization process as will be fully discussed in the case of silica.

Apart from the aforementioned technologies, miniemulsion polymerization also provides a versatile route to polymer encapsulation of pigments and nanoparticles. Contrary to emulsion polymerization which involves the formation of large monomer droplets dispersed in the aqueous phase, in a miniemulsion process, the monomer phase is stabilized in the form of small droplets with diameters in the range of typically 30–500 nm. Miniemulsions are typically obtained by shearing a system containing water, an oil phase, a surfactant, and an hydrophobe. The role of the hydrophobe is to supress the Ostwald ripening process responsible for droplet coalescence. The hydrophobe must be able therefore to regulate the osmotic pressure inside the monomer droplets in order to ensure both size and composition stability of the oil phase. Many different molecules (hexadecane, hexadecanol, silanes, cyclosiloxanes, …) or macromolecules (high molecular weight polystyrenes, polyesters, silicone oils, …) can be used for this purpose. Because of their small size and large surface area, the monomer droplets can efficiently compete for radical capture and hence become the major locus of particle nucleation. Consequently, polymerization can take place into the monomer droplets which play the role of nanoreactors. This concept of nanoreactor is particularly attractive for the design of a variety of nanoparticulate materials as well as for encapsulation purposes. The potential of miniemulsion in the preparation of new nanoparticles including polycondensates, metals, ceramics, hybrid polymers, and nanocomposites has been recently reviewed [145,146].

Based on the miniemulsion principle, a variety of inorganic particles have been successfully encapsulated including titanium dioxide pigments [147–149], carbon black [150, 151], calcium carbonate [150], magnetic nanoparticles [152], and organic pigments [153]. The principle of pigment encapsulation through miniemulsion polymerization is schematically illustrated in Figure 12. The general process involves forming a stable dispersion of the pigment particles in the monomer and polymerizing the nanoparticle-loaded miniemulsion. In an alternative procedure, a co-miniemulsification technique was developed that allowed the monomer droplets to split and heterocoagulate onto the surface of carbon black particles previously dispersed in water [151]. Monomer deposition on the pigment surface was promoted by a fusion/fission process induced by ultrasound.

Because miniemulsion droplets have small sizes, the pigment particles must be highly dispersed in the monomer to accommodate them inside the droplets. To reach this goal, Erdem and co-workers described the use of a polybutene succinimide pentamine dispersing agent (OLOA 370, Structure 2) that proved to be an efficient stabilizer in case of titanium dioxide pigments and styrene monomer [147]. Stearic acid derivatives were shown to play the same role during the encapsulation reaction of $CaCO_3$ powders by polystyrene [150]. Figure 13 shows a transmission electron microscopy (TEM) image of core–shell $CaCO_3$/polystyrene particles obtained by this technique.
Structure 2. Chemical structure of OLOA 370 (polybutene-succinimide pentamine).

The problem of nanoparticle dispersion is much less critical for organic pigments since they can be readily dispersed in the monomer phase. We recently described the encapsulation reaction of an organic phtalocyanine blue pigment (Structure 3) via miniemulsion polymerization. We showed that the organic pigment played the role of hydrophobe and was able to stabilize the miniemulsion. Better long-term stability was observed, however, when the pigment was used in combination with a costabilizer such as hexadecane or a low molecular weight polystyrene [153]. Pigmented latex particles as well as pure polystyrene latexes were produced in this work suggesting that both monomer droplet nucleation and conventional homogeneous nucleation mechanisms were taking place under our experimental conditions. Similar results have been reported by Chern and Liou during the miniemulsion polymerization of styrene in the presence of a blue dye molecule, sparingly soluble in water [154].

Magnetic Colloids Another important class of nanocomposite particles is the magnetic colloid. As mentioned previously, magnetic latexes are of major interest in the biological and medical fields [155–157]. It has been shown for instance that thermosensitive magnetic latexes with covalently immobilized antigens (so-called magnetic
Figure 13. TEM image of calcium carbonate nanoparticles encapsulated in polystyrene by miniemulsion polymerization. Reprinted with permission from [150], N. Bechthold et al., *Macromol. Symp.* 151, 549 (2000). © 2000, Wiley–VCH.

immunomicrospheres) are particularly suitable for antibody purification applications [158]. The immunomicrospheres were prepared by covalent immobilization of bovine serum albumin onto magnetic poly(styrene/NIPAM/methacrylic acid) latex particles using the carbodiimide method. The thermosensitive encapsulated magnetic particles could be easily flocculated or redispersed by controlling the temperature or the ionic strength and could be quickly separated upon application of a magnetic field. Encapsulated magnetic microspheres tagged with fluorescent dyes also proved to have interesting applications in labeling and separation of cells [159, 160]. They have been used in the magnetic separation of red blood and lymphoid cells and in the detection of the labeled cells by fluorescent microscopy. As patented by Richard and Vaslin [161], magnetic particles can be widely used for therapeutic or analytical purposes and provide useful applications in, for instance, radioimmunological assays, enzyme immobilization, drug targeting, and so on. Magnetically responsive particles are usually prepared by conventional emulsion polymerization methods (similar to those described previously) using colloidal iron oxides (so-called ferrofluids) as magnetic seeds. As before, oleic acid derivatives with strong interactions with the magnetic particles have been preconized in order to stabilize the nanoparticles against aggregation and enhance the affinity of the growing polymer chains for the inorganic surface [155]. Highly charged, monodisperse superparamagnetic latex particles, prepared according to this procedure, have been assembled into colloidal crystals and were found particularly suitable for the creation of unique magnetically induced photonic bandgap materials [162–164]. Alternatively, polymerizable olefin-terminated surfactants have been reported in order to increase the long-term stability of the coating. The fatty acid surfactant was shown to form bilayers on the iron oxide surface and to actively participate to the polymerization reaction [165]. Other techniques include polymerizations in

reverse emulsion [166, 167] and microemulsion [168], emulsification processes [169, 170], and the controlled assembly of preformed polymer latexes and magnetic nanoparticles through electrostatic attraction as described in the previous section. Only a few typical examples of magnetic colloids are described here. Extensive details on synthesis and applications of magnetically responsive nanospheres and nanocomposites can be found elsewhere [64, 65].
Structure 3. Chemical structure of the phtalocyanine blue pigment.

Silica-Based Colloidal Nanocomposites Colloidal silica is widely used as a reinforcing agent in the coating and rubber industries, as the thickener or thixotropic agent of liquid resins, and as fillers for plastics. The incorporation of silica particles into nanocomposite colloids offers a lot of promising perspectives. It is expected that the mechanical strength, stiffness, impact resistance, and optical properties of the resulting composite materials could be significantly improved if the inorganic particles were finely dispersed into the polymeric matrix. Various methods have been thus developed in the last 20 years to improve silica dispersibility by coating the inorganic fine particles with a polymer layer [171–193]. The first studies have been reported by Hergeth who described the elaboration of composite particles made of quartz powders and polyvinyl acetate through seeded emulsion polymerization [171–174]. He showed that the number of seed particles must exceed a minimal value to prevent formation of new particles and thus promote seed particle growth. The polymerization was proved to take place in the vicinity of the surface and the so-produced "interfacial" polymer was shown to display physical properties different than those of the bulk polymer. In the 1990s, Espiard and co-workers described the use of a polymerizable silane coupling agent (3-trimethoxysilyl propyl methacrylate: Structure 4) to covalently attach the polymer shell on the seed surface [175–180]. The silane molecule allowed the grafting of a significant amount of polymer since the early stages of polymerization. The grafted polymer chains formed tight loops on the silica surface into which the free polymer chains were entangled. The films prepared by coalescence of the latexes were fully transparent up to high silica contents and showed remarkable mechanical properties similar to those of vulcanized elastomers reinforced with solid particles [181–183].

Structure 4. Methacryloxy propyl trimethoxy silane (γ-MPS) coupling agent.

Aqueous dispersions of silica/polymer composite particles with a core–shell morphology have been prepared according to this procedure and recently patented [184]. It is worth mentioning also the series of articles from our group on the synthesis of well-defined organic–inorganic silica/polystyrene colloids through dispersion polymerization of styrene using MPS as the coupling agent and PVP as the steric stabilizer [185–188]. We have clearly demonstrated in the first article of the series that the use of the coupling agent was a prerequisite condition for encapsulation to succeed [185]. As a matter of fact, no polymer was produced around the silica particles when the polymerization was carried out in the absence of MPS. In a following work, the diameter of the silica beads was varied in a large range (from 13 up to 630 nm), and we have investigated the influence of the silica bead number on the shape and composition of the composite particles. The average number of silica beads per polymer particle was statistically determined from the TEM images and was found to vary from one to several thousand with increasing number of silica beads in the suspension medium. While the particles containing only one silica bead had an irregular contour, those loaded with a larger amount of silica presented a spherical shape (Fig. 14). Nanocomposite particles with some exotic morphologies were additionally obtained under given experimental conditions. It was shown that small segregated polymer domains were formed on the silica surface since the early stage of polymerization by copolymerization of styrene with the methacrylate group of the coupling agent. These polymer nuclei continued to grow until they formed a continuous contour by coalescence with neighboring growing latex particles, the shape of which was determined by the initial number of growing polymer domains. Regular core–shell morphologies were thus obtained using poly(styrene-*b*-ethylene oxide) block copolymers as stabilizers [187]. In this case, indeed, the number of polymer particles synthesized was much larger than the number of silica beads, and the polymer nuclei could recover the inorganic surface since the beginning of polymerization. Subsequent

growth allowed the formation of a thin and smooth polymer layer surrounding the particles. Free latexes, which did not contain silica beads, were also formed under these conditions, but they could be easily separated from the composite particles by centrifugation (Fig. 14b).

Following a similar route, Sondi and co-workers also described the formation of a protective poly(tert-butyl acrylate) layer on the surface of MPS-functionalized silica nanoparticles [189]. The amount of bound polymer was found to depend on the MPS-grafting density, which in turn was function of the initial MPS concentration. The silica particles, whose surface was efficiently recovered by both grafted and ungrafted polymers, showed an improved resistance to chemical etching. This work highlights the potential interest of encapsulated mineral oxide particles in photoresist technology. In another example of a compatibilizing approach, Yoshinaga and co-workers described the synthesis of a series of oligomeric silane molecules and their use in encapsulation reactions. However, the reaction was performed without surfactant, and it appeared almost impossible to avoid aggregation of the particles in these conditions [190–193].

Since silica colloids are acidic (isoelectric point is around pH 2), basic molecules strongly adsorb on their surface via electrostatic attraction and acid–base chemistry. Such an interaction, similar to that described in Section 2, can be advantageously used in polymerization reactions in order to provide a controlled and specific attraction of the growing polymer chains on the silica surface through a cooperative assembly–growth process. Typical examples of this general concept involve the use of surface active agents, initiator, and monomer molecules having strong affinity for the inorganic surface. These molecules can be regarded as coupling agents with a double function. Part of the molecule is attracted onto silica while the other part participates to the polymerization process by means of initiation or propagation reactions. Nagai and co-workers described for instance the aqueous polymerization of a series of surface active cationic monomers having different alkyl chain lengths (CnBr, Structure 5) immobilized on the surface of silica gel [194, 195]. Using a similar procedure, Yoshinaga et al. described the spontaneous formation of small polymer plots on the surface of silica particles by self-polymerization of a series of adsorbed cationic surface active monomers in tetrahydrofuran solutions [196].

Structure 5. Quaternary alkyl salts of dimethylaminoethyl methacrylate (CnBr).

In a series of articles, Armes et al. synthesized polymer/silica nanocomposite particles through soapless emulsion copolymerization of styrene and acrylic monomers using 4-vinyl pyridine (4-VP) as a basic comonomer

[197, 198]. The presence of the 4-VP comonomer ensured strong interaction of the vinyl polymers with the acidic silica surface resulting in the formation of nanocomposite colloids with a "currant-bun" morphology characterized by silica beads assembled into colloidal aggregates cemented together by the polymer synthesized during the emulsion polymerization reaction. The small silica particles emerging from the composite surface were shown to participate to the colloidal stability of the particles. Similar conclusions have been adressed by Tiarks et al. concerning the miniemulsion polymerization of styrene using silica nanoparticles as spickering stabilizer [109]. Based on this same general idea, colloidal dispersions of nanocomposite particles made of silica cores and polymeric overlayers have been successfully prepared using appropriate cationic radical initiators and cationic vinyl monomers as described in a recent Japanese patent [199]. Recently, our group also demonstrated the successful formation of nanosize silica/PMMA composite colloids using a cationic initiator, 2, 2′-azobis (isobutyramidine) dihydrochloride (AIBA), and a nonionic polyoxyethylenic surfactant (NP$_{30}$) [200–203]. Composite particles made of silica beads surrounded by small heterocoagulated PMMA latexes or a thin polymer layer were produced depending on the size of the silica beads (Fig. 15). The role of the suspension pH and the influence of the monomer, silica, and initiator concentrations on the assembly process have been investigated in depth and analyzed in a quantitative way. Electrostatic attraction between the polymer end groups and the negatively charged silica surface proved to be the driving force of polymer assembly at high pH whereas polymerization in the adsorbed surfactant bilayers appeared to be the predominant mechanism at lower pH. Finally, it is worth noting also the recent work by Percy and Armes on the surfactant-free synthesis of colloidal silica/PMMA nanocomposites in the absence of auxiliary comonomers using a commercial dispersion of silica beads into isopropyl alcohol [204]. The assembly process was suspected to be driven in this case by simple hydrophobic interactions.

Conducting Metal Oxide/Polymer Nanocomposites

Electrically conducting organic polymers have drawn the attention of scientists for several decades due to their unique physical and chemical properties (redox, acid–base, ion-exchange, . . .). Conducting polymers have been found to
Figure 15. TEM micrographs of the silica/PMMA nanocomposite particles obtained through emulsion polymerization in alkaline solutions using AIBA as a cationic initiator. be particularly suitable for numerous applications as optical and electrical sensors, molecular electronic devices, and anticorrosion, and antistatic coatings [205–207]. Polypyrrole (Ppy) and polyaniline (PAN) are two important examples of conducting materials with high electrical conductivity and significantly good stability in air and water. These highly conjugated conducting materials, however, have some inherent limitations such as poor mechanical strength and poor processability. Bulk Ppy and PAN are infusible, intractable, and insoluble in commun solvents which drastically reduces their potential uses as thin films or coatings. Various attempts have been made to improve the processability of these otherwise intractable conducting powders. Sterically stabilized dispersions of conducting polymers have been elaborated for instance using various types of polymeric dispersants [208–211]. The particles usually exhibit good long-term conductivity and conductive films can be easily fabricated from the colloidal dispersions. Another alternative solution consists of the elaboration of conducting nanocomposites that combine the advantages of conducting polymers and those of inorganic particles. There have been numerous publications describing the preparation of conducting O/I nanocomposite colloids in recent literature [212–240].

Matijevic et al. [212–215] described for instance the formation of PAN and Ppy coatings over a series of metal oxide particles (α-Fe$_2$O$_3$, CeO$_2$, CuO, TiO$_2$, SiO$_2$). The conducting polymers were produced by chemical oxidation of the monomers in a mixture of ethanol and water in the presence of poly(vinyl alcohol) in order to produce stable colloidal suspensions. The coating reaction was catalyzed by air in the case of α-Fe$_2$O$_3$ and SiO$_2$ and the metal oxide surface was found to be inactive in the oxidation mechanism. On the contrary, the hydroxylated surfaces of CuO or CeO$_2$ could initiate the polymerization of the adsorbed monomer through a reductive-dissolution process, in which the monomer was oxidized while the metal oxide was reduced into metal ions. In the case of copper oxide, the released Cu$^+$ ions were reoxidized by air to Cu^{2+} cations which in turn were able to extend further the molecular chain and increase the thickness of the shell or give new independent polyaniline or polypyrrole (latex) particles in addition to the coated CuO particles. A regular core–shell morphology or more irregular coatings with free polymer particles coagulated on the core surface were obtained depending on the experimental conditions.

Armes and co-workers [216–223] and Perruchot et al. [224] also described the synthesis of composite materials made of various ultrafine inorganic oxide particles (silicium, tin, titanium, yttria, . . .) and polypyrrole or polyaniline. The polymerization reactions were performed in water without any stabilizer and using FeCl$_3$ or (NH$_4$)$_2$S$_2$O$_8$ as chemical oxidants. Macroscopic precipitation of the conducting polymer was prevented by the presence of the inorganic sol resulting in the formation of stable colloidal dispersions of organic–inorganic particles, the metal oxide playing the role of a *particulate* colloidal dispersant (Fig. 16). The resulting nanocomposites were made of microaggregates of the original oxide nanoparticles "glued" together by the polypyrrole or the polyaniline components as demonstrated by small-angle X-ray scattering [225]. Chemical analysis of the surface composition of polymer/silica nanocomposites by X-ray

photoelectron spectroscopy [226] proved that they had silica rich surfaces suggesting that the conducting polymer was somewhat depleted from the surface of the nanocomposite particles. The raspberry colloids were shown to display large surface area making them suitable for catalysis or chromatographic applications [227]. A similar approach has been developed in the case of zirconium dioxide [228], and similar results were obtained. The resulting polypyrrole/ZrO_2 nanocomposites showed a significant increase in conductivity in comparison to bare polypyrrole. Other typical examples include the elaboration of conducting polyaniline-coated barium sulfate nanoparticles in inverse microemulsion [229], the elaboration and physical characterization of polyaniline and polypyrrole–montmorillonite nanocomposites [230–233], the uptake of palladium [234] or gold [235] from aqueous solutions of conducting particles, and the synthesis of polypyrrole–ferric oxide conducting nanocomposites [236].

The elaboration of conducting nanocomposites is not restricted to silica and metal oxide colloids. In an original approach, Selvan and Nogami described for instance the synthesis of gold/polypyrrole core/shell nanoparticles via a simultaneous cooperative precipitation/polymerization mechanism [237]. Gold particles have also been reported to be useful templates for the growth polymerization of conductive polypyrrole and poly(N-methyl pyrrole) on their surface [238–240]. The polymer–gold composite particles were converted in a subsequent step into hollow polymeric nanocapsules by chemical etching of the colloidal gold template. Not only were the gold particles useful templates but they also made it possible to entrap guest molecules in the capsule core: rhodamine B isothiocyanate (Structure 6). The
Structure 6. Rhodamine B isothiocyanate.

loaded dye remained encapsulated in the hollow spheres after gold etching. This synthetic method obviously offers an interesting approach to guest encapsulation and could potentially be extended to the entrapment or enzymes and proteins.

3.2.2. Polymerization Initiated by Inorganic Particles

Apart from the formation of dense coatings, core–shell O/I particles can also be elaborated by templating inorganic colloids with polymer brushes using living polymerization techniques. The grafting reaction can be done in various ways through anionic [241–243], cationic [244, 245], or free radical processes [246, 247]. A variety of colloidal materials including silica and gold nanoparticles are concerned by these approaches. Since the growth reaction of polymers from inorganic surfaces is a very broad field of research [17, 248–253] a full description of these systems will not be attempted here. Only recent and typical examples will be reported in this section.

Hybrid nanoparticles with a block copolymer shell structure have been synthesized for instance by ring opening polymerization of norbornenyl groups immobilized onto gold colloids [254]. Ring opening polymerization of ε-caprolactone has also been recently conducted from the surface of silica gel and cadmium sulfide nanoparticles [255, 256]. Amine or alcohol groups have been attached to the inorganic surface using silane coupling agents in order to provide a covalent anchoring of the macromolecules into hydrolytically stable polymer brushes. Tsubokawa et al. described the grafting of various polymers from the surface of silica nanoparticles [257–261]. Cationic polymerization of styrene was initiated by surface-grafted acylium perchlorate groups whereas peroxyester and diazo functions were involved in free radical polymerizations of styrene and methyl methacrylate monomers, respectively. In azo-initiated reactions, ungrafted polymer chains were also produced since the initiator was attached to the surface by only one end. In order to achieve better control of the grafting density, Prucker and Rühe described the designed synthesis of an asymmetric diazo silane coupling agent [262–264]. The azo compound contained a cleavable ester group in order to facilitate degrafting of the polymer chains for analytical purposes and was monofunctional to control self-assembly of the chlorosilane azo initiator on the silica surface. Polymerization was performed in toluene at 60 °C and afforded grafted and free polymer chains. The graft density was found to be dependent on the silane concentration and polymerization time. Despite the confinement of the growing active centers on the silica surface, high molecular weight polymers were formed without the occurrence of excessive branching or cross-linking reactions. In recent years, several groups have reported the synthesis of polymer-grafted nanoparticles with controlled molecular weights and molecular weight distributions, using the atom transfer radical polymerization (ATRP) technique [265–270]. The general synthetic strategy involves the covalent attachment of various halide-functionalized ATRP macroinitiators on the inorganic surface (Table 1) and the subsequent controlled/living growth reaction of the polymer

chains from the anchored initiator molecules (Fig. 17). One key advantage of controlled radical polymerization (CRP) in comparison to conventional free radical processes is the possibility to synthesize well-defined polymers which can

be grown with the desired thickness and composition. The technique allowed the formation of densely grafted and hairy outer polymer layers on nanoparticulate silica surfaces. Owing to the narrow molecular weight polydispersity of the polymer chains, the grafted particles organized into two-dimensional (2D) arrays with controlled interparticle distances a function of the degree of advancement of the reaction. Hollow polymeric microspheres have been produced by this technique by templating silica microspheres with poly(benzyl methacrylate) and subsequently removing the core by chemical etching [271]. The ATRP technique has also been recently reported to work effectively in aqueous media using hydrophilic water-soluble acrylic monomers [272]. Not only silica but also aluminum oxide particles [273], magnetic colloids [274], gold [275, 276], and photoluminescent cadmium sulfide nanoparticles [277, 278] have been used as macroinitiators. When cast from solution, the resulting nanocomposite film materials exhibited hexagonal ordering of the photoconductive cores (Fig. 17b) and were

shown to retain the photoluminescent properties of the precursor CdS nanoparticles, but no mention was made of the colloidal stability of these systems.

It has been shown recently that the so-called stable free radical polymerization can also be used to initiate the polymerization of vinyl monomers from inorganic surfaces [279]. Following this route, shell-cross-linked polymeric capsules have been elaborated in a multistep procedure by templating colloidal silica with polymeric compounds and cross-linking the polymer shell. Micrometric silica beads were first modified by grafting on their surface a chlorosilane alkoxyamine initiator (see Table 1). Copolymers were then grown from the surface-attached initiator using an appropriate amount of sacrificial "free" alkoxyamine. The copolymer chains were designed to carry maleic anhydride functional groups for further cross-linking reactions (Fig. 18). A diamine cross-linker was added in a third step to effect interchain coupling via the formation of a bisimide. The inorganic silica template was finally removed in a last step by chemical etching. In an alternative strategy, styrene monomer was copolymerized with 4-vinylbenzocyclobutene, and the resulting nanocomposite core/shell particles were heated at 200 °C for thermal cross-linking.

3.2.3. Cross-Linking of Self-Assembled Monolayers

As mentioned previously (Section 2), self-assembly also provides an original and efficient way to modify inorganic particle surfaces [280]. The formation and structure of self-assembled monolayers (SAMs) and their use in surface engineering have been much described and reviewed in recent years [281]. Alkane-thiol derivatives for instance are known to self-assemble onto gold colloid surfaces in a monolayer fashion via a surface complexation reaction [282]. If convenient reactive groups are incorporated into the SAM, further chemical reactions can be envisaged in order to elaborate core–shell particles and hollow capsules after degradation of the internal core (Fig. 19).

Shell-cross-linked polymeric nanocapsules have been synthesized for instance by metathesis polymerization of

Figure 19. Principle of formation of shell-cross-linked nanocomposite particles from self-assembled monolayers on colloidal surfaces and the resulting polymeric capsules after core removal by chemical etching.

alkene-functionalized alkylthiolate monolayers attached on gold surfaces [283]. The thiolated ligands were designed to maximize polymer cross-linking and contained three alkene groups. In a related work, Sun and co-workers reported the preparation of monolayer-thick polymeric spheres by assembling thiolated-β-cyclodextrins (β-CD-SH) (Structure 7) around gold nanoparticles (Fig. 20) [284]. The core dissolved upon addition of iodine to the suspension while simultaneously disulfide bonds were formed on the surface to produce structurally rigid cross-linked nanocapsules.

3.3. Polymer Latexes as Colloidal Templates

Coating of polymer colloids with materials of different chemical compositions gives access to nanocomposite particles with tailored structures and morphologies. Contrary to inorganic templates that require relatively harsh conditions to decompose, organic colloids can be easily removed either chemically or thermally from the nanocomposite particles without damaging the shell materials. A large variety of such structures involving polymer latexes as sacrificial templates can be found in recent literature.

3.3.1. Sol–Gel Nanocoating

The coating of organic templates by metal oxides can be easily conducted in solution by the sol–gel technique. The sol–gel process involves the reaction of metal salts or organometallic precursor molecules to produce a three-dimensional inorganic polymer network. The coating of polystyrene latex particles with amorphous titanium dioxide has been achieved for instance by the hydrolysis of titanium tetrabutoxide [285, 286] and titanium tetraethoxide [287] in ethanolic suspensions. Due to the fast reactivity of the titanium alkoxide precursor in the sol–gel process, mixed suspensions with secondary titania particles were mostly produced. Optimal conditions were found to avoid the formation of separate particles and afford a regular coating. In order to overcome these difficulties, another approach, which consists of using cationic polystyrene particles as the seed, has been developed [288]. The positive charges on the surface ensured quick deposition of the titania precursors on the seed particles in the early stages of the sol–gel reaction. Very thin (in the range typically a few nanometers up to 50 nm) and smooth coatings were thus produced in a one-step method. Crystalline hollow spheres were further obtained by calcination of the TiO_2-coated particles at elevated temperatures. Increasing the temperature up to 600 °C yielded hollow crystalline anatase titania particles whereas the rutile form of TiO_2 was obtained by calcining at 900–1000 °C. As an alternative solution, the latex core was dissolved by suspending the coated particles in toluene, a good solvent for the polymer. Using a similar technique, Margel and co-workers described the coating of large polymer beads with silica and magnetic iron oxide [289]. The coating was performed by seeded polymerization of tetraethoxysilane and iron salts on micrometer-sized polystyrene seed particles. The polymer surface contained adsorbed PVP which obviously played an active role in the coating procedure. Freestanding inorganic nanoparticles were also procuded in this process but they could be easily separated from the coated polymer beads by repeated centrifugations. Core removal was performed thermally and the hollow capsules were visualized by TEM from cross-sections of the particles. With the aim to improve chemical interaction between the core and shell materials, we have recently developed a coating strategy based on a two-step procedure (Fig. 21). Polymer latex particles carrying silanol groups on their surface were first synthesized in emulsion polymerization using γ-MPS as a functional comonomer [290, 291]. The SiOH-functionalized latexes have been extensively characterized using AUGER, solid state nuclear magnetic resonance, and infrared spectroscopies [291]. The surface charge

Tissot et al., *Macromolecules* 34, 5737 (2001). © 2001, American Chemical Society.

density was determined by chemical titration and was found to vary between 1.15 and 3.7 $\mu C/cm^2$ depending on the MPS content in the monomer mixture. Then, a silica shell was produced onto the functionalized PS seed particles by addition of tetraethoxysilane and ammonia to the colloidal suspension either in water [290] or in a mixture of ethanol and water [291]. No separate silica particles were formed in this work, indicating the strong affinity of the sol–gel precursor for the polymer colloid. Burning of the latex core resulted in the formation of hollow nanometer sized silica capsules The nature of the core, the particle size, and the shell thickness can be finely tuned by conventional polymer colloid chemistry. Core–shell latexes with a soft polybutylacrylate core and a rigid silica shell have also been successfully produced by this technique.

Not only can inorganic precursors be used for coating, but preformed particles can also be homogeneously deposited onto colloidal templates to generate core–shell structures. For instance, colloidal clay nanosheets have been adsorbed onto cationic polystyrene latexes as a thin and crystalline layer [292]. Tetramethoxysilane was used as inorganic precursor to consolidate the coating and increase shell stability. The polymer template was removed in the next step to generate hollow silicate capsules. Hollow titania shells have been produced in a similar way by alternate deposition of polyethylenimine and titania nanosheets on polymer latexes and removal of the organic template by heat or ultraviolet (UV) treatment of the core–shell nanocomposite particles [293]. Valtchev also recently reported the coating of micrometer-sized polystyrene beads by zeolite

A nanocrystals using a cationic polymeric agent as binder between the core and shell materials [294].

In addition to polymer latexes, inorganic colloids can also be advantageously used as templates to generate inorganic capsules. A range of hollow spheres have been prepared in this manner using silica materials as sacrificial templates. For example, monodisperse core–shell colloidal spheres of silica (SiO_2) and zinc sulfide (ZnS) have been elaborated by templating silica colloids [295]. Coating of SiO_2 with ZnS was performed in water/ethanol solutions by direct precipitation of ZnS onto the silica seed using thermally activated thioacetamide as a source of sulfide ions and acidic zinc nitrate aqueous solutions. Hollow ZnS spheres were obtained in a subsequent step by dissolving the SiO_2 core in hydrofluoric acid. Surprisingly, the ZnS shell only dissolved slowly under these conditions and the particles retained their original shape. The reverse structure composed of ZnS core coated with silica was elaborated in a similar way by templating zinc sulfide colloids with tetraethoxysilane using a seeded growth technique adapted from the Stöber method. A mineral nitric acid, much less aggressive than HF, was used in this case to selectively dissolve the ZnS core from the structured particles. The resulting hollow spheres (either the silica shells or the high dielectric ZnS capsules) were shown to display interesting optical properties with potential applications as colloidal crystals in photonic devices. Another extensively described templating material is gold colloid [296, 297]. The coating of gold nanoparticles with silica has been reported by Mulvaney and co-workers. The coating serves first to stabilize particles against coagulation and also promotes ordering of the nanoparticles into two-dimensional arrays. Their method involves three successive steps. The gold surface was first rendered vitreophilic by addition of 3-aminopropyl trimethoxysilane which strongly adsorbed on the metal. The anchored silanol groups were then involved in the formation of a thin silica layer by direct precipitation of a native sodium silicate solution. In the final step, extensive growth was performed in ethanol/water mixtures to afford silica-coated gold nanoparticles with shell thickness up to 80 nm. Again, the coated nanosized silica/gold colloids were shown to display very interesting optical properties [298]. Hollow silica capsules were obtained from the coated colloids by exposing the particles to cyanide ions. The oxidized gold cores completely dissolved and diffused out of the silica shell. Several studies on silica particles grown using TEOS clearly attest to the presence of micropores ranging in size from 2 to 50 nm. The resulting microporous and hollow shell particles are potential carriers for slow release and drug delivery.

3.3.2. Metal Deposition

The immobilization of fine metal colloids onto nanoparticle surfaces has received a lot of attention in recent years because of the potential use of metal-decorated particles in optics, electronics, and heterogeneous catalysis [299, 300]. A variety of methods have been successfully reported for the coating of colloidal templates with metallic nanoparticles. Two approaches can be distinguished. In the first method, the nanoparticles are precipitated *in-situ* onto the colloidal templates by the reaction of the metal salt precursors previously adsorbed on their surface through ion exchange or

complexation chemistry [301–310], whereas in the second method, preformed metal colloids are adsorbed onto colloidal templates of opposite charges through electrostatic interaction as extensively reported in the previous section. In both methods, the colloidal templates must contain surface groups with strong affinity for the metal precursors and/or the nanoparticles. Functional groups such as carboxylic acid (-COOH), hydroxy (-OH), thiol (-SH), and amine ($-NH_2$) derivatives can be easily introduced into polymer latexes by copolymerizing their corresponding monomers. The surface-complexed metal salts are then directly transformed into metal colloids by the addition of reducing agents. Following this route, palladium [301–303, 306, 310], rhodium [301–303, 309], nickel [305], cobalt [305], silver [304], and gold [310] nanoparticles have been successively anchored onto the surface of a series of functional polymer microspheres. The resulting composite colloids were shown to display high catalytic activity in, for instance, the hydrogenation of alkenes. In alternative procedures, the coating can also be produced by the controlled hydrolysis of the metal salts into metal oxide followed by reduction of the oxide into the corresponding metal [311–316]. Submicrometer-sized composite spheres of yttrium and zirconium compounds and hollow metallic spheres have been prepared this way by coating cationic polystyrene latex particles with basic yttrium carbonate [311–312] and basic zirconium sulfate [313], respectively, followed by calcination of the so-coated latexes at elevated temperatures. Uniform coatings of copper [314] and iron oxide [315, 316] compounds have been formed in a similar procedure by aging at high temperature aqueous solutions of the metal salt in presence of urea, PVP, and anionic polystyrene latexes. The coating was shown to proceed by *in-situ* heterocoagulation of the precipitating metal colloids on the organic seed surface. Voids were produced in a subsequent step by complete thermal oxidative decomposition of the polymer core.

Not only metal but also semiconductor nanoparticles can be used for coating. Polymer micro- and nanoparticles have been successively reported as host matrices for CdS nanocrystal formation [317, 318]. Monodisperse poly(methyl methacrylate-co-methacrylic acid) (PMMA–PMAA) latex particles were prepared by emulsion polymerization and ion exchanged with a $Cd(ClO_4)_2$ solution. The Cd^{2+} ions thus introduced into the electrical double layer were further reduced into CdS nanoclusters by addition of a Na_2S solution. The CdS loaded nanocomposite particles were subsequently recovered by a film forming polymer shell by reacting methyl methacrylate and butyl acrylate monomers. The resulting colloidal nanocomposites were finally assembled in 3D periodic arrays consisting of rigid PMMA–PMAA/CdS core particles regularly distributed within the soft polymer matrix. Periodic structures of polyacrylic/silver colloids have been elaborated in a similar way using Ag^+ ions as precursors. The method obviously opens a new avenue for producing optically responsive materials with a controlled periodicity. Nanocomposite materials with several other functions can be elaborated by this technique using different types of nanoparticles and organic polymers.

3.4. Vesicle and Block Copolymer Templating

O/I nanocomposite colloids can also be elaborated from the assembly of preformed polymers into spherical aggregates and their subsequent use as host materials or templates for the growth reaction of metal oxides and metal colloids. The ability of amphiphilic diblock copolymers, dissolved in a selective solvent, to self-assemble into colloidal size aggregates has been studied for several decades and their use as nanoreactors has been much described. Core–shell architecture of micelles prepared from amphiphilic polymers permits the dissolution of large amounts of poorly water soluble drugs, for instance, and affords protection against a potentially damaging environment. On the other hand, phospholipid molecules and synthetic amphiphiles with two long aliphatic chains attached to an ionic head group are insoluble in water and are known to form highly ordered layers. The bilayer structures separate an aqueous interior from an aqueous exterior and are versatile carriers in the area of drug delivery. The elaboration of vesicular, micellar, and related aggregate structures as host materials for inorganic polymerization is briefly reviewed in this section. A complete description of these systems can be found elsewhere [319, 320].

3.4.1. Vesicle Templating

Surfactant vesicles are an important class of bilayer aggregates extensively used as model membranes for artificial cells. They are nonequilibrium structures mostly kinetically stabilized. Vesicles are usually produced by shear-assisted means including sonication and extrusion. However, owing to the noncovalent interactions responsible for their formation, these nanoobjects have only a limited stability and inherently return to their native lamellar phase state. A variety of techniques have been employed in order to increase vesicle stability. One method involves using reactive polymerizable surfactants and polymerizing the vesicle. Another technique takes advantage of the bilayer morphology of the surfactant aggregates to solubilize organic substances such as monomers. Subsequent polymerization of the vesicles gives hollow spheres whose shape is the replica of the original bilayer structure (so-called morphosynthesis). The shell is cross-linked so as to afford rigid and stable capsules after extraction of the templating surfactant matrix. In addition to morphosynthesis, vesicles can also be used as templating materials for transcription into inorganic capsules as described by Hubert and colleagues [321]. The transcriptive synthesis approach (see Fig. 22) is identical to the colloidal templating strategy described in the previous section. Cationic dioctadecyldimethylammonium vesicles were shown to provide effective receptors for silica growth due to electrostatic interaction of the alkoxysilane precursors with the surfactant molecules. The so-produced "petrified" vesicles were stable to dehydratation and could be visualized by conventional TEM without additional staining agents.

3.4.2. Block Copolymer Templating

Block copolymers can adopt a variety of supramolecular structures in selective solvents. Gohy and co-workers described for instance the synthesis of pH-sensitive core–shell–corona (CSC) polystyrene-b-poly(2-vinyl pyridine)-b-poly(ethylene oxide) triblock copolymer micelles [322]. The
Figure 22. Schematic representation of the vesicle-templating strategy (transcriptive synthesis) for the elaboration of hollow inorganic spheres.

micelles were loaded with $HAuCl_4$ gold salt, which was transformed in the next step into metal colloids by $NaBH_4$ reduction. Due to preferred interaction between the protonated P2VP block of the terpolymer and the metal ions, precipitation of gold nanoparticles took place on the P2VP outerlayer of the triblock micelle. Similarly, CSC polyisoprene-b-poly (2-cinnamoylethyl methacrylate)-b-poly(tert-butyl acrylate) micelles (PI-b-PCEMA-b-PtBA: Structure 8) have been produced by Stewart and Liu [323]. The micelles were solidified by UV cross-linking of the PCEMA shell while the PI block was degraded by ozonolysis to generate nanospheres with a central cavity. The so-obtained nanocapsules were loaded with rhodamine B (Structure 6), a model molecule which size is similar to that of drug compounds. In a related work, iron oxide magnetic nanoparticles have been precipitated inside the core of the PI-b-PCEMA-b-PtBA triblock micelles [324]. For that purpose, the triblock nanospheres were first rendered water dispersible by hydroxylation of the polyisoprene block. The PtBA block was then converted into polyacrylic acid (PAA) by hydrolysis. The resulting polymeric triblock nanospheres were loaded with Fe^{2+} metal ions by exchange of the PAA protons and the iron oxide nanoparticles were finally precipitated by addition of NaOH. Based on the same general concept, the synthesis of a variety of triblock and diblock copolymer micelles has been reported in the literature [325–327]. Hollow particles have been produced for instance from shell-cross-linked (SCL) micelles after degradation of the internal part of the micellar aggregates. These SCL micelles can serve further as nanoreactors to precipitate organic and/or inorganic particles using strategies
Structure 8. Polyisoprene-b-poly (2-cinnamoylethyl methacrylate)-b-poly(tert-butyl acrylate) (PI-b-PCEMA-b-PtBA).

similar to those reported previously for CSC micelles. pH-responsive SCL micelles have been used for instance as reservoirs for the preparation of gold colloids [328]. Organic polymerization reactions can also be conducted in the confined space of nanocapsules. As a typical example, an aqueous solution of hydrophilic monomers containing acrylamide has been entrapped inside the water pool of hollow spheres. Subsequent polymerization produced cross-linked poly(acrylamide) gels filling the whole volume of the capsule. The imprinted latexes were found to adopt the dimensions and spherical shape of the mold [329].

4. HYBRID COLLOIDS

Composite materials where the organic and inorganic components are intimately intertwined within one another on the molecular level are an important class of materials whose properties are controlled by the functionality and connectivity of the molecular precursors. There have been a huge number of works in recent years describing the elaboration of hybrid structures of this type by, for instance, *in-situ* polymerization of inorganic precursors within a polymer matrix or by embedding of organic polymers into inorganic glasses [16–22]. Such materials are usually produced by the sol–gel technique and processed as thin films, powders, gels, or monoliths [330]. But, surprisingly, there are only few examples of nanoparticle synthesis by reacting simultaneously organic and inorganic precursor molecules into a kind of organic/inorganic interpenetrated network. An example of morphology that can be produced by this strategy is reported in Figure 23 which represents a colloidal particle composed of an organic–inorganic network condensed into a gellike structure. It is expected that the properties of those hybrid colloids will be significantly different than a simple combination of the properties of the two components. We describe in this section typical examples of this general approach.
4.1. Poly(organosiloxane/vinylic) Copolymer Hybrids

The combination of various polymers and copolymers with inorganic structures, like silica and silsesquioxanes, to yield inorganic particles doped with organic polymers or vitreophilic polymer colloids can be readily conducted in multiphase media. As a matter of fact, silica networks and structured silicate for instance are easily obtained by hydrolysis and condensation of tetrafunctional [Si(OR)$_4$] or trifunctional [R$'_n$Si(OR)$_{4-n}$] alkoxysilanes in various dispersion systems. In addition, the polymerization reaction of a variety of acrylic monomers and comonomers can be carried out in these systems as well. So, provided that the rates of both reactions are not too much different and that a coupling agent is used to link the inorganic network and the organic polymer, hybrid colloids with interpenetrated organic–inorganic networks could be formed. Microemulsion for instance is a convenient system for both metal oxide and polymer latex synthesis. On one hand, alcohols are usually used as short chains cosurfactants in conjunction with sodium dodecyl sulfate to stabilize the microemulsion. On the other hand, the sol–gel reaction can take place in alcohol–water mixtures. Consequently, the sol–gel reaction of TEOS and the polymerization of acrylic monomers can be performed simultaneously in microemulsion systems in which the continuous phase is a mixture of alcohol (typically methanol) and water and the organic phase is composed of TEOS and the acrylic monomer. In a typical recipe, the inorganic precursor, the organic monomer, and the coupling agent are added simultaneously, and interpenetrated networks can be obtained by adjusting the kinetics of the organic and inorganic reactions. Organoalkoxysilane molecules with a terminal double bond reactive in free radical polymerization processes are particularly well suited in order to attach the polymer chains to the inorganic network as described in the previous section. Methacryloxypropyl trimethoxysilane (γ-MPS) is the most commonly used functional monomer for such applications.

Following this route, Donescu et al. have synthesized hybrid materials by the simultaneous reaction of TEOS and methyl methacrylate in the presence of alcohol [331]. A cross-linker was introduced to promote the formation of the polymer network and γ-MPS was used to avoid phase separation. Although it is not clear whether colloidal particles have been successfully obtained in this work, the formation of simultaneous interpenetrated polymer–inorganic networks was indirectly evidenced by the increase in glass transition temperature and the improved thermal resistance of the organic network in the presence of the inorganic phase. In a related study from the same group, vinyl acetate was used as the organic monomer and it was argued that monostructured materials or dispersed particles were obtained depending on the ratio of the organic over the aqueous phase and the nature of the comonomer (e.g., butyl acrylate versus di-2-ethyl hexyl maleate) [332]. It has also been reported in a recent work from Uricanu

Gel-type colloidal particle with interpenetrated organo-mineral network

Figure 23. Schematic representation of nanocomposite colloids with organic/inorganic interpenetrated network.

and Panayiotou that silica–polystyrene nanocomposites can be obtained in one reaction step through miniemulsion polymerization [333]. However, the silica nanoparticles were shown to form agglomerates in the final composite latexes, and phase separation occurred during polymerization.

We have recently demonstrated in our group that the MPS molecule can also be reacted with acrylic and styrene monomers to produce functional hybrid copolymer latexes with interpenetrated organic/inorganic networks via emulsion polymerization [290, 291, 334]. The polymer latex particles were synthesized in batches or semibatches. In the semibatch reactions, the silane molecule was introduced as a shot after consumption of part of the acrylic and styrene monomers. Core–shell colloids with a polymer core and a hybrid shell were thus produced by this technique. The core-to-shell ratio could be easily adjusted by addition of the silane molecule at different seed conversions. The silane concentration was varied from 5 to 40 wt% with respect to the monomer without significant influence on particle size and particle stability except when nonionic surfactants were used as stabilizers. Not only did the presence of the silanol group enable the successful overgrowth of a silica layer on the polymer particle surface, but the hybrid structure of the shell also proved to have unusual solubility behavior [335]. Hybrid polymeric capsules were produced from the core–shell nanocomposite colloids by suspending the hybrid latexes into a good solvent of the core, THF. The latex core was shown to diffuse through the hybrid shell and instantaneously dissolve into THF giving rise to hybrid and soft nanocapsules. Figure 24 shows the morphology of the hybrid capsules after observation with a conventional transmission electron microscope and by cryogenic transmission electron microscopy, respectively. While the dried capsules collapsed on the grid support due to the very low shell thickness and presumably also because of the low Tg of the hybrid copolymer membrane, cryo-TEM observation enabled visualization of the spherical shape of the capsules by preserving their morphology into a thin film of freeze-dried water. The hybrid shell structure thus played the role of a dialysis membrane that enabled water exchange in and out of the capsules.

Film forming copolymer latexes were also produced by this technique by reacting MPS, styrene, and butyl acrylate monomers. The composite films were fully transparent up to 15% MPS content suggesting an homogeneous distribution of the silane units within the organic/inorganic network and the absence of macroscopic phase separation. The resulting materials were characterized by dynamic mechanical spectroscopy and were shown to display significantly improved mechanical properties in comparison to their polymeric counterparts.
Not only can tetrafunctional and trifunctional alkoxsilanes be reacted with vinylic monomers, but polysiloxanes with difunctional repeating units can also be incorporated into polymer latexes via the emulsion copolymerization reaction of silicon monomers, namely octomethyltetracyclosiloxane and methacryloxypropyl trimethoxysilane, and a series of acrylic compounds (e.g., MMA, butyl acrylate, acrylic acid, and N-hydroxyl methyl acrylamide) [336–341]. In order to obtain stable latexes, the copolymerization reaction must be carried out under specific experimental conditions. It was shown for instance that stable monodispersed particles were formed only when the monomers were pre-emulsified in water and added dropwise at 85 °C into an aqueous solution of the initiator. The silane coupling agent was used to control particle morphology and provide a successful incorporation of the silicone polymers into the acrylic latexes. The films produced from the hybrid latexes were shown to display improved water resistance and a higher gloss.

4.2. Polyorganosiloxane Colloids

Organoalkoxysilanes of the type described previously $[R_nSi(OR')_{4-n}]$ can also be processed separately as fine particles by emulsion polymerization as extensively reported by Schmidt and co-workers in recent literature [342–348]. The colloids were elaborated by the sol–gel process in aqueous solution through hydrolysis and condensation of various organoalkoxysilane precursors in the presence of benzethonium chloride surfactant (Structure 9) and a base catalyst. Spherical elastomeric micronetworks (so-called organosilicon microgels) of narrow size distribution were produced by this technique. Typical examples of alkoxysilane derivatives which have been used in these syntheses are listed in Table 2. From the mechanistic point of view, the inorganic polymerization reaction can be regarded more as a polycondensation in microemulsion than a conventional emulsion polymerization process. Particle sizes were principally governed by the ratio of surfactant to monomer concentration, and in a limited range, the final microgel diameters could be well described by the theory of μ-emulsion although the suspensions were not fully transparent. The main interest of the technique is the possibility to synthesize highly functionalized nanoparticles with nearly uniform diameters typically in the range 10–40 nm. The cross-linking density of the microgel particles could be finely

Figure 24. (a) Conventional TEM picture and (b) cryo-TEM micrograph of poly(styrene-co-MPS) hybrid capsules. Scale bar: 100 nm.
Structure 9. Benzethonium chloride surfactant.

tuned by using a mixture of trifunctional (T) trialkoxysilane and difunctional (D) dialkoxysilane molecules. Particle sizes were shown to increase with increasing content of D units suggesting intraparticle gelation. Other critical parameters influencing colloidal stability were the dispersion concentration, the amount of catalyst, the temperature, and the monomer addition rate. The particles could be additionally rendered chemically inert toward further interparticle condensation reactions and hydrophobic by end capping of the –SiOH groups into –SiOSi(CH$_3$)$_3$ or –SiOSi(CH$_3$)$_2$H moieties. The curing process was performed by addition of trimethyl methoxysilane or dihydridotetramethyldisiloxane, respectively. The resulting colloids could be easily solubilized or redispersed into organic solvents making it possible to grow polystyrene chains from their surface by the hydrosilylation reaction of vinyl-terminated polystyrene macromonomers with the SiH functional groups [345]. Those model systems have been shown to be particularly suitable for the elaboration of thermodynamically stable homogeneous mixtures of the hybrid colloids with linear polymeric chains.

In addition to copolycondensates, well defined core/shell structures can also be prepared by the subsequent addition of different types of monomers on particle seeds [346, 347]. The cores were made for instance of linear chains of polydimethylsiloxane while the shell was cross-linked by reacting different trialkoxysilane precursors. One important feature of these core–shell colloids is that specific reactivities can be imparted to the cores by the reaction of convenient functional monomers. These topologically entrapped functional molecules are confined reactive sites that can undergo further chemical reactions. According to this principle, organic dye molecules have been selectively attached to microgel particles by the reaction of the dye labels with chlorobenzyl functional groups previously incorporated in the internal part of the colloid [348, 349]. In a similar procedure, functionalized μ-network gel particles were used as nanoreactors to entrap metal clusters [350, 351]. The microstructure of

the host microgel particles was designed so as to contain reducing SiH moities in their core. Metal ions were subsequently loaded into the microgel particles by diffusion of the metal salt solution [H(AuCl$_4$)] through the shell. Metal salt reduction was taking place *in-situ* by means of the confined SiH reactive sites. The aqueous dispersion of the metal cluster entrapped colloids was finally transferred to organic solvents by reaction of SiOH with monoalkoxy silanes as reported previously.

An original approach that combines templating techniques and organoalkoxysilane chemistry has been reported by Büchel and co-workers [352]. The authors described the synthesis of silica core/mesoporous shell (SCMS) colloids by reacting a mixture of triethoxysilane and *n*-octadecyl trimethoxysilane (C18-TMS; see Table 2) on the surface of nanometer-sized silica particles produced by the Stöber process. Calcination of the C18-TMS porogen molecules resulted in the formation of inorganic spheres whose surface porosity can be finely tuned by the concentration of the organoalkoxysilane precursor incorporated into the shell. Following this line, Yoon et al. reported the fabrication of carbon capsules by templating the mesopores of the SCMS colloid with a phenolic resin followed by carbonization [353]. Hollow spheres were produced in the last step by dissolution of the silica core. More recently, the technique was extended to the synthesis of complex shell-in-shell nanocomposite particles and gold loaded nanocapsules using silica-coated gold colloid as the seed instead of pure silica spheres [354]. Hall and co-workers also recently described the use of silica-coated gold particles as templates for the subsequent overgrowth of a polyorganosiloxane shell on their surface [355]. The process involves the hydrolysis and condensation reaction of a mixture of functional alkoxysilanes on the surface of gold colloids previously rendered vitreophilic according to the procedure of Liz-Marzan and co-workers [296]. Gold/polysiloxane core/shell nanoparticles with various functionalities (allyl, phenyl mercapto, amino,

Table 2. Examples of organoalkoxysilanes involved in the preparation of organosilicon microgel colloids.

Organoalkoxysilances	Chemical structure	Abreviation
Tetraethoxysilane	(CH$_3$CH$_2$O)$_4$Si	TEOS
Methacryloxypropyl trimethoxysilane	(CH$_3$O)$_3$Si(CH$_2$)$_3$OCOC(CH$_3$)=CH$_2$	γ-MPS
Triethoxysilane	(CH$_3$CH$_2$O)$_3$SiH	TMS
Vinyl trimethoxysilane	(CH$_3$O)$_3$SiCH=CH$_2$	VMS
Allyl trimethoxysilane	(CH$_3$O)$_3$SiCH$_2$CH=CH$_2$	AMS
Mercaptopropyl trimethoxysilane	(CH$_3$O)$_3$Si(CH$_2$)$_3$SH	MPTMS
Mercaptopropyl triethoxysilane	(CH$_3$CH$_2$O)$_3$Si(CH$_2$)$_3$SH	MPTES
Methyl trimethoxysilane	(CH$_3$O)$_3$SiCH$_3$	MMS
Dimethyl dimethoxysilane	(CH$_3$O)$_2$Si(CH$_3$)$_2$	DMMS
Trimethy methoxysilane	(CH$_3$O)Si(CH$_3$)$_3$	TMMS
Dihydridotetramethyl disiloxane	HSi(CH$_3$)$_2$OSi(CH$_3$)$_2$H	DTDS
Hexamethyldisilazane	(CH$_3$)$_3$SiNHSi(CH$_3$)$_3$	HMDS
Cyanatopropyl triethoxysilane	(CH$_3$CH$_2$O)$_3$Si(CH$_2$)$_3$CN	CPTMS
Chlorobenzyl trimethoxysilane	(CH$_3$O)$_3$SiPh(CH$_2$)Cl	CMS
Phenyl trimethoxysilane	(CH$_3$O)$_3$SiPh	PMS
Glycidoxypropyl triethoxysilane	(CH$_3$CH$_2$O)$_3$Si(CH$_2$)$_3$OCH$_2$CHOCH	GLYMO
Aminopropyl trimethoxysilane	(CH$_3$O)$_3$Si(CH$_2$)$_3$NH$_2$	APTMS

cyano, . . .) and controlled shell thicknesses have been successfully prepared by this technique.

5. CONCLUSION

Although organic/inorganic colloids represent a relatively new category of nanocomposite materials, they have demonstrated a lot of potential in a variety of domains from the coating industry to the biomedical field. O/I colloids have indeed attracted increasing attention in the last 10 years because they offer the unique possibility to combine the properties of organic and inorganic components within a nanoparticle space. Catalytic, electronic, and optical features of inorganic colloids can thus be combined with the mechanical characteristics of polymers such as film formation, structural flexibility, and easy processing. In addition to combining distinct properties, new and unexpected synergetic phenomena may also arise from the nanometer-scale dimensions of the composite material. Because small particles offer the promise of large interfacial areas and size confinement effects, new physical, chemical, or biological properties can be expected by size scaling. Many new properties may also result from the possibility of ordering the inorganic components into the polymer matrix. As such, it can be anticipated that nanocomposite colloids will provide numerous exciting and new opportunities in the near future.

O/I colloids can be elaborated in a variety of ways through seeded-growth reactions, structure-directing templates, and self-assembly strategies using chemical or physicochemical routes, and a variety of nanocomposite particles of different compositions and structural characteristics can be produced by these techniques. Among the various synthetic schemes, emulsion polymerization offers great potential that has been largely exploited in the paint industry. The unique flexibility of emulsion processing makes it possible to produce coated particles with controlled size, composition, and shell thickness in large volumes. Nanoengineering of particle surfaces (coating and encapsulation) enables the elaboration of a new class of composite products of higher quality and better end-use properties.

The synthesis of O/I colloids in multiphase systems, including miniemulsion and dispersion polymerizations, can be successfully achieved provided that the inorganic surface has been previously modified and rendered compatible with the organic polymer. A number of compatibilizing synthetic approaches have been described in this chapter. These include polymer grafting from inorganic surfaces via the covalent attachment of initiator or monomer molecules, *in-situ* polymer precipitation through electrostatic attraction, or polymerization in adsorbed surfactant bilayers. The nature of the link at the interface between the organic and inorganic components (i.e., ionic, ionocovalent, van der Waals, hydrogen bonding, . . .) and the functional group concentration are of paramount importance in controlling particle morphology. The variety of different types of connections which have been investigated have indeed demonstrated the possibility to achieve different degrees of control over the assembly process. Thin polymer layers or nanoparticles can be deposited on the seed surface depending on the affinity between the organic and inorganic entities. Each partner obviously plays an active role in this process by directing

their dual association by means of complementary functionalities. Preformed organic and inorganic particles can also be connected this way into "supracolloidal" architectures.

Templating of polymer latexes with minerals also provides a versatile way for the elaboration of nanocomposite colloids and capsules using either organic or hybrid particles as sacrificial templates. The general LbL nanocoating strategy gives access to tailor-made, reproducible, and optimized systems for biotechnological applications. Among the advantages is the possibility to manipulate the size and permeability of the capsules. One major limitation, however, is the time consuming elaboration process of the shell membrane. To this respect, direct inorganic polymerization techniques offer alternative strategies to grow smooth and controlled mineral oxide layers on organic templates. We also described in this work the use of block copolymer and surfactant assemblies into vesicles and related aggregate structures to produce nanocomposite colloids and small permeable capsules. These hollow spheres can be additionally loaded with metal ions and provide confined spaces for further chemical reactions. The copolymers can also be designed to carry recognition groups and affinity ligands to be directed toward specific target sites. Supramolecular assemblies and their use as structure directing agents is a very broad field of research, and only a limited number of examples have been presented here.

Hybrid colloids with interpenetrated organomineral networks also constitute a real challenge. Not only can the mechanical and physical properties of these materials be significantly enhanced, but new, unexpected properties can also arise from the intimate association of the organic and inorganic components. The preliminary investigations in this field are promising but further knowledge is needed to develop this new area of research.

Obviously, the synthesis of organic–inorganic colloids has opened interesting perspectives in the field of colloidal science. It can be expected that these early achievements will see further expansion and find extensive development in the near future. For example, the elaboration of multi-scale nanocomposite particles with complex morphologies and containing colloids of different nature could provide a new class of materials and expand the range of properties that can be achieved in the field of nanotechnologies. To this end, a variety of inorganic compounds having different sizes and shapes could be used as precursors from layered silicate, nanofibers, and colloidal metals to ordered mesoporous silica and other related materials. These multicomposite colloids additionally could be assembled into higher hierarchical superstructures to fabricate novel types of sensor devices with optical or electro-optical properties.

GLOSSARY

Colloidal nanocomposites Particles which are inhomogeneous in composition and contain at least two incompatible domains.

Colloids Organic and/or inorganic particles stabilized in a suspension medium and which have at least in one direction a dimension in the colloidal range (i.e., comprised roughly between 1 nm and 1 μm).

Core–shell particles Nanostructured colloids comprised of at least two phases, one of which is in the center (core) and the other which forms a concentric outer layer (shell).

Heterocoagulation The interaction of unlike colloidal particles (e.g., for instance organic and inorganic colloids) with different sign of charge by means of electrostatic attraction.

Latex A colloidal dispersion of polymer particles in a liquid phase (water, alcohols, or organic solvents). Surfactants or polymeric dispersants are typically used to stabilize the suspension.

Living free radical polymerization (LFRP) Controlled/living free radical polymerization techniques that allow the formation of organic polymers with controlled molecular weights and narrow molecular weight distributions.

Miniemulsion Oil in water (O/W) or water in oil emulsions in which the diameter of the disperse phase is typically in the range from around 50 to 500 nm. The emulsion droplets are stabilized against diffusion degradation (Ostwald ripening) by a molecule contained in the disperse phase. This compound is typically a water-insoluble substance in case of the O/W miniemulsions.

Nanocapsules/Hollow particles Core–shell particles of colloidal dimension wherein the core is a liquid (nanocapsule) or a gas (hollow particles).

Nanostructured colloids Multicomponent particles which have been designed in an attempt to obtain specific structures.

Polymerizations in multiphase systems Organic and or inorganic polymerizations (including free radical processes, organic and inorganic polycondensations) resulting in the formation of organic and/or inorganic polymer particles suspended in a liquid phase.

Self-assembly The assembly of molecules and/or polymeric substances into micelles, vesicles, and related aggregates. Polymers and or modifying agents, for instance polyelectrolytes and silane or organothiols, can also be assembled onto colloidal templates giving rise to molecules and/or macromolecules surrounding (covering) the core material. Colloids can also be assembled into aggregates of controlled shapes and size (e.g., with for instance raspberrylike morphologies) the process of which is most often known as heterocoagulation.

Silane coupling agents Organosilane molecules (halides or alkoxydes) of the type $R_{4-n}SiX_n$ ($n = 1 - 3$, X = halide or OR′) carrying an organic functionality R useful for the derivatization of inorganic materials. R is typically a thiol, an amine, an epoxy, or a methacryloyl group.

Sol–gel nanocoating Formation of inorganic coatings on templates (for instance polymer particles or any other substrate) by the polycondensation/precipitation reaction of metal alkoxides and/or metal salts through the sol–gel route.

Oxide Nanoparticles

K. P. Jayadevan, T. Y. Tseng

National Chiao-Tung University, Hsinchu, Taiwan

CONTENTS

1. INTRODUCTION

Nanotechnology has emerged as one of the most exciting fields in science and engineering in recent years. Major academic institutions as well as industries around the world have opened exclusive centers to focus on nanoscale research as a part of miniaturization in devices. The trend in miniaturization had been foreseen forty years ago by Feynmann in the most often quoted text of his lecture, "There's plenty of room at the bottom" [1], in which he intuitively suggested the idea of storing bits of information in atomic dimensions. The predictions of Feynmann were partly realized when information storage at such a minute scale was made possible in two dimensions using a scanning tunneling microscope (STM) [2]. In particular, the field of electronics has focused on the fabrication of scaled-down data storage devices to meet the predictions of Moore's law [3]. The rapid advancements in feature size reduction in electronic circuits can be attributed partly to the successful implementation of a wide variety of nanostructured materials in various devices. Now at the dawn of the new century, nanotechnology has become the most fascinating area of research, as it encompasses almost all fields of science and engineering. For instance, in biomedical applications, it has been found that nanotechnology has a major role to play in medical diagnostics and drug delivery as demonstrated by the investigations into nanocrystal fluorophores for imaging, nanoscale biodevices as sensors, and nanobubbles for drug delivery [4–7]. A novel concept termed "nanoclinic"

in medical diagnostics refers to exploitation of the unique properties of oxide nanoparticles for biomedical applications. A typical example of a "nanoclinic" is the iron oxide (Fe_2O_3) nanoparticles encapsulated by silica shell, which can be used in contrast magnetic resonance imaging in medical diagnosis [8]. There are also examples of biomolecules being used for the derivatization of nanoparticle surfaces to form novel nanostructures [9]. Moreover, the presence of a large number of cavities and bonded networks that result from intra- and intermolecular interactions in biomolecules make them attractive templates for developing technologically useful nanomaterials [10].

1.1. Size and Dimensionality

Nanomaterials have unique features that are suitable to a variety of industrial applications. To examine these features, let us consider the definition of the term "nanomaterial." A material can be termed as a nanomaterial if one of its linear dimensions is less than 100 nm. In other words, at least in one dimension, the size of a nanomaterial is in between the sizes of atoms and bulk materials, which results in size- and dimension-dependent unique material properties. By taking into consideration the metastable nature of the nanomaterial, defining the size limits for the formation of a stable nanocrystal would be difficult. However, it is possible to define the tentative size limits for nanomaterials with the lowest limit corresponding to the clusters of molecules having sizes on the order of 1 nm or even less. The highest size limit would correspond to a few crystallites (grains), forming a nanoparticle of dimension close to 100 nm. As the grain size approaches the particle size, we have single-crystal nanoparticles. However, depending on the dimension in which the size-effect on the resultant property becomes apparent, the nanomaterials can be classified as zero-dimensional (spherical nanoparticles of ~ 5 nm diameter), one-dimensional (quantum wires), two-dimensional (thin films), or three-dimensional (nanostructured material built of nanoparticles as building blocks) [11]. The schematic diagram in Figure 1 illustrates the typical dimensional characteristics of nanomaterials. In this chapter, we intend to focus on the recent developments in synthesis, spectroscopic
Figure 1. Schematic illustration of dimensionality in nanostructured materials: zero-dimensional nanoparticles (0-D), one-dimensional nanowires (1-D), two-dimensional nanostructured thin films (2-D), and three-dimensional nanostructure (3-D).

characterization, properties, and industrial applications of oxide nanoparticles and nanostructures.

1.2. Selection of Synthesis Route

The drive for finding novel routes for the synthesis of nanomaterials has gained considerable momentum in recent years, owing to the ever-increasing demand for smaller particle sizes. In particular, controlling the microstructure at the atomic level has been of great multidisciplinary interest to fields such as physics, chemistry, materials science, and biology.

Nanomaterials and related devices can be classified into three major categories, and suitable preparative routes are identified depending on the desired resultant structure as proposed by Gleiter [12]. i) The first category of nanomaterials consists of isolated, substrate-supported, or embedded nanoparticles, which can be synthesized by physical vapor deposition (PVD); chemical vapor deposition (CVD); inert gas condensation; aerosol processing; precipitation from supersaturated vapors, liquids, or solids; or relatively novel routes such as ultrasonication. Nanostructured metal oxide catalysts [13] and electronic devices incorporating quantum dots [14] are examples wherein this class of nanoparticles have been employed. ii) The second category refers to materials having a thin nanometer-sized surface layer, which can be processed by techniques such as PVD, CVD, ion implantation, or laser ablation. The major advantage associated with these techniques is that the processing parameters can be suitably tuned to obtain a nanometer-sized surface layer. A recent study demonstrates the formation of a self-organized and ordered oxide nanostructure on the surface of nonstoichiometric metal oxides under ultra-high vacuum deposition conditions [15]. The self-organization and chemical self-assembly are also emerging as very important techniques for the deposition of materials layer-by-layer with controlled particle size and composition [16–18]. A single protective layer grown on the surface of bulk materials also provides enhanced stability, such as lower susceptibility to corrosion [19, 20].

iii) Three-dimensional (3-D) materials having nanometer-sized grains belong to the third category. The crucial aspect related to the processing of these materials is control of the chemical composition and the grain size. For example, the metastable 3-D nanostructures such as glass, gels, supersaturated solid solutions, or implanted materials can be prepared by quenching the high-temperature phases at equilibrium to the room temperature. The quenching helps to freeze the disordered structure with the composition varying on an atomic scale. Nanostructured-glass ceramics, which belong to the category of metastable three-dimensional nanostructures, have been studied with immense interest in recent years because of the potential engineering applications [21]. Another type of material that belongs to this group is a three-dimensionally ordered solid having building blocks as nanocrystals [22]. The microstructures of such solids comprise crystals with varying orientations separated by interfaces, which may be coherent, semicoherent, or incoherent. The ideal preparative route for such structures would involve the optimization of the processing conditions to ensure the formation of a microstructure with controlled grain growth so that the unique properties of the nanobuilding blocks are preserved.

1.3. Microstructure

As the particle size is scaled down to a few nanometers, the constituting atoms exhibit highly defective coordination environments. Most of the atoms have unsatisfied valences and reside at the surface. In short, microstructural features such as small grain size, large number of interfaces and grain boundary junctions, pores, and various lattice defects that result from the chosen routes for their synthesis contribute significantly to the unique physical and chemical properties of nanomaterials [23–25].

1.3.1. Grains

Grains are crystallized domains that combine to form a larger polycrystalline particle. Except for a single-crystal nanoparticle, in which the grain size and the particle size are identical, the nanoparticles have randomly oriented grains. The atomic planes within a grain can be directly imaged using high-resolution transmission electron microscopy (HRTEM) [26–30]. For example, it has been demonstrated that HRTEM characterization provides a clear insight into the grain structure for a cluster-deposited nanophase material [28]. The size distribution of the clusters formed in the gas-condensation method is very narrow ($\pm 25\%$ Full-width at half maximum (FWHM)) as evidenced by a dark-field TEM study for cluster-consolidated nanophase TiO_2. However, methods such as mechanical activation and crystallization result in a broader grain size distribution [27].

The higher density of the consolidated nanophase material as compared to the theoretical density (74%) of powder compact may be attributed to the filling up of the pores by the enhanced diffusion, which arises out of an extrusion-like deformation in the consolidated nanophase. This process has been experimentally verified by the STM and the atomic force microscopy (AFM) studies on metal nanoparticles [31]. The grains of the consolidated nanophase

materials do not exhibit any preferred orientations in contrast to the micrograined samples. The random orientations of the grains in nanophase suppress the dislocation motion in these materials.

1.3.2. Interfaces

In order to account for the unique properties of nanomaterials, it is imperative to understand the interface characteristics, perhaps on an atomic scale. In nanomaterials, the randomly oriented crystals have incoherent interfaces where the atoms are far from being in a perfect order, as in a lattice. The misfit among the crystals also results in the modification of the grain boundary atomic structure by reducing the atomic density and altering the coordination numbers of the atoms. The characterization of the Fe-containing nanomaterials by Mossbauer spectroscopy revealed the grain boundary structures of these materials with defective coordination environments compared to a perfect lattice [32]. The defective coordination environments also make the atoms at the interface more reactive. In other words, the relatively positive enthalpies and Gibbs energies associated with the formation of nanocrystalline ceramic oxides can be attributed to the reactive surfaces or interfaces present in the samples [33, 34]. The quantitative determination of the thermodynamic parameters may help to correlate the size of the nanoparticles to the degree of metastability and the crystal structure. For instance, in the case of oxide ceramics, which are known to crystallize in systems different from that of the bulk (e.g., cubic $BaTiO_3$ [35], tetragonal ZrO_2 [36], monoclinic Y_2O_3 [37], and γ-Al_2O_3 [38, 39]), a quantitative estimation of the thermodynamic parameters for the nanocrystalline state would provide much needed insight into the resultant microstructure, as well as the hierarchy of transition states [34]. The parameter, strain, may also govern the stability of the finely divided particles, as it has been found that the presence of large number of interfaces in a nanomaterial leads to the generation of intrinsic strain in nanosized particles [40]. Apart from the intrinsic strain, the method of preparation may induce an extrinsic strain in these materials. The line broadening obtained by X-ray diffraction helps to estimate the strain present in the sample [41].

1.3.3. Defects

Siegel et al. [26], Eastman et al. [42], and Balachandran et al. [43] have demonstrated the cluster deposition method for the synthesis of metal oxide nanoparticles. One of the major issues during such processing is to minimize the formation of defects, which can be done by annealing the sample at a suitable temperature in a chosen atmosphere. It has been found that annealing at a fixed partial pressure of oxygen would compensate the oxygen vacancies in metal oxide nanophase samples. The increase in oxygen permeability through the nanophase material can be attributed to the highly defective surfaces of the metal oxide nanoparticles, which eventually provides easy pathways for the oxygen diffusion. For instance, the nonstoichiometry in the as-prepared nanophase TiO_2 ($TiO_{1.89}$) samples caused the broadening and the shifting of Raman bands, but could be oxidized to stoichiometric TiO_2 without a change in nanometer grain size ($\sim$12 nm) when annealed in oxygen

atmosphere [44–46]. It has been experimentally verified that the defects such as dislocations are rare in nanoparticles [28, 47, 48]. The reason for the lack of dislocations in nanophase materials can be attributed to the image forces in the finite atomic ensembles that pull the dislocations out of the grains. The absence of dislocations also affects the mechanical properties of nanoparticles [49].

1.3.4. Pores

Porous solids have been recognized as an important class of materials that can find applications in various fields [50–52]. Therefore, the determination of porosity in a consolidated solid product has become very relevant in recent times. Upon consolidation, the nanoparticles form a porous structure, which can be characterized by positron annihilation spectroscopy (PAS) [26, 53, 54], Archimedes densitometry [55], porosimetry [56–58], and small angle neutron scattering (SANS) [59]. The percentage of porosity varies from $\sim$5% to $\sim$25% in nanophase materials. The value is higher for the consolidated oxide nanoparticles compared to the metal nanoparticles. The pore sizes obtained from the various measurement techniques mentioned above have dimensions comparable to the grains of the ceramic. Pores are usually associated at the triple junction grain boundaries with interconnected structures and intersections at the surface. The consolidation of nanoparticles at elevated temperature would uniformly remove the porosity without significant increase in the grain growth. The porosity also enhances the diffusion in nanophase ceramics. However, the diffusion rate would tend to be lower for the high-temperature-sintered fully dense ceramic. For example, the diffusion of Hf in sintered nanophase TiO_2 has been suppressed after the densification [60]. In the case of fully dense nanomaterial, the diffusion of the impurity atoms is mostly through the grain boundaries. Doping of oxide nanomaterials with various types of dopants enables tuning of the properties to fit in a variety of applications. This has been a major area of research in recent years.

1.4. Size Effects on the Properties of Oxide Nanoparticles

In this section, we summarize the important consequences of size reduction on various properties of oxide nanoparticles. Over the years, numerous studies have been carried out to understand the interesting properties exhibited by nanomaterials [61, 62]. Careful examinations of the microstructure and the atomic structure of nanomaterials supported by strong theoretical understanding of the phenomenon under investigation are required in order to arrive at a satisfactory explanation for the observed characteristics. For example, in the case of electrically conducting nanoceramics, microstructure effects such as highly defective grain boundaries have been found to have a great influence on the resultant characteristics. At reduced grain sizes, the interfacial contribution dominates the total conductivity. Theoretically, the enhancement in electrical conductivity is predicted for nanosized conducting ceramics as a result of space charge contribution from the interfaces [63]. The experimentally obtained value of the enhanced conductivity of the nanocomposite AgI:Al_2O_3 [64] could be

explained based on the interfacial and the space charge effects. Increase in conductivity has also been observed in nanocrystalline CeO_2 [65] and Y_2O_3-stabilized ZrO_2 [66].

Size effects play a crucial role in influencing the domain-dependent magnetic and dielectric characteristics. As the particle size of the oxide is progressively reduced to nano-dimensions, the size ultimately becomes identical to that of a single domain in which the magnetic or dipole moments are aligned. At this critical size, the magnetization or the polarization is no longer nonlinear in the presence of an applied field with the disappearance of hysteresis loops. For example, the critical size for γ-Fe_2O_3 and ferroelectric $PbTiO_3$, which exhibit distinctly different behaviors compared to larger particles, is about 8 nm [67, 68]. However, the critical size may vary depending on the processing history of the sample, which will be discussed in detail while considering size-dependent properties in a subsequent section in this chapter.

Another interesting effect is size quantization in semiconducting nanoparticles [69]. As the sizes of the semiconductor particles are reduced to dimensions (<5 nm) comparable to an exciton diameter, the energy gap between the valence and the conduction band increases. Consequently, the optical absorption shows a blue shift. For example, semiconducting ZnO nanoparticles exhibit a blue shift in the optical spectra due to quantum size effect [70].

Reduction in particle size also enhances self-diffusion, solute diffusion, and solute solubility in nanomaterials. Enhanced diffusivity and solubility can be attributed to defective atomic coordination at the grain boundaries in the nanocrystals [23]. The higher fraction of the grain boundaries in nanocrystals also results in higher values of specific heat compared to conventional polycrystals [71]. Consolidated TiO_2 nanoparticles have improved mechanical properties such as hardness comparable to the coarse-grained TiO_2 [72]. The improved ductility of a brittle ceramic oxide when prepared in nanocrystalline form is worth noting. The enhanced interdiffusion among the grains in nanocrystals helps the grain boundaries slide by one another, thereby improving the ductility [73].

1.5. The Need for High Surface Area Nanomaterials

High surface area (300–2,000 m^2/g) is an important feature of nanosized and nanoporous materials, which can be exploited in many potential industrial applications, such as separation science and catalytic processing, because of the enhanced chemical reactivity [74, 75]. The major drive is to develop inexpensive materials that exhibit superior properties. High surface area nanomaterials have already been used in applications that require rapid and responsive sampling, selective separations, high throughput catalytic processing, enhanced chemical activity, or 3-D packaging of supported or entrained nanoscopic structured species [76–78]. The detection sensitivities of the high surface areas lie in the range of parts per billion on a short time scale. This enables rapid sampling and chemical processing of large volumes of reactants. By controlling the pore sizes or surface structures at the nanostructure level (<1 Å), several orders

of enhancement in separation or catalytic process selectivities can be realized. Magnetic high surface area materials for oxygen separation and optically transparent high surface area monoliths (films, spheres, fibers) for chemical sensor applications [79–82] are some of the industries where high surface area materials such as nanostructures and nanoporous materials have potential applications. Figure 2 illustrates the pore formation in silica glass (SiO_2) [83]. The dimensions of the pores are on the order of a few nanometers. High surface area nanostructures should be characterized to determine certain figure-of-merit variables that are relevant in a variety of applications. Some of the important variables are the void space in the case of porous structures for molecular recognition, transition state lifetimes, sorption and the desorption rates in the case of catalytic processes, surface activity, chemical and the mechanical stability, defect, and interface properties in the case of synthesis and tuning of the properties of composites.

High surface area materials are also useful in the preparation of metastable phases by creating the necessary interfaces for the stability of processed composites, as well as promoting the thermal transport in low-density packaging. The major challenge is to fabricate the appropriate form of the nanostructure, for example, in thin film forms, fibers, or microspheres for the desired applications. After the selection of the appropriate structure, the nano-building units have to be carefully assembled to obtain multidimensional control of their properties. This, undoubtedly, is one of the most exciting areas in materials technology [84, 85].

1.6. Relevance of Nanoparticles in Device Fabrication

Nanoparticles form the basic building unit for 3-D nanostructures, which can be considered as primary components in nanostructure-based devices. For the successful fabrication of nanostructure-based devices, the synthesized nanostructures have to be suitably incorporated to device structures. The ultimate objective of the modern day industry is to fabricate cost-effective, nanostructure-based, miniaturized devices with superior characteristics. For
Figure 2. Nanopore formation in SiO_2-glass sintered at 1000 °C for 10 min [83].

instance, nanostructure-based memory devices have high information storage and computational capacity. These characteristics result from the packing density and the short information transit time from site to site. For optical applications, a wide range of nanostructure-based optical sources that include high performance lasers to general illumination can be fabricated. These industrial requirements can be accomplished by selecting an appropriate fabrication method of functional nanostructures with controlled size, shape, and composition. However, assembling nanoparticles to form a nanostructure is a complex process. Numerous research groups are working out different synthetic strategies to find economically affordable ways for fabricating the nanostructures and simultaneously preserving the superior characteristics of the basic building units (the nanoparticles) in various devices. For example, self-organization and chemical self-assembly are promising techniques that provide inexpensive routes for the fabrication of nanostructures [16–18]. In the immediate future, one can expect the miniaturization revolution in device fabrication to reach its peak in various industries. However, a recent study predicts that there is an optimum limit for miniaturization, beyond which the second law of thermodynamics no longer holds [86]. The study is significant as it implies a possible device breakdown at molecular or atomic scale because of energy accumulation.

Oxide nanoparticles are of particular interest in the fabrication of electronic devices based on the ultra-large scale integration (ULSI). Integrated circuits become more and more complex with increasing layers of metallization and interlayer dielectrics. This has led to the search for a method to planarize the wafers between the deposition and the processing steps. The method adopted is chemical mechanical polishing (CMP), which involves pressing the Si wafers against a polishing pad in the presence of colloidal slurries of metal oxides such as SiO_2, Al_2O_3, CeO_2, or ZrO_2. The size, shape, surface chemistry, and stability of the oxide particles govern the efficiency of the process. The CMP process has turned out to be an important step in the semiconductor industry [87].

2. SYNTHESIS

Prior to the synthesis of a nanophase material, the size and the dimensional features of the material to be prepared have to be defined. Accordingly, a suitable preparative method can be adopted. This is very crucial because the particle size, dimensionality, and composition govern the resultant properties of the nanostructured materials that are assembled from nanoparticles as building units in order to achieve certain desired properties. For instance, the fascinating electronic, electrical, optical, catalytic, thermal, and mechanical properties of the nanoparticles and the nanostructured materials have triggered enormous multipronged research activities in recent years in this area.

Several methods have been developed over the years for the synthesis of nanomaterials. The various routes include synthesis using liquid, solid, or gas phase precursors, which come under physical or chemical processing. The major issues for the synthesis of nanoparticles are i) the control of the particle size and composition, and ii) the control of the

interfaces and the distributions of the nanobuilding blocks within the fully formed nanostructured materials.

The oxide nanomaterials are of interest in a variety of structural and functional applications. The advantages of equiaxed, dispersive, submicron ceramic oxide particles with a narrow size distribution have been discussed much before the onset of the present nano era in materials research [88]. Typical nanoparticles are agglomerates of several primary particles. The agglomerates are termed as secondary particle. The secondary particle size is obtained by scanning electron microscopy (SEM), whereas the X-ray line broadening helps to estimate the primary particle size or crystallite size. Minimizing the agglomeration and deriving the properties exclusive to the primary particles are the important objectives in the synthesis of oxide nanoparticles. In the subsequent sections, important methods for the preparation of oxide nanoparticles are described.

2.1. Gas Phase Condensation Methods

The production of nanoparticles by condensation of gaseous precursor molecules generally comes under the category of aerosol processes [89, 90]. For the synthesis of nanoparticles or ultra-fine particulates (particle size <100 nm), the gas phase condensation is a suitable method. The initial step in this process is the formation of gaseous precursor molecules by a suitable physical or chemical method in aerosol reactors [91–95]. The precursor molecules then react in the vapor phase to form tiny nuclei of the desired phase (gas-to-particle conversion). The size of a typical nucleus thus formed has dimensions comparable to that of a molecule of a refractory oxide. Subsequently, the primary particles undergo collision and coalescence to form aggregates, which in turn form agglomerates held together by the weak van der Waals forces [96, 97]. The method is suitable for the production of nanoparticles in laboratories as well as in industries. The mechanism involved in the gas phase condensation process allows one to link the properties of gaseous precursor to the nanoparticles formed. The important parameters involved in the processing are time, temperature, and the amount of particles produced per unit volume. The decisive characteristics of the prepared nanoparticles include the size distribution of the primary particles, the grain boundaries, the pore sizes, the defect concentrations, and crystallinity. Apart from these characteristics, the fractal dimension of the aggregates and the particle bond energies are also of interest for investigation. The various methods used for the gas phase condensation of oxide nanoparticles are summarized as a block diagram in Figure 3 [98]. We discuss two important preparative routes—flame processing and laser ablation and related techniques such as sputtering for oxide nanoparticles. The microwave plasma-assisted chemical reactions in the gas phase for the preparation of oxide nanoparticles will be described in a subsequent section on microwave plasma processing.

2.1.1. Flame Processing

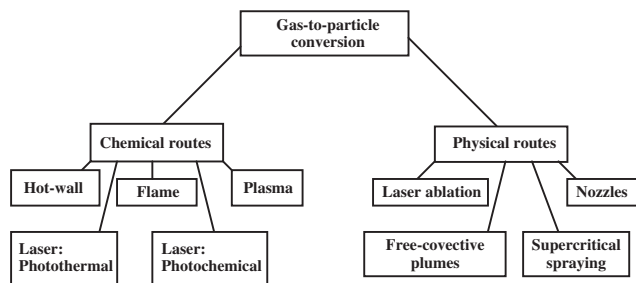
Oxide nanoparticles are produced commercially on a large scale in a flame reactor [94, 95]. The precursor in vapor phase is fed into a reactor in the presence of oxygen and ignited. The burning step may also take place in


Figure 3. Methods used for gas phase condensation of nanoparticles. Reprinted with permission from [98], T. T. Kodas and M. J. H. Smith, "Aerosol processing of materials," Wiley-VCH, New York, 1999. © 1999, Wiley.

other gaseous atmospheres such as inert gas, hydrogen, or methane. The schematic diagram for the particle formation in a flame reactor is shown in Figure 4 [98], which illustrates the eventual formation of nanoparticles through collision, coalescence, and agglomeration in an aerosol reactor. Temperatures as high as 1200–2500 K can be achieved in a typical flame reactor. The method is commercially used for the production of industrially useful silica (SiO_2) from silicon

tetrachloride vapor. It is also important to correlate the particle size of the material produced to the processing conditions and the material properties in order to standardize the production method for the nanoparticles. The particle size and the surface area of the oxide can be tuned by adjusting the process temperature. The lower the process temperature, the smaller the particle size and larger the surface area. The sizes of the oxide nanoparticles that are produced using the aerosol technique fall in the range of 7 to 27 nm. Other examples of oxides prepared using aerosol process are Al_2O_3 and TiO_2 from $AlCl_3$ and $TiCl_4$, respectively.

Large-scale production of nanoparticles in industrial aerosol generators is governed by particle collision and coalescence. Industrial flame reactors are operated at high particle concentrations, which result in high rates of particle collisions. The particle size of the product is determined by the rates of the particle collision and the subsequent coalescence. The collision/coalescence mechanism for the particle formation is based on a series of steps assumed to proceed as follows [96, 97]: i) transformation of gaseous precursors to condensable molecules, ii) formation of a cloud of stable nuclei from condensable molecules, iii) coalescence of the stable nuclei to form larger particles, iv) formation of the agglomerates of the phase, and v) coalescence within the agglomerate.

The above five steps may proceed either step by step or simultaneously at a faster rate. The monomer molecules produced from the precursor coalesce to form a primary particle. The size of the primary particle, which is formed as a result of the coalescence of the monomer molecules, depends on the temperature/time history of the process. For example, at a high temperature, the enhanced coalescence leads to the formation of the particle agglomerates with reduced specific surface area, whereas at a low temperature, with the slower coalescence rate fractal-like agglomerates are produced with a high specific surface area. The size of the primary particle also depends on the diffusion characteristics of the material; the higher the diffusion coefficient, the larger the primary particle size. Also, the solid-state diffusion being a thermally activated process, high temperature heat treatment enhances the formation of larger particles with minimum surface area.

In the processing of ceramic powder compacts, one should have a clear understanding of the bond energies and the agglomerate rigidity of the particles. After deriving sufficient experimental evidence for agglomeration, the processing conditions can be optimized for obtaining desired particle characteristics. The processing can also be tuned as a function of temperature, from which the activation energy for the process can be estimated.

2.1.2. Laser Ablation and Related Methods

Recently, researchers have developed a laser vaporization technique to synthesize nanoparticles of controlled particle sizes and compositions [70, 99–102]. The technique involves the vaporization of a target using pulsed laser, which is then followed by controlled condensation in a diffusion cloud chamber under well defined conditions of temperature and pressure. A wide variety of metal oxides, carbides, and nitrides can be synthesized in nanoscale dimensions using

this technique. The process of laser ablation is schematically illustrated in Figure 5 [98].

An ArF excimer laser ($\lambda = 193$ nm) can be used for the ablation of the target. The sintered pellet that can be used as a target is mounted on a rotating target holder in the ablation chamber and is rotated during the laser irradiation. The sputtering technique can also be used to prepare nanoparticles from a preformed solid target. Nanoparticles are collected on a selected substrate such as carbon-coated mica, quartz glass, and silicon wafers at room temperature. The substrate is placed at an off-axial position in order to suppress the deposition of the droplet-like large particles and collect the monodispersed nanoparticles. The background gas pressure can be varied from 0.133 Pa to 13.3 kPa of Ar gas.

By varying the ablation pressure, the morphology of the nanoparticles can be controlled. Sasaki et al. [103], Li et al. [104], Koshizaki et al. [105], and Zbroniec et al. [106] have investigated in detail the dependence of the particle morphology on the ablation pressure. They observed that the deposited products have morphologies that are typically dependent on the different pressure regions of Ar at 200 mJ/pulse. At a pressure of 26.7 Pa and below, a continuous film formation was observed on the substrate, whereas the nanoparticles of sizes in the range 2–9 nm formed under higher values of gas pressures in the range 66.7 Pa to 133 Pa. Upon increasing the gas pressure to about 1.07 kPa and above, the sizes of the primary particles did not change. However, the higher values of gas pressure affected the sizes of the aggregates. The formation of the aggregates indicated that the nanoparticles when formed in the gas phase undergo collisions with gaseous molecules dissipating their kinetic energy. A similar dependence of nanoparticle morphology has been reported for cobalt oxide nanoparticles [104]. Interesting observations were also made on the evolution of various cobalt oxide phases as a function of gas pressure using X-ray diffraction.
Figure 5. Schematic diagram to illustrate particle formation during laser ablation. Reprinted with permission from [98], T. T. Kodas and M. J. H. Smith, "Aerosol processing of materials," Wiley-VCH, New York, 1999. © 1999, Wiley.

The mechanism leading to the formation of thin films, nanoparticles, and aggregates can be sequenced against increasing gas pressure [104–106]. At low pressure, the ablated molecules have larger available volume for expansion. Molecules have higher kinetic energy with fewer collisions in the gas phase. But as the ambient gas pressure increases, the number of collisions between the metal and the oxygen species in the gas phase increases, leading to the formation of primary nanoparticles. With further increase in the ambient pressure, the primary particles lose their kinetic energy due to frequent collisions, resulting in the quenching of the nanophase. The small nanoparticles stick together by weak van der Waals forces to form nanoparticle agglomerates. The recent advancements in the laser ablation process indicate that nanoparticles with desired microstructure and properties can be synthesized by suitably optimizing the experimental conditions.

2.2. Microwave Plasma Processing

Microwave plasma processing has emerged as a major processing route for oxide ceramics [107–109]. The method is attractive because the kinetic and thermodynamic barriers that are usually encountered in conventional solid-state synthesis can be overcome with a short processing time. The faster reaction rate may be attributed to the reverse heating profile during the exposure of reactants to microwaves as compared to conventional furnace heating. Moreover, the basic reaction mechanism involving various species in the microwave plasma can be exploited for the synthesis of nanophase oxide powders [108, 110–114]. The compound forms when energy transfer occurs between the electrons and the other species in the plasma. Stable plasma can be achieved in a microwave cavity by reducing the pressure, thereby controlling the collision frequency to less than the source frequency (2.45 GHz and 0.915 GHz) [115]. The parameters that decide the energy transfer between the electrons and the neutral or ionized species in the plasma are the frequency of the source and the number of collisions made. A recent thermodynamic study on the oxidation of silver in oxygen-microwave plasma indicates that the gaseous species in the plasma have very high chemical potentials, which are equivalent to normally unattainable high pressures of neutral diatomic oxygen ($\sim 10^{10}$ MPa) [116]. This extraordinarily high thermodynamic driving force in the microwave plasma can be exploited for the synthesis of a wide variety of nanoscale metastable materials.

The precursor used for the preparation of nanophase oxide powders can be a homogeneous solution or a gaseous precursor. The precursor solution is introduced into the microwave cavity through a nozzle [117]. Both aqueous and nonaqueous solutions are used for the synthesis of oxide powders. The aqueous precursor solution is usually a nitrate solution containing the metal ions of the desired phase [112]. Water, being highly polar, absorbs the microwaves quickly and evaporates from the precursor solution. The residual material, upon further exposure to the plasma, reacts with the oxygen species in the plasma. This results in the formation of fine metal oxide particles. The technique has been used for the preparation of some model binary oxides

such as zirconia (ZrO_2), alumina (Al_2O_3), or solid solution between them. It is interesting to note that the nanocrystallites of metastable cubic zirconia (ZrO_2) complex solid solution with 3% Y_2O_3 and 20% Al_2O_3 could be processed at a much lower temperature in a short amount of time compared to the conventional high-temperature solid-state synthesis [108]. Nonaqueous solutions such as metal halides can also be used as precursors for the processing of nanopowders. For example, for the synthesis of ZrO_2 powders, the nonaqueous solution can be $ZrCl_4$ in CH_3CN [108]. The various steps involved in the processing of oxide nanoparticles from a nonaqueous halide solution are vaporization of the solvent in the plasma, evaporation of the metal halide, oxidation of the metal halide, and formation of the oxide powder particles by agglomeration. The particle sizes of the oxides formed depend on the final temperature of the oxidation, which implies that at a higher oxidation temperature, larger zirconia particles are produced.

In order to reduce the processing complexities of using a precursor solution for the synthesis of oxide nanoparticles, high vapor pressure metal halide can be directly exposed to microwave plasma in an oxidizing atmosphere. This ensures better homogeneity, as the reactant species are all in the gas phase. The ionized gaseous species in the plasma reacts with the metal halide vapors and promotes oxidation, resulting in the formation of fine metal oxide particles. Synthesis of single crystalline cubic ZrO_2 nanoparticles of sizes ~ 4 nm with a narrow size distribution have been realized by this method [108].

2.3. Hydrothermal Synthesis

Hydrothermal synthesis involves the exploitation of the properties of water under high pressure and temperature for the preparation of fine powders of advanced ceramic oxides [118]. The typical values of the reaction temperatures are between the boiling point of water and the critical temperature of 374 °C and pressures up to 15 MPa. However, continued revision of the process has led to high temperature hydrothermal processes at greater pressures [118]. The advantage of the hydrothermal method over other solution routes is that the final product readily forms at a low temperature without calcination. Fine crystallites of the desired phase with excellent composition, morphology control, powder reactivity, and purity can be obtained using the hydrothermal method [119].

The precursor sol is prepared from oxides, hydroxides, nitrates, or halides of the corresponding metallic elements. The prepared sol is subjected to hydrothermal synthesis, which is carried out in a high-pressure apparatus or hydrothermal bomb (autoclave) [120]. The basis of the technique is the enhanced solubility of the precursor in water under hydrothermal conditions, which ensures the formation of the product with very good composition control and uniformity. Under hydrothermal conditions, water may be termed as a superior solvent with the ability to dissolve even nonpolar entities. This anomalous solvation characteristic under hydrothermal conditions effectively brings down the activation energy for the formation of the final phase, which otherwise forms only when heated at high temperature as

in the case of a conventional solid-state reaction or calcination of the coprecipitated powders. The hydrothermal technique has been demonstrated as a very effective route for the preparation of nanoscale ceramic oxides [121–123] and many novel materials such as porous and open-framework solids [124].

The hydrothermal process is advantageous for the preparation of electronic ceramic powders and their solid solutions, with a potential for commercial scale-up because of the relatively low temperature associated with the crystallization of the final phase when compared to conventional solid-state synthesis or coprecipitation route [125, 126]. A typical flow chart for the hydrothermal process is presented in Figure 6 [119]. For an ABO_3 perovskite oxide, the general hydrothermal reaction that involves dissolution and precipitation can be written as

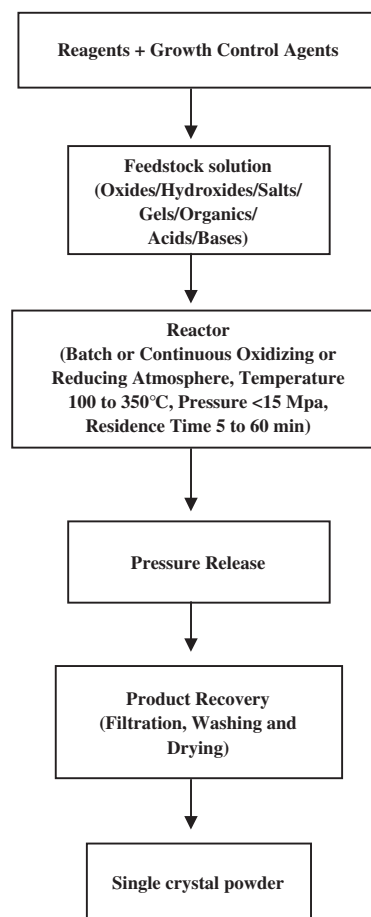
$$A(OH)_s + B(OH)_s \text{ (dissolution)}$$
$$\rightarrow A(OH)_{(aq)} + B(OH)_{(aq)} \text{ (precipitation)} \rightarrow ABO_{3(s)} \quad (1)$$
The perovskite $BaTiO_3$ with several dopants has been prepared by the hydrothermal technique [127]. Fine powders of the hydrothermally prepared dielectric ceramics exhibit improved dielectric characteristics. For instance, a thin layer


Figure 6. Flow chart for the synthesis of oxide nanoparticles using hydrothermal process. Reprinted with permission from [119], W. J. Dawson, *Am. Ceram. Soc. Bull.* 67, 1673 (1988).

of fine-grained ceramic can enhance the capacitance stored per unit volume in a multilayered capacitor, which is relevant from the point of view of miniaturization.

Hydrothermal synthesis also promotes the crystallization of high temperature metastable phases at much lower temperatures. For example, zirconia has several polymorphs—cubic, tetragonal, or monoclinic—and can crystallize in any of these systems, depending on the process variables such as the reaction time and the temperature, the presence of impurities, and the concentration of the precursor solution. By the conventional solid-state technique, the synthesis of metastable phases requires higher energy input, with the resultant products being far from pure. Apart from being a single process for the synthesis of fine powders, various other techniques can be combined with the hydrothermal technique to form a kind of hybrid technique for the synthesis of nanoparticles. Examples of such techniques are hydrothermal-sonochemical [128] and hydrothermal-microwave processing [129].

2.4. Electric Dispersion Reaction

The electric dispersion reaction is a precipitation reaction that is carried out in the presence of a pulsed electric field to synthesize ultrafine precursor powders of advanced ceramic materials. The technique involves subjecting the reactor liquid (metal-alkoxide solution) to a dc electric field (3 to 10 kV/cm at pulsing frequencies in the range 1 to 3 kHz). Under the applied electric field, the sol is shattered to micron-sized droplets, termed as microreactors, that contain hydrous precursor precipitate. The formed precursor powders can be thermally processed to obtain oxide nanoparticles. Harris and coworkers have developed this technique for the synthesis of various ultrafine ceramic powders from the corresponding metal alkoxide solution [130–133]. A typical microreactor droplet for the formation of nanosized oxide particles is schematically represented in Figure 7. Metal alkoxide and metal salt solutions have been used for the synthesis of ceramic precursor powders (including SiO_2, Al_2O_3, ZrO_2, and 1:2:3 yttrium-barium-copper oxide) with chemical homogeneity at submicrometer level [130]. The method also allows control and modification of the particle morphology. Moreover, the method has been shown to be a viable means for the production of microspheres and porous spherical shells. A scanning electron micrograph of hydrous 1:2:3 Y-Ba-Cu oxide particles synthesized by an electric dispersion reaction from the corresponding metal
Figure 7. Typical microreactor droplet for the formation of nanosized oxide particles during an electric dispersion reaction [130].

nitrates revealed that the particle sizes were in the micrometer range (~ 5 μm), which on further thermal processing form submicrometer powders [130].

2.5. Combustion Synthesis

Another interesting method for the preparation of oxide nanoparticles is the combustion technique, which involves the exploitation of an excess heat-generating or exothermic reaction to overcome the activation energy barrier for the formation of products [134–138]. The precursor is a redox mixture that contains an organic compound (fuel) as the reducing agent and a metal salt as the oxidizing agent. When heated to the ignition point of the fuel, the mixture instantaneously burns to form the product. Large volumes of gas produced during the process also help the precursor particles to disintegrate to smaller particles. The major advantage of the method is that it is fast, requiring the least external energy input. Moreover, the synthesis gives high output with the possibility of producing a wide variety of ceramic oxides. The carbonaceous residue left over as a result of the combustion can be detrimental to the powder characteristics. Therefore, the fuel or organic compound should have a relatively low carbon content, but at the same time should ignite easily. For the preparation of yttria (Y_2O_3)-stabilized zirconia (ZrO_2) powders, for example, the precursor solution was first prepared by dissolving the metal nitrate in distilled water followed by the addition of the fuel (oxalic dihydrazide) [135]. The solution was then spray-dried prior to combustion. By controlled heating of a small amount of the dried precursor, combustion was initiated. Less vigorous reactions that do not form flames during combustion can be initiated by directly placing the precursor solutions inside a preheated furnace or a microwave oven [138].

The rate of the reaction depends on the amount of the fuel in the initial mixture. Upon increasing the fuel concentration, the reaction propagates to completion in a self-sustained manner producing large volumes of gases as by-products. However, an optimum fuel concentration has to be selected for obtaining high surface area nanoparticles with the sizes in the range of 10–20 nm. By suitably tuning the various parameters in the combustion synthesis, the crystallization of high temperature metastable phases such as the cubic/tetragonal phase in Y_2O_3-stabilized ZrO_2 can be achieved at a lower temperature from precursor solutions with moderately high fuel content [136].

Because of the vigorous reaction during a combustion process, particles formed in the gas phase undergo collision and form agglomerates. The agglomerate formation during the combustion synthesis has to be controlled by suitably tuning the properties of the precursor. The method is economically affordable and has the potential for commercial production of oxide nanoparticles.

2.6. Sol–Gel (Colloidal) Processing

Sol–gel processing is a popular processing route for the synthesis of a wide variety of materials in desired shapes (particles, fibers, or films). The formation of a sol by dissolving the metal alkoxide, metal-organic, or metal-inorganic salt precursors in a suitable solvent is the primary step in a sol–gel

process. Upon drying the sol, a polymeric network is formed in which the solvent molecules are trapped inside a solid (gel) [139, 140]. Subsequent drying of the gel followed by calcination and sintering leads to the final ceramic product. As the reacting species are homogenized at the atomic level in a sol–gel process, the diffusion distances are considerably reduced compared to a conventional solid-state reaction; thereby the product forms at much lower temperatures.

Depending on the nature of the precursor, which can be an aqueous solution of an inorganic salt or metal-organic compound, the species involved in the intermediate steps of the sol–gel process differ. The nature and composition of the intermediate species formed also depend on the oxidation state, the pH, or the concentration of the solution. These factors are crucial in the formation of a colloid and its stability. Metal alkoxides are noted for the very high reactivity toward hydrolysis and are therefore being used as a common starting material for the sol–gel synthesis [141]. Electronegativity, valence states, and the coordination number of the metal affect the rate of hydrolysis and hence the nature of the colloidal solution. The resultant properties of the synthesized powder depend on the colloidal aggregate formed as a result of the hydrolysis step. This has been demonstrated in the case of many ceramics, as the chemical tuning of the precursor sol and the nature of the colloid formed have affected the final product [142, 143].

The preparation of powders with the desired microstructure from colloids depends on the tuning of the interparticle forces in the colloid, which differ depending on the nature of the suspension—well-dispersed, weakly flocculated, or strongly flocculated. The total interparticle potential energy can be expressed as

$$V_{\text{total}} = V_{\text{vdW}} + V_{\text{elect}} + V_{\text{steric}} + V_{\text{structural}} \qquad (2)$$

where V_{vdW} is the attractive potential energy due to long range van der Waals interaction between particles, V_{elect} is the electrostatic repulsive potential energy between like-charged particles, V_{steric} is the potential energy arising out of the steric interactions among bulky groups present on the particle surface, and $V_{\text{structural}}$ is the potential energy due to various nonadsorbed species in solution [144]. Tseng and coworkers have demonstrated the use of sol–gel (colloidal) method for the synthesis of advanced ceramic oxides such as silica (SiO_2) [16, 83, 145–147], stabilized zirconia (ZrO_2) [148–150], ferrites [22, 151, 152], and superconducting oxides [153–156]. The grain sizes in the nanometer range were obtained when samples were sintered from nanoparticles with a uniform green microstructure prepared through colloidal processing. Recently, our group has demonstrated that the grain sizes of high permittivity thin films can be suitably tuned by varying the sol–gel precursor concentration as well as the subsequent annealing temperatures of the films [157]. Some of our major results that are relevant to oxide nanoparticle synthesis are summarized in the subsequent paragraphs.

Silica (SiO_2) is a potential material in optical, electrical, and thermal applications. To understand the densification and sintering characteristics of silica powders, monodisperse, spherical hydrous silica (SiO_2) was synthesized through a colloidal sol–gel process and the resultant powder

was characterized in detail [16, 83, 146, 147]. The preparative step involved the addition of tetraethylorthosilicate ($Si(OC_2H_5)_4$, TEOS) to a reagent-grade ethanol and concentrated NH_4OH solution with constant stirring at room temperature. The TEOS undergoes hydrolysis/condensation reactions, forming polysilicic acid, which is then followed by the precipitation of silica particles. The reactant concentration controlled the average diameter of the particles that are formed during the synthesis. The precipitate was washed with distilled water, dried, and subsequently calcined in loose stack in the temperature range of 200 °C to 1050 °C. The diameters of the spherical particles ranged from 200 to 600 nm. However, by tuning the reactant concentration and the thermal processing conditions, the particles can be crystallized within the nanograin size range. The sample calcined at 200 °C was suspended in distilled water using ultrasonication and pH adjustments. The powder was then allowed to settle down in plastic tube under gravity to form a green compact. The SEM characterization of the green compact formed by the particle sedimentation showed the two-dimensional, hexagonal close-packed array of particles with an ordered array extending to a few micrometers. Figure 8 illustrates the hexagonal pore formation in SiO_2 [83]. The hcp layers are stacked one over the other to form a self-organized three-dimensional ordered structure. The striking feature of these investigations was the tuning of the diameter of the nano-sized pores in the compact, which was prepared by dispersion and flocculation techniques. The green compact of the dispersed particles had smaller pores compared to that of flocculated particles. The pore size distributions were narrower and bimodal in nature because of the presence of three-particle and four-particle pore channels. The study showed that by appropriate tuning of the sol preparation, colloid formation, and dispersion conditions, three-dimensional ordered SiO_2 powder compact can be formed.

Low magnetic loss is the characteristic of soft ferrites with highly dense fine-grained microstructure of nanoparticles. In order to obtain the desired microstructure for low loss soft ferrites, a colloidal precipitation technique was selected [22, 151, 152]. The TEM image of the highly sinter-active Ni-Zn ferrite ($Ni_{0.5}Zn_{0.5}Fe_2O_4$) powders prepared by the colloidal precipitation technique is presented in Figure 9 [152]. The particle size of the prepared powder was 26.7 nm with specific surface area of 116 m^2/g obtained from BET measurements. The samples when sintered at temperatures in the range of 1000 °C–1200 °C showed that the dense

Figure 9. TEM picture of $Ni_{0.5}Zn_{0.5}Fe_2O_4$ powders prepared by colloidal precipitation [22].

microstructure with some intergranular porosity and had a very low magnetic loss [22]. The sintered samples were magnetically characterized to obtain the grain-size dependence of magnetic permeability [22]. At temperatures below 1100 °C, the magnetic permeability was found to be proportional to (grain size)$^{1/2}$, which was in accordance with the model proposed by Igarashi and Okazaki [158]. However, at high temperature, the permeability data did not agree with the model, perhaps due to the loss of zinc from the sample, which could have affected the Fe^{2+}/Fe^{3+} ratio. Moreover, the high-temperature sintered sample exhibited higher magneic loss, possibly because of the formation of larger pores.

Using ethylene di-amine tetra-acetic acid as a chelating agent in a sol–gel process, the 2223 superconducting ceramic powder belonging to the Bi-Pb-Sr-Ca-Cu-O system was prepared and characterized by Chen et al. [156]. The TEM micrographs obtained from the ultrastructures of Bi-Pb-Sr-Ca-Cu-O EDTA colloid after aging treatments at 40 °C and 90 °C are shown in the Figure 10. It can be inferred from the pictures that each EDTA cluster exhibited a fractal structure at two different temperatures. The absence of an additional aggregation of clusters could be due to the evaporation of the solvent when the colloid was placed on a highly hydrophilic grid and exposed to the electron beam. The average size of the primary colloidal particle was about
Figure 10. TEM micrographs for the ultrastructures of Bi-Pb-Sr-Ca-Cu-O EDTA colloid after aging treatments at 40 °C and 90 °C [156].

10 nm, implying that the particles had a large specific surface area along with very high chemical reactivity during subsequent heat treatment. Moreover, the ultrastructures shown in Figure 10 exhibited different fractal dimensions. The fractal structure of colloidal EDTA formed at 90 °C is more open than that formed at 40 °C. The temperature dependence of the fractal formation could be explained by two distinct mechanisms of cluster aggregation, namely reaction-limited aggregation (RLA) and diffusion-limited aggregation (DLA). The RLA meachanism was probably responsible for the formation of dense aggregates formed at 40 °C, whereas DLA caused the formation of less dense aggregates at 90 °C.

2.7. Sonochemical Processing

Application of ultrasound in chemical synthesis has initiated a new fascinating field in processing technology [159]. As the name of the route suggests, the sound waves act as the energy source, when the respective sol of the material to be prepared is exposed to high-intensity ultra sound (50 to 500 W/cm^2). The underlying mechanism of sonochemical processing route consists of the formation, growth, and collapse of the bubbles of the sol upon exposure to acoustic waves to form the product phase. The collapse of the bubbles leads to very high temperature ($\sim$5273 K), high pressure ($\sim$1.01325 $\times$ 10^8 Pa), high heating and cooling rate (10^{10} K/s), and short-lived transient species [160]. The extreme conditions during acoustic cavitation enable the reactants to cross the activation energy barrier in a very short amount of time to form the product phase. The rapid heating and cooling rate during acoustic cavitation leads to the formation of amorphous nanoparticles [161]. Apart from the liquid sol, a dispersion of the ceramic (liquid-solid systems) can be subjected to ultrasonic irradiation. The sonicated dispersions are characterized by enhanced mass transport due to turbulent mixing and acoustic streaming, surface damage at liquid-solid interfaces by shock waves and microjets, generation of high-velocity interparticle collisions in slurries, and increase in surface area of the particles [162–165]. Interparticle collision during the ultrasonic agitation leads to changes in particle morphology, composition, and reactivity.

The magnetite Fe_3O_4 is useful as a magnetic ferrofluid in applications such as data storage. In order to prepare fine-grained magnetite particles, an efficient alternative to high-energy milling is the use of sonochemical preparation from volatile organometallic precursors. Suslick and coworkers were able to prepare a stable ferromagnetic colloid from an organometallic precursor [163]. The Fe_3O_4 particles had a narrow particle size distribution and exhibited superparamagnetic properties. By varying the concentration of the sol used, the particle size of the oxide powder can be tuned. Nanosized powders are obtained when dilute sol is subjected to sonochemical processing. Moreover, the type of the surfactant used in the sol preparation also influences the morphology of the oxide nanoparticles [166, 167]. Sonochemical processing has been found to be very useful for the preparation of mesoporous materials [168]. The ultrasonic method is superior to other techniques for the preparation of porous solids having fine, dense spherical pores. Recently,

nested fullerene-like oxides, which can be used as a host material for organic molecules, have been synthesized using this technique [169]. The ability of porous solids to act as host material for organic molecules may be exploited for the removal of toxic organic substances from the environment so that major ecological disasters can be prevented. However, tuning of pore sizes in porous solids and their large-scale commercial production at affordable cost are desirable in order to achieve this objective.

2.8. Spray Pyrolysis

As an alternate method to sophisticated processing routes with the potential for commercial scale-up, spray pyrolysis has been widely used for the synthesis of ultrafine particles [170–174] and thin films [175]. The method can be briefly described as follows: The precursor solution (sol), which contains the metal ions dissolved in the desired stoichiometry, is sprayed through a nozzle and suspended in gaseous atmosphere (aerosol generator). The suspended droplets are thermally processed to the product phase by allowing the sol droplets to drift through the heated zone of a furnace. Spray pyrolysis has many variations based on the differences in thermal processing step. Some of them are aerosol decomposition, evaporative decomposition, spray roasting, and spray calcination [98]. The schematic diagram in Figure 11 illustrates the sequence of transformation of the sol droplets to final particulate material in spray pyrolysis.

Compared to the gas phase condensation techniques, spray pyrolysis is more advantageous because of its simplicity and the ability to produce complex multicomponent oxides in particulate as well as thin film forms from comparatively cheaper nonvolatile starting materials. In comparison with the sol–gel method and related precipitation techniques, the powders produced by spray pyrolysis are less agglomerated with improved crystallinity. Submicrometer-sized composite particles with excellent compositional homogeneity can be prepared by this method. For instance, Ag-YBa$_2$Cu$_3$O$_7$ composite powders synthesized by spray pyrolysis maintained identical Ag to ceramic ratio in each particle [176]. However, it is difficult to control the particle morphology of powders prepared through spray pyrolysis. Moreover, the production costs can be high when large volumes of gases have to be handled during the spray pyrolysis.

2.9. Mechanochemical Synthesis

The drive for low cost commercial production of nanophase materials has led to the development of a mechanical milling process, which involves continuous milling of the reactive powders over a period of time. The apparatus used for milling should have the following features: generating high energy through high impact velocity and frequency during the milling process to enhance the reaction rate and the productivity, and easy scale-up of the mill capacity. In order to improve the design of conventional mills (planetary, vibratory, or attrition mills), Basset et al. [177] incorporated a modified design for the milling apparatus. The goal of design was to rectify the drawbacks of conventional mills by enhancing the generated energy as well as the capacity for production in large quantities.
Figure 11. The sequence of formation of solid particles from sol droplets in spray pyrolysis. Reprinted with permission from [98], T. T. Kodas and M. J. H. Smith, "Aerosol processing of materials," Wiley-VCH, New York, 1999. © 1999, Wiley.

The reactive components, after prolonged milling, undergo reduction in size and increase in surface area, which leads to enhanced diffusion of the reactants. Hence, the product phase crystallizes at much lower temperatures compared to conventional solid state synthesis. Moreover, the incorporation of high energy and generation of defects in the crystalline lattice during the intense grinding contribute to higher diffusion rates. The process has been employed for the synthesis of a wide variety of oxide nanoparticles [178–182].

The nanocrystalline ferroelectric Bi$_2$VO$_{5.5}$ (BiV) has been synthesized by a mechanochemical processing of stoichiometric amounts of Bi$_2$O$_3$ and V$_2$O$_5$ powders [178]. The evolution of the product phase has been systematically characterized by X-ray diffraction (XRD) and differential thermal analysis (DTA) of the samples milled for different durations. Based on the detailed characterizations, it was concluded that the nanocrystalline (BiV) phase nucleated through a ferroelastic intermediate phase BiVO$_4$ and the reaction reached completion in 54 h to yield 30 nm BiV crystallites.

Though the process can be used for the preparation of large amounts of nanophase materials at low cost, there are certain disadvantages associated with the process. As the process involves physically dividing the solid reactant particles through high energy collisions, the resultant product obtained through this method may have inherent strain present in the lattice. Also, there are chances of contamination after prolonged milling. Although the time required for the completion of the reaction depends on the kinetics of specific systems, relatively longer duration is required for the completion of the reaction in mechanochemical processing.

2.10. Microemulsion Synthesis

During the past few years, there has been tremendous motivation among scientists to find novel preparative routes that can precisely control the particle size of the final solid product. Among the various techniques, the microemulsion-mediated synthesis has been particularly of interest to size-selective preparation and self-assembly of nanoparticles because of the excellent control on the particle size that can be achieved through appropriate surface modification of the micelle [183]. Microemulsion can be defined as an isotropic, thermodynamically stable system constituting the micrometer-sized droplets (micelle) dispersed in an immiscible solvent and an amphiphilic surfactant species on the surface of the micelle [184, 185]. The crucial aspect of the microemulsion route is the control of the nanoparticle size through suitable selection and addition of a surfactant prior to the hydrolysis of the metal alkoxide sol (reverse micelle or water-in-oil emulsion). The addition of the surfactant molecules creates aqueous domains (nanoreactors) in the range of 0.5–10 nm. By properly tuning the water/surfactant ratio, which is critical in deciding the final particle size, the diameter of the aqueous droplets can be tuned. The difference between the conventional sol–gel method and emulsion-mediated synthesis is that the rate of hydrolysis is controlled by the diffusion of the precursors from the oil phase to the aqueous droplets. The method has been recognized as the most appropriate for the synthesis of ultra-fine magnetic nanoparticles for potential applications in magnetic recording media, biomedical, and related fields [186–188]. The ability to control the particle size when prepared through an emulsion route has also prompted the synthesis of nanosized ferroelectric materials with a motivation to implement them in various electronic devices [189–191]. The microemulsion-derived size-selective oxide nanoparticles are also potential materials for catalytic applications as demonstrated in recent years [192–194].

When the metal ions have different reactivities, the conventional preparative routes do not yield a homogeneous product. In such cases, the microemulsion route may be preferred for the oxide nanoparticle synthesis. For instance, as a potential catalyst for the hydrocarbon decomposition, Zarur et al. [192] have synthesized nanoparticles of barium hexa-aluminate ($BaO \cdot 6Al_2O_3$, BHA) with good homogeneity, which cannot be achieved through conventional synthesis, because of the different reactivities of barium and aluminium, using a reverse microemulsion route. The prepared nanoparticles showed excellent catalytic activity for

methane combustion, high surface area, high thermal stability and ultrahigh dispersion of cerium oxide on their surfaces. The morphology, structure, and surface area of the synthesized BHA nanoparticles have been carefully tailored by the water to oil ratio, aging time, powder recovery, and drying time. For water content in the range 5–20 wt%, discrete spherical BHA particles of 3–10 nm were reported. These nanoparticles were subsequently subjected to thermal processing at relatively low temperatures (1050 °C) to obtain fully crystallized BHA phase with high surface area. Even though the microemulsion method is effective in the size-selective preparation of nanoparticles, the as-prepared powder may have organic impurities. Table 1 summarizes the advantages and disadvantages of different synthesis routes for oxide nanoparticles discussed in this section.

3. SPECTROSCOPIC CHARACTERIZATION

The exciting developments in nanoparticle research must be effectively supported by a variety of structural characterization tools, as the characterization of nanoparticles provides invaluable information on the various microstructural, crystallographic, molecular, and atomic features, which can shed light on unique properties exhibited by these fascinating materials. In the previous sections, we have illustrated the use of electron microscopy in obtaining the microstructural features of some of the oxides (Figs. 2, 8, 9, and 10). In this section, we briefly summarize the use of various spectroscopic characterization tools in nanoparticle research in light of some recent studies on a variety of oxide nanoparticles.

3.1. X-Ray Diffraction

As a primary characterization tool for obtaining the critical features such as crystal structure, crystallite size, and strain, X-ray diffraction (XRD) patterns have been widely used in nanoparticle research [104, 194–197]. Except for single crystalline nanoparticles, the randomly oriented crystals in nanoparticles cause broadening of the diffraction peaks. This has been attributed to the absence of total constructive and destructive interferences of X-rays in a finite-sized lattice [195]. The effect becomes more pronounced when the crystallite sizes are on the order of a few nanometers. Moreover, inhomogeneous lattice strains and structural faults also lead to broadening of peaks in diffraction patterns. Detailed analytical procedures for XRD patterns for polycrystalline and amorphous materials have been discussed by Klug and Alexander [198]. The simplest and most widely used method for estimating the crystallite size is from the full width at half maximum (FWHM) of a diffraction peak using the Scherrer equation, which can be expressed as,

$$D = \frac{K\lambda}{\beta \cos \theta} \tag{3}$$

where D is the crystallite size, λ is the wavelength of the X-ray used, β is the FWHM, θ is the diffraction angle, and K is a constant close to unity. The major assumptions are that the sample is free of residual strain and has a narrow grain

Table 1. Major advantages and disadvantages of different synthesis routes for oxide nanoparticles.

Process	Advantages	Disadvantages
Gas phase deposition methods	Particle formation can be controlled by tuning the gas pressure in the reactor, narrow particle size distribution, high purity	Sophisticated instrumentation and costly reactants, unsuitable for large scale production, difficulty in producing multicomponent oxides, agglomerate formation at high particle concentration
Microwave plasma processing	Short processing time, preparation of metastable materials, use of solid or liquid reactants, small particle size of the product with narrow size distribution	High reaction rate with inside-out heating profiles, difficult to measure exact process temperature, microwave susceptible starting materials needed
Hydrothermal synthesis	Less agglomerated fine powders with narrow size distribution, good control on chemical composition, microstructure, crystallinity, no separate calcination step, synthesis of metastable materials	Hydrothermal slurries are potentially corrosive, careful release of the pressure from the hydrothermal bomb, prior knowledge on solubility of starting materials required
Electric dispersion reaction	Liquid-liquid reaction system requires less energy compared to liquid-gas systems, soft agglomerates, use of surfactant (water-in-oil) to control green body density	Complex reaction setup, difficult for commercial scale up
Combustion synthesis	Exothermic reaction gives product almost instantaneously, preparation of multicomponent oxide, high surface area materials, low cost for commercial scale-up	Contamination due to carbonaceous residue, particle agglomeration, no control on particle morphology, reliable data on fuel characteristics needed, violent reaction—requires special protection
Sol–gel (colloidal) processing	Fine sinter-active powders, crystallization at low temperature, simple apparatus, preparation of wide variety of oxides, metastable materials in desired shapes, particle size controllable by changing reactant concentration	Costly starting materials such as metal alkoxides, particle agglomeration, contamination due to undecomposed group in the low-temperature crystallized samples
Sonochemical processing	Processibility of a wide variety of materials including metastable materials, fine powders with high surface area and green density, amorphous nanoparticles, and nanoporous materials for catalytic applications	The enormous energy concentration during the collapse of the bubble may leave residual strain in the powders, interparticle collision may lead to change in morphology or composition
Spray pyrolysis	Preparation of multicomponent oxides, volatile precursors are not required, more crystalline and less agglomeration compared to liquid-phase precipitation, ability to produce composite particles	Relatively low production rate and high processing costs when large volumes of reactants have to be handled
Mechanochemical processing	Low cost starting materials, ability to produce large amounts of nanoparticles at low production cost, crystallization at low temperature	Long processing time, chance of contamination due to prolonged milling, no control on particle morphology, formation of agglomerates, residual strain in the crystallized phase
Micro-emulsion synthesis	Size-selective oxide nanoparticles with very narrow size distribution, less agglomeration compared to sol–gel	Undecomposed organic contaminants in low-temperature crystallized samples, complex route compared to sol–gel

size distribution. However, the analysis becomes more complex when contribution due to strain is taken into consideration. The Warren–Averbach method involves separating the crystallite size and strain effects on line broadening using Fourier analysis [199]. Another analytically simpler technique for the estimation of strain is the Williamson-Hall procedure, which involves plotting the breadth of reciprocal lattice points ($1/D = \beta \cos \theta / K\lambda$) as a function of their distance from the origin ($d_{hkl} = 2 \sin \theta / \lambda$) [200]. The method, which is more popular among metallurgists for the diffraction profile analysis of nanocrystalline metals [201], has been used recently to characterize the strain in a variety of oxide samples [34, 202, 203]. A horizontal Williamson–Hall plot would signal the absence of strain in the prepared ceramic powders as reported in the case of nanocrystalline $MgAl_2O_4$

[34]. By recording the XRD patterns as a function of pressure and temperature, several important characteristics such as grain boundary and thermal and elastic properties of the nanocrystals can be estimated [195]. Highly intense XRD peaks at low angle indicate the formation of an ordered superstructure of nanoparticles [204].

3.2. Energy Dispersive X-Ray (EDX) Spectroscopy

The main use of energy dispersive spectrometers is to accurately determine the composition of the sample under investigation. While electron microscopic images provide real-time pictures of the size and morphology of the nanoparticles, the supplimentary EDX analysis provides exact

composition of the sample. Upon exposing the samples to high energy electron beams, the various atoms present in the sample emit characteristic X-rays, which can be observed as several distinct peaks on an energy scale. The intensities of the peaks can be compared with the peaks of a standard sample to obtain the relative amounts of each atomic species; thereby accurate composition of the sample can be determined. The EDX composition analysis has been proven to be very critical, especially when the composition plays a crucial role in the resultant properties as in the case of high-T_c cuprates [205–207].

The use of EDX has been demonstrated in oxide nanoparticle research, particularly in the determination of the composition of substituted or nanoparticle composite materials as reported for Zn-substituted Fe_3O_4 magnetic colloids [208], Eu_2O_3-coated spherical ZrO_2 or stabilized ZrO_2 [209], and polymer γ-Fe_2O_3 nanocomposites [210]. The EDX analysis provides information on the concentration of Eu on the surface of the spherical ZrO_2 nanoparticles, which suppliments the TEM evidence for the presence of Eu_2O_3 coating on spherical ZrO_2 nanoparticles [209]. Similarly, the EDX analysis of polystyrene γ-Fe_2O_3 nanoparticle composite has signature peaks of Fe, confirming the presence and concentration of iron in the nanocomposite samples. The EDX analysis has been used for obtaining the composition of TiO_2 nanotubes as reported in a recent study by Du et al. [211]. The results of their EDX analysis of several TiO_2 nanotubes showed that the ratios of intensities of Ti peaks and O peaks are not identical in all nanotubes, which indicates that the composition of the nanotubes can be represented as TiO_x.

3.3. Extended X-Ray Absorption Fine Structure Spectroscopy

Probing the local order in disordered systems such as glass and nanostructures has been of great interest to scientists. Extended X-ray absorption fine structure spectroscopy (EXAFS), which involves obtaining the characteristic X-ray absorption spectrum for individual elements present in the sample, provides a partial radial distribution function (RDF) for each element as compared to a single averaged RDF from conventional diffraction techniques [212]. The technique has been extensively used in obtaining the local order in glass systems and amorphous alloys [213–216].

Advancements in the preparative strategies of oxide nanoparticles have led to further reduction in derived particle sizes, which implies that the increasingly disordered surfaces, interfaces, or atomic sites contribute significantly to the resultant properties of nanoparticles. This has prompted scientists to look for more effective techniques such as EXAFS to probe the local order in nanoparticles. For instance, the technique has been proven to be very effective in probing the local structure in nanoferrites [217, 218], luminescent phosphors [219, 220], and surface-modified nanostructured catalysts [221]. Spinel ferrites exhibit structural disorder at the cationic sites. As an accurate method for the determination of the cationic disorder parameter x in spinel, the EXAFS technique can be used [222]. Recently, Oliver et al. [218] carried out EXAFS study on nanocrystalline $ZnFe_2O_4$ in order to obtain the cationic disorder (x) in their spinel sample $(Zn_{1-x}^{2+} Fe_x^{3+})_t[Zn_x^{2+}Fe_{2-x}^{3+}]_oO_4$ where "t" and

"o" refer to tetrahedral and octahedral sites, respectively. The typical Fourier-transformed EXAFS spectrum of nanocrystalline $ZnFe_2O_4$ is presented in Figure 12 [218]. The intense peaks at r-space values 2.6 Å and 3.1 Å have been attributed to the octahedral and the tetrahedral occupancies of cations, respectively. By comparing the intensities of the peaks for Zn and Fe cations in the respective spectra, it is possible to qualitatively infer the exent of cation mixing at the two sites. The disorder parameter can be quantitatively determined by least squares fitting of the Fe and Zn EXAFS spectra to the idealized scattering results for a spinel lattice [223]. From the EXAFS-derived disorder parameter, Oliver et al. [218] obtained the quantitative distribution of the Zn and Fe cations in tetrahedral and octahedral sites for their nanocrystalline ferrite spinel sample, which can be expressed as $(Zn_{0.55}Fe_{0.18})_t[Zn_{0.45}Fe_{1.82}]_oO_4$. The degree of disorder at the grain boundaries of nanocrystalline samples can be derived from the EXAFS study of doped nanocrystalline sample with an impurity that is not soluble in the lattice and segregate at the grain boundaries. The local order around the impurity element would provide an estimate on the grain boundary order in a nanocrystalline sample under investigation [224].

3.4. X-Ray Photoelectron Spectroscopy

Reactive solid surfaces have generated lot of interest among researchers because of their potential in catalyzing chemical reactions and influencing various transport properties. In particular, determining the structure and composition of the surfaces is of utmost importance for understanding the basic mechanisms in catalytic reactions, as well as for fabricating novel nanostructured catalysts [225, 226]. One of the important characterization tools in surface chemical analysis is X-ray photoelectron spectroscopy (XPS), which has the ability to probe the surface to a few atomic layers deep (2–20 atomic layers, 0.5–5 nm) and obtain a semiquantitative elemental analysis of the surface without standards [227]. The valence states of the elements that constitute the surfaces can also be deduced from the XPS characterization.
Figure 12. Fourier transform EXAFS spectra of Fe (top) and Zn (bottom) atoms for the nanocrystalline spinel $ZnFe_2O_4$ plotted against radial coordinates with a k^3 weighting [218].

The technique involves measurement of the binding energy of the ejected electrons from the atomic core shells of the material when bombarded with monochromatic soft X-rays. XPS has been extensively used for thin film characterization in order to monitor the surface layer growth as well as to obtain the valence states of various elements at the surface [116, 228–230].

As a part of innovative design of nanoparticles, oxide nanoparticles with surfaces different in chemical composition from the grain interior have attracted attention. For example, CrO_2 nanoparticles with Cr_2O_3 surface layers have been characterized for exploring magneto-transport properties through intergranular tunnel junctions [196]. XPS study of the CrO_2 nanoparticles indicates that the Cr is in a trivalent state on the 1–3 nm thick surface layer, which confirms the presence of the Cr_2O_3 on the surface of CrO_2. Similar studies have been reported for the XPS characterization of oxide nanoparticle surfaces such as CuO surface layers on Cu_2O nanoparticles [231] and Co_3O_4 layers on CoO [232]. XPS spectroscopy is an inevitable technique for the study of metal nanoclusters with oxide coated surface layers. For instance, systems like Sn/SnO_2 are important candidates for the study of confinement effects on core level XPS spectra of clusters and quantum dots, the development of metal supported catalysts, and the understanding of various electronic transport properties [233]. Another related effect of photoelectron emission is the Auger electron emission or secondary electron emission, which is essentially a relaxation process of the ionized atom [234]. The technique is noted for high lateral resolution and relatively high sensitivity along with the ability to probe the surface to ∼10 nm depth [227]. Oxide layer formation on the surfaces can be characterized using Auger spectroscopy [116, 235].

3.5. Secondary Ion Mass Spectroscopy

Another important surface analytical technique is secondary ion mass spectroscopy (SIMS), which has been extensively used for the characterization of thin film heterostructures [236–240]. The sample under investigation is exposed to a primary ion beam, which then sputters atoms and molecules from the surface to the interior of the sample. The masses of the sputtered species are then analyzed using a time-of-flight analyzer and recorded as mass spectrum. The SIMS depth profile, which provides elemental concentrations in the sample as a function of depth, is the most commonly sought after information, especially in thin film heterostructure characterization.

SIMS profiling has great potential in characterizing the concentration profiles of self-organized or consolidated nanostructures. In particular, being a highly sensitive technique with sensitivity levels on the order of parts-per-billion (ppb), SIMS is the most appropriate technique to study diffusion reactions. As an example, it is worth noting the studies on oxygen diffusion through nanocrystalline zirconia [241]. The study involved monitoring the diffusion of the isotopic oxygen (^{18}O) tracer in densified monoclinic ZrO_2 samples with grain sizes in the range of 80–300 nm. The densified ZrO_2 nanocrystals have large number of interfaces, which provide easy pathways for oxygen diffusion compared to microcrystalline ceramic samples. SIMS depth

profiles corresponding to the ^{18}O diffusion through nanocrystalline ZrO_2 are presented in Figure 13 for densified samples diffusion-annealed at three different temperatures for 1 h: 500 °C, 700 °C, and 800 °C [241]. The variation of the tracer concentration profile with annealing temperature is obvious from the figure. For samples annealed at 500 °C, the ^{18}O concentration decreases dramatically to ∼5% of its initial value at a depth of about 100 nm. This can be attributed to the small bulk diffusion distances at relatively low temperature. For samples annealed at 700 °C, the tracer concentration registers a slower rate of decrease, due to the enhanced diffusion through well-formed interfaces of the densified nanocrystalline ZrO_2 samples. The ^{18}O-depth profile for sample annealed at 800 °C shows that the isotopic tracer penetrates to greater depths on the order of several micrometers. As a sensitive technique for the detection of impurities and related diffusion, SIMS has been used for the characterization of photonic materials such as porous silicon (Si) [242] or doped ZnO [243], in which the presence of trace impurities affects the resultant optical characteristics. A recent study probes the potential application of SIMS in the characterization of inorganic materials by recording the mass spectra of oxide species in the binary Cu-O and the ternary Fe-Cr-O systems [244].

3.6. Optical Absorption-Emission Spectroscopy

Spectacular changes in optical characteristics of nanocrystalline oxides when compared to those of bulk counterparts have triggered tremendous interest among scientists in order to understand the basic mechanisms responsible for the fascinating optical absorption-emission, which also would help to examine their potential use in a variety of optical applications [245–251]. Optical absorption and emission arise as a result of electronic transitions in solids upon exposure to excitation energies in the range ∼10^2 to 10^3 kJmol^{-1} that cover the near infrared through visible to ultraviolet. There are various types of optical transitions in solids. One type of transition is the promotion of an electron from a localized orbital to a higher energy localized orbital of the same atom (d-d, f-f transitions) or from a localized orbital
Figure 13. SIMS profile for ^{18}O diffusion through sintered nanocrystalline ZrO_2 for diffusion anneals for durations of 1 h at three different temperatures as quoted in the diagram [241].

in one atom to a higher energy localized orbital on an adjacent atom (charge-transfer spectra). Another type of transition can be the promotion of electrons from a localized orbital in one atom to the delocalized energy band (conduction band) of the solid as seen in the case of photoconductive materials. The transition that helps to quantify the band gap in solids is the transfer of electrons from the valence band to the conduction band. The transition energies associated with these processes differ, thereby requiring different excitation frequencies for obtaining their absorption and emission spectra [212].

Understanding the quantum confinement effect on optical absorption and emission characteristics has been the major objective of optical characterization of oxide nanocrystals. For example, the photoluminescence spectra of In_2O_3 nanocrystals dispersed in mesoporous silica indicate a blue shift for smaller crystallites, which also implies an expansion in the energy gap between the valence and conduction band upon size reduction [245]. Particularly interesting is the investigation of size effects on the photoluminescence imaging of ZnO nanocrystals [249]. The intensities of the high energy components of the PL spectrum increased with decreasing spot sizes or crystallite sizes (Fig. 14), implying a size quantization effect in ZnO nanocrystals. Recently, optical characterization of nanocrystalline rare earth doped oxides, which are termed as phosphor materials, has become a major area of research because of their potential applications in the development of display devices [252–255]. From the optical absorption-emission spectra of nanophosphor materials, the various optical transition mechanisms such as charge-transfer or host-matrix absorption can be identified [255].

3.7. Raman Spectroscopy

The Raman spectroscopic technique has been extensively used for structure, composition, and phase characterization of materials. For example, the information derived from the Raman spectra of superconducting cuprates [256] and collossal magnetoresistive manganates [257] helps to explain the fascinating electronic transport properties in these materials. The Raman spectra provide various characteristic vibrational frequencies, such as those associated with lattice defects or surfaces, and derive crucial data on the electronic band structures in solids.
In nanoparticle research, monitoring the characteristic vibrational frequencies of atoms would be of great interest in understanding the bonding and coordination environments of the increased fraction of atoms residing at the surface. Raman spectroscopy, which measures the inelastic light scattering due to the excitation of various vibrational modes in materials [227], can be used for obtaining the characteristic frequencies associated with surface states in nanoparticles. In one of the earlier investigations into vibrational modes in nanophase oxides, the Raman spectra of oxygen-deficient TiO_2 nanoparticles showed characteristic broadening and shifting of peaks due to the oxygen vacancies present in the rutile or anatase TiO_2 lattice [45]. Raman analysis of SnO_2 nanoparticles of sizes in the range of 3–90 nm indicates the appearance of two additional peaks in the Raman spectrum for the particle sizes below 10 nm. These additional peaks are ascribed to the surface phonon modes of SnO_2 [258]. The evidence for optical phonon confinement appear in Raman spectra as asymmetric broadening of Raman bands as obtained for ZnO nanoparticles of sizes 4.5 nm and 8.5 nm [259]. The experimental results are fitted into a theoretical optical phonon confinement model, which takes into account various asymmetric phonon modes in nanosized ZnO wurtzite structure. Asymmetric broadening of the Raman peak, which is in comparison with symmetric Raman peak at a wavenumber 464 cm^{-1} for an ideal CeO_2 crystal, has been observed in a systematic Raman characterization of single crystal nanocrystalline CeO_2 of sizes in the range of 6 to 25 nm. The peak also shifts to lower energy values for smaller crystals. The peaks corresponding to micrometer-sized single crystal CeO_2 appear to be symmetric, sharp, and intense (Fig. 15) [260]. The characteristic changes in Raman peak for smaller crystallites can be attributed to the expansion of the nanocrystalline CeO_2 lattice due to increased point defects. A similar systematic Raman characterization for nanocrystalline CeO_2 thin films has shown a similar trend with varying grain sizes of CeO_2 from nanometers (4–150 nm) to micrometer-sized single crystals [261]. The quantitative analysis on the effects of phonon confinement, strain, size dispersion, and defects on the Raman spectral lines have been discussed recently by Spanier et al. [262] for oxygen-deficient ceria (CeO_{2-x}).

Figure 14. Relative PL intensities (I_{PLR}) ($=I_{PL}$ at 370 ± 2.5 nm)/(I_{PL} at 380 ± 2.5 nm) of PL-imaging of ZnO nanocrystallites as a function of spot sizes (representing the corresponding crystallite sizes) [249].
Figure 15. Raman spectroscopic characterization of 464 cm^{-1} Raman peaks for nano- and micrometer-sized CeO_2 particles [260]. Peaks shift to lower energy with asymmetric broadening as particle size decreases.

3.8. Infrared (IR) Spectroscopy

The characteristic vibrations of atoms in solids have frequencies in the range 10^{12} to 10^{13} Hz, which implies that an infrared (IR) excitation source can resonate these vibrations, thereby exciting them to higher energy levels [212]. A plot of I/I_0 versus frequency, which is represented as wavenumber (cm^{-1}), is the typical IR spectrum. The IR absorption bands characterize qualitatively and quantitatively the chemical species, stress, and structural inhomogeneity in solids and thin film materials [227]. The use of IR spectroscopy for the characterization of phase transformation in gel-derived stabilized zirconia powders has been demonstrated by Tseng et al. [148]. In particular, the IR technique can be the most appropriate method to characterize various functional groups present on surface-modified oxide nanoparticles as shown in the case of amorphous Fe_2O_3 nanoparticles [263]. When it is required to obtain the surface characteristics of a few monolayers or even a single atomic layer of the nanosized particles, the Fourier transform infrared (FTIR) technique has been found to be highly suitable [264]. For example, the FTIR spectra for the molybdenum oxide $(Mo_2O_5 \cdot xH_2O)$-silica (SiO_2) nanocomposite [265], Eu_2O_3-coated ZrO_2 nanoparticles [209], or hydrothermally derived CeO_2 nanoparticles [266] exhibit characteristic absorption bands of chemical species present at the surface. Another very important application of FTIR is to delineate the mechanism of adsorption and formation of various species on the catalytic metal oxide surfaces such as the carbonate decomposition on metal oxide to form metal carbonyl bonds [267].

3.9. Mössbauer Spectroscopy

Mössbauer spectroscopic analysis involves exciting various nuclear transitions that are induced in the Fe or Sn nuclei of the sample when bombarded by γ-rays, which are emitted by corresponding radioactive nuclei $(^{57}Fe^*_{26}$ or $^{119}Sn^*_{50})$ from a γ-ray source. The energy of the incident monochromatic γ-rays is varied by movement of the source either toward or away (Doppler shift) from the Mössbauer-active sample [212]. A typical Mössbauer spectrum is a plot of γ-ray absorption against Doppler velocity. When the γ-ray emitting nuclei and absorbing nuclei are identical, the absorption peak appears as a sharp dip at 0 Doppler velocity. However, the chemical environments such as valence state, outer electronic configuration, and coordination number of the nuclei in Mössbauer-active samples are not the same as those in the γ-ray source. These effects are reflected in the spectra as characteristic chemical shifts, δ, of the absorption peaks of the spectrum. Moreover, the hyperfine splitting in the Mössbauer absorption spectra indicate the possible effects of quadrupole splitting or magnetic exchange interaction in the sample.

The Mössbauer spectrum has been extensively used for the characterization of Fe-containing oxides [268]. In particular, the technique provides crucial information about the local order and associated magnetic properties in nanocrystalline ferrites [269–275]. For instance, the Mössbauer spectroscopic characterization of $Mn_{0.5}Zn_{0.5}Fe_2O_4$ (MnZn-ferrite) reveals the effect of temperature on the hyperfine field effect in Mössbauer spectra. The calculated values of the isomer shifts at two temperatures 295 K and 78 K correspond to the trivalent Fe in the nanocrystalline MnZn-ferrite samples [272]. The Mössbauer spectra recorded at two different temperatures (300 K and 4.2 K) for the polymer-$CoFe_2O_4$ nanocomposite exhibit distinct features due to quadrupole splitting and magnetic hyperfine splitting. At 300 K, the quadrupole splitting dominates the magnetic splitting, which indicates the superparamagnetic nature of the sample, whereas at 4.2 K, only the magnetic splitting is present, implying the ferrimagnetic nature of the sample [273]. The presence of both types of splitting has been attributed to the typical particle size distribution of the ferrite $(4.8 \pm 1.4$ nm) in the composite. It is also possible to estimate the ratio of distribution of Fe on A and B sites in spinel ferrites as obtained by Moumen and Pileni [274] for nanosized $CoFe_2O_4$ and Morales et al. [275] for γ-Fe_2O_3 nanoparticles.

4. PROPERTIES

4.1. Electronic Structure

Electronic transition in solids is a major physical phenomenon that accounts for varied and interesting properties of solids such as electronic conduction and optical absorption. The overlapping energy levels in the valence and conduction bands of a bulk solid separate as the size of the solid is reduced. The major effects of size reduction include the discretization of the electron energy levels, concentration of the oscillator strength, formation of the highly polarizable excited states, and increased electron-electron correlation [276]. In particular, the size effects on the electronic energy levels in semiconductors are of interest because of their potential applications in the fabrication of a wide range of electronic and optoelectronic devices. For solids of dimensions on the order of a few nanometers, the increased separation between the valence and the conduction band results in bandgap expansion [277]. The consequences of bandgap expansion are reflected in the resultant electronic structure and the binding energy values of the core electrons [278–281]. The optical properties of the material also undergo remarkable changes upon reduction in size, as evidenced by the peaks shifting to higher energy levels in the photoluminescence spectra [282–285]. Other noteworthy effects of size quantization are the suppression of the dielectric constant and the blue shift in the photo absorption, as the particle dimension approaches the limit of an exciton diameter (electron-hole separation) [286–288].

Among the various models proposed, the quantum confinement theory satisfactorily explains the effects of size quantization [289–291]. According to this theory, which has been developed based on the concept of "particle in a box," the electrons in the conduction band and the holes in the valence band are confined spatially by the potential barrier of the surface. As the particle size approaches the limit of the exciton diameter, the charge carriers gain more energy, and the width of the confined band gap increases or expands. The confinement of electrons and holes leads to the shifting of the lowest energy optical transition to higher energy values. While a large amount of literature is available on

the synthesis, characterization, and related quantum size effects in II-VI sulfide and selenide semiconductors [292], relatively fewer studies have focused on the size quantization in oxide nanoparticles. Semiconducting oxide nanoparticles such as CuO, NiO, CoO, and ZnO have been characterized to understand the effect of size quantization on the electronic energy levels [279, 293–295].

Being a narrow band covalent semiconductor of band gap between 1.21 and 1.5 eV [296, 297], cupric oxide (CuO) has strong electron correlation and hence complicated optical properties [279]. XPS has been used by Borgohain et al. [279] to study the electronic structure of electrochemically prepared CuO nanoparticles (4 nm, 6 nm and 25 nm). When the particle size decreases, the transitions of electrons in various energy levels are affected. This is reflected in the recorded XPS spectrum for different particle sizes of CuO. The $2p$ core level XPS spectra obtained by Borgohain et al. [279] for CuO nanoparticles are shown in Figure 16. The broad peaks indicate the presence of a large number of atoms residing at the surface of the nanoparticle. The broadening of the peaks can also be attributed to the adsorbed oxygen and the surface passivated groups on the defective nanoparticle surface. Similar studies on CoO and NiO nanoparticles have proved that oxygen and the water vapor adsorption on the defective surface indeed contribute to the peak broadening [232, 293]. As shown in Figure 16, the Cu $2p_{3/2}$ peaks shift toward higher energy as the particle size decreases. For all the three different sizes of CuO nanoparticles, the recorded XPS spectra have satellite peaks, which confirmed the absence of Cu_2O [279]. The ratio of the satellite peak (Cu $2p_{1/2}$) intensity to the major peak (Cu $2p_{3/2}$) intensity (I_s/I_m) increases systematically with decreasing particle size. The energy separation between the two maxima registers a slight decrease for smaller CuO particles. On comparing these observations with the XPS study on divalent copper halides, CuX_2 (X-Br, Cl, or F) [298], where increase in ionicity of the ligand from Br to Cl to F led to similar results, it was concluded that the Cu-O bonds have higher ionicity in smaller CuO particles. The contributing factors that cause an increase in the ionicity of Cu-O bonds were presumed to be the defective coordination of the atoms
near the surface and the formation of discrete energy levels in the CuO nanoparticles [279].

In the present era of advanced technology, low-voltage, high-efficiency phosphors are potential materials for the development of vacuum fluorescent displays (VFD) and field-emission displays (FED) [299]. As an efficient low-voltage blue-green emitting phosphor, the semiconductor ZnO has been identified as an important material for the fabrication of display devices [295, 300]. Recently, van Dijken et al. [300] have studied the particle size effects on the energy band structure and the related emission process in ZnO nanoparticles. The authors suggested two possible mechanisms for visible emission as either the recombination of a delocalized electron with deeply trapped hole or delocalized hole with deeply trapped electron, and experimentally verified the transition. The two possible mechanisms for the visible emission were explained using a schematic energy level diagram as shown in Figure 17. The dashed lines in the Figure 17A and 17B depict the energy levels associated with the deeply trapped hole and electron, respectively. The size dependence of the band gap E^* can be represented by the following equation:

$$E^* = E_g + \frac{h^2}{8\mu R^2} - \frac{1.8e^2}{4\pi\varepsilon_0\varepsilon_\infty R} \tag{4}$$

where E_g is the band gap of the macrocrystalline material, h is the Planck's constant, μ ($1/\mu = 1/m_e^* + 1/m_h^*$) is the effective mass of the exciton, ε_∞ is the high frequency dielectric constant, and R is the radius of the particle [301]. The variations of the conduction band ($1/m_e^* R^2$) and valence band ($1/m_h^* R^2$) as a function of particle size (R) are schematically represented in Figure 17 as curves (e) and (h). The R^{-2} variation corresponds to the confinement potential, whereas R^{-1} variation is the Coulomb potential in Equation (4). Effective mass approximation has been used by van Dijken et al. [300] for their ZnO nanocrystalline samples to sketch the energy level diagram, as the samples were made up of 50 to 5000 molecular units of ZnO (0.7 nm–3.5 nm). By taking into consideration the effective mass approximation, the absolute values for the shift of the band edges can be written as

$$(e) = E_g + \frac{h^2}{8m_e^* R^2} - \frac{0.9e^2}{4\pi\varepsilon_0\varepsilon_\infty R} \tag{5}$$

$$(h) = \frac{h^2}{8m_h^* R^2} - \frac{0.9e^2}{4\pi\varepsilon_0\varepsilon_\infty R} \tag{6}$$

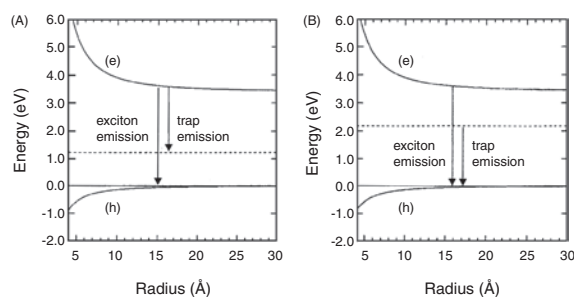
Figure 16. Cu $2p_{3/2}$ core level XPS spectra for CuO nanoparticles: (a) 4.0 nm, (b) 6.0 nm, (c) 25 nm [279].


Figure 17. Schematic energy level diagram as a function of particle size for ZnO nanoparticles illustrating the two possible mechanisms for trap emission [300].

where all symbols have the same meaning as in Equation (4). The variation of the conduction band edge as a function of the particle size is determined by the effective mass of the electron (m_e^*). The value is $0.28 m_e$ for ZnO. Similarly, the valence band edge variation is decided by the effective mass of the hole (m_h^*, $0.50\ m_e$ for ZnO) [302]. The difference in these values is shown in the respective band edge variations for the ZnO sample. However, the energy levels of the trapped charge carriers are size-independent as shown by the dashed lines in Figure 17A and 17B. The shift in the visible emission is governed by the variation of the conduction band against particle size as shown in Figure 17A for the emission process involving the recombination of delocalized electrons and deeply trapped holes. Similarly, for the delocalized holes and deeply trapped electrons, the variation of the valence band with particle size decides the energy associated with the recombination leading to the visible emission.

By plotting the maximum values of the exciton emission energy and the trap emission energy obtained for each particle size of ZnO, van Dijken et al. [300] found that the relationship is linear with a slope of $\mu/m_e^* = 0.6$, which represents the situation in Figure 17A and agrees with the calculated value of 0.64. The important conclusion from the plot was that the visible emission in ZnO nanocrystals involves the transition of an electron from the conduction band to the trap level approximately 2 eV below the conduction band edge. In other words, the recombination of electrons with deeply trapped holes (in the case of nanocrystalline ZnO, positively charged oxygen vacancies $V_O^{\cdot\cdot}$) was responsible for the visible emission in ZnO nanocrystals [303].

4.2. Optical Properties

We have discussed the effect of particle size reduction on the electronic band structure and the resultant optical absorption and emission for nanosized ZnO [300] in the previous section. In this section, we briefly review the studies on optical properties of oxide nanoparticles including the rare-earth-doped luminescent phosphors. As a material of immense interest to the microelectronics industry, it is worth noting the optical characterization of thermally oxidized Si nanoparticles [304]. Light emission from thermally oxidized Si nanoparticles exhibited a shift toward higher energy for smaller particles due to the quantum size effect. Molecular dynamic simulations of optical properties of Si clusters constituting varying number of atoms (Si_{20}, Si_{60}, and Si_{70}) indicate that the optical response has a strong dependence on the configuration of the atoms in various clusters [305]. Such studies indeed contribute to the basic understanding of the complex correlation among atomic configuration, size quantization, and optical properties of nanoparticles. The more recent optical absorption studies on SnO_{2-x} [251], Cu_2O [306], and ZnO [307] nanoparticles, which have dimensions comparable to the exciton diameter, provide further experimental evidence for the size quantization effect as shown by the blue shifts in the corresponding absorption spectra.

The phenomenon of luminescence in ultrafine powders (phosphors) has been attracting great attention in recent years. The absorbed energy (UV photons in photoluminescence) is emitted as light in phosphor materials that are in focus for the development of various optical devices [308, 309]. The two types of processes in luminescent phosphors are fluorescence and phosphorescence, which are distinguished by the time delay between the absorption of the energy and its emission (decay time $\leq 10^{-8}$ s for fluorescence, longer decay time for phosphorescence) [212]. A typical doped photoluminescent material has a host lattice having small amounts of activator ions as guest species. It is the optical absorption-emission characteristics of these activator ions and their interaction with the host lattice that decide the resultant luminescent properties. Of particular interest is the study of nanocrystalline rare-earth-doped phosphor materials, which include a lanthanide ion doped in an insulating nanocrystalline ceramic oxide [252, 253, 255, 310, 311]. The interest in this particular class of materials is to understand the changes in the energy levels of the guest species when confined in a nanometer-sized host, as well as to explore their potential use in a wide variety of applications [312, 313]. The spatial confinement would also result in interesting optical properties that are different from the corresponding bulk counterparts.

A trivalent lanthanide ion has the characteristic electronic configuration in which the overlying 5s and 5p electronic shells effectively shield the inner 4f levels from interacting with the neighboring atoms, thereby preserving the hydrogenic character [314]. Hence, the transitions within the 4f levels are sharp regardless of the host material. However, the number of lines appearing in the optical spectra of the lanthanide ions depends on the characteristic chemical environment in the host lattice, as the 4f shells are split by the crystal field effect of the host lattice, thereby generating various possibilities for electronic transition. The observed spectral characteristics of lanthanide-doped luminescent phosphors would, therefore, provide much needed insight into complex ion-lattice interactions, which will be helpful for the design of novel phosphor materials.

A schematic representation of the partial energy level diagram for Eu^{3+} ion in solids is depicted in Figure 18 [312].
Figure 18. Schematic partial energy level diagram of Eu^{3+} ions in solids. The two upward arrows correspond to absorptions, and the downward arrow corresponds to the strong red emission $^5D_0 \rightarrow\ ^7F_2$. Reprinted with permission from [312], B. M. Tissue, *Chem. Mater.* 10, 2837 (1998). © 1998, American Chemical Society.

Each energy level can be further split into $2J + 1$ levels. The two upward arrows in Figure 18 correspond to absorption transitions, whereas the downward arrow represents the strong red luminescence for the transition $^5D_0 \rightarrow {}^7F_2$. For nanoparticles, the luminescence spectrum is expected to show a shift toward higher energy. No significant shifts in spectral lines were observed at a measuring temperature of 93 K, which may be attributed to the thermal broadening effect for high surface area Eu_2O_3 powders having particle diameters ≤ 100 nm [315]. However, the excitation spectra corresponding to the transition $^7F_0 \rightarrow {}^5D_0$ when recorded at a much lower temperature of 12 K for Eu_2O_3 nanoparticles in the size range 4 to 18 nm exhibited sharp peaks for 18 nm and broadened peaks for 4 nm sample. The broadening of the spectral lines for smaller particles can be attributed to the high degree of disorder in the corresponding samples (Fig. 19) [312, 316].

Apart from quantum confinement, which influences the electronic transitions and luminescence in nanocrystals [317], the increased fraction of interfaces would also contribute to the observed optical properties and sometimes dominate size quantization [318, 319]. The luminescence characteristics of nanocrystalline $Eu^{3+}:Y_2O_3$ phosphors have been extensively studied [252, 253, 255, 310, 312], as the relatively high quantum efficiency (close to unity) of their red emission makes them a future material in a variety of photonic applications [320]. In addition to the red emission, there could also be a charge transfer (CT) band in the optical spectra, which arises due to the transfer of electrons from the $2p$ orbital of O^{2-} to $4f$ orbital of Eu^{3+} [321]. In order to understand the surface effects on the CT spectra of nanocrystalline $Eu^{3+}:Y_2O_3$ phosphors, Song et al. [310] excited the phosphors using UV-light and studied the characteristics of the resultant emission spectra. It has been reported that the changes in the CT band spectra could have been caused by the increased fraction of surface atoms ($\sim 80\%$ for 5 nm crystal) in $Eu^{3+}:Y_2O_3$ phosphors as the local environments of Eu^{3+} ions at or near the surface of the nanoparticles get rearranged upon UV irradiation. Apart from the red emission and the CT band, a weak size-dependent excitonic band corresponding to Y^{3+}-O^{2-} host matrix absorption has been reported in this system on UV excitation [255]. The observed excitonic absorption and optical storage luminescence of nanocrystalline $Eu^{3+}:Y_2O_3$ phosphors (10–20 nm) have been attributed to the possible existence of various defects, as well as chemisorbed species on the surface of the nanocrystals. Recently, the studies on the visible up-conversion emissions in $Lu_{1.98}Er_{0.02}O_3$ (50 nm) and $Y_{1.98}Er_{0.02}O_3$ (20 nm) nanoparticles indicate comparable features in the emission processes, except for the strong blue up-conversion emission recorded for Er-doped lutetia ($Lu_{1.98}Er_{0.02}O_3$) [311]. This may be due to reduced surface area and less porosity of lutetia samples compared to the yttria counterpart. Another important area in photonics is the development of optical band gap materials, which will be reviewed briefly later in this chapter as potential materials for future photonic applications.
4.3. Electrical Conductivity

Electrical conductivity in ceramics has been a topic of immense interest for researchers due to the potential applications in the development of various electrochemical devices [321–323]. The electrical conductivity (σ) of a material can be considered as the sum of the contributions from electronic conductivity (σ_e) and ionic conductivity (σ_i); the former type is caused by the transport of electrons or holes, whereas the latter type can be attributed to the ion transport through the vacant or interstitial lattice sites [324]. A recent review presents a detailed picture on the dependence of ionic and electronic conductivities as a function of concentration and spacing of interfaces in nanosized mixed oxide ion conductors [325]. For an oxygen-deficient metal oxide ($MO_{1-\delta}$), the defect equation corresponding to the formation of charged oxygen vacancies is represented by

$$O_O^X = V_O^{\cdot\cdot} + 2e' + \frac{1}{2}O_2 \qquad (7)$$
The condition for electroneutrality corresponds to

$$2[V_O^{\cdot\cdot}] = n + [A_M'] \qquad (8)$$

where the A_M' is the acceptor-type lower valent dopant impurity that substitutes a cationic site in the lattice. According to the defect formation equation, the electronic conductivity of an oxygen-deficient metal oxide ($MO_{1-\delta}$) is dependent on the partial pressure of oxygen P_{O_2}, which can be written as

$$\sigma_e = ne\mu_e = \frac{A_0}{T}\exp\left(-\frac{E_a}{kT}\right)P_{O_2}^{-x} \qquad (9)$$

where the Arrhenius expression for electronic conductivity has n as the charge carrier concentration, e the charge of an electron, μ_e the electron mobility, A_0 ($=ne\mu_0$) the pre-exponential factor, E_a the activation energy for conduction, and x the exponent that represents the variation of conductivity with partial pressure of oxygen. The expression for the ionic conductivity in $MO_{1-\delta}$ lattice can be written as

$$\sigma_i = 2e[V_O^{\cdot\cdot}]\mu_{V_O^{\cdot\cdot}} \qquad (10)$$

Figure 19. $^7F_0 \rightarrow {}^5D_0$ excitation spectra of nanocrystalline Eu_2O_3 at $\sim$12 K for different particle sizes. Reprinted with permission from [312], B. M. Tissue, *Chem. Mater.* 10, 2837 (1998). © 1998, American Chemical Society.

The total conductivity (σ), which can be represented by the following equation as a sum of the Equations (9) and (10), is a function of the partial pressure P_{O_2} as well as temperature T:

$$\sigma = \frac{A_0}{T} \exp\left(-\frac{E_a}{kT}\right) P_{O_2}^{-x} + 2e[V_O^{\cdot\cdot}]\mu_{V_O^{\cdot\cdot}} \tag{11}$$

From the variation of the conductivity ($\log \sigma$) with partial pressure of oxygen ($\log P_{O_2}$), it is possible to distinguish between the two distinct regions of the conductivity—extrinsic and intrinsic—as indicated by the slopes (x). For the extrinsic region, where the ionic defects predominate, the electroneutrality condition gets modified to $2[V_O^{\cdot\cdot}] = [A'_M]$. Consequently, the partial pressure dependence has a value of 1/4 (slope x). In the intrinsic region, the electroneutrality condition is $2[V_O^{\cdot\cdot}] = n$, as the electronic charge carrier concentration (n) predominates $[A'_M]$. The value of x for the intrinsic region corresponds to 1/6. The activation energy associated with the conductivity can be estimated from a plot of $\ln \sigma T$ vs $1/T$. The activation energies for extrinsic and intrinsic conductivity can be related to the enthalpy of defect formation (ΔH) by the expressions

$$\text{Extrinsic conduction: } E_a = \frac{\Delta H}{2} + E_h \tag{12}$$

and

$$\text{Intrinsic conduction: } E_a = \frac{\Delta H}{3} + E_h \tag{13}$$

where E_h is the hopping energy [326].

Recently, the defect model for oxygen-deficient oxides has been employed to explain the observed conductivity behavior of nanocrystalline $CeO_{2-\delta}$ [327]. The study focused on the conductivity measurements of a series of thin film samples having grain sizes in the nanometer range (20 to 150 nm). It has been inferred from the conductivity measurements on $CeO_{2-\delta}$ samples that the films with the largest grains (150 nm) exhibited predominantly extrinsic behavior at very low partial pressures $<10^{-10}$, such that conductivity increases with decreasing partial pressure showing a 1/4 power dependence. The conductivity (σ) was independent of P_{O_2} at partial pressures in the range $\sim 10^{-8}$–10^0 at the lowest measurement temperature of 600 °C. The pressure-independent conductivity behavior for larger grains of n-type nonstoichiometric oxide such as ceria may be due to the presence of the acceptor-type impurities that can pin the oxygen vacancy concentration [328]. For the samples with 65 nm grain size, the 1/6 power dependence became apparent at higher measurement temperature, or in other words the onset of intrinsic conductivity was evident at 900 °C, with the conductivity no longer independent of P_{O_2}. Further reduction in grain size led to predominantly intrinsic conduction in the sample at relatively lower temperatures and higher partial pressures with the 20 nm sample exhibiting only intrinsic conduction in the higher partial pressure range (10^{-5}–10^0). In the case of finer nanoparticles, the energy required for the oxygen defect formation would be considerably less when compared to fully grown larger grains because of the larger number of interfaces as well as lack of pinning along grain boundaries; therefore the conductivity

registers an increase with decreasing particle size (Fig. 20). The conductivity measurements by impedance spectroscopy have been found to be useful to separate the contributions from the bulk and the interface as well as to propose a possible mechanism for conductivity in finer nanoparticles. For instance, the impedance measurements on finer oxide nanocrystals (≤ 20 nm) such as CeO_{2-x} [327, 328], ZrO_2 [329, 330], and ZnO [331] provided evidence for the reduction in grain boundary impedance with decreasing particle size, which may be attributed to reduced pinning as well as increase in vacancy concentration at the interfaces for finer nanoparticles having larger interfacial area [328–331].

4.4. Ferroelectric and Dielectric Characteristics

In recent years, studies on ferroelectric and related ceramics have been major fields of research because of the potential applications of thin films of these materials in the fabrication of memory devices [332]. The particle size effects on ferroelectricity are analogous to magnetic characteristics. Corresponding to the magnetization in the presence of a magnetic field, ferroelectricity involves alignment of dipole moments (polarization) in the presence of an electric field. Comparison also arises from the assumption that both phenomena are governed by the mechanism of formation of domains and domain wall motion [333]. However, for particle sizes much less than the critical domain size, there is scarcity of experimental data that can provide evidence for a superparaelectric state analogous to superparamagnetic state, which will be discussed in a subsequent section on magnetic nanoparticles. The particle size effect on the ferroelectric phase transition in these materials has been well documented in the literature [334–342].

As a classical example of a displacive ferroelectric with excellent dielectric, pyroelectric, and piezoelectric properties, $PbTiO_3$ has been characterized for the size effects on its phase transition [336–341]. The size effects have been found to be predominant below 100 nm in these ferroelectric oxides. The phase transition studies on nanocrystalline $PbTiO_3$ with crystallite sizes in the range of 20–80 nm showed that the nanocrystals exhibited a reduction
Figure 20. Electrical conductivity (σ) as a function of the grain size (d) for nanocrystalline CeO_2 thin films at 1000 K. Data from Ref. [327].

in tetragonal distortion according to an exponential function $\sim 1\text{-}e^{-d}$, ultimately transforming to a cubic phase for smaller particles (critical size ~ 7 nm at room temperature) [339]. The transition was in accordance with the internal stress model predicted by Buessem et al. [343]. The model assumes that when particles of dimensions close to single domains are cooled to T_c, each grain experiences a complex system of internal stresses that are developed depending on the orientation of the surrounding grains. In order to relieve these stresses, the crystal transforms from a spontaneously polarized distorted tetragonal phase (ferroelectric) to a less-polarized cubic phase (paraelectric). The consequences of this transformation being the gradual reduction in permittivity, a shift in T_c values to lower temperatures ($\sim 20\,^\circ$C lower) and a diffused phase transition, which almost disappears eventually for particle sizes in the range 26 nm (Fig. 21) [339]. The dielectric constant in the vicinity of the ferroelectric phase transition T_c can be expressed by a semiempirical relation [344, 345]

$$\frac{1}{\varepsilon} - \frac{1}{\varepsilon_{\max}} = \frac{1}{A}(T - T_c)^\gamma \qquad (14)$$

where ε is the dielectric constant, $\varepsilon_{\max}$ is the maximum dielectric constant value at the transition temperature T_c, A is a constant, and γ is the order of phase transition within the range $1 < \gamma < 2$. When γ equals 1, the phase transition is Curie–Weiss type, and when γ approaches 2, the phase transition can be regarded as diffused type. The γ value is ~ 1 for 80 nm $PbTiO_3$ crystals and increases to 1.5 for 30 nm crystals [339].

The critical dimension for the phase transformation of $PbTiO_3$ nanocrystals from ferroelectric to paraelectric phase at room temperature can be estimated by extrapolating the experimentally determined c/a ratio and crystallite size d from the X-ray diffraction data of the nanocrystalline samples. The least-squares fitted expression for the c/a ratio versus average crystallite size d can be written as

$$y = y_\infty - C \exp[C(d_{crit} - x)] \qquad (15)$$

where $x \equiv d_{\mathrm{XRD}}$, $y \equiv c/a$, $y_\infty = 1.065$, and $C \equiv y_\infty - 1$. The critical crystallite size corresponds to the c/a ratio being unity. The estimated value of the critical crystal dimension was around 7 nm for nanocrystalline $PbTiO_3$ [339]. The phase transformation in $PbTiO_3$ is probably similar to the
crystallization of a more symmetric phase for nanocrystals in a certain model of binary oxide systems such as Al_2O_3 and Fe_2O_3 [346]. The driving force for such crystallization may be attributed to the tendency to minimize the surface Gibbs energy associated with high surface area. The molecular dynamic simulation of relative enthalpies of alumina polymorphs predicted the possibility of a more symmetric γ-alumina phase being stabilized compared to the α-phase [347].

The characteristics of the ferroelectric phase transition, such as lowering of the dielectric constant peak, the diffused maximum, and the shift in T_c values have been observed to register a reverse trend when the nanocrystalline ferroelectric materials have charged ion-vacancy dipoles. These dipoles contribute to the space charge effect along grain boundaries; thereby the total polarization in the material is increased. Moreover, the defect formation is energetically more favorable in finer particles due to the large surface-to-volume ratio in the material. For instance, a reverse trend in ε–T curves has been reported for ferroelectric phase transitions in nanocrystalline $Bi_4Ti_3O_{12}$ [348] and $Bi_2VO_{5.5}$ [349]. The crystal structure of $Bi_4Ti_3O_{12}$ comprises layers of ionic conducting $[Bi_2O_2]^{2+}$ layers stacked between insulating pervoskite-like $(Bi_2Ti_3O_{10})^{2-}$ layers [350]. Jiang et al. [348] explained the ε–T curves for $Bi_4Ti_3O_{12}$ samples of crystallite sizes in the nanometer range (19 to 56 nm) by taking into consideration the formation of defect dipoles, which orient in the applied electric field and contribute to the total polarization. The contribution to the dielectric constant from the defect dipoles decreased when the crystallite size was increased as a result of annealing out of the defects. The observed enhancement in the dielectric constant for $Bi_2VO_{5.5}$ ceramics on crystallite size reduction has been attributed to the increase in oxygen vacancy concentration [349].

4.5. Magnetic Properties

In the present era of advanced technology, magnetic materials have a significant role in the development of various devices. Ferromagnets have been identified as potential materials for the development of information storage devices [351], magnetic refrigeration [352], and ferrofluids [353, 354]. The enormous potential of magnetic fluids has been currently expanded to biological processes. For instance, the magnetic fluid based on maghemite (γ-Fe_2O_3) has been proved to be a biocompatible material for the purpose of transporting antibodies through human tissue [355].

The observed magnetic properties of oxide nanoparticles depend on the particle size or large surface area-to-volume ratio. The correlation between the nanostructure and the magnetic properties has been investigated for the model oxide γ-Fe_2O_3 nanoparticles [275, 356–359]. In analyzing these results, one can conclude that the chosen preparative route also governs the nanostructure and the resultant magnetic properties. Pelecky and Rieke [360] have classified different types of magnetic nanostructures according to a schematic diagram shown in Figure 22. The illustration provides insight into the possible interparticle interactions and the extent to which it affects the magnetic properties.

Figure 21. Dielectric constant as a function of temperature for different average grain sizes of the nanocrystalline $PbTiO_3$ [339].
Figure 22. Schematic representation of the different types of magnetic nanostructures [360]. Type A—noninteracting nanoparticles, Type B—nanoparticles with core-shell morphology, Type C—nanocomposite, and Type D—nanocrystals (ordered regions represented by hollow spheres or black spheres) dispersed in a disordered solid matrix (black colored circles). Reprinted with permission from [360], D. L. L. Pelecky and R. D. Rieke, *Chem. Mater.* 8, 1770 (1996). © 1996, American Chemical Society.

The classification ranges from type A material of noninteracting particles to type D with dominant interparticle interactions. An example of type A material is a ferrofluid in which the particle surfaces have been modified by surfactant molecules, thereby minimizing the interaction through steric hindrance between the particles [361–363]. Type D material comprises a three-dimensional solid built of nanoparticles dispersed in a disordered solid matrix, wherein the interparticle or intergranular interactions predominantly contribute to the total magnetization. When the atoms that consitute the nanoparticles and the corresponding solid matrix are the same, we may describe the Type D system as fully grown grains separated by disordered interfaces as shown schematically in the second possibility for Type D [22]. The intermediate nanostructure of type B depicts the ultrafine particles with core shell morphology (e.g., a shell of oxide layer formed over a magnetic core, Co/CoO [364]), and type C refers to nanocomposite materials (e.g., γ-Fe$_2$O$_3$ nanoparticles dispersed in SiO$_2$ matrix in which the magnetic interactions are determined by volume fraction of the magnetic nanoparticles [358, 365]).

The magnetic characterization of a material includes tracing of a hysteresis loop (M–H curve, where M is the

magnetization and H is the applied field) to obtain typical values of saturation magnetization (M_s), remanent magnetization (M_r), and coercive field (H_c). Ideally, the hysteresis loop for a material should have a near square shape with high value of remanent magnetization (M_r), and moderate coercivity [360]. Magnetization in a material has been found to be dependent on various types of anisotropies arising out of the crystal system, particle morphology, stress, external field, and exchange interaction [366]. A large magnetic particle can be considered as made up of several magnetic domains or multidomains. Within each domain, spins have the same orientation and are associated with a critical dimension and energy depending on the material. The applied magnetic field provides the necessary activation energy for the spins in multidomains to align and reach a state of saturation magnetization. When the field is applied in the opposite direction, domain wall motion reverses the magnetization. However, as the particle size decreases and reaches a value close to the critical single domain dimension, D_c, the multidomain formation becomes energetically unfavorable. The underlying domain wall mechanism involving the reversal of the magnetic moments in bulk particles no longer holds true for single domain particles. The reversal of the magnetic moments in the single domain particles takes place through a coherent rotation of spins, which require higher coercive fields. For particles smaller than the critical domain dimension, the spins are increasingly affected by thermal fluctuations, coercivity decreases, and the system becomes superparamagnetic [360]. Magnetic behavior as a function of particle size is schematically represented in Figure 23. The shaded region refers to the decrease in coercivity as the particle sizes decrease below D_c. The surface modified noninteracting nanoparticles with sizes less than D_c have superparamagnetic properties [273, 274, 361, 363].

From the magnetization measurements, it is possible to draw an important conclusion regarding the distribution of particle size, provided that the form of the distribution is known [367]. The magnetization in a system of noninteracting magnetic particles as in the case of a surface modified
Figure 23. Schematic variation of the coercivity (H_c) as a function of the domain size in ultrafine magnetic nanoparticle systems. Reprinted with permission from [360], D. L. L. Pelecky and R. D. Rieke, *Chem. Mater.* 8, 1770 (1996). © 1996, American Chemical Society.

ferrofluid can be represented by Langevin function

$$L\left(\frac{\mu H}{k_B T}\right) = \coth\left(\frac{\mu H}{k_B T}\right) - \frac{k_B T}{\mu H} \qquad (16)$$

where $\mu = M_s V$ is the magnetic moment of a single particle and H is the external field. In a real system, the field dependence of the magnetization is the integral of the Langevin function over the size distribution. A lognormal distribution, which was suggested by O'Grady and Bradbury [368], has been proved to be adequate to describe the magnetization in a noninteracting nanoparticle assembly [274]. The width and mean particle size can also be estimated from the distribution. The expressions for calculating the particle diameter (D_{mag}) and standard deviation (σ) can be written as

$$D_{mag} = \left[\frac{18kT}{\pi m_s}\sqrt{\frac{\chi_i}{3M_s}\frac{1}{H_0}}\right]^{1/3}; \quad \sigma = 1/3\left[\ln\left(\frac{3\chi_i}{M_s}\bigg/\frac{1}{H_0}\right)\right]^{1/2}$$
(17)

where M_s and m_s are the saturation magnetization of the nanoparticles and the bulk phase, respectively. χ_i is the initial susceptibility calculated at low fields, in the region where the variation of M against H is linear. The factor $1/H_0$ is obtained by extrapolating M to 0 at high fields, in the region where the relationship between M and $1/H$ is a straight line [275]. Exact superposition of M–H curves at different temperatures implies a very narrow particle size distribution in the sample [360].

Moumen and Pileni [274] estimated the average particle size of the cobalt ferrite ($CoFe_2O_4$) superparamagnetic sample (2–5 nm) using the Langevin function assuming a lognormal size distribution based on the magnetization measurements for dry nanoparticles and particles dispersed in a fluid. The calculated average particle size for dry powder was greater than the value obtained by TEM or XRD. The differences in the particle diameters obtained for the dry powder and the ferrofluid implied that the magnetization curves of the two samples were different. In the dry powder, the interparticle interactions are no longer weak compared to ferrofluid where the weight fraction of the particles in the fluid is very low. Moreover, the bulky surfactants on the particles provided steric hindrances; therefore the interactions between the particles were minimized. The interparticle interactions in dry powder would have perturbed the Langevin function and caused an increase in apparent magnetic diameter of the particle. The authors also reported the magnetic property measurements on samples heated at 200 °C, 400 °C, and 600 °C for 30 min. The thermally processed samples had larger particle size. The adsorbed surfactant molecules decomposed with increasing annealing temperature, resulting in higher values of reduced remanence (M_r/M_s) and the coercivity (H_c) for $CoFe_2O_4$ nanoparticles. Moreover, the samples annealed at higher temperatures showed improvement in coercivity due to better crystallinity and the release of surfactant to the particle interface.

The intrinsic cationic vacancy disorder in γ-Fe_2O_3 has been found to influence the orientation of magnetic moments through a phenomenon termed as canting effect [369] that affects the resultant magnetic properties. The

effect is more pronounced for particle diameters less than 20 nm [370]. Below 20 nm, the surface contribution to the total magnetization also becomes significant. Morales et al. [275] studied the size effect and structural ordering on the magnetic properties of γ-Fe_2O_3 nanoparticles less than 20 nm prepared through a coprecipitation technique and laser ablation. The saturation magnetization (M_s) for γ-Fe_2O_3 nanoparticles decreased with decreasing particle size as shown in Figure 24 as two distinct regimes—one for particle sizes greater than 5 nm and the steeper region for particle sizes less than 5 nm. The observed reduction in the saturation magnetization has been explained based on the spin canting effect and the vacancy disorder. The change in the slope of the M_s versus particle size plot signaled a possible order-disorder transformation of cationic sites in γ-Fe_2O_3 nanoparticles of sizes below 5 nm. Compared to the earlier reports on the particle size limit for the cationic order-disorder transformation in γ-Fe_2O_3 [370], the study by Morales et al. [275] set a lower size limit for order-disorder transformation. As the size limit also depends on the method of preparation, samples prepared through different routes would have different degree of order-disorder in the lattice. This would apparently explain the reason for difference in magnetization (M_s) values for similar sized particles that are prepared by different synthesis routes. The high value of coercivity (H_c) measured for γ-Fe_2O_3 nanoparticles particles less than 5 nm at low temperature (5 K) was attributed to the pinning of core magnetic moments through direct exchange interaction with frozen spin-glass surface layer. The order-disorder transformation for γ-Fe_2O_3 nanoparticles of average diameter 5 nm when placed in a magnetic field can be explained using a schematic diagram (Fig. 25) [275]. The spinel-like γ-Fe_2O_3 lattice has cationic vacancies that may be ordered in a tetragonal superstructure, partially ordered in a cubic superstructure, or completely disordered resulting in vacancy aggregation. The completely disordered state gives rise to spin canting effect in γ-Fe_2O_3 nanoparticles as schematically shown in Figure 25. The shaded outer layer represents the

surface layer. The studies on magnetic oxide nanoparticles indicate that magnetic properties are strongly dependent on parameters such as the preparative conditions, particle size, surface area, and degree of vacancy disorder.

4.6. Catalytic Properties

The research on catalysis and related materials has become very relevant at present as an effective means of disposing the increasing amounts of pollutants from industry and automobiles. Catalytic convertors are already being used in automobiles to reduce the levels of carbon monoxide emission. Of the two types of catalytic processes, heterogeneous and homogeneous, heterogeneous catalysis has been widely used in industries. The heterogeneous catalysis can be further divided into two categories—structure-insensitive and structure-sensitive catalysis [371]. As the term indicates, in structure-insensitive catalysis, the process does not depend on the individual microstructure such as the crystallite size and the crystal structure of the catalytic material, but only on the composition, the number of active catalytic sites available, and the electronic structure of the active species involved in the process. The structure-sensitive catalytic process is affected by the microstructure of the catalytic material such as its crystallite size, crystal structure, and interatomic spacing [372].

Utilizing high surface area nanoparticles having a large number of active sites is one way to boost the reaction rate in the two types of heterogeneous processes mentioned above. The role of nanoparticles is more pronounced in the structure-sensitive catalytic process where small crystallite size affects the overall rate of the reaction. Various methods for the preparation of oxide-supported-nanostructured metal catalysts have been established. The process involves dispersing metal clusters on oxide by ion-exchange or impregnation [373–378]. Relatively recently, the processing and catalytic applications of nanostructured nonmetallic systems have been developed [379]. In order to produce high surface area oxide nanoparticles for catalytic applications,

suitable synthesis techniques can be chosen. Table 2 summarizes different oxide materials used for catalytic applications, their preparative routes, and catalytic activities.

Nanocrystalline catalysts have high surface-to-volume ratio and exhibit size quantization effect for very small grain sizes (<5 nm). Because of these unique features, catalytic activities of nanocrystals are different from the bulk. The large fraction of unsatisfied valences at the surfaces, interfaces, and grain boundaries of nanocrystals provide active catalytic centers, thereby influencing the rate of formation and the nature of the intermediate species. The study of the catalytic activity of nanocrystals would be complete only if extensive surface characterization is carried out to understand the reaction mechanism leading to the formation of final product. For instance, by coupling scanning tunneling electron microscopy (STEM) and energy dispersive X-ray analysis (EDX), precise compositional mapping of the surface for doped polycrystalline TiO$_2$ has been reported [386]. Another efficient procedure for composition analysis would be to combine STEM and electron energy loss spectroscopy (EELS), which could provide insight into the atomic and the electronic structure of the surfaces. The morphological examination of the surface is carried out by the atomic force microscopy (AFM) [371]. Besides providing the surface morphology of the nanocrystalline compact, the formation of pores can also be clearly observed from the AFM picture.

Enhanced catalytic activity has been demonstrated recently in catalytic combustion of methane using barium hexa aluminate (BaO · 6Al$_2$O$_3$, BHA) nanoparticles [192]. The difference in catalytic activities of sol–gel-derived conventional BHA, reverse microemulsion-derived BHA nanoparticles, and reverse-microemulsion-derived CeO$_2$-BHA nanocomposite is depicted as curves c, b, and a, respectively, in Figure 26. The reactant stream consisted of 1 vol% CH$_4$ in air at a space velocity of 60,000 h^{-1}. Combustion (light-off) was initiated at temperature as low as 590 °C for nanocrystalline BHA (curve b) compared to 710 °C (curve c) required for conventional BHA. For the CeO$_2$-BHA nanocomposite particles, the combustion was initiated at a very low temperature of 400 °C (curve a).

Another interesting development in catalysis is the exploitation of the typical surface chemical properties of the metal oxide nanoparticles to reduce the polluting effects of toxic gases. Besides being ionic with good thermal stability, the edges and corners of fine-grained metal oxides may exhibit acid/base properties [387, 388], which enable the oxides to react chemically with a wide range of toxic materials, thereby reducing the pollution. A well-known example of a Lewis type acid-base reaction is the adsorption of CO onto the surface of a metal-oxide catalyst by metal-carbonyl bonding. The bonding results from the donation of a pair of electrons from carbon to the empty orbitals of metals. This particular type of binding has been found to be prevalent at low temperature in the oxidation of CO by SO$_2$ in the presence of nanocrystalline CeO$_2$ [389].

Nanocrystalline metal oxides with intrinsic oxygen deficiency are potential materials in catalysis [389]. Examples of these types of oxides are substoichiometric titanium oxide (TiO$_{2-x}$) [390], tungsten oxide (WO$_{3-x}$) [391], and cerium oxide (CeO$_{2-x}$) [382, 385, 389]. Particularly, CeO$_{2-x}$ is of interest because of its ability to oxidize CO and CH$_4$

Table 2. Different types of nanostructured oxide catalysts, their preparative routes, and catalytic activities.

Oxide catalyst	Preparative route	Catalytic activity	Ref.
Zirconia (ZrO_2)-Silica (SiO_2) composite aerogel	Sol–gel	Isomerization of 1-butene	[380]
Titanium dioxide, TiO_2	Sol–gel	Photocatalysis	[381]
Cerium oxide, CeO_{2-x}	Gas phase deposition	Selective reduction of SO_2 by CO at a low temperature of 460 °C	[382, 385, 389]
Vanadium phosphorous oxide (γ-$VOPO_4$)	Flame processing	Selective oxidation of C_4 carbons to maleic anhydride	[383]
α-alumina (Al_2O_3)	High energy milling of γ-Al_2O_3	Inert catalyst support for partial oxidation and high temperature combustion applications	[384]
Mesoporous transition metal oxides (TiO_2, ZrO_2, V_2O_5, Nb_2O_5, MoO_3, Ni/Co oxides)	Modified sol–gel route	Photocatalytic decomposition of organic compounds (TiO_2), solid acid isomerization, and alkylation (sulfated ZrO_2), partial oxidation (V_2O_5, MoO_3), and hydro-desulfurization (Ni/Co oxide)	[371]
Barium hexa aluminate ($BaO \cdot 6Al_2O_3$, BHA)	Microemulsion route	Catalytic oxidation of methane	[192]
Nanocrystalline CaO, ZnO, Al_2O_3, MgO	Sol–gel or aerogel synthesis	Enhanced catalytic activity towards H_2S	[392, 393]

[389]. Studies on the ceria-based catalysts by Tschope et al. [389], involved a detailed characterization and comparison of microcrystalline and nanocrystalline ceria, nonstoichiometric ceria, and ceria-supported metal catalysts. The nanoparticles of ceria prepared by inert gas condensation were nonstoichiometric. The nonstoichiometric ceria, CeO_{2-x}, catalyzes the oxidation of CO in the presence of O_2 at a lower temperature (200 °C; curve c in Fig. 27) compared to the oxidation of CO by SO_2 in the presence of stoichiometric nanocrystalline CeO_2 (560 °C curve a in Fig. 27). For comparison, the simple oxidation CO by O_2 is presented as curve b in Figure 27 (360 °C). The intermediate species involved in the oxidation of CO in the presence of stoichiometric nanocrystalline CeO_2 has been characterized using Fourier transform infra-red spectroscopy (FTIR) at various stages [389]. The study showed that the mechanism involved the chemical adsorption of CO to the metal followed by the formation of bidentate carbonate with low-coordinated terminating oxygen. The metal-carbonyl bonds were stable only at low temperature, whereas the carbonates were stable up to 500 °C. On the other hand, the electrons associated with charged oxygen vacancies in the nonstoichiometric ceria lattice, CeO_{2-x}, might have enhanced the chemisorption of oxygen, thereby promoting the oxidation of CO at a much lower temperature [389].

Klabunde et al. [75], Carnes and Klabunde [392], Richards et al. [393], and Khaleel et al. [394] have reported excellent catalytic properties for the high surface area nanocrystalline oxides such as CaO, ZnO, Al_2O_3, and MgO. These oxides are also associated with high surface chemical reactivity. A recent study from the same group sequenced a series of nanocrystalline oxides based on their reactivity towards H_2S [299]. They found that at selected elevated temperatures, the order of the reactivity of the oxides towards H_2S was CaO > ZnO > Al_2O_3 > MgO. At lower temperatures, the reactivity sequence was ZnO > CaO > Al_2O_3 $\approx$ MgO. As the reaction enthalpy is the most important factor that decides the course of the reaction with H_2S, an optimum temperature should be selected to achieve a favorable reaction rate. The Al_2O_3 and MgO have thermodynamically less favorable enthalpies of reaction with H_2S in this series.

Figure 26. Comparison of catalytic activities of sol–gel-derived conventional BHA (curve c), reverse microemulsion-derived BHA (curve b) nanoparticles, and reverse-microemulsion-derived CeO_2-BHA nanocomposite (curve a) [192]. Figure 27. Comparison of catalytic oxidation of CO a) by SO_2 in the presence of nanocrystalline stoichiometric ceria, b) by O_2, c) by O_2 in presence of nonstoichiometric ceria [389].

Therefore, heating to a moderately elevated temperature would have increased the reaction rate for Al_2O_3 and MgO, whereas the reaction rate reached optimum value at lower temperature for CaO and ZnO. The reaction temperature should be selected in such way as to compensate for the unfavorable enthalpy as well as to avoid sintering, which will lower the surface area for the consolidated sample at elevated temperature [392].

4.7. Thermal Conductivity

Another topic of great industrial interest is the thermal transport properties exhibited by oxide nanoparticles. As a part of miniaturization in devices, particularly in the microelectronics industry, a comprehensive knowledge of thermal transport at reduced dimension is essential to minimize possible device failures due to localized heating. Heat transfer through solids depends on the microstructure such as particle size, porosity, and type of material. For instance, heat-transfer fluids that consist of metal-oxide or metal nanoparticles dispersed in water or ethylene glycol have improved thermal conductivity [395, 396], whereas nanocrystalline zirconia coatings with grain sizes on the order of 40 nm or less have reduced thermal conductivity [397]. According to the kinetic theory of heat transfer, the thermal conductivity, k, of a material is directly proportional to the heat capacity C_p, the sound velocity v, and the phonon mean free path l [398]. The heat capacity measurements indicate that there is only a slight increase (up to 15%) in the C_p of the nanocrystalline materials compared to their coarse-grained counterparts [399, 400]. However, further studies on the heat capacities of different types of nanocrystalline solids are required in order to derive a final conclusive picture of their grain size dependence. Heat conduction is indirectly related to sound velocity (v) through the Young's modulus, which has insignificant dependence on grain size, but depends on the processing-induced porosity [401]. The thermal conductivity (k) value, however, may have a stronger dependence on the phonon mean free path (l). For instance, in defect-free crystals such as diamond, the l value is significantly reduced by about three orders of magnitude from a few mm for single crystals to a few μm for polycrystals having micrometer-sized grains [402]. In defective crystals such as yttria-stabilized zirconia (YSZ), the reduction in mean free path is less pronounced compared to the defect-free crystals because of the relatively small separation between the oxygen vacancies in single crystals and polycrystals [403]. Small mean free path implies a lower thermal conductivity, which can be exploited for thermal barrier applications [404, 405]. In other words, the interfaces in oxide nanoparticles scatter phonons and resist heat flow, which ultimately results in a temperature discontinuity between the grains in the presence of a temperature gradient (Kapitza resistance) [406, 407]. There have been efforts to understand the thermal transport across interfaces in polycrystalline and nanocrystalline materials [408–411]. Assuming that the grain boundaries are associated with identical thermal resistance, Yang et al. [411] formulated expressions for determining the Kapitza resistance in nanocrystalline YSZ sample. The heat

flux (q) through a polycrystalline sample in a temperature gradient (dT/dx) can be represented by

$$q = -k\left(\frac{dT}{dx}\right) \tag{18}$$

where k refers to thermal conductivity. For grains of width d, dT/dx is equivalent to T^*/d where T^* is the temperature across a single grain consituting two distinct temperature regions, namely, T_0 as the grain interior temperature and T_{gb} as the average temperature discontinuity at each grain boundary. The temperature T^* across a single grain can be written as

$$T^* = T_0 + T_{gb} \tag{19}$$

By considering the above assumptions, the expression for effective thermal conductivity (k) of a polycrystalline material becomes

$$k = \frac{-qd}{T_0 + T_{gb}} \tag{20}$$

where $T_0 = \frac{-qd}{k_0}$ and $T_{gb} = -qR_k$ where k_0 is the bulk or single crystal thermal conductivity and R_k is the Kapitza resisitance. Substituting the various parameters in Equation (20), the equation for the thermal conductivity can be expressed as

$$k = \frac{k_0}{1 + \frac{k_0 R_k}{d}} \tag{21}$$

The Kapitza resistance (R_k) of the 10 nm-sized YSZ has been found to be relatively low ($R_k = 4.5 \times 10^{-10}$ m$^2 \cdot$ K/W) when compared to identical grain-sized $Si_{0.8}Ge_{0.2}$ samples ($R_k = 1 \times 10^{-8}$ m$^2 \cdot$ K/W) [411]. The grain-size dependence of thermal conductivity for nanocrystalline YSZ samples indicates that thermal conductivity gradually increases with increasing grain size (Fig. 28). The rate of increase is rapid for crystallites below 40 nm. For grain sizes above 40 nm, the thermal conductivity registers a lesser rate of increase. The rapid rise in conductivity for small nanocrystals (<40 nm)
Figure 28. Thermal conductivity of nanocrystalline yttria-stabilized zirconia (YSZ) as a function of grain size at 480 K. Data taken from [411].

may be attributed to the high rate of reduction in the number of grain boundary interfaces when subjected to thermal processing. The important challenge is to understand the various factors that control the thermal conductivity in oxide nanoparticles and optimize them in order to implement in device fabrication.

4.8. Mechanical Properties

Unique and fascinating mechanical properties of nanocrystalline materials, especially gas-phase deposited nanoparticles, have motivated detailed theoretical and experimental studies on characteristics such as elastic moduli, high hardness and strength, and increased ductility reaching the superplastic behavior for the nanosized grains, when compared to their coarse-grained counterparts [412].

The verification of the empirical Hall–Petch equation [413, 414] helps to draw important conclusions on the mechanical properties of nanocrystalline materials. The expression that relates the yield stress (σ_y) to the average grain size (d) and can be written as

$$\sigma_y = \sigma_0 + \frac{k}{\sqrt{d}} \qquad (22)$$

where σ_0 is a friction stress and k is a constant. As the grain size decreases to nanometer dimensions, the yield strength increases. For example, the yield strength increases by a factor of about 30, as the grain size decreases by about two orders of magnitude from 10 μm. However, this is an ideal prediction and in reality the relation is yet to be completely satisfied for a wide range of nanocrystalline metals studied. A similar inverse relation holds true for grain size dependence of hardness [415]. In the case of nanocrystalline ceramics, mechanical characterization has been reported on model oxide systems such as TiO$_2$ [72]. The Hall–Petch plot that relates the hardness (H_v) and the grain size (d) for the nanocrystalline TiO$_2$ is presented as Figure 29. Although the reduction in slope of the curves was observed for the grain sizes smaller than 200 nm, the increase in the hardness of the TiO$_2$ samples with decreasing grain size was not in accordance with Hall–Petch relation. The break in the slope of the curve at smaller grain sizes (Fig. 29) indicates a reduction in the rate of increase in hardness values with decreasing grain sizes for the low temperature crystallized TiO$_2$ samples. This abrupt rate change in the measured
Figure 29. Hall–Petch plot relating hardness (H_v) and grain size (d) for nanocrystalline TiO$_2$ [415].

hardness values can be attributed to decreased diffusion through the grain boundaries for samples crystallized at low temperature ($T \leq 400\,°C$). The observations were consistent with the studies on the nanostructured alloy TiAl [416–418]. Comparable hardness values have been reported for dense TiO$_2$ nanocrystals by Karch and Birringer [419]. The dense nanosized TiO$_2$ also had high values of fracture toughness ($\sim$14 MPa m$^{-1/2}$). The verification of the Hall–Petch relation provided insight into improving the strength and hardness of nanomaterials.

Another important mechanical property is superplasticity, which refers to the ability of materials to undergo extensive tensile deformation without necking or fracture. Though the superplastic deformation is a well-established industrial process in metals [420], in the case of brittle materials, the phenomenon needs to be explored further for large-scale industrial use. Among the oxide ceramics, polycrystalline tetragonal zirconia has been characterized for superplasticity [421]. The decisive factors for a material to exhibit superplasticity are small grain sizes (<5 μm), equiaxed grains, high energy grain boundaries, and crystallization from a heterogeneous phase [422]. These features are invariably present in nanocrystalline materials and hence in principle should exhibit superplasticity. For instance, enhanced diffusion along the grain boundaries of a nanomaterial implies the high energy associated with it as compared to coarse-grained samples [423]. This can also lead to rapid grain growth in nanomaterials at moderately elevated temperatures. However, in nanocomposite materials, the additional phase present in the sample hinders the grain growth, thereby preserving the essential small grain size feature for superplasticity [424].

The condition for superplasticity can be derived from the general expression for diffusional creep mechanism, which can be represented as

$$\dot{\varepsilon} = \frac{A D_b G b}{kT} \left(\frac{b}{d} \right)^p \left(\frac{\sigma}{G} \right)^n \qquad (23)$$

where A is a constant, G the shear modulus, b the Burger's vector, n the stress exponent, p the grain size exponent, $\dot{\varepsilon}$ the diffusional creep rate, and σ is the stress [422, 425, 426]. The condition for superplasticity is that the strain rate sensitivity m must be greater than 1/3, which can be expressed by the following equation:

$$m = \partial \ln \sigma / \partial \ln \varepsilon > 1/3 \qquad (24)$$

For materials with grain sizes less than 10 μm, the stress exponent $n \geq 2$ ($m \leq 0.5$) and the grain size exponent $p \approx 2$ [422, 425].

Superplasticity was observed in nearly nanometer-sized ($\sim$300 nm) yttria-stabilized tetragonal zirconia crystals (Y-TZP), as the crystals elongated to about 100% under applied load [421, 427]. Another well-studied example is the mechanical characterization of composite crystals of 20 wt% Al$_2$O$_3$ and Y-TZP. The value of the grain size exponent p was in the range 1.5–1.8 and the stress exponent $\sim$2 for the alumina-doped Y-TZP composite [428, 429]. The basic microstructure for superplasticity was maintained in these composite crystals by hindering the grain growth. These studies have derived the grain size and the stress exponents

using a diffusion model [Eq. (23)] for nearly nanocrystalline stabilized zirconia, and hence can be considered as fundamental experimental data to understand the superplastic behavior in fine-grained oxide ceramics.

In one of the earlier studies on model oxides such as titania (TiO_2), a low temperature deformation bending was observed at 180 °C for nanocrystals with grain sizes less than 20 nm [430]. The TiO_2 nanocrystals were also found to exhibit a brittle-to-ductile transition at room temperature. The strain rate sensitivities [m in Eq. (24)] of nanocrystalline ZnO and TiO_2, obtained by Mayo et al. [431], were found to decrease from 0.04 to 0.015 during sintering. The higher values of m in nanocrystalline oxides may imply the onset of superplasticity in these materials. But the values are much less than the ideal value of m for superplasticity, that is, 1/3. Recently, mechanical characterization has been reported for a variety of technologically important ceramics [432–441]. The studies ranged from simple oxide such as stabilized ZrO_2 [433] to complex garnets [436], 1-2-3 $YBa_2Cu_3O_{7-x}$ superconductor [437], and composites [441]. However, the grain sizes of the oxide ceramics in these studies were on the order of 0.5 μm or above. A recent study discusses the superplasticity behavior for the ZrO_2-reinforced

Al_2O_3 nanocomposite with finer grains of the constituent phases (∼100–400 nm) [442]. From the technology point of view, it is important to obtain sufficient data on plasticity and ductility of nanocrystalline ceramic oxides for various industrial uses. Superplasticity finds use in net shape forming processes, extrusion or rolling, whereas ductile nature of a ceramic can be exploited to develop various composite materials [23]. Table 3 summarizes preparative routes, particle sizes, size-dependent properties, and potential areas of application of important oxide nanoparticles, which we have identified as representative classes of oxides having unique properties with tremendous application potential in various fields.

5. APPLICATIONS

5.1. Electronics

The present revolutionary changes in dimensions of functional nanoscale and microscale devices are summarized in a schematic diagram in Figure 30 [443]. The dimensions of nanoscale devices range between 0.1 nm to 50 nm. However, 0.1 nm represents only the possible lowest size limit and

Table 3. Summary of some model oxide nanoparticles noted for their unique size-dependent properties.

Oxide	Preparative route	Particle/Crystallite size (nm)	Size-dependent properties	Potential areas of application	Ref.
CuO	Electrochemical route	4, 6, 25	Electronic band structure	Catalysis	[279]
ZnO	Sol–gel	3.5 ± 1.5	Optical absorption-emission	Optical display devices	[300]
SiO_2	Thermal oxidation of Si nanoparticles prepared through microwave plasma-gas phase synthesis	∼8 nm core with 1–1.5 nm oxide layer	Optical absorption-emission	Microelectronic and optoelectronic devices	[304]
Eu_2O_3	Laser ablation	4, 6, 12, 18	Optical absorption-emission	Optical display devices	[312]
Eu:Y_2O_3	Sol–gel	Range: 10–20	Optical absorption-emission	Optical display devices	[255]
$CeO_{2-\delta}$	Sol–gel	10, 20, 30, 150	Electrical conductivity	Gas sensors, fuel cells, and ionic membranes	[327]
$PbTiO_3$	Coprecipitation	31, 39, 59, 81	Dielectric constant and phase transition	Nonvolatile memory devices	[339]
γ-Fe_2O_3	Coprecipitation and laser pyrolysis	Range: 3–14	Magnetization, superparamagnetism at a critical size of ∼5 nm	Information storage devices, medical imaging	[275]
$CoFe_2O_4$	Microemulsion	Range: 2–5	Comparison of magnetic susceptibility of as prepared ferrofluids and samples annealed at different temperatures	Magnetic memory, ferrofluids, medical diagnosis, bioprocessing	[274]
$Ni_{0.48}Zn_{0.48}Fe_{2.04}O_4$	Colloidal precipitation	Range: 10–30	Magnetic permeability	Low loss soft ferrites in memory devices	[22]
$BaO \cdot 6Al_2O_3$	Microemulsion	30	Enhanced catalytic activity	Catalytic combustion of hydrocarbons	[192]
CeO_{2-x}	Inert gas condensation	—	Catalytic conversion of CO to CO_2 at lower temperatures	Catalytic convertors	[389]
$(Y_2O_3)ZrO_2$	Metal-organic chemical vapor deposition	Range: 10–100	Thermal conductivity	Thermal barrier coating	[411]
TiO_2	—	Range: ∼14–400	Hall–Petch behavior	Net shape forming processes, extrusion, rolling, fabrication of ductile composites	[415]
Figure 30. Schematic classification of functional devices on a nanometer scale [443].

requires addressing of several issues related to the device fabrication based on particles of such small dimensions. For example, complexities associated with the electrical measurements on quantum dots have been a major area of research [444]. Among various nanodevices, nanoparticle-based single electron tunneling (SET) devices are of interest to electronics. The SET devices have been developed based on the concept of controlling the charge transfer through the Coulomb gap by applying a suitable potential across a nanoparticle, which when connected in circuit can be described as an island surrounded by high potential walls [445]. The island can be considered as electrically neutral initially with a specified number of electrons present as in any other material. In order to add an electron to the island, the electrostatic repulsive forces between the electrons present in the island and incoming electrons have to be overcome with sufficient electric field potential. The electric field E is inversely proportional to the island size, implying that charging of nanoscale islands takes place under strong electric field. The charging phenomenon is more adequately explained based on the charging energy E_c, which is given by the expression

$$E_c = e^2/2C \tag{25}$$

where e is the electronic charge and C is the capacitance of the island [446]. As the island sizes approach De Broglie wavelength, discretization or size quantization of the energy levels set in [447, 448]. The electron addition energy (E_a) under such conditions can be expressed as a sum of charging energy [E_c; Eq. (25)] and quantum kinetic energy (E_k) of the added electron. The expression can be written as

$$E_a = E_c + E_k \tag{26}$$

where $E_k = 1/g(\varepsilon_F)V$ in which $g(\varepsilon_F)$ is the density of states and V is the volume of the island. For devices having nanoscale islands of dimensions $\sim$100 nm, the electron addition energy is dominated by the term E_c and is about 1 meV for temperature corresponding to 10 K. Thermal fluctuations suppress the single electron charging phenomenon when $E_a < 10k_BT$. However, for islands of sizes on the order of $\sim$10 nm, E_a is about 100 meV and single electron charging

may occur at much higher temperatures close to room temperature [445]. In most of the digital single electron devices, the E_a limit has to be even higher (a few electron volts) in order to overcome the thermal fluctuations and facilitate single electron conduction. In other words, the island size must be scaled down to $\sim$1 nm so that the two energy terms, E_k and E_c, in Eq. (26) are comparable. The successful fabrication of devices based on islands of such small dimensions (quantum dots) is of utmost importance for the purpose of operating the device at temperatures close to room temperature. However, the device fabrication processes are highly complicated and require advanced preparative routes, especially to incorporate nanoparticles in large-scale integrated circuits.

Single electron conductivity through nanoparticles results in a characteristic I–V curve, which shows step-like behavior (Coulomb staircase) [444, 449]. This step-like behavior can be attributed to the increase in the potential energy for each electron transfer, which arises out of the electrostatic repulsion between the incoming electron and the additional electron(s) already present in the nanoparticle. Another feature of the monoelectron conductivity in nanoparticle systems is the negative differential resistance (NDR), which is related to the quantized energy levels due to the zero-dimensional sizes of the particles [450]. As an important development in the exploration of the single electron conductivity phenomenon, the use of a scanning tunneling microscope (STM) for measurements on nanoparticles was experimentally demonstrated [451]. Some of the important results on single electronic conductivity through the nanoparticles are the studies on Coulomb gap in single junctions [452], Coulomb gaps and Coulomb staircases in a single metal granule [453], the correlation of nonlinear current characteristics to the particle sizes [454], and the peculiar effects of energy level quantization [455, 456]. These contributions have initiated urgent research activities for further exploitation of their use in electronic device fabrication.

The use of single charge trapping in the design of digital memory was demonstrated as early as in 1986 by Averim and Likharev [457]. The sustained efforts in subsequent years have resulted in the fabrication of a number of devices based on the principle of single electron tunneling. Some examples are sensitive high-frequency electromagnetic wave detectors and digital electronic devices [458], high sensitivity electrometers [459], and quantum dot transistors [460]. Presently, there is increasing interest in the fabrication of nanoelectronic devices aided by the simulation studies called quantum computing, which has been developed based on the laws of quantum mechanics [461]. Apart from the objective of miniaturization in electronic devices, exploitation of single electron tunneling may greatly simplify electronic circuits, as well as improve device performance. In particular, oxide nanoparticles, which are characterized by a relatively high chemical and thermal stability, can be incorporated in the fabrication of various electronic devices. Presently, fine oxide nanoparticle slurries are being used in the microelectronic industry for the chemical mechanical planarization (CMP) process [87, 462, 463]. The process enables multilevel metallization (MLM) on planar wafers. However, the sizes of the particles used for CMP are very critical and

have to be in the nanometer range, as larger particles damage the wafer surface, and the effects would be detrimental to further fabrication process [87]. The potential use of oxide nanoparticles in the development of information storage devices will be discussed in the next section. Currently, researchers are also trying to implement high dielectric constant polymer-ceramic nanocomposite materials in decoupling capacitor applications [464], which will have a promising impact on microelectronic device packaging. Further development in integrated circuit (IC)-related devices is the exploitation of ultra-low k nanoporous SiO_2 dielectric for interconnect dielectrics [465].

5.2. Information Storage Devices

The storage of voluminous information or data in a small chip is a major requirement in academica as well as in industry. This ever-increasing demand for high information storage capacity has led to the development of innovative fabrication of memory devices. In particular, nanocrystal-based memory devices have attracted great attention in recent years [466–476]. A typical nanocrystal-based flash memory device has metal-oxide semiconductor field effect transistor (MOSFET) configuration in which the conventional gate dielectric is replaced by a gate stack consisting of a thin tunneling oxide layer, a layer of semiconductor nanocrystals (crystallite size <10 nm) embedded in SiO_2, and a thicker oxide layer (Fig. 31). The storage process can be initiated by applying a positive potential to the gate. Consequently, the conduction band of the thin tunneling oxide layer is lowered. This results in the tunneling of electrons from the substrates to the nanocrystals. The Coulomb blockade effect controls the flow of electrons to the nanocrystals, thereby making single-electron charging a self-limited process. The electrons get trapped inside the nanocrystals, as the overlying thick oxide layer acts as a barrier and inhibits further tunneling. The charging potential for nanocrystals increases in steps (Coulomb staircase), which in this case is called the MOSFET threshold potential. The step-like increase in the threshold potential enables the storage of the multibit information in the device [475]. The information stored in the device can be read by measuring the saturation current corresponding to a gate potential significantly less than that required for programming. The application of a reverse potential leads to erasing of the memory as the
reverse electron flow takes place from the nanocrystals to the channel.

The thickness of the tunneling oxide layer in a nanocrystal memory device is on the order of 2 nm, which is less than the oxide layer thickness (>7 nm) in conventional electrically erasable programmable read-only memory (EEPROM). EEPROM requires programming voltages larger than 10 V, whereas nanocrystal memory works at a much lower operating voltages (3 V). Therefore, the endurance to write-erase cycles and power consumption are superior in nanocrystal memories compared to EEPROM [470]. But the retention time of the nanocrystal memories is poor compared to commercially available EEPROM (∼10 years). Barring the poor retention time, the nanocrystal memory can be considered for applications in quasi-nonvolatile memory where write-erase cycles and low power consumption are considered important [475]. King et al. [470] fabricated a quasi-nonvolatile memory cell incorporating nanocrystalline Si-rich oxide as the charge storage layer, which was deposited using a low-pressure chemical vapor deposition process (LPCVD). The refresh time and the endurance of the device were found to be improved when compared to the devices incorporating Si or Ge nanocrystals as charge storage layers [468]. The device performance was assessed by recording the write/erase time at different operating voltages (4 to 6 V). The device registered fast write/erase time approaching that of dynamic random access memory (DRAM) at a relatively low operating voltage.

On the other hand, we have witnessed outstanding growth in the fabrication of high-density information storage devices based on magnetic materials. Remarkable storage capacity has been achieved in such devices [477–480]. As the bit density increases, the issues related to the integration of the device also become complex. Among the various challenges, obtaining an acceptable signal-to-noise ratio in high-density recording media needs considerable attention. One way to achieve low noise in magnetic recording devices is to incorporate completely decoupled single domain particles or particles having dimensions comparable to that of a single magnetic domain in high-density recording bits. The spin reversal in these small particles takes place at much higher coercive fields (H_c, ∼2000–3000 Oe) through coherent rotation of magnetization [481]. The magnetic recording medium is a continuous multigrain film with no specific patterning. The decisive parameter in the fabrication of magnetic recording device is the width-to-length ratio of the rectangular shaped bit. As the bit size is scaled down, the grain size becomes comaparable to the bit length. This essentially leads to an increase in noise level, which can be imaged directly using magnetic force microscopy (MFM). The MFM image reveals the irregular transition between bits as the total bit length gets reduced to about 200 nm (longitudinal recording media) [481]. The solution for smoothing the bit edges, thereby reducing the noise level, is the incorporation of magnetic nanoparticles in the recording devices. Surface-modified single domain superparamagnetic oxide nanoparticles [273, 274, 361, 363] are potential candidates for this purpose. However, the issues related to the stability of superparamagnetic nanoparticles have to be addressed in order to implement them successfully in the fabrication of magnetic recording devices [481].

5.3. Photonics

In recent years, nanoparticles of sizes in the range 1–10 nm are being studied as potential optoelectronic materials. Their unique features, which can be attributed to electron-hole pair (exciton) quantum confinement, lead to bright luminescence or appearance of forbidden transitions [482]. The prospective areas of application of these materials include the development of solid-state lasers for color displays [483], high-density optical data reading and storage [484, 485], and infrared laser viewers and indicators [486, 487]. Among oxides, rare-earth ion-doped oxide nanocrystals have been an important class of materials because of their interesting luminescence properties, which can be exploited in various multicolor phosphor applications [488, 489]. The luminescence properties are dependent on the electronic structure and the concentration of the dopant ion when confined in a host matrix. The emission characteristics become enhanced when the matrix crystallites are on the order of a few nanometers, so that the rare earth ions are quantum confined in crystals of sizes comparable to the exciton diameter (<10 nm). Under these confined states, the luminescence efficiency is enhanced due to the hybridization of various electronic states of the rare earth ion in a nanoparticle environment [490].

Fluorescence intermittency has been observed in II-VI CdSe semiconductor quantum dots on a variable time scale [491]. Recently, Barnes et al. [488] have demonstrated spectacular "on-off" blinking characteristics on a variable time scale in Eu^{3+} ion doped Y_2O_3 nanocrystals (5–15 nm) on continuous illumination of the sample with an Ar ion laser. From the varying intensities of the diffraction limited spots as a function of time, the "on-off" profiles in the luminescence of the doped nanocrystals were sketched. The duty factor ("on" time as a percentage of total measurement time) was found to vary significantly from particle to particle. The intensity-versus-time spectra indicated an inverse relation between the two variables, that is, some nanoparticles exhibited a very short "on" time with high intensity, whereas for some other lower intensity has been recorded for longer "on" time. The possible reasons for the intermittent fluorescence were attributed to local symmetry fluctuations and resultant excited state partitioning. It is interesting to correlate the effect of local symmetry variations on the observed intermittent fluorescence. Upon schematically plotting the electric dipole transition moment against the local symmetry coordinate, one can derive various logic states that can be randomly accessed by the dopant ion in the crystal. Depending on the number of ions in a single particle, there would also be multiple bright states due to transitions between intermediate states [488]. The laser source provided the required amounts of thermal energy for dipole transitions among various intermediate states within the oxide nanocrystal. The distinct "on-off" states in fluorescent emission of the doped oxide nanocrystals can be suitably tuned for the development of relatively faster and efficient data storage devices. However, for the larger particles, the fluorescence was no longer discrete due to the overlap of emissions from various energy levels.

Silicon (Si)-based nanostructures have been the focus of research in photonics due to their potential use in the fabrication of various optical and optoelectronic devices [492].

The quantum confinement mechanism responsible for the photoluminescence in Si nanocrystals has been well documented in the literature [100, 493]. Being the luminescent centers in porous Si, studies on the photoluminescence of small clusters of Si has been of great interest [494]. Photoluminescence of small clusters of SiO_x (1 to 10 nm) prepared by laser vaporization of c-Si target has been investigated *in-situ* during processing and compared with *ex-situ* scanning electron microscopy (SEM) analysis by Geohegan et al. [495]. The study reveals the advantage of probing the luminescence of individual nanoparticles prior to their deposition onto a substrate to form a thin film. By carefully controlling the oxidation, the interfacial oxide thickness and hence the resultant properties of individual nanoparticles can be varied.

Nanostructures with three-dimensional periodicity comparable to the wavelength of visible light have great significance, as they play a major role in the development of a variety of modern day optoelectronic devices. With such materials, it is possible to have microscopic light manipulation by tuning the photonic bandgap [496, 497]. The optical band gap arises in this special class of three-dimensional photonic crystals due to periodic variations in the dielectric constant, which essentially prohibits electromagnetic wave propagation throughout a specified frequency band. Self-assembly has been developed in recent years as a cost effective and efficient method for the preparation of such three-dimensionally ordered structures. Processing of a typical self-assembled three-dimensionally ordered structure of colloidal spherical silica have been discussed and illustrated under Section 2.6 Sol–Gel (Colloidal) Processing (Fig. 8) [83]. The method can easily replace conventional lithographic techniques because of less complexity associated with the process. The three-dimensional self-assembled colloidal spherical silica (SiO_2) particles have characteristic photoluminescence and are called as opals [498]. However, the theoretical calculations showed that the opals have a pseudo-optical band gap [499]. This has further triggered the quest for finding novel materials with complete optical band gap. The result was the discovery of "inverse opals," which have a characteristic microstructure of air spheres separated by dielectric medium [500–502]. Blanco et al. [502] used inverse silica (SiO_2) opal as a template and replaced the SiO_2 spheres with Si using a CVD process to prepare a complete three-dimensional optical band gap material. The SEM pictures of the sample clearly showed the microstructure comprising air spheres surrounded by Si. The photoluminescence study of the three-dimensional inverse opal crystals indicated that the center and the width of the optical band gap were sensitive to the degree of Si filling. The study also illustrated an effective method of tuning the optical band gap of an inverse opal photonic crystal by appropriate filling.

5.4. Sensors

Detecting the presence of various types of gases so as to prevent health hazards to people in industry as well as to reduce pollution in the environment is a major modern day requirement. As traditional methods such as gas chromatography and chemical routes are tedious and time consuming, the motivation is to find an alternative technique involving

miniaturized, highly sensitive solid state "electronic noses" or sensors [503]. Semiconducting metal oxide materials have been especially attractive for this purpose because of their easy availability, relatively low cost, and simplicity. An example of such a sensor is the semiconductor oxide-based multisensor array fabricated for environmental monitoring, which is carried out by measuring the change in oxide ion conductivity due to space charge effect arising out of gas adsorption or defect formation on the surface [504]. As the critical parameters that improve the sensitivity and selectivity of the sensing devices are the contributions from surfaces and interfaces to the total conductivity, a comprehensive knowledge of atomic level diffusion along surfaces and interfaces is highly desirable. Because of the higher values of surface to bulk ratio, the gas sensors based on nanomaterials exhibit improved performance. Some of the semiconducting oxide materials that have been used for environmental and air quality monitoring are listed in Table 4.

Critical parameters such as sensitivity and selectivity can be improved by suitably doping or tuning the materials' microstructures. The gas sensitivity implies quantifying the gas concentration at the ppm level in a gaseous mixture, whereas the gas selectivity is the detection of specific gases from the mixture. The gas sensitivities of nanocrystalline semiconductor oxides have been found to increase with decreasing particle size. Improved sensitivities have been reported for oxide particle sizes in the range of 5–50 nm [514, 517–519]. For instance, the sensitivity of the H_2 gas sensor based on SnO_2 has been found to improve dramatically (~an order of magnitude increase) for particle sizes smaller than 10 nm (Fig. 32) [503]. However, the critical particle size for dramatic improvement in sensitivity depends on the sample history, such as the electronic structure, the dopant concentration, and the preparative method used.

The particle size effect on the observed improvement in sensitivity can be explained by relating the depth of the space charge formation (surface depleted layer) to the particle size. The depth of the space charge formation can be represented by Debye length, which can be related to other experimental parameters such as temperature and carrier concentration by the expression

$$L_D = \left(\varepsilon_0 KT/n_0 e^2\right)^{1/2} \tag{27}$$

where L_D is the Debye length, ε_0 is the static dielectric constant, n_0 is the total carrier concentration, e is the carrier charge, K is the Boltzmann constant, and T is the absolute temperature. When L_D is less than or close to particle

Table 4. Nanocrystalline oxide gas sensors [503].

Oxide type	Sensitive to	Ref.
SnO_2	H_2, CO, NO_2, H_2S, CH_4	[504–506]
TiO_2	H_2, C_2H_5OH, O_2	[507, 508]

radius, the oxide nanoparticles have maximum sensitivity. Under these conditions, the sensitivity (S), which can be expressed as a ratio of change in the conductivity to the total conductivity, can be related to the Debye length (L_D) by a proportionality constant ($\Delta n/n_0$) where Δn is the charge carrier concentration. The equation for sensitivity (S) corresponds to

$$S = \Delta\sigma/\sigma_0 = (\Delta n/n_0)L_D \tag{28}$$

The above expression helps to optimize various parameters that improve the sensitivity of sensors based on semiconducting oxide nanoparticles [503]. Another parameter, selectivity, of the gas sensor shows marked improvement with enhanced gas adsorption on nanoparticles with larger surface to volume ratio or chemically modified particles [506, 520]. A recent study illustrates the successful synthesis of various nanostructured semiconducting oxides (ZnO, SnO_2, In_2O_3, CdO, and Ga_2O_3) in a belt-like morphology [521]. The unique features of these oxide nanobelts, such as well-defined geometry and perfect crystallinity, could be exploited for the development of novel gas sensors.

5.5. Catalysts and Fuel Cells

We have discussed some of the frontier areas where oxide nanoparticles have been identified as potential materials for future developments. Now we will briefly scan other possible areas wherein these versatile materials can be used. Table 5 presents a summary of emerging applications of oxide nanoparticles in different fields. The second and third columns list the energy, catalysis, structural, and biological applications of nanoparticles [522, 523].

Oxide nanoparticles having very high surface area are attractive in catalytic applications. Recent advances in sol–gel and aerogel preparative routes have enabled the preparation of high surface area powders, which when consolidated form a porous structure [524]. The consolidated porous nanostructures have enormous potential in catalytic applications. Moreover, the surface chemical properties of consolidated nanocrystalline powders can be exploited to adsorb toxic chemicals [388]. Recently, inorganic mesoporous oxides with well-controlled pore sizes in the range

1 to 10 nm have been developed [525]. The applications of these oxides include catalysis, filtration, and separation. The role of nanostructured metal oxides in catalyzing various chemical reactions has already been summarized in Table 2. Many of these reactions have the potential for commercial production or have already been employed in various industrial processes.

Apart from potential use in catalytic applications, mesoporous transition metal oxides are also suitable for use in electrochemical applications as anode materials [526], as they improve cell performance by increasing storage capacities, lifetimes, and charge/discharge rates. The use of nanoporous or mesoporous materials in the development of fuel cells results in superior characteristics such as high storage capacity, higher rates of charge and discharge, and good control over absorption and charge transfer process. For example, materials with high storage capacity for H_2 (or CH_4) in small volume are of particular interest to the fuel cell industry for developing cost effective, efficient, environmentally friendly fuel cell-powered vehicles or fuel cell power generation units [527–529]. The porous nanostructured materials can also be used in the effective removal of H_2S, H_2O, CO, and/or CO_2 from natural gas wells; therefore the oil transfer process from the well to the end-user takes place efficiently.

5.6. Structural and Biological Applications

Rapid advancements in nanoscience have led to the discovery of various forms of nanostructured materials having unique features, which could probably revolutionize diverse fields ranging from electronics to biology. A recent overview examines the future potential applications of a variety of exciting nanomaterials including nanotubes, nanobundles, nanoparticles, and supramolecular nanostructures [530]. Oxide nanoparticles embedded in a polymer matrix form a nanocomposite structure, which is of interest in a variety of industrial applications such as microelectronic packaging [464]. Composite materials can also be very effective candidates in lightweight replacement for conventional metals in automobiles in order to improve fuel efficiency and stability against corrosive environments. However, successful dispersion of nanoparticles in polymer matrix and moulding them to desired shapes require advanced processing routes. The range of application of nanocomposites is not only restricted to automobiles but also to manufacturing various components for the building and construction industry, and various home appliances [523].

The beginning of the new century has witnessed groundbreaking preparations by nations to counter unconventional warfare against humanity. One of the major threats is the biological weapon, which becomes operative when small amounts of deadly disease-causing microorganisms are easily spread among living beings. It is interesting to note that the ultrafine powders can play a rescuer's role in such situations. For example, airborne heat-resistant anthrax bacteria are killed at room temperature by the airborne formulation of MgO nanoparticles and other reactive components. The entire colony forming units (CFU) of the deadly bacteria are detoxified within 5–20 minutes when bombarded with the nanoparticle formulations. Similarly, several nanoparticle formulations are found to be effective in the treatment against *E. coli* bacteria [523, 531].

Another prospective field for the application of nanoparticles is the pharmaceutical industry, where nanoparticles act as vehicles for drug delivery. The hydrophobicity of pharmaceutical drugs often prevents their assimilation in the body. Suitable nanoparticle formulations allow the drugs to be assimilated in the body by acting as an effective medium for the transportation [523]. Mesoporous silica (SiO_2) coatings are being investigated as potential materials for medical applications [532].

6. SUMMARY

In this chapter, we have reviewed various processing routes, characterization, properties, and potential areas of applications of oxide nanoparticles. Significant progress has been made in the development of processing routes for oxide nanoparticles. These routes range from the simplest possible solution techniques to sophisticated laser ablation processes. Over the years, each processing route has been modified to prepare oxide nanoparticles with desired properties. In particular, plasma-assisted processing, sonication, hydrothermal, and sol–gel (colloidal) processing have been regularly used for the synthesis of a wide variety of oxide nanoparticles. Being one of the earliest well-established methods, sol–gel (colloidal) processing has been proven to be very effective for the synthesis of oxide nanoparticles and their self-assembly, which is currently being pursued as one of the frontier areas in the processing of nanostructured materials. Another major achievement in processing is the successful synthesis of surface-modified single-domain superparamagnetic nanoparticles.

As nanoparticle dimensions are progressively scaled down, highly accurate spectroscopic measurements are often required for obtaining crucial information about the structure of oxide nanoparticles. Frequently used spectroscopic characterization techniques have been reviewed based on the developments in oxide nanoparticle characterization. X-ray diffraction (XRD) continues to be the most common technique for the determination of grain size, strain, and phase characterization of oxide nanoparticles. However, for very small particles of dimensions less than 5 nm, probing the local structure using extended X-ray absorption fine structure (EXAFS) spectroscopy is preferred. While techniques such as X-ray photoelectron spectroscopy (XPS) and secondary ion mass spectra (SIMS) probe the surface structure and composition, the optical absorption-emission spectra reflect the band gap expansion due to quantum confinement in oxide nanoparticles. As for the characterization of the vibrational frequencies of various atoms in oxide nanoparticles, Raman and IR spectroscopies have been used. More specialized technique such as Mössbauer spectroscopy correlates the local order and magnetic properties of nanoferrites.

The unique properties of nanoparticles have always been subjects of interest since their discovery. We have reviewed the varied and interesting properties of oxide nanoparticles (electronic, optical, electrical, ferroelectric and dielectric, magnetic, catalytic, thermal, and mechanical) based on selected recent studies from the literature. The objectives of these studies were to understand the changes in properties as a function of particle size. An important conclusion from the extensive review of the properties of the oxide nanoparticles is that there exists a critical size regime below which the properties are truly unique. The review indicates that the critical size regimes for various characteristics need further investigation. Hence, the major future challenge would be to obtain concrete experimental evidence to prove theoretical predictions in those critical size regimes and delineate the transition in properties, which would help to unravel the intricate processing-nanostructure-property relationship in oxide nanoparticles. Research in this direction will also be helpful in selecting the critical size and dimension for the purpose of implementing oxide nanoparticles in various devices.

Potential areas of application of oxide nanoparticles have been identified with a major focus in areas such as electronics, information storage devices, photonics, and sensors. The applications in other areas such as catalysis and biology have significant relevance at present. We have briefly scanned the catalytic, structural, and biological applications of oxide nanoparticles. As nanoparticle research spreads its wings at a rapid pace, a complete review on this subject is an arduous task. However, we have made a modest attempt to analyze significant developments in the oxide nanoparticle research and their possible applications in various industries.

GLOSSARY

Agglomeration The term refers to the formation of agglomerates (secondary particles) when primary particles are held together by weak surface forces (soft agglomerates) such as van der Waals forces or capillary forces or by strong chemical bonds (hard agglomerates) during the synthesis of ceramic powders.

Domains Under favorable energetics, certain regions termed domains are formed in materials within which a given property is identical with respect to magnitude and direction. For example, the formation of domains, wherein each domain has identical electric or magnetic dipole moments aligned in a particular direction, in ferroelectric or ferromagnetic samples.

Grains Individual crystals, which combine to form a polycrystalline structure. The sizes of the grains in a material can be estimated from the broadening of the peaks in X-ray diffraction (XRD) patterns.

Microstructure A term used to describe details such as the grain size, structure of interfaces, various defects, and pores present in a synthesized material.

Nanomaterials A broad class of materials that includes nanometer-sized crystallites, nanometer-sized powders, macroscopic objects, and films composed of nanometer-sized particles or any phases combined with a spatial distribution that involves nanometer length scale of less than 100 nm in at least one dimension.

Nanoparticles The term refers to particles of sizes in the range of 1–100 nm. Depending on the preparative conditions, nanoparticles may have polycrystalline or single crystalline structure. Nanoparticles of sizes less than 5 nm are termed as quantum dots.

Nanoscale devices Nanostructure-based devices that exhibit unique characteristics such as multistate switching phenomena, resonant tunneling, quantum interference, and single electron effects due to quantum size effect.

Nanostructure Typical structure of a material with nanometer-sized microstructure.

Quantum size effect The size effects on the properties of nanoparticles, as the charge carriers in nanoparticles are quantum confined for particle sizes comparable to the wavelengths of the de Broglie electrons or phonons, or the mean-free-paths or diameters of the excitons.

Self-assembly Spontaneous stepwise assembly of molecules or nanoparticles onto a substrate.
