1. INTRODUCTION

There is a plethora of reasons why the simple capsule containing pure active drug is not an acceptable delivery system for a drug at any stage of its life (Fig. 1). Conventional formulations are usually thought of as oral (tablets and capsules), topical (ointments, creams, etc.), and injections. It is often desirable for a drug to be delivered at a steady, uniform rate; zero order is ideal. This implies that the concentration of the drug in blood or tissue is independent of the concentration of the drug at the site of absorption. None of the conventional formulations meet these demands. Controlled drug delivery occurs when a polymer, whether natural or synthetic, is judiciously combined with a drug or other active agent in such a way that the active agent is released from the material in a predesigned manner. The release of the active agent may be constant over a long period, it might be cyclic over a long period, or it may also be triggered by the environment or other external events. Over the past few decades, there has been considerable interest in developing biodegradable nanoparticles as potential candidates for controlled drug delivery. Various polymers [1] have been used in drug delivery research as they are expected to be capable of delivering drugs to target site and thus increase the therapeutic benefit, while minimizing side effects [2].

Nanoparticles were first developed by Speiser and co-workers [3] around 1970 and are defined as solid colloidal particles, less then 1 μm in size, that consist of macromolecular compounds. Since then, a considerable amount of work on nanoparticles is being carried out around the world in the field of drug/gene delivery (Fig. 2). They were initially devised as carriers for vaccines and anticancer drugs [4]. The use of nanoparticles for ophthalmic and oral delivery was also investigated [5]. Drugs or other biologically active molecules are dissolved, entrapped, or encapsulated in the nanoparticles or are chemically attached to the polymers or adsorbed to their surface. The selection of the appropriate method for preparing drug-loaded nanoparticles depends on the physicochemical properties of the polymer and the drug. On the other hand, the procedure and the formulation conditions will determine the inner structure of these polymeric colloidal systems. Two types of systems with different inner structures are possible: (i) a matrix-type system composed of an entanglement of oligomer or polymer units, defined here as a nanoparticle or nanosphere; (ii) a reservoir-type system, consisting of an oily core surrounded by a polymer wall, defined here as a nanocapsule. Various colloidal nanoparticulate systems in use for drug/gene delivery are as shown in Figure 3. The term nanoparticle shall be used to refer to both systems including nanoparticles as well as nanocapsules. In this chapter we discuss preparation techniques, characterization, and some reported nanoparticulate delivery systems and their applications.

2. FEATURES OF POLYMERIC PARTICLES

2.1. Small Size and Volume

It is practically impossible to fabricate a polymeric particle less than 5 nm in size, considering the fact that polymer molecules usually have a molecular weight higher than 10,000 Da. Particles composed of 1000 units of polymers with molecular weight 10,000 Da would be 30 nm in size.

Volume 9: Pages (1–19)

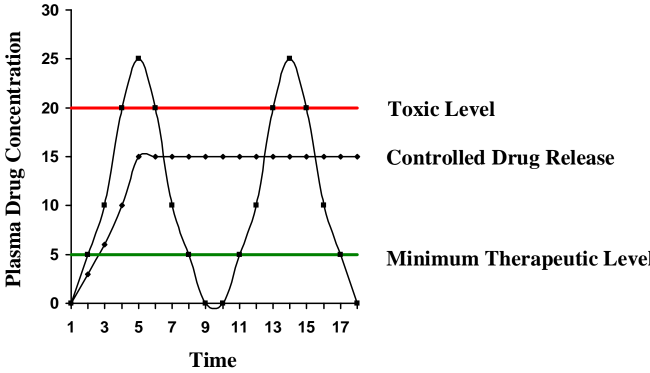

Figure 1. Comparison of typical pharmacokinetic profiles seen for conventional vs controlled release formulations. (*Source:* Science Finder, reports included until July 2002)

Their small volume enables the whole body of particles to respond quickly to stimuli. The relaxation time of volume change of a gel was indicated to be proportional to the square of its radius [6]. Therefore, fine particles can be a microreactor with a high reaction rate.

2.2. Large Specific Surface Area

The large surface area of the particles would be available for sites of absorption and desorption, chemical reactions, light scattering, etc. The total surface area of 1 g of particles having a diameter of 0.1 μm would be about 60 m^2. The total surface area is inversely proportional to the diameter.

2.3. High Diffusibility and Mobility

Polymer colloids have a low viscosity and high fluidity compared to solutions containing the same amount of solid. The viscosity of polymer colloids is a universal function of apparent volume fraction of the particles. The apparent volume fraction of particles can be changed by environmental conditions such as pH and temperature for some polymer colloids [7]. In dispersion the particles can move macroscopically through the medium by gravity, electric field, etc. and microscopically via Brownian motion. These movements keep a fresh interface between the particles and the medium. Particles having soft layers on the surface allow water to penetrate the layer and meet less resistance when they move through water. Such particles occasionally exhibit a fairly high electrophoretic mobility even if they have little charge [8]. This explains the extraordinarily high electrophoretic mobility of cells and other biocolloids.

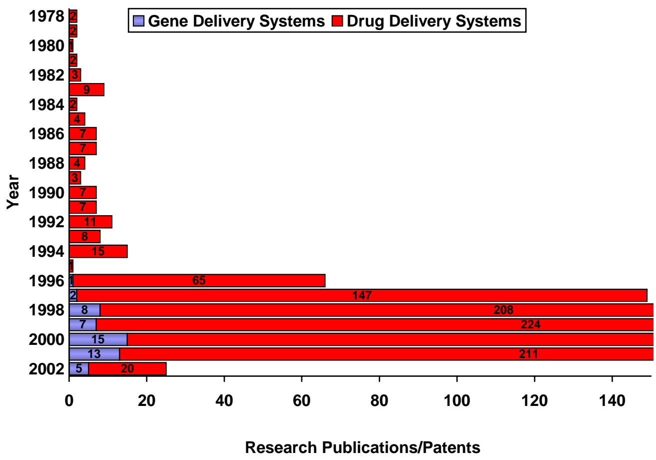

Figure 2. Updates on nanoparticle research (*Source:* Science Finder).

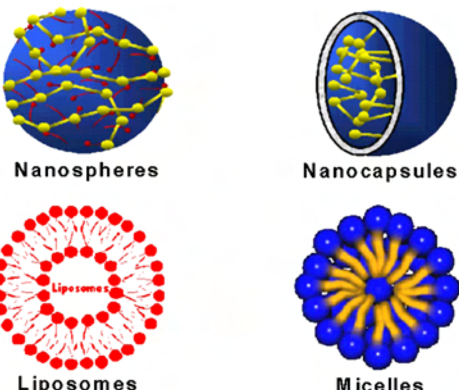

Figure 3. Various colloidal particles in use for numerous pharmaceutical applications.

2.4. Stable Dispersions

The potential energy and stability of the polymer particles in the dispersion are decided collectively by the three factors, viz., electrostatic repulsive forces, van der Waals attractive forces, and steric repulsive forces among the particles. If the particle has a potential energy larger than 15 kT, it has a high stability ratio W and is stable enough to be stored for a relatively long period, say, more than one month [9]. The stability ratio $[W]$ is expressed as $W = K_q/K_s$, where K_q and K_s are the rate constants for rapid and slow flocculation, respectively.

The surface potential energy is affected significantly by environmental factors such as ionic strength and pH. The minimum concentration of a salt to flocculate the particles is termed flocculation concentration [10]. Steric repulsive interactions are a crucial force for microspheres covered with polymer layers protruding in solution. The steric stabilization effect consists of both an enthalpy and an entropy effect. The overlap of the surface layers of two vicinal particles results in a shift from the equilibrium state of the layer (i.e., enthalpy gain) and a decrease in the conformational freedom of solvated polymer chains (i.e., entropy loss) [11]. If the polymer layers on the particles are sensitive to temperature, the stability of the dispersion due to the steric stabilization effect is influenced by temperature. The critical temperature for flocculation, in such systems, is called the critical flocculation temperature. Dissolved, but nanoadsorbable, polymer molecules cause the coagulation of particles. This phenomenon is referred to as the depression effect [12, 13]. This effect may work in many practical uses of polymer colloids, although it has not been considered extensively. The high stabilities of polymer colloids may bring about some difficulties in the separation of particles from the dispersion medium. Centrifugation sometimes fails

for dispersions of very fine particles because the sedimentation rate is proportional to the square of the diameter. Coagulation with salt is one of the most conventional methods to separate particles from water. Magnetic or electric fields are sometimes applied for collecting particles from dispersion.

2.5. Uniformity

Techniques for the preparation of monodisperse polymer colloids received greater attention during 1980s [14, 15]. The use of monodisperse particles makes it possible to give sharp, reliable, and reproducible results for their respective applications. Emphasis should be on their uniformity and size; the chemistry and morphology of the particles also deserve attention. Technologies to satisfy these conditions have been developed with an understanding of the principles for particle nucleation and growth in particle-forming polymerizations.

2.6. Variety

Polymer particles can be prepared by physical methods, such as emulsification, coacervation, and spray-drying, and by chemical methods like heterogeneous polymerization. These preparative methods give a variety of particles in terms of size, surface chemistry, composition, surface texture, and morphology.

3. PREPARATION AND CHARACTERIZATION OF NANOPARTICLES

3.1. Cross-Linking of Amphiphilic Macromolecules

Nanoparticles have been prepared from polysaccharides, proteins, and amphiphilic macromolecules by inducing their aggregation followed by stabilization by either heat denaturation or chemical cross-linking. It can be done by a water-in-oil emulsion system or in aqueous environment. The cross-linking technique was first used by Kramer et al. in 1974 [16]. In this technique, an aqueous solution of protein was emulsified in oil using a high-speed homogenizer/sonicator and the water-in-oil emulsion was then poured in a hot oil having a temperature greater than 100 °C and held for a specific time (to denature the protein), thereby leading to the formation of submicroscopic particles. These particles were finally washed with organic solvents and subsequently collected by centrifugation. The crucial factors in nanoparticle production were emulsification energy and stabilization temperature; however, the limitation of high stabilization temperature was overcome by adding a chemical cross-linking agent (e.g., glutaraldehyde) to the system. To achieve the variable size of the nanosphere, several formulations were adopted and optimized. Protein and polysaccharide nanoparticles can be obtained by a phase separation process in aqueous medium. This can be induced by desolvation of the macromolecule, by change in pH or temperature, or by adding counterions in acid medium [17].

3.2. Polymerization of Acrylic Monomers

Couvreur et al. [18, 19] carried out extensive investigations on nanoparticles and nanospheres composed of polyalkylcyanoacrylate (PACA) polymers, which are bioresorbable and were used as surgical glues for several years. PACA nanoparticles have been prepared by an emulsion polymerization method in which droplets of water-insoluble monomers are emulsified in aqueous/acidic phase containing a stabilizer. The monomers polymerize relatively faster by an anionic mechanism, the rate of polymerization being pH dependent. The system is maintained under magnetic agitation while the polymerization reaction takes place. The duration of polymerization reaction is determined by the length of the alkyl chain varying from 2 to 12 h for ethyl and hexylcyanoacrylate, respectively. Finally, the colloidal suspension is neutralized and lyophilized following incorporation of glucose as a cryoprotectant. Water-soluble drug may be associated with PACA nanosphere either by dissolving the drug in the aqueous polymerization medium or by incubating blank nanospheres in an aqueous solution of the drug. The drug loading efficiency is dependent on various factors, including the pK_a and polarity of the drug, size and surface charge of the nanospheres, and the drug concentration in aqueous medium [18].

In another method of encapsulation of lipophilic drugs into PACA polymers, the monomers and the drug have been dissolved in a mixture of a polar solvent (acetone or methanol), an oil (coconut oil or benzyl benzoate), and a lipophilic surfactant, such as lecithin. The organic phase is added into aqueous phase having a hydrophobic surfactant (e.g., Poloxamer 188) under magnetic agitation. Thus, diffusion of the polar solvent into aqueous phase and the polymerization of the monomer at the oil–water interface take place simultaneously. Polymerization is initiated by the hydroxyl anions and leads to the formation of nanocapsules having an oily core surrounding by a polymer coat. The organic solvent is eliminated completely from the colloidal suspension. The selection of the oil has a great role to play, as it influences the size of the nanocapsules, the molecular weight of the polymer coat, and the stability of the suspension after storage [19].

3.3. Polymer Precipitation

Solvent precipitation techniques have been generally applied for hydrophobic polymers, except for dextran nanospheres. Several techniques described in the literature are based on the mechanism of polymer precipitation.

3.3.1. Solvent Extraction–Evaporation

In this technique, hydrophobic polymer is dissolved in an organic solvent, such as chloroform, ethyl acetate, or methylene chloride, and is emulsified in an aqueous phase having a stabilizer [e.g., polyvinyl alcohol (PVA)]. Just after the formation of nanoemulsion, solvent diffuses to the external phase until saturation. The solvent molecules that reach on the water–air interphase evaporate, which leads to continuous diffusion of the solvent molecules from the inner

droplets of the emulsion to the external phase. Simultaneously, the precipitation of the polymer leads to the formation of nanospheres. The extraction of solvent from the nanodroplets to the external aqueous medium can be induced by adding an alcohol (e.g., isopropanol), thereby increasing the solubility of the organic solvent in the external phase. A purification step is required to assure the elimination of the surfactant in the preparation. This technique is most suitable for the encapsulation of lipophilic drugs, which can be dissolved in the polymer solution.

3.3.2. Solvent Displacement or Nanoprecipitation

In this method, the organic solvent selected is completely dissolved in the external aqueous phase; thus there is no need for evaporation or extraction for polymer precipitation. Polymer and drug are dissolved in acetone, ethanol, or methanol and incorporated under magnetic stirring into an aqueous solution of surfactant. The organic solvent diffuses instantaneously to the external aqueous phase followed by precipitation of the polymer and drug. After the formation of nanoparticles, solvent is eliminated and the suspension concentrated under reduced pressure. This method is surfactant-free. However, this method is limited only to the drugs that are highly soluble in a polar solvent.

3.3.3. Salting Out

A technique based on the precipitation of a hydrophobic polymer is useful for the encapsulation of either hydrophilic or hydrophobic drugs because of a variety of solvents, including polar (e.g., acetone or methanol) and nonpolar (methylene chloride or chloroform) solvents, can be chosen for dissolving the drug. This procedure is just like nanoprecipitation; however, the miscibility of both phases is prevented by the saturation of the external aqueous phase with electrolytes. Precipitation occurs when a sufficient amount of water is added to allow complete diffusion of the acetone in the aqueous phase.

3.4. Nanocapsule Preparation

We considered PACA while discussing the preparation and characterization techniques of nanoparticles for the sake of convenience. Nanocapsules of PACA are obtained via an interfacial polymerization process in emulsion. Nanocapsules are formed by mixing an organic phase with an aqueous phase. The organic phase is generally an ethanolic solution of the monomer mixed together with the oily core material and the lipophilic drug to be encapsulated and occasionally, soya bean lecithin is added as an additional surfactant. Oils, viz., Miglyol, benzylbenzoate, ethyl oleate and lipiodoal, have been frequently used in preparation of nanocapsules. The encapsulation efficiency of a lipophilic drug is dependent on its partition coefficient between the oil and the aqueous phase, so the oil must be chosen accordingly. The aqueous phase is a solution of a nonionic surfactant, usually Synperonic PE-F68 at 0.5% at a pH between 4 and 10. Nanocapsules are formed by adding the organic phase dropwise into the aqueous phase under stirring, through a wide-bore syringe needle or a micropipette tip. The mixture immediately becomes opalescent. After stirring for 15–30 minutes the ethanol is removed by evaporation under reduced pressure. If required, the nanocapsules can be further concentrated by evaporation; this allows them to be rediluted in a physiological buffer for injection. Nanocapsules formed by this way have a mean diameter between 200 and 300 nm with a narrow polydispersity [20]. The speed of the magnetic stirring has no influence on the particle size, which depends solely on the nature and the volume of the oil and on the volume of the diffusing organic phase. The proportion of the monomer must be correctly chosen to avoid simultaneous formation of either flakes of polymer or of a single oily emulsion. The presence of surfactant in the aqueous phase is, in fact, not necessary for the successful formation of nanocapsules but does prevent them from aggregating on storage to a cake, which is difficult to disperse. Nanocapsules formed in this way are physically stable for several years at ambient temperature and may be sterilized by autoclaving at 120 °C for 20 min. However, as a result of their vesicular character, nanocapsules are not easily lyophilized, since they tend to collapse releasing the oily core [20].

The colloids formed by the interfacial polymerization of PACA could be influenced by many factors, viz. the nature of the aqueous phase, the pH, the composition of the organic phase (monomer, oil, ethanol), the ratio of monomer to the aqueous phase, and the emulsification conditions. The degree of polymerization, and therefore the molecular weight, depends on a balance between initiation, propagation, and termination [21]. The number of growing chains depends on the concentration of initiators. For the same quantity of monomer, when the number of live chains is high, the degree of polymerization (DP) is low. However, DP is reduced when the concentration of the terminating agents is high [22, 23]. The concentration of the initiating and the terminating agents available for the monomer depends on the physicochemical nature of the system in which the components are dispersed at the moment of the formation of the colloid.

In the case of a system composed of two immiscible phases, such as an emulsion, the presence and the concentration of the solutes in the different phases is a function of the polarity of the solute molecules and of the dielectric constant of the medium. In contrast, at an interface between an aqueous and an organic medium, there can be large local variations in properties, which can themselves cause changes in the interfacial properties in a dynamic system. Nevertheless, the degree of polymerization depends on the propagation reaction; other characteristics of the colloids, viz. particle size and morphology, depend on interfacial phenomena inducted by the dynamic mixing of an organic phase with an aqueous phase.

Since the preparation of nanocapsules of PACA is rather similar to the preparation of PACA nanospheres, it is necessary to verify that the colloidal suspension does not consist of a simple mixture of an oil-in-water emulsion containing polymeric nanospheres of similar size. Rollot et al. by their various experiments confirmed that the preparation indeed was composed of oil-filled nanocapsules [24].

3.5. Nanosuspensions

The nanosuspension technique is an alternative and promising approach for the production of drug nanoparticles, where the drugs are poorly soluble in both aqueous as well organic medium. The major advantages of this technology are its general applicability to most of the drugs and its easy fabrication/handling. The disintegration principle for obtaining nanosuspensions is the cavitation forces in high pressure homogenizers (e.g. piston-gap homogenizers like APV gaulin types). The preparation method involves the dispersion of the drug powder in an aqueous surfactant solution by high speed stirring. The obtained macrosuspension is then passed through a high pressure homogenizer applying typically 1500 bar and 3 to 10 up to a maximum of 20 passes (=homogenization cycles). The suspensions pass a very small homogenization gap in the homogenizer, typically having a width of 25 μm at 1500 bar. Due to the narrowness of the gap the streaming velocity of the suspension increases tremendously with an increase in fluid pressure. Simultaneously, the static pressure on the fluid decreases below the boiling point of water at room temperature [25, 26]. As a consequence, water starts boiling at room temperature due to the high pressure; gas bubbles are formed which implode cavitation when the fluid leaves the homogenization gap. These cavitation forces are strong enough to break the drug microparticles to drug nanoparticles [25]. The mean particle size in the nanometer range obtained by this procedure depends on the pressure and number of cycles applied; in addition it is affected by the hardness of the drug itself. Mean diameters of 330 and 600 nm are reported for paclitaxel nanosuspensions [26] and clofazemine [27] respectively. Müller and co-workers pioneered the field of nanosuspensions [28–32]. Müller [33] et al. in their recent article reviewed the preparation of nanosuspensions on a laboratory scale, and large scale, physical and chemical properties of nanosuspensions, surface modification of nanosuspensions, biological properties, and perspectives were also discussed.

3.6. Characterization

Nanoparticles as a colloidal carriers mainly depend on the particle size distribution, surface charge, and hydrophilicity. These physicochemical properties affect not only drug loading and release, but also the interaction of these particulate carriers with biological membranes.

3.6.1. Particle Size Analysis

Two main techniques have been used to determine the particle size distribution of colloidal systems: photon correlation spectroscopy (PCS) and electron microscopy including both scanning electron microscopy (SEM) and transmission electron microscopy (TEM). The quasi electron light scattering technique for Brownian moment measurement offers an accurate procedure for measuring the size distribution of nanoparticles. The PCS technique does not require any particular preparation for analysis and is excellent due to its efficiency and accuracy. However, its dependency on Brownian movement of particles in suspended medium may affect the particle size determination.

Electron microscopy provides an image of the particles to be measured. In particular, SEM is used for vacuum dried nanoparticles that are coated with a conductive carbon–gold layer for analysis and TEM is used to determine the size, shape, and inner core structure of the particles. TEM in combination with freeze–fracture procedures differentiates among nanocapsules, nanospheres, and emulsion droplets. Atomic force microscopy (AFM) is an advanced microscopic technique and its images can be obtained in aqueous medium. AFM images nowadays are powerful support for the investigation of nanoparticles in biological media.

3.6.2. Surface Charge and Hydrophobicity

The interaction of nanosphere with biological environment and electrostatic interaction with biological compounds occur due to the charge on the surface (e.g., negative charge promotes the adsorption of positively charged drug molecules such as aminoglucosides as well as enzymes and proteins). The surface charge of colloidal particles can be determined by measuring the particle velocity in an electric field. Nowadays laser light scattering techniques, in particular laser Doppler anemometry, are fast enough to measure the surface charge with high resolution. Hydrophobicity of the nanoparticles can be determined by the methods including adsorption of hydrophobic fluorescent or radiolabeled probes, two phase partitions, hydrophobic interaction chromatography, and contact angle measurements. Recently, X-ray photoelectron spectroscopy has been developed which offers the identification of chemical groups in the 5-Å-thick coat on the external surface of nanospheres. Gref et al. [34] have characterized the poly(ethylene glycol) (PEG)-coated poly(lactide-*co*-glycolide) (PLGA) nanosphere and identified the PEG chemical elements that were concentrated on the nanosphere's surface.

3.6.3. Methods of Changing Particle Size and Surface Characteristics

The fate of colloidal particles inside the body depends on three factors: particle size, particle charge, and surface hydrophobicity. Particles with a very small size (less than 100 nm), low charge, and a hydrophilic surface are not recognized by the mononuclear phagocytic system and, therefore, have a long half-life in the blood circulation. In general, nature and concentration of the surfactant play an important role in determining the particle size, as well as the surface charge (e.g., nanospheres with mean size of less than 50 nm were prepared by increasing concentration of Poloxamer 188 [35]). The approaches for modifying surface charge and hydrophilicity were initially based on the adsorption of hydrophilic surfactants, such as block copolymers of the poloxamer and poloxamine series. The *in vivo* studies of hydrophilic nanospheres limit their usefulness due to their toxicity in intravenous injection. Lately, the idea of using diblock copolymers made of poly(lactic acid) (PLA) and poly(ethylene oxide) (PEO) is widely accepted due to the safety and stability of the hydrophilic coat. For this purpose, the copolymer is dissolved in an organic solvent and then emulsified in an external aqueous phase, thereby orienting the PEO toward the aquous surrounding medium, while in

another method PLA–PEO copolymer is adsorbed onto preformed PLGA nanoparticles. It is found to be efficient in prolonging the nanosphere circulation time following intravenous administration.

3.7. Drug Incorporation and Adsorption

For a nanoparticulate system to be highly successful it should have a high drug loading capacity, which in turn reduces the quantity of carrier required for administration. Two theoretical curves can be proposed to describe the adsorption of drugs onto nanoparticles: Langmuirian-type and constant partitioning-type isotherms. In fact, it was found that nanoparticles can entrap a drug according to a Langmurian adsorption mechanism, because of their large specific area [36]. The drug can either be incorporated into nanospheres during the polymerization process or adsorbed onto the surface of preformed particles. There are reports on vidarabine, an antiviral agent, whose nucleophile N in positions 3 and 7 may play a role of initiator for the anionic polymeric mechanism of the cyanoacrylic monomer [37], which suggests drug–polymer interaction as a covalent linkage. A similar study in this direction was described with peptide compounds such as growth hormone-releasing factor (GRF) [38]. In these studies it was demonstrated that if the drug was added within 5 min of the polymerization process, 50% of the peptide was found to be covalently linked to the polymer. In contrast to these findings, the drug loading capacity was found to be very low when the peptide was added after 60 min during polymerization, but no chemical modification was observed. These findings suggest that there is a narrow window of time for the addition of GRF to the polymerization medium resulting satisfactory drug-loading capacity as well as preservation of chemical structure of the peptides [38]. Generally, the longer the alkyl chain length, the higher the affinity of the drug. Moreover, the Langmurian isotherm states that the percentage of drug adsorption generally decreases with the quantity of drug dissolved in the polymerization medium [39].

Reports were also available on the attempts made for the association of synthetic fragments of deoxy ribonucleic acid (DNA) to PACA nanospheres [39]. The association of antisense oligonucleotides with nanoparticles was achieved only in the presence of a hydrophobic cation, such as triphenylphosphonium or quaternary ammonium salts [40]. The poor yield of oligonucleotide association without cations could be explained by the hydrophilic character of nucleic acid chains that are known to be soluble in water. The adsorption efficiency of oligonucleotide–cation complexes on nanospheres was found to be highly dependent on several parameters: oligonucleotide chain length, nature of the cyanoacrylic polymer, hydrophobicity of the cations used as ion-pairing agents, and ionic concentration of the medium [39].

3.7.1. Biodegradation and Drug Release

The rate of cyano copolymer degradation is dependent on their alkyl chain length. The dominating mechanism of particle degradation was found to be surface erosion [40], resulting via the hydrolysis by the enzymes of the ester side chain of the polymer [41]. This process keeps the polymer chain intact, but it becomes more and more hydrophilic until it is water soluble. The degradation pathway is consistent with the production of alcohol during the bioerosion of PACA nanospheres *in vitro* in the presence of esterases [41]. Indeed, the action of rat liver microsomes and tritosomes on the ester hydrolysis of polyisobutylcyanoacrylate nanospheres was clearly demonstrated [41]. Since the biodegradability of polyalkycyanoacrylate depends on the nature of the alkyl chain, it is possible to choose a monomer whose polymerized form has a biodegradability corresponding to the established program for the drug release [41]. Lenaerts et al. [42] demonstrated that the drug release from nanospheres was a direct consequence of the polymers bioerosion, by using a double radiolabeled technique. Later this was confirmed using GRF, another model drug [42]. No drug release was reported in the absence of esterase with this peptide compound, whereas in the nanosphere suspension turbidity remained unchanged, indicating no polymer bioerosion. Drug release appeared to be esterase dependent. In other studies, dextran sulfate was employed as a stabilizer in the preparation of PACA nanospheres, which slowed down the release rates of drug rose Bengal [42].

4. RECENT DEVELOPMENTS IN NANOPARTICLE TECHNOLOGY

Other than the commonly used synthetic hydrophobic polymers, various other polymers like chitosan, sodium alginate, gelatin, etc. are also being explored in drug delivery [43]. A drug delivery system is most often associated with fine particulate carriers, such as emulsion, liposomes, and nanoparticles, which are designed to localize drugs in the target site. From the clinical point of view, they might have to be biodegradable and/or highly biocompatible. In addition, high drug content is desirable, because in many cases actual drug loading efficiency is often too low to secure an effective dose at the target site. Biodegradable nanoparticles have received considerable attention as potent vehicles for targeting a site and controlled release of drugs/bioactive components [43–47]. Various nanoparticlulate systems composed of different materials are constantly being explored in the areas of drug and gene delivery as shown in Table 1. We hereby discuss some nanoparticulate systems developed by various researchers.

4.1. Doxorubicin Nanoparticle Conjugates

Natural and synthetic polymers have widely been used for conjugating the drugs for improved circulating times in the bloodstream, targeting a specific organ, and sustained release at the injection site [48–50]. The polymer conjugation approach, along with formulations with polymeric micelles and liposomes, is an attractive means to selectively suppress tumor growth [51, 52]. Some of the earlier studies suggested the use of high molecular weight polymers would eventually cause problems [53, 54]. Yoo et al. [55] reported doxorubicin-poly(D, L-lactic-*co*-glycolic acid) (PLGA) conjugates (Fig. 4). Doxorubicin was chemically conjugated to a terminal end group of PLGA by an ester linkage and the doxorubicin–PLGA conjugate was later formulated into nanoparticles. They have observed a 1-month release of

Table 1. Nanoparticle types and their applications.

Nanoparticles	Application
Poly(lactide-*co*-glycolide)	drug/gene delivery
Chitosan	drug/gene delivery
Solid lipids	drug/gene delivery
Liposomes	drug/gene delivery
Block copolymers	drug/gene delivery
Poly(ethylene glycol)	drug/gene delivery

conjugated doxorubicin from the nanoparticles vs a 5 day release of unconjugated doxorubicin. *In vivo* antitumor activity assay also showed that a single injection of the nanoparticles had comparable activity to that of free doxorubicin administered by daily injection [55]. Recently, Mitra et al. [56] and Janes et al. [57] reported dextran–doxorubicin conjugates using chitosan as the nanoparticle carrier.

4.2. Lipid Coated Cisplatin Nanocapsules

Cisplatin is one of the most widely used agents in the treatment of solid tumors, but its clinical utility is limited by toxicity. The poor solubility of the cisplatin results in low

Figure 4. Synthetic route of DOX–PLGA conjugate. Reprinted with permission from [55], H.-S. Yoo et al., *J. Control. Release* 68, 419 (2000), © 2000, Elsevier Science.

encapsulation efficiency [58, 59]. Researchers have tried to use lipophilic derivatives of cisplatin to improve the encapsulation efficiency [60]. Recently, Burger et al. [61] reported a novel procedure to efficiently encapsulate native, nonderivatized cisplatin in lipid formulations. The methodology is based on simple freeze thawing of concentrated solution of cisplatin in the presence of negatively charged phospholipids [61]. The authors claim this procedure as novel with maximum encapsulation efficiency with cisplatin aggregates being covered with a single lipid bilayer. It was found that the *in vitro* cytotoxicity was raised 1000-fold with this new technology [61].

4.3. Poly(DL-lactide-*co*-glycolide) Nanoparticles

The most widely used emulsion solvent evaporation method for preparation of nanoparticles using PLGA requires surfactants to stabilize the dispersed particle [62]. This method often has a problem in that the surfactant remains at the surface of the particles and hence is difficult to remove especially where PVA is used as surfactant. Other surfactants such as span series or tween series, PEO, etc. are also used to stabilize with some disadvantages like removal of solvents, toxicity, low particle yield, consumption of more surfactant, and multisteps.

The most important factor that needs to be considered while using surfactants, is that they are nonbiodegradable and nondigestible and tend to affect humans with allergic reactions. Recently, Jeon et al. [63] proposed a surfactant-free method for preparation of PLGA nanoparticles as an alternative.

The surfactant-free PLGA nanoparticles were prepared by dialysis method using various solvents and their physiochemical properties were investigated against used solvent. Release kinetics of norfloxacin showed that a higher drug content leads to larger particle size and slow release [63].

Kwon et al., [64] reported estrogen loaded PLGA nanoparticles employing emulsification-diffusion method using PVA or didodecyl dimethylammonium bromide (DMAB) as stabilizers. They have studied the influence of process variables on the mean particle size of the nanoparticles. The particle size was less than 100 nm when DMAB was used a stabilizer [64]. Stabilizers like D-α-tocopheryl polyethylene glycol 1000 succinate (vitamin E-TPGS) were also tried by other groups [65].

Santos-Magalhaes et al. [66] reported PLGA nanocapsules/nanoemulsions for benzathine pencillin G. Nanoemulsions were produced by spontaneous emulsification and nanocapsules by interfacial deposition of preformed polymer. They have observed similar release kinetics from both formulations [66].

4.4. Poly(ethylene oxide)-poly(L-lactic acid)/poly(β-benzyl-L-aspartate)

Polymeric micelles are expected to self-assemble, when block copolymers are used for their preparation [67]. Micelles of biocompatible copolymer, viz., PEO with PLA or with poly(β-benzyl-L-aspartate) (PBLA), have been reported in the literature [68, 69]. The synthetic process of

Figure 5. (a) Poly(ethylene oxide)-*co*-b-benzyl-L-aspartate and (b) poly(ethylene oxide)-*co*-L-lactide micelles with aldehyde groups on their surface. Reprinted with permission from [67], J. Jagur-Grodzinski, *React. Funct. Polym.* 39, 99 (1999). © 1999, Elsevier Science.

such nanospheres with functional groups on their surface is shown in Figure 5.

Aldehyde groups on the surface of the PEO–PLA micelles might react with the lysine residues of a cell's proteins and may facilitate attachment of the amino-containing ligands. These hydroxyl groups on the surface of the PEO–PBLA micelles can be further derivatized and conjugated with molecules capable of targeting the modified micelles to specific sites of a living organism. Such nanospheres have been tested as vehicles for delivery of anti-inflammatory and antitumor drugs [70, 71].

4.5. Poly(lactide-*co*-glycolide)–[(propylene oxide)-poly(ethylene oxide)]

Biocompatible and biodegradable poly(lactide-*co*-glycolide) (PLG) nanoparticles (80–150 nm) have been prepared by the following nanoprecipitation technique [72]. The nanoparticles were coated with a 5–10 nm thick layer of polypropylene (PPO)-PEO block copolymer or with tetrafunctional $(PEO\text{-}PPO)_2$–*N*-CH_2-CH_2-*N*–$(PPO\text{-}PEO)_2$ [72]. Such coats are bound to the core of the nanosphere by the hydrophobic interactions of the PPO chains, while PEO chains protrude into the surrounding medium and form a steric barrier, which hinders the adsorption of certain plasma proteins onto the surface of such particles. On the other hand, the PEO coat enhances adsorption of certain other plasma compounds. As a consequence, the PEO-coated nanospheres are not recognized by macrophages as foreign bodies and are not attacked by them [73].

4.6. Polyphosphazene Derivatives

Allock and co-workers developed derivatives of the phosphazene polymers suitable for biomedical applications [74, 75]. Long-circulating in the blood, 100–120 nm in diameter, PEO-coated nanoparticles of the poly(organophospazenes) containing amino acid have been prepared. PEO–polyphosphazene copolymer, or poloxamine 908 (a tetrafunctional PEO copolymer), has been deposited on their surface [76]. Chemical formulae of such polyphosphazene derivatives are shown in Figure 6.

4.7. Poly(ethylene glycol) Coated Nanospheres

Nanospheres of PLA, PLG, or poly(ε-caprolactone) coated with PEG may be used for intravenous drug delivery. PEG and PEO denote essentially identical polymers. The only difference between the respective notations is that methoxy groups in PEO may replace the terminal hydroxyls of PEG. PEG coating of nanospheres provides protection against interaction with the blood components, which induce removal of the foreign particles from the blood. PEG

Figure 6. Structures of polyphosphazenes for medical applications. (a) Poly([(phenylethylalanine ethylester)40%(glycine ethyl ester)60%] phosphazene) PF(GL-PhAL). Reprinted with permission from [75], H. R. Allock et al., *Macromolecules* 10, 824 (1997). © 1997, American Chemical Society.

coated nanospheres may function as circulation depots of the administered drugs [34, 77]. Slow release of the drugs into plasma alters the concentration profiles leading to therapeutical benefits. PEG-coated nanospheres (200 nm), in which PEG is chemically bound to the core, have been prepared, in the presence of monomethoxy PEG, by ring opening polymerization (with stannous octoate as a catalyst) of such monomers as ε-caprolactone, lactide, and/or glycolide [77]. Ring opening polymerization of these monomers in the presence of such multifunctional hydroxy acids as citric or tartaric acid, to which several molecules of the monomethoxy monoamine of PEG (MPEG-NH_2) have been attached, yields multiblock $(PEG)_n$–$(X)_m$ copolymers. PEG–PLA copolymer in which NH_2 terminated methoxy PEG molecules have been attached to tartaric acid is shown in Figure 7. It has been demonstrated that morphology, degradation, and drug encapsulation behavior of copolymers containing PEG blocks strongly depends on their chemical composition and structure. Studies of nanoparticles composed of the diblocks of the PLG with the methoxy terminated PEG (PLG–PEG) or of the branched multiblocks PLA–$(PEG)_3$, in which three methoxy terminated PEG chains are attached through a citric acid residue, suggested that they have a corecorona structure in an aqueous medium. The polyester blocks form the solid inner core. The nanoparticles, prepared using equimolar amounts of the PLLA–PEG and PDLA–PEG stereoisomers, are shaped as discs with PEG chains sticking out from their surface.

Their hydrophobic/hydrophilic content seems to be just right for applications in cancer and gene therapies. Such nanospheres are prepared by dispersing the methylene chloride solution of the copolymer in water and allowing the solvent to evaporate [77]. By attaching biotin to its free hydroxyl groups and complexing it with avidin, cell specific delivery may be attained. Nuclear magnetic resonance studies of such systems [78] revealed that the flexibility and mobility of the thus attached PEG chains are similar to those of the unattached PEG molecules dissolved in water. Recently, PLG microspheres, with the PEG–dextran conjugates attached to their surface, have been investigated as another variant of the above-described approach. Microspheres with a diameter of 400–600 nm have been prepared [79].

4.8. Poly(isobutylcynoacrylate) Nanocapsules

Intragastric administration of insulin-loaded poly(isobutylcyanoacrylate) nanocapsules induced a reduction of the glycemia to normal level in streptozotocin diabetic rats [80] and alloxan induced diabetic dogs [81]. The hypolglycemic effect was characterized by surprising events including a lag time period of 2 days and a prolonged effect over 20 days. Insulin is a very hydrosoluble peptide and should be inactivated by the enzymes of the gastrointestinal tract. Thus, that insulin could be encapsulated with high efficiency in nanocapsules containing an oily core and why these nanocapsules showed so unexpected biological effect remained unexplained. Nanocapsules were prepared by interfacial polymerization of isobutylcyanoacrylate [82]. Any nucleophilic group including those of some of the aminoacids of insulin [83] could initiate the polymerization of such a monomer. In this case, insulin could be found covalently attached to the polymer forming the nanocapsule wall as was recently demonstrated with insulin-loaded nanospheres [84].

Aboubakar et al. [85] studied physicochemical characterization of insulin-loaded poly(isobutyl cyanoacrylate) nanocapsules obtained by interfacial polymerization. They claimed that the large amount of ethanol used in the preparation of the nanocapsules that initiated the polymerization of isobutylcyanoacrylate preserved the peptide from a reaction with monomer resulting in a high encapsulation rate of insulin. From their investigations, it appears that insulin was located inside the core of the nanocapsules and not simply adsorbed onto their surface.

Lambert et al. [86] used poly(isobutyl cyanoacrylate) nanoparticles for the delivery of oligonucleotides. Nanoparticles of size ranging from 20 to 400 nm were prepared. The authors claimed that this technology might offer interesting perspectives for DNA and peptide transport and delivery.

4.9. Folic Acid Conjugated Nanoparticles

Drug targeting has been an issue in the pharmaceutical industries of late and progress in this area of research is noteworthy. Literature suggests the use of nonionic polymers, viz. poly(ethylene glycol), for surface modification would certainly increase the circulating time of the colloidal drug carriers [87–89]. Stella et al. [90] introduced a new concept in drug targeting. The concept involved design of poly(ethylene glycol) coated biodegradable nanoparticles coupled to folic acid to target the folate-binding protein, a soluble form of the folate receptor, which is overexpressed on the surface of many tumor cells. The detailed studies

suggested that the interaction with the folate-binding protein was achieved only when folate conjugated nanoparticles were used, and no interaction resulted with the nonconjugated nanoparticles used as controls [90]. Thus the authors claimed that the folate-linked nanoparticles represent a potential new drug carrier for tumor cell-selective targeting.

4.10. Dextran Hydrogel Nanoparticles

Dextrans are polysaccharides composed of glucose units coupled into long branched chains mainly through a 1–6 and some 1–3 glucosidic linkages. Dextrans are colloidal, hydrophilic, and water-soluble substances, inert in biological systems, and do not affect cell viability. Dextrans have been explored for the delivery of various pharmaceuticals [91–93]. Kim et al. [94] reported hydrogel nanoparticles prepared from glycidyl methacrylate dextran and dimethacrylate poly(ethylene glycol). Drug release studies were performed using clonazepam as a hydrophobic model drug which was found to be dextranase and pH dependent [94].

4.11. Poly(γ-benzyl-L-glutamate)/poly(ethylene oxide)

Hydrophilic–hydrophobic diblock copolymers exhibit amphiphilic behavior and form micelles with core–shell architecture. These polymeric carriers have been used to solubilize hydrophobic drugs, increase blood circulation time, obtain favorable biodistribution, and lower interactions with reticuloendothelial systems [95]. In the same direction, Oh et al. [96] reported the preparation and characterization of polymeric nanoparticles containing adriamycin as a model drug. The nanoparticles are obtained from PBLG/PEO diblock copolymer, which forms a hydrophobic inner core and a hydrophilic outer shell of micellar structure [97, 98], by adopting a dialysis procedure. Their results indicate that only 20% of the entrapped drug was released in 24 h at 37 °C and the release was dependent on the molecular weight of the hydrophobic polymer.

4.12. Chitosan–Poly(ethylene oxide) Nanoparticles

Hydrophilic nanoparticle carriers have important potential applications for the administration of therapeutic molecules [29, 99]. Most of the recently developed hydrophobic–hydrophilic carriers require the use of organic solvents for their preparation and have a limited protein-loading capacity [100, 101]. Calvo et al. [102] reported a new approach for the preparation of nanoparticles, made solely of hydrophilic polymer, to address these limitations. The preparation technique, based on an ionic gelation process, is extremely mild and involves the mixture of two aqueous phases at room temperature.

One phase contains the polysaccharide chitosan (CS) and a diblock copolymer of ethylene oxide and polyanion sodium tripolyphosphate (TPP) (Fig. 8). It was stated that the size (200–1000 nm) and zeta potential (between +20 and +60 mV) of nanoparticles can be conventionally modulated by varying the ratio CS/PEO-PPO. Furthermore,

Figure 8. Schematic representation of chitosan nanoparticle preparation. Reprinted with permission from [102], P. Calvo et al., *J. Appl. Polym. Sci.* 63, 125 (1997). © 1997, Wiley-VCH.

using bovine serun albumin (BSA) as a model protein, it was shown that these new nanoparticles have great protein loading capacity (entrapment efficiency up to 80% of the protein) and provide a continuous release of the entrapped protein for up to 1 week [102].

4.13. Methotrexate-*o*-carboxymethylate Chitosan

Nanoparticles of methotrexate (MTX) were prepared using *o*-carboxymethylate chitosan (*o*-CMC) as wall forming materials and an isoelectric-critical technique under ambient conditions [103]. Drug controlled releases were studied in several media including simulated gastric fluid, intestinal fluid, and 1% fresh mice serum. It was found that acidic media provide a faster release rate than neutral media. The effects of MTX/*o*-CMC ratio and amount of crosslinking agents of drug release in different media were evaluated. The changes of size and effective diameter of *o*-CMC nanoparticles were detected by SEM and a laser light scattering system before and after the drug release. Authors claimed that the *o*-CMC nanoparticles constitute an attractive alternative to other anticancer drugs and enzyme carriers [103].

4.14. Solid Lipid Nanoparticles

Solid lipid nanoparticles (SLNs), one of the colloidal carrier systems, have many advantages such as good biocompatibility, low toxicity, and stability [104]. Schwarz and Mehnert [105] studied the lipophilic model drugs tetracaine and etomidate. The study highlights the maximum drug loading, entrapment efficacy, and effect of drug incorporation on SLN size, zeta potential (charge), and long-term physical stability. Drug loads of up to 10% were achieved with a

good maintenance of physically stable nanoparticle dispersion [105]. They claimed that the incorporation of drugs showed no or little effect on particle size and zeta potential compared to drug-free SLNs [105]. In another study, Kim and Kim [106] studied the effect of drug lipophilicity and surfactant on the drug loading capacity, particle size, and drug release profile. They prepared SLNs by homogenization of melted lipid dispersed in an aqueous surfactant solution. Ketoprofen, ibuprofen, and pranoprofen were used as model drugs and tween and poloxamer surfactants were tested [106]. Mean particle size of prepared SLNs ranged from 100 to 150 nm. It was found that the drug loading capacity was improved with the highly lipophilic drug and low concentration of surfactant [106]. Despite some setbacks, lipid nanoparticles continued to be of great interest in the fascinating area of drug delivery technology [107–109].

4.15. Cholic Acid and Methoxy Poly(ethylene glycol)

Cholic acid (CA) is one of the major bile acids, the main product of cholesterol metabolism, and biologically one of the most detergent-like molecules in the body. Cholic acid acts as a hydrophobic core and represents a potential drug incorporation site. Methoxy poly(ethylene glycol) (MPEG), a modified form of poly(ethylene glycol), is known to be nontoxic, nonimmunogenic, highly biocompatible, and, moreover, very well known to prevent interactions with cells and proteins due to its hydrophilic nature [110]. Kim et al. [111] took advantage of these wonderful properties of CA and MPEG for developing amphiphilic polymeric nanoparticles following their previously reported methods (Fig. 9) [112–114]. The physicochemical characteristics of the polymer conjugates were investigated [111]. Clonazepam was used as a model drug in their studies and the drug loading content was 16.2 wt%. They monitored the drug release and found pseudo-zero-order kinetics [111].

4.16. Poly-L-lysine Nanoparticles

Poly-L-lysine finds application in various biomedical areas, viz., controlled drug delivery [115] and gene delivery [116]. Many hydrophilic polymers have been linked covalently to poly-L-lysine and copolymers such as poly-L-lysine poly(ethylene glycol) block [117, 118], poly-L-lysine poly(ethylene glycol) graft [119], and poly-L-lysine hyaluronic acid graft [120] have been synthesized for biomedical applications. Reports are also available on synthesis of lipid bearing poly-L-lysines, where lipid units are attached to terminal lysine amino units [121]. Recently, Wang et al. [122] reported the covalent attachment of both hydrophilic and hydrophobic units to poly-L-lysine and further fabrication of nanoparticles. The nanoparticles were prepared by sonicating poly-L-lysine graft copolymer amphiphiles in aqueous media [122]. The influence of polymer architecture and molecular weight on the properties of the nanoparticles has also been investigated [122]. The schematic representation of the nanoparticle architecture is shown in Figure 10.

4.17. Surface Modified Silica Nanoparticles

Surface modified silica nanoparticles were synthesized by modification of commercially available silica particles (IPAST, Nissan Chemical Industries, Tokyo, Japan) with

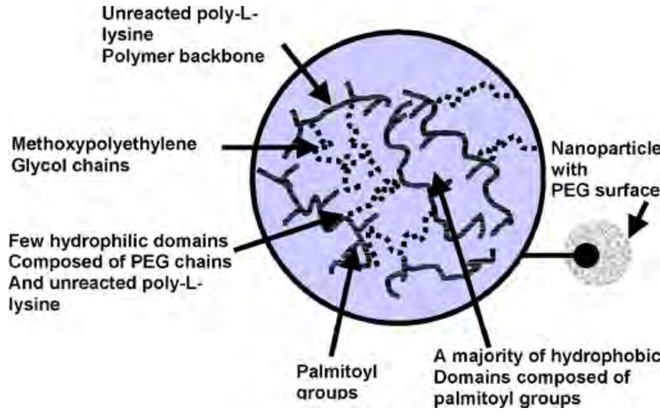

Figure 10. Schematic representation of PLP nanoparticle architecture. Reprinted with permission from [122], W. Wang et al., *Langmuir* 16, 7859 (2000). © 2000, American Chemical Society.

various aminoalkylsilanes, viz., *N*-(2-aminoethyl)-3-aminopropyltrimethoxysilane (AEAPS) and *N*-(6-aminohexyl)-aminopropyltrimethoxysilane (AHAPS). The resulting particles have a hydrodynamic diameter of 26 nm and a zeta potential up to +31 mV [123, 124]. The scheme for modification of the silica particles is shown in Figure 11.

5. NANOPARTICLES FOR SOME SPECIFIC APPLICATIONS

5.1. Gene Delivery Systems

For more than two decades, researchers have been working to alleviate disease through gene therapy. In this type of treatment a gene is delivered to cells, allowing them to produce their own therapeutic proteins. Traditionally, DNA delivery systems have been classified as viral vector mediated systems and nonviral vector mediated systems [125]. Currently, because of their highly evolved and specialized components, viral systems are by far the most effective means of DNA delivery, achieving high efficiencies (>90%) for both delivery and expression [126]. The most promising nonviral gene delivery system thus far, other than the "gene gun," is DNA vaccine applications, comprised of ionic complexes formed between DNA and polycationic liposomes [127, 128]. A major problem in the practical application of gene transfer for therapeutic purposes (gene therapy) is the efficient delivery of the genetic material to the desired place of action, the target tissue. Nanotechnology appears to be one of the potential solutions to take up this technological challenge. In nature, efficient gene delivery is achieved by viruses which have evolved over millions of years into well adapted gene delivery particles. Hence, one approach to improving the chances of successful gene therapy may be the design of fully synthetic virus equivalents with the means of nanotechnology.

The typical components of a virus include (i) the genomic nucleic acid, which is usually condensed by (ii) nucleic acid binding proteins (NBPs) to form a core which is further surrounded by (iii) a capsid formed of proteins and/or a lipid envelope. The overall particle size ranges between 20 and 200 nm. Figure 12 describes the architecture of human adenoviruses which are currently very popular for viral gene therapy trials. The nucleic acid of a virus can be RNA or DNA, single or double stranded, and linear or circular. A common and important property of the nucleic acid binding proteins is their high positive charge excess to achieve efficient binding and condensation of nucleic acids. Each histone complex, probably the best studied nucleic acid binding unit, contains 220 cationic lysine and arginine residues, has a dimension of $10 \times 18 \times 11$ nm, and can bind 146 base pairs of double stranded DNA per unit. These structural characteristics are shared by all other NBPs and were the basis for the design of synthetic equivalents.

5.1.1. Technologies for Production of DNA Nanoparticles

Two major technological approaches to the production of DNA nanocarriers can be distinguished: "conventional" nanoparticle preparation as described in Section 3 and the

(A) Hydrolysis: $R-Si(OR)_3 + nH_2O \longrightarrow R-Si(OR)_{3-n}(OH)_n + nROH$

Condensation: $\sim Si-OH + RO-Si\sim \longrightarrow \sim Si-O-Si\sim + ROH$

(B) Aminoalkylsilanes: n=1 → AEAPS; n=2 → AHAPS

(C) IPAST $\xrightarrow{H^+}$ SURFACE MODIFIED PARTICLES

Figure 11. (A) Hydrolysis and condensation of unmodified particles, (B) alkyaminoalkanes, (C) modification scheme.

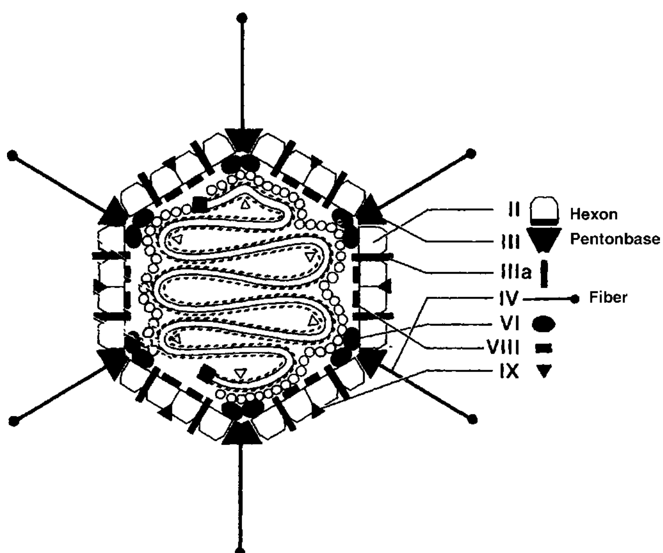

Figure 12. Structure of type 2 adenovirus according to Stewart and Burnett [189]. Adenoviruses consist of a core containing linear double stranded DNA of 40 kilo base pairs which is surrounded by a complex capsid. They do not possess a lipid envelope. The average size of adenovirus particles ranges between 70 and 110 nm. The genomic DNA is covalently capped at its ends with the terminal protein, tp ■. pVII (–), the cationic virus protein VII, forms dimers that fit into the major groove of the DNA double helix and compensate approx. 80% of the negative charge of the DNA in order to pack the genome into dense, nucleosome-like structures. Further components form the capsid surrounding the core, including pIII, the major hexon protein pII, and the fiber protein pIV. pIV und pIII mediate specific receptor mediated uptake of the virus particle by target cells.

self-assembly technique which utilizes interpolyelectrolyte interactions between the polyanionic nucleic acid and polycationic polymers or particles.

Approach 1 Some of the available technologies for production of nano- and microparticles have been adapted for the encapsulation of plasmid DNA. Complex coacervation, as described in Section 3.1, has been used successfully to incorporate the nucleic acid within a matrix of gelatin [129]. Addition of sodium sulphate as desolvating agent to a mixture of DNA and type A gelatin followed by vigorous vortexing produced precipitation of particles that were typically around 400 nm in size. This reaction is favored by slightly acidic pH, suggesting a role for electrostatic interactions, and the formed complexes can be hardened with calcium chloride (0.5 M). DNA encapsulation efficiencies reached >98% at a loading level of 25–30% (w/w). In addition, further bioactive molecules present during the precipitation step can be efficiently incorporated as demonstrated for chloroquine which enhances transfection by inhibition of intracellular inactivation of the transgenic DNA.

Other protocols for the preparation of DNA nanoparticles have used the solvent extraction–evaporation technique as described in Sections 3.3 and 4.3. Due to the low solubility of DNA in many organic solvents, a water–in oil–in water double emulsion is produced and the solvent is removed from the oily phase to form a polymer nano- or microcapsule around the hydrophilic core containing the DNA. Suitable capsule materials include biodegradable polymers like the polyanhydride PLGA. Using this material, Cohen et al. [130] reported the production of DNA nanocapsules with diameters between 400 and 700 nm that did also show significant transfection of mammalian cells *in vitro*. With optimized conditions, the efficiency of DNA encapsulation can exceed 75%. However, the homogenization steps involved cause considerable damage to the plasmid DNA and thereby greatly reduce its activity. To reduce physical stress to the DNA, stabilizing agents like poly-L-lysine [131], EDTA, or carbohydrates [132] can be added and the inner water phase may be frozen before the second homogenization step [132]. The highest reported DNA encapsulation efficiency after utilization of these measures was 90% with a preservation of >90% DNA integrity. However, the overall content of nucleic acid exceeds 1% only occasionally.

Approach 2 Most "conventional" methods for preparation of nanoparticles involve homogenization steps that irreversibly inactivate the relatively fragile nucleic acids. Self-assembly techniques offer the possibility to avoid such damage. The currently most popular self-assembly protocols employ suitable polycationic polymers. Driven by polyelectrolyte interactions, they react with DNA into small, usually toroid structures termed *polyplexes* [133]. Their size can range from 10 to approximately 200 nm and if one of the reactants is used in excess (usually the cationic polymer), the resulting suspension will be stabilized by repulsive forces between the particles. Further stabilization has been achieved by surface modification with hydrophilic polymers as described in Section 4.7. Suitable cationic polymers that have been successfully used in the past include poly-L-lysine [134], polyethylenimine [135], aminoalkylmethacrylate based (co)polymers [136], dendrimers [137], and chitosan [138].

A major limitation of the polymers is the difficulty to include additional bioactive molecules (in order to enhance or modify the DNA activity) during the self-assembly process, unless these are covalently linked to the polymer backbone. This drawback can be overcome if cationic nanoparticles are used instead of polymers. Studies on cationically modified silica nanoparticles have shown that this is, in principle, possible [139], especially for small particles with diameters between 10 and 30 nm that have dimensions similar to naturally occurring NBP like the histone complex produced biological active complexes. A representative example of such a nanoparticle–DNA complex (*nanoplex*) is depicted in Figure 13. *In vitro* gene delivery has also been achieved using nanoparticles consisting of a PLA core and a cationic surface modification with polylysine [140].

A further advantage can be provided by cationic SLNs described in Section 4.14. Nanosuspensions of these are produced by high pressure, hot homogenization of a mixture of matrix lipid, tenside, and cationic modifier. The latter mediates electrostatic binding to DNA and the proximity of multiple SLNs on the DNA macromolecule can induce particle coalescence as observed by AFM (Fig. 9). However, matrix lipid and modifier have to be selected carefully in order to avoid dissociation of the cationic modifier from the particle surface after DNA binding and to retain sufficient fluidity to allow for particle coalescence [141].

5.1.2. Outlook

Further significant improvement of the efficiency of nanoparticular and all other synthetic gene delivery vehicles will be required for their clinical success. This may be achieved by a combination of the basic core containing the

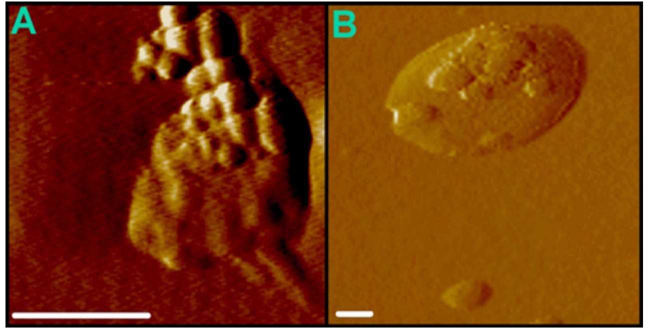

Figure 13. Nanoplexes: Complexes of plasmid DNA and cationic nanoparticles. Imaging was performed by atomic force microscopy (bar = 100 nm). nucleic acid or the nucleic acid carrier with additional functional units. The latter can include a capsid for protection and target recognition, nucleic acid modifications for intracellular delivery to the cell nucleus, and inhibitors and modulators of "undesired" cellular activities. Such components have been identified in many viruses and are known to be critical for high efficiency. Ogris et al. [142] described a synthetic prototype.

5.2. Peptide Delivery

Recently, colloidal carrier systems, especially nanoparticles, have been receiving much attention in the field of drug targeting because of their high loading capacity for drugs, particularly macromolecules, as well as their unique disposition characteristics in the body [143, 144]. It is well known that the bioavailability of peptide and protein drugs after oral administration is very low because of their instability in the gastrointestinal (GI) tract and low permeability through the intestinal mucosa [145, 146]. Therefore, injectable dosage forms are currently used to obtain therapeutic effects. Due to poor compliance of these administration routes, it is indispensable to develop alternatives such as nasal, buccal, rectal, vaginal, pulmonary, and transdermal routes [147]. Oral administration is the most convenient route for drug delivery, and several approaches such as chemical modification to alter the physicochemical properties of peptide drugs [148], the use of an absorption enhancer to promote drug absorption [149–151], and the use of a protease inhibitor to protect drugs against degradation by enzymes [150] have been investigated in order to achieve oral peptide delivery. Many pharmaceutical scientists have also reported that particulate drug delivery systems such as nanoparticles [152–154], microcapsules [153, 155], liposomes [156], and emulsions [157] are useful in improving the absorption of peptide drugs via the GI tract.

Much of the research has focused on the absorption enhancement of peptide and protein drugs and vaccine antigens. Couvreur and co-workers have been studying whether nanoparticles composed of polyalkylcyanoacrylate derivatives enhance the absorption of orally administered insulin, using animal models [158–161]. They found that insulin encapsulated in polyisobutylcyanoacrylate nanocapsules reduced glycemia by 50–60%, although free insulin did not affect glycemia when administered orally to diabetic rats. Kawashima et al. [162] reported that the absorption of elcatonin, which is a calcitonin of eel, via the GI tract of rats was enhanced by poly(-lactide-glycolide) nanoparticles coated with chitosan, which is a mucoadhesive cationic polymer. They also studied the effect of chitosan-coated liposomes on the intestinal absorption of insulin in rats and reported that the blood glucose concentration decreased significantly after oral administration of insulin-loaded liposomes [163]. Sakuma et al. also demonstrated that nanoparticles composed of novel graft copolymers having a hydrophobic backbone and hydrophilic branches can improve the absorption of salmon calcitonin in rats [164–167].

In general, absorption of a drug via the GI tract is closely related to its solubility. Many drugs with poor absorption characteristics are highly water-soluble and this high polarity causes the low permeability through the intestinal membrane which is mainly composed of hydrophobic lipids. Numerous peptide and protein drugs fall into this category [168–170]. There are two ways to incorporate a hydrophilic drug in a nanoparticle. One is to encapsulate it into the nanoparticle core and the other is to adsorb it onto the nanoparticle surface [170].

5.3. Brain Delivery

The blood–brain barrier (BBB) represents an insurmountable obstacle for a large number of drugs, including antibiotics, antineoplastic agents, and a variety of central nervous system-active drugs, especially neuropeptides. One of the possibilities to overcome this barrier could be drug delivery nanoparticulate systems to the brain. The nanoparticles may be especially helpful for the treatment of the disseminated and very aggressive brain tumors. The mechanism of the nanoparticle-mediated transport of the drugs across the blood–brain barrier at present is not fully elucidated. The most likely mechanism is endocytosis by the endothelial cells lining the brain blood capillaries [171]. The brain blood vessel endothelial cells are characterized by having tight continuous circumferential junctions between them thus abolishing any aqueous paracellular pathways between these cells [172]. Drugs may be bound in the form of a solid solution or dispersion or adsorbed to the surface or chemically attached. Alyautdin et al. claimed that the poly(butyl cyanoacrylate) nanoparticles are the only nanoparticles to date that were so far successfully used for the *in vivo* delivery of drugs to the brain [171]. This polymer has the advantage of rapid biodegradability [173, 174]. Kreuter and co-workers reported the delivery of hexapeptide dalargin (Tyr-Ala-Gly-Phe-Leu-Arg), a Leu-enkephalin analog with opioid activity, the first drug that was delivered to the brain using nanoparticles. The antinociceptive activity after intravenous injection of dalargin-loaded poly(butyl cyanoacrylate) nanoparticles of a size around 250 nm overcoated with polysorbate 80 was demonstrated by the tail-flick test [174] as well as by the hot-plate test [175, 176]. Both tests showed the same tendencies. A circadian-phase dependency of the reaction time in the hot-plate test was also observed by Ramge et al. [176] in Balb/c and DBA/2 mice. The pharmacokinetics of doxorubicin bound to nanoparticles and/or coated with polysorbate 80 after intravenous injection to rats was investigated by Gulyaev et al. [177]. Schroeder et al. [178] also showed that polysorbate 85 coated poly(butyl cyanoacrylate) nanoparticles enable a brain transport after oral administration. The pharmacokinetics of another drug, amitriptyline, normally a tricyclic antidepressant, however, is able to penetrate the BBB [179]. Results demonstrated that intravenous injection of polysorbate 80 coated nanoparticles showed an improvement in brain AUC, whereas their serum AUC was reduced [179].

In vitro experiments using brain blood vessel endothelial cells were conducted to gain insight in the quantitation and possible mechanism of the nanoparticle-mediated transport of drugs into the brain. The first *in vitro* experiments employed poly(methyl-[2-14C]-methacrylate) nanoparticles [180]. More recently, rat brain endothelial cells of the RBE4 cell line and poly(butyl cyanoacrylate) nanoparticles were used to study the nanoparticle uptake by these

cells [181]. As mentioned before, poly(butyl cyanoacrylate) particles are very rapidly biodegradable and are slightly more hydrophilic than the poly(methyl methacrylate) particles reported by Borchard et al. [180]. The poly(butyl cyanoacrylate) nanoparticles in the RBE4 cell experiments were produced using fluoresceine isothiocyanate dextran 70000 instead of the normal dextran as in most of the *in vivo* experiments reported. The toxicity of poly(butyl cyanoacrylate) nanoparticles was determined in the MTT test [182] using RBE4, bovine, and human brain microvessel endothelial cells. The highest toxicity was observed in the RBE4 cells at a nanoparticle concentration of 10 μg/ml and no decrease in viability was observed. Fenart et al. [183] used the Cecchelli model to investigate the effect of charge and lipid coating on the ability of maltodextrin 60 nm nanoparticles to cross the brain capillary endothelial cell layer of the model.

Nanoparticles represent a tool to transport essential drugs across the BBB that normally are unable to cross this barrier. Drugs that have successfully been transported into the brain using this carrier include the hexapeptide dalargin, the dipeptide kytorphin, loperamide, tubocurarine, the NMDA receptor antagonist MRZ 2/576, and doxorubicin [171]. Nanoparticle-mediated drug transport to the brain depends on the overcoating of the particles with polysorbates, especially polysorbate 80. This material seems to act as an anchor for apolipoprotein E (apo E) or other substances following injection into the blood stream. The adsorption of apo E from blood plasma onto the nanoparticle surface has been detected *in vitro* [171].

5.4. Colon Targeting

In several studies the involvement of macrophages and dendritic cells in active inflammatory bowel disease (IBD) has been indicated. An efficient manipulation of those cells might be considered as an interesting potential therapeutic pathway for IBD treatment, since it was reported that biodegradable microspheres can be sufficiently taken by macrophages and M cells [184]. Based on these results, the direct uptake of anti-inflammatory agents by macrophages, achieved with the use of microspheres, appears to have a superior immunosuppressive effect and to be more useful for the treatment of patients with IBD [185, 186]. Nanoparticles showed a size dependent accumulation in the inflamed tissue and were, therefore, thought to be even more promising in the treatment of this disease. They proved the ability to target the macrophages and ruptures (Fig. 14) inside the ulcerated tissue in IBD for a specific local drug delivery [187, 188]. This type of new strategy aims to selectively accumulate the drug delivery system at the site of action. Polymeric nanoparticulate carrier systems were expected to target the inflamed tissue in inflammatory bowel diseases. Since no sedimentation occurs with colloidal drug carriers, they might be less or not at all affected by the streaming due to their diffusing properties. With the anti-inflammatory model drug rolipram, the entire drug loaded nanoparticle formulations proved to be as efficient as the drug in solution in mitigating the experimental colitis. First, the inflammation activity score and myeloperoxidase activity decreased significantly after the oral administration of rolipram nanoparticles or solution. When animals were kept without drug treatment the drug solution group displayed a strong relapse, whereas the nanoparticle groups maintained reduced inflammation levels. Moreover, when free drug was administered, the rolipram solution group exhibited a high adverse effect index, whereas the rolipram nanoparticle groups proved their potential to retain the drug from systemic absorption as evidenced by a significantly reduced index. An essential advantage of this strategy seems to be the direct contact of the carriers with the inflammation site which allows a much higher local drug concentration. Moreover, nanoparticles were found not only to accumulate in the ulceration but also to adhere distinctly to the mucus which allows an increased specificity to nonulcerated inflamed tissue since mucus production is highly increased all over the inflamed tissue.

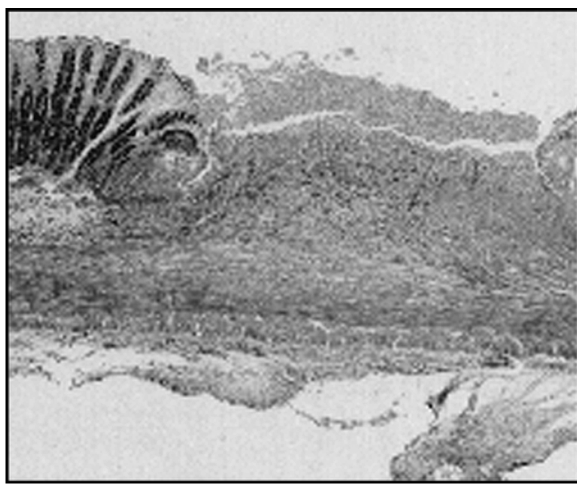

Figure 14. Histological section across inflamed colonic tissue. The ulceration exhibits distinct immune related cell extravasion while the mucus production is highly increased in intact mucosa (black areas on the left). Reprinted with permission from [187], A. Lamprecht et al., *J. Pharmacol. Exp. Ther.* 299, 775 (2001). © 2001, American Society for Pharmacology and Experimental Therapeutics.

These new delivery systems allow the desired drug to accumulate in the inflamed tissue with a relatively high efficiency including two major advantages. The drug is concentrated at its site of action, which reduces possible adverse effects and enhances the effect of the administered dose. Moreover, the sustained drug release allows pharmacological effects to be extended due to the prolonged residence time of the carrier system at the targeted inflamed area. This deposition of polymeric carrier systems in the inflamed tissues might be promising in the design of new carrier systems for the treatment of inflammatory bowel disease.

GLOSSARY

Atomic force microscopy (AFM) A technique for analyzing the surface of a rigid material all the way down to the level of the atom. AFM uses a mechanical probe to magnify surface features up to 100,000,000 times, and it produces 3D images of the surface.

Biodegradable The ability of a substance to be broken down into simpler, smaller parts by a biological process. Many plastics are not biodegradable.

Blood-brain barrier (BBB) The walls of blood vessels in the brain have a special property that prevents large molecules from moving out of the bloodstream and into the brain. This property, called the blood-brain barrier, serves to protect the brain by keeping potentially harmful substances from entering the brain.

Central nervous system (CNS) The central nervous system is that part of the nervous system that consists of the brain and spinal cord.

Colloids These are finely divided dispersions of one material in a second continuous phase. The size of colloidal particles is between that of individual small molecules and macroscopic objects. It is convenient to take a limit as; at least one dimension should be less than or of the order of a micrometer (10^{-6} m). The colloid consists of a dispersed phase in a continuous dispersion medium.

Critical aggregation concentration In mixed solutions of surfactants and polymers there is often association at a surfactant concentration below the normal critical micelle concentration, (CMC). Binding of surfactant to the polymer molecules usually causes this. There will be a discontinuity in the slope of a plot of surface tension versus concentration at this concentration.

Critical coagulation concentration When salt is added to a charge stabilized colloid, the screening length is reduced and at a particular concentration the dispersion is no longer stable (such that there is no secondary minimum in the DLVO potential). The concentration of salt at which the particles are no longer stable and begin to aggregate is the critical coagulation concentration (CCC).

Critical micelle concentration (CMC) This is the concentration above which surfactants form micelles in solution. The change in properties that occur as micelles form is marked by sharp transitions in many physical quantities such as the surface tension of the solution, conductivity, turbidity, and nuclear magnetic resonance chemical shifts.

Deoxy ribonucleic acid (DNA) The molecule that carries the genetic information for most living systems. The DNA molecule consists of four bases (adenine, cytosine, guanine, and thymine) and a sugar phosphate backbone arranged in two connected strands.

Emulsion A colloidal dispersion of one liquid in another liquid (usually an oil and water). It is often "stabilized" with a surfactant or with polymers. Emulsions are not usually truly stable but may be metastable. This contrasts with microemulsions.

Emulsion polymer A polymer that is prepared by polymerization of a dispersion of monomer in a liquid. It is often stabilized with a surfactant or with polymers. This preparation involves an emulsion but the product is a colloidal dispersion of a polymer that is usually solid in the liquid. The product is known as latex. Typically many vinyl polymers are prepared with radical initiators in this way.

Flocculation Colloids are described as flocculated when the individual particles have aggregated together to form clusters. This occurs when the repulsive potential that provides stability in dispersion becomes less than the attraction. Critical flocculation concentration and temperature are the parameters above which the individual particles aggregate to form clusters.

Fluoresceine isothiocyanate (FITC) Green fluorescent dye used to 'tag' antibodies for use in immuno-fluorescence.

Gastrointestinal tract (GIT) Organs that are part of the digestive tract, which include the esophagus, stomach, small intestine, and large intestine (rectum and colon).

Inflammatory bowel disease (IBD) A chronic inflammatory condition of the digestive tract. Ulcerative colitis and Crohn's disease are the most common forms of IBD.

Mononuclear phagocytic system (MPS) A system comprising blood monocytes and tissue macrophages.

Nanoparticles A material with dimensions less than 1000 nanometers and often below 100 nanometers.

Photon correlation spectroscopy (PCS) The correlation of scattered photons is measured. This can be used to determine the dynamic behaviour of particles or polymer molecules at length scales determined by the reciprocal of the scattering vector, $Q = (4\pi/\lambda)\sin(\theta/2)$ and if there is a simple exponential decay characterised by a relaxation time, t, the diffusion coefficient, D and hence hydrodynamic radius, can be determined as follows: $D = 1/\tau Q^2$.

Poly(lactide-*co*-glycolide) (PLGA) Copolyester of lactic acid and glycolic acid.

Reticuloendothelial system (RES) A rather old term for the network of phagocytes and endothelial cells throughout the body.

Ribonucleic acid (RNA) A nucleic acid molecule similar to DNA but containing ribose rather than deoxyribose. RNA is formed upon a DNA template. There are several classes of RNA molecules. They play crucial roles in protein synthesis and other cell activities.

Scanning electron microscopy (SEM) Scanning electron microscopy is performed by scanning a focused probe across the surface of the sample to be studied. Secondary electrons emitted from the sample are typically detected by a photomultiplier system, the output of which is used to modulate the brightness of a TV monitor that is rastered in synchronization with the electron beam scan. The more electrons a particular region emits, the brighter the image at that point. SEM images typically contain a good deal of topographical detail.

Transmission electron microscopy (TEM) The electron beam is passed through a thin film sample (typically ~1–200 nm thick). Bright field diffraction contrast images are formed with the direct (undiffracted) beam. Dark field images are formed with a selected diffracted beam.

1. INTRODUCTION

In the last few years there has been a huge demand to monitor different chemical environments, such as urban indoor and outdoor atmospheres, food aromas, etc. Chemical sensors are among the most promising devices to be exploited for these applications, because they have the great advantage of allowing an online measure suitable for remote control [1].

The structure of a generic chemical sensor can be ideally divided in two subunits: the sensing material and the transducer. The sensing material interacts with the chemical species present in the environment by changing some of its physico-chemical properties, while the transducer transforms these variations in a readable signal, generally an electric signal.

The sensor performances in term of sensitivity, reproducibility, and selectivity strictly depend on the properties of the sensing materials. For this reason great effort has been made to develop sensing materials with improved properties [2].

From this point of view, the exploitation of organic compounds as sensing materials is particularly advantageous. The progress made in designing synthetic receptors [3] allows the orientation of the sensor selectivity toward different classes of compounds via modulation of weak interactions occurring between the sensing material and the analytes.

Among the different classes of receptors developed, porphyrins and metalloporphyrins represent one of the most promising, because of the richness of their properties, their stability, and the development of the chemistry of these macrocycles that allow the possibility to modulate their properties by synthetic modifications or by changing the coordinated metal. In these applications porphyrins mimic their functions in biological systems, where they are able, for example, to reversibly bind oxygen. Because generally target analytes are also good ligands for metal ions, porphyrins represent a perfect match for the properties required to sense materials.

For this reason research in this area has experienced significant growth in the last decade and porphyrin based chemical sensors are now going to be as famous as those based on related phthalocyanines. In this chapter we want to highlight their exploitation in sensors based on different transduction mechanisms and devoted to detecting analytes in both liquid and gaseous phase.

2. GAS PHASE OPTICAL SENSORS

Optical sensors are based on the variation of one optical property, such as absorption or luminescence, of the sensing material as a consequence of the interaction with the target

analyte. A general setup of an optical sensor is reported in Figure 1. Porphyrins have been called the “pigment of life” and for these peculiar optical properties it is quite obvious that they have been considered as sensing materials for optical sensors. The first examples reported in the literature were related to gas detection and in particular to the development of oxygen sensors.

2.1. Oxygen Sensors

These devices are based on the quenching of the phosphorescence of some metalloporphyrins due to their interaction with molecular oxygen. The dependence of phosphorescence quenching to the oxygen concentration is described by the Stern–Volmer relationship

$$I_o/I = 1 + K_{sv}(PO_2)$$

where I_o represents the native phosphorescence of the lumophore in the absence of oxygen. K_{sv} is the Stern–Volmer constant and represents a useful parameter to compare the sensor performances. K_{sv} is obtained experimentally from the Stern–Volmer equation taking the partial pressure of oxygen at which the initial sensor phosphorescence is decreased by 50% ($I_o/I = 2$). In Table 1 we report a list of the K_{sv} values of the some porphyrin based oxygen sensors.

The most widely used metalloporphyrins for these applications are Pt and Pd derivatives, due to their high phosphorescence quantum yields and short lifetimes. The detection limit of these porphyrin based sensors can be lower than 0.1 Torr of oxygen partial pressure and for this reason they can be exploited for vacuum control, for determination of surface pressure in wind-tunnel tests [4], or for determination of the metabolic activity of cell cultures [5].

In chemical sensors the sensing material should be deposited as thin films onto the transducer surface. In these devices porphyrins are generally deposited dispersed into a supporting matrix. Although is not directly involved in the sensing mechanism, the matrix is of critical importance for sensor performance, because its oxygen permeability determines the detection limit of the resulting sensor.

Another fundamental feature to be considered in optical devices is the photostability of the sensing material.

To obtain stable and reliable devices it is necessary to improve the photostability of the lumophore and to obtain a perfect match between matrix and lumophore properties and for this reason a large part of the research in this area has been devoted to improving sensor performances by increasing porphyrin stabilities and by tuning the matrix characteristics.

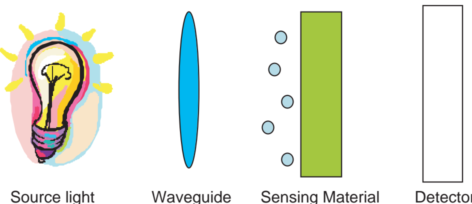

Figure 1. General setup of an optical sensor.

The first metalloporphyrins exploited in these sensors were PtOEP (see Table 2 for abbreviations) and PdOEP (Fig. 2) [6, 7], which showed significant photobleaching under the operative conditions [6]. From this point of view one of the approaches has been to modify the porphyrin by introducing different substituents, in order to increase its stability under operative conditions.

DBS	dibutyl sebacate
AAO	ascorbic acid oxidase
OA	oleic acid
AP	acetophenone
DOP	dioctyl phthalate
NaTPB	sodium tetraphenylborate

Oxochlorin, generally called porphyrin ketone (OEPK) (Fig. 3), has been proposed by Papkovsky and co-workers [8]; the dye showed higher photochemical stability to respect OEP, conserving the optical properties useful for phosphorescence sensing, with only shortened lifetime values. Following this approach the same author proposed also dioxobacteriochlorin, or octaethylporphyrin-diketone (OEPDK) (Fig. 4), as sensing material, with the hope that the introduction of a second oxo group at the peripheral positions resulted in a further increase of the photostability of the resulting porphyrin [9]. This result was effectively achieved, but, on the other hand, Pd and Pt complexes of these porphyrins showed weak phosphorescence and reduced quantum yields, making them unusable for oxygen sensing.

Following a similar approach, β-halogenated TPPs have been proposed as sensing materials [10]. These porphyrins have been widely used as oxidation catalysts, where they were shown to be more resistant to degradation than TPP. The same effect was obtained for photostability and PtBr_8TMP was indeed more stable than PtTPP under operative conditions.

On the other hand, significant effort has been devoted to improving the characteristics of the supporting matrix, to improve both stability and sensitivity of the resulting sensor. The matrix can be either organic or inorganic, but the most common materials used to encapsulate porphyrins are organic polymers. A general requirement for these polymers is to be oxygen permeable with a low diffusion barrier for the gas. The permeability to oxygen of course strongly influences the characteristic of the resulting sensor.

A careful choice of polymer and plasticizer is necessary to obtain reliable sensors. Of course polymers or additives should not interfere with the sensing mechanism of the porphyrin; for example the widely used plasticizer 2-nitrophenyl octyl ether cannot be exploited in luminescence based sensors, because it acts as a quencher of the porphyrin luminescence, interfering in the sensing mechanism [11].

Plasticizers are necessary to increase the oxygen permeability of the organic polymers and for this reason they strongly influence the working range of the resulting sensor. Detailed studies of the plasticizer influence on the sensor characteristics have been carried out for Pd and Pt complexes of OEP and OEPK [12]. These studies showed that addition of plasticizers to PVC, PS, CAB and PMMA polymers allows the modulation of the O_2 pressure working range of the sensor, by effectively increasing the oxygen permeability of the polymer matrix. On the other hand, addition

Figure 2. Molecular structure of OEP.

Figure 3. Molecular structure of OEPK.

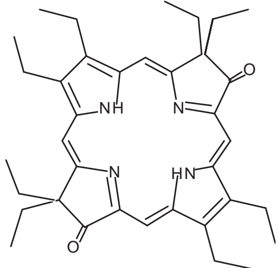

Figure 4. Molecular structure of OEPDK.

of plasticizers can induce a deviation from the linearity of the Stern–Volmer relationship at higher oxygen concentration. This feature has been attributed to the presence of two oxygen accessible sites in the polymeric thin films; one is easily accessible and the other one is an oxygen site difficult to access. The different oxygen sites where the porphyrin can be present result in different phosphorescence quenching constants and consequently in the nonlinear Stern–Volmer plot [13]. This effect is not favorable, because makes calibration of the sensors more difficult.

An increase of the oxygen permeability can resolve this problem and for this reason novel polymeric matrices have been tested in recent years to obtain sensors with improved performances [14–18]. Poly(TMSP) demonstrated high oxygen permeability, and the detection limit for PtOEP dispersed in poly(TMSP) film was less than 0.3% [14]. Furthermore the Stern–Volmer plot was linear in the oxygen low concentration range and PtOEP-poly(TMSP) based sensors were promising for trace oxygen detection. PtOEP-poly(TMSP) films showed a 3% decrease after 12 h of continuous irradiation, indicating a promising photostability, although this aspect was not completely characterized [14].

Another promising approach was related to the exploitation of fluoropolymers, because the presence of fluorine increases the oxygen permeability of the resulting matrix. Furthermore these polymers are also stable toward photooxidation, due the electron-withdrawing character of the fluorine. Fluoropolymers are obtained by co-polymerization of a fluorinated monomer with a standard precursor, such as styrene [15] or acrylate [16–19], in different compositions. The high oxygen permeability of these fluoropolymers resulted in a good linearity of the Stern–Volmer plots for both PtOEP and PdOEP based sensors. For PdOEP sensors the phosporescence of the sensing material was completely quenched for 20% oxygen concentration. Furthermore the photostability of these sensing films was enhanced and a maximum of 3% decrease of the starting intensity was noted after 24 h of continuous irradiation [16–18].

Nafion® has also been used as supporting matrix for Pt, Pd, and Rh complexes of water-soluble porphyrins [19]. The resulting sensing films showed linear Stern–Volmer plots, and promising sensitivity and photostability for practical applications, considering also the simple procedure for the immobilization of the lumophores into the supporting matrix.

Recently Douglas and Eaton [20] studied the response characteristics of Pd and Pt complexes of OEP encapsulated in different polymeric matrices, showing that it is possible to develop luminescent oxygen sensors with a very broad concentration working range, by combination of polymers with different oxygen permeability and Pd and Pt OEP, having different lifetimes. Deviations from the linearity of the Stern–Volmer plots have been modeled by a Freundlich-like isotherm, which can be used to obtain simple and precise calibration data. The heterogeneity inducing nonlinear Stern–Volmer behavior was attributed to a distribution of oxygen permeability present in the polymers and not to distribution of different lumophore lifetime. The same authors showed that ambient humidity strongly influenced the sensing behavior of PtOEP based luminescent sensors when a hydrophilic polymer, such as EC or CAB, was used as supporting matrix, while no significant effects were observed for hydrophobic matrices, such as silicone rubber, PVC, or PS [21]. Luminescence decay kinetics studies in the presence of oxygen showed that the influence of humidity is in the change of gas permeability, rather than modification of the porphyrin distribution sites in the polymer. Addition of plasticizers strongly reduced the humidity effects on the sensing behavior.

Although polymers are the most widely used matrices, it is also possible to disperse lumophore into inorganic supports, such as glasses. The advantages of glasses can be related to their transparency, chemical stability, and photostability. The sol–gel technique is a simple way to disperse an organic dye into a glass matrix. Lee and Okura prepared PtOEP doped silica gel glasses by basic hydrolysis of tetraethylethyl orthosilicate [22]. The addition of a surfactant, Triton X-100, was necessary to give homogeneity to the resulting monoliths. Optical properties of PtOEP in silica glass were similar to those observed in acetone solution, indicating that the silica matrix does not interfere with the optical sensing of PtOEP. Sol–gel films were dried at room temperature, at 150 and 180 °C. The best sensitivity was obtained at 150 °C, although good results were obtained at room temperature, showing that the sintering step is not necessary. Higher drying temperature resulted in a marked decrease of the sensor performance, attributed by the authors to some variation of the sol–gel microenvironment, although decomposition of the dye cannot be excluded. Stern–Volmer plots showed deviations from the linearity, evidencing the presence of different oxygen accessible sites in the matrix. High response time and reversibility were observed for such sensors, and these superior characteristics were attributed to the microporous texture of the silica matrix. The stability of the PtOEP doped glasses was optimal in the dark, while under irradiation the results obtained were similar to those observed for polymeric matrices.

Amao et al. explored also the possibility to avoid the need for a supporting matrix, depositing a monolayer of the sensing dye by a chemisorption technique [23, 24]. Pt and Pd complexes of TCPP (Fig. 5) were deposited onto alumina plates using the carboxy functional groups to directly attach the lumophore to the inorganic surface. Excitation spectra were similar to those observed in ethanol, an indication of the absence of aggregation between macrocycles in the chemisorbed film. Phosphorescence of the films was effectively quenched by oxygen; Stern–Volmer plots were linear at low oxygen concentration, while significant nonlinearity

Figure 5. Molecular structure of TCPP.

was observed for higher concentrations. A good photostability was also observed, indicating that these films are suitable for oxygen sensing devices. To improve the sensitivity of such a device, the same authors deposited monolayers of a modified Pd porphyrin bearing a peripheral alkyl chain substituent (Fig. 6) [25].

PtTPP and PdOEP thin films were also deposited by a electropolymerization technique [26]. Indium tin oxide glass slides were used as substrates and PtTPP polymeric films were deposited by a CV technique. In the case of PdTPP it was necessary to add 2,6-di*tert*-butylpyridine as catalyst for the electropolymerization process. The sensitivities of the developed devices were comparable to similar oxygen sensors, but the long-term photostability was greatly improved.

The electropolymerization deposition technique is particularly promising for the fabrication of miniaturized devices, because the sensing film can be directly deposited at the end of the optical fiber.

The measurement of luminescence intensity is the most exploited technique, because it is a simple technique. However, it can be affected by different parameters, the most important being photobleaching or leaching of the dye and the intrinsic sample fluorescence. These problems can be overcome by measuring the luminescence decay time of the sensing dye, because this measure is independent of the emitted light intensity and it is compatible with fiber optics exploitation. In this case the Stern–Volmer equation is related to the lumophore lifetime:

$$\tau_o/\tau = 1 + K_{sv} pO_2$$

Following this approach, different examples of oxygen sensor based on phosphorescence lifetime decay have been reported [27–29]. For example Trettnak and co-workers reported for example an oxygen sensor comprised of simple and low-cost optoelectronic components, such as light emitting diodes (LEDs) and photodetectors [27], working in both liquid and gaseous phase. The exploited lumophore was the PtOEPK supported in a polystyrene matrix.

Amao et al. reported an oxygen sensor based on the triplet–triplet reflectance quenching using laser flash photolysis [28, 29]. PtOEP and PtTFPP immobilized on PS matrices were used as sensing dyes and the authors obtained the same results by using diffuse reflectance laser flash photolysis and the classical luminescence lifetime measurements by laser excitation [28]. Diffuse reflectance laser flash photolysis can also allow the use of nonphosphorescent compounds as oxygen sensing dye, and this has been successfully demonstrated by the exploitation of different Zn porphyrins immobilized in various polymeric matrices [29].

More recently Douglas end Eaton pointed out that careful attention should be paid for the Stern–Volmer analysis of data using conventional phosphorimeters or instruments incorporating pulsed xenon lamps [30], because of systematic errors in quantitative emission intensity measurements due to the fact that the total emission of the lumophore is not completely within the instrument gate time [31].

2.2. Nitrogen Oxides Sensors

Oxygen sensors based on phosphorescence quenching generally do not suffer interference due to the presence of other gases, with the only exception being nitrogen oxides, which are powerful luminescence quenchers. For this reason, Papkovski and co-workers explored the potential exploitation of PtOEP immobilized on PS matrices and PdCP-III Langmuir–Blodgett films as NO_x optical sensors. For both films NO_x acted as a strong luminescence quencher, but in this case a fast chemical interaction of the dye with NO_x and consequent film degradation ruled out their exploitation in the sensor field [32].

More recently the exploitation of Langmuir–Blodgett (LB) films of substituted porphyrins as optical sensors for NO_2 detection has been deeply studied [33–37]. The sensing mechanism is based on the variations of the optical absorption spectra of LB films of TEHOPP, bearing the 2-ethylhexyloxyphenyl substituents at the peripheral positions (Fig. 7). The deposition of LB films was performed at a higher rate than the conventional method; this resulted in an inhomogeneous morphology of the resulting film, constituted by grain assemblies of porphyrin, and incomplete coverage of the sensor substrate. This structure, however, is not detrimental for sensor applications, because it led to porous films, which allows easy diffusion of the gas in the bulk of the sensing material.

The change in the optical spectrum consisted of a redshift of the Soret band with the appearance of a new band

Figure 6. Molecular structure of PdATTP.

Figure 7. Molecular structure of TEHOPP.

around 700 nm, which is consistent with a protonation of the macrocycle core. The optical is highly sensitive to low concentration of NO_2, reaching the ppm level. The 60% of relative absorbance change (at 434 nm) was obtained for 4.4 ppm of NO_2 [33, 34], with the original spectrum fully recovered after exposure to NO_2, by fluxing with N_2, indicating a reversible interaction. The optical response is also sensitive to the temperature and decrease with the increase of the temperature. This effect was used to increase the recovery rate after the measure, by heating the substrate at 350 °C for a few seconds [33, 34]. The adsorption isotherm followed the Langmuir model.

The sensing behavior of two asymmetrically substituted porphyrins, obtained by substitution of two peripheral 2-ethylhexyloxyphenyl substituents by 4-nitrophenyl or 4-aminophenyl groups, toward NO_2 detection was also studied [35]. While both porphyrins showed in the presence of NO_2 the same change in the optical spectra recorded in solution, similar to those observed for the symmetrical porphyrin, the LB films of these porphyrins showed a different behavior, and only the 4-aminophenyl substituted porphyrin was sensitive to NO_2. This different behavior was ascribed to a different arrangement of the porphyrin rings in the LB films, with the 4-nitrophenyl substituted porphyrins having a molecular orientation that did not allow a diffusion of the gas and consequently the interaction with the macrocycles [35].

The dependence of the sensing performances to the LB film thickness was investigated for multilayer films of TEHOPP ranging from 1 to 20 excursions. Comparison of the response time taken at 50% and 90% of the overall response allowed the interpretation of the sensing mechanism in terms of surface and bulk interaction of the LB film with the gas. The response time reached a minimum value for films obtained by 5–10 excursions; after that the response magnitude of the sensing layer can increase, but the effective sensitivity of the film can decrease [36].

2.3. Other Gas Sensors

Porphyrin based optical sensors are not only limited to oxygen or nitrogen oxide detection. Similar devices have been tested, for example, for the detection of chlorine [38–40]. The first approach was based on the fluorescence changes of TPP encapsulated on silicone rubber, induced by exposure to chlorine [38]. The change observed can be attributed also in this case to the formation of the porphyrin dication; due to the insolubility of the porphyrin dication into the silicone matrix, the measurement should be carried in a kinetic mode and a faster reversibility can be obtained by temperature control, by heating the film after each measurement. This optical sensor cannot discriminate between chlorine, hydrogen chloride, or nitrogen dioxide, because all of these gases induce the protonation of the sensing film, which is the sensing mechanism of this device.

A similar protonation process was observed after exposure to gaseous chlorine by recording optical absorption spectra of monolayers of TDSAPP deposited onto glass plates [39]. In this case the influence of porphyrin orientation on the sensor behavior was observed, with a faster response for monolayer deposited at lower surface pressure, where porphyrins are assumed to be oriented flat on the surface and consequently more accessible to interaction with gaseous chlorine. Also in this case heating the substrate after the measurement reduced the recovery time of the device. Similar behavior was observed for monolayers of TSPP [40].

Changes in the optical absorption spectra were exploited in a similar fashion for HCl detection [41–43]. TPP and substituted analogs were encapsulated in different polymeric matrices and changes in the reflectance spectra induced by protonation of the macrocyclic cores were used for the detection of gaseous HCl. An increase of the sensor responses was observed when electron-releasing substitutents, such as OH groups, were introduced at the peripheral phenyl groups of the porphyrin rings, reaching a detection limit in the sub-ppm range [42]. However, this synthetic modification also induced longer response and recovery times and to overcome this problem, different alkoxy substituted TPPs encapsulated in various polymeric matrices were tested as sensing elements [43]. The results obtained showed that saturation of the sensors was reached for 4 ppm of HCl concentration and that the sensor behavior was mostly controlled by the polymeric matrices and not by the length of the peripheral alkoxy chain. Best results were obtained by using PBMA as supporting matrix [43].

Leray and co-workers used water-soluble porphyrins (Fig. 8) encapsulated in PVP or PMMA matrices for benzene detection [44]. These porphyrins are know to interact with benzene in aqueous solution; the changes induced in the optical spectra by interaction with benzene were similar in solution and in the polymeric matrices and consisted in a hypochromic effect. Best results were achieved with DTMABP and PVP as matrix, although the sensitivity and response time were not sufficient for exploitation in urban air monitoring, although the sensitivity was comparable to other devices reported in the literature [44].

Figure 8. Molecular structure of TMPyP and DTMABP.

The same author proposed sol–gel grafted Co porphyrins for amine detection [45]. Grafting of the porphyrin to the sol–gel matrix was achieved by introducing triethoxysilyl groups at the peripheral positions of the porphyrin ring (Fig. 9). Grafting the porphyrin resulted in the oxidation of the coordinated cobalt atom to the +3 oxidation state. Diffusion of amines was possible in solution and in the gaseous phase and resulted in optical changes characteristics of axial coordination to the metal center. The same interaction was not possible in the case of Co(II)TMPyP, which was insensitive to the presence of amines; this result was attributed to a strong interaction of the cationic porphyrin to the anionic centers of the inorganic matrix. Response time of the developed sensor was very long, due to a slower diffusion rate than those observed in polymeric matrices [45].

Figure 9. Molecular structure of silyl modified TPP.

Very recently Qin and co-workers proposed an optical sensor for the detection of amines in the gaseous phase, based on In(OEP)OH as sensing material [46]. The sensing mechanism operating in such a device is similar to that observed in potentiometric sensors later described (see Section 4) and it is based on a monomer–dimer equilibrium of In(OEP)OH in polymeric films. In the presence of lipophilic anion, in fact, this equilibrium can be expressed as

$$2\,\mathrm{In(OEP)^+} + \mathrm{H_2O} + \mathrm{R^-} \rightleftharpoons [\mathrm{In(OEP)_2OH}]\mathrm{R} + \mathrm{H^+}$$

Amines can break the dimer by coordination to the metal center:

$$[\mathrm{In(OEP)_2OH}]\mathrm{R} \rightleftharpoons \mathrm{In(OEP)OH} + [\mathrm{In(OEP)RNH_2}]\mathrm{R}$$

This reaction can be easily monitored by optical absorption spectra, because the blueshifted Soret band of the dimer ($\lambda = 390$ nm) disappeared with the concomitant formation of the absorption of the $\mathrm{In(OEP)^+}$ ($\lambda = 406$ nm). The presence of water is necessary for the formation of the dimer and all the measurements were carried at 80% of relative humidity. In these conditions the sensor response to the different amines depends on the relative partition coefficient of the amine into the polymeric films and to their ability as coordinating ligand for the InOEP. In the best situation the detection limit can reach 0.1 ppm in the case of butylamine, while for the less lipophilic ammonia it is in the range of 10 ppm [46].

3. LIQUID PHASE OPTICAL SENSORS

3.1. Heavy Metal Ions

Porphyrin based optical sensors have been developed to detect Hg and other heavy metals in solution [47–51]. These sensors are based on the well-known ability of porphyrins to coordinate a wide range of different metals in the inner core. Coordination of the metal induces changes in both the absorption and emission spectra that can be used for the sensing mechanism.

Plaschke and co-workers immobilized water soluble TSPP into silica glasses by the sol–gel technique [47]. Interaction with Hg(II) ion was monitored by following the emission of Hg porphyrin complex at 612 nm. The acid or basic catalysis for the preparation of the sol–gel gave films with different characteristics. The acidic prepared films were more stable in terms of dye leaching but were insensitive to the presence of Hg ions, while the basic catalyzed films gave the opposite behavior. This result was attributed to the different morphologies of the films, with the acidic prepared films more packed and less permeable to the diffusion of the Hg ions. For this reason a dextran covalently linked porphyrin was prepared and used in the basic sol–gel process; in this case a better stability of the resulting film was observed. An ideal detection limit of 2 μg/L of Hg(II) was obtained for the basic catalyzed films, although the instability of the film

toward dye leaching prevented the exploitation for sensing applications [47].

To overcome the problem of the sensing element leaching, the same group developed a polymeric matrix with a covalently bound porphyrin [48]. The polymeric matrix was a hydroxyethyl substituted PMMA, deposited onto a PMMA disk. The change of absorption spectra after metal coordination was exploited to develop the optical sensor. Cd(II) and Hg(II) ions were the target analytes and a detection limits of 63 and 20 μg/L were obtained respectively for these ions, with a response time of 10 min. The different ions can be easily discriminated because they have different absorption bands and for this reason a simultaneous determination is possible. Due to the covalent binding the sensor was stable over 6 weeks of working period, while a simple dispersed porphyrin was completely leached from the polymeric membrane within some days.

TMpyP was adsorbed in sol–gel matrix or grafted onto a glass surface to develop optical sensors for the detection of Hg(II), Pb(II), and Cd(II) ions, by following changes both in the absorption or in the emission spectra [49]. In sol–gel the detection limit observed was 10^{-3} mol/L, but the porphyrin–metal ion interaction was strongly limited by the ion entrapping action of the silica matrix. When the porphyrin was grafted onto glass plates by covalent bonding (Fig. 10), shorter response time and higher sensitivity were obtained to respect the bulk sol–gel material.

An optical sensor for the detection of Hg(II) ions has been developed by encapsulating TPP into a PVC membrane [50]. Detection of Hg was carried out by following the fluorescence quenching of the porphyrin operated by coordination of the metal ion. More recently an increase in the sensor performances has been obtained by using a porphyrin dimer as sensing element [51]. The presence of two porphyrin rings in the sensing material allowed a higher sensitivity and selectivity for the Hg(II) ion in the pH range of 2.4–8. A detection limit of 5.2×10^{-7} mol/L with a response time of 9 min was obtained. The presence of a wide range of different ions, including Cd and Pb, did not affect the Hg detection, with a relative error less than 5%, acceptable for practical applications.

Figure 10. Molecular structure of TPyP grafted on silica surface.

3.2. Anions

Metalloporphyrins have axial sites available for interactions with different analytes. This approach has been exploited for anion detection, by following optical changes due to the interaction of metalloporphyrins with the target analytes.

Solid-state phosphorescent probes for the detection of sulphite have been developed by immobilization of a Pt(II)CP-I covalent conjugate with bovine serum albumin on a preactivated biodyne ABC membrane [52]. A flow-injection system for the determination of sulphite was developed by placing the membrane in a flow cell and using a fiber optic phosphorescent detector. Quenching of the phosphorescence was observed at acidic pH and was attributed to the formation of SO_2. The detection limit reported for this system was 10^{-5} mol/L.

Changes of the optical absorption spectra of metal complexes of T(4-APP) or TMPyP immobilized in thin films of Nafion® were exploited for the detection of different anions, such as iodide and thiocyanate [53]. The selectivity and sensitivity of such a films depended on both the coordinated metal ion and the porphyrin used. Co(II)TMPyP gave fast and reversible responses, with thiocyanate, showing also a good long-term stability.

Polymeric membranes doped with In(III) porphyrin complexes and a lipophilic dichlorofluorescein (DCF) derivative were studied for the development of anion optical sensors [54]. With InOEPCl DCF acted as axial ligand, and interaction of the chromophores induced modification of the absorption spectrum of the diad. Anions competed with DCF as axial ligand and this resulted in an increase of the Soret band absorption, which can be used for optical sensing. In the case of a In(III) complex of a picket-fence porphyrin, DCF was not coordinated, as evidenced the absence of modification of the absorption spectrum. This complex was exploited for the development of acetate anion or acetic acid optical sensors.

More recently, Zhang and co-workers have developed an optical chloride sensor based on the previously described monomer–dimer equilibrium of In(OEP)OH in plasticized PVC films [55]. In the absence of chloride anion, the blueshifted Soret band of the In porphyrin dimer was observed. Chloride acts as axial ligand for In porphyrin and increasing the amount of chloride induced the breaking of the dimer with the formation of the monomeric complex. This resulted in an increase of the redshifted Soret band of the monomeric species. A good selectivity toward a wide range of different anions was observed, although the interference of salicylate was observed.

3.3. Other Analytes

PVC membranes doped with TPP and MnTPPCl were used to develop an optical fiber optic sensor for the determination of berberine, an anti-inflammatory drug for the heart [56]. The sensing mechanism was based on the fluorescence quenching of TPP-MnTPPCl operated by berberine. The sensor operated in the 7.5×10^{-7} to 5.6×10^{-4} mol/L working range of berberine concentration, with fast response time and fair selectivity toward common interfering species. The exploitation of the TPP-MnTPPCl mixture gave better results than the use of the simple TPP.

4. ELECTROCHEMICAL SENSORS

4.1. Potentiometric Sensors

Among the different examples of porphyrin based chemical sensors, their exploitation as ionophores in the development of ion selective electrodes (ISE) is probably one of the most popular. These electrodes (Fig. 11) are generally comprised of a polymeric membrane, where the sensing materials are dispersed, an internal filling solution, and an electrode for the electrical connection to the external circuit. Such sensors respond to the activity of target ions by an intrinsic ion-exchange mechanism between the organic polymeric phase and the aqueous phases. In Table 3 we report the detection limits of some porphyrin based ISEs reported in the literature. The basic theory describing the working mechanism of such a sensor has been developed [58], but the contribution of the different constituents (e.g. ionophore, additives, etc.) is still a matter of further researches. The membrane, usually comprised of a PVC disk, has ion-exchange properties that depend on the ionic sites present in the polymeric structure. The sensor responds to the activities of the ions present in the sample and the selectivity depends on the relative solubility of the ions into the polymeric membrane solvent (plasticizer). It is the ionophore that drives the selectivity of the sensor toward the target analyte. Under certain conditions [58], the response of the ISE to the target analyte concentration follows the Nernst equation:

$$E = E^o + RT/zF \ \ln(a_i)$$

The developed coordination chemistry of metalloporphyrins has attracted interest for their exploitation in the development of anion-selective sensors. In the absence of metalloporphyrins, there are no specific interactions and the selectivity of ISE depends on the anion lipophilicities and results in the so-called Hofmeister series. The presence of metalloporphyrin in the membrane induces deviations on this series, which depend in large part on the coordination of the anion to the metalloporphyrin. After the first report by Chaniotakis co-workers [59], the importance of coordination interactions has been demonstrated, in terms of both the nature of the central metal and the substituents present in the porphyrin ring [60, 61]. Metalloporphyrins can act as neutral or charged ion carriers, depending on the oxidation state of the coordinated metals. While coordinated metals in a +2 oxidation state lead to neutral carriers, and metals in a +4 oxidation state lead to charged carriers, with metals in a +3 oxidation state can give either neutral or charged carriers, depending on both the coordination number of the metal and the nature of the incoming axial ligand (neutral or anionic) [62]. The performances of metalloporphyrin based ISEs depend also on the addition on lipophilic ionic additives, such as triphenylborate or trialkylammonium salts, which improve the potentiometric behavior of the resulting sensors, in terms of selectivity and long-term stability. The nature of the positive effect of these additives has been studied in detail and both the nature and the amount of the ionic additive to be added for the membrane compositions can be rationally predicted [63, 64].

Furthermore, the origin of the so-called “super-Nernstian” behavior reported for several metalloporphyrin-based ISEs has recently been clarified [65]. These non-Nernstian responses are characteristic of anion-selective electrodes based on Mn(III), Sn(IV), In(III), and Ga(III) porphyrins and are derived from a monomer–dimer equilibrium occurring in the PVC membrane. The occurrence of this equilibrium and the degree of dimerization have been demonstrated by ultravoilet-visible spectroscopy, following the blueshifted Soret band characteristic of the hydroxy-bridged dimer. Furthermore In and Ga complexes of picket-fence porphyrins, which do not dimerize, showed slightly sub-Nernstian slopes. A theoretical model based on the dimerization equilibrium was shown to be able to predict the super-Nernstian behavior of the resulting ISEs.

Different metalloporphyrins have been proposed in recent years for the development of ISEs devoted to the detection of various analytes [62, 66–69]. A free base TPP modified with appended urea group (Fig. 12) has been proposed as ionophore to develop an ISE for acetate and it was demonstrated to be able to measure the concentration of acetic acid in vinegar samples [70].

Among the shortcomings observed with these metalloporphyrin-PVC based ISEs, one of the most important is their reduced long-term stability because of the ionophore leaching from the membrane. To avoid this problem, a covalent binding of the porphyrin to the polymeric matrix has been proposed [71, 72]. This immobilization effectively overcame the problem of ionophore leaching but also contributed to reducing the interference of lipophilic anion, such as salicylate, because of size exclusion from the polymeric matrix. This steric effect also prevented the super-Nernstian behavior due to metalloporphyrin dimerization and the resulting Mn(III) porphyrin showed a Nernstian behavior to iodide.

Although PVC is the most widely used membrane, some examples of different matrices have been proposed for particular applications. Malinowska and co-workers have studied the potentiometric behavior of ISEs based on In(III), Ga(III), and Co(III) porphyrin complexes encapsulated in PU membranes, in comparison with that observed with conventional PVC ISEs [73]. The same sensing mechanism is observed in both membranes, although the presence of endogeneous cationic sites in PU, instead of anionic sites as in PVC, strongly influences the potentiometric response if no lipophilic salt additives are added.

Silicon rubber has also been proposed for the development of all-solid-state ISEs [74]. In these devices the membrane is directly attached to the electrode surface, without the presence of the internal solution (Fig. 11). Mn(III) and In(III) porphyrins encapsulated in SR matrices were used to develop chloride selective electrodes, suitable for the measure of chloride in clinical samples. Silicon rubber is necessary for the development of all-solid-state sensors because of its adhesion properties to the electrode surfaces. It was necessary to add plasticizers in order to obtain potentiometric responses. In(III)OEPCl gave the best results as ionophore, because of reduced interference from salicylate, and an InOEPCl based ISE was demonstrated to be suitable for serum chloride measurement.

Other than inorganic anions, metalloporphyrin based ISEs have been exploited for the measurement of particular target analytes, such as aminoacids [75, 76], and drugs [77, 78].

Free base porphyrins have also been used as ionophores for cation selective electrodes [79, 80] although cation sensing is far less developed than anion detection. TPP and TTP encapsulated in PVC membranes have been used to develop Ni(II)-selective sensors [79], although only moderate selectivity was effectively achieved. More recently two examples of Zn(II)-selective electrodes have been reported in the literature [80, 81] In the first example the PP-IX dimethyl ester was encapsulated into a PVC membrane, along with

Figure 12. Molecular structure of urea-functionalized TPP.

sodium tetraphenylborate and dioctyl phtalate as plasticizer [80]. The resulting Zn-ISE showed fast response time, good long-term stability, pH range 2.1–4.0, and a working concentration range of 10^{-5} to 10^{-1} mol/L. The second sensor was developed using T(2-APP) as ionophore in PVC membranes [81]. This ISE showed good selectivity toward other metal ions in a pH range 3.0–6.0 and it was successfully applied for the determination of Zn in pharmaceutical samples.

The development of ISEs that do not include a polymeric support has also been investigated. Alternate deposition of water soluble anionic TSPP and cationic polypyrrole was used to obtain the deposition of a multilayer film onto a 2-aminothiol modified silver electrode [82]. This chemical modified electrode (CME) was used as iodide ISE, showing a Nernstian behavior and detection limit of 10^{-6} mol/L, with fast response time and low resistance.

An interesting approach for the development of all-solid-state ISEs has been the modification of the electrode surfaces by an electropolymerization technique [83–85] T(2-APP) and the related TETMAPP were used as precursors to deposit polymeric films onto the surfaces of different electrodes. Free base and Fe(III), Ni(II), Co(II), and Cu(II) complexes of T(2-APP) were deposited by an electropolymerization technique onto the surfaces of different metal electrodes [83]. The films obtained were not conductive, probably because of the three-dimensional, spongelike structure of the polymeric film. They were tested as ISEs for the detection of different anions and, in the case of the free base, both anions and cations. It is interesting to note that useful potentiometric data were obtained when the electrode was positively polarized at positive potential before use, so inducing positive charge on the film. These ISEs generally showed sub-Nernstian slopes for iodide ions, with detection limits ranging from 10^{-4} to 10^{-3} mol/L. However, different parameters influenced the responses of these ISEs and for this reason it was sometimes difficult to give a rationale for the results obtained. In the case of the electropolymerized electrodes developed by Volf and co-workers [84], the anion selectivity pattern shown was attributed to coordination interactions in the case of polymeric films containing metalloporphyrins, and to ion-exchange polyporphyrin free base. When applied to the determination of amino acids [85], a remarkable selectivity for cysteine was observed.

4.2. Amperometric and Voltammetric Sensors

The working mechanisms of these devices are based on the well known ability of metalloporphyrins to catalyze oxidation or reduction of different substrates. Thin films of metalloporphyrins have been deposited onto electrode surfaces to develop chemical modified electrodes (CME) and the electrocatalytic action of the developed CMEs has been used for the detection of different analytes. Particular attention has been devoted to the detection of NO, starting from the seminal paper of Malinski and Taba [86]. NiTMHPP (Fig. 13) was deposited by the electropolymerization technique to give conductive films onto the surface of carbon fiber electrodes. An additional layer of Nafion® was necessary to avoid the interference of anion present in real matrices, such as nitrite. A major advantage of this approach was the extremely small dimension in which the electrodes can be

Figure 13. Molecular structure of TMHPP.

fabricated. The sensor is miniaturized by thermal sharpening of the electrode carbon fiber. The diameter of the carbon fiber is reduced to 500 nm and the fiber is mounted into a truncated needle (Fig. 14) [87]. The tip of the fiber (500 nm length) is coated with the polyNiTMHPP by electropolymerization and then an additional layer of Nafion® is added by a dipping technique. The resulting CMEs were demonstrated to be useful for the detection of NO in biological samples, because the developed nanosensors induced minimal damage for biological tissues, so allowing both *in vitro* and *in vivo* measurements [86–89]. In Table 4 we report examples of detection limits of some sensors reported in the literature. Furthermore the small size of these sensors was necessary to allow the monitoring of transient concentration of NO produced in physiological processes, because the half-life of this reactive molecule is very short in biological samples. While the miniaturization and the exploitation of these nanosensors has been greatly improved, the exact mechanism of electrochemical NO detection by the poly-NiTMHPP sensors is still unclear. In the first reports by Malinski and Taba and coworkers the electrocatalytic role of the coordinated Ni(II) ion has been involved for the oxidative reaction of NO, and coordination of NO and formation of the Fe-nitrosyl complex [Fe(III)P]NO was confirmed by cyclic voltammetry and spectroscopic data by Bedioui and co-workers [90]. On the other hand the same authors showed that in the case of Ni

complexes the coordination of NO to the metalloporphyrin is probably not involved in the electrocatalytic process [91]. The hypothesis that the role of the porphyrin layer could not be related to the axial coordination chemistry of the Ni ion was later confirmed, showing that the nonmetalated poly-TMHPP coated CME presented the same electroctalytic activity toward NO detection [92]. The same authors showed that the thickness of the porphyrin layer influenced the efficiency of the NO detection, and a tentative oxidation mechanism, where the porphyrin polymer acted as a three-dimensional structure, was proposed [93].

The external Nafion® has been added to increase the selectivity toward interfering anions present in biological matrices, such as nitrite, which cannot diffuse through the Nafion layer. On the other hand Nafion can increase the interference of cation species of biological relevance, such as catecholamines. For this reason, Ciszewski and Milczarek proposed the exploitation of electropolymerized eugenol as external layer, in order to preserve the selectivity toward anions and to reduce the interference of cationic species [94]. Pontié and co-workers developed a NO multilayer microelectrode composed of a poly-NiTMHPP layer, Nafion®, and *o*-phenylenediamine [95]. The developed sensor showed a detection limit as low as 40 nmol/L, a NO concentration expected in some biological system.

Mitchell and Michaelis reported a composite multilayer electrode having poly-NiTHMPP as sensing material and layers of Nafion®, acorbic acid oxidase, and either polylisine or polypyridinium to preclude interferences by physiological concentrations of both anionic and cationic electroactive species [96]. The resulting microdevice was used for *in-situ* NO detection, showing a NO detection limit of 8 nmol/L for *in vitro* and 173 nmol/L for *in vivo* tissue sample analyses.

Several metalloporphyrins were later exploited to develop CMEs devoted to the determination of different analytes [97–99]. Reducing anions such as nitrite and sulfite has been determined by dip coating modified glassy carbon electrodes with a tetraruthenated cobalt porphyrin (Fig. 15) [97]. These electrodes showed excellent performance for the determination of nitrite and sulphite, even at ppb level, both in conventional and in flow injection conditions. The same authors developed modified glassy carbon electrodes by deposition of an electrostatically assembled film of the tetraruthenated cobalt porphyrin and Zn(II)TSPP [98]. These electrodes were successfully exploited for nitrite detection in flow injection analysis with a detection limit of 10^{-5} mol/L. The same electrode can be used for nitrate ion detection

Figure 15. Molecular structure of the cobalt complex of tetraruthenated-TPP.

after reduction to nitrite in a reductor column containing copperized cadmium. Graphite electrodes functionalized by cobalt(II)TPP permitted the detection of a wide range of different organohalides, including compounds that are industrial pollutants [99]. A further advantage of these electrodes was the absence of interference from oxygen.

5. NANOGRAVIMETRIC SENSORS

Nanogravimetric sensors are generally based on the piezoelectric properties of crystalline quartz. Quartz crystal is cut along a certain symmetrical axis, usually AT cut, to obtain material able to sustain bulk electroacoustical oscillation at frequencies from 5 to 30 MHz. The quartz property making it interesting as a sensor is that the resonance frequency is, in a limited linear range, inversely proportional to the mass gravitating onto the surfaces of the quartz, as described by the Sauerbrey law:

$$\Delta f = -K_q \Delta m$$

This behavior is exploited to turn quartz into a chemical sensor when some chemically interactive material, able to capture molecules from the environment, is used as coating.

The resolution of these transducers is generally in the order of nanograms and for this reason such devices have been called quartz microbalances (QMBs).

In recent years metalloporphyrins have been proposed as sensing elements in mass transducers for the detection of volatile organic compounds (VOCs) [100–103].

Different from optical and electrochemical transducers, a QMB does not influence the selectivity of the sensing layer because, since they respond to mass variations, any kind of material–analyte interaction is recorded.

In the case of metalloporphyrins, both specific interaction, such as coordination to the metal center or π–π interaction with the aromatic system, and nonspecific interaction contribute to the sensing mechanism, so allowing the detection of virtually any kind of VOC. This feature has been confirmed by studying the adsorption isotherm of metalloporphyrin coated QMBs [100, 101]. In the case of ligands that cannot give specific interaction, such as alkanes, the

adsorption isotherm is linear and depends on the solubility of the analyte into the porphyrin matrix, according to the Henry law. When specific interaction can occur, the isotherm showed a Langmuir-like behavior at low concentrations, while at higher concentrations, after the saturation of the specific sites only nonspecific interaction occur and the isotherm became linear [100–103].

Because of the described sensing mechanism, the selectivity of the metalloporphyrins as sensing materials can be finely tuned by modifications of both coordinated metal and peripheral substituents [100–103]. A huge number of the elements present in the periodic table have been coordinated to the porphyrins and furthermore the organic chemistry of these compounds is well developed, and a wide range of different substituents can be introduced at their peripheral positions. All together these characteristics increase the versatility of these molecules as sensing elements for QMB sensors, all showing outstanding properties of these materials in terms of stability, sensitivity, and reproducibility.

Among the different factors influencing the selectivity, the coordinated metal was demonstrated to be one of the most important and this influence was interpreted according to Pearson's principle [104]. In Figure 16 the sensitivity properties of some metalloporphyrins toward model VOCs are reported. The versatility of porphyrins as a chelating system allows the development of a large set of different sensors by changing the coordinated metal. Furthermore the selectivity is influenced by tuning the peripheral substitution patterns of the macrocycle, thus influencing the electronic distribution on the π-aromatic system of the porphyrin and modifying the interaction of the metalloporphyrin with the axial ligands [104].

Another important aspect is represented by the technique chosen for the deposition of metalloporphyrin thin film onto the quartz surface, because the morphology of the film can also influence sensing of the material–analyte interaction.

Because of the stability and versatility of porphyrins, different techniques are available for this purpose and in the case of QMBs, the following have been successfully exploited: (a) spray casting, (b) Langmuir–Blodgett, (c) self-assembled monolayers, and (d) electropolymerization.

Spray casting is the simplest technique and consists of the dissolution of the metalloporphyrin in an organic solvent and then this solution is sprayed onto the QMB surface.

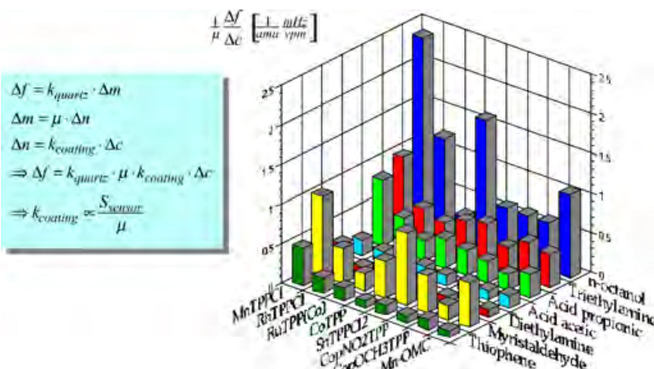

Figure 16. Sensitivities of metalloporphyrin-coated QMB toward different VOCs.

On the other hand, this technique does not control the morphology of the growing film and the reproducibility of the film characteristics can be reduced [104].

Langmuir–Blodgett is a well-known method and allows the deposition of ordered multilayers of porphyrins. It was advantageous to study in detail the mechanism of the metalloporphyrin–analyte interaction [105]. On the other hand the porphyrin should be functionalized in order to have the amphiphilic character necessary for the LB deposition. Alternatively, porphyrin can be deposited in a mixture of fatty acids, but this can be a problem in the case of QMBs, because the adsorption properties of the fatty acid matrix cannot be ignored.

The self-assembled monolayer technique consists of the preparation of functionalized surfaces by chemisorption of functionalized metalloporphyrins onto inorganic substrates. In the case of QMBs, porphyrins bearing sulphide groups at the peripheral positions (Fig. 17) have been chemisorbed onto the gold pad of a QMB [106]. The performances of these sensors have been measured with respect to model volatile compounds of interest for practical applications. While the sensitivities showed by these sensors were higher compared to the corresponding casting coated sensors, the presence of a single layer of the sensing material induced a saturation of the specific sites at very low concentration of the analytes. In Figure 18 the sensitivities of these sensors toward different VOCs have been reported.

Very recently, a chemisorbed chiral porphyrin diad (Fig. 19) has been used for enantiodiscrimination [107]. The enantiodiscrimination properties of such a sensors toward the enantiomeric pairs of chiral analytes have been studied. While in the case of analytes bearing donor ligand atoms no significant enantioselectivity was observed, a significant degree of chiral discrimination has been observed in the case of limonene. In Figure 20 we report the responses of the diad toward saturated vapors of different compounds. The results obtained fitted nicely with the changes observed on the solution visible and CD spectra of the diad. This result

Figure 17. Molecular structure of thiol-functionalized TPP.

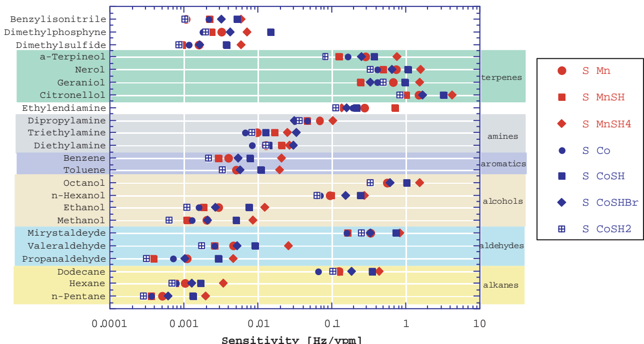

Figure 18. Sensitivities of self-assembled monolayers of metalloporphyrin-coated QMBs toward different VOCs.

was particularly encouraging for the potential development of enantioselective chemical sensors.

The suitability of electropolymerization as a deposition technique has been demonstrated for the development of CMEs. In the case of QMBs, the quartz has been used as a working electrode in an electrochemical cell to deposit thin films of metal complexes of PP-IX [108]. The resulting sensors showed promising performances for the detection of VOCs.

QMB sensors have also been used to investigate the molecular recognition properties of cast films of Zn(II) complexes of porphyrin-resorcinol derivatives (Fig. 21) [109]. These compounds are known to form hydrogen bonded inclusion complexes with appropriate guests and the selectivity showed by these QMB sensors depended on both the formation of hydrogen bond with peripheral OH groups and coordination to the central Zn ion. Furthermore a size dependence in guest selectivity was observed.

One of the drawbacks of QMBs is generally their low resolution for some particular applications. To overcome this problem it has been attempted, maintaining the mass transduction principle, to use surface acoustic wave (SAW) devices as transducers [110]. These devices exploit the propagation of SAWs along layered structures consisting of a piezoelectric substrate coated by a thin film of the sensing material. Changes produced by the adsorption event on the sensing material properties can affect both the phase velocity and the propagation loss of the acoustic wave, although the first is the most generally used. This effect

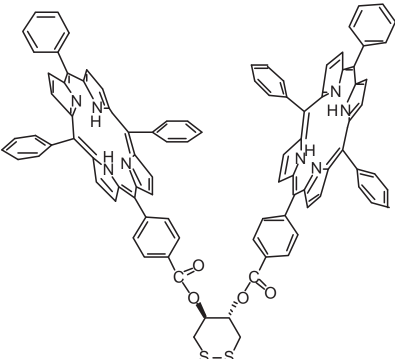

Figure 19. Molecular structure of the porphyrin diad.

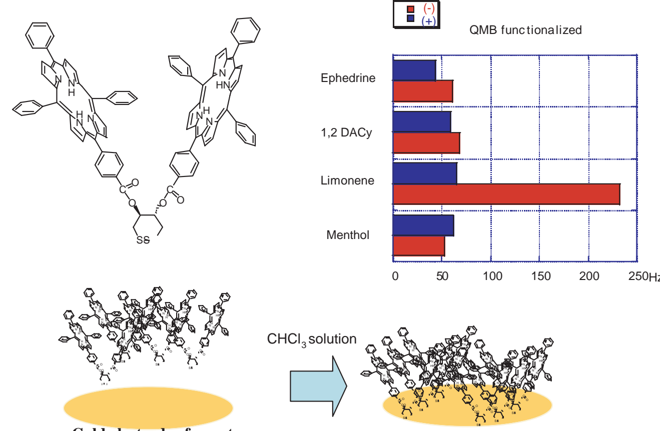

Figure 20. The responses of diad-coated QMB toward saturated vapors of enantiomeric pairs of chiral compounds.

can be easily converted in a frequency shift, provided that a device is configured as a SAW oscillator. Metalloporphyrin-coated SAWs showed positive results for VOC detection, representing an interesting solution for applications in which a high-resolution transduction is necessary, although this approach is more difficult for practical applications, due to the need for more complicated electronic circuits and read-out instruments [110].

Cobalt(II) complexes of picket-fence or picnic-basket porphyrins have been exploited as SAW sensing coatings for the detection of O_2 [111]. The resulting devices were stable toward oxidation and were shown to bind molecular oxygen following a Langmuir isotherm. Although the responses obtained were lower than those observed in solution, the developed SAWs were demonstrated to be useful for the measurement of a wide range of oxygen partial pressures.

6. MISCELLANEOUS

The richness of properties of porphyrins has allowed the exploitation of other kind of transduction mechanisms, although they are not common as these previously described.

The deposition of thin films of metalloporphyrins on the gate of metal oxide semiconductor field effect transistors

Figure 21. Molecular structure of the Zn complex of resorcinol porphyrin.

(MOSFETs) led to the development of the so-called chemFET [112–114]. LB films of different metal complexes of a functionalized T(4-APP) (Fig. 22) used as sensing layers of chemFET were tested for the detection of ambient gases such as NO_2, NH_3, CO, and H_2S. Also in this case the coordinated metal induced the selectivity of the sensor and only the Co derivative was sensitive to NO_2, with 0.5 ppm as the detection limit [112, 113]. More recently metalloporphyrins were deposited on the MOSFET gates by a spray-coating technique or by self-assembly, and the resulting sensors were exploited for the detection of VOC [114]. The performances of the sensors strongly depended on the gate thickness and, among the deposition techniques, the deposition of monolayers showed better sensitivity and stability.

The Kelvin probe has also been used as a transducer to test sensing properties of metalloporphyrin thin films [115]. The Kelvin probe is a well-established method for the measurement of the work function and it has been extensively studied for the characterization of metals and inorganic semiconductor surfaces. It consists of a noncontact, nondestructive vibrating capacitor inducing an alternate current between the sample and a vibrating tip, as a consequence of the contact potential difference resulting from the different work functions of the sample and the reference tip. From the chemical sensor point of view, the Kelvin probe is a simple and relatively fast technique to monitor the variation of surface potential during the adsorption and desorption of gases from and to the vapor phase. Interaction of metalloporphyrin monolayers with different VOCs gave significant Kelvin probe signals, demonstrating the suitability of this technique as a transducer [115]. Dimers of Ni(II)OEP units linked by a butadiyne bridg (Fig. 23) were deposited in mixture with arachidic acid as LB-thin films by Arnold and co-workers [116]. These films were used as sensing layers in chemoresistive sensors and tested for the detection of ammonia. This sensor worked at low temperature (50 °C) and showed a detection limit of 30 ppm.

A novel oxygen sensor has been developed by chemisorption of a disulphide bearing two imidazole groups onto the surface of CdSe; this ligand was used to hinge Fe(III)PP-IX units [117, 118] The sensing event, based on the metalloporphyrin interaction with molecular oxygen, is communicated to the semiconductor surface by the ligand and the transduction mechanism was based on change of the photoluminescence of the semiconductor. The detection limit obtained was in the 0.1 atm oxygen pressure range [118].

Figure 22. Molecular structure of modified T(4-APP).

Figure 23. Molecular structure of the Ni complex of OEP-butadiyne dimer.

A similar approach was used for the immobilization of FeTPPCl on the GaAs surface and the resulting device was able to detect NO in solution at very low concentration (3×10^{-5} mol/L) [119]. This device, in fact, changes its electrical resistivity after adsorption of molecules on the semiconductor surface. Higher resolutions were obtained when hemin was directly chemisorbed, through the peripheral carboxylic chain, to the GaAs surface [120]. This device was able to detect NO at a concentration of 10^{-6} mol/L in physiological solutions and for this reason it represents a fast and simple method for the biosensing of NO.

7. SENSOR ARRAYS

Since its beginning chemical sensor science has been devoted to the development of chemical sensors with improved properties in terms of sensitivity, selectivity, reproducibility, and stability. However, while the sensitivity, reproducibility, and stability are properties necessary to be satisfied, the selectivity needs to be further discussed.

An absolute selectivity of the sensing material (i.e., the ability to detect only a single analyte in any complex mixture) leads to a specific sensor. This kind of sensor is required when we have to qualitatively and quantitatively detect a target compound, such as a toxin, but it is not helpful when we have to assess the quality of an indoor environment or judge the edibility of a food sample. Furthermore it should be considered that to obtain absolute selectivity is a very difficult task and biosensors, where the almost unique catalytic properties of enzymes were exploited, fulfilled in some cases these requirements, whereas the development of supramolecular chemistry concepts has been used to improve the selectivity characteristics of chemical sensors.

For this reason a different concept of selective sensors was introduced at the end of the 1980s [121]. In this approach the sensors should not be specific, but they have to interact with almost all the chemical compounds present in the environment, but with different sensitivities. These sensors should be used in an array configuration and in analogy to the mammalian olfaction these arrays offered the chance to develop artificial olfaction systems.

Although an absolute selectivity is strictly no longer essential, it is, however, of great importance that the sensors

have different sensitivities toward the analytes characterizing the samples under measurement; in this way the sensor responses will not be completely correlated and the maximum of chemical information can be extracted by the sensor array, which can provide recognition and classification of the different measured matrices.

Porphyrins are particularly suitable for this kind of application, because they showed interesting properties as sensing materials and their properties can be tuned by synthetic modifications. For example their selectivity can be modified by changing the coordinated metal and by tuning the peripheral substitution patterns of the macrocycle, thus influencing the electronic distribution on the π-aromatic system of the porphyrin and modifying the interaction of the metalloporphyrin with the axial ligands. Furthermore different transduction mechanisms can be exploited with porphyrins and it is possible to develop sensors operating both in the liquid and in the gaseous phase.

7.1. Gas Phase Sensor Arrays: Electronic Noses

Since 1995 a sensor array based on metalloporphyrin-coated QMBs has been developed. The performance of the developed electronic nose, called LibraNose, has been tested in different fields of applications, ranging from food to clinical analysis [122–132].

For food analyses the objectives of the experiments were different, depending on the particular matrices analyzed, ranging from the recognition of storage time to assessment of food quality.

In the case of the analysis of cod fish and veal meat [122, 123], the aim of the analysis was the classification and recognition of days of storage. In both cases the electronic nose provided a good classification of the data, which was in perfect agreement with the food aging. More recently codfish fillet aging has been studied over a period of 17 days and it was demonstrated that the electronic nose followed the variation of the headspace chemical composition [129]. Furthermore it was showed that misclassification errors were due to the nonlinear evolution of the headspace chemical composition during the spoilage process and not to lack of resolution of the sensor array.

For red wine the electronic nose was exploited to monitor the aroma modification when the wine was exposed to the air; a significant modification was observed three hours after the opening of the bottle, with a qualitative agreement with the expected variation of the taste: it is well known that red wine needs contact with air to enhance its taste [123].

A significant result was obtained in the analysis of tomato paste; in this case the aim of the experiment was the classification of different tomato pastes produced by two different cultivations: biological and traditional. The data obtained with the electronic nose were compared with those obtained by a human panel of trained tasters. Data analysis indicated a good agreement between the classification obtained by the electronic nose and the human panel, but electronic nose showed a lower dispersion of the data and consequently a better definition of classes [124, 125]. A similar comparison was carried out for the analysis of UHT milk samples [123]. In this test, 13 different commercially available brands of UHT milk were taken into consideration. Each of them was analyzed with the electronic nose, while the panel searched the presence and the intensity of a specific sensation, which is a drawback for this particular product: the aroma of burned milk. There was perfect agreement between sensorial analysis and electronic nose results and this was surprising because sensorial analysis was aimed at evaluating only one of the aroma features, while the electronic nose data were related to the whole aroma composition. The same approach was recently followed for the analysis of fruit samples, such as peaches and nectarines, with the aim to define a sensorial profile for these fruits [132].

A different experiment was aimed to measure the aroma decay of oranges over a period of time of about one month, while in the case of apples the study was devoted to the measure of mealiness and skin damage. Results obtained showed that electronic nose was able to correctly predict the amount of defects (apple) and storage days (for oranges) [128].

Electronic nose and spectroscopic techniques were recently integrated to give a virtual instrument devoted to the measurement of some analytical parameters of peach samples [127]. The fusion of visible spectra and electronic nose data gave an interesting method to probe fruit samples in a nondestructive way.

Different olive oils have also been classified by electronic nose analysis [130]. Two different electronic noses were exploited in this study and their data were compared and integrated.

Although food analysis has been the most explored field of application for electronic noses, more recently the medical field was also taken into consideration and the application of the electronic nose to detect diseases was proposed [133–136]. The hypothesis of these studies was that body odor is correlated with human health. Human odor is in fact correlated with the combined action of both gland and bacterial population and any change of the complex equilibrium regulating the organism can induce a change in the nature and amount of volatile organic compounds excreted by the organism. On the other hand medicine recognizes that some pathologies produce unpleasant characteristic odors (for example diabetes and hepatic diseases). As a consequence the exploitation of electronic nose, which is a noninvasive probe, can represent an eligible tool for a preliminary diagnosis of diseases. In particular, the sensor array was able to detect 5a-androst-16-en-3-one, a steroid present in human sweat and supposed to be a male pheromone, with a resolution comparable to that of human olfaction [133]. In a different paper correlation between electronic nose measurements and the ovulation cycle phases in fertile women has been claimed [135].

The metalloporphyrin-QMB sensor array was also exploited for the analysis of the headspace of urines belonging to patients affected by kidney diseases [134]. The electronic nose showed good performance in distinguishing samples containing blood, one of the pathologies induced by the kidney disease, also giving some indication of the blood amount.

More recently, LibraNose has been exploited for the diagnosis of lung cancer [136]. Volatile organic compounds present in expired breath may give a potential source of

information about general metabolic conditions and, in particular, on lung physiology; and breath analysis carried out by combined gas chromatography–mass spectroscopy evidenced that different volatile patterns occur in diseased individuals. The exploitation of the electronic nose to analyze breath from individuals affected by lung cancer resulted in a good classification among the groups of individuals according to their known pathologies, discriminating them from a sample of healthy people measured as reference. A number of patients were measured after the surgical removal of the cancer mass. In this case the nose considered these patients to be healthy. These preliminary results demonstrated a very promising field of application for electronic noses, with an enormous impact for the early diagnosis of diseases.

Other than QMBs, the same authors proposed an electronic nose based on metalloporphyrin based optical sensors [137]. The optoelectronic nose was developed by deposition of thin films of two metalloporphyrins, CoTPP and RhTPPCl, a Mn(III) corrole and a sapphyrin as sensing materials onto a transparent substrate. Commercial, low-price blue-LEDs and photodetectors were used to develop the sensor array. In order to reduce as much as possible the influence of LED intensity fluctuations, a differential measurement strategy was chosen and one position was left free of porphyrin and used as blank reference. In Figure 24 a sketch of the array is reported. The array was exposed to different concentrations of VOCs and was able to discriminate among them. If compared with QMB sensors, optical transduction was demonstrated to give higher resolutions for the same sensing material (Table 5).

Very recently an optical sensor array was constituted of LB films of FeTPPCl, MnTPPCl, CoTMPP, and CoOEP co-deposited with arachidic acid [138]. The system used four LEDs operating at different wavelengths (645, 615, 601, and 546 nm) as light sources. Fiber optics were used to illuminate LB films and to receive the reflected lights. The responses of such a sensors were fast and reversible and the array was able to discriminate the aroma of three different capsicum samples.

Following a different approach, Suslick and co-workers have recently reported a colorimetric electronic nose based on metalloporphyrins [139–142]. The array is formed by spots of different metalloporphyrins deposited onto a silica

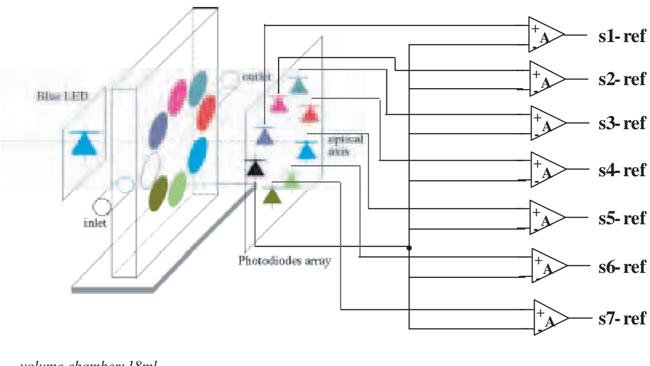

Figure 24. Sketch of the porphyrin-based optical sensor array. Reprinted with permission from [137], C. Di Natale et al., *Sens. Actuators B* 65, 220 (2000). © 2000, Elsevier Science.

support. The image of the array was digitalized by a scanner before and after the interaction with VOC and color change profiles represent the response of the array and are characteristic of the analyzed VOC. In Figure 25 the colorimetric changes observed have been reported. This electronic nose approach has been called SmellSeeing™ [140, 141]. Resolutions down to 2 ppm were obtained for such an array and in some case responses in the range of 100 ppb were recorded. The inherent simplicity, the absence of complicated data analysis, the high sensitivity, and the fast and reversible sensor responses make this approach particularly attractive. Furthermore this approach did not suffer from humidity variation, a parameter of significant importance for practical applications.

Exploitation of this approach to the detection of bacterial growth has been recently reported [142]. The SmellSeeing™ array was able to detect a wide range of VOCs, which can be related to bacterial growth, in the ppb range. This results in the detection of culture of *E. coli* bacteria in short time; promising results were also obtained with the growth of skin and mouth bacteria, making this array particularly promising for the development of real-time, portable, and easy-to-use sensors for bacteria identification.

7.2. Liquid Phase Sensor Arrays: Electronic Tongues

While electronic noses are an established research and development topic, surprisingly, only a few examples of the relative concept applied to liquid samples have been developed, although multivariate analysis with arrays of ion selective electrodes were proposed in the late 1980s [143] and the first electronic tongue, based on ion selective electrodes functionalized with lipid membranes, was proposed at the beginning of the 1990s by Hayashi et al. [144].

The excellent performance of metalloporphyrins in vapor phase chemical sensors led to the exploration of the development of liquid phase sensors based on metalloporphyrins as sensing material, where the metalloporphyrins were immobilized into PVC membranes. The developed electrodes were integrated in an array to develop an electronic tongue based on potentiometric sensors [145, 146]. The developed electronic tongue was integrated with a metalloporphyrin-QMB based electronic nose in the fields of clinical and food analysis. In this way it was possible to extract information from both the liquid and the headspace of the analyzed matrix, resulting in a net increase of performances. This is the first approach to develop a complete artificial sensorial system. More recently CMEs were fabricated by the electropolymerization of different metal complexes of TMHPP on glassy carbon electrodes, using the cyclic voltammetric method [147]. The resulting electrodes were used as potentiometric sensors and demonstrated higher resolution and stability than the corresponding PVC based electrodes. These CMEs were assembled in an array configuration and utilized to analyze several samples. In particular, this array was able to discriminate compounds, each one used as a model of the five classical tastes. These preliminary results were a basic step for the development of porphyrin based taste sensor systems for a variety of applications.

Table 5. Resolution of optical and QMB based porphyrin sensors.

	VOC range (ppm)	$CopNO_2TPP$		RhTPPCl		MnOMC	
		Δc optic.	Δc QMB	Δc optic.	Δc QMB	Δc optic.	Δc QMB

7.3. Data Analysis for Sensor Arrays

Artificial sensorial systems are attempts to reproduce the functions of the natural chemical senses (olfaction and taste). Currently, a sort of standard electronic nose model common to the available implementations of artificial olfaction may be identified. In this model three major subsystems may be identified: sampling, sensor array, and data analysis. While sensor arrays are oriented to exploit the analogies with natural receptors (e.g., cross-selectivity and redundancy) the data analysis does not take advantage of natural data treatment paradigms. The principles of data processing of natural olfaction receptor signals are still rather unknown and the differences in terms of sensors signals make them hardly applicable to process sensor data, although the topic is evolving and first attempts to derive analysis methodologies from natural paradigms have already been proposed [148].

Electronic nose data analysis is rather based on techniques borrowed from other disciplines and chosen among that vast class of algorithms known as pattern recognition.

Pattern recognition in chemistry appeared at the end of the 1960s. Among the first applications the use of the Learning Machine on behalf of the analytical chemists at the Washington State University has to be mentioned. They classified molecules according to molecular structural categories used to form patterns [149].

In the gas sensing area, multivariate methods of pattern recognition are commonly required when sensor arrays, composed of real, nonselective, cross-sensitive sensors, are utilized. Pattern recognition, exploiting the cross-correlation, extracts information contained in the sensor outputs ensemble. Only a few of the manifold of pattern recognition techniques introduced in other disciplines have been utilized ([150–152] offer reviews of the most practiced ones).

Formally, pattern recognition may be defined as "the mapping of a pattern from a given pattern space into a class-membership function" [153].

A pattern can be defined as an ordered set of real numbers. In analytical chemistry, the response of a multichannel instrument to one sample (e.g., gas chromatographs and spectrophotometers) is considered to form patterns. For a sensor array, the responses of the sensors to a sample take the name sensor pattern.

Class-membership space represents either a quantitative or qualitative set of quantities. When quantification is considered the class-membership function turns out to be a vectorial function defined in a metric space. In the case of quality recognition, the class membership is an ensemble of

abstract sets to which each measured sample is assumed to belong. In the first case we prefer to talk of multicomponent analysis while the term pattern recognition is usually referred to for the second case.

Mathematically, a pattern is a vector belonging to its own vector space. The vector space where the sensor responses are represented is the sensor space. The simplest of these representations considers one scalar response for each sensor. This response is called the sensor feature and feature extraction is the operation that extracts, from a sensor response, a number of synthetic descriptors to form patterns.

When a sensor (independently from its working principle) is exposed to a gas or a mixture of gases, it gives a response depending on the nature of the gas and its concentration. Almost the totality of the examples reported in literature are considered, as the sensor response is either the absolute or the relative change in sensor signal measured in two steady-state conditions: in the absence and in the presence of the gas and when all the transients vanished.

Pattern recognition applied to several disciplines and practical problems produced a huge number of algorithms and techniques that are, in principle, applicable to classify electronic nose data. Several of these techniques have been actually utilized and frequently appear in literature. On the other hand, there is not yet an analysis approach based on natural olfaction paradigms. This makes the field almost totally dependent on the developments achieved in other fields. A comparison among the various techniques has also been attempted by some authors, but since the variables determining electronic nose performances are very numerous (choice of sensors, samples, sampling systems, ...) the results achieved are scarcely indicative enough for a sure direction that is valid in general.

Nonetheless some of these techniques became classics of this field (such as scaling and normalization, PCA, and discriminant analysis) and nonetheless, they are often used without a deep understanding of the hypotheses on which they are based and the potentiality of these methods is not yet fully exploited. As for the other components of electronic noses (e.g., sampling system) a rethinking of the assumptions, the implementations, and the interpretation of the methods and solution adopted is highly advised for meaningful improvement in the field.

GLOSSARY

Chemical sensor A device that transforms chemical information, ranging from the concentration of a specific sample component to total composition analysis, into an analytically useful signal (IUPAC). It is composed of two components: a sensing material and a transducer system.

Electronic nose An analytical instrument which comprises an array of electronic chemical sensors with partial specificity and an appropriate pattern-recognition system, capable of recognizing simple or complex odors [by Gardner and Bartlett, *Sensors Actuators* 18–19, 21, (1994)]. An important component of the electronic nose is also a sampling system, which introduces the analytes into the sensor chamber.

Electronic tongue A multisensor instrument for liquid analysis, based on broad selective liquid-phase chemical sensor or arrays and pattern-recognition system.

Metalloporphyrin Metal complex of a porphyrin. The four nitrogen atoms of the inner core of the macrocycle represent a square planar chelating system where the metal ion is coordinated. The coordination sphere of the metal can be completed by additional ligands coordinated at the axial positions.

Porphyrin A tetrapyrrolic macrocycle in which the four pyrrole rings are joined through their α-carbon atoms by four methine bridges. They possess an 18-electron aromatic system, with a conjugation path analogous to that of the annulene series. They are the active nucleus of hemoglobin and chlorophylls.

Sensor array A collection of sensors in which the sensors are all exposed to the same sample, and the responses of the sensors should be interpreted together.

Transducer A device that transforms energy from one kind of system (for example, chemical) to another (for example, physical). In the case of chemical sensors, the interaction of the analyte with the sensing material produces a change in physical/chemical properties, and the transducer generates a proportionally related electrical or optical signal, suitable for further processing.

1. WHAT ARE VESICLES (LIPOSOMES)?

1.1. Introduction

Vesicles—more precisely "*normal* vesicles"—are a particular type of polymolecular aggregate (polymolecular assembly) of certain amphipathic molecules, formed in aqueous solution. A vesicle is composed of one or more closed shells (which are usually 4–5 nm thick) that entrap a small volume of the aqueous solution in which the vesicle is formed. Vesicles are often spherical (under osmotically balanced conditions) and can have diameters between about 20 nm and more than 0.1 mm. If an analogous type of aggregate is formed in a water-immiscible, apolar solvent, the aggregate is called a *reversed vesicle* (see Section 4). In the following, the term "vesicle" or "lipid vesicle" always stands for a normal type of vesicle and *not* for a reversed vesicle.

For the sake of simplicity, a so-called *uni*lamellar vesicle is first considered. It is a closed lamella with an aqueous interior. The lamella is composed of amphipathic molecules, compounds that comprise at least two opposing parts, a hydrophilic part (which is soluble in water) and a hydrophobic part (which is not soluble in water but is soluble in an organic solvent that is not miscible with water, in this context also called "oil"). Amphipathic molecules have a "sympathy" as well as an "antipathy" for water. Because of the mixed affinities within the same chemical structure, amphipathic molecules are also called *amphiphiles* (meaning "both loving," water as well as oil). They are *surfactants*, which stands for "surface active agents" and means that they accumulate at the surface of liquids or solids. The accumulation of surfactant molecules on the surface of water (at the water-air interface) leads to a reduction in the surface tension of water, as a result of an alteration of the hydrogen bonds between the interfacial water molecules.

The aqueous solution in which vesicles form is present outside of the vesicles as well as inside. Figure 1 is a schematic representation of a unilamellar spherical vesicle formed by the amphiphile POPC (1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphocholine) in water at room temperature. The vesicle drawn in Figure 1 is assumed to have an outer diameter of 100 nm. The bilayer has a thickness of only about 4 nm, which corresponds in a first approximation to about two times the length of an extended POPC molecule.

Lipid vesicles in the size range of 0.1 μm (=100 nm) can be visualized by electron microscopy, for example, by the freeze-fracture technique [1, 2], or by cryofixation [2, 3] (see Fig. 2A and B). For vesicles in the micrometer range, light microscopy can be applied [4] (see Fig. 2C).

Based on simple geometric considerations, one can calculate the approximate number of lipid molecules present in a particular defined vesicle. In the case of the unilamellar vesicle shown in Figure 1 (outer diameter 100 nm), about 8.1×10^4 POPC molecules form the shell of one vesicle, and all of these molecules are held together by noncovalent bonds. The single lamella of the giant vesicle shown in Figure 2C (diameter ~ 60 μm) contains about 2.6×10^{10} POPC molecules. The shell is a molecular bilayer with an arrangement of the POPC molecules in such a way that the *hydrophobic* ("water-hating") acyl chains are in the interior of the bilayer and the *hydrophilic* ("water-loving") polar head groups are on the two outer sites of the bilayer, in direct contact with either the trapped water inside the vesicle or with the bulk water in which the vesicle is dispersed. Since the bilayer shell in a sphere is necessarily curved, the number of amphiphiles constituting the inner layer is expected to be smaller than the number of amphiphiles present in the outer layer. For the 100-nm vesicle of Figure 1, the calculated number of POPC molecules is 3.74×10^4 in the inner layer and 4.36×10^4 in the outer layer, assuming a mean head group area of one POPC molecule of 0.72 nm^2 [5]

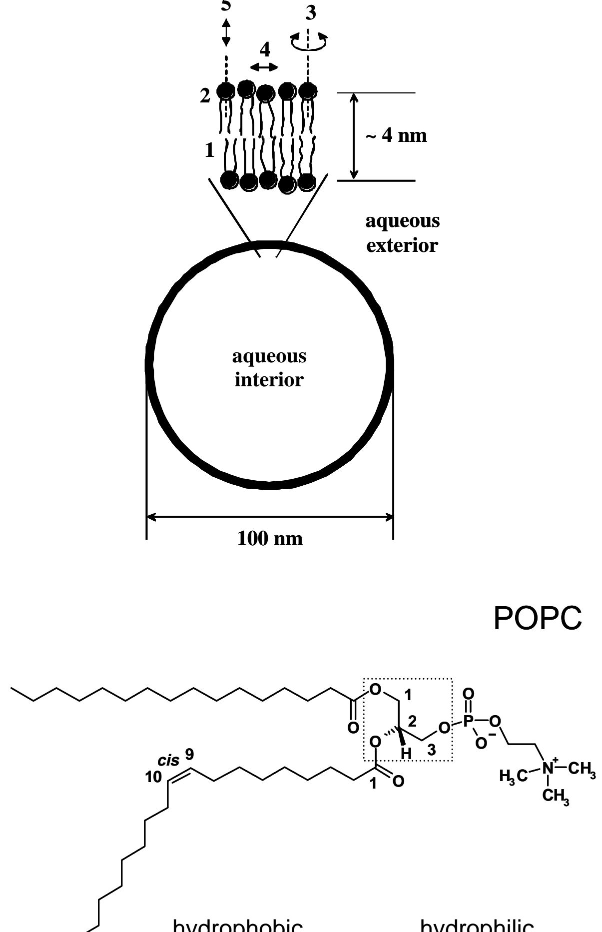

Figure 1. Schematic representation of the cross section through a particular unilamellar, spherical vesicle that has an assumed outer diameter of 100 nm and is formed in water from the surfactant POPC (1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphocholine). POPC constituting the single, closed lamellar shell of the vesicle is represented as a filled circle to which two tails are connected. The tails stand for the two hydrophobic (water-insoluble) chains of POPC, and the filled circle symbolizes the hydrophilic (water-soluble) phosphocholine head group. POPC in the vesicle bilayer is present in the fluid-disordered state, above T_m (see Section 2.3). The chemical structure of POPC, which is a naturally occurring glycerophospholipid, is also shown. The glycerol moiety with its stereospecifically numbered carbon atoms is localized inside the dotted rectangle. The important molecular motions above T_m are indicated: (1) conformational transitions in the hydrophobic tails; (2) conformational transitions in the head group; (3) rotational diffusion about the axis perpendicular to the surface of the bilayer; (4) lateral diffusion within the bilayer plane; (5) vertical vibrations, out of the bilayer plane; and (not shown) collective undulations of the membrane. See text for nomenclature details and [392] for a detailed description of the vesicle membrane dynamics.
S

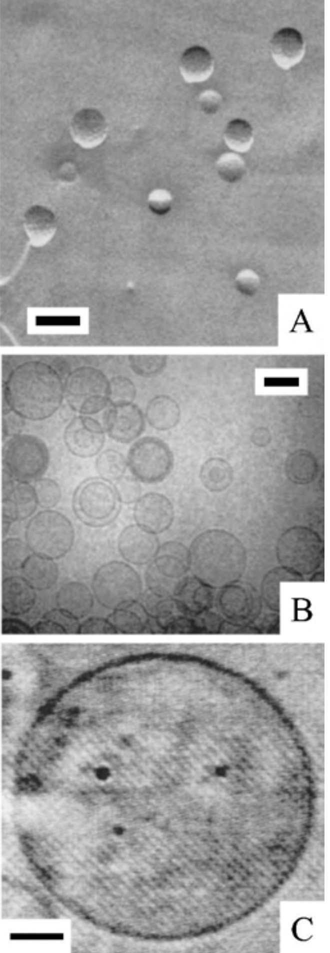

Figure 2. Electron and light microscopic visualization of vesicles prepared from POPC in water at ~ 25 °C. (A and B) Transmission electron micrographs of a suspension containing LUVs (FAT-VET$_{100}$), prepared by the extrusion technique (see Section 3.8 and Fig. 3). The samples were analyzed by the freeze-fracture technique (A) and by cryo-fixation (B). The length of the bars corresponds to 100 nm. (C) Light micrograph (differential interference contrast mode) of a single GUV prepared by the electroformation method (see Section 3.3). Length of the bar: 10 μm. The electron micrographs were taken by M. Müller, E. Wehrli, and N. Berclaz, Service Laboratory for Electron Microscopy, in the Department of Biology at the ETH Zürich. The light micrograph was taken by R. Wick at the Department of Materials Science at the ETH Zürich.

and a bilayer thickness of 3.7 nm [6]. This is certainly a rough estimation, and the real situation in a curved bilayer is always asymmetric with different packing conditions (and mean surfactant head group areas) in the inner and outer layers [7, 8]. Whether vesicles are thermodynamically stable or not (see Sections 2 and 6) depends critically on whether the chains are flexible enough to accommodate these asymmetric constraints [7].

The mean head group area of a surfactant, abbreviated a_0, corresponds to the area that is occupied on average by the polar head group packed within the vesicle's bilayer as a consequence of the actual molecular size and the interaction between the neighboring surfactant molecules. A simple geometric model that, in addition to a_0, takes into account the overall geometric shape of the surfactant as a critical packing parameter (or "shape factor"), p $(=v/(a_0 l_c))$, has been developed [7–10] and successfully applied in a useful simple theory toward an understanding of molecular self-assembling systems at large [11]; v is the volume of the hydrophobic portion of the molecule and l_c is the critical

length of the hydrophobic tails, effectively the maximum extent to which the chains can be stretched out. According to this simple theory, lipid bilayers and vesicles can be prepared if p for a particular amphiphile has a value between 0.5 and 1.0 (conditions under which the surfactants will pack into flexible, curved, or planar bilayers).

1.2. Terminology

There are a large number of amphiphiles that form vesicles. The most intensively investigated are certain lipids present in biological membranes, glycerophospholipids, lipids that contain a glycerol-3-phosphate unit. Actually, the geometric structure of vesicles as *spherulites*—which is the term originally used [12]—containing one (or more) concentric bilayer shell(s) was elaborated for the first time with vesicle preparations made from (mixtures of) naturally occurring glycerophospholipids [12, 13]. This is why it has been proposed to call these aggregates *lipid vesicles* [14] or *liposomes* (actually meaning "fat bodies") [15, 16]. Since the type of aggregate shown in Figures 1 and 2 has not so much to do with a "fat body," it is in principle more appropriate to use the term *lipid vesicle* or just *vesicle* instead of *liposome* [17]. In any case, all of the terms *liposome, lipid vesicle,* and *vesicle* are used here for the same type of polymolecular aggregate. Sometimes, however, one also finds the term *synthetic vesicles* [18, 19], referring to vesicles formed by synthetic, often charged, nonnatural surfactants. Others use the term *vesicle* exclusively for a closed *unilamellar* (not multilamellar) aggregate of amphiphiles [20, 21], such as the one shown schematically in Figure 1. Other names appearing in the literature are *niosomes* (vesicles prepared from nonionic surfactants) [22, 23], *polymer vesicles* or *polymersomes* (vesicles prepared from polymeric surfactants) [24–26], and so on. Table 1 summarizes different terms to describe a particular type of vesicle. Whenever one uses one of these terms, one should specify how it is used and how it is actually defined, to avoid any possible confusion or misunderstanding.

1.3. Nomenclature and Chemical Structures of Vesicle-Forming Glycerophospholipids

Although the basic principles of vesicle formation are for all types of vesicle-forming amphiphiles in the end the same—independently of whether they are charged, neutral, or polymeric—the descriptions in Sections 2 and 3 focus on just one particular group of phospholipids, the so-called phosphatidylcholines (PCs). POPC (see Fig. 1) is a particular PC, namely 1-palmitoyl-2-oleoyl-phosphatidylcholine, more precisely, 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphocholine (also called 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphorylcholine). Since the nomenclature of glycerophospholipids (such as POPC) is often not so well known to those not working with this particular type of biological molecule, a short overview of the main nomenclature rule is given next. The nomenclature of lipids outlined and used here has been proposed by the International Union of Pure and Applied Chemistry–International Union of Biochemistry (IUPAC-IUB) [27, 28].

POPC is a chiral phospholipid with one chiral center at that carbon atom that is localized in the middle of the glycerol moiety; POPC belongs to the *glycerophospholipids*, the quantitatively most important structural group within the class of phospholipids. Glycerophospholipids have a *glycerol* backbone to which a *phosphate* group is bound through a phosphoric acid ester linkage to one of the glycerol hydroxyl groups. To designate the configuration of this glycerol derivative, the carbon atoms of the glycerol moiety are *numbered stereospecifically* (indicated in the chemical name as prefix -*sn*-). If the glycerol backbone is written in a Fischer projection (see, for example, [29]) in such a way that the three carbon atoms are arranged vertically and the hydroxyl group connected to the central carbon atom is pointing to the left, then the carbon atom on top is C-1, the carbon atom in the middle is C-2 (this is the actual chiral center common to all glycerophospholipids), and the carbon atom at the bottom is C-3. With this convention, the chemical structure of 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphocholine is defined. It is the naturally occurring form of the two possible enantiomers. The mirror image of POPC is 2-oleoyl-3-palmitoyl-*sn*-glycero-1-phosphocholine. In the Cahn-Ingold-Prelog nomenclature system (also called the R/S convention) [29], the configuration of C-2 in POPC is R. (Another shorthand description of POPC sometimes used is PamOleGro*P*Cho or PamOlePtdCho [27, 28]; Pam stands for palmitoyl, Ole for oleoyl, Gro for glycerol, P for phosphate, Cho for choline, and Ptd for phosphatidyl).

All naturally occurring diacylglycerophospholipids that have a zwitterionic phosphocholine head group are also called 3-*sn*-phosphatidylcholines, or just *phosphatidylcholines*. In the biochemical and biophysical literature, phosphatidylcholine is also called *lecithin* (or L-α-lecithin because of its stereochemical relationship to the naturally occurring L-α-glycerol-phosphate). Therefore, POPC is a lecithin. The name *lecithin* implies that egg yolk (*lekithos* in Greek) contains large amounts of phosphatidylcholines. According to the IUPAC-IUB, the use of the term *lecithin* is permitted but not recommended [27]. It is indeed better to avoid using this term since it may have another meaning in the food technology literature. The International Lecithin and Phospholipid Society (ILPS) of the American Oil Chemists Society (AOCS) defines *lecithin* as a mixture of lipids obtained from animal, vegetable, or microbial sources, which includes PCs but also contains a variety of other substances, such as sphingosylphospholipids, triglycerides, fatty acids, and glycolipids [30].

Egg yolk is one of the cheapest commercial sources for the isolation of phosphatidylcholines; the other one is soybeans. Phosphatidylcholines from egg yolk contain a number of chemically different phosphatidylcholines. All of these PCs have, however, the same glycerol backbone and the same polar head group (phosphocholine). They only differ in the acyl chains esterified with the glycerol hydroxyl groups at C-1 and C-2 (see Table 2) [31].

Many studies on the preparation and characterization of lipid vesicles have been carried out with egg yolk PC. On average, in position C-1 in egg yolk PC is often palmitic acid, and in position C-2, oleic acid [31]. POPC is therefore a representative PC molecule for egg yolk PCs. In contrast to egg yolk PCs, however, POPC has a well-defined chemical

Table 1. List of some of the terms used to describe a particular type of vesicle.

Term	Meaning and use of the term in the literature
Algosome	Vesicle prepared on the basis of 1-*O*-alkylglycerol [485].
Archaesome	Vesicles prepared from archaebacterial, bolaamphiphilic lipids [359, 486].
Bilosome	Vesicle prepared from a particular mixture of non-ionic surfactants (1-monopalmitoyl-glycerol), cholesterol, dihexadecylphosphate (5:4:1 molar ratio), and bile salt (particularly deoxycholate) [487].
Catanionic vesicle	Vesicle prepared from a mixture of a cationic and an anionic surfactant [59, 488].
Cerasome	Vesicle with a silicate framework on its surface [366, 489].
Ethosome	Vesicle that contains in the final preparation a considerable amount of ethanol (prepared by a particular method described in Section 3.20) [229–231].
Fluorosome	SUV containing a fluorescent dye embedded in its bilayer to monitor the entry of molecules into the bilayer [490–492].
Hemosome	Hemoglobin-containing vesicle [493].
Immunoliposome	Vesicle as a drug delivery system that contains on the external surface antibodies or antibody fragments as specific recognition sites for the antigen present on the target cells [69, 373, 494].
Lipid vesicle	Vesicle prepared from amphiphilic lipids [31, 69].
Liposome	Vesicle prepared from amphiphilic lipids [31, 69].
Magnetoliposome	Vesicle containing magnetic nanoparticles (e.g., magnetite Fe_3O_4) [495–498].
Marinosome	Vesicle based on a natural marine lipid extract composed of phospholipids (PCs and phosphatidylethanolamines) containing a high amount (~65%) polyunsaturated aycl chains [499].
Niosome	Vesicle prepared from non-ionic surfactants [23, 500]. In some cases, at room temperature polyhedral niosomes exist, which transform into spherical niosomes upon heating, cholesterol addition, or sonication [501–503].
Novasome	Oligo- or multilamellar vesicle prepared by a particular technology that involves the addition of vesicle-forming surfactants in the liquid state (at high temperature) to an aqueous solution (Section 3.10) [185].
Phospholipid vesicle	Vesicle prepared from (amphiphilic) phospholipids [71].
PLARosome	Phospholipid-alkylresocinol liposome: phospholipid vesicle containing resorcinolic lipids or their derivatives [504].
Polymer vesicle	Vesicle prepared from polymeric amphiphiles, such as di- or triblock copolymers [24, 26].
Polymerized vesicle	Vesicle prepared from polymerizable amphiphiles that were (partially) polymerized after vesicle formation [33, 352, 353, 505].
Polymersome	Vesicle prepared from polymeric amphiphiles, such as di- or triblock copolymers [24, 26].
Proliposomes	A preparation that upon mixing with an aqueous solution results in the formation of vesicles. The preparation contains vesicle-forming amphiphiles and an alcohol (ethanol, glycerol, or propyleneglycol) (see Section 3.19). Dry (ethanol-free) granular preparations of vesicle-forming amphiphiles, which upon hydration lead to vesicle formation, are also called proliposomes (Section 3.19) [506].
Proniosomes	A dry, granular product containing mainly (but not exclusively) non-ionic surfactants which, upon the addition of water, disperses to form MLVs [507].
Reversed vesicle	Inverted vesicle formed in a water-immiscible, apolar solvent in the presence of a small amount of water (Section 4) [508].
Spherulite	Onion-like vesicle prepared with spherulite technology, which involves the use of shear forces (Section 3.11).
Sphingosome	Vesicle prepared on the basis of sphingolipids present in human skin [69, 509].
Stealth liposome	Sterically stabilized vesicle, achieved through the use of co-amphiphiles that have PEG (poly(ethyleneglycol))-containing hydrophilic head groups [510–512]. Stealth liposomes are not so easily detected and removed by the body's immune system (they are long-circulating in the blood). The name stems from an analogy to the American "Stealth bomber" aircraft, which is not easily detected by radar. Alternatively to PEG, polysaccharides have also been used [373].
Synthetic vesicle	Vesicle prepared from synthetic surfactants (surfactant mixtures) that are not present in biological membranes. The surfactants usually have a single hydrophobic tail [17, 488].
Toposome	Vesicle that has a surface that is site-selectively (toposelectively) modified in a stable manner at specific and deliberate locations (e.g., through chemical modifications or chemical functionalizations) [513].
Transfersome	Ultradeformable ethanol-containing mixed lipid/detergent vesicle claimed to transfer water-soluble molecules across human skin (Section 3.28) [275, 276].
Ufasome	Vesicle prepared from unsaturated fatty acid/soap mixtures [330].
Vesicle	General term to describe any type of hollow, surfactant-based aggregate composed of one or more shells. In the biological literature, the term *vesicle* is used for a particular small, membrane-bounded, spherical organelle in the cytoplasm of an eukaryotic cell [97].
Virosome	Vesicle containing viral proteins and viral membranes, reconstituted from viral envelopes, the shells that surround the virus [69, 514–516].

Note: In this chapter, all of the terms listed in the table are called vesicles (or lipid vesicles), independent on the chemical structure of the amphiphiles (surfactants) constituting the vesicle shell(s).

structure. For more basic studies, POPC may be more suited than the egg yolk PC mixture. For applications, however, the cheaper egg yolk PCs may be advantageous.

Although lipid vesicles prepared from egg yolk PCs are similar in many respects to vesicles prepared from POPC, the properties of POPC vesicles at a particular fixed temperature may be very different from those of the chemically related DPPC (1,2-dipalmitoyl-*sn*-glycero-3-phosphocholine) vesicles, for example. The reason for this is outlined in Section 2.

Table 2. Main approximate fatty acid content in egg yolk and soybean PCs (see [31]).

		Relative abundance in phospholipids					
		Egg yolk			Soybeans		
Fatty acid (trivial name)	Abbreviation	Total (%)	at *sn*-1 (%)	at *sn*-2 (%)	Total (%)	at *sn*-1 (%)	at *sn*-2 (%)
Hexadecanoic acid (palmitic acid)	C 16:0	~35	~69	~2	~17	~34	
Octadecanoic acid (stearic acid)	C 18:0	~14	~26	~1		~8	
Cis-9-octadecenoic acid (oleic acid)	C 18:1*c*9	~27	~5	~49	~23	~30	~16
Cis, cis-9,12-octadecadienoic acid (linoleic acid)	18:2*c*9*c*12				~48	~24	~71
Cis, cis-6,9-octadecadienoic acid	18:2*c*6*c*9	~6		~11			
All *cis*-9,12,15-octadecatrienoic acid	18:3*c*9*c*12*c*15				~9	~4	~13
All *cis*-5,8,11,14,17-eicosapentaenoic acid	20:5*c*5*c*8*c*11*c*14*c*17	~4		~7			
All *cis*-4,7,10,13,16,19-docosahexaenoic acid	22:6*c*4*c*7*c*10*c*13*c*16*c*19	~13		~25			

Note: The abbreviation 16:0, for example, indicates that the linear fatty acid has 16 carbon atoms without any double bonds; 18:1*c*9 indicates that the linear fatty acid is composed of 18 carbon atoms with one *cis* double bond in position 9,10 (starting at position 9), where the carboxy C atom is carbon number 1.

1.4. There Are Not Only Unilamellar Vesicles

Vesicles are not only classified by the chemical structure of the molecules constituting the vesicle shell(s) as reported in Table 1, but also according to their size, lamellarity and morphology, and method of preparation (see Table 3). Small unilamellar vesicles (SUVs) have one lamella and diameters of less than about 50 nm. So-called large unilamellar vesicles (LUVs) have one lamella and diameters between about 50 nm and about 500 nm (see Fig. 1 and Fig. 2A and B). Giant vesicles (GVs) can be observed by light microscopy and have diameters of more than about 0.5–1 μm (Fig. 2C). Oligolamellar vesicles (OLVs) have a few and multilamellar vesicles (MLVs) have many concentrically arranged lamellae. Multivesicular vesicles (MVVs) contain nonconcentrically arranged vesicles within a larger vesicle.

As described in detail in Section 3, the preparation of vesicle suspensions generally involves the use of a particular technique, a particular preparation method. Depending on the technique applied, the vesicle suspensions are characterized by a certain degree of homogeneity, a certain mean size and mean lamellarity, and a certain trapped volume. The trapped volume is the aqueous volume that is encapsulated by the lipid vesicles, expressed as microliters of aqueous solution per micromole of lipid (=liters/mol). A trapped volume of 1 μl/μmol means that in a vesicle suspension containing 1 μmol lipid, for example, only 1 μl of the aqueous solution is trapped by the vesicles. The spherical unilamellar POPC vesicle shown in Figure 1 has a trapped volume of about 3 μl/μmol, as calculated based on simple geometric considerations. This means that in a vesicle suspension prepared from 10 mM POPC (=7.6 g/liter), only 30 μl out of 1 ml is trapped by the vesicles (3 volume %). The total lipid-water interfacial area in this vesicle suspension is 4.3×10^3 m^2!

Since, in many cases, the vesicle suspensions prepared by one particular technique are not further characterized with respect to mean size, size distribution, and lamellarity, the vesicles are just named according to the method used. Examples include REVs (reversed-phase evaporation vesicles, vesicles prepared by the so-called reversed-phase evaporation method), VETs (vesicles prepared by the so-called extrusion technique), etc.; see some entries in Tables 1 and 3.

2. VESICLES AND THE LIQUID CRYSTALLINE STATES OF SURFACTANTS

2.1. Introduction

Since in most cases, lipid vesicles can be considered as dispersions of a liquid crystalline state of a vesicle-forming surfactant, it is useful to give a short introduction to some of the liquid crystalline phases of amphiphilic molecules, particularly focusing on the so-called L_α- and L_β- or L'_β-phases, which are considered to be the relevant thermodynamic equilibrium states of most glycerophospholipids under the conditions in which vesicle formation is observed. For a recent excellent general review on surfactant liquid crystals, see [32].

Table 3. List of some of the abbreviations often used for a particular type of ve sicle.

Abbreviation	Meaning of the abbreviation	Characteristics
DRV	Dehydrated-rehydrated vesicle (or dried-reconstituted vesicle)	Vesicle prepared by the dehydration-rehydration method (Section 3.7) [31]
EIV	Ethanol-injected vesicle	Vesicle prepared by the ethanol injection method (Section 3.18)
FATMLV	Vesicle prepared by repeatedly freezing and thawing a MLV suspension	Equilibration and homogenization procedure (Section 3.6) [133]
v FPV	Vesicle prepared with a French press	Unilamellar vesicle or OLV prepared with a French press for vesicle size homogenization (Section 3.8) [72]
GUV	Giant unilamellar vesicle	Unilamellar vesicle with a diameter larger than about 500 nm
GV	Giant vesicle	Vesicle with a diameter larger than about 500 nm
IFV	Interdigitation-fusion vesicle	Vesicle prepared by the interdigitation-fusion method (Section 3.21) [232, 517]
LUV	Large unilamellar vesicle	Unilamellar vesicle with a diameter between about 50 nm and 500 nm
LUVET	Large unilamellar Vesicle prepared by the extrusion technique	Vesicles prepared by the extrusion technique are usually large and mainly unilamellar (Section 3.8)
MLV	Multilamellar vesicle	The vesicle contains several concentrically arranged lamellae osmotically stressed after formation because of an exclusion of solute molecules during their formation [76]
MVL	Multivesicular liposome	A large vesicle that contains internal, nonconcentrically arranged vesicular compartments; also called MVV [211, 212]
MVV	Multivesicular vesicle	A large vesicle that contains internal, nonconcentrically arranged vesicular compartments; also called MVL [210]
OLV	Oligolamellar vesicle	The vesicle contains a few concentrically arranged lamellae
REV	Reversed-phase evaporation vesicle	Vesicle prepared by the reversed-phase evaporation technique (Section 3.14)
RSE vesicle	Rapid solvent exchange vesicle	Vesicle prepared by the rapid solvent exchange method [238]
SPLV	Stable plurilamellar vesicle	Similar to MLV but not osmotically stressed after its formation [76]
SUV	Small (or sonicated) unilamellar vesicle	Unilamellar vesicle with a diameter of less than about 50 nm, as typically obtained by sonicating MLVs (Section 3.5)
ULV	Unilamellar vesicle	Vesicle with only one lamella
UV	Unilamellar vesicle	Vesicle with only one lamella
VET	Vesicle prepared by the extrusion technique	Vesicles prepared by the extrusion technique are usually large and mainly unilamellar (Section 3.8)

Note: The abbreviations are based on the size and morphology, the lamellarity, or method of preparation.

2.2. Lamellar Phase and "Gel Phase"

A liquid crystalline state (also called the "mesophase") of a substance is a state between a pure crystal (characterized by a high order of rigid molecules) and a pure liquid (characterized by rapid molecular motions of disordered molecules) [32]. There are dozens of different liquid crystalline states, all characterized by a different degree of molecular mobility and order. Liquid crystals can be produced either by heating a particular crystalline solid—called a "thermotropic liquid crystal"—or by dissolution of particular substances in a solvent—called a "lyotropic liquid crystal." Many surfactants in water form lyotropic liquid crystalline phases, such as the lamellar phase (L_{α}), the so-called gel phase (L_{β} or L'_{β}), the normal or reversed hexagonal phase (H_I or H_{II}), or one or more of the known cubic phases (Ia3d, Pn3m, Im3m). The type of phase formed depends on the chemical structure of the surfactant used and on the experimental conditions (such as concentration and temperature, or the presence of other compounds).

In the L_{α}-phase (also called the liquid-analogue [33] or liquid-disordered state [34, 35]), the surfactant molecules are arranged in bilayers, frequently extending over large distances (1 μm or more) [32]. The hydrophobic chains are rather disordered, with a lot of *gauche* conformations in the saturated hydrocarbon parts of the hydrophobic chains, making the bilayers fluid, characterized by fast lateral and rotational diffusions of the surfactant molecules, similar to a liquid. Comparable molecular motions are also present in the liquid-disordered state of vesicles. In the case of SUVs prepared from POPC, for example, the lateral diffusion coefficient seems to be on the order of $3–4 \times 10^{-8}$ cm^2/s, as determined between 5 °C and 35 °C [36]. The rotational correlation time is on the order of 10^{-9} to 2×10^{-8} s [37].

The L_{β} (or L'_{β}-)-phase of surfactant molecules (also called solid-analogue [33] or solid-ordered state [34, 35]) closely resembles the L_{α}-phase in the sense that the surfactant molecules are also arranged in bilayers. The viscosity is very high, however. This is a consequence of the rigidity of the individual surfactant molecules which are mostly present with all-*trans* conformations in the saturated hydrocarbon parts of the hydrophobic chains. The motion of the molecules is rather restricted, similar to the molecules in a crystal. To specify the relative arrangement of the lipid molecules, the gel phase may be abbreviated as L'_{β} or L_{β},

depending on whether the alkyl chains are tilted (P'_{β}) or not titled (L_{β}) with respect to the normal of the lipid bilayer. If it is not known whether the chains are tilted, L_{β} is often used as a general abbreviation.

The phase behavior of a number of phosphatidylcholines [38, 39] and a number of other lipids and lipid mixtures [38, 40] has been determined and reviewed.

2.3. Main Phase Transition Temperature T_m of Glycerophospholipids

In the case of conventional glycerophospholipids, either DPPC or POPC, the P'_{β}-phase is formed at thermodynamic equilibrium at temperatures at least 5–10° below a lipid specific temperature called the main phase transition temperature (or lamellar chain melting temperature) (T_m). T_m is also called the lamellar gel-to-liquid crystalline phase transition temperature and can be determined, for example, as the endothermic peak maximum in heating scans of differential scanning calorimetry (DSC) measurements [41–43]. Above T_m the lipids are in the L_{α}-phase.

Between the L_{β}- (or P'_{β}-) phase and the L_{α}-phase, an intermediate gel phase, called the ripple phase (abbreviated as P'_{β}) is often observed at high water content in the case of PCs [44]. This particular lipid phase takes its name from the fact that in freeze-fracture electron micrographs, a "ripple" structure can be seen if the lipid dispersion is rapidly frozen from the particular temperature interval in which the ripple phase is formed [44–47]. The transition from the "gel phase" to the "ripple phase" is called *pretransition*.

With respect to certain practical aspects in the methods for lipid vesicle preparations described in Section 3, the T_m value of the lipid (or the lipid mixtures) used is important to know. In the case of dilute POPC-water systems, for example, T_m is around −3 °C [48, 49]. If the water content is decreased below ~10 wt%, T_m increases above 0 °C, until it reaches a value of 68 °C in the anhydrous system [49].

A list of different T_m values for a number of dilute aqueous phosphatidylcholine systems (MLVs) is given in Table 4. For a more detailed list of T_m values, including other glycerophospholipids, see [38, 40, 50]. Please note that in the case of phospholipids with charged head groups, the T_m values depend on the degree of protonation and may depend considerably on the chemical nature of the counter-ions present [51]. Furthermore, measurements carried out with SUVs give values about 4–5° lower than the T_m values obtained from MLVs [43, 52, 53].

Table 4. Main $P_{\beta'}$-L_{α} phase transition temperature (T_m) values of dilute aqueous dispersions of certain common bilayer-forming phosphatidylcholines, data taken from [39] and [518] (for soybean PCs).

Phosphatidylcholine	T_m (°C)
DMPC (1,2-dimyristoyl-*sn*-glycero-3-phosphocholine), 14:0/14:0	23.6 ± 1.5
DPPC (1,2-dipalmitoyl-*sn*-glycero-3-phosphocholine), 16:0/16:0	41.3 ± 1.8
DSPC (1,2-distearoyl-*sn*-glycero-3-phosphocholine), 16:0/16:0	54.5 ± 1.5
POPC (1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphocholine), 16:0/18:1*c*9	−2.5 ± 2.4
SOPC (1-stearoyl-2-oleoyl-*sn*-glycero-3-phosphocholine), 18:0/18:1*c*9	6.9 ± 2.9
DOPC (1,2-dioleoyl-*sn*-glycero-3-phosphocholine), 18:1*c*9/18:1*c*9	−18.3 ± 3.6
Egg yolk PCs (see Table 2)	−5.8 ± 6.5
Soybean PCs (see Table 2)	−15 ± 5
Hydrogenated soybean PCs	51–52

Note: 16:0/18:1*c*9, for example, indicates that the linear acyl chain at *sn*-1 has 16 carbon atoms without any double bonds; the linear acyl chain at *sn*-2 has 18 carbon atoms with one *cis* double bond in position 9,10 (see also Table 2).

3. METHODS FOR PREPARING NORMAL VESICLES

3.1. Introduction

The thermodynamic equilibrium state of glycerophospholipids (and many other bilayer-forming amphiphiles) in water (or in a particular aqueous solution) is—probably under most experimental conditions—a stacked bilayer arrangement of the surfactant molecules, either as L_{α}-phase (above T_m) or as L_{β}-, P'_{β}- (or $P_{\beta'}$)-phase (below T_m) in equilibrium with excess aqueous phase (see Section 2).

Upon dispersing in an aqueous solution, vesicles generally form from an amphiphile (or a mixture of amphiphiles) that forms a lamellar L_{α}-phase at thermodynamic equilibrium. Depending on how the dispersion is actually prepared (in other words, which method or technique is applied), the vesicles formed by the dispersed amphiphiles are either very heterogeneous or rather homogeneous and are mainly small (below about 50 nm), mainly large (between about 50 nm and 500 nm), or mainly very large (above about 500 nm). It all depends on the lipid (or lipid mixture) used, on the aqueous solution, and particularly on the preparation method.

In the following, the principles of some of the best known and widely used methods for the preparation of lipid vesicle suspensions—mainly on a laboratory scale of a few milliliters up to about 100 ml—will be described. For each method, a different vesicle preparation with different typical general characteristics is obtained.

It is important to point out once more that in most of the cases the resulting vesicle suspension is not at thermodynamic equilibrium, but represents only a metastable, kinetically trapped state. The equilibrium phases are L_{α}, $P_{\beta'}$, L_{β} or L'_{β}, as discussed in Section 2. A particular vesicle dispersion prepared is therefore physically (with respect to vesicle size and lamellarity) not indefinitely stable; it may slowly transform into the thermodynamically most stable state (stacked bilayers), as a result of a so-called aging process [54, 55]. This aging may occur either through the fusion of vesicles or because of an exchange of amphiphiles that are not aggregated (free, monomeric surfactant) [55]. This latter process—called Ostwald ripening (in analogy to the corresponding process occurring in emulsion systems)—is expected to be particularly relevant in the case of synthetic short-chain amphiphiles with a high monomer solubility (10^{-8} M). In the case of DPPC (and probably also POPC), the monomer solubility is on the order of 10^{-10} M [56], which means that aging through an Ostwald ripening process is less likely in these cases.

Although often only metastable, vesicle suspensions may be stable for a prolonged period of time, for example, for days, weeks, or months, provided that the vesicle-forming amphiphiles are chemically stable during this period of time [57, 58].

In the presence of other amphiphilic molecules (cosurfactants), the situation may change, particularly if the cosurfactant tends to form micellar aggregates, characterized by a packing parameter $p \sim 1/3$ (relatively large head group cross-sectional area, a_0). In this case mixed micelles may exist at thermodynamic equilibrium (in equilibrium with cosurfactant monomers), if the micelle-forming surfactant is present to a large extent. Such mixed micellar systems are used as a starting solution in the case of the so-called detergent depletion method described in Section 3.27. Furthermore, there are also known cases where there appear to be thermodynamically stable vesicles (particularly composed of mixtures of surfactants) [59, 60] (see Section 6).

The presence of cholesterol (or other sterols)—molecules that are water insoluble and do not form vesicles alone—may also influence the properties of lipid vesicles, depending on the amount of cholesterol present [61, 62]. In the case of DPPC, for example, up to 33 mol% cholesterol, the T_m value of hydrated bilayers changes only slightly [63]. With increasing cholesterol concentration, however, the phase transition temperature is completely eliminated at 50 mol% (1:1 molar ratio of DPPC to cholesterol). The fluidity of the bilayer membrane is thereby changed, resulting in an increase in the fluidity below T_m of the PC and a decrease in fluidity above T_m, a state of the membranes that is intermediate between solid-ordered and liquid-disordered (see Section 2.3). This state is called liquid-ordered [34].

For all of the methods outlined in the following, more detailed descriptions can be found in the original literature cited. Furthermore, most of the generally known methods have already been summarized before—more or less extensively—in review articles or books about lipid vesicles (liposomes) [14, 31, 64–75].

Most of the methods can be roughly divided into two groups:

(i) Methods that are based on the simple swelling of initially dried, preorganized lipids and the mechanical dispersion and mechanical manipulation of the dispersed bilayers (Sections 3.2–3.12).

(ii) Methods that involve the use of (a) a cosolvent in which the lipids are soluble (Sections 3.14–3.26 and 3.30), (b) an additional non-bilayer-forming "helper amphiphile," a coamphiphile (Sections 3.27 and 3.30), or (c) certain ions that influence the initial aggregational state of the lipids (Sections 3.13 and 3.29). All three type of molecules control the assembly process of the bilayer-forming amphiphile in a particular way during the vesicle preparation process, and all three types of molecules may at the end be difficult to remove completely from the final vesicle suspensions.

3.2. MLVs, GUVs, or Myelin Figures Formed by Thin Lipid Film Hydration

One of the easiest ways to prepare a vesicle suspension is to disperse a dried lipid film in an aqueous solution [13, 76, 77]. The vesicle-forming and swellable [78] amphiphile is first dissolved in an organic solvent in which the amphiphile is soluble (usually chloroform). This solution is then placed inside a round-bottomed flask, and the solvent is completely removed by rotatory evaporation under reduced pressure, followed by high-vacuum drying overnight. The remaining amphiphiles form a dry thin film that is oriented in such a way as to separate hydrophilic and hydrophobic regions from each other [31]. If an aqueous solution is added to this film at a temperature above the main phase transition temperature T_m (see Section 2.3), the head groups of the dry lipids become hydrated and hydrated bilayers form. The hydration and swelling process is usually speeded up by gentle or vigorous shaking (using a vortex mixer), thereby dispersing the bilayers in the aqueous solution, resulting in the formation of mainly MLVs, which are very heterogenous with respect to size and lamellarity. Lipid film thickness and extent of shaking have an influence on the properties of the resulting vesicle suspension. The interlamellar repeat distance in equilibrated, completely hydrated PC bilayers above T_m is around 6.5 nm [79, 80]. This means that in a MLV formed from POPC as example, the aqueous space between two neighboring lipid lamellae is about 2.5 nm thick (taking into account a bilayer thickness of 4 nm). On average, a MLV may be composed of up to 10 bilayers [81].

The formation of closed bilayers (vesicles), in contrast to open bilayers, can be easily understood on the simple basis that interactions between the hydrophobic chains of the amphiphiles and the water molecules—as would be the case in open bilayers—are energetically unfavorable and therefore rather unlikely.

The preparation of MLVs by the dispersal of a dried lipid film (also called hand-shaken MLVs [31]) is often a first step in the preparation of more defined vesicle suspensions (see, for example, Sections 3.5 and 3.8). With respect to the equilibration of water-soluble molecules between the bulk aqueous medium and the inner aqueous compartments of MLVs, ionic species may be unevenly distributed [76]. A more even distribution can be achieved by applying freeze/thaw cycles (see Section 3.6).

The experimental conditions under which a dried lipid film is hydrated affect the resulting lipid aggregates obtained. In the case of phospholipid mixtures containing 90 mol% PC and 10 mol% of a negatively charged phospholipid (egg yolk phosphatidylglycerol, bovine brain phosphatidylserine, or bovine heart cardiolipin), the dried lipid film prepared inside a test tube can first be prehydrated at 45 °C with water-saturated nitrogen gas for 15–25 min. Afterward, an aqueous solution containing water-soluble molecules to be entrapped (e.g., 100 mM KCl and 1 mM $CaCl_2$) is gently added, and the tube is sealed under argon and incubated at 37 °C for 10–15 h. During this incubation, the lipid film is completely stripped from the glass surface and forms vesicular aggregates as a kind of white, floating precipitate in the aqueous solution. The analysis of this

precipitate indicated the presence of many mainly unilamellar giant vesicles (not MLVs) with diameters on the order of tens of micrometers up to more than 300 μm [82]. In addition, much smaller vesicles, large multilamellar vesicles as well as myelin figures (see below) and undispersed lipid material, could also be observed [82]. In the case of egg PC alone (no negatively charged phospholipids present), no giant unilamellar vesicles (GUVs) formed under the experimental procedure used [83]. It therefore seems that electrostatic repulsions between the charged head groups facilitate the formation of unilamellar membranes by opposing the intrinsic adhesive force between the membranes [83]. If divalent cations (1–30 mM Ca^{2+} or Mg^{2+}) are present, giant vesicle formation is also observed with zwitterionic phospholipids alone (POPC), with the use of a procedure almost identical to the one just described [84]. Divalent cations seem to promote giant unilamellar vesicle formation in the case of POPC due to a binding of the ions to the free phosphate oxygen of the lipid head group, which is known to alter the mean head group conformation [85] and the fluidity of the lipid bilayer [86], and which makes a zwitterionic PC molecule positively charged overall [87].

In an independent study and with a different experimental procedure, the formation of giant vesicles from PCs (DOPC or soybean PCs) in the presence of Mg^{2+} ($<$10 mM) has also been observed [87].

The general role of ions (including buffer ions)—as well as dissolved gas molecules—in vesicle formation and in physical chemistry at large is an open question [88] (see Section 6).

The preparation of MLVs by thin lipid film hydration generally involves the use of round-bottomed flasks and gentle shaking. If flat-bottomed flasks are used instead and if additionally the lipid swelling process occurs undisturbed (no shaking) above T_m of the lipids [89] over a period of several hours, the vesicles formed are no longer mainly multilamellar but rather mainly unilamellar, with diameters between 0.5 and 10 μm [90] or even at 300 μm [91]. These are GUVs.

The preparation of GUVs by simple hydration of certain amphiphiles deposited from an organic solution (e.g., a chloroform-methanol mixture) on a flat surface can be considerably improved to yield a higher fraction of unilamellar vesicles by using a roughened flat disk of Teflon (polytetrafluoroethylene) [92]. The vesicles formed (e.g., from DMPC after a slow swelling at a temperature of 30–35 °C) can be harvested by gentle pipette aspiration for further individual investigation and micromanipulation [92, 93]. The sizes of the vesicles thus formed are in the range of 20–40 μm [93, 94].

The slow swelling of dried phosphatidylcholines with the addition of water had already been observed and investigated by light microscopy in the middle and at the end of the nineteenth century by Rudolf Virchow [95] and Otto Lehmann [96]. The elongated, tubular structures that are observed to grow from a deposit of PC molecules (e.g., egg yolk PCs) with the addition of water under undisturbed conditions (no shaking) are called myelin figures, as named by Virchow [95] while making these observations with a (PC-containing) lipid extract from myelin, the isolating lipid sheath surrounding the elongated portion of nerve cells [97]. Myelin figures are structures dozens of micrometers long and a few micrometers thick. In the case of egg yolk PCs and 25 °C, water addition leads to the formation of myelin figures that have a diameter of about 20 μm and a length of several hundred micrometers [98]. Myelin figures are cylindrical, rodlike structures composed of many lamellae formed by the amphiphiles, stacked coaxially around the rod axis, with water between all of the bilayers [98, 99].

The conventional solid surface on which the lipid film is initially dried—glass, as described above—has been replaced by a support made from microcrystals (such as zeolite X with a crystallite size of 400 nm) [100]. Using very dilute mixtures of egg yolk PC and the positively charged amphiphile hexadecyltrimethylammonium bromide, the swelling in water (or 5 mM NaCl) of the very thin dried film deposited on zeolite X led neither to the formation of MLVs nor to GUVs or myelin figures, but to uniform SUVs with diameters around 22 nm [100]. In general, the size distribution can be controlled to some extent by the topography of the surface upon which the phospholipid film is deposited [101].

3.3. GUVs Prepared by the Electroformation Method

If the swelling of PCs (or other phospholipids) in water (or in an aqueous solution with low ionic strength) is carried out in a controlled way by applying an alternating electric field, instead of myelin figures, GUVs form, with diameters typically between 5 and 200 μm, depending on the chemical structure of the lipids used, on the lipid composition, on the swelling medium, and on the external electric field parameters [102–104]. The vesicles are often formed under a light microscope in a specially designed cell on platinum wires that are positioned at a certain fixed distance [103, 104]. This so-called electroformation method has been proved to be rather powerful for the investigation (including microinjection [105, 106]) of individual GUVs of defined size by light microscopy [103–110].

The mechanism of GUV electroformation in an alternating electric field is not fully understood. It is likely, however, that the electroosmotic motion of the water molecules is responsible for a controlled swelling and separation of the bilayers deposited on the platinum wires, leading to the formation of unilamellar vesicles on or close to the metal wires [103, 109]. The individual giant vesicles formed seem to be connected to the platinum wires through thin lipid bilayer tubes (so-called tethers [111, 112]) and possibly myelin-like protrusions [113].

In comparison with other methods for the preparation of giant unilamellar PC vesicles, the electroformation method offers several advantages with respect to reproducibility and later vesicle manipulations [114].

3.4. MLVs Prepared by Hydration of Spray-Dried Lipids

Instead of the preparation of a thin lipid film first, followed by hydration (Sections 3.2 and 3.3), the lipids can first be spray-dried and then hydrated [115]. With respect to the reproducibility and mass production of MLVs, the spray-drying method has several advantageous over the thin-film dispersion method, although it seems that lipids with low T_m

(e.g., egg yolk PCs) cannot be used, because of adhesion to the containers in which the vesicles are prepared [115].

In the spray-drying method, the vesicle-forming amphiphiles are first dissolved in chloroform or methylene chloride (in which, advantageously, mannitol is dispersed) and then spray-dried with a commercial spray-dryer. Vesicle formation is observed after hydration of the spray-dried lipids and vortexing above T_m of the amphiphile used. The presence of the mannitol prevents adhesion of the (saturated) lipids to the reaction containers and leads to a better hydration behavior. (The role of sugars in surfactant assembly at large has hardly been touched on.)

The vesicles prepared are rather heterogeneous with respect to size and lamellarity. One of the homogenization procedures described below may follow the spray-drying and hydration step.

3.5. SUVs (and Possibly LUVs) Prepared by Sonication (and Storage)

The treatment of a MLV suspension with ultrasound at a temperature at least about 5 °C above T_m leads to a homogenization of the vesicles by reducing the size of most of the vesicles to probably the smallest possible diameter (about 20 nm in the case of egg yolk PC mixtures [10, 116] or POPC), due to simple molecular packing considerations. The vesicles thus prepared are unilamellar and called SUVs, an abbreviation that stands for sonicated unilamellar vesicles or small unilamellar vesicles. If the sonication is performed below T_m, structural defects within the bilayers are observed that result in an increased bilayer permeability [117, 118].

So-called probe sonication (the insertion into the vesicle suspension of a metal rod that releases ultrasound waves from the tip of the rod) [119–121] is more efficient than bath sonication [31, 122]. In both cases, however, the sizes of the vesicles (20–50 nm usually) in the sonicated suspension depend on the sonication time [122], on the lipid composition, and on whether other compounds (such as cholesterol) are present [14, 119, 123]. Furthermore, the vesicle suspension may not be free from larger MLVs, and a separation step, for example, size exclusion chromatography (using, for example, sepharose 4B) or high-speed centrifugation, is usually necessary [119, 121, 124]. A centrifugation step may also be used in the case of probe sonication to remove the possibly released metal particles from the tip of the metal rod [125].

The ultrasound used in the treatment of MLVs consists of pressure waves with frequencies around 20 kHz, and the ultrasound propagation gives rise to periodic changes in local pressure and temperature [126]. Therefore, the heat generated during sonication has to be controlled and compensated for by cooling, otherwise the vesicle-forming lipids may undergo a partial chemical degradation [125, 127]. Furthermore, it has been reported that nonvesicular aggregates may be generated as a result of the high-energy input into the system, and the ultrasound treatment may lead to a drastic decrease in the surface tension of sonicated MLV suspensions due to the accelerated movement of lipid molecules form the vesicles to the water-air interface [128]. This process is usually much slower in the case of vesicles that have been prepared under milder conditions, such as by extrusion (Section 3.8) [128].

Based on this latter observation, more uniform and reproducible SUV preparations may be obtained by annealing at elevated temperatures (50 °C in the case of DMPC:1,2-dimyristoyl-*sn*-glycero-3-phosphoserine vesicles), followed by a removal of possibly present large aggregates by centrifugation at $100{,}000 \times g$ (30 min at 37 °C in the particular case) [129].

If carefully prepared SUVs from the saturated DPPC at a concentration in the range of 20–120 mM (in a 20 mM piperazine-N',N''-bis(2-ethanesulfonic acid) buffer, pH 7.4, containing 10 mM NaCl) are kept at a temperature considerably lower than the T_m of DPPC (which is around 41 °C; see Table 4), then the vesicles fuse into uniform LUVs with a diameter of about 70 nm (after 7 days at 4 °C) or 95 nm (after 3–4 weeks at 4 °C) [130]. At higher temperatures (21 °C) but still below T_m, the fusion process is slower [131], whereas at 50 °C (above T_m), no appreciable fusion occurs over a period of at least 5 days [130]. A similar fusion of SUVs below T_m is observed for DSPC, resulting in vesicles of about 60- and 100-nm diameter [132], with an apparently higher fusion rate [130].

The implications of these experimental observations are twofold: (a) LUVs of about 70 or 100 nm can be prepared from saturated PCs by simple storage of SUVs below T_m. (b) SUVs should not be stored below T_m, if one likes to keep the vesicle sizes small; otherwise the vesicles may fuse to form larger vesicles.

In general, SUVs are often prepared in a first step to fuse them in a second step to LUVs by using another methodology, for example, in the case of the cochleate-cylinder method (see Section 3.13) or in the case of the interdigitation-fusion method (see Section 3.21).

3.6. MLVs and MVVs (and Possibly LUVs) Prepared by Repetitive Freezing and Thawing

A MLV suspension—as prepared by the thin-film dispersion method—is put, for example, inside a thick-walled test tube and repetitively (3–6 or, better, 10 times) completely frozen in liquid nitrogen (at −195 °C) and then thawed in a water bath kept at a temperature above T_m. In this way, the vesicle suspension undergoes a sort of equilibration procedure caused by the water crystals and transient rigidification of the lipid molecules. It is a kind of homogenization process, and it has been reported that the population of MVVs may increase [133] and that the amount of very small vesicles tends to decrease [134, 135], depending on the lipid used and on the salt content [136]. It may also be that freeze-thaw cycles lead to a fragmentation of large MLVs into large or small unilamellar vesicles [136, 137]; it all very much depends on the experimental conditions, such as type and concentration of lipid (or lipid mixture) and salt content [136, 138].

A further effect of freezing and thawing of vesicle suspensions is the removal of dissolved gas [88], which has not yet been explored. It is known that removal of dissolved gas strongly affects hydrophobic interactions and colloidal stability, as well as the structure of water [88, 139].

Freeze-thaw cycles have been applied to a series of phospholipid vesicular suspensions, particularly focusing on phospholipids with unsaturated acyl chains (DOPC) and DOPC/DOPA mixtures (DOPA is the abbreviation for the negatively charged 1,2-dioleoly-*sn*-glycero-3-phosphate) [136]. It has been shown that freeze-thaw cycles can be applied successfully to the preparation of mainly LUVs starting from MLVs, depending on the experimental conditions [136]. With the use of a 0.1 M Hepes (4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid) buffer of pH 8.0 containing 0.1 M KCl and 5 mM EDTA, 10 freeze-thaw cycles of aqueous suspensions of DOPC (or POPC) MLVs, for example, led to suspensions that contained about 98% unilamellar vesicles with diameters below 200 nm. The remaining 2% were multilamellar. The vesicles obtained by repetitively freezing and thawing MLVs are often abbreviated as FATMLVs [140]. In the case of DOPC/DOPA (80:20 mol%), almost no MLVs could be detected after the freeze-thaw procedure; the vesicles again had diameters below 200 nm after 10 freeze-thaw cycles [136]. After 50 cycles, the vesicle diameters decreased to below 100 nm [136]. In the case of saturated PCs (DMPC or DPPC), MLV suspensions remained essentially multilamellar, even after 10 freeze-thaw cycles under the conditions used [132].

Fusion of SUVs into larger vesicles upon repetitive freezing and thawing [31, 136, 140, 141] seems to occur efficiently only in pure water (without added salt) [136]. Furthermore, freeze-thaw cycles may not only affect the mean vesicle size and lamellarity, but also the entrapment efficiency for water-soluble molecules [142–145]. In some cases, the trapping efficiency may be dramatically increased [142]. Furthermore, the composition of the aqueous solution may generally influence the freeze-thaw behavior of the vesicles; all of the freeze-thaw effects depend on the experimental conditions [136, 138].

Depending on the phospholipid(s) used, freezing and thawing of SUVs may lead to the formation of giant MLVs with diameters ranging from 10 to 60 μm in the presence of salt (30–500 mM KCl, in the case of phospholipid mixtures containing egg yolk phosphatidylethanolamine and bovine brain phosphatidylserine, 7:3, mol/mol, at pH 7.0, for example) [146].

Although the process is not completely understood, freeze-thaw cycles often precede a further downsizing of the vesicles, for example, by extrusion (Section 3.8).

3.7. MLVs Prepared by Dehydration and Rehydration

The dehydration of a vesicle suspension followed by a controlled rehydration at a temperature above T_m leads to the fusion of small vesicles present in the suspension, resulting finally in the formation mainly of MLVs [147–149]. This procedure is based on the instability of dried SUVs and a lipid lamellae formation (SUV fusion) during the water removal. The resulting vesicle suspensions are referred to as dehydration-rehydration vesicles or dried-reconstituted vesicles (DRVs) [31]. DRVs are often prepared to obtain high entrapment efficiencies (high encapsulation yields) for water-soluble enzymes and other water-soluble molecules. The entrapment efficiency is defined as the percentage amount of the encapsulated molecule in relation to the total amount of molecules present during the vesicle formation and entrapment process.

In a typical, originally described preparation of DRVs [148], SUVs of the appropriate lipid composition are first prepared in distilled water by probe sonication. After centrifugation to remove large vesicles and titanium particles released from the sonicator probe (see Section 3.5), the SUV suspension is mixed with an equal volume of an aqueous solution of the compounds to be trapped. After rapid freezing of the mixture, it is lyophilized with the use of a commercial freeze-dryer at reduced pressure. After freeze-drying, the preparation is rehydrated with a volume of distilled water equivalent to one-tenth of the total volume of the initial SUV suspension. The use of a small volume necessarily has a positive effect on the entrapment yield. The rehydration is usually aided by light vortexing and equilibration for 30 min. Nonentrapped molecules are removed by centrifugation or dialysis after an appropriate dilution of the vesicle preparation [148].

Since DRVs are generally not uniform with respect to size and lamellarity, a second downsizing process often follows a DRV preparation, such as extrusion (Section 3.8) or microfluidization (Section 3.9).

The essential process in the preparation of DRVs is the *disintegration* of the initially prepared SUVs during the dehydration step, which finally results in high entrapment yields of the DRVs. If the experimental conditions during dehydration (during freeze-drying) are such that the vesicles remain largely intact, the rehydration will not lead to exceptionally high entrapment yields of DRVs. One particular such case is the use of lyoprotectants, chemicals that protect the lipid vesicles against drying stress (also called cryoprotectants [150]), such as trehalose [151], glucose [152], sucrose [153], or maltose [154], used typically at concentrations of 10% (wt/wt) [153]. For a particular lyoprotectant, the lyoprotection effect is very much dependent on the type of vesicle-forming lipid used, on the bilayer composition, on the size of the vesicles, on the temperature at which the vesicles are kept before rehydration, and on the freezing rate [153, 155, 156]. Lyoprotectants are thought to prevent the increase in the T_m of the lipid during dehydration (see Section 2.3), to bind water molecules and to interact with the polar head groups of the lipids. In the latter case, water molecules around the head groups would be replaced by the lyoprotectants, thereby protecting the vesicles from aggregation and fusion during the freeze-drying process [157, 158]. In the particular case of POPC, the presence of sucrose or sorbitol results in a value of T_m in an almost dry state of less than 6 °C, in comparison with about 60 °C in the absence of lyoprotectant [159] (see Section 2.3).

Lyoprotectants are only effective in protecting the lipid vesicles if the proper concentrations of the added lyoprotectants are used. If, for example, the potentially effective lyoprotectant sucrose is used at a concentration below the one known to preserve the stability of vesicles during dehydration [157], DRVs can be prepared from SUVs, which are characterized by high entrapment yields and a size no greater than that of the initially prepared SUVs, but also not as large as the size obtained in the absence of sucrose: 90–200 nm in the presence of low sucrose concentrations

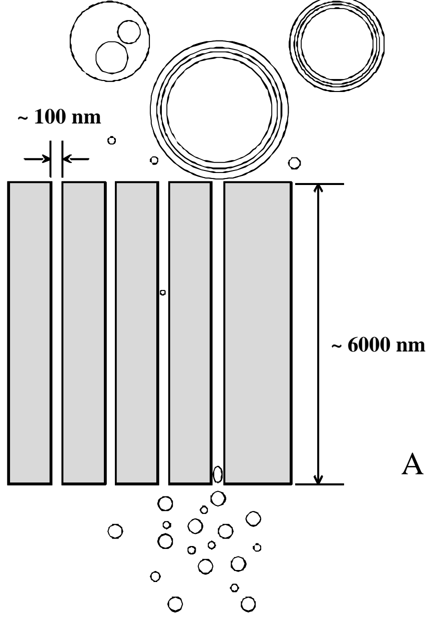
(<150 mM, with an optimal entrapment efficiency at a molar ratio of sucrose to lipid of 1), in comparison with about 1–6 μm in the absence of sucrose [160].

3.8. LUVs Prepared by the Extrusion Technique

This method is one of the most popular for the reproducible preparation of rather homogeneous vesicle suspensions containing LUVs, often with a mean diameter of about 70 nm or 100 nm [161–163]. The principle of the method is the following (see Fig. 3): a MLV suspension is passed under moderate pressure repetitively (usually 10 times) at a temperature at least 5 °C above the T_m [164, 165] through the pores of track-etched polycarbonate membranes. The pores are almost cylindrical, and vesicles (unilamellar or multilamellar) that are larger than the mean pore diameter are reduced in size and lamellarity during the passage through the pores, resulting in a final mean vesicle size that corresponds in a first approximation to the mean size of the pores. Vesicles smaller than the pore diameters pass through the pores without significant size change. Usually a MLV suspension is first passed 10 times through polycarbonate membranes with a relatively large mean pore diameter of 400 nm, followed by a passage 10 times through membranes with 200-nm pores and, finally, 100-nm pores. If desired, membranes with 50-nm pores or even 30-nm pores can be used for final extrusions. The corresponding vesicle suspensions obtained are abbreviated as VET_{400}, VET_{200}, VET_{100}, VET_{50}, or VET_{30}. VET stands for "vesicles prepared by the extrusion technique." The subscript indicates the pore size of the membranes used for final filtrations. The mean vesicle diameter of VET_{200} is usually less than 200 nm because of the presence of vesicles considerably smaller than 200 nm in the original vesicle suspension [166, 167], unless the very small vesicles are first eliminated by freeze-thaw cycles [162, 163] (see Section 3.6). If freezing-thawing is used as a homogenization method before extrusion, the resulting vesicles are often abbreviated as FAT-VET (e.g., FAT-VET_{100}: repetitively frozen and thawed vesicles that have been repetitively extruded through polycarbonate membranes with mean pore diameters of 100 nm for final extrusions).

In the early stages of the development of the extrusion technique, freeze-thaw cycles were not performed [166, 168, 169], and, depending on the application, it may even be better to avoid it, for example, in the case of the preparation of vesicles containing entrapped enzymes that may be inactivated during freeze/thaw cycles [75].

VET_{100}- or FAT-VET_{100} suspensions are generally rather monodisperse, containing vesicles with a mean diameter close to 100 nm. The mean vesicle diameter of VET_{50} or VET_{30} is generally larger than 50 nm or 30 nm, respectively. This observation can be explained on the basis of the possible mechanism by which the vesicles transform during the passage through the pores [170–172]: most likely, spherical vesicles change their shape to cylindrical structures within the pores. Because of a velocity profile inside the pores—with a low velocity close to the pore wall and a high velocity toward the center of the pores—the cylinders pearl off ellipsoidal vesicles, which then relax in size and transform into spheres upon leaving the pores. Figure 3 shows a schematic



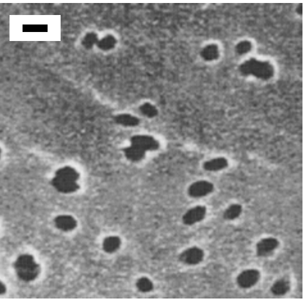


Figure 3. Illustration of the extrusion technique, which is the most popular technique for the reproducible preparation of sub-micrometer-sized unilamellar lipid vesicles from a heterogeneous multilamellar vesicle suspension (see Section 3.8). (A) Schematic representation showing (more or less) cylindrical pores with a mean diameter of 100 nm (as an example), spanning a polycarbonate membrane of about 6 μm thickness; MLVs; a MVV; and LUVs before and LUVs after repetitive extrusions (passages through the pores). (B) Transmission electron micrograph of a commercial polycarbonate membrane (Nucleopore) with pores that have a nominal mean diameter of 100 nm. Length of the bar: 100 nm. The electron micrograph was taken by E. Wehrli, Service Laboratory for Electron Microscopy, at the Department of Biology at the ETH Zürich.

drawing of the extrusion method (Fig. 3A) together with an electron micrograph of a top view of a section of a 100-nm polycarbonate membrane (Fig. 3B).

There are several commercially available devices that have been developed for the preparation of extruded vesicle suspensions [173] with volumes between 0.2 ml and 1.0 ml (e.g., LiposoFast [174]), between 1.0 ml and 10 ml (called the Extruder [163]), between 100 ml and 800 ml (the Extruder), or between 200 ml and 1 l (e.g., the Maximator [175]). A comparison between lipid vesicles prepared with the different devices (and the same set of lipids) has been performed [173], and it has been found—with the exception of FAT-VET_{50}—that the vesicles prepared with the LiposoFast were smaller than the vesicles prepared with the Maximator,

most likely because of higher flow rates and pressure drops. In the case of FAT-VET$_{50}$, the vesicles had the same mean diameter (around 50–60 nm) [173].

Since the vesicles prepared by the extrusion techniques are large (LUVs as defined in Table 3) and mainly unilamellar, extruded vesicle suspensions are often abbreviated as LUVET (e.g., LUVET$_{100}$, meaning large unilamellar vesicles prepared by the extrusion technique, using for final extrusions polycarbonate membranes with 100-nm pore diameters) [161]. FAT-VET$_{200}$ and particularly FAT-VET$_{400}$ suspensions usually contain a considerable amount of oligolamellar vesicles [162].

The extrusion technique can be applied as final down sizing and homogenization in principle for any type of vesicle suspension, MLVs, DRVs (Section 3.7), or REVs (Section 3.14), resulting in MLV-VET, DRV-VET, or REV-VET suspensions, respectively.

With a so-called French press cell—a device that does not contain any polycarbonate membranes at all but is often applied for the disintegration of biological cells—a vesicle suspension can be "extruded" through a small orifice at high pressure, resulting in the formation of unilamellar or oligolamellar vesicles with diameters between about 30 and 80 nm, depending on the pressure [31, 66, 71, 176, 177]. These vesicles are referred to as vesicles prepared by the French press (FPVs) [72]. The mechanism of the change in vesicle size in a French press is very different from the actual extrusion technique using polycarbonate membranes [66]. In the French press, shear forces seem to play a particular role [66] (see also Section 3.11).

3.9. LUVs and OLVs Prepared by the Treatment of a MLV Suspension with a Microfluidizer

Vesicle suspensions containing a mixture of mainly large MLVs can be downsized at a temperature above T_m with a high-pressure homogenizer (a microfluidizer) [178–181]. The resulting vesicles usually have a relatively narrow size distribution centered around a value between about 50 and 300 nm [179–181]. The mean size of the vesicles obtained (LUVs and OLVs) depends on the experimental conditions, such as homogenization pressure [182], number of cycles [181–183], ionic strength [181], lipid concentration [183], and lipid composition [182]. Relatively high lipid concentrations can be used, and a large-scale production is possible [181, 184]. To achieve high entrapment yields, a microfluidization step can be performed on vesicles first prepared by the dehydration-rehydration method, which itself results in high entrapment yields [180] (see Section 3.7).

3.10. Preparation of Oligolamellar and Multilamellar Novasomes

Novasomes, also called novasome vesicles [185], can be manufactured from a variety of amphiphiles (including PCs and many nonphospholipid surfactants) by a unique and cheap process on a laboratory scale (a few milliliters) or for industrial bulk applications.

The bilayer-forming amphiphile (including any bilayer-modulating molecules to be added, such as cholesterol) is first heated above the melting temperature (above about 70 °C in the case of POPC; see Section 2.3) to give a liquid. This liquid is then injected at high velocity (10–50 m/s) through small channels with 1–3-mm diameters (or through a needle) with turbulent mixing into excess aqueous phase and immediately cooled to room temperature. The rapid injection leads to the formation of tiny droplets of the amphiphiles that are quickly converted into small aggregates. The subsequent cooling under conditions of continued turbulence then leads to the formation of vesicles (the Novasomes) within milliseconds [185]. Novasomes are OLVs or MLVs with diameters typically between 200 nm and 1 μm, depending on the experimental conditions. The size of the vesicles is controlled by the chemical structure of the amphiphile used and by the hydrodynamic shearing during the fusion of the small aggregates during the cooling process. Furthermore, the diameter of the exit channel plays a role [185].

3.11. Preparation of Multilamellar Spherulites

Spherulites (also called onions or multilamellar spherulites) are relatively uniform, densely packed MLVs that are prepared by shearing of a lyotropic lamellar phase under controlled conditions [186, 187]. The MLVs formed show very little polydispersity and can have mean diameters somewhere within 100 nm and 20 μm [188] or within 200 nm and 50 μm [187], depending on the formulation (i.e., the chemical structure of the amphiphile and possible additives) and the shear rate.

The starting lamellar phase is concentrated and composed of a stack of bilayers of the amphiphiles, separated by water layers. This lamellar phase can be composed of a large number of different amphiphiles or mixtures of amphiphiles [189–192], including soybean PCs [193]. During the shearing, which is performed in specially prepared Couette cells [186], the lamellar phase reorganizes into spherical or polyhedral microdomains [186], which can be dispersed in an excess amount of aqueous phase. The process is called spherulite technology [186, 187, 189]. Spherulites can be considered droplets of dispersed lamellar phase [188, 193], and the technology allows the entrapment of a variety of different water-soluble compounds at high yields, including enzymes [194], nucleic acids [195], and metal ions for nanoparticle synthesis [187, 190].

The formation of spherulites is a direct consequence of global packing constraints [196].

3.12. MLVs Prepared by the Bubble Method

This method is based on the bubbling of an inert gas (nitrogen) over several hours through a coarse dispersion of (initially) nonhydrated lipid particles (containing phospholipids or non-ionic surfactants) and results in vesicle preparations with a clearly non-uniform size distribution [197]. The actual bubbling unit consists of a round-bottomed flask with three necks, one used for a water-cooled reflux, one for a thermometer, and one for the gas supply. A continuous stream of gas bubbles is generated at the bottom of the flask. A coarse vesicle dispersion is first formed usually with a

homogenizer, and the gas bubbling is carried out at a temperature above the T_m of the lipids (actually at 80 °C in the case of a mixture of hydrogenated soybean PCs and dicetylphosphate (10:1, mol:mol). The T_m of hydrogenated soybean PCs is about 51–52 °C (see Table 4). Depending on the experimental conditions, the resulting vesicles have a mean diameter between 200 and 500 nm [197].

3.13. LUVs and GUVs Prepared by the Cochleate Cylinder Method

A so-called cochleate cylinder is a precipitate of a cylindrical, cigar-like phospholipid aggregate that looks like a snail with a spiral shell (its Greek name is *cochleate* [198]).

In the standard procedure, cochleate cylinders form upon stepwise addition of Ca^{2+} to SUVs prepared by bath sonication from phospholipid mixtures containing negatively charged amphiphiles, such as phosphatidylserine (or phosphatidylglycerol) [31, 199].

Cochleate cylinders are rolled bilayers that do not contain an interlamellar aqueous space. The divalent cation brings the negatively charged lipids into close contact and excludes water. A majority of the lipid present must therefore be negatively charged [198], and an excess of Ca^{2+} with respect to the negative charges present has to be added.

Instead of adding Ca^{2+} to the SUVs prepared, the vesicle suspension can also be dialyzed against an aqueous solution that contains the required amount of Ca^{2+} ions [198]. Furthermore, instead of SUVs, unilamellar vesicles prepared by the detergent-depletion method (see Section 3.27), with D-glucopyranoside as a detergent, can be applied [198].

Once cochleate cylinders are prepared, LUVs are formed under the appropriate conditions upon removal of the Ca^{2+} ions by the complexing agent EDTA (ethylenediaminetetraacetate) at a controlled pH of around 7.4. Experimentally, the cochleate cylinders are first separated from the bulk Ca^{2+}-containing solution by centrifugation to form a tight pellet, which is further used and made free from lipid-bound Ca^{2+} by one of three different procedures, with the use of EDTA (direct EDTA addition, rotatory dialysis, or agarose plug diffusion [198]). EDTA binds Ca^{2+}, which leads to an unrolling of the bilayers and then to a formation of (not very uniform) unilamellar vesicles with diameters in the range of below 1 μm to about 10 μm, depending on the experimental conditions used, such as the Ca^{2+} complexation procedure (see above) [198]: while the direct EDTA addition results in vesicle sizes below 1 μm, rotatory dialysis yields vesicles with an average size of 0.5–1 μm, and the agarose plug diffusion method gives vesicles below 1 μm or 5–10 μm, depending on the procedure.

3.14. LUVs, OLVs, MLVs, and SPLVs Prepared by the Reversed-Phase Evaporation Technique

For vesicles prepared by the so-called reversed-phase evaporation technique, cosolvents are used [31, 200]. The bilayer-forming amphiphile (e.g., POPC) is first dissolved in a water-immiscible organic solvent of low boiling point (e.g., diethylether, isopropylether, or mixtures of these ethers with chloroform or methanol). This solution is then mixed with an aqueous solution in which the final vesicles are to be formed. After vortexing and brief sonication in a bath-type sonifier, a reverse emulsion (a so-called water-in-oil emulsion, abbreviated w/o emulsion) is formed in which aqueous droplets are stabilized for a certain period of time by the amphiphiles at the interface between the droplets and the bulk organic solution. The organic solvent is then removed under reduced pressure at a temperature above T_m. During the solvent removal, the reversed emulsion collapses and is transferred into bilayered vesicles. The resulting vesicles (abbreviated REVs) are often unilamellar or oligolamellar vesicles [200], and the size is usually not very uniform, ranging from about 200 nm to 1 μm [200] or even more. Therefore, a homogenization step, such as extrusion (Section 3.8), often follows REV preparation [169, 201].

Vesicles prepared by the reversed-phase evaporation technique are useful for obtaining high encapsulation yields for water-soluble molecules (similar to the DRV preparation described in Section 3.7).

In a modification of the originally developed REV method, the experimental conditions are altered in such a way that the phospholipid/water ratio in the water-in-oil emulsion is changed; and the vesicles formed are no longer mainly uni- or oligolamellar, but mainly MLVs with sizes above 600 nm, thereby allowing higher encapsulation yields for water-soluble compounds [202–204].

With the aim of applying the principles of the REV method to large scale productions, the original method has been modified with the use of the nontoxic and cheap supercritical fluid CO_2 [205]. CO_2 has a critical temperature of 31 °C and a critical pressure of 73.8 bar [205], above which CO_2 exists as liquid. For the preparation of DPPC vesicles, the temperature was set at 60 °C (well above T_m; see Table 4) and the pressure was kept at 200 bar [205]. The resulting suspension contains mainly unilamellar vesicles with diameters between ~0.1 and 1.2 μm and high trapping efficiencies [205].

Another procedure that is rather similar to the originally developed preparation of REVs has been described; it resulted in the formation of stable MLVs (SPLVs, stable plurilamellar vesicles [76], to distinguish them from the MLVs obtained by the thin-film method, as described in Section 3.2). In the case of SPLVs, a dry phospholipid film is first dissolved in diethyl ether. After the addition of a buffer solution, the two-phase mixture formed is emulsified with a sonication bath, during which a gentle stream of nitrogen gas is passed over the mixture, until the ether is almost completely evaporated. The resulting mass ("cake") is resuspended in buffer solution, followed by a pelleting by centrifugation and washing with buffer [76].

3.15. LUVs Prepared From W/O- and W/O/W-Emulsions

This multistep procedure for the formation of vesicles [206, 207] is very similar to the reversed-phase evaporation method (Section 3.14). It starts with the preparation of a w/o emulsion containing the water-soluble molecules to be entrapped in the final vesicle preparation. The emulsion is formed from soybean PCs, cholesterol, and benzene

(or methylene chloride). This w/o emulsion is then emulsified with another aqueous phase to form a water-in-oil-in-water emulsion (w/o/w emulsion), paralleled by evaporation of the solvent molecules, which is speeded up by mechanical agitation and a stream of nitrogen gas [207]. The mainly unilamellar vesicles thus obtained have a reported mean diameter of about 400 nm [207]. The size of the vesicles (apparently always between 50 and 500 nm) depends on the experimental conditions, such as the intensity of the second emulsification step (to form the w/o/w emulsion) [206] and the chemical nature of the organic solvent used [207]. With increasing boiling point of the solvent, the mean size of the vesicles tends to decrease [207].

3.16. MLVs, GUVs, and MVVs Prepared by the Solvent-Spherule (W/O/W Emulsion) Method or DepoFoam Technology

This particular method is called the solvent-spherule method by its inventors [208], since solvent spherules (surfactant-stabilized o/w emulsion droplets) are the starting system from which the oil (the solvent) is removed in a particular way, resulting in the formation of micrometer-sized MLVs [208]. The method is conceptually similar to the methods described in Sections 3.14 and 3.15.

The vesicle-forming amphiphiles (necessarily containing a small amount of negatively charged surfactants) are first dissolved in a 1:1 (v/v) mixture of chloroform and diethyl ether. This lipid solution is placed under the surface of an aqueous solution (5% glucose) with a glass capillary pipette. After agitation for about 1 min, surfactant-stabilized solvent spherules (droplets) form in the aqueous phase (w/o/w emulsion). The volatile solvent mixture is then removed in a particular way by careful dropwise addition to a flask to which a stream of nitrogen gas is added. The flask is kept at 37 °C and gently swirled. The average size of the MLVs formed is affected by the lipid concentration and the size of the lipid spherules formed by mechanical agitation.

In a modification of the method, which involves the additional use of triolein and a certain complex way of mixing, evaporation and centrifugation steps, GUVs in the 5–10-μm size range can be prepared, depending on the experimental conditions (strength and duration of the initial vortexing to form the o/w emulsion droplets) [31, 209].

In a further variation of the method, multivesicular vesicles (MVVs), with sizes between about 5 and 30 μm, can be prepared by a similar stepwise procedure (which involves pelleting by centrifugation), using a particular lipid mixture and, as solvents chloroform, diethyl ether and triolein [31, 210]. The technology for the preparation of this type of MVV is known as DepoFoam technology [211].

DepoFoam technology is a double emulsification process that has been developed based on initial observations [210] of the formation of MVVs. The vesicles formed are multivesicular vesicles (also called multivesicular liposomes), micrometer-sized vesicles that contain internal, nonconcentrically arranged compartments. The internal packing is comparable to the way gas bubbles are packed in a gas-liquid foam [211, 212]. The contacts between the compartments exhibit a tetrahedral coordination.

The first step in the formation of DepoFoam MVVs is the preparation of a w/o emulsion by dissolving a mixture of vesicle-forming amphiphiles (e.g., phospholipids) containing at least one neutral lipid (e.g., triolein) in one or more volatile, water-immiscible organic solvents (e.g., chloroform) and the addition of an aqueous solution containing water-soluble molecules to be entrapped in the final vesicles formed. In a second step, the w/o emulsion is mixed with a second aqueous solution, followed by mechanical mixing to yield solvent spherules suspended in the second aqueous phase (a w/o/w emulsion [212]). The organic solvent is then removed from the spherules by evaporation at reduced pressure or by passing a stream of nitrogen gas over or through the suspension [211]. The properties of the MVVs formed (such as captured volume) depend on the experimental conditions, such as molar fraction of the neutral lipid [210].

The presence of a neutral lipid like triolein is important since it allows a particular type of compartmentation [211]. Triolein acts as a hydrophobic space filler at bilayer intersection points and stabilizes these junctions. Furthermore, triolein is also present as oil droplets dispersed in the encapsulated aqueous space [211].

3.17. GVs Prepared from an Organic/Aqueous Two-Phase System

Giant vesicles—claimed to be unilamellar [213]—can be prepared rapidly by first dissolving the vesicle-forming amphiphiles in a chloroform-methanol solution in a round-bottomed flask, and then adding carefully along the flask walls an aqueous solution (water or buffer) that may also contain water-soluble molecules to be entrapped. After removal of the organic solvent in a rotatory evaporator under reduced pressure and at elevated temperature (40 °C), a suspension is obtained that contains many giant vesicles with diameters up to 50 μm, which can be removed for further investigation [213, 214].

3.18. SUVs and LUVs Prepared by the Ethanol Injection Method

This method is a rather simple one that uses ethanol as a cosolvent and does not require homogenization devices [31, 215, 216]. The bilayer-forming amphiphile (e.g., POPC or another PC) is first dissolved at a certain concentration in ethanol (or methanol [217]). A transparent solution is obtained. If a small amount of this ethanolic (or methanolic) lipid solution is now rapidly added at a temperature above the T_m to an aqueous solution, the formation of vesicles is observed. The reason for vesicle formation is the miscibility of ethanol (or methanol) with water and the migration of alcohol molecules—originally surrounding the lipid molecules—away from the lipids into the bulk solution. Depending on the experimental conditions (e.g., lipid concentration in the alcohol, speed of adding the alcoholic lipid solution, final concentration in the aqueous suspension, and stirring rate), the vesicles formed are more or less homogeneous with respect to size and lamellarity. The most important factor seems to be the concentration of the lipid in the alcohol injected into the buffer solution.

Vesicles prepared from DMPC (at 35 °C) or DPPC (at 55 °C), for example, were mainly unilamellar vesicles with diameters between about 30 nm and about 120 nm if the PC concentration in the ethanolic solution was varied between about 3 mM and about 40 mM (with an ethanol concentration in the buffer after the addition of 2.5–7.5%, v/v) [210]. Similar results were obtained with a mixture of soybean phospholipids [218].

In the case of POPC injected as a methanolic solution, POPC concentrations in methanol up to 25 mM result in vesicles with diameters between 40 and 70 nm [217].

The ethanol (or methanol) present in the final vesicle suspension may be removed almost completely by dialysis if required [216].

One of the limitations of the method is the limited solubility of the phospholipids in the alcohol (e.g., 40 mM soybean PC in ethanol [218]). This necessarily results in relatively dilute vesicle suspensions (a few millimolar). Furthermore, whereas entrapment yields for ethanol-soluble substances are high [218], the encapsulation efficiency for water-soluble compounds is low [218], unless a sophisticated cross-flow injection technique is used [219], which also allows an upscaling to at least several 100 ml [220].

The ethanol injection method has also been combined with high-speed homogenization [221, 222], thereby allowing the preparation of uniform vesicles with a diameter of 170–200 nm on an industrial scale [222].

In a further modification of the method, an ethanolic lipid solution is not injected into an aqueous solution, but water is poured into a concentrated lipid-ethanol solution, followed by the removal of the ethanol in an evaporator and the addition of water [223]. The particular lipid mixture contained a defined amount of soybean PC, cholesterol, β-sitosterol β-D-glucoside, and oleic acid, and the resulting polydisperse vesicles had mean diameters between about 150 nm and 1.3 μm, depending on the experimental conditions [223].

3.19. ULVs and OLVs Prepared by the Proliposome Method

This method is related to the ethanol injection method described in Section 3.18 in the sense that ethanol is also used as a cosolvent. An initial mixture (called proliposome mixture [224]) containing vesicle-forming amphiphiles (egg PCs [225], soybean PCs, or hydrogenated soybean PCs [224]), ethanol (or glycerol or propyleneglycol), and water is converted into vesicles by a dilution step [224–226]. It is a method that seems to be particularly applicable to the bulk production of lipid vesicles.

The vesicles (liposomes) only form after water addition since the proliposome mixture does not contain enough water to trigger vesicle formation. The proliposome mixture is probably built up of extended hydrated lipid bilayers that are separated by an ethanol-rich hydrophilic medium [224].

The encapsulation efficiencies for water-soluble or bilayer soluble compounds are rather high [224, 226]. The vesicles formed by the proliposome method may be predominantly unilamellar or oligolamellar vesicles with a broad size distribution between 20 nm and about 400 nm [218]. The mean size and lamellarity of the vesicles obtained seem, however, to depend on the actual experimental conditions. In the case of vesicles formed from a "proliposome mixture" containing egg yolk PC:ethanol:water at a ratio of 100:80:20 (w/w/w), the mean size varied between 100 nm and 1.2 μm, and most vesicles were oligo- or multilamellar [225].

In a modification of the actual proliposome method, a large-scale production of lipid vesicles could be achieved by diluting about 10–20 times—with an aqueous phase using a dynamic mixing device above T_m of the lipids—a water-miscible solvent mixture composed of N-methylpyrrolidone and *tert*-butyl alcohol (1:4, v/v) containing POPC:1,2-dioleoyl-*sn*-glycero-3-phosphoserine (7:3, mol/mol) and a drug to be entrapped [227]. The resulting mean size of the mainly unilamellar vesicles formed after the dilution varied with the composition of the aqueous phase between about 50 and 150 nm [227].

Please note that the term "proliposome" has also been used for particular dry granular phospholipid preparations which, upon dispersion in water, result in the formation of MLVs [31, 228]. These preparations do not contain ethanol at all.

3.20. Preparation of Multilamellar Ethosomes

With a third method in which ethanol plays an important role, so-called ethosomes can be prepared. Ethosomes are lipid vesicles that contain in the final preparation a considerable amount of ethanol. Ethosomes are prepared by first dissolving a phospholipid (such as soybean PC mixtures) in ethanol. Water is then slowly added in a fine stream with constant mixing to a specially prepared container, followed by an equilibration of the system at 30 °C. The final vesicle preparation contains 2% (w/w) soybean PCs and 30% (w/w) ethanol and seems to be particularly useful in pharmaceutical applications for drug transport across the skin (transdermal drug delivery) [229–231]. The vesicles formed are mainly MLVs and are apparently relatively monodisperse, with a mean reported diameter of about 150 nm [229]. The size of the vesicles seems to increase with decreasing ethanol concentration [229]. At 20% (w/w) ethanol, the mean ethosome diameter is around 190 nm; at 45% (w/w) it is around 100 nm [229]. The mean vesicle size is also dependent on the lipid concentration. At 30% (w/w) ethanol, the vesicles' mean diameter varies from about 120 nm to about 250 nm on going from 0.5% (w/w) to 4% (w/w) soybean PCs [229].

In transdermal drug delivery applications, the ethanol present in an ethosome preparation may act as a skin permeation enhancer because of the interaction with the lipid layers of the skin's horny layer (stratum corneum), thereby allowing the passage of drugs across the skin.

3.21. GVs Prepared by the Interdigitation-Fusion Method

A fourth method that uses ethanol is based on the fact that under certain conditions certain glycerophospholipids are known to form bilayers that have interpenetrated (interdigitated) hydrophobic chains. This means that the methyl groups localized at the end of the hydrophobic chains of a monolayer in a bilayer are in contact with the methylene groups of the hydrophobic chains of the other monolayer

and vice versa. Such interdigitated structures (interpenetrated lamellar sheets) are formed upon the addition of ethanol to SUVs prepared from specific saturated PCs (e.g., DPPC), at a temperature below T_m. When the temperature is increased above T_m, the interdigitated lamellar sheets fuse and transform into vesicles that are mainly unilamellar and have diameters above 1 μm (called IFVs, vesicles prepared by the interdigitated fusion method [232]).

The trapped volume of the IFVs depends on the chemical structure of the lipid, the concentration of ethanol used to induce interdigitation fusion, and the size of the precursor SUVs [232].

3.22. ULVs and MLVs Prepared by the Coacervation Technique

The starting system in this method of vesicle preparation is a mixture of naturally occurring egg yolk phospholipids (including about 81% PCs), an alcohol in which the phospholipids are soluble (methanol, ethanol, *n*-propanol, or 2-propanol), and water [233]. Under appropriate conditions, phase separation is observed in this three-component system, corresponding to a region in the phase diagram that is related to a so-called coacervation. *Coacervate* is an old term used in colloid chemistry [234]. It refers to a system in which an amphiphile-rich aqueous phase is in equilibrium with an amphiphile-poor aqueous phase. It seems that coacervates actually correspond to the so-called sponge phase (the L_3-phase), a disordered version of the bilayered bicontinuous cubic phase [235].

After the initial coacervation system is dialyzed against water, vesicles form that seem to be either relatively homogeneous and unilamellar vesicles (in the case of methanol or propanol) or mainly MLVs (in the case of ethanol), ranging in size from about 100 nm to 1 μm, depending on the experimental conditions used [233].

3.23. Vesicles Prepared by the Supercritical Liposome Method

With the use of a specially designed, technically rather complex apparatus, vesicles with an average size of about 200 nm can be prepared by mixing at low pressure an aqueous solution with supercritical CO_2 (kept at high pressure (25 MPa) and 60 °C) containing the vesicle-forming amphiphile (POPC:cholesterol, 7:3, mol/mol). The mean vesicle sizes vary with the experimental conditions, such as geometric dimensions of the important parts of the apparatus [236].

3.24. Vesicles Prepared by the Ether Injection Method

Vesicles can be prepared by slowly injecting (at 0.2 ml/ml) a diethyl ether/phospholipid solution into an aqueous phase that has been warmed to a temperature (55 °C) above the boiling point of diethyl ether [31, 237]. The diethyl ether vaporizes upon contact with the aqueous phase, and the dispersed lipids form preferentially (but not entirely) unilamellar vesicles. These vesicles can then be sized down by extrusion (see Section 3.8) or simple Millipore filtration. In the latter case, the reported vesicle diameters are in the range of 100 to 300 nm [237].

3.25. OLVs Prepared by the Rapid Solvent Exchange Method

The rapid solvent exchange (RSE) method has been specifically designed for the preparation of vesicles from phospholipid-cholesterol mixtures containing high amounts of cholesterol [238]. The method is based on a rapid transfer of the vesicle-forming lipids from an organic solvent to an aqueous buffer solution in which the vesicles are meant to be formed. This rapid solvent exchange avoids the transient formation of solid lipid mixtures, which often demix (phase separate) and result in inhomogeneous vesicle preparations.

The lipids and the membrane soluble additives (i.e., cholesterol) are first dissolved in a solvent that is not miscible with water (e.g., chloroform or methylene chloride). This lipid solution is then added to an aqueous solution above the T_m of the lipids in a particular manner at reduced pressure with a specially designed apparatus in such a way that the solvent is rapidly (within 1 min) and almost completely evaporated, as a result of pressure changes during the injection process.

Vesicles prepared by the RSE strategy from POPC, for example, are oligolamellar with an expected lamellar repeat distance of 6.5 nm (see Section 3.2) and an entrapped volume of about 4.5 liters/mol [238].

3.26. Vesicles Prepared from an Initial O/W Emulsion

In this simple method [239], an o/w emulsion is first formed by bath sonication from a vesicle-forming amphiphile (egg yolk PC and cholesterol), an aqueous solution (containing the water-soluble molecules to be entrapped), and *n*-decane. This o/w emulsion is then transferred to a second aqueous solution, which gives two separated phases, an upper organic phase and a lower aqueous phase. The two-phase system is centrifuged at 3500 × *g* for 10 min, resulting in the movement of the amphiphiles from the organic phase into the aqueous phase and, as a consequence, the formation of vesicles in the lower aqueous phase, which is separated from the upper phase. The resulting vesicles, which may contain small amounts of *n*-decane in the bilayer, have a diameter in the range of 50–200 nm and are characterized by relatively high encapsulation yields [239].

3.27. ULVs Prepared by the Detergent-Depletion Method

If a bilayer-forming lipid is mixed in an aqueous solution with a micelle-forming surfactant (often called detergent, from the Latin word *detergere*, meaning to wipe off or to clean) under such conditions that the detergent molecules "dominate," mixed detergent/lipid micelles are formed [240–243]. These aggregates are composed of bilayer-forming amphiphiles as well as micelle-forming amphiphiles and are disc-like, sheet-like, or cylindrical structures.

In the detergent-depletion method (also called the detergent dialysis or detergent removal method), the starting system from which the vesicles are formed is mixed detergent/lipid micelles. The micelle-forming detergent molecules (with their large a_0; see Section 1.1) are expected to be distributed in the mixed-micelle aggregate in such a way that they particularly occupy the highly curved edges of the aggregates [31]. The micelle-forming surfactant is also present in a relatively high amount in the bulk phase as nonaggregated, monomeric detergent, at a concentration corresponding in a first approximation to a value a bit lower than the detergent's cmc, the critical concentration for micelle formation determined separately under comparable conditions.

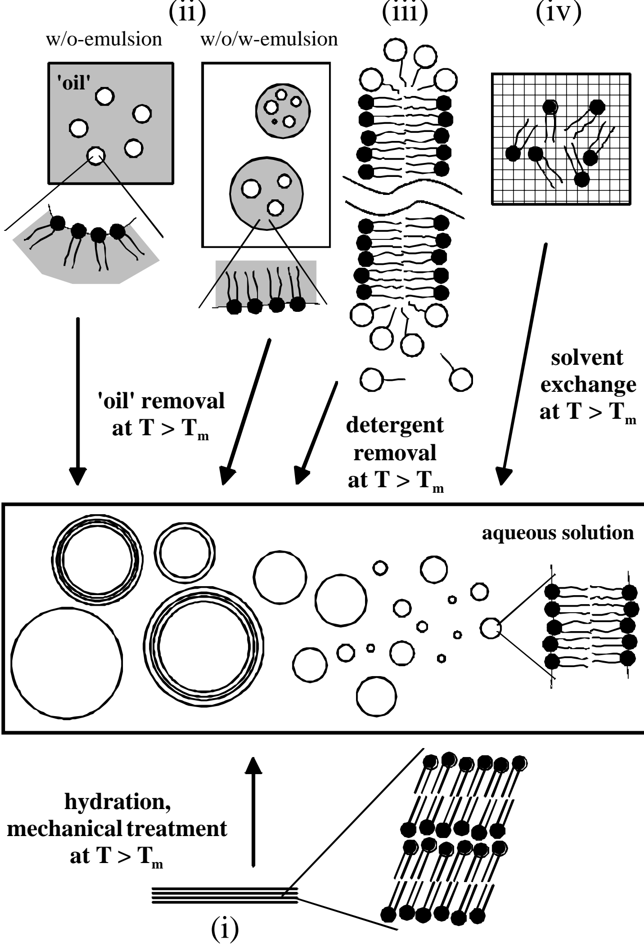

Figure 4. Simplified schematic representation of the principal pathways for the preparation of (normal) lipid vesicles in the case of "conventional amphiphiles" (surfactants that do not form a true vesicle phase at thermodynamic equilibrium). The pathways involve, as starting state of the amphiphiles, (i) preorganized dry lipids, which are hydrated and (possibly) mechanically manipulated above the T_m of the lipids; (ii) preorganized lipids in w/o emulsions (or w/o mircoemulsions or reversed micelles) or w/o/w emulsions prepared in a volatile solvent that is removed during the vesicle preparation procedure above T_m of the lipids; (iii) preorganized lipids in the presence of micelle-forming detergents (mixed detergent/lipid micelles) existing in dynamic equilibrium with free detergent monomers that are removed during the vesicle preparation procedure above the T_m of the lipids; or (iv) lipids dissolved in a solvent that is miscible with water and is exchanged with water during the vesicle preparation procedure above the T_m of the lipids. Once a vesicle suspension is formed, the mean vesicle size and size distribution can always be altered by mechanical treatments above T_m.

The amount of monomeric detergent in the mixed micellar system is important, as it is this nonaggregated amphiphile that is removed from the solution during the detergent removal process, which finally leads to the formation of vesicles [31, 66, 69, 71, 244–247]. The principle of the detergent-depletion method is the following: mixed detergent/lipid vesicles, present in rapid equilibrium with detergent monomers, are put into a dialysis bag or another dialysis device [31] at a temperature above T_m of the lipid used [248]. The dialysis membrane is characterized by a permeability for the monomers, whereas the much larger mixed micelles cannot pass the membrane. Then, at a temperature above T_m [248], the dialysis device is put in contact with a buffer solution in which the mixed micelles were formed. Since the monomers can pass the dialysis membrane, the amount of monomers in the solution inside the dialysis device continuously and slowly decreases, and detergent monomers move from the mixed micellar aggregate into the bulk solution. This process continues until the amount of detergents in the micellar aggregates is so low that mixed micelles can no longer exist, and extended mixed bilayer fragments (sheets) and finally mixed lipid/detergent vesicles form. Extensive dialysis leads to the formation of vesicles that are almost (but not necessarily completely [249]) free from detergent molecules. These vesicle suspensions are often to a large extent unilamellar and have a narrow size distribution. The mean size depends on the experimental conditions, such as type of detergent used, initial lipid and detergent concentrations in the mixed micellar solution, and speed of detergent removal [247, 250–252].

Table 5 lists detergent molecules that are often used for the preparation of vesicles by the detergent-depletion method, together with characteristic size ranges of the mainly unilamellar vesicles formed.

In the case of a system containing egg yolk PC and the bile salt sodium taurochenodeoxycholate (which aggregates itself stepwise into a particular type of unconventional, small micelles [253–255]), the mixed micelle-mixed vesicle transformation process—initiated by a rapid dilution process—has been investigated by time-resolved static and dynamic light-scattering measurements [256]. The scattering data analysis indicates that the key kinetic steps during vesicle formation are the rapid appearance of disc-like intermediate micelles, followed by growth of these micelles and closure of the large discs formed into vesicles [256].

In addition to detergent removal through dialysis, gel permeation chromatography [256, 257] (which is based on the partitioning of detergent monomers into the pores of a swollen gel matrix) or so-called Bio Beads [246, 247, 258, 259] (which bind detergent monomers) can also be applied.

In the case of saturated PCs like DMPC and DPPC and octyl-β-D-glucopyranoside, the originally developed detergent-dialysis method has been modified slightly because of the relatively high T_m value of these lipids (see Table 4) [248]. The important modification is a slow dilution step before the actual dialysis procedure [248], resulting in mainly unilamellar vesicles with a mean diameter of 98 nm

Table 5. Some of the detergents most often used for the preparation of vesicles by the detergent depletion method (Section 3.27) and approximate mean sizes of the vesicles formed in the case of egg yolk PCs.

Detergent	cmc at 25 °C (mM)	Method for removing the detergent	Reported approximate vesicle diameters (nm)	Refs.
Sodium cholate	~11	Gel permeation chromatography	30	[257]
		Dialysis	60	[244]
			70	[252]

CHAPS (3-[(3-cholamidopropyl) dimethylammonio]-1-propane sulfonate)	~5–10	Dialysis	380	[519]

Note: The size of the vesicles may very much depend on the experimental conditions (see text). In particular, the resulting sizes may also depend on the presence of bilayer soluble substances (e.g., cholesterol [245, 246]) or in particular cases (cholate) on the presence of divalent cations (e.g., Ca^{2+}) [519]. The approximative cmc values given in the table are taken for the bile salts from [520]; for $C_{12}E_8$ from [521, 522]; for CHAPS from [522, 523]; and for *n*-octyl-*β*-D-glucopyranoside from [522].

(DMPC) and 94 nm (DPPC) under the corresponding conditions used [248].

It is quite generally possible to first simply dilute the mixed micellar system, followed by dialysis to completely remove the detergent [260]. If the detergent is not completely removed, the vesicle preparation by simple dilution will always contain detergent molecules, even if the dilution is 100- or 200-fold [250].

In a particular case [261], SUVs with a mean diameter of 23 nm were first prepared by sonication from egg yolk PC at a concentration of 20 mM. The detergent sodium deoxycholate was then added to give an aqueous mixture at a ratio of deoxycholate to PC of 1:2 (mol/mol). This mixture contained vesicles that were considerably larger than the SUVs used, because of the uptake of the detergent molecules. Deoxycholate was then removed to about 96–98% first by gel filtration and then almost completely by a second gel filtration. The final preparation—containing less than one deoxycholate molecule per PC molecule—were dispersed unilamellar vesicles with a mean diameter of 100 nm [261]. The same mean vesicle sizes were also obtained if instead of SUVs a dry egg yolk PC film was treated with deoxycholate, followed by bulk sonication and detergent removal [261].

Large-scale production of vesicles by detergent dialysis is possible (e.g., [262]), and commercial devices are available under the trade names Liposomat and Mini Lipoprep.

The detergent depletion method is the method of choice for the reconstitution of water-insoluble membrane-associated proteins, which in a first step are extracted from the biological membrane by a mild detergent that does not lead to an irreversible protein denaturation [258, 263]. The membrane protein-containing mixed detergent/lipid micelles are then converted to membrane protein-containing vesicles by one of the detergent removal techniques described above.

3.28. (Mixed) Vesicles Prepared by Mixing Bilayer-Forming and Micelle-Forming Amphiphiles

As mentioned in Section 3.27, mixed lipid/detergent vesicles form transiently during detergent removal from detergent/lipid micelles. Such mixed vesicles can also be prepared by adding to preformed lipid vesicles (prepared by any method) above T_m an appropriate amount of a particular detergent [264, 265] or by simply diluting a mixed detergent/lipid micellar solution [266]. Examples of detergents that have been used include sodium cholate [267], *n*-octyl-*β*-D-glucopyranoside [268], or 3-[(3-cholamidopropyl)dimethylammonio]-1-propane sulfonate (CHAPS) [269]. The size of the resulting mixed lipid/detergent vesicles depends on the experimental conditions, such as the size (and lamellarity) of the initial vesicles, the chemical structure of the lipid, the lipid concentration, the chemical structure of the detergent, and the detergent concentration.

Phosphatidylcholines like POPC, SOPC, DMPC, DPPC, or the mixtures extracted from egg yolk or soybeans are the amphiphiles whose mixed lipid/detergent vesicle (bilayer) formation has been studied most extensively. These PCs all have two long hydrophobic acyl chains containing 14 to 18 or 22 carbon atoms (see Tables 2 and 4).

PCs with two short acyl chains, containing fewer than 10 carbon atoms, do not form bilayers (vesicles) in dilute aqueous solution, but rather micelles (as long as the concentration is kept above the cmc) [270, 271]. While a very short-chain PC (1,2-dibutanoyl-*sn*-glycero-3-phosphocholine) forms more or less spherical micelles, an increase in the chain length up to eight carbon atoms leads to the formation of extended, elongated micellar structures. All of these short-chain PCs are detergents in the sense of the term used here (Section 3.27) [272], and unilamellar vesicles composed of long-chain PCs and short-chain PCs can easily be prepared, for example, by the addition of a micellar solution of 1,2-diheptanoyl-*sn*-glycero-3-phosphocholine (final concentration 5 mM) to a DPPC dispersion (final concentration 20 mM) in an aqueous solution [273]. The resulting vesicles are rather stable and have mean diameters below as well as above 1 μm [274], depending on the experimental conditions, such as the ratio of the short-chain PC to the long-chain PC and cholesterol content [274].

One particular type of mixed lipid/detergent vesicular system (also containing ethanol)—not prepared by detergent dialysis, but by simple detergent and lipid mixing—are the so-called Transfersomes, vesicles that are claimed to be able to transfer water-soluble drugs through the skin to the blood circulation (transdermal drug delivery), particularly through the outermost physical barrier of the skin, the horny layer, called the stratum corneum. Transfersomes seem to be ultradeformable and may squeeze through the stratum corneum pores, which have diameters only one-tenth of the size of the Transfersomes. In this way, encapsulated water-soluble drugs may be transported across the skin [231]. Transfersomes are prepared by mixing an ethanolic solution of soybean PCs with (for example) sodium cholate to yield a suspension typically containing 8.7% (w/w) soybean PCs and 1.3% (w/w) cholate as well as approximately 8.5% (v/v) ethanol [275, 276]. For a reduction in vesicle size to about 500 nm, the suspension was treated by sonication, freeze-thaw cycles, and processing with a homogenizer.

In the case of the particular non-ionic industrial amphiphile Brij 30 (*n*-dodecyl tetraethylene glycol ether, abbreviated as $C_{12}E_4$ or $C_{12}EO_4$, also called Laureth-4), vesicles have been prepared by simple dilution from so-called hydrotrope solutions, which contained in addition to $C_{12}EO_4$ the micelle-forming surfactant sodium xylene sulfonate [277]. Through a detailed elaboration and analysis of the three-component phase diagram containing $C_{12}EO_4$, sodium xylene sulfonate, and water, the conditions under which vesicles form have first been established. Appropriate starting conditions were then chosen, and a corresponding dilution resulted finally in the desired vesicular system, which contained not only the vesicle-forming amphiphile, but also the hydrotrope (as constituent of the aqueous phase) [277].

3.29. Vesicles Prepared from Lipids in Chaotropic Ion Solutions

This method is related to the detergent-depletion method described in Section 3.27. Chaotropic substances (e.g., urea, guanidinium hydrochloride, potassium thiocyanate, trichloroacetate, or trichlorobromate) are known to disturb (break) the structure of water, and lipids are soluble in chaotropic solutions [278]. Solutions of trichloroacetate, for example, dissolve PCs as micellar solution [279], through a binding of the ions to the head groups, which leads to an increase in a_0 (see Section 6). If a SUV suspension prepared from phospholipids in buffer solution by probe sonication is mixed with an aqueous solution containing sodium trichloroacetate, a micellar solution is first obtained (at about 1–3 M sodium trichloroacetate in the case of 0.1–0.5 mM phospholipids). This solution is then extensively dialyzed against a buffer solution to remove all of the chaotropic ions, resulting in the formation of uni- or oligolamellar vesicles with diameters between 10 and 20 μm, although many small vesicles are also present [278]. If freeze-thaw cycles are used, the amount of chaotropic ions needed to generate giant vesicles is lowered considerably [278].

3.30. GVs Prepared from a W/O Emulsion with the Help of a Detergent

This method involves the use of nonphospholipid amphiphiles in a four-step procedure [280]. First, a w/o emulsion is formed by homogenization of an aqueous solution, *n*-hexane and a mixture of soybean phospholipids and the non-ionic surfactant Span 80 (sorbitan monooleate). Second, *n*-hexane is removed by rotatory evaporation from the emulsion under reduced pressure, resulting in the formation of a water-in-lipid mixture. Third, this mixture is mixed with an aqueous solution containing a water-soluble detergent (such as sodium dodecyl sulfate, hexadecytrimethylammonium bromide, or Tween 80 (POE (20) sorbitan monooleate, which is a modified sorbitan monooleate that contains on average a total of 20 hydrophilic oxyethylene units). Fourth, the highly water-soluble detergent is removed by dialysis, leading to the formation of micrometer-sized vesicles.

4. PREPARATION OF REVERSED VESICLES

There seems to be a kind of symmetry among most self-organized surfactant aggregates with regard to the distribution of the hydrophilic and the hydrophobic parts of the surfactants in the aggregate [281–283]. There are (normal) micelles (L_1-phase) and reversed micelles (L_2-phase), a (normal) hexagonal phase (H_I) and a reversed hexagonal phase (H_{II}), and (normal) emulsions (oil-in-water, o/w) and reversed emulsions (water-in-oil, w/o) [235]. In the case of vesicular aggregates, the existence of reversed vesicles has been demonstrated [283], for example, for a system containing the non-ionic surfactant tetraethyleneglycol dodecyl ether (*n*-dodecyl tetraethyleneglycol monoether, abbreviated $R_{12}EO_4$, $C_{12}EO_4$, or $C_{12}E_4$), the solvent *n*-dodecane, and water [281, 282]. These reversed vesicles form first upon the preparation of a mixture composed of 1 wt% water and 99 wt% of a *n*-dodecane solution which contains 2.5 wt% $C_{12}EO_4$ [281]. After equilibration at 25 °C, a two-phase system forms that is composed of a lamellar liquid crystalline

phase that is in equilibrium with an excess *n*-dodecane phase. When these two phases are mixed by hand-shaking, a heterogeneous dispersion of mainly multilamellar reversed vesicles forms with diameters of the reversed vesicles from less than 1 μm to 10–20 μm [281]. Strong vortexing leads to a reduction in size below 200 nm [282]. Without water, no reversed vesicles form.

A reversed vesicle formed in an oil (in a water-immiscible, apolar solvent) is composed of an oily core and one or several closed "reversed" surfactant bilayer shells. The reversed bilayers are organized in such a way that the hydrated hydrophilic head groups of the amphiphiles are facing toward the center of the reversed bilayer, while the hydrocarbon chains are in contact with the oil [281].

The particular type of reversed vesicles formed from $R_{12}EO_4$, water, and *n*-dodecane seem to be rather unstable and convert back into the thermodynamically stable two-phase system within hours or days [281]. Considerably more stable reversed vesicles can be obtained from a mixture of the non-ionic surfactants sucrose monoalkanoate (which is, to at least 95%, a monoester containing 10 wt% tetradecanoyl, 40 wt% hexadecanoyl, and 50 wt% octadecanoyl chains [283]), hexaethyleneglycol hexadecyl ether (abbreviated $R_{16}EO_6$, $C_{16}EO_6$, or $C_{16}E_6$), *n*-decane, and water [284]. The two surfactants are mixed at a weight ratio of sucrose monoalkanoate to $C_{16}EO_6$ of 85:15, and vesicle formation is observed at typically 3 wt% surfactant in *n*-decane with a typical weight ratio of surfactant to water of 6 [283]. Treatment of the vesicle suspension with a probe sonicator at 30 °C leads to a reduction in the reversed vesicle size to about 150–300 nm, depending on the experimental conditions, such as the water-to-surfactant ratio and the surfactant concentration [284].

The formation by vortexing of micrometer-sized reversed vesicles (and reversed myelin figures) has also been observed in *m*-xylene at a surfactant-to-water weight ratio around 0.8 for a number of polyethyleneglycol oleoyl ethers (abbreviated $R_{18:1}EO_x$ or $C_{18:1}EO_x$, with mean values of x varying between 10 and 55) [285]. Furthermore, it seems that some phospholipids can also form reversed vesicles under particular conditions, as reported in the case of a system containing soybean phosphatidylethanolamine and triolein, saturated with water through vapor equilibration [286]. The particles formed—which are most likely reversed vesicles—have diameters in the range of 500 nm to 1.7 μm [286].

5. CHARACTERIZATIONS AND APPLICATIONS OF VESICLES

5.1. Characterizations of Vesicles

There are a number of typical properties that characterize a vesicle suspension, particularly the mean vesicle size, the vesicle size distribution, the mean number of lamellae per vesicle, and the chemical and physical stability [287]. All of these properties depend on (i) the chemical structure of the amphiphiles (or mixtures of amphiphiles) from which the vesicles are formed; (ii) the solution in which the vesicles are formed (e.g., salt and buffer content in the case of (normal) vesicles and aqueous solutions); and (iii) the method of vesicle preparation (see Section 3). A minimal characterization of a vesicle suspension prepared is always needed. In many cases, a routine size measurement is appropriate, particularly by photon correlation spectroscopy (PCS), also called dynamic light scattering or quasi-elastic light scattering. PCS provides information about the homogeneity of a vesicle suspension, and it is relatively straightforward to find out whether the vesicles in a preparation are relatively monodisperse or whether they are polydisperse. For monodisperse and spherical vesicles, the mean hydrodynamic diameter of the vesicles can be determined relatively easily. In the case of polydisperse vesicle preparations and/or nonspherical vesicles, the interpretation of the scattering curves is more delicate, and it is recommended to apply additional methods as well, such as electron microscopy. A most probable vesicle size can be obtained by cryotransmission electron microscopy (cryo-TEM), although this method is limited to sizes below about 250 nm, and the sizes and morphologies obtained have to be taken with caution [288–290]. The use of different independent methods is always recommended.

Table 6 lists a number of methods that are used for characterizing vesicle suspensions. In many cases, fluorescently labeled amphiphiles are used in the vesicle membranes at a concentration of 1–2 mol%. These amphiphiles contain fluorescent groups, and the behavior of these molecules is then taken as a measure for the behavior of the bulk vesicle-forming amphiphiles, for example, for the determination of the lateral diffusion coefficient of the amphiphiles. Since the fluorescent groups are sometimes rather bulky, the kinetic constants obtained with these labeled molecules may be different from the actual membrane-forming lipids [291, 292]. The same is true for nitroxide-labeled amphiphiles used for ESR (electron spin resonance) measurements [292] (see Table 6).

For the detection of the internal aqueous volume in (normal) vesicles—usually expressed as microliter of trapped aqueous solution per micromole of amphiphile (μl/μmol)—dye molecules are often used, which can be easily quantified spectroscopically. Meaningful results, however, can only be obtained if the dye molecules do not interact with the vesicle membrane (no incorporation inside the membrane, no adsorption to the membrane).

In the case of permeability measurements, the use of dye molecules is convenient, and the release of vesicle-trapped molecules into the external medium can easily be quantified. In this case, however, one should always be aware that the permeability measured is the permeability of the particular dye molecules used under the particular experimental conditions. In this respect, NMR methods that are based on the use of paramagnetic shift reagents are better. The external addition of the shift reagents allows a distinction between the particular solute molecules present inside the vesicles and the solute molecules present outside of the vesicles, presuming that the shift reagent does not permeate the membranes. This has first to be proved. The permeability may very much depend on the experimental conditions, such as the presence of certain buffer species [293].

The list in Table 6 is certainly not complete. However, it gives a few hints about the general principles and problems of the vesicle characterization and lists some of the methods and techniques used. Depending on the vesicle preparation, a particular characterization may be more useful than

Table 6. Some of the principles and analytical methods used for characterizing the properties of vesicles (see also [66, 287]).

Property	Methods used and comments	Ref.
Mean vesicle size and size distribution	*PCS* Analysis of the time dependence of intensity fluctuations in scattered laser light due to the Brownian motion of the vesicles, which is related to the mean hydrodynamic radius (R_h) of the vesicles. If the vesicle suspension is very polydisperse and/or contains non-spherical vesicles (e.g., caused by an osmotic imbalance between the inside and the outside of the vesicles), the size analysis is rather complex and difficult	[2, 31, 528–531]
	SLS Average scattering intensities are measured as a function of the scattering angle and the vesicle concentration, allowing the determination of the mean radius of gyration (R_g) of the vesicles	[532–534]
	FFEM Replicas of fractured vesicles are analyzed. The vesicles are fractured at low temperature (-100 °C) under conditions where the water is in an uncharacterized (amorphous), "glassy" solid state. Nonequatorial fracturing leads to replicas that do not represent the "true" vesicle size	[1, 2, 136, 162, 300, 535]
	Cryo-TEM The vesicles are directly observed at low temperature (-170 °C) after rapid freezing ($\sim 10^6$ °C/s)—under conditions where the water is in an amorphous solid state—to represent the state of the vesicles at the temperature from which the sample is cooled. The observed diameters of the vesicles correspond to the "true" vesicle diameters. Only applicable for vesicles with sizes below ~250–500 nm. Not free of "artefacts" ("artifacts"), i.e., formation of microstructures due to specimen preparation, electron optics, or radiolytic effects [288–290]	[2, 3, 536]
	LM Only for GVs	[4, 66, 89, 91, 536]
	Size exclusion chromatography Conventional and high-performance liquid chromatography (HPLC) separation based on the principle that the partitioning behavior of vesicles in the pores of a solid column matrix depends on the size of the vesicles	[66, 386, 537]
	NMR Size determinations possible from ^{31}P-NMR spectra of phospholipid vesicles that have sizes below 1 μm with the help of a comparison with simulated spectra. For spectra simulation, the dynamics of the vesicles and the phospholipids in the vesicle membranes are considered	[136]
	AFM The vesicles have to be deposited on a solid surface, which may lead to vesicle deformations and vesicle aggregations	[538, 539]
	SANS Measurements in D_2O that may influence the vesicle size *via* altered head group interactions. Relative complex analysis involving fitting of experimental data	[540, 541]
Bilayer thickness	*X-ray* Based on the interaction of X-rays with the electrons of the amphiphiles in the vesicles	[80, 300, 542]
	Cryo-TEM	[543]
	SANS Measurements in D_2O. Bilayer thickness determinations possible in the gel, in the ripple, and in the lamellar phase of the vesicle-forming surfactants (see Section 2)	[540, 541, 544–546]
Vesicle shape and morphology	*LM* Only for GVs. Detection of MVVs	[547–552]
	FFEM Detection of MVVs	
	Negative staining EM Heavy metal ions have to be added to the vesicle dispersion, which always alters the vesicles. Furthermore, the vesicles are observed in a dry state	[12]

continued

Table 6. Continued

Property	Methods used and comments	Ref.
	Cryo-TEM Only for vesicles with sizes below ~250–500 nm	[553]
Lamellarity	*Cryo-TEM* Only for vesicles with sizes below ~250–500 nm	[3, 293]
	Negative Staining EM Addition of heavy metals (osmium tetroxide) needed. The number of lamellae detected may not represent the "true" number of lamellae	[12, 31]
	NMR ^{31}P-NMR in the case of phospholipid vesicles. Externally added membrane-impermeable Mn^{2+} influences the ^{31}P-NMR signal of the phospholipids in the outermost monolayers by broadening the resonance beyond detection. The resonances of the inner phospholipids are unaffected. Paramagnetic shift reagents may also be used (e.g., Pr^{3+} and Eu^{3+})	[161, 162, 293, 554]
	Fluorescence quenching An appropriate amphiphilic fluorescent probe molecule is used in the vesicle preparation, and the fluorescence of the amphiphiles in the outermost layers is quenched by adding to the vesicles a membrane-impermeable reagent	[555]
	SAXS Based on the interaction of X-rays with the electrons of the amphiphiles in the vesicles	[556]
	Chemical modification Functional groups present in the hydrophilic head groups of the amphiphiles in the external layer(s) of the vesicle and exposed to the bulk aqueous solution are chemically modified by externally added reagents that do not permeate the membranes and therefore do not react with the amphiphiles that are present in the inner layer(s) of the vesicles with their head groups exposed to the trapped aqueous space. The chemically modified amphiphiles are then quantified	[31]
Lipid domains in the membranes (rafts)	*Two-photon fluorescence microscopy* Use of membrane soluble fluorescent probes. Only for GVs	[557]
	NMR ^{31}P-, ^{13}C-, or ^{2}H-NMR	[558, 559]
	Confocal fluorescence microscopy Distinction between solid-ordered and fluid-disordered domains in vesicle membranes made with two fluorescent probes that have different affinities for the two domains. Only for GVs	[560]
Phase transition temperature (T_m)	*DSC* A vesicle sample and an inert reference are heated independently to maintain an identical temperature in each. In endothermic solid-ordered/liquid-ordered phase transitions, heat is required in excess in the vesicle sample over the heat required to maintain the same temperature in the reference	[43, 300, 540]
	Fluorescence Fluorescence polarization measurements of a membrane soluble fluorescent probe (e.g., 1,6-diphenylhexatriene, DPH)	[31, 561, 562]
	CD Induced circular dichroism below the T_m of an achiral probe (1,6-diphenylhexatriene, DPH) embedded inside the vesicle membrane constituted by chiral amphiphiles. No CD signal above T_m	[563]
Mobility of the amphiphiles in the vesicle membranes	*NMR* ^{1}H-, ^{2}H-, ^{13}C-, ^{31}P-NMR	[37, 564–567]
	ESR Use of spin-labeled amphiphiles	[568]
	Quasi-elastic neutron scattering	[569, 570]

continued

Table 6. Continued

Property	Methods used and comments	Ref.
	Fluorescence Use of fluorescent amphiphiles	[571]
	Fluorescence correlation spectroscopy Analysis of the translational diffusion of a fluorescent probe. Only for GVs	[560]
	Fluorescence recovery after photobleaching Lateral diffusion of fluorescently labeled amphiphiles determined by first bleaching the lipids with an intense laser pulse, and then analyzing the fluorescence recovery kinetics in the bleached area, due to the diffusion of unbleached molecules into the previously bleached area	[37]
Molecular conformation of the amphiphiles in the vesicle membranes	*NMR* ^{13}C- or ^{2}H-NMR using labeled phospholipids	[300, 559, 564, 565, 572]
	FT-IR and *Raman* Determination of the equilibrium conformational characteristics of the amphiphiles	[37, 300, 573]
	CD For vesicles composed of chiral amphiphiles	[563]
Membrane fluidity and order	*Fluorescence* Use of fluorescent membrane probes. Measurements of static or time-resolved fluorescence anisotropy	[37]
	NMR Use of partially and specifically deuterated amphiphiles	[300, 564]
	ESR Use of amphiphiles that have a nitroxide radical. The ESR spectrum of these amphiphiles is sensitive to the motions of the molecules	[37]
Transmembrane lipid diffusion (flip-flop)	*ESR* Use of spin-labeled amphiphiles (nitroxide radical)	[292, 574]
	Fluorescence Use of fluorescently labeled amphiphiles	[292]
Surface charge	*Zeta potential measurements, microelectrophoresis* Problematic, since the method is derived from classical theories of the double layer that do not include specific ion effects (see Section 6). Limited to particular background salt conditions (usually NaCl)	
Internal volume and entrapment (encapsulation) yield	*Use of dye molecules* The dye molecules (often fluorescent) are water-soluble and should not interact with the vesicle membrane. The dye molecules are entrapped during vesicle preparation, and the amount of entrapped dye molecules is determined quantitatively either after separation of the nonentrapped molecules from the vesicles or by addition to the vesicles of a membrane-impermeable reagent, which leads to a complete quenching of the fluorescence of the externally present dyes (e.g., calcein with quencher Co^{2+}) [575]. Simple dilution of the externally present dye may also be possible [577]	[31, 66, 575–577]
	NMR ^{17}O-NMR of the water oxygen. Addition of the membrane-impermeable paramagnetic shift reagent $DyCl_3$ to the vesicles below T_m leads to a shift in the ^{17}O resonance corresponding to the external water. The internal water peak remains the same. Above T_m, only one peak is observed because of rapid water equilibration	[554]
Membrane permeability	*Use of dyes or radioactively labeled molecules* Determination of the release of dye molecules entrapped inside the aqueous interior of the vesicles as a function of time under particular storage conditions	[31, 578]
	NMR Use of ^{1}H- or ^{17}O-NMR and an externally added membrane-impermeable paramagnetic shift reagent (Mn^{2+}, Pr^{3+}) to distinguish between internal and external permeants	[579–582]

continued

Table 6. Continued

Property	Methods used and comments	Ref.
	Use of ion-selective electrodes The ions present outside of the vesicles can be detected	[583]
Chemical stability	*Thin-layer chromatography* Analysis of possible degradation product due to hydrolysis and oxidation reactions	[72]
	High-performance liquid chromatography Analysis of possible degradation product due to hydrolysis and oxidation reactions	[72]
Physical stability	*Turbidity, PCS, FFEM, Cryo-TEM*, and others Analysis of possible size changes during storage due to vesicle aggregation and fusion	[66, 69, 584]

Abbreviations: AFM, atomic force microscopy; CD, circular dichroism; cryo-TEM, cryo-transmission electron microscopy (also called cryo-fixation); DSC, differential scanning calorimetry; EM, electron microscopy; ESR, electron spin resonance (also called electron paramagnetic resonance, EPR); FFEM, freeze-fracture electron microscopy; FT-IR, Fourier transformed infrared; LM, light microscopy; NMR, nuclear magnetic resonance; PCS, photon correlation spectroscopy (also called dynamic light scattering (DLS) or quasi-elastic light scattering (QELS)); SANS, small-angle neutron scattering; SAXS, small-angle X-ray scattering; SLS, static (or classical) light scattering.

another, and certain methods may not be applied at all (e.g., ^{31}P-NMR obviously cannot be used for the determination of the lamellarity of vesicles that are not composed of phosphorous-containing amphiphiles).

5.2. Applications of Vesicles

Lipid vesicles are used successfully in many different fields as interesting and versatile submicrometer- or micrometer-sized compartment systems [69, 294–297]. This wide applicability of vesicles and the broad interest in vesicles can be understood at least on the basis of the following four reasons:

(i) Lipid vesicles can be considered membrane or biomimetic systems [298, 299], since the molecular arrangement of conventional vesicle-forming amphiphiles in a vesicle is a (more or less curved) bilayer, like the lipid matrix in biological cell membranes [97, 300] or in the outer coat of certain viruses [97].
(ii) Vesicles prepared from amphilphiles present in biological systems allow applications as biocompatible and biodegradable systems.
(iii) Water-soluble as well as certain water-insoluble molecules can be entrapped inside the aqueous or hydrophobic domains of the vesicles, allowing the use of vesicles as carrier systems and nanometer- or micrometer-sized reaction compartments.
(iv) Vesicles can be prepared not only from the conventional PC type of bilayer-forming amphiphiles, but also from a large number of different nonphospholipid surfactants (or mixtures of surfactants), allowing the preparation of application-tailored and specifically designed and functionalized systems.

Among the more than 30,000 known surface active compounds [301], a large number of surfactants and surfactant mixtures (including many nonphospholipid amphiphiles) have been reported to form vesicles. The basic principles that lead to the formation of vesicles are the same for all, that is, the requirements of (i) an effective packing parameter $p\ (=v/a_0 l)_{\text{eff}} \approx 1$ (see Section 1.1), (ii) chain flexibility ($T > T_m$), and (iii) sufficiently low amphiphile concentration (global packing constraints) [7]. Examples of vesicle-forming amphiphiles include

- cationic di-*n*-alkyldimethylammonium ions [302, 303] (such as di-*n*-dodecyldimethylammonium bromide (DDAB) [304] and other di-*n*-dodecyldimethylammonium halides [305] and di-*n*-octadecyldimethylammonium chloride [306–308] or bromide [308, 309] or other counter-ions [310]);
- the cationic oleyldimethylaminoxide [311];
- anionic phospholipids (such as egg yolk phosphatidic acid mixtures and ox brain phosphatidylserine mixtures [312, 313]);
- anionic di-*n*-alkylphosphates [314–316] (e.g., di-*n*-dodecylphosphate [317], di-*n*-hexadecylphosphate [318–322], and various di-polyprenylphosphates [323, 324]);
- anionic linear and branched monoalkylphosphates (such as different polyprenylphosphates [325], *n*-dodecylphosphate [326], 6-propylnonylphosphate [327], 4-butyloctylphosphate [327], and 2-pentylheptylphosphate [327]);
- anionic tridecyl-6-benzene sulfonate in the presence of salt (sodium chloride) [328];
- anionic fatty acid/soap mixtures (e.g., *n*-octanoic acid/*n*-octanoate [329], *n*-decanoic acid/*n*-decanoate [329–331], oleic acid/oleate [332–334]);
- anionic surfactant/alcohol mixtures (such as sodium *n*-dodecylsulfate/*n*-dodecanol [329, 335] and sodium *n*-decanoate/*n*-decanol [336], or sodium oleate/*n*-octanol [337], which can form a highly viscous phase of densely packed vesicles);
- mixtures of cationic and anionic surfactants, so-called catanionic mixtures (such as *n*-hexadecyltrimethylammonium tosylate/sodium *n*-dodecylbenzenesulfonate [20, 59], *n*-hexadecyltrimethylammonium bromide/sodium *n*-octylsulfate [338–342], and sodium *n*-dodecylsulfate and di-*n*-dodecyldimethylammonium bromide [343, 344]);
- ganglioside GM3 [345, 346];
- phosphatidylnucleosides (such as 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphocytidine [347, 348]);
- diblock copolymers [24] (such as the ethylene oxide (EO)/butylene oxide (BO) diblock copolymers EO_6BO_{11}, EO_7BO_{12}, $EO_{11}BO_{11}$, $EO_{14}BO_{10}$, and $EO_{19}BO_{11}$ [349]);

- triblock copolymers (such as the ethylene oxide (EO)/propylene oxide(PO)/ethylene oxide (EO) triblock copolymer $EO_5PO_{68}EO_5$ (called Pluronic L121) [350] and the polymerizable poly(2-methyloxazoline)/ poly(dimethylsiloxane)/ poly(2-ethyloxazoline) triblock copolymers [351]);
- polymerizable amphiphiles [33, 352, 353];
- perfluorated surfactants [354] (such as short-chain perfluorophosphocholines [355] and perfluoroalkyl PCs [356]);
- bolaamphiphiles, which are membrane-spanning amphiphiles with two hydrophilic head groups at the two ends of the molecule and actually form vesicles containing not bilayered but monolayered shells [357–360];
- gemini surfactants that contain two hydrophobic tails and two hydrophilic head groups linked together with a short linker [361, 362];
- industrial, not very well defined surfactant/cosurfactant mixtures (such as *N*-methyl-*N*-alkanoyl-glucamine/ octanol or oleic acid mixtures [363]);
- calixarene-containing [364] or cryptand-containing amphiphiles [365];
- fullerene-containing amphiphiles with two hydrophobic chains and two charged head groups [366];
- double-chain amphiphiles with a polar alkoxysilyl head group, allowing the preparation of a kind of organic-inorganic hybrid vesicle, called cerasomes [367];
- triple-chain amphiphiles containing three hydrophobic chains and two charged polar head groups [365, 368];

and many more (e.g., [33, 358, 369]).

Finally, complex vesicle-based surfactant aggregates can be prepared (e.g., large vesicles composed of one or more types of amphiphiles may contain vesicles of another type of amphiphile), based on principles that include the specific molecular recognition between different types of vesicles initially prepared by one of the established methods described in Section 3 [370–372].

It is rather obvious that one consequence of the fact that vesicle formation is observed from so many different classes of amphiphiles (or mixtures of amphiphiles) is the very broad range of applications in very different fields. Vesicles are applied—or investigated for potential applications—at least in the following areas:

- in pharmacology and medicine [69, 73, 296, 297, 373–378] as parenteral or topical drug delivery systems [297, 379–381], in the treatment of infectious diseases, in anticancer therapy, as gene delivery systems, as immunoadjuvants, and as diagnostics;
- in immunoassays [382–385];
- in chromatographic separations using immobilized vesicles [386, 387];
- in cosmetics as formulations for water and nutrient delivery to the skin [388–391];
- in a variety of biophysical investigation of biological membrane components, including the reconstitution and use of membrane-soluble proteins [4, 69, 258, 263, 392];
- in research on membrane-soluble ion channels [393–399];
- in research related to the question of the origin and evolution of life, as models for the precursor structures of the first cells [400];
- in research aimed at constructing artificial (or minimal) cells [401, 402], for example, for potential biotechnological applications [402];
- in food technology and nutrition as carrier systems for food additives and ingredients and for the control of certain food processes (e.g., cheese ripening) [403–405];
- in agrochemistry [406];
- as nanometer- or micrometer-sized bioreactors containing catalytically active enzymes [75, 407–411];
- in nanoparticle technology [190, 299, 412–414], for example, for the preparation of semiconductor particles [412];
- in catalytic processes as simple models for enzymes [415–420] or simple models of other protein functionalities (e.g., as catalysts for the unfolding [421] or folding [387, 422] of proteins);
- in biosensor developments [423–425], particularly for the controlled preparation of bilayers adsorbed to solid surfaces [426–429];
- in the extraction of heavy metal ions with the help of functionalized, metal-sorbing vesicles [430];
- as supramolecular, nanostructured polymeric materials (as polymerized vesicles) [431–433];
- in biomineralization [434–436];
- as templates for the synthesis of inorganic mesoporous materials [437, 438] or biomaterials [436] and in the preparation of hollow polymer capsules [356, 439–441];
- as templates for modifying the distribution of reaction products, for example, in reactions that lead to products that are only sparingly soluble in the absence, but soluble in the presence, of vesicles [442, 443];
- as a medium for the preparation of size-defined polymer particles from monomers that are soluble in the vesicle shell [444];
- as supramolecular, self-assembly-based devices [33, 298, 299, 358, 445], for example, for the conversion of light energy into chemical energy (artificial photosynthesis) [446, 447], for signaling and switching [448, 449], for the construction of molecular wires [450], and for a number of different redox processes [418];

and many more (e.g., [295, 299]).

One illustration of vesicles loaded with water-soluble molecules is shown in Figure 5. A cryo-transmission electron micrograph of POPC vesicles containing the protein ferritin is shown. The vesicles were prepared in the presence of ferritin, and the nonentrapped protein molecules were separated from the vesicles by size exclusion chromatography after vesicle preparation [451, 452]. Since this particular protein has a dense iron core with a size of about 8 nm, it is visible by electron microscopy, and the actual number of protein molecules per individual vesicle can be directly counted. This type of loaded vesicles can be used, for example, in basic studies on vesicle transformation processes [451, 452]. If the vesicles contain catalytically active proteins (enzymes), they may be used in drug delivery or as small bioreactors [75, 410, 411].

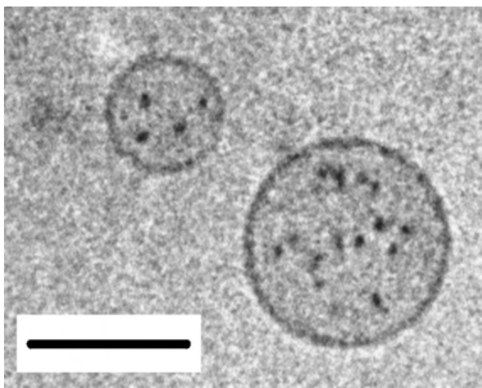

Figure 5. Cryo-transmission electron micrograph of two unilamellar vesicles that have been prepared from POPC by the reversed-evaporation technique (see Section 3.14) loaded with the iron storage protein ferritin, followed by extrusion ($REV\text{-}VET_{100}$). Nonentrapped ferritin molecules were removed by size-exclusion chromatography. Each black spot inside the vesicles represents one iron core (the core of an individual protein). The length of the bar corresponds to 100 nm. The electron micrograph was taken by M. Müller and N. Berclaz, Service Laboratory for Electron Microscopy, at the Department of Biology at the ETH Zürich. See [451, 452] for experimental details and for an application of ferritin-containing vesicles in the investigation of vesicle transformation processes.

Conceptually, an interesting principle of vesicle applications is vesicle transformation (at the site of application) to another type of surfactant assembly as a result of temperature changes that lead to changes in the surfactant packing parameter p (see Section 1.1). One particular example is the transformation of a 1-monoolein MLV suspension (L_α-phase) into a 1-monoolein bicontinuous cubic phase [9, 453–456].

There is no doubt that the number of applications will increase with increasing molecular complexity of the vesicular systems. Vesicles—and other surfactant assemblies (e.g., hexagonal and cubic phases)—will be applied more and more in all fields related to nanoscience and nanotechnology. The title of a recent publication in the field of vesicle drug delivery is an example of one of the directions in which vesicle research and application may go: "Biotinylated Stealth Magnetoliposomes" [457], a particular vesicle preparation that combines steric stabilization (Stealth) with molecular recognition (biotin) and magnetic nanoparticle properties. In other words, it is likely that the complexity of the vesicles prepared and investigated will increase to make them functional, possibly by combining the principles of supramolecular chemistry and surfactant self-assembly, to prepare nanometer- or micrometer-sized synthetic systems that may carry out some of the functions biological systems do rather efficiently [458, 459].

6. CONCLUDING REMARKS

There are many different methodologies that have been described in the literature for the preparation of lipid vesicles. Some (but not all), and certainly the most prominent and well known, are mentioned in this review, focusing on normal lipid vesicles (Section 3), although reversed vesicles are briefly mentioned as well (Section 4).

As outlined in Sections 1 and 2, the use of a number of different terms in the field of vesicles (and surfactant assemblies at large) is often rather confusing, and confusion even exists over the general use of the term "surfactant." It is worth pointing out that a reduction in the surface tension of water by surfactants can be achieved not only with classical micelle-forming, single-chain amphiphiles (such as sodium *n*-dodecyl sulfate, SDS) [460], but also with typical vesicle-forming double-chain phospholipids (such as SOPC or DPPC). Certainly, the kinetics and extent of adsorption of a particular surfactant at the water-air interface very much depend on the precise experimental conditions [461]. In the case of DPPC, for example, the equilibrium surface tension and rate of monolayer formation at the water-air interface depend on the temperature [462]. Below T_m, in the solid-ordered state of the molecules (see Section 2), the decrease in the surface tension of water by DPPC is considerably lower than that above T_m [462]. However, there is no doubt that glycerophospholipids like SOPC, POPC, or DPPC are surfactants in the sense of the definition of this term given in Section 1.1.

Since in dilute aqueous solution many of the bilayer-forming surfactants known (at least the most studied phospholipids) at thermodynamic equilibrium do not form a true vesicle phase (with a defined vesicle size, size distribution, and lamellarity), but under the appropriate conditions rather form a lamellar phase (L_α, L_β, L'_β or P'_β) with extended stacked bilayers, the preparation of vesicle dispersions necessarily involves the use of a particular method, a particular technology.

Depending on the experimental conditions, as mentioned in Section 3, depending on the chemical structure of the amphiphile or mixtures of amphiphiles used, the amphiphile concentration, the substances that may be encapsulated in the vesicle's aqueous interior or in the vesicle membrane, etc., there may be one particular method that is more advantageous in comparison with others.

Some of the methods described in Section 3 involve the use of organic solvents. This may be a problem for certain applications. Some methods can be scaled up to a bulk preparation [287], some methods involve mechanical treatments that may cause an inactivation of sensitive molecules one may like to entrap [75]; some methods are cheaper than others; some methods lead to very small vesicles (SUVs); other methods lead mainly to MLVs or LUVs or GUVs, or even MVVs; some methods are fast; some methods are relatively time consuming, etc.

There is no "best method." The choice of a certain method that may be useful very much depends on the particular problem one is trying to solve [67]. There are, at least in the case of the conventional type of phospholipids (or in the case of lipid mixtures containing phospholipids, particularly PC), a few general findings that are often valid; but one should be aware of the existence of possible exceptions:

- The hydration of a dried thin lipid film above the T_m of the lipids usually leads to the formation of MLVs if the film is dispersed vigorously (vortexing or hand-shaking) (see Section 3.2).
- The hydration of a dried thin lipid film above the T_m of the lipids usually leads to the formation of GUVs if

the film is undisturbed while being hydrated slowly (see Section 3.2).

- The electroformation method can be used for the preparation of GUVs with diameters between about 10 and 50 μm (or more) in the case of certain lipids (and lipid mixtures) and buffers with low ionic strength (Section 3.3).
- Relatively homogeneous preparations of SUVs with diameters around 50 nm or below can often be obtained by probe sonication (Section 3.5), although degradation of the surfactants and consequences of the possibly present metal particles (which may be a source of nucleation for vesicle transformation processes) have to be taken into account.
- Rather homogeneous preparations of LUVs with diameters around 50 or 100 nm can be obtained by the extrusion technique as FAT-VET$_{50}$ or FAT-VET$_{100}$ (Section 3.8, Fig. 3).
- The dehydration-rehydration method usually results in high encapsulation yields (Section 3.7).
- Freeze-thaw cycles may lead to vesicle size homogenization and solute equilibration between the external bulk solution and the trapped aqueous solution (Section 3.6).
- The detergent-depletion method often results in rather uniform vesicles with sizes below 100 nm, although the possibility of an incomplete removal of the detergent should be considered (Section 3.27, Table 5).
- The use of volatile cosolvents (oils) during vesicle preparation is often based on the principle that either w/o or w/o/w emulsions are formed from which the solvent is removed, limiting the solvents to all those that have a boiling point considerably lower than the boiling point of water (Sections 3.14–3.17, 3.24, and 3.25).

The physicochemical properties (such as chemical and physical stability, membrane permeability) of the vesicles formed very much depend on the surfactant (or surfactant mixtures) used. Depending on the surfactant, the characteristic properties may be very different from those of the conventional PC type of vesicles. Furthermore, the whole equilibrium phase behavior may be different, and cases are known where even true vesicle phases seem to form "spontaneously" [7, 463–465] and seem to exist at thermodynamic equilibrium [7, 59, 60, 463]. In these cases, vesicles of a certain size and lamellarity just form by mixing, independent of the method of preparation. The stability of the vesicles is understood in the case of the so-called catanionic vesicles (which are composed of a mixture of positively and negatively charged amphiphiles) on the basis of a most likely uneven distribution of the amphiphiles in the two bilayers. This allows the required differences in curvature and molecular packing in the two halves of a bilayer [60, 466], similar to the case of lipid vesicles prepared from mixtures of long-chain and short-chain PCs (Section 3.28) [273, 274]. With respect to the spontaneity in the formation of this type of vesicles, it has been argued, however, that shear forces present during the preparation (mixing of solutions) play an important role in vesicle formation [467].

An interesting case of unilamellar vesicles as thermodynamic equilibrium state has been described in the case of certain ionized phospholipids (e.g., 1,2-dimyristoyl-*sn*-glycero-3-phosphoglycerol, DMPG) [468–472]. Under the experimental conditions used, unilamellar DMPG vesicles apparently only form at the critical temperature (T^*) of 31.6 °C [471], which is different from T_m. Above T^* MLVs are formed; below T^* the phospholipids arrange into a sponge phase [471]. Further investigations are needed to fully understand this critical phenomenon and to clarify whether this unilamellar vesicle formation is a particular case or whether it can be more generally observed.

With the exception of a few cases—such as the detergent depletion method (Section 3.27) (e.g., [256])—the general mechanism of vesicle formation is not yet completely understood in its details, although general principles have been elaborated [7, 69, 473–477].

From a more practical point of view, and by looking at all of the methods described in Section 3, it is evident that the vesicles often form from a preorganized state of the lipids. This preorganization may be

(i) Lamellar sheets present in a dry film deposited on a solid surface (Sections 3.2 and 3.3) or in the ethanolic pro-liposome state (Section 3.19).
(ii) W/o or w/o/w emulsion droplets (Sections 3.14, 3.15, and 3.30).
(iii) Mixed micelles in the case of the detergent-depletion method (Section 3.27) or micelles in the case of chaotropic ion solutions (Section 3.29).

In a few cases, the vesicle formation is triggered as a result of a direct contact of a nonorganized state of the lipids with an aqueous environment, as in the case of the Novasome technology (Section 3.10), the ethanol injection method (Section 3.18), or the ether injection method (Section 3.24). A simple summarizing schematic representation of some of the different pathways for the formation of (normal) lipid vesicles is given in Figure 4. It is expected that more methods for the preparation of vesicles will be developed, although the general pathways may remain the same. The range of pre-organized starting systems from which vesicles can be formed may be expanded, and more will probably soon be understood for the vesicle formation at large.

(Normal) vesicles are just a particular state of aggregation of surfactants (or surfactant mixtures) in an aqueous solution that are topologically closed with an internal aqueous space. Vesicles can be unilamellar or multilamellar, and the general principles of surfactant assembly have been outlined [7–11]. As mentioned above, vesicles sometimes appear to be thermodynamically stable, sometimes not. Like all self-assembled amphiphile aggregates—micelles, microemulsions, cubic phases, even biological membranes, etc.—the formation of vesicles depends on only a few things: (i) local curvature, (ii) global packing constraints (including interaggregate interactions), and (iii) flexibility of the hydrophobic chain(s). All of the methods described essentially depend on satisfying these criteria.

Physicochemical conditions of inside and outside of vesicles often differ greatly. This is a consequence of the closed topology. This fact, together with adverse packing conditions, can often result in a stable state of so-called supra-self-assembly (e.g., surfactant micelles existing inside surfactant *vesicles*) [478–480].

The basic principles that underlie self-assembly of vesicles are quite general and are firmly based in thermodynamics and statistical mechanics [7, 9, 10, 481]. The requirements for “designing” a vesicle are conceptually simple: a packing parameter close to unity (which means effectively a double-chain surfactant or mixed single-chain surfactants), flexible hydrophobic chains (a temperature above T_m), and control of inter- and intraaggregate interactions. Local and global packings are the key principles to consider.

Vesicles, however, are a very small part of a much larger class of self-assembled surfactant aggregates that include cubic phases, which are usually bicontinuous structures of zero average curvature. “Bicontinuous” means that both the aqueous and “oily” parts of the structure are continuously connected over the whole system. Cubic phases or bicontinuous structures in general are ubiquitous in biology for directing biochemical traffic [11]. Likewise, hexagonal phases and microtubules are close to lamellar (and vesicular) phases in a phase diagram [11].

Although these things are known and are even beginning to be understood, quantitative predictions remain a problem. This can be traced to the fact that the underlying theory of molecular forces that underpins physical chemistry and colloid and surface science is flawed [482, 483]. Previous theories cannot deal with specific ion effects (so-called Hofmeister series), dissolved gas, and other solutes that change the water structure. There is rapid development in this area at the moment, which is likely to provide predictability in vesicle design [482–484], which is certainly what one is aiming for.

GLOSSARY

Amphiphile A molecule that comprises at least two opposing parts, a *solvophilic* (for example “hydrophilic”, meaning water-loving) and a *solvophobic* (for example “hydrophobic”, meaning water-hating). Amphiphiles are surfactants.

Detergent A surfactant that in dilute aqueous solution forms micelles, spherical or non-spherical aggregates that contain in the interior of the aggregate the hydrophobic part of the surfactant and on the surface the hydrophilic part of the surfactant.

Glycerophospholipid A particular phospholipid that contains a glycerol backbone to which a phosphate group is bound.

Lamellar phase, L_α A particular liquid crystalline equilibrium state of surfactant molecules, also called liquid-disordered state. In an aqueous environment, the surfactant molecules are arranged in layers in which the hydrophobic part of a surfactant is in the interior of the layer and the hydrophilic part on the two surfaces of the layer, exposed to the aqueous environment.

Liposome Vesicle prepared from amphiphilic lipids.

Phase transition temperature, T_m Characteristic temperature (also called lamellar chain melting temperature) of surfactants that form a lamellar phase. Above the phase transition temperature, the surfactant molecules are in a liquid-disordered state, below in a solid-ordered state.

Phosphatidylcholine, PC A particular glycerophospholipid that contains a choline group in the hydrophilic part, bound to the phosphate.

Phospholipid A surfactant that is present in some of the biological membranes and contains at least one phosphate group.

Reversed vesicle Inverted vesicle formed in a water-immiscible, apolar solvent in the presence of a small amount of water.

Surfactant A molecule that is surface active, meaning that it accumulates at the surface of liquids or solids. Surfactants are amphiphiles.

Vesicle General term to describe any type of hollow, surfactant-based aggregate composed of one or more shells. In the biological literature, the term *vesicle* is used for a particular small, membrane-bounded, spherical organelle in the cytoplasm of an eukaryotic cell.

ACKNOWLEDGMENTS

The author thanks Barry W. Ninham (Department of Applied Mathematics, Australian National University, Canberra, Australia) for extensive discussions on the principles of surfactant self-assembly and for critically reading the manuscript. Manuscript reading and literature advice by Pasquale Stano (Department of Materials Science, ETH, Zürich, Switzerland) are also acknowledged. Furthermore, discussions with Saša Svetina (Institute of Biophysics, University of Ljubljana, Slovenia), Martien A. Cohen Stuart, Frans A. M. Leermakers, and Mireille M. A. E. Claessens (all from the Laboratory of Physical Chemistry and Colloid Science, Wageningen University, Wageningen, The Netherlands) are appreciated.

1. INTRODUCTION

Bioactive materials are of increasing interest for technological and nanotechnological applications [1]. Biological macromolecules, and even whole cells, have been intimately linked to inorganic or organic matrices to exploit their specific functions that are otherwise extremely difficult to mimic only with inorganic–organic molecules. These nanobiocomposites are very frequently based on proteins. Proteins are biological macromolecules able to perform a wide range of functions: (i) antibodies selectively recognize and strongly bind antigenes; (ii) carriers selectively recognize and reversibly bind small molecules transferring them from one location to another in living organisms; (iii) receptors selectively recognize specific compounds and trigger intra- and intercellular signals; (iv) enzymes recognize specific substrates and catalyze their transformation into products. Proteins achieve their functions via a fine tuning of the three-dimensional structure and conformational dynamics. Proteins are labile molecules and their native active state is stabilized over inactive, denatured states by only a few tens of kcal/mole, the energy of a few hydrogen bonds. Versatility, specificity, and efficiency of proteins are attractive properties that boost interest in their usage in technological applications. Most of these applications rely on the nanobioencapsulation of proteins into inorganic or organic matrices in order to increase stability, confine in space, obtain fast separation, convert a chemical reaction in optical or electrical signals, and isolate defined protein conformations. Among the different inorganic materials, silicates are by far the most used to adsorb, covalently link, and encapsulate proteins. In particular, in the past 10 years there has been an explosion in the use of sol–gel technology to trap proteins [2–5]. The field was reviewed with particular emphasis on bioencapsulation within synthetic polymers [6–8], bioactive sol–gel coatings [9], functional properties of immobilized proteins [10], sol–gel glass as a matrix for chemical and biochemical sensing [11], and properties and applications of proteins within sol–gel derived materials [12]. The great advantages of sol–gel methods for the entrapment of proteins are the very mild conditions of pH, solvents, and temperature required to prepare stable protein-doped nanoporous gels, the possibility to fabricate materials of different size and geometry, such as monoliths, films, fibers, nanospheres, sandwiches, powders, either in the absence of water (xerogels) or in its presence (hydrogels), the gel optical quality that makes them suitable for the detection of signals by spectroscopic techniques, and the very reduced rate of protein leaching. Because the conformational flexibility and the biological activity of the entrapped proteins are usually maintained, protein-doped silica gels have been used for the development of bioreactors, biosensors, photonic devices, biocoating, and controlled protein release. Furthermore, silica gel encapsulation selects defined conformational states of proteins by decreasing the rate of their interconversion [10]. This feature is exploited to investigate functional properties of defined tertiary and quaternary states of allosteric proteins.

2. PREPARATION AND PHYSICO-CHEMICAL PROPERTIES OF SILICA GELS

2.1. General Properties

Bioimmobilization allows one to exploit functional properties of biological species, such as proteins, peptides, nucleic acids, and whole cells, for biotechnological applications.

In order to obtain a suitable material, it is necessary that the immobilized biological reagents are characterized by a high concentration, a high degree of activity, long term stability even in adverse environmental conditions, free accessibility to reagents or analytes, and absence of leaching [10, 12]. However, in specific cases, like protein drug delivery *in vivo*, encapsulation methods have been designed to entrap biomolecules and slowly release them as a consequence of the erosion of the matrix.

Typical techniques to immobilize biomolecules are based on physical adsorption [13], surface covalent binding [14], entrapment in semipermeable membranes [15], and micro-encapsulation into polymeric microspheres and gels [16, 17]. Most of these methods are not generic; thus they are often limited to a selected type of biomolecules. Encapsulation of biological components into silica-based matrices is an immobilization procedure that, for a long time, has only been exploited for organic polymers and small molecules. Labile biomolecules do not withstand high temperature processing of glasses. Therefore, initially, immobilization techniques were studied that linked biomolecules on the surface of porous glasses via chemical agents. However, chemical modifications might affect the bioactivity of proteins and cells. Therefore, entrapment methods based on the physical encapsulation in sol–gel glasses (sol–gel process) were developed. First reports on the sol–gel encapsulation of enzymes were published in the early 1970s [18]. The method was extended to a wide range of biological species, immobilized in a variety of silica-based biocomposite materials.

Several features make the silica-based sol–gel technique an ideal method to immobilize proteins. The polymeric network limits the mobility of the protein, preventing aggregation and/or leaching. Nevertheless, the entrapped proteins usually retain their native structure and function. The nanoporous structure makes the protein active sites accessible to small reagents that diffuse in the solvent phase, and the pore size and distribution can be tuned. Futhermore, the silica matrix is characterized by a high thermal, mechanical, and chemical stability [19, 20]. In addition to being a long-term storage site, it gives to encapsulated biomolecules a greater resistance toward thermal and chemical insults (see Section 3.2). Silica gels are optically transparent above 300 nm [4, 21–25]. This allows one to detect spectral changes induced by ligand–protein binding and thus to develop optical sensors. Silica gels are not able to conduct electrons, but the addition of electron transport mediators allows one to obtain electrochemical sensors (see [7] and references therein and also [21]). Beyond all these properties, simple reaction conditions are the basis for the great success of protein immobilization via sol–gel methods. The absence of coupling agents, the aqueous medium, and room temperature processing are conditions that favor the maintenance of biological structure and function. The polymerization reaction is compatible with the pH and ionic strength required for protein function (typical pH range 4–10; ionic strength range 0.01–1 M). The amount of protein loaded depends on both gelation conditions and the necessity to avoid intermolecular interactions which could cause aggregation and alteration of protein function. The size of the protein does not seem to be a limiting factor for the encapsulation [21]. The addition of low concentrations of organic molecules affects the network formation.

2.2. Materials and Protocols for Gel Preparation

Sol–gel derived biocomposite materials are generally prepared via the partial or complete hydrolysis of a suitable silicium-containing precursor leading to the formation of an aqueous sol. The most frequently used precursors are tetraalkoxysilanes, mono-, di-, or tri-alkyl alkoxysilanes. Although we focus on silica derived glasses, other metal centers, such as Al, Ti, V, or Ce, can be used to modulate the material properties. The precursors may comprise functional groups ranging from alkenyl, aryl, amino, carboxyl, thiol, or other groups as well as redox-active moieties, flavins, or quinones. The hydrolysis reaction can be either acid or base catalyzed and forms a mixture of $R_xSi(OH)_y$ molecules (Fig. 1). Sonication of the mixture is frequently used to obtain a homogeneous sol. Hydrolysis may be followed by transesterification with additives, such as glycerol, to form polyglyceryl silicates which are more biocompatibile than alkoxysilane. The hydrolized precursor is mixed with an aqueous buffered solution containing the biomolecule and additives required to modify the properties of the final material (catalysts, drying control additives, polymers, templating agents, redox species). A polymeric network is achieved from the condensation between the silanol groups (Si–OH) obtained from hydrolysis, forming an oxo bridge (O–Si–O) with removal of a water molecule. As the condensation reaction proceeds, a wide range of linear, branched, and colloidal polysilicates is obtained, viscosity increases, and gelation occurs over a period of minutes to hours. The polymerization reaction

occurs spontaneously and irreversibly but changes in pH, temperature, salts, and catalysts can promote it. The gel consists of an amorphous solid with an interstitial liquid phase. When a biomolecule is added, the silica network, growing around the biomolecule, entraps it within the porous gel. The initial gels are soft and have a high water content (50–80%) and large pores (up to 200 nm diameter). After gelation, gels are subjected to an *aging* process, during which the condensation reaction and the cross-linking continue, leading to gel shrinkage and strengthening. Aging typically causes a 10–30% shrinkage of the matrix, the average pore diameter decreases by about 25%, and the relative proportion of siloxane to silanol groups increases [19]. Hydrolysis and condensation by-products, such as methanol when the precursor is tetramethylorthosilicate (TMOS), are easily removed from the matrix by repeated washing procedures. These aged gels can be partially or completely dried at room temperature by slow removal of the liquid phase (solvents, water, and alcohol). During this process, the gel shrinks significantly and further cross-linking of the matrix occurs. The decrease of the pore size causes the reduction of the volume of the liquid phase, and, eventually, a collapse of the pores takes place. The resulting xerogels are more rigid and dimensionally stable than the corresponding hydrogels, with pore diameter ranging typically between 1 and 10 nm. Transmission electron microscopy of TMOS-derived dried gels prepared in the absence and presence of hemoglobin exhibited pore size of 3–5 nm (Fig. 2). Bulk glasses can be obtained upon densification around 1000 °C, but high temperatures destroy the entrapped biomolecules.

Therefore, this stage of the sol–gel process is limited to the preparation of inorganic–organic-doped silica glasses.

According to the types of precursors and additives employed in sol–gel synthesis of hybrid materials, inorganic glasses, organically modified glasses, and organic–inorganic nanocomposite materials can be prepared [12]. The silica alkoxides most frequently used to obtain inorganic glasses are TMOS and tetraethylorthosilicate (TEOS). The conventional method involves acid-catalyzed hydrolysis and the use of methanol as a co-solvent. Indeed, the low water solubility and reactivity of these compounds requires the presence of co-solvents and catalysts that can be deleterius to the viability of entrapped biomolecules. Hydrolysis of alkoxides leads to the production of the corresponding alcohol, while the condensation reaction releases water and alcohols that are potentially protein denaturating agents. The method was improved by purging the sol with a nitrogen flow for 40 minutes at 4 °C prior to the addition of the protein, as in the case of hemoglobin-doped silica gels [26]. The gas flow allows one to remove at least part of the methanol produced by the sol–gel reaction. TMOS and TEOS are the most used precursors because methanol and ethanol are less detrimental for proteins than longer chain alcohols. Buffer systems, such as acetate and monobasic phosphate, were showed to stabilize cytochrome *c* against aggregation in a solution containing greater than 90 vol% methanol [27]. Currently, the sol–gel process with alkoxide silanes precursors is often performed in two steps. The first step is the hydrolysis of the alkoxide in acid medium in order to hydrolyze alkoxy groups. Sols are prepared by sonicating, in the absence of co-solvent, a mixture of TEOS or TMOS, water, and HCl until the mixture becomes clear and monophasic [28]. Then, upon mixing the sol and a buffer solution to adjust the pH to a value between 6 and 7, a solution containing a protein and a suitable buffer is added to the sol in ratios that vary from case to case. Condensation occurs at room temperature within a few minutes and without denaturation of most proteins. Following gelation, the hybrid material formed is allowed to age either in buffer (wet aging) or in air (dry aging).

An alcohol-free sol–gel process to encapsulate biological materials in inorganic glasses employs precursors such as sodium silicate or silicic acid to obtain aqueous silica gels [29, 30]. The method involves the mixing of a colloidal silica sol, commercially available in spherical particles at about pH 10.3, with a solution of acidified 0.1 M sodium silicate (Na_2SiO_3). After mixing, the resulting pH is close to physiological values (about 6.2–8.2). Then, a buffered protein-containing solution is mixed with an equal volume of the colloidal solution at the same pH value. An optically trasparent, solidlike, protein-containing gel is formed. After aging, the gel can be dried at 4 °C over a period of two to four weeks [29].

Poly(glyceryl silicate) (PGS) is a novel class of biocompatible precursors, namely, polyol esters of silicates, which allow one to overcome some complications encountered with other compounds, such as large-scale shrinkage and pore collapse during xerogel formation, and protein denaturation due to alcohol release. The important features of these precursors were summarized by Gill and Ballesteros [31]: high water solubility, autohydrolysis in aqueous media, and

hydrolysis reaction that liberates a nonvolatile, bioprotective alcohol, which also functions as a drying control additive [32–35]. Among various polyhydroxylated compounds, glycerol was selected for its high biocompatibility and functionality. PGS is a stable, water soluble solid formed by the partial hydrolysis and condensation of TMOS to poly(methylsilicate) followed by transesterification with glycerol, in a one-step process catalyzed by hydrocloridric acid or poly(antimony(III) ethylene glycoxide). In the absence of any catalyst and in the presence of an aqueous, buffered medium, PGS rapidly hydrolyzes and forms silica hydrogels in a few minutes. If polymerization occurs in the presence of proteins or cells, a very efficient entrapment of this species results, with little loss of activity. To yield bioactive silica glasses, after aging, the material is washed to remove glycerol and then dried to produce physically stable silica xerogels. The hydrolysis and polymerization rates of polyol silicates are higher than those of other precursors [36, 37]. This probably stems from the increased reactivity of the silicon center due to the electron-withdrawing effect of the polyol moieties and to the internally assisted hydrolysis by the hydroxyl function [32, 33]. Reactivity is controlled by adjusting the precursor composition.

The synthesis of inorganic materials does not offer the possibility to easily tune some fundamental characteristics of the hybrid material such as hydrophobic or hydrophilic properties, pore size, and mechanical stability. As outlined by Keeling-Tucker and Brennan [38], key problems with inorganic materials are (i) the relatively high polarity and surface charge due to high siloxide levels at neutral pH, (ii) the relatively rigid solvent phase due to adsorption of the solvent to the pore walls, and (iii) the heterogeneity in pore size, polarity, and mobility of the reactants. Therefore, other methods that allow better control over the final properties of a sol–gel derived glass have been developed. The addition of organically modified silanes to TEOS- or TMOS-based glasses provides organically modified silicates (Ormosils). A variety of organosilanes were used to form these materials [38]. Sol–gel methods involving these compounds were discussed [39, 40]. Although the organically modified silane is usually added to TEOS or TMOS, sometimes gels were obtained using the organosilane as the sole precursor [38]. With Ormosils it is possible to enhance the stability of hydrophobic proteins. Lipases provide a nice example showing how the chemical control of the gelation process could improve the enzymatic activity. Indeed, in aqueous media lipases catalyze hydrolysis of fats and oils to fatty acids and glycerol, whereas in organic media they catalyze esterification reactions. The active site is accessible to the substrate only when the displacement of an amphiphilic peptidic loop occurs. In aqueous solution this loop covers the active site, while at the lipid/water interface the loop undergoes the conformational rearrangement required to optimize function. Organic modified silicates offer a more lipophilic environment than hydrophylic silica matrices, and this type of encapsulation increases the activity of lipases [41] (see also Section 4). Ormosils are characterized by poor mechanical stability because of the presence of alkyl groups that reduce the degree of cross-linking. The same effect might contribute to increase the pore size and, thus, to improve the mobility of species in the glass. Phase separation occurs if several organic groups are added. In turn, this results in poor optical quality and cracking, perhaps owing to the existence of a critical point for the self-association of components. However, if the organosilane level increases over 50%, a homogeneous material is obtained [38]. Finally, nanocomposite materials are formed from inorganic or organic silicate precursors in combination with additives, such as hydrophobic or hydrophilic polymers [poly(ethylene glycol), poly(vinylimidazole), poly(ethyleneimine)], silicones, ionic or zwitterionic surfactants, micelles, liposomes, emulsions, liquid crystals, sugar, dyes, and redox species. These additives are usually dispersed into the silicate-containing solutions during the hydrolysis step. This might involve interaction with silica or segregation into independent phases, thus modifying the properties of the final material. Studies performed with fluorescent probes suggest that hydrophobic polymers tend to form a unique phase within silica derived nanocomposites, whereas hydrophilic polymers are characterized by a greater miscibility with aqueous solutions and, thus, are more frequently used. However, with high molecular weight hydrophilic polymers a segregation phase occurs [38].

2.3. Gel Structure and Interactions with Encapsulated Biomolecules

The design of useful biocomposites requires the optimization of the material features in order to adapt their properties to the performance required from the encapsulated protein. To this aim, the local environment around the active biomolecule has to be taken into account, as it may be affected by the physico-chemical properties of the silica matrix. Therefore, key sol–gel synthesis parameters are (i) the nature of the interactions between the gel matrix and the dopant protein and/or substrates/analytes and (ii) the influence of sol–gel glass on protein conformation and dynamics.

The surface chemistry of amorphous silica was extensively reviewed by Zhuravlev [42]. Here, we focus on the silica properties and synthesis parameters which affect protein bioactivity. One critical feature that controls the interaction between the biomolecule and the sol–gel silica matrix is the microstructure of the glass and, therefore, the formation and the characteristics of the pores that contain the protein molecules. In an enzyme doped silica matrix, pores should be large enough to unrestrict the free diffusion of solvent and ligand molecules, such as buffer ions, analytes, substrates, and products of enzymatic reactions. At the same time, they should be small enough to prevent leakage of the encapsulated macromolecules. The primary tool for characterizing the microstructure (i.e., the micropore volume and geometry) of xerogel samples is the measurements of nitrogen adsorption isotherms. Up to now, these experiments have showed that a unimodal pore size distribution does exist in protein-doped silica gels. The specific surface area and the pore size distribution of trypsin doped xerogels using Brunauer, Emmit, and Teller (BET) and Kelvin equations from nitrogen adsorption isotherms were calculated [43]. Glasses were characterized by an average distribution of pore diameter of 3–4 nm. The absence of autodigestion

by encapsulated trypsin, together with no detectable leakage from the gel, was interpreted as proof of the lack of diffusion within the matrix. Competion assays, performed to investigate the interaction of the substrate *N*-benzoyl-L-arginine-4-nitroanilide (BAPNA) with the active site, gave an indirect evaluation of the pore size. The inhibitory effect of polylysine polymers on BAPNA hydrolysis suggested that this effect is not stereospecific and is probably due to coating of the pore surface, interfering with BAPNA diffusion. More specific inhibitors were tested and found to be ineffective above 18,000 M_r, a cutoff value in agreement with the estimated pore size.

In aqueous silica xerogel doped with glucose-6-phosphate dehydrogenase and horseradish peroxidase, the pore distribution was determined and found to be relatively large [30]. Pores as small as 20–30 Å and as large as 800 Å were present. The mean pore size was approximately 200 Å. This finding is rather surprising because such large pores should allow the protein to escape from the gel (in the absence of interactions between protein surface and pore walls). Encapsulation of glucose-6-phosphate dehydrogenase and horseradish peroxidase in aqueous silica gel showed that, over the pH range 4–7, it is possible to tune the mean pore size and the volume fraction porosity: the lower the pH of the buffer used, the lower the mean pore size and volume fraction porosity [30]. Indeed, the pore size and porosity of a silica matrix are a strong function of reaction parameters as precursor ratio, pH, and temperature. Although the essential chemistry is simple, variation of one or more experimental parameters can dramatically affect the microstructure of the resulting gel. The dependence of pore structure and morphology on the relative rates of condensation and hydrolysis was investigated in the case of undoped silica gels [19, 44]. The measured value of times t_{clear} and t_{gel} provides information concerning the relative rates of hydrolysis and condensation [19]. t_{clear} is defined as the time after which two separate liquid phases are no longer discernible and is taken as an indication of the completion of the hydrolysis reaction, whereas t_{gel} is the time required for gelation. Studies performed on TEOS derived silica gels showed that t_{clear} decreases as the reactant ratio H_2O:TEOS increases at a fixed pH. This might reflect the faster hydrolysis rate due to a finer dispersion of the TEOS droplets in the aqueous phase. On the other hand, these results also suggested that the kinetics of the condensation reaction strongly depends on the reactant ratio, being more rapid as the ratio decreases at a fixed pH, due to more frequent interparticle collision [44]. The effect of pH on reaction kinetics and, thus, on gel microstructure, was also studied [19]. The hydrolysis and condensation reactions may be catalyzed by either an acid or a base. The condensation reaction proceeds via a base-catalyzed mechanism for pH values above the isoelectric point of silica (pH $\sim$ 2) and is acid-catalyzed for pH values below the isoelectric point. Gelation occurs rapidly at intermediate pH values (3–8) and relatively *mesoporous* gels are obtained. In these conditions, condensation is fast relative to hydrolysis and the formation of highly branched silica species is achieved. These species form loosely packed, clusterlike structures that coalesce leaving mesoporous regions between them. As the pH decreases and approaches the isoelectric point of silica, condensation becomes rate-limiting and randomly branched and relatively linear silicates result. The tightly interwoven gels, characterized by smaller pores, are defined as *microporous* structure.

Aging and, mainly, the hydration state affect the properties of the polymeric network microstructure. Xerogels possess an 8–10-fold smaller volume, reduced pore size, and higher mechanical strength than the corresponding wet gels. During drying, protein-containing pores behave differently from the empty ones. The former shrink but are adapted to the size of the protein, whereas the latter shrink and even collapse [27]. Although pore shrinkage is a common phenomenon in gel drying, the magnitude of the process is different in alkoxide based silica and in aqueous silica gel. Essentially, the shrinkage is much smaller in the latter, because some solid fraction already exists in the colloidal solution. The average pore size of the dried aqueous gel, determined using the BET adsorption method, was 5.3 nm in diameter, in contrast to the value of 2–3 nm found in dried alkoxide gels. It was also demonstrated that, in spite of the total shrinkage after complete drying being the same for a hemoglobin doped thin film and for bulk monoliths, the higher the rate of shrinkage (in a thin film pore contraction occurs rapidly), the higher the retention of native protein conformation, hence the protein stability [29].

PGS-derived silica gels form exceptionally porous matrices. Thermoporometric analysis of trypsin-doped sol–gels indicates that the mesoporous structure and pore volume of the hydrogels were substantially preserved upon formation of xerogels [31]. Gel shrinkage and pore collapse can be minimized by using additives acting as pore fillers or templating agents [45–47]. Nonsurfactant organic compounds as D-glucose, dibenzoyl-L-tartaric acid, or D-maltose might act as templating or pore-forming agents. A nonsurfactant pathway to mesoporous silica materials doped with acid phosphatase was reported [47]. D-glucose was added to HCl-catalyzed prehydrolyzed TEOS sol to affect the mesophase formation in polycondensation and gelation. After removal of the nonsurfactant molecule by solvent extraction at room temperature, a mesoporous silica matrix with high surface area and pore diameter in the range of 20–30 Å, with narrow pore size distribution, was obtained. The pore size, volume, and surface area were found to be tuneable by varying the concentration of the templating compounds in the preparation procedure.

The entrapment of the protein is achieved from the initial dispersion of an aqueous solution of the biomolecule into a silica sol. Since the protein is added prior to gelation, it is plausible that the dopant molecule could act as a template around which the gel network grows. Horseradish peroxidase and glucose 6-phosphate dehydrogenase are globular proteins with diameters of 64 and 88 Å, respectively. They were immobilized in wet silica gels with average pore size of 200 Å [30]. Hence, they should be able to diffuse within the pores and channels of the silica matrix, although at a slower rate than in solution. However, over time and during repeated washes, no significant leaching was observed, suggesting that the enzyme molecules could be sterically confined in smaller pores. Entrapped proteins could also be retained by electrostatic interactions or hydrogen bonds (directly or via hydration water molecules) between the silanols groups, which are negatively charged

above pH 3, and charged or polar groups on the protein surface. Polar interactions mainly depend on the isoelectric point of the protein. Strong adsorption was shown to occur in the case of cationic proteins [48, 49]. A high ionic strength of the buffer should minimize electrostatic interactions, as suggested by data on horseradish peroxidase and glucose 6-phosphate dehydrogenase silica gels in the presence of 1 M phosphate buffer [30]. Studies performed on silica gels doped with photochromic probes (azobenzene derivatives) indicated that the interaction between the host matrix and guest compounds affects the physico-chemical properties of the dopant and thus its reactivity [50]. The results suggest that a close interaction between large portions of the protein surface and the matrix does exists. In fact, it was found that the dye Comassie blue was not able to cover the complete surface of trypsin encapsulated in silica gel [50]. This tight binding could explain the thermal and chemical stability of the glass-encapsulated proteins. Indeed, experiments performed with fully acetylated trypsin showed that the encapsulated enzyme was not active, indicating the important role of ionic bonds between the lysine and arginine side chains and the negatively charged silicates for good dispersion and protein stability in the gel [43, 51].

Absorbance measurements of entrapped proteins such as cytocrome *c* have suggested that mixing the biomolecules into a silica sol prior to gelation leads to biomolecules dispersed homogeneously on a macroscopic scale [4]. At a molecular level, however, several absorbance and fluorescence studies using both small organic probes and fluorescent proteins indicated that dispersed species are actually distributed between several microenvironments within sol–gel derived materials.

Typical methods to study sol–gel materials, including ^{13}C and ^{29}Si nuclear magnetic resonance (NMR), infrared and Raman spectroscopies, cryogenic gas adsorption analysis, and small-angle X-ray scattering, report on the average properties of the bulk materials.

Electronic spectroscopy of specific probe molecules, especially emission spectroscopy, offers sensitive methods for studying the local environment around the probe molecule. If the dopant biomolecule itself cannot act as a probe, other optical probes are added during the sol stage. Studies probing the local microenvironments via electronic spectroscopy within biocomposite materials were the subject of several extensive reviews [23, 34, 38, 52]. An important issue arises from the macroscopic location within the gel of the dopant molecule, whose properties can also be affected by the microscopic heterogeneity of the pores. Depending on the nature of the protein and the specific precursors and additives used to obtain the biocomposite material, it is possible to identify four very general locations of the dopant molecules within the sol–gel matrix [52]: (i) the solvent region within the interior of a pore; (ii) the interface between the liquid solvent and the solid pore wall; (iii) the pore wall; (iv) the constraining region, where the distance between the pore walls is about the same as the dimension of the probe molecule itself. If a molecule is incorporated in the constraining region, it should be effectively confined in the solid state, because of the surrounding rigid solid matrix. Nevertheless, since proteins are added at the sol stage, they preferentially remain in the liquid phase of the gel. Thus, the most probable locations are the solvent filled pores and the pore walls. Indeed, frequent collisions between the molecule and the pore walls could favor the interactions, such as adhesion or hydrogen, electrostatic and covalent bonding between the protein and the pore walls.

The fluorescence properties of pyranine (8-hydroxy-1,3,6-trisulfonated pyrene) are sensitive to proton transfer phenomena and were employed to determine the solvent composition during the sol–gel process. The data also shed light on the nature of the hydrolysis and condensation reactions of the precursors. The first studies were carried out on TMOS-derived gels [53]. The results, also reviewed by Dunn and Zink [52], showed that hydrolysis and condensation processes concomitantly advance toward an equilibrium point, representative of the final solvent composition. pH influences the rate at which the equilibrium is reached, low pH allowing rapid hydrolysis and slow condensation rate. Since the condensation reaction proceeds slowly, these studies were able to ascertain that it occurs much later than the gelation point. Another important result is related to the possibility for the entrapped molecules to be affected by the external solvent and solutes. Although the processes are the same, the sol–gel dynamics differ significantly for bulk monoliths and thin films. The sensitivity of the luminescence spectrum of pyrene to changes in polarity allows one to investigate the characteristics of the solvent inside the pores of the matrix. In the sol and in the aged gel the liquid phase behaves similarly to an aqueous alcohol environment. A few studies were performed using pyrene as a photoprobe [54–57].

By affecting the microstructure of the gel network, drying produces changes in the polarity of the environment. When the xerogel stage is achieved, the residual solvent evaporates, and the pores collapse around the dopant molecule. Thus, especially in the case of silicate systems based on TMOS or TEOS, a more polar environment develops, since the hydrated surface of the pore comes in contact with the probe molecule. In organically modified silicates, experiments carried out with pyrene showed that the final stages of drying lead to a less polar environment, because of the introduction of organic groups into the matrix. Low levels of organosilanes tend to be well dispersed within the matrix and to reside at the solvent–silica interface, thereby reducing the number of silanol groups (and the amount of bound water), as suggested by several experiments performed on a considerable variety of Ormosils [38].

pH measurements within the solvent filled pores and at the interface region tackle another critical issue, especially for encapsulated proteins and organometallics sensitive to proton concentration. pH sensors, based on bromophenyl blue-doped sol–gel materials, showed a broad shape of the titration curve attributed to the entrapment of the probe in a series of chemical inequivalent microenvironments [58]. Titrations performed with acid–base indicators spanning a pH range from 3 to 10 suggested that the pH in the proximity of the pore walls might be one unit lower than that in the aqueous buffer solution [52]. These findings are supported by data on glucose-6-phosphate dehydrogenase and horseradish peroxidase-doped aqueous silica gels [30]. The effect of pH on the maximal catalytic activity (V_{max}) of both the enzymes was studied. In both cases, V_{max} versus pH

curves are shifted to higher pH values (about one unit) for the encapsulated enzymes with respect to the free form. This probably derives from the partitioning of hydrogen ions between the inside and the surface of the matrix. Because of the negatively charged silanol groups, an electrical double layer consisting of cationic buffer ions and hydrogen ions exists inside the silica matrix. Thus, the excess of protons makes the pH in the double layer lower than in the bulk solution. Since the average pore size is about 10 nm, a double-layer overlap into the pores might occur, leading to the presence of an excess of protons and, therefore, to the lowering of pH experienced by the embedded protein. However, it should be noted that the protonation of the solvent-shielded chromophore of green fluorescent protein mutants exhibits a pKa value essentially unchanged with respect to solution [59]. The same was observed for the alkaline Bohr effect of human hemoglobin [26, 60]. These apparently contradicting findings might be explained by the different location of the protein ionizable groups with respect to the proton gradient on the surface of the pore. The kinetics and the equilibrium behavior of the reaction between substrates and encapsulated proteins are determined by the accessibility of analytes to the entrapped protein. The latter is affected by both gel characteristics (such as thickness, hydration, pore size, and net charge), which are tuneable by controlling the synthesis conditions, and the physico-chemical properties of diffusing molecules. Even in the same sample, it could be that some of the protein molecules are encapsulated in pores that are completely accessible to analytes, some in partially accessible pores, and some in completely inaccessible pores. It is important to determine the fraction of the protein molecules actually accessible to the analytes. This appears to be highly dependent on the size of the protein [28]. Moreover, if repulsive or attractive interactions exist between the analyte and the silica matrix, a partial or a very high uptake of the reagent could occur. Thus, diffusion of charged species between silica glass and the surrounding solution results in different concentrations of species in the two phases, even when the system is in equilibrium. Neutral and charged quenchers, such as O_2, acrylamide, Co^{2+}, and I^-, were used to monitor the accessibility of small molecules to entrapped proteins and their partitioning within the gel [22, 50, 61, 62]. Studies performed on small proteins such as parvalbumin or oncomodulin (molar volume of 12–15 nm^3) showed that these proteins remain completely accessible to both neutral and charged analytes [63, 64]. A larger protein like monellin (molar volume 23 nm^3) showed an inaccessible fraction between 8 and 15%. Bovine serum albumin (molar volume 43 nm^3) may have as much as 50% of the protein in inaccessible locations [45, 65]. These measurements suggest that large proteins probably block the entrance of the pore within which they reside, preventing the entry of analytes.

A kinetic study of the photoinduced redox reaction of zinc cytocrome *c* by laser flash photolysis investigated the effects of pH and ionic strength on the diffusion of charged solutes ($[Fe(CN)_6]^{3-}$, $[Ru(NH_3)_6]^{3+}$, and $[Ru(NH_3)_5Cl]^{2+}$) and on the transport of electroneutral small species (*p*-benzoquinone, dioxygen) [22, 61]. The partitioning coefficient of charged quenchers strongly depends on ionic strength and pH; that is, high ionic strength and low pH values minimize the exclusion of the $[Fe(CN)_6]^{3-}$ from the interior of the gel, because the degree of interaction with silica surface is reduced. Experiments performed on azobenzene derivatives confirmed that sol–gel silica can act as a hydrogen donor to an acceptor molecule. This could induce an enormous excess in the uptake of hydrogen-bonding solutes from solution, a phenomenon called imbalanced uptake [50]. Neutral species are not excluded from the glass, but their diffusion is delayed by the matrix because of pore connectivity and tortuosity increasing the effective diffusion distance. Therefore, in the case of these species, it is possible to define a hindrance of diffusion in glasses. All these results suggest that incorporation of charged polymers, manipulation of pH and aging conditions, and the addition of templating agents to promote larger pores could affect and maximize the accessibility of the protein by analytes.

3. STRUCTURE, DYNAMICS, AND STABILITY OF PROTEINS ENCAPSULATED IN SILICA GELS

Proteins perform a variety of functions in living organisms, from enzymatic catalysis to metabolite transport and storage, from cell movement and mechanical support to signal transduction and cell regulation. Most of these activities require structural flexibility and the interconversion among conformational states and substates, controlled by ligand binding and/or variations of the physical and chemical environment. Encapsulation in a silica gel matrix can alter protein function by distorting the structure of functional conformations or, more likely, by posing thermodynamic and/or kinetic restraints to structural dynamics and conformational equilibria underlying protein function and regulation. In many cases, the stabilization of selected conformers with defined properties is not a shortcoming but a desired characteristic of encapsulated macromolecules, for example, in the fabrication of biosensors or whenever the isolation of stable or metastable conformers is required for biochemical and biophysical investigations (see Section 4). A large number of studies have been reported dealing with functional properties of proteins encapsulated in silica gels [10]. Less abundant is the information currently available on protein stability in the gel, and lesser yet the number of investigations that specifically tackled the problem of achieving detailed information on the effect of encapsulation on protein structure.

3.1. Structural and Dynamic Properties

The nature of the gel limits spectroscopic investigations on entrapped proteins to techniques that can probe the global structural properties but, apart from Raman and fluorescence spectroscopy, are characterized by poor spatial resolution. To date, a limited number of studies exploiting Raman or circular dichroism spectroscopy to gather direct structural information on encapsulated proteins have been published. Steady state fluorescence and emission decays of intrinsic and extrinsic probes have been shown to provide a wealth of useful information on structure, dynamics, and function of encapsulated proteins [28]. However, these techniques do not probe conformational events that do not perturb the

fluorophore microenvironment. Furthermore, the interpretation of data can be challenging when fluorescence signals arise from multiple probes (e.g., most proteins contain more than one tryptophan residue), or whenever the effects on fluorescence of solvent structure and polarity are not perfectly understood. Time-resolved fluorescence anisotropy investigations allow one to calculate the scope and speed of local motions and the global rotational diffusion times. The comparison of these parameters with those observed in solution also yields important information on the microenvironment experienced by the encapsulated proteins, since they are related to protein conformation and flexibility and to the nature and strength of protein–gel matrix interactions.

In many reports the observation of unperturbed absorbance spectra has been assumed as indirect evidence of conserved local structural features in the gel. Such an inference, originally expressed by Zink and co-workers [4], is reasonable at least for hemoglobin, myoglobin, cytochrome *c*, and other metalloproteins, whose specific spectral bands are extremely sensitive to the metal ion and active site geometry. Stronger evidence of native structure and dynamics in the gel arises from the quantitative conservation of functional properties and ligand regulation, as in the case of hemoglobin and several enzymes (see Section 4). In this regard, it is of paramount interest to relate the amplitude of conformational dynamics required by protein function and regulation, often known from X-ray studies, to the extent of function conservation in the gel. The emerging scenario, supported by an increasing amount of data, is one where silica gel encapsulation impedes large-scale quaternary conformational changes while allowing, though usually slowing down, local structural dynamics [6]. Whether the uncoupling of tertiary and quaternary conformational changes originates mainly from thermodynamic or kinetic restraints is not obvious and is likely to be case-dependent. The most extensive biophysical investigations on tertiary and quaternary structural dynamics in silica sol–gel systems have been carried out on hemoglobin and fructose-1,6-bisphosphatase. The results will be mainly reviewed in Section 4, together with other studies providing functional characterization of encapsulated proteins.

3.1.1. Structural Properties

Zink and co-workers investigated the structural properties of encapsulated bacteriorhodopsin by circular dichroism and Raman spectroscopy [25]. The results indicated that bacteriorhodopsin was encapsulated along with its membrane lipids and that neither the quaternary conformation nor the local structure of the retinal chromophore was significantly affected.

The sol–gel encapsulation of the complex cytochrome *c* : cytochrome *c* peroxidase allowed one, for the first time, to measure electron paramagnetic resonance signals of biomacromolecules at room temperature [66]. This made it possible to investigate the coordination and spin state, the charge transfer activity, and the structural orientation of the complex and its constituents.

The polypeptide backbone and the heme group conformation of native and Zn-cytochrome *c* have been investigated by ultraviolet(uv)-visible absorption, circular dichroism, and resonance Raman spectroscopy [22]. Far-UV circular dichroism spectra of native cytochrome *c* encapsulated in hydrogels indicated a very modest perturbation of the secondary structure. A more significant loss of α-helicity was observed for Zn-cytochrome *c*, which also exhibited a more evident perturbation of the near-UV spectrum, sensitive to the heme environment conformation. However, visible circular dichroism and resonance Raman spectra indicated that for both proteins the conformational changes of the heme pocket induced by encapsulation must be small. This result was confirmed by resonance Raman experiments carried out by Zink and co-workers [67], suggesting that neither sol–gel encapsulation, gel aging, nor drying significantly alters the heme site geometry.

The structural properties of three encapsulated metalloproteins, cytochrome *c*, horseradish peroxidase, and ascorbate oxidase, have been studied by circular dichroism, absorbance, and fluorescence spectroscopy [68]. Circular dichroism spectra of cytochrome *c* and horseradish peroxidase in the Soret region indicated that in both cases the heme microenvironment and the protein backbone to which the heme is covalently bound are unaffected by gel encapsulation. Absorbance and fluorescence spectra of tryptophan residues and the extrinsic probe ANS indicated a partial denaturation of ascorbate oxidase, which nevertheless retained the bound copper atoms. Partial denaturation has been reported for other encapsulated proteins, like apo-myoglobin [65, 69] and, upon aging of the gels, human [70, 71] and bovine serum albumin [70].

Encapsulation of the isozyme II of bovine carbonic anhydrase caused only minor changes of near- and far-UV circular dichroism spectra, which are sensitive to the aromatic side chains microenvironment and backbone conformation, respectively [62]. Thus, both the secondary and tertiary structure appeared to be generally conserved.

A series of elegant studies by Friedman and co-workers demonstrates that hemoglobin encapsulated in silica sol–gels retains the conformational markers of T and R quaternary conformations, as monitored by ultraviolet [72] and visible resonance Raman spectroscopy [73]. Ultraviolet Raman spectra are sensitive to the environment of aromatic aminoacids and allowed one to demonstrate that the quaternary structure-dependent $\alpha_1\beta_2$ interface of hemoglobin was unperturbed upon encapsulation [72]. Resonance Raman spectra of the Soret band can probe the perturbations of the heme iron-proximal histidine stretching mode, exhibiting frequencies that are characteristic of different tertiary and quaternary conformations [73]. The effect of mutations of cysteine β93 on T and R state conformation was also investigated [74]. The intensities and frequencies of Raman bands were found to be the same as in solution also for encapsulated deoxy-myoglobin [75].

Near- and far-UV circular dichroism spectra in the gel were found to be similar to those measured in solution also for hen egg-white lysozyme, bovine α-lactalbumin, and met-myoglobin [69]. Apo-myoglobin, however, was found to be largely unfolded upon encapsulation [69], as already observed by fluorescence spectroscopy [65]. The secondary structure was insensitive to ionic strength and pH values above the isoelectric point of the protein, ruling out the possibility that the partial unfolding was due to electrostatic

interactions between the positively charged protein and the negatively charged silica oxide groups. Instead, salts other than KCl induced a concentration-dependent increase in the α-helical content, and the ion effect was in accordance with the Hofmeister series, suggesting an important role of the "unusual" water structure in the gel pores on the conformation of encapsulated apo-myoglobin. The spectroscopic and kinetic heterogeneity of sol–gel encapsulated carbonmonoxy (CO)-myoglobin was investigated by resonance Raman and absorption spectroscopy [76]. The authors compared the visible Raman spectra and CO rebinding kinetics after photodissociation of myoglobin encapsulated in the deoxy or liganded state. Differences in the resonance Raman frequency of the iron-proximal histidine stretching mode were attributed to different positions of the F helix, which in turn account for differences in CO rebinding. The CO binding-induced conformational changes were reported to be qualitatively similar to the tertiary changes occurring within both the T and R quaternary states of gel-encapsulated hemoglobin: a clam-shell-type rotation of the E–F helices. Differences between the two proteins in the relaxation kinetics were attributed to different hydrogen bonding and salt bridging patterns.

3.1.2. Dynamic Properties

The rotational dynamics in silica sol–gels have been investigated for several proteins. The results span the whole range of rotational freedom, from unrestricted rotation to complete "freezing" of the entrapped molecules. The observed variability could in part originate from differences in the gel matrix, dependent on precursors, gelification protocols, aging, and drying. However, most likely the main source of diversity resides in the physical and chemical characteristics of the encapsulated proteins. For instance, the templating effect of the gel would hinder the global tumbling of macromolecules with a pronounced oblate or prolate shape. Moreover, one should take into account the possibility of chemical interactions between polar and/or charged groups on the protein exterior and the gel pore surface, carrying several functional groups which account for a net negative charge at neutral pH. Such interactions would be peculiar of each protein and are expected to be pH- and ionic strength-dependent.

Dielectric relaxation measurements on cytochrome *c* suggested that the rotational movement of the protein within a TMOS-derived matrix is only slightly restricted, as indicated by a small 1.1 kcal/mol increase of the activation energy for dipolar relaxation [77, 78].

Luminescence anisotropy decays of Zn-deutero-myoglobin, Zn-cytochrome *c* peroxidase, and [Zn, Fe^{3+}L] mixed-metal hemoglobin hybrids encapsulated in wet TMOS-derived gels indicated that a minor fraction of each of the three proteins is immobilized in the sol–gel, presumably by interactions with the silicate backbone [79]. A larger fraction, ~94%, ~70%, and ~85% respectively, appeared to rotate freely within the sol–gel, though more slowly than in solution (on a time scale of 20 μs or less).

Bright and co-workers reported that the global rotational mobility of bovine and human serum albumin, as monitored by time-resolved fluorescence anisotropy of the extrinsic probe acrylodan covalently attached to cysteine 34, was restricted by a factor of 2–3, while local motions of the probe were unperturbed in aged wet gels with respect to solution [70]. Upon gel drying, the data suggested an opening of the pocket hosting the acrylodan reporter. Doping the gel with polyethylene glycol resulted in slightly increased global rotational dynamics of bovine serum albumin, while the local acrylodan motion was relatively unaffected [46]. Time-resolved anisotropy of the coenzyme FAD indicated that the tumbling motion of glucose oxidase was slowed down by less than twofold upon encapsulation [80]. FAD local motions and, remarkably, the opening of the active site pocket upon binding of the substrate glucose were not significantly altered. Authors from the same group reported that the rotational reorientation dynamics of intact immunoglobulin G antidansyl antibodies are hampered in aged gels, despite roughly conserved equilibrium binding constants for the target hapten [81].

Brennan and co-workers carried out several studies in order to characterize the conformational flexibility and the rotational diffusion of gel encapsulated proteins, like monellin [82, 83] and human serum albumin [71]. The emission spectra of monellin upon excitation at 295 nm were identical in wet-aged and dry-aged gels and in solution, indicating the conservation of protein structure in the proximity of the single tryptophan residue, while steady-state anisotropy data and the changes in fluorescence properties upon denaturation were indicative of a reduced protein mobility [82] and conformational flexibility [83]. The acrylamide quenching indicated that the range of conformational motions is reduced for encapsulated monellin with respect to solution [83]. Entrapped human serum albumin exhibited a large residual anisotropy, consistent with a restriction of global rotational dynamics [71]. The higher fractional contribution of local motions to anisotropy decays, and the shortening of the longer rotational correlation time with respect to solution suggested a partial denaturation of encapsulated albumin, consistent with the observation of perturbed spectroscopic properties of the single tryptophan residue.

The anisotropy decays of magnesium protoporphyrin IX substituted myoglobin, which due to the chromophore rigidity are sensitive only to the global protein motion, indicated that the rotational dynamics in gels prepared with different protocols are almost completely hampered, with rotational correlation times of the order of 1 μs [84].

The structural and dynamic properties of a highly fluorescent mutant of the green fluorescent protein, GFPmut2, appeared to be conserved in silica sol–gels, for both the chromophore moiety and the whole protein molecule [59]. The pH-dependent emission spectra, fluorescence lifetimes, anisotropy, and rotational dynamics are essentially equal to those observed in solution. The impressive photostability of gel-encapsulated GFPmut2 allowed single-molecule imaging by confocal spectroscopy, a first-time experiment for biomolecules encapsulated in silica sol–gels. These results demonstrate that the system exhibits ideal properties for biochemical and biophysical studies at a single-molecule level.

Indirect evidence of structural dynamics in the gel arises from the observation of the interconversion between functionally distinct species. Once again, hemoglobin is the paradigm molecule for the investigation of allosteric transitions. Tertiary and quaternary conformational changes

appear to be kinetically well separated in gel-encapsulated hemoglobin, and for both the time course is slowed down by orders of magnitude with respect to solution, as demonstrated by oxygen binding [26, 60, 85–87], CO rebinding after photodissociation [88, 89], and resonance Raman studies [72, 73]. This allows one to trap nonequilibrium species of hemoglobin and probe both structural and functional properties of intermediate conformations.

The series of conformational changes following carbon monoxide binding to gel-encapsulated human adult hemoglobin has been characterized by ultraviolet resonance Raman spectroscopy [72]. The results indicated that ligand binding in the gel triggers, more than a single concerted switch, a sequence of conformational steps starting at the distal heme pocket with E helix motion and leading to shifts of the "switch" and the "hinge" region of $\alpha_1\beta_2$ interface which are characteristic of the T to R quaternary structure transition. Conformational dynamics in the gel were slower than ligand diffusion times and could be investigated in the absence of the traditional experimental limitation of geminate rebinding of the ligand leading to mixed populations of partially liganded species. Resonance Raman spectra of oxygenated hemoglobin at various times after oxygen scavenging with dithionite revealed a marked slowdown of tertiary and quaternary relaxations [73]. In the gel, these transitions are strongly temperature-dependent, both relaxations being essentially prevented at 4 °C. The carbon monoxide rebinding studies to horse myoglobin by Abbruzzetti et al. [89, 90] showed an enhanced amplitude of the geminate rebinding phase with respect to solution, indicating a decreased flexibility of the protein matrix that reduces the efficiency of CO escape to the solvent following photodissociation. The slower rate for the transition between conformational substates was tentatively attributed to high effective viscosity inside the gel matrix. Friedman and co-workers reported that upon bathing gel-encapsulated deoxy- and carbonmonoxy (CO)-myoglobin in 100% glycerol, not only are tertiary relaxations slowed down but also equilibrium and nonequilibrium conformations can be efficiently locked [76]. The authors attributed this observation, beyond possible viscosity effects, to the templating behavior of the gel. Conformational modifications requiring transition states with enhanced volume and hydration changes might be efficiently hampered by steric hindrance and solvent shell stabilization effects by the gel matrix [73, 76]. The latter hypothesis is supported by the observation of dramatically slowed relaxations of encapsulated hemoglobin below 10 °C, suggesting a relevant role in the immobilization of hydration shell water molecules [73].

Beyond the several studies on heme proteins, a few papers reported detailed investigation on tertiary and quaternary conformational dynamics accompanying function and regulation of proteins encapsulated in silica gels. Encapsulation of pig kidney fructose-1,6-bisphosphatase largely restrained the structural transition between the T and R quaternary conformations, while allowing the local conformational changes induced by allosteric regulators [91]. Interestingly, glutamate dehydrogenase, a large six-subunit enzyme, retains function and allosteric regulation in the gel, indicating that encapsulation does not hinder the large-scale conformational changes that have been structurally resolved, accompanying substrate and coenzyme binding, catalysis, and regulation [92].

The conformational changes induced by calcium binding in cod III parvalbumin were probed by measuring intrinsic tryptophan fluorescence and acrylamide binding [63], absorbance, and steady-state and time-resolved fluorescence of the extrinsic probes fluorescein, acrylodan, and nitrobenzoxadiazole attached at cysteine 18 [93]. Single tryptophan mutants of oncomodulin, another calcium-binding protein, retained in the gel the calcium concentration dependence of thermodynamic stability and terbium binding capacity [64].

The light-sensitive and proton-pumping function and the relative conformational changes are conserved in immobilized wild-type bacteriorhodopsin [25, 94, 95] and in the D96N mutant [14, 96–98].

An elegant work by Hoffman and co-workers [79] describes the effect of encapsulation on photoinitiated electron transfer within three protein–protein complexes: (i) [Zn, Fe^{3+}L] mixed-metal hemoglobin hybrids, (ii) the Zn-cytochrome *c* peroxidase complex with ferri-cytochrome *c* and (iii) the [Zn-deuteromyoglobin, ferri-cytochrome b_5] complex. In all cases transient absorption experiments allowed one to observe electron transfer in the encapsulated complexes. The effect of encapsulation on electron transfer was different for the three complexes that were selected for their largely different affinities and dynamic processes. No complex formation or dissociation was observed in the gel.

Brennan and co-workers observed reversible dissociation of a complex between bovine calmodulin and the peptide melittin, upon introduction in the gel of the denaturant guanidine hydrochloride or small antagonists of the complex [99]. The detection of reversible interprotein interactions in the gel is striking, provided that quaternary transitions in entrapped oligomeric proteins are normally hampered, and points out that silica sol–gels can be a suitable device to host biological systems more complex than single macromolecules, for both biophysical studies and biotechnological applications (see [12] and references therein).

3.2. Stability of Proteins Encapsulated in Silica Gels

Several authors observed thermal and/or chemical stabilization of gel-encapsulated proteins. Such effect could derive, at least in part, from a reduced conformational freedom in the limited space of gel pores (Fig. 3a), preventing a complete denaturation of polypeptide chains and the irreversible aggregation often observed for partially or fully denatured proteins [12]. For proteins existing as an equilibrium between different conformers, stabilization could arise from a lower probability to sample thermodynamically unfavorable conformations, when species interconversion occurs through conformationally expanded transition states. Steric effects could also facilitate refolding by virtue of an "easier" search of the native topology [100]. However, several authors reported either slower refolding kinetics, as in the case of acid-denatured myoglobin [101] or irreversible though incomplete unfolding, as for acid-denatured bovine serum albumin [65] and heat- or guanidinium chloride-denatured carbonic anhydrase II [62]. Depending on experimental protocols and recipes, gel aging, and hydration state,

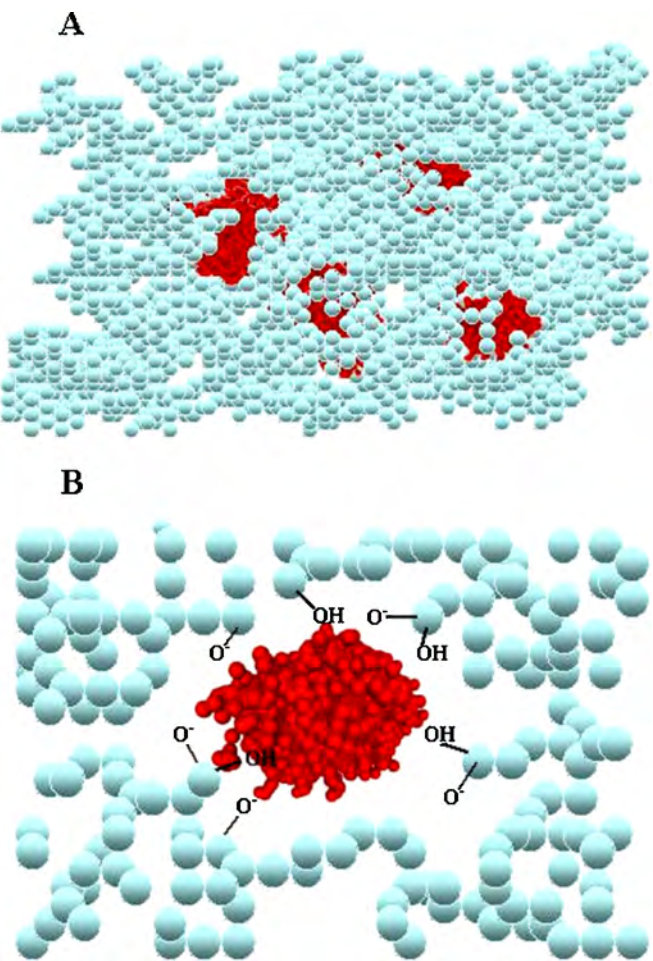

Figure 3. Schematic representation of protein-doped silica gels (A) and protein–gel matrix interactions (B).

variable amounts of functional groups can be present on the pore surface, like siloxane (Si–O–Si), silaketone (Si=O), silanol (Si–OH), and siloxide ($Si–O^-$) groups (Fig. 3b). Therefore, multiple polar and/or electrostatic interactions between surface aminoacids and the pore wall are likely to play a relevant role in protein kinetic and/or thermodynamic stabilization. Once again, general rules cannot be drawn from the data currently available, and one should take into account the relevant study by Heller and Heller [49], suggesting that electrostatic interactions between positively charged arginine surface residues and polysilicate anions could disrupt the function or structure of gel-encapsulated lactate oxidase and glycolate oxidase. When the enzymes were complexed with polycations prior to immobilization, they were stabilized instead of being deactivated. Moreover, the peculiar structure of the solvent and the high effective viscosity within gel pores could play a key role in limiting conformational dynamics, thus stabilizing the structure of entrapped proteins [69, 73, 76, 83]. Finally, it should be noted that the behavioral variability of encapsulated proteins does not only arise from the different properties of the macromolecules and of the hosting matrices, but even in the same system gel aging time and conditions can influence protein conformation, dynamics, stability, accessibility, and function (see [71] and references therein).

Increased thermal stability has been reported for alkaline phosphatase [102, 103], acid phosphatase [31, 43, 47], β-glucosidase [31, 104], lipases (see [31, 105, 106] and references therein), lipoxygenase [107], glucose oxidase [48], monellin [83], carbonic anhydrase II [62], urease [108], cytochrome *c* [67], lysozyme, α-lactalbumin and apomyoglobin [69], antibodies [109], pronase and α-chimotrypsin [110], and human serum albumin [71]. Stabilization with respect to pH, alcohols, or chemical denaturants has been reported, for instance, for bovine serum albumin [65], β-glucosidase [104], cytochrome *c* [27, 77, 78, 111], catalase [111], lipoxygenase [107], lipases (see [106] and references therein and also [112]), alcohol dehydrogenase [113], deoxy- [75] and CO-myoglobin [101], cod III parvalbumin [63], monellin [83], carbonic anhydrase II [62], horseradish peroxidase and myoglobin [114], and antibodies [109]. Enhanced stability toward photodegradation has been reported for a light-transducing protein, phycoerythrin [115], which, unlike the other phycobiliproteins phycocyanin and allophycocyanin, was shown to undergo only minor changes in its native structure.

Only in a few cases have the thermodynamic and kinetic aspects of thermal or chemical denaturation been investigated in detail. Such studies are of extreme interest for at least two reasons: (i) they pursue a qualitative and quantitative description of the behavior of gel-encapsulated proteins with respect to physical and chemical insults, which is fundamental for a rational design of biotechnological applications; (ii) they display to the fundamental research community the unique opportunity provided by sol–gel techniques to isolate "pure" conformational states out of complex conformational equilibria, slow down kinetics, or stabilize metastable intermediates, making this species accessible to biophysical investigations.

One of the earliest studies on unfolding/refolding of proteins encapsulated in silica gels was carried out on bovine serum albumin (BSA) and horse heart myoglobin by Saavedra and co-workers [65]. Based on the steady-state fluorescence properties of intrinsic (tryptophans) and extrinsic (acrylodan) probes, the authors concluded that complete and reversible denaturation of encapsulated BSA by guanidine hydrochloride could be achieved, while acid denaturation, involving a significant increase in the overall size of the molecule, was incomplete and irreversible.

Thermal unfolding of human serum albumin in gels at early aging times occurred at higher temperature with respect to solution [71]. However, the unfolding temperatures decreased upon aging. This observation, together with the spectroscopic evidence of incomplete unfolding and non-native conformation after entrapment, led the authors to raise two major concerns, which should be taken into account for any gel matrix-encapsulated protein system: (i) it is possible that the unfolding temperatures do not reflect denaturation from a fully native to the same fully unfolded conformations ensemble observed in solution, which limits their reliability as stability indicators; (ii) it is not obvious that encapsulation will lead to a higher long-term thermal stability.

The thermal and guanidinium chloride-induced unfolding of monellin has been investigated by measuring the fluorescence spectra, steady-state anisotropy, and acrylamide quenching of the single tryptophan residue [83]. Wet-aged gels did not show a significant thermal or chemical stabilization of the encapsulated monellin. In dry-aged gels, thermal unfolding was characterized by a 14 °C increase of T_m and a broader transition with respect to solution, suggesting a distribution of microenvironments endowed with different thermodynamic stability. Chemical denaturation also showed a broadened transition. The spectral changes upon unfolding and the calculated thermodynamic parameters were different with respect to solution and indicated conformational restrictions upon encapsulation leading to incomplete denaturation or unfolding to a different final state. The enhanced stability was attributed to the gel pores sterically restricting the mobility of the encapsulated protein, and thus limiting the sampling of thermodynamically unfavorable conformations, and to the highly structured nature of the solvent in the gel matrix. Complete unfolding of cod III parvalbumin by urea was achieved in the gel, as indicated by the denaturant dependence of tryptophan fluorescence intensity and emission wavelength [63]. As in solution, calcium binding provided a significant stabilization of the protein. Both in the absence and in the presence of calcium ions, higher denaturant concentrations were required to achieve denaturation in the gel with respect to the protein in solution. Reversible thermal denaturation of oncomodulin has been reported by Brennan and co-workers [64].

Resonance Raman studies by Friedman and co-workers [75] demonstrated that the native structure of deoxy-myoglobin is stabilized toward acid denaturation in the gel. At pH 2.6, the Raman bands assigned to the heme propionate and vinyl groups shifted to values similar to those observed in solution for the first acid intermediate, which occurs at pH between 4.5 and 3.5 and is characterized by the cleavage of the iron–proximal histidine bond, while the heme remains five-coordinate high spin, with water as the fifth ligand (see [75] and references therein). The cleavage of the iron–proximal histidine bond was markedly slowed down in the gel, even at pH values as low as 2. At pH 2.6, it took about 20 h to obtain spectroscopic indications of a small amount of the second acid intermediate, exhibiting a four-coordinate heme still bound in the pocket and occurring in solution at pH between 3.5 and 2.5. The authors suggested that the formation of acid denaturation intermediates of deoxy-myoglobin requires large amplitude conformational fluctuations, like an opening of the heme pocket to allow cleavage of the iron–proximal histidine bond, loss of the heme, and globin unfolding, which are strongly inhibited in the gel. The acid denaturation and refolding of CO-myoglobin have been studied by fluorescence, absorption, and visible resonance Raman spectroscopy and by geminate recombination in order to explore the heme conformation and environment, the globin, and the exposure to solvent of the A helix [101]. Both unfolding and refolding kinetics were dramatically slowed down by gel encapsulation. Different encapsulation and unfolding/refolding protocols allow one to stabilize several intermediate species, some of which have not been observed previously in solution studies. Moreover, the results suggested that the initial step in acid denaturation of CO-myoglobin is the unfolding or the increased exposure to the solvent of A helix residues and that the refolding of the A helix is a late process along the refolding pathway.

Both thermal and guanidinium chloride-induced denaturation of carbonic anhydrase II, as monitored by circular dichroism, appeared to be incomplete and largely irreversible [62]. The broad thermal unfolding transition has been attributed to some degree of heterogeneity in the microenvironment of the encapsulated molecules, which affects their stability toward unfolding. The incomplete unfolding and refolding were ascribed to steric effects of the gel pores, restricting the required protein mobility.

Complete and reversible denaturation of cytochrome *c* encapsulated in aged wet gels was induced by 3.5 M guanidinium chloride and monitored by circular dichroism spectra of the Soret region [68]. The unfolding reaction was dramatically slowed down with respect to solution. In xerogels, only partial denaturation was observed following 24 h incubation in the presence of 3.5 M guanidinium chloride.

Reversible thermal denaturation was observed for lysozyme, α-lactalbumin, and apomyoglobin [69]. The increased thermal stability is discussed in terms of theoretical models of crowding effects on protein stability [116], mimicked by molecular confinement in the gel pores, and perturbed water structure. Different from solution, calcium binding to encapsulated α-lactalbumin was unable to rescue the native structure upon reduction of one of the four intramolecular disulfide bonds. Furthermore, removal of calcium caused a loss in secondary and tertiary structure in the absence of reducing agents.

4. APPLICATIONS OF PROTEIN-DOPED SILICA GELS

4.1. Bioreactors

A biorector is a device in which one or more enzymes are physically confined. The purpose of a biorector is to obtain the selective and efficient transformation of substrates in products and an easy separation between catalysts and reagents. The requirements of a biorector are the maintenance of the catalytic activity of entrapped enzymes, long-term protein stability and reusability, and no limitation for reagents and products to diffuse in and out of the matrix. Immobilization of enzymes in silicic acid gels was first achieved by Dickey [117] and several years later by Johnson and Whateley [18], but only in the last 20 years or less have sol–gel methods became widely used to prepare biorectors and biosensors [3, 4, 34, 43, 102, 118, 119]. A list of enzyme-doped silica gels is reported in Table 1. Several classes of enzymes have been encapsulated in silica gels, ranging from lipases to oxidoreductases and proteases, without any specific limitations. Silicate precursors characterized by different hydrophobicities, and additives as glucose, polyethylene glycol, or polyvinylalcohols, were used to achieve better performances.

A critical issue that is not always properly addressed in the evaluation of the catalytic activity of encapsulated enzymes is the diffusion of substrates within the gel pores to reach

Table 1. Enzyme-doped silica gels.

Enzyme	Precursor	Ref.
C. cylindracea lipase	TMOS[a]–alkylmethoxisilanes	[202]
P. cepacia lipase	TMOS–alkylmethoxisilanes	[47]
Lipase	cellulose acetate–TiO_2 gel fiber	[203]
C. antartica lipase	cellulose acetate–TiO_2 gel fiber	[204]
C. cylindracea lipase	trimethoxypropylsilanes–TMOS	[128]
P. cepacia lipase	phyllosilicate	[205]
R. miehei lipase	cellulosae acetate–TiO_2 gel fiber	[206]
Lipase	TEOS[b]–PEG	[127]
Lipase	TMOS–alkylsiloxanes	[207]
P. cepacia, C. antarctica lipase	MTMOS[c]–alkylsiloxanes	[208]
Lipase	TMOS–alkylsiloxanes	[124]
Lipase	different matrices	[209]
Lipase		[210]
Lipase	MTMOS–TMOS–celite 545	[105]
HRP[d]	TMOS	[136]
HRP	different alkylsiloxanes precursors	[211]
Pronase, α-chymotripsin	TMOS	[110]
Serine proteases		[212]
Lactate oxidase/ glucose oxidase	different matrices	[213]
Urease	TEOS	[214]
Urease	TMOS	[215]
Urease, glucose oxidase, invertase	different matrices	[135]
HRP, GOD[e]	sodium silicate	[30]
HRP-cholesterol oxidase	TEOS	[216]
HRP, ascorbate oxidase	TMOS	[68]
Soybean lipoxygenase	TMOS	[142]
Lipoxygenase	alginate–TMOS	[107]
20 different lipases and proteases, enzyme array (solzymes)		[171]
HRP, GOD		
Acid phosphatase	TMOS + D-glucose	[47]
Alkaline phosphatase	TMOS	[103]
Carbonic anydrase II	TMOS	[62]
Glutamate dehydrogenase	TMOS	[92]
GOD	TEOS–veratryaldehyde	[217]
GOD, lactate oxidase, glycolate oxidase	TMOS	[48]
Glycolate oxidase, lactate oxidase	TMOS	[49]
Lactate dehydrogenase	TEOS	[218]
Bilirubin oxidase	alginate–TMOS	[219]
Atrazine-degrading enzymes	TMOS	[143]
Formaldehyde dehydrogenase/ formate dehydrogenase/ alcohol dehydrogenase	TMOS	[144]
Atrazine chlorohydrolase	TMOS–alkylsiloxane	[141]
Butyrylcholinesterase	TMOS	[220]
Acetylcholinesterase, butyrylcholinesterase	TMOS	[221]
α-amylase	chitosan–SiO_2 membrane	[222]
β-galactosidase	TMOS	[138]
Catalase	colloidal silica–sodium silicate	[223]
Parathion hydroxilase	TMOS	[224]
Cytochrome *c*, Myoglobin Hemoglobin, HRP	TMOS	[225]
Tryptophan synthase *O*-acetylserine sulfhydrylase	TMOS	[201]

[a] Tetramethylorthosilicate, TMOS.
[b] Tetraethylorthosilicate, TEOS.
[c] Methyltrimethoxysilane, MTMOS.
[d] Horseradish peroxidase, HRP.
[e] Glucose oxidase, GOD.

the active sites [120]. It is often assumed that small solutes can freely and rapidly diffuse within the gel and, therefore, there is no limitation to the enzyme activity by the size and geometry of the gel [3, 8, 94]. However, this might not be true, as was previously recognized in the investigation of the enzymatic activity of enzyme crystals [10, 121, 122]. The size of the crystals required to avoid effects on enzymatic parameters critically depends on the rate of the catalytic reaction. Only microcrystals with dimensions in the micrometer range can be used. In several investigations mm size silica gel monolythes were used, and, not surprisingly, the observed catalytic activities were much lower with respect to the soluble enzyme. On the other hand, alcohols released during the sol–gel process might lead to enzyme inactivation, and constraints placed by the Si–O–Si network to the protein might decrease the enzyme flexibility required for function.

Lipase, glucose oxidase, and horseradish peroxidase are among the enzymes more frequently encapsulated in silica gels and for which several studies were carried out to define the influence of the precursor alkylsiloxanes and additives on the catalytic activity and stability. The interest originated in their use for biotechnological applications, including biosensors.

4.1.1. Lipase

Lipases are used as hydrolases in detergent additives and as synthases in the formation of enantiomeric compounds [123–125]. Lipase silica gels are now commercially available. The most critical issue for enzymatic catalysis by lipases is the interfacial activation (i.e., the increase in activity at the interphase between polar and apolar solvents). This is due to an amphiphilic loop that covers the active site and undergoes a closed-to-open transition at a lipid–water interface, making the active site accessible to substrates. Several studies were carried out to produce active lipase-doped silica gels [105, 106, 112, 126]. TMOS-based silica gels led to encapsulated lipases characterized by very reduced activity, indicating a detrimental effect of the polar microenvironment of silica gels [106]. Different $RSi(OCH_3)_3$ precursors and mixtures of these and TMOS were used to encapsulate lipases from *Pseudomonas cepacia*. The use of 100% $CH_3Si(OCH_3)_3$ led to an immobilized lipase with 1300% of the activity of the commercial enzyme [106]. Higher activity was obtained using other R-groups, such as ethyl, *n*-propyl, *n*-buthyl, and *n*-$C_{18}H_{37}$, and additives such as polyethylene glycol and polyvinyl alcohol [112, 126, 127]. The immobilized enzyme is remarkably stable even after several catalytic cycles. Higher esterification activity was also observed when methyltrimethoxysilane and TMOS were used as precursors in a 3:1 ratio and the gel was casted on the surface of Celite 545 [105]. The enantioselective aminolysis of ethyl 2-chloropropionate was also found to increase by carrying out the reaction with *Candida cylindracea* lipase encapsulated in silica gels [128]. An alternative strategy to immobilize lipases was designed, making use of matrices derived from poly(hydroxymethylsiloxane) [129]. This method leads to a biocomposite silicone material with higher activity and stability with respect to the native enzyme. Encapsulation of enzymes within silicate, siloxane, and hybrid sol–gel polymers provides an efficient and generic approach to the

preparation of stable and active sol–gel bioceramics [31]. PGS was used to prepare transparent, mesoporous, and physically stable silica xerogels containing lipases as well as several other enzymes [31]. It was found that, because of the absence of released alcohols that might cause protein denaturation or aggregation, PGS-based biogels retain 83–98% of the activity of the native enzyme, with an 88–98% entrapping efficiency at loading concentration as high as 20% w/w of xerogel. The resulting materials exhibit high stability and low release of proteins after several washing cycles. This remarkably extensive study [31] provides a very careful and detailed investigation of the influence of (i) metallosilicate sol–gel precursors on the activity of subtilisin, aldolase, glycerol 3-phosphate oxidase, glucose oxidase, and pyruvate decarboxylase; (ii) alkylsiloxanes sol–gel precursors on the activity of thermolysin, alcohol dehydrogenase, lipoxygenase, esterase, and phospholipase D; (iii) polyol ester-derived functionalized siloxane on the activity of proteinase K, sialic acid aldolase, bacteriorhodopsin, aspartatate aminotransferase, almond oxynitrilase, β-glucosidase, tyrosinase, glucose oxidase, and carboxypeptidase; (iv) composite sol–gel polymers on the activity of β-glucoronidase, penicillin acylase, and luciferase. *Mucor javanicus* lipase was encapsulated in silica aerogels, retaining about half of the activity of the native enzyme even after incubation at 100 °C in the presence of organic solvents [130]. The comparison of the activity of *Psudomonas cepacia* lipase encapsulated in silica and aluminosilicate xerogels and aerogels indicates that the enzyme is more active in the latter ones. In aerogels the pore size does not shrink during CO_2 supercritical drying as, on the contrary, was observed with drying by evaporation [131]. Esterification rates were found to be higher when aerogels were obtained using a base catalyst as sodium fluoride in the presence of polyvinyl alcohol [132]. However, so far only lipase and myoglobin [133] have been entrapped in aerogels and demonstrated to remain active. The conditions for aerogel preparation, CO_2 at supercritical state, might not be favorable for most proteins.

4.1.2. Glucose Oxidase

Glucose oxidase catalyzes the formation of gluconic acid and hydrogen peroxide, using D-glucose and oxygen as substrates. This enzyme that contains flavin as a coenzyme is widely used in the development of biosensors for the detection of glucose, oxygen, and hydrogen peroxide (see Section 4.4, Table 2 [11, 134]). For example, co-immobilization of the enzyme with horseradish peroxidase and quinonamine dyes was exploited to detect spectrophotometrically glucose [24, 94]. Glucose oxidase activity of aged gels and xerogels was found to be 20% and 10% of that determined for the enzyme in solution. When only glucose oxidase was encapulated, the K_M was twofold higher than in solution and the turnover number was very similar to that in solution, suggesting that the lower activity of the enzyme in the coupled assays was due to slow diffusion of substrates and products within the gel. Enzyme activity in silica gels prepared in the presence of different additives, urotropin, veratraldehyde, glyoxal, glutaraldehyde, and aminocapronic acid, was measured using a calorimetric method [135]. The aminocapronic acid was found to be quite efficient in increasing enzyme activity.

4.1.3. Horseradish Peroxidase

Horseradish peroxidase catalyzes the oxygen peroxide-dependent oxidation of a variety of substrates via a multistep process involving the iron of bound heme. For the development of biosensors, the enzyme is co-immobilized with either glucose oxidase or oxalate oxidase (see Section 4.4 and Table 2). The rate of pyrogallol oxidation by horseradish peroxidase gels was found to be about 30-fold less than that of the soluble enzyme and to decrease as a function of gel aging, suggesting that the reaction was limited by the diffusion of the substrates through the pores of the gel [68]. This finding was confirmed by investigating the rate of formation of compounds I and II, two spectroscopically detectable reaction intermediates [68]. Sol–gel encapsulation was demonstrated to protect heme enzyme peroxidase activity of horseradish peroxidase and methemoglobin from inactivation by hydrogen peroxide, especially at high substrate concentrations [114]. Interestingly, in the sulfoxydation of thioanisole by hydrogen peroxide, catalyzed by horseradish peroxidase silica gels, a decrease of the enantiomeric excess and a similar yield of methyl phenyl sulfoxide enantiomers in the presence and absence of protein-doped gels were observed. These findings indicate that silica glasses are not necessarily inert with respect to particular reactions, thus requiring proper controls [136]. To avoid the formation of alcohols in gel preparation, sodium silicate was used as a precursor and gelation was achieved at neutral pH in the presence of either horseradish peroxidase or glucose-6-phosphate dehydrogenase [30]. The specific activity was 73% and 36% of that of the soluble enzyme, respectively, and the K_M values were higher than those of the enzyme in solution. A pH shift of 0.5–1 units was also observed in the pH dependence of the catalytic activity for both enzymes.

4.1.4. Other Enzymes

Other enzymes that have been encapsulated in silica gels include ascorbate oxidase, β-glucosidase, superoxide dismutase, catalase, and several proteases.

Ascorbate Oxidase is a homodimer containing four copper ions and catalyzing the oxidation of vitamin C. The enzyme, previously immobilized in calcium alginate gels [137], has been also encapsulated in silica gels [68]. The enzyme retains the catalytic activity and exhibits a K_M value similar to that observed in solution. However, the activity of fresh gels was about 2% of the soluble enzyme and further decreased as a function of aging in the first four days. Since no control of gel thickness was carried out it is likely that the reduced activity is due to a limited diffusion of substrates within the gels.

β-Glucosidase might be used for the improvement of the aroma of wine by the degradation of naturally present glycosides. The enzyme was encapsulated in an alginate–silicate sol–gel matrix [104]. The recovery of activity in the gels was about 46%, with a K_M for the substrate methylumbelliferyl-β-D-glucose sixfold higher than that of the soluble enzyme. The inhibition by glucose and ethanol was similar in solution and in gels. Increased stability was also detected for β-galactosidase in silica gels that exhibit kinetic parameters close to those observed in solution [138].

Superoxide dismutase, a copper-zinc dimeric enzyme, encapsulated in aged silica gels and xerogels, was investigated by studying the reaction with cyanide [4]. Spectral changes at 680 and 530 nm take place as in solution, suggesting that, at least qualitatively, aged enzyme gels and xerogels retain catalytic activity. Encapsulation of the enzyme does not perturb the spectral properties that are very sensitive to metal ion geometry. Furthermore, the removal of the metal from the encapsulated enzyme was achieved, leading to an apo-enzyme with spectral properties similar to the apo-enzyme in solution. However, metal rebinding on aged hydrogels led to an enzyme characterized by spectral properties different from those of the soluble enzyme, suggesting that encapsulation stabilizes a non-native conformation of the apo-enzyme.

Catalase was encapsulated either in TMOS-derived silica gels [111] or using a colloidal silica sol to avoid the formation of alcohol during gelation [29]. The rate of oxygen formation, catalyzed by the enzyme trapped in the latter gels, was found to be about fivefold higher than that in TMOS-derived gels, but still much lower than in the soluble enzyme.

Trypsin was one of the first enzymes to be immobilized using TMOS as a precursor [43], either in the absence or presence of polyethylene glycol or albumin. Activity was about 21% of the soluble enzyme in the absence of additives and 47% in the presence of polyethylene glycol. The activity of the encapsulated enzyme was found to be affected by protein concentration, the high enzyme concentration exhibiting lower activity likely due to aggregation. However, 100% activity was found when albumin was co-immobilized with trypsin, at a ratio of albumin/trypsin of 20:1. The enzyme in silica gels retained activity for several months upon storage at room temperature, without leaching and autodigestion. This latter finding suggests that a single enzyme molecule is present in each pore of the gel. Other proteolytic enzymes encapsulated in silica gels are pronase and chymotrypsin. Enzymes were prepared and casted into thin films or incorporated into an oil-based paint formulation, retaining catalytic activity and exhibiting higher thermostability than the soluble enzyme [110]. The protease-containing silicate was resistant to fouling by nonselective protein binding of human serum albumin [139].

Acid and alkaline phosphatases were encapsulated under a variety of protocols retaining most of their activity [43, 47, 103, 140]. For alkaline phosphatase it was found that the pore size (30 Å) of mesoporous gels, obtained in the presence of D-glucose template, is greater than that obtained using the classical method (15 Å) [47, 103]. This finding might correlate with the 2–10-fold increased enzymatic activity in the former gels, as diffusion of substrates within the gel is less restricted [47]. It might also correlate with a less tight inorganic network, leading to an increased protein flexibility. The activity of fine particles of enzyme-doped gels (60–100 mesh) was measured by monitoring the absorption changes at 405 nm caused by the cleavage of the substrate analog *p*-nitrophenye phosphate to *p*-nitrophenol [102]. Product formation was linear as a function of time for at least four hours. The enzyme kinetics did not follow the Michaelis–Menten behaviour, likely due to a heterogenous population of entrapped protein molecules.

Carbonic anhydrase in silica gels catalyzes the hydrolysis of *p*-nitrophenyl acetate with an apparent K_M similar to that in solution, but the k_{cat} is only 1–2% of the value determined for the soluble enzyme, due to restricted diffusion of substrates within silica monoliths sized $8 \times 8 \times 27$ mm [62]. No attempt was made to correlate the decreased activity with the size of the gel.

Atrazine chlorohydrolase was encapsulated in silica gels using different alkyloxysilanes as precursors. A 40% activity with respect to the free enzyme was obtained even after three weeks of aging on dried crushed gels prepared from mixtures of TMOS and the more hydrophobic methyltrimethoxysilane [141].

Lipoxygenase catalyzes the selective dioxygenation of polyunsaturated fatty acids to form hydroperoxy products. The enzyme entrapped in alginate–silicate gels, ground and vacuum-dried, exhibited an activity about 30% of the free enzyme and no decrease even after 25 days of storage in glycerol [107]. A more detailed comparison indicated that the optimal temperature for the soluble enzyme is 25 °C, whereas the immobilized enzyme has a broader optimal temperature range, between 25 and 35 °C. The K_M and v_{max} values of the enzyme in the two physical states were close, within a factor of two [142].

Co-immobilization of different enzymes was used to obtain coupled reactions leading to either colorimetric detections or production of valuable compounds. Silica gels containing glucose oxidase and horseradish peroxidase were prepared for the detection of D-glucose. In aged crushed gels and xerogels the activity was about 20% and 10% of that observed for the soluble enzyme, respectively [24, 94]. A similar approach was used to detect oxalate by encapsulating oxalate oxidase and horseradish peroxidase [21, 94]. An interesting application was the encapsulation of a cell-free crude extract of *Pseudomonas sp*. in TMOS derived gels [141, 143]. The extract was able to degrade atrazine both in solution and (to a much lesser extent) in gel. Silica gels doped by the three enzymes involved in the conversion of carbon dioxide to methanol, formate dehydrogenase, formaldehyde dehydrogenase, and alcohol dehydrogenase, were prepared [144]. The striking result was that methanol formation takes place at a rate 3–10-fold higher than in solution depending on the concentration of added NADH, indicating that enzyme confinement increases the catalytic efficiency. This biorector might be used for the decrease of the greenhouse effect and the concomitant production of methanol for energy technology. Remarkably, increased catalytic efficiency was also observed upon the co-entrapment of six enzymes involved in the formation of α-(2,6)sialyl-*N*-acetyllactosamine from *N*-acetyllactosamine and *N*-acetylmannosamine, sialic acid aldolase, myokinase, pyruvate kinase, pyrophosphatase, CMP-sialate synthetase, and α(2,6)sialyl transferase [31].

4.2. Biosensors and Biomaterials

A biosensor is a device that exploits the functional properties of a biomolecule to selectively recognize and quantitate an analyte in a complex medium (see [145, 146] and references therein). The recognition process is transduced in optical or electrochemical signals to obtain an analytical

information. Therefore, a biosensor is made by a biological recognition element and a transducer. Selectivity, sensitivity, detection limit, reversibility, response time, size, ruggedness, reliability, signal recovery, and cost are features that are addressed in the development of biosensors. The biological element, usually a protein, but also a whole cell, can be immobilized in a variety of matrices [147], including silica gels [7, 12, 148, 149], tightly coupled to optical, electric, and electronic devices. The most frequently used transducers are electrochemical, such as electrodes or potentiometers, and optical ones, such as absorbance and fluorescence detectors [150–154]. For *in-situ* monitoring, fiber-optic biosensors have been demonstrated to be very useful [21, 155, 156]. Low-cost screen-printed electrodes have been developed that allow both *in-situ* and real time monitoring [157]. In these systems, an important issue is the immobilization of a very thin layer of biomolecules on the electrode surface [31]. A cutting edge field of research is the development of nanobiosensors [158] and nanomaterials [159] based on protein-doped silica gels. A branch of increasing relevance in which such devices are strongly required is protein profiling via chip array [160, 161].

The analyte to be monitored diffuses in the silica gels and interacts with the proteins, triggering signals that are dependent on its concentration, or on the concentration of co-substrates or catalytic products. The analytes for which protein-doped silica gel biosensors have been developed are listed in Table 2. For the detection of glucose, biosensors were developed based on encapsulated glucose oxidase in silica gels, either in the absence or presence of additives and other enzymes to improve biosensor performance [147]. Some of the first biosensors for glucose were based on the enzyme immobilized on the surface of an oxygen electrode [134] or on an electrode in the presence of ferrocene as a mediator [162]. A screen-printed electrode containing immobilized glucose oxidase was obtained [163, 164], as well as immobilized horseradish peroxidase [163]. The comparison of three different procedures for glucose oxidase immobilization indicated that a sandwich configuration containing a sol–gel film and a layer of the enzyme was the best system to achieve fast response and high enzyme loading [165]. Co-immobilization of glucose oxidase and horseradish peroxidase was also achieved for glucose detection, exploiting hydrogen peroxide transformation by the latter enzyme [166]. By preparing a composite gel using polyol silicate/siloxane precursors, high activity and fast response were found for a sensor for glucose using immobilized glucose oxidase [31]. Galactose oxidase, lactate oxidase, and horseradish peroxidase were immobilized on the same plate, forming a multidetecting system for galactose, lactose, and lactate [31]. The same approach gave high performance biosensors for acetylcholine/choline, based on immobilized acetylcholine esterase and choline oxidase [31]. For the detection of hydrogen peroxide, horseradish peroxidase is usually encapsulated in biosensors exploiting amperometric detection methods. Hydrogen peroxide was also detected using a chemiluminescent [167, 168] flow-through sensor based on hemoglobin silica gels [169]. For the detection of a wealth of other analytes, such as pesticides, nitrate, nitrite, and urea, specific enzymes or proteins were encapsulated in silica gels (Table 2). A detailed comparison of three different

methods of acetylcholine esterase immobilization, including the sol–gel approach, was carried out for the preparation of screen-printed electrodes designed for the detection of pesticides [170]. Of particular interest is the preparation of an array of enzymes for the detection of multiple compounds [171] and of devices with a sandwich configuration [21, 24, 94], where two coupled reactions are catalyzed within a silica gel by distinct immobilized enzymes. This latter setup increases the speed of the detection and the overall biosensor performance.

Another approach for analyte detection makes use of fluorescent signals. It was demonstrated that the activity of the enzyme glucose-6-phosphate dehydrogenase could be monitored by the change both in absorbance and fluorescence emission of the coenzyme nicotinamide adenine dinucleotide phosphate, taking place upon oxidation of D-glucose-6-phosphate [172]. The entrapping of fluorescently labeled proteins [173] or the co-entrapping of fluorescently labelled dextran was also exploited, as in the case of urease or lipase for the detection of urea and glyceryl tributyrate [174]. Enzyme activity causes pH changes that, in turn, affect fluorescent properties of the dye. A similar approach was applied to detect ionic surfactants, such as cetyltrimethylammonium bromide [175]. Bovine serum albumin, labelled with the fluorescent dye acrylodan, was encapsulated in a silanized silica optical fiber. The interaction of the surfactant with the protein structure is signalled by a change of the fluorescence emission of acrylodan. By using the fluorescence changes of iodoacetoxy-nitrobenzoxadiazole bound to bovine serum albumin, proteins were detected [176]. Furthermore, by exploiting the fluorescence changes of intrinsic probes of aequorin [177], parvalbumin [63, 93], and oncomodulin [64] silica gels, calcium ions were detected. Similarly, ground gels of pyoverdin, a natural peptide pigment, were used to detect trace amounts of iron (III) in tap water and human serum by monitoring fluorescence quenching [178].

Gaseous species, such as oxygen, carbon monoxide, and nitric oxide, were detected by measuring the absorbance or fluorescence changes of the hemoproteins cytochrome *c*, cytochrome *c′*, Mn myoglobin, and hemoglobin, encapsulated in silica gels [4, 26, 60, 67, 85, 179–184]. The interaction of carbon dioxide with myoglobin was investigated in supercritical CO_2, the condition required to obtain highly porous aerogels [185].

Antibodies encapsulated in silica gels were used to detect specific antigens. Antifluorescein antibodies retain their ability to bind the antigen in the gel, but the affinity appeared to be decreased by two orders of magnitude with respect to free antibodies [186]. Antiatrazine monoclonal antibodies in gel were able to bind between 60 and 91% of atrazine, loaded on silica sol–gel columns doped with the antibody [187]. The leaching of the antibody was negligible and the gels were stable for at least two months [188]. Similarly, antibodies against trinitrotoluene [109, 189], isoprotrun [190], and dansyl [81] were encapsulated. In the latter case, binding affinity decreases only fivefold with respect to the antidansyl antibody in solution [81].

High-throughput compound screening is a key step in the discovery of new drugs. Immobilization on the same platform of several biological targets allows one to speed up the

search and to decrease the amount of naturally or chemically synthesized compounds. The sol–gel immobilization of the complex between the calcium binding protein calmodulin and mellitin was used for the screening of mellitin antagonists [99]. The change of luminescence of Tb(III) calmodulin, originated from an energy transfer from tryptophan emission of mellitin, provided a signal to monitor the competition between mellitin and antagonists. This study evidences that protein-doped gels might be a valuable tool for protein nano- and microarray technologies [191].

Optical memories and branched three-dimensional memories are electronic devices that have made use of biomolecules. Light-addressable systems were developed on the basis of the spectroscopic properties of immobilized native and D96N bacteriorhodopsin [14, 25, 96–98, 192, 193] and phycoerythrin [115, 194]. These proteins in the gel maintain their light-sensitive properties and exhibit different absorbance bands depending on the on–off cycle of the illuminating light.

By encapsulating in silica gels the iron storage protein ferritin, magnetic glasses can be prepared [195]. It was possible to release the iron from holo-ferritin but the reverse process was hampered.

Protein-doped silica gels have potential pharmaceutical technology applications. Controlled release of drugs from microcapsules is a therapeutic goal. When the drug is a protein the goal is even more challenging. Sol–gel derived cages were used to encapsulate the pharmaceutically transforming relevant growth factor–β1 [196] and the model protein trypsin inhibitor [197]. In both cases, a slow protein release was observed over several days. Since the growth factor is involved in eliciting bone tissue reactivity, this composite biomaterial might be useful for bone regeneration. Furthermore, by using as a precursor bis[3-(trimethoxysilyl)-propyl]ethylenediamine, a gel was fabricated that leads to different intakes and releases of cytochrome *c*, myoglobin, and hemoglobin [198]. Biocomposite layers of silica, entrapping collagen, gelatine, and collagen hydrolysate, were used to coat bone implants for the stimulation of hydroxyapatite deposition and bone regeneration [199]. The highest cell adhesion and proliferation of fibroblasts on the layer were observed using acidic biocomposite sols. The coatings were found to be not toxic and to exhibit good biocompatibility.

4.3. Biochemical Investigations

The discovery that proteins can be encapsulated in silica gels retaining biological activity was exploited by researchers to deepen the understanding of the functional properties of the allosteric proteins hemoglobin and fructose-1,6-bisphosphatase. In particular, it was found that encapsulation decreases by several orders of magnitude the rate of quaternary conformational changes and allows one to fix both proteins either in the T or R state, depending on the experimental conditions [60, 73, 85, 86, 91].

4.3.1. Hemoglobin

Hemoglobin is the paradigm of allosteric proteins. This protein has been investigated by a large variety of biophysical methods in order to understand the mechanism of oxygen binding and release and allostery. The fixation of the T and R state of hemoglobin by encapsulation in TMOS-derived gels has provided surprising insights on hemoglobin function and regulation. Trasmission electron microscopy of silica gels prepared in the absence and presence of T state Hb (Fig. 2) indicates that the pore/channels are about 3 and 4 nm, respectively. As hemoglobin diameter is about 6 nm, the protein cannot leach. The T and R states of hemoglobin were first characterized by measuring oxygen binding curves [26, 60, 85, 87, 89]. The oxygen binding curves of both the T and R states were characterized by a Hill coefficient very close to unity, indicating that the ligand binds noncooperatively, in agreement with the prediction of the Monod et al. model [200]. By varying the procedure of encapsulation, it was possible to isolate two distinct tertiary conformations of the T state of hemoglobin that exhibit a 10-fold difference in oxygen affinity [26]. The oxygen affinities of the two states closely correspond to those observed in solution for the binding of the first oxygen to T state hemoglobin under selected conditions, indicating that even tertiary transitions are slowed down in silica gels without altering ground state properties. The kinetics of carbon monoxide rebinding to R and T state hemoglobin gels was investigated (Fig. 4) [88, 90]. Carbon monoxide bound to the heme iron was laser-flash photolyzed and the time course of ligand rebinding was monitored by a nanosecond laser spectrometer. The T and R states exhibited a geminate phase and bimolecular phase similar to those observed in solution. When the kinetics was monitored on the high and low affinity T states striking differences were observed, indicating that encapsulation in silica gels strongly decreases the rate of not only quaternary changes but also tertiary transitions. This feature might be exploited to investigate the structure–dynamics–function relationships of complex conformational distributions. Functional information was correlated to the structural and dynamic characterization of T and R states hemoglobin gels, carrying out resonance Raman studies [72, 73] (see Sections 3.1.1 and 3.1.2). Hemoglobin gels exhibit the same marker bands as in solution. In particular, a band associated with the heme iron–proximal histidine stretching mode, diagnostic of the tertiary–quaternary

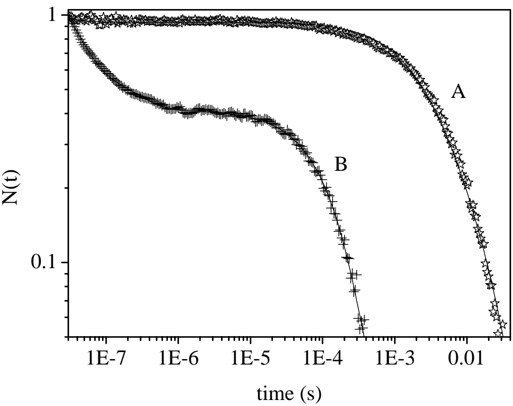

Figure 4. Transient absorption at 488 nm following 532 nm photolysis of T state (A) and R state (B) hemoglobin, encapsulated in silica gels, at 15 °C. Reprinted with permission from [89], S. Abbruzzetti et al., *J. Nanosci. Nanotech.* 1, 407 (2001). © 2001, American Scientific Publishers.

state of hemoglobin, was used to monitor the conformational transitions as a function of time upon exposure of T state hemoglobin gels to carbon monoxide.

4.3.2. Fructose-1-6-bisphosphatase

In the case of fructose-1,6-bisphosphatase, the enzyme was encapsulated either in the T or R state in the presence and absence of the allosteric effector AMP [91]. The k_{cat} of the R state was 4-fold less than that of the enzyme in solution; the K_M was 350-fold higher. Interestingly, the cooperative binding of magnesium ions, an enzyme activator, was observed at lower concentrations for the encapsulated enzyme than in solution. As for hemoglobin ligand-induced conformational changes, binding of AMP triggers the R to T quaternary transition at rates much smaller than in solution. The inactivation process is biphasic, suggesting a direct effect of the allosteric effector on the enzyme active site, followed by the quaternary switch.

4.3.3. Glutamate Dehydrogenase

The allosteric enzyme glutamate dehydrogenase encapsulated in TMOS gels was active, as shown by recording spectrophotometrically the formation of the coenzyme NADH [92]. The enzyme exhibited a 40-fold decrease in v_{max} with respect to the soluble enzyme, whereas the K_M was very similar. Binding of the positive and negative allosteric effectors GTP and ADP, respectively, parallels the effects observed in solution on the catalytic activity. The low activity was explained by a limited diffusion of substrates in the gel. However, it is also possible that the encapsulation conditions have entrapped a different conformation of the enzyme with respect to that predominant in solution.

4.3.4. Pyridoxal 5′-Phosphate-Dependent Enzymes

The catalytic activity of several proteins is associated with open-closed conformations of flexible lids or domains, covering or forming the active site. A class of enzymes in which these conformational changes have been crystallographically characterized is represented by pyridoxal 5′-phosphate-dependent enzymes. Silica gel protein encapsulation is a valuable method to isolate conformations or to dramatically decrease the rate of tertiary transitions. Taking advantage of the chromophoric properties of the bound coenzyme, investigations on the effect of silica gel encapsulation on the enzyme activity and the distribution of tertiary conformations of tryptophan synthase, *O*-acetylserine sulfhydrilase [201], tryptophanase, and tyrosine phenol lyase are being carried out in our laboratory.

5. CONCLUSIONS

Composite biomaterials are generated via either adsorption, covalent attachment of biomolecules to activated surfaces or encapsulation in organic, silicate, or organo-silicate matrices. The latter approach has led to the development of biorectors, biosensors, and biocoatings that are successfully used in industrial catalysis, the food industry, environmental protection, and biomedical diagnosis. The present technological challenge is to expand the use of protein-doped nanoporous gels for advanced electronic devices, and for nanodevices containing protein molecules arrays, able to simultaneously detect a large variety of analytes.

GLOSSARY

Absorbance The absorption of light by a substance, calculated as the $-\log(I/I_O)$, where I and I_O are the intensities of the light before and after passing through the sample, respectively. It is proportional to the concentration of the substance and the optical pathlength.

ANS 8-Anilino-1-naphthalenesulphonic acid, an apolar dye characterized by an enhanced fluorescence upon binding to hydrophobic patches of proteins. It is often used to detect unfolding intermediates.

Bioreactor A device in which one or more enzymes are physically confined, allowing one to obtain the selective and efficient transformation of substrates in products, and an easy separation between catalysts and reagents.

Biosensor A device exploiting the functional properties of a biomolecule for the selective recognition and quantitation of an analyte in a complex medium.

Circular dichroism Differential absorption of left and right circularly polarized light by optically active molecules.

Fluorescence The emission of light by a substance immediately after the absorption of energy from light of shorter wavelength.

Fluorescence anisotropy The measurement of the average angular displacement of the fluorophore which occurs between absorption and the subsequent emission of light by fluorescence. The angular displacement depends on the rate and extent of the rotational diffusion.

Protein A biological macromolecule formed by a sequence of aminoacids. Proteins perform a variety of functions, most of which require the recognition of other molecules.

Raman emission Discrete bands originating from molecular normal mode of vibrations, serving as a specific fingerprint of three-dimensional structure, intermolecular interactions, and conformations.

R- and T-state “Relaxed” and “tense” quaternary conformations of an allosteric protein. For hemoglobin R and T conformations are endowed with high and low oxygen affinity, and for enzymes with high and low catalytic efficiency, respectively.

Sol–gel process A versatile solution process for making ceramic and glass materials, involving the transition of a system from a liquid “sol” phase (mostly colloidal) into a solid “gel” phase.

ACKNOWLEDGMENTS

This work was supported by grants from the Italian Ministry of Instruction, University, and Research (COFIN 2002-2003 to A.M.) and the Italian Institute for the Physics of Matter. Support was also provided by NIH grant 1 P01GM58890 from the U.S. Public Health Service.

1. INTRODUCTION

Rapid progress in nanoscale fabrication technology ("nanotechnology") has enabled us to make various types of semiconductor devices using quantum dots (QDs). Quantum dots are small regions defined by tailor-made confining potentials in semiconductor materials, in which the number of electrons can vary between one and several hundred and whose size is comparable to the Fermi wavelength of the electrons. Because QDs are analogous to real atoms, they are often referred to as artificial atoms. Unlike real atoms, though, current and voltage leads can be attached to probe a QD's electronic state. The interplay between quantum confinement and charging effects manifests itself in a wide range of physical phenomena [1–3]. The single-electron charging effect is one of the more important of these and will be addressed in this chapter. When the charging energy of a small quantum dot is larger than the thermal energy, electrons in the lead cannot transfer into the dot ("Coulomb blockade effect"). By coupling several quantum dots, we can create artificial molecules. An important feature of these artificial molecules is that the couplings between different dots can be tuned by changing gate voltages or interdot distances. This tunability allows us to achieve various interesting phenomena, ranging from the formation of a "chemical bond" between two coupled dots to the manipulation of a single electron in "turnstiles" and "pumps."

If we consider a QD artificial atom as a building block, we can create QD arrays. Electrons in QD arrays can move around and interact with each other through the Coulomb interaction, and many interesting effects manifest themselves in magnetic, transport, and optical properties. When QDs are arranged on a periodic lattice and are coupled to each other coherently, a band structure is obtained. This type of dot lattice or artificial crystal was first proposed by Sakaki [4] and it is called quantum dot superlattice (QDSL). It is analogous to quantum well superlattices [5], in which a sequence of semiconductor layers with different bandgaps produces new materials and devices. The energy spectrum of the superlattice is determined by the artificial periodicity and the coupling between quantum wells (dots) rather than by the properties of the individual semiconductor materials.

This chapter is organized as follows. Section 2 surveys the studies of the single-electron effect in a single QD. Starting from a classical single-charge theory as a basis, we extend it to include the quantized single-particle-energy and the exchange interaction and discuss the physics of single QD systems. Section 3 describes multiple-dot systems or QD molecules. Section 4 covers the physics in quantum dot arrays, stressing theoretical predictions and proposals that will stimulate future study. Finally, Section 5 makes some concluding remarks and suggests future directions.

2. SINGLE QUANTUM DOT (ARTIFICIAL ATOM)

2.1. Single-Electron Tunneling in Semiconductor Structures

In this section, we focus on two QD structures that are commonly used in the study of single-electron phenomena. One is the lateral QD shown in Figure 1a. Metal electrodes are

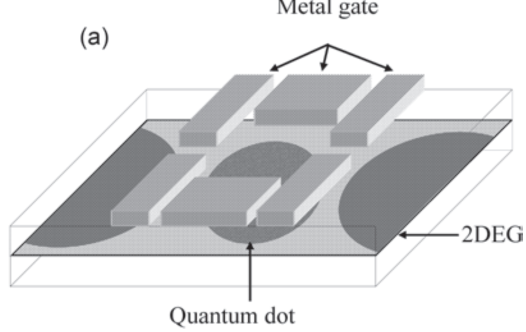

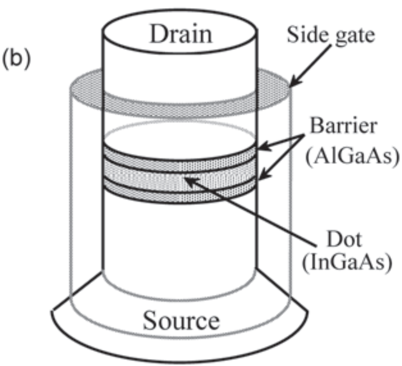

Figure 1. (a) Schematic of a lateral QD. Negatively biased metal electrodes patterned on the surface of a 2DEG heterostructure of GaAs depletes the underlying 2DEG in the vicinity of the gates. (b) Schematic of a vertical QD fabricated in a heterostructure where a disk of GaAs is sandwiched by two thin barriers of AlGaAs. A negatively biased gate-electrode surrounding the pillar depletes electrons in the outer region of the pillar.

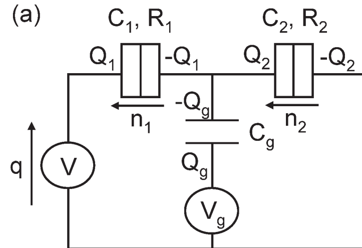
patterned on the surface of a two-dimensional electron gas (2DEG) heterostructure of GaAs/AlGaAs. A negative voltage applied to the gates raises the electrostatic potential and depletes the underlying 2DEG in the vicinity of the gates. Under suitable biasing conditions, a small region of 2DEG remains at the center of the structure and is separated from the rest of the 2DEG by two narrow constrictions. When electrostatic potential at the constriction is higher than the Fermi energy of the 2DEG, there arises an energy barrier under which electrons can tunnel. In many cases, an additional gate is capacitively coupled to the QD to modify the electrostatic potential inside the QD. This additional gate can be a separate surface electrode near the QD or a back-gate on the other side of the 2DEG.

The other structure is obtained in the vertical QD illustrated in Figure 1b. A narrow pillar is fabricated in a heterostructure where a disk of GaAs is sandwiched between two thin AlGaAs barriers. A negatively biased gate-electrode surrounding the pillar depletes electrons in the outer region of the pillar and shrinks the quantum disk. Consequently, the electrons are confined at a very narrow region in the center of the pillar. Current flowing along the pillar is measured between the source and drain electrodes on the top and bottom of the pillar. The lateral confining potential has a circular symmetry approximated by a two-dimensional parabolic potential. This allows us to observe a shell structure having highly degenerate levels, as will be described in the following section. Another type of vertical dot structure has been proposed by Ashoori et al. [6, 7]. The dot is located in the GaAs quantum well between AlGaAs barriers and its size is controlled by the top gate voltage as in the lateral QD. Electrons tunnel vertically to the bottom electrode. The addition spectra are measured in a unique ac capacitance measurement by varying the gate voltage. Singlet–triplet transition and Landau level transition have also been observed in these kinds of structures [7].

2.2. Classical Model of the Single-Electron Charging Effect

If one considers a quantum dot to be a classical conductor having capacitance C, the charging energy needed to add one electron to it is expressed by $E_c = e^2/C$. For a sphere, $C_{\text{sphere}} = 4\pi\varepsilon R$ and, for a disk, $C_{\text{disk}} = 8\varepsilon R$, where ε is the dielectric constant around the dot. At low temperatures, the charging energy E_c can be larger than the thermal energy $k_B T$ in the QD, where the number of electrons does not fluctuate.

The quantum dot is coupled to external electrodes to add or remove electrons and modify the electrostatic potential in the dot. Figure 2a illustrates the equivalent circuit of the single-electron transistor (SET), which consists of two tunnel junctions in series that form a QD capacitively coupled to the gate-electrode with voltage V_g, capacitance C_g, and accumulated charge Q_g. Each tunnel junction has capacitance C_i, resistance R_i, and accumulated charge Q_i. The



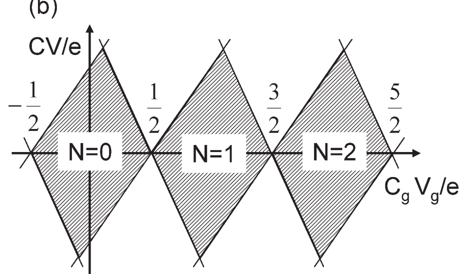


Figure 2. (a) Equivalent circuit of the single-electron transistor. Two tunnel junctions with capacitance C_i, resistance R_i, and accumulated charge Q_i $(i = 1, 2)$ form a QD capacitively coupled to the gate-electrode with voltage V_g, capacitance C_g, and accumulated charge Q_g. The transport voltage V induces a net flow of charge through the device. (b) Stability diagram of a SET. Inside the shaded regions, tunneling events are suppressed by the Coulomb blockade effect and the number of electrons N is well defined. For low V, the current oscillates periodically when $V_g \simeq (n + 1/2)e/C_g$.

transport voltage V induces a net flow of charge through the device. Consider the situation where R_1 and R_2 are much larger than the resistance quantum h/e^2 and electrons n_i tunnel through tunnel junction i. The electrostatic energy of the whole system is given by

$$E(n_1, n_2) = \frac{Q_1^2}{2C_1} + \frac{Q_2^2}{2C_2} + \frac{Q_g^2}{2C_g} - (en_1 + Q_1)V - Q_g V_g \tag{1}$$

where the charges must satisfy the relations

$$\frac{Q_1}{C_1} + \frac{Q_2}{C_2} = V \quad \frac{Q_g}{C_g} + \frac{Q_2}{C_2} = V_g \quad -Q_1 + Q_2 - Q_g = eN \tag{2}$$

where $N = n_1 - n_2$ is the number of electrons in the QD. Substituting Eq. (2) into Eq. (1), we obtain

$$E(n_1, n_2) = \frac{1}{2C}(C_1 V + C_g V_g + eN)^2 - en_1 V \tag{3}$$

Tunneling is prohibited at junction 1 if $E(n_1 \pm 1, n_2) > E(n_1, n_2)$ and at junction 2 if $E(n_1, n_2 \pm 1) > E(n_1, n_2)$. Under these conditions, the Coulomb blockade occurs if

$$\frac{C_g V_g}{e} - \left(N + \frac{1}{2}\right) < \frac{(C_2 + C_g)V}{e} < \frac{C_g V_g}{e} - \left(N - \frac{1}{2}\right)$$
$$-\frac{C_g V_g}{e} + \left(N - \frac{1}{2}\right) < \frac{C_1 V}{e} < -\frac{C_g V_g}{e} + \left(N + \frac{1}{2}\right) \tag{4}$$

where we define the total capacitance as $C = C_1 + C_2 + C_g$ and assume $E_c \gg k_B T$. In the $V - V_g$ plane shown in Figure 2b, rhombus-shaped regions ("Coulomb diamonds") appear along the axis of V_g, within which the QD is charged with a fixed number of electrons. Inside these regions, tunneling events are suppressed and no current flows through the device ("Coulomb blockade effect"). For low V, the current flows only when $C_g V_g = e(N + 1/2)$, and the gate capacitance C_g can be determined from the current peak separations. C_1 and C_2 can be deduced from the slopes of the two edges of the rhombus.

When a QD having N electrons is in equilibrium with reservoirs with the chemical potential μ, the thermodynamic potential is given by $\Omega(N) = E(N) - N\mu$. When $\Omega(N') > \Omega(N)$ for all $N'(\neq N)$, electron tunneling is prohibited by the Coulomb blockade effect. When the chemical potential satisfies the condition $\Omega(N+1) = \Omega(N)$ at some μ, a small bias between the source and drain reservoirs induces a current through the dot via a transition between states N and $N+1$. This condition can be simply expressed by $\mu(N) = E(N+1) - E(N)$. This quantity is called an addition energy and represents the energy necessary to add an electron to the dot. By changing the external gate-electrode V_g, the chemical potential μ in the reservoirs is also modulated, where these two quantities are related via the relation $\mu(N) = \alpha e V_g(N)$. The factor α can be determined by fitting the conductance peak to a $\cosh^{-2}$ line shape [8].

The classical model described here gives the current oscillations with an equal spacing $\Delta V_g = e/C_g$ as a function of the gate voltage. Measured current oscillations in the vertical QD are shown in Figure 3. The separation of the current peaks is not exactly periodic. In the vertical QD shown in Figure 1b, the actual QD is much smaller than the diameter of the pillar, since the negatively biased side-gate depletes the electrons and the electrostatic potential strongly confines them in the center of the quantum disk. When the side-gate voltage is just above the threshold voltage, a small number of electrons remain in the QD. When the actual diameter of the GaAs QD is $d = 20$ nm, for example, the single-particle level spacing is as large as $\hbar^2/m^*d^2 \simeq 6$ meV ($m^* = 0.07$), which is comparable to the Coulomb energy $e^2/4\pi\epsilon d \simeq 12$ meV ($\epsilon = 13$). In this situation, it is obvious that the classical charging model is insufficient and we have to take into account the quantum size effect. Coulomb interactions also become important, as we will see in the following sections.

2.3. Constant Interaction Model with Exchange Term

We consider the Hamiltonian for a QD expressed by

$$\mathscr{H} = \sum_{\alpha\sigma} \varepsilon_\alpha c_{\alpha\sigma}^+ c_{\alpha\sigma} + \frac{1}{2} \sum_{\alpha\alpha'\beta\beta'} \sum_{\sigma\sigma'} U_{\alpha\beta\beta'\alpha'} c_{\alpha\sigma}^+ c_{\beta\sigma'}^+ c_{\beta'\sigma'} c_{\alpha'\sigma} \tag{5}$$

where $c^+_{\alpha\sigma}(c_{\alpha\sigma})$ is the creation (annihilation) operator for the state α with energy ε_α and spin σ, and $U_{\alpha\beta\beta'\alpha'}$ is the matrix element of Coulomb interaction. To go beyond the classical charging model, let us start from the reduced Hamiltonian including the single-particle, direct, and exchange terms [9]. Neglecting the off-diagonal terms, the interacting Hamiltonian $\mathscr{H}_I$ is reduced to

$$\mathscr{H}_I = \mathscr{H}_{\text{Coulomb}} + \mathscr{H}_{\text{exchange}} \tag{6}$$

$$\mathscr{H}_{\text{Coulomb}} = \frac{1}{2}\sum_{\alpha\beta}\sum_{\sigma\sigma'} U_{\alpha\beta\beta\alpha} c^+_{\alpha\sigma} c_{\alpha\sigma} c^+_{\beta\sigma'} c_{\beta\sigma'} \tag{7}$$

$$\mathscr{H}_{\text{exchange}} = -\frac{1}{2}\sum_{\alpha\beta}\sum_{\sigma\sigma'} U_{\alpha\beta\alpha\beta} c^+_{\alpha\sigma} c_{\alpha\sigma'} c^+_{\beta\sigma'} c_{\beta\sigma} \tag{8}$$

It is convenient to introduce operators of the number of electrons $\hat{n}_\alpha$ and the spin $\widehat{\mathbf{S}}_\alpha$ on the QD such that

$$\hat{n}_\alpha = \sum_\sigma c^+_{\alpha\sigma} c_{\alpha\sigma} \qquad \widehat{\mathbf{S}}_\alpha = \frac{1}{2}\sum_{\sigma\sigma'} c^+_{\alpha\sigma} \vec{\sigma}_{\sigma\sigma'} c_{\alpha\sigma'} \tag{9}$$

where $\vec{\sigma}$ is the Pauli matrix. When one assumes the matrix elements in the Coulomb term and the exchange term are given by $U_{\alpha\beta\beta\alpha} = U$ and $U_{\alpha\beta\alpha\beta} = J$, one can express $\mathscr{H}_{\text{Coulomb}}$ and $\mathscr{H}_{\text{exchange}}$ in a simple form as

$$\mathscr{H}_{\text{Coulomb}} = \frac{1}{2}\sum_{\alpha\beta}\sum_{\sigma\sigma'} U_{\alpha\beta\beta\alpha} \hat{n}_{\alpha\sigma} \hat{n}_{\beta\sigma'} = \frac{U}{2}\widehat{N}^2 \tag{10}$$

$$\begin{aligned}\mathscr{H}_{\text{exchange}} &= -\sum_{\alpha\beta} U_{\alpha\beta\alpha\beta}\left[\widehat{\mathbf{S}}_\alpha \cdot \widehat{\mathbf{S}}_\beta + \frac{1}{4}\sum_{\sigma\sigma'} \hat{n}_{\alpha\sigma}\hat{n}_{\beta\sigma'}\right] \\ &= -J\left[\widehat{\mathbf{S}}^2 + \frac{1}{4}\widehat{N}^2\right]\end{aligned} \tag{11}$$

where we define $\widehat{N} = \sum_\alpha \hat{n}_\alpha$, $\widehat{\mathbf{S}} = \sum_\alpha \widehat{S}_\alpha$, and use the identity $\vec{\sigma}_{\sigma\sigma'}\vec{\sigma}_{\sigma_1\sigma'_1} = 2\delta_{\sigma\sigma'_1}\delta_{\sigma'\sigma_1} - \delta_{\sigma\sigma'}\delta_{\sigma_1\sigma'_1}$. Then, by adding the single-particle term in Eq. (5), the total Hamiltonian is simply expressed by

$$\mathscr{H} = \sum_{\alpha\sigma} \varepsilon_\alpha \hat{n}_{\alpha\sigma} + E_c\widehat{N}^2 - J\widehat{\mathbf{S}}^2 \tag{12}$$

where $E_c = U/2 - J/4$ is the charging energy of the QD. The last two terms in Eq. (12) represent the dependence of the energy of the QD on the total number of electrons and the total spin respectively. They commute with each other and with the first term in Eq. (12). Therefore, all states of the QD can be classified by n_α and $\mathbf{S}_\alpha$. Choosing the direction of the total spin of the system in the z axis, we can express the energy of this system in terms of the occupation numbers $n_{\alpha\sigma}$ as

$$E(N, S) = \sum_{\alpha\sigma} \varepsilon_\alpha n_{\alpha\sigma} + E_c N^2 - JS(S+1) \tag{13}$$

where $N = \sum_{\alpha\sigma} n_{\alpha\sigma}$ and $S = |\sum_\alpha (n_{\alpha\uparrow} - n_{\alpha\downarrow})|/2$. This Hamiltonian represents the constant interaction model with the exchange term (CIE model). Without the last (exchange) term, it is simply called the constant interaction (CI) model.

Let us consider the situation where the number of electrons is fixed by the Coulomb blockade effect. The lowest energy is obtained by minimizing E with respect to the occupation numbers $n_{\alpha\sigma}$ satisfying Pauli's principle. When two levels at the Fermi energy are nearly degenerate with a small energy splitting Δ, the energy difference between the lowest energy states with the singlet $S = 0$ and the triplet $S = 1$ state is given by $E(N, 1) - E(N, 0) = \Delta - 2J$. The triplet state becomes energetically more favorable than the singlet one when $J > \Delta/2$. In general, when we fill $2p(\geq 2)$ electrons in $q(\geq 2p)$ degenerate levels with a splitting Δ near the Fermi energy, the energy difference between spin $S = k - 1$ and $S = k$ $(1 \leq k \leq p)$ states is given by $E(N, k) - E(N, k-1) = (2k-1)\Delta - 2kJ$. By doing a similar algebra for the odd number of electrons $2p + 1$, the energy difference between spin states $S = k + 1/2$ and $S = k - 1/2$ is given by $E(N, k+1/2) - E(N, k-1/2) = 2k\Delta - (2k-1)J$. The largest spin state $S = p$ (or $S = p + 1/2$) becomes the lowest state when the exchange energy is larger than the energy splitting such that $J > (2p-1)\Delta/2p$ (or $J > 2p\Delta/(2p-1)$). This is known as Hund's first rule. This rule generally holds when the separation between two (or more) single-particle levels is smaller than the exchange energy, for example, in the presence of magnetic fields.

The CIE model described here is quite simplified. The Coulomb and exchange energies $U_{\alpha\beta\beta\alpha}$ and $U_{\alpha\beta\alpha\beta}$ differ from state to state, and it is not obvious that the off-diagonal terms can be neglected. Nevertheless, it does qualitatively explain many features observed in experiment for a single QD, as we will see in the next subsection.

2.4. Quantum Dot in Parabolic Potential

Here, let us consider the single-electron charging effect in a vertical QD. Figure 3a shows the gate-voltage dependence of the current through QDs with diameters of $D = 0.5$ and $0.44\ \mu$m [10]. In these devices, the number of electrons in the QD starts from one. It can be seen that the peaks of Coulomb blockade oscillations are not equally spaced. The peak spacings versus the number of electrons are plotted in Figure 3b. The 2nd, 6th, and 12th peak spacings are quite large. The 4th, 9th, and 16th ones are also large. As mentioned in the previous subsection, the confinement of the vertical QD can be represented by a two-dimensional isotropic parabolic potential. Let us examine the single-particle energies for this potential. In the presence of a magnetic field threaded perpendicularly to the 2D plane, the single-particle Hamiltonian is given by

$$H_0 = \frac{(\mathbf{p} - e\mathbf{A})^2}{2m^*} + \frac{1}{2}m^*\omega_0^2(x^2 + y^2) \tag{14}$$

where $\mathbf{A} = (-By/2, Bx/2)$, m^* is the effective mass of an electron, and ω_0 is the frequency of the parabolic confinement. The eigenvalue of the Hamiltonian H_0 is given by

$$\varepsilon_{nm} = (2n + |m| + 1)\hbar\omega - \frac{1}{2}m\hbar\omega_c \qquad (n = 0, 1, 2, \ldots \quad m = 0, \pm 1, \pm 2, \ldots) \tag{15}$$

where $\omega = \sqrt{\omega_0^2 + (\omega_c/2)^2}$ and $\omega_c = eB/m^*$. In the absence of the magnetic field $B = 0$, the single-particle levels are classified as shell structures; that is, $\varepsilon_l = l\hbar\omega_0$ $(l = 1, 2, \ldots)$,

where the energy shells are separated in an equal spacing $\hbar\omega_0$ and the lth shell has l degenerate levels distinguished by the magnetic quantum number $m = -(l-1), -(l-3), -(l-5), \ldots, l-3, l-1$ as shown in Figure 3. When the magnetic field is applied, the degeneracy of the levels in each shell is lifted and the energy levels have a magnetic field dependence called the Darwin–Fock spectrum [11, 12].

When we consider the single electron phenomena in the presence of highly degenerate levels, the CIE model serves as a starting point in examining what happens to the Coulomb blockade. As described in the previous section, the CIE model has degenerate single-particle levels in the topmost shell and shows the ground state with the largest total spin obeying Hund's first rule: In a zero magnetic field, first l electrons with up-spin fill the levels in the lth shell, and then the next l electrons with down-spin occupy the shell, satisfying the Pauli's principle. The configuration of electrons having the largest spin on (or above) the third shell is not always unique. For example, the third shell has three levels with the magnetic momenta $m = 2, 0, -2$ and there are three possibilities for filling two electrons with up-spins. The CIE model cannot predict how the up-spin electrons are filled in the degenerate levels with different magnetic momentum. The shell filling depends on the distribution of wavefunctions in each orbital, which results in different matrix elements of the Coulomb interaction $U_{\alpha\beta\beta\alpha}$. Many theoretical studies have been performed to take this orbital effect properly into account. These include Hartree–Fock calculations [13–17], numerical diagonalizations of the many-electron Hamiltonian [18–22], density-functional methods [23–30], Monte Carlo calculations [31, 32], and other techniques [33–35]. Figure 4 shows the chemical potential difference versus the number of electrons calculated by a self-consistent Hartree–Fock approximation [14]. The large peaks at $N = 2, 6, 12, 20$ reflect the shell structure and the peaks at $N = 4, 9, 16$ reflect high-spin states based on Hund's rule. These qualitative features are

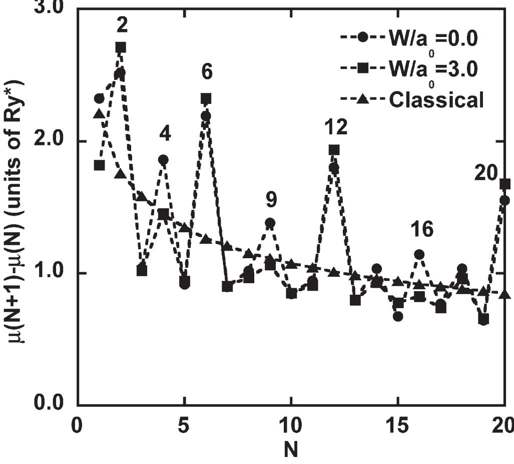

Figure 4. Calculated difference of adjacent chemical potentials as a function of the number of electrons in quantum disks having thickness W of $W/a_0 = 0.0$ and 3.0. Here, $a_0 = \sqrt{\hbar/2m^*\omega_0}$ and Ry^* is the effective Rydberg constant. Classical dependence is obtained at high temperature $k_B T/\hbar\omega_0 = 0.3$. in good agreement with the experiment. Experimental [36] and theoretical [36, 37] investigations on ellipsoidal deformation of vertical quantum dots have also been done. Theoretical calculations in the three-dimensional QD have been performed [19, 26, 38, 39].

When magnetic fields are applied, the degenerate levels in each shell are lifted depending on the magnetic momentum and form the Darwin–Fock spectrum. The magnetic field dependence of the peak positions measured in the vertical QD is plotted in Figure 5 [40]. Figure 6 shows the calculated addition spectra $\mu(N)$ in the CIE model as a function of $\omega_c = eB/m^*$. Another interesting feature in Figures 5 and 6 is that cusps appear when the two single-particle levels cross. If we neglect the exchange term in Eq. (13) in the CIE model as plotted by dotted lines in Figure 6, two curves of chemical potential simply approach and depart with the magnetic field, whereas, when the exchange term is included as plotted by solid lines, cusps appear when two single-particle levels cross. These cusps are clear evidence of the appearance of the high-spin state ("generalized Hund's rule") when the two single-particle levels cross by applying a magnetic field [14, 41, 42].

In magnetic fields $\omega_c \gg \omega_0$, Landau levels of filling factor $\nu = 2$ are formed, where N electrons occupy the lowest Landau level with the lowest total spin. As the magnetic field becomes stronger, the adjacent level spacing in the Landau level decreases. When the difference between the highest unoccupied level for up-spin and the highest occupied level for down-spin becomes smaller than the exchange energy, one electron flips its spin and the total spin increases by one. This spin-flip event continues until there are no more down-spin electrons and the total spin becomes maximum $S_{\max} = N/2$. This transition region is called the spin-flip region.

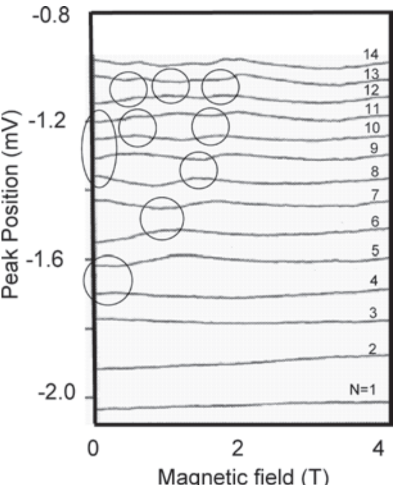

Figure 5. Peak positions of Coulomb oscillations in the vertical QD ($D = 0.54$ μm) having electron number $N = 1$ to 14 as a function of magnetic field. Circles at $B = 0$ indicate the region where Hund's rule holds in the shell structure and circles for $B > 0$ indicate the region where the generalized Hund's rule holds when two single-particle levels cross. Figure 6. Addition spectra in the constant interaction model with (solid lines) and without (dotted lines) exchange term as a function of magnetic field. Here, $\hbar\omega_0 = U = 1$ and $J = 0.1$. The features in Figure 5 are well reproduced.

Spin-polarized electrons occupy adjacent orbitals with consecutive angular momenta. This compact occupation of states maximizes the electron density, and so it is called the maximum density droplet [43]. The maximum density droplet state has been observed in experiments [7, 44–46] and has been theoretically analyzed [47–49]. The root-mean-squared extent of orbital $|m\rangle$ with angular momentum m is expressed by $\langle \delta r\rangle = \langle m|r^2|m\rangle^{1/2} = \sqrt{2(m+1)(\hbar e/B)}$, where orbitals having smaller m are distributed in the inner area. A further increase of the magnetic field squeezes the QD and Coulomb repulsion becomes much stronger. The electrons jump from the lower levels with lower angular momentum to the higher ones distributed in the outer area of the QD to relax the Coulomb repulsive energy. This is called the reconstruction region [46]. The CIE model simply predicts that electrons in the innermost levels move to the outermost levels [43] and a hole of electron density is created in the center of the QD. Chamon and Wen [50] found that Hartree–Fock calculations predict a ring of high-density electrons that breaks off from the edge of the maximum density droplet. This has been confirmed by other authors [51–53]. Another interesting possibility in edge reconstruction is the formation of spin textures at the edges of the QD when the Zeeman splitting is included [54, 55]. These textures are driven by the same physics that leads to "skymions" in bulk quantum Hall system [56–59].

Transport and capacitance spectroscopy analyses of QDs have revealed many other interesting properties of electrons in artificial atoms. In the nonlinear transport regime, the current is measured as a function of source–drain voltage eV_{sd} as well as gate voltage. One can probe the level distribution in the energy window eV_{sd} by measuring the dependence of the current with respect to this energy window. For small bias $eV_{sd} \ll \Delta$ (Δ is the single-particle-level spacing), usual Coulomb blockade oscillations are observed. For large bias $eV_{sd} > \Delta$, the source–drain voltage gives not only broadened peaks but also additional structures caused by the excited states. From the structure in the energy diagram, a lot of valuable information on the ground and excited states has been obtained [60, 61]. Transport spectra of lateral [62–64] and self-assembled QDs [65–67] have been measured and the shell structure has been observed. The Coulomb oscillations in a vertical dot containing a very large number of electrons have exhibited a surprising behavior in magnetic fields [68]. The addition spectra as observed in capacitance spectroscopy measurements group into bunches. A theoretical explanation has been proposed [69], but further study is needed in order to understand this phenomenon.

2.5. Spin-Blockade Effect

In the previous sections, we have described the Coulomb blockade effect based on the classical and CIE charging models, where the large charging energy makes the number of electrons well defined in the isolated QD. In these models, the coupling Γ between electrons in the QD and the leads through the tunneling barriers is not taken into account. When the thermal energy $k_BT(\gg\Gamma)$ is much smaller than the single-particle-level spacing Δ, tunneling occurs through only one level. The conductance peak has a lineshape of the derivative of the Fermi–Dirac distribution, where its peak height scales as $1/T$ and its peak width as T. On the other hand, multiple levels can contribute to the tunnel current when the thermal energy exceeds the level spacing. The temperature dependence of conductance oscillations becomes complicated, since the elastic coupling to leads differs from level to level depending the spatial or spin distribution and the symmetry of wavefunction. Meir et al. [70] have employed the Anderson model and the Landauer conductance formula to investigate the transport properties through multiple levels in a QD having very different elastic couplings. They predicted that participation of the multiple levels can give rise to an increase of current with increasing temperatures. This anomalous temperature dependence explained experimental observations [71].

It is not always true that a tunneling event occurs when the Coulomb blockade condition is broken and the current should flow in the classical model. The transition amplitude is closely related to the matrix elements between two states of N and $N+1$ electrons in the QD, and the tunneling probability is suppressed when the matrix element vanishes. To analyze this possibility quantum mechanically, we have to deduce the conductance formula including the transition amplitudes explicitly [72, 73]. When we define $|N, i\rangle$ and $E(N, i)$ as the ith state and energy for N electrons in the QD and $P_{\mathrm{eq}}(N, i) = \exp(-E(N, i)/T)/\sum_{M,j}\exp(-E(M, j)/T)$ as the equilibrium probability of the state, the tunnel current at low bias ($V \ll T$) is expressed by

$$I = V\frac{e^2}{T}\sum_{i,j} P_{\mathrm{eq}}(N, i) f(\epsilon_{ij})\frac{\Gamma_L\Gamma_R}{\Gamma_L+\Gamma_R} \tag{16}$$

$$\Gamma_{L(R)} = 2\pi N(0)|t_{L(R)}|^2\left|\sum_k\langle N+1, j|c_k^+|N, i\rangle\right|^2 \tag{17}$$

where $f(\epsilon)$ is the Fermi–Dirac distribution, $N(0)$ is the density of states in the leads, $t_{L(R)}$ is the tunnel amplitude from the left (right) lead, and $\epsilon_{ij} = E(N+1, j) - E(N, i)$. If we

assume $2\pi N(0)|t_L|^2 = 2\pi N(0)|t_R|^2 = \Gamma$ for simplicity, the above expression becomes

$$I = V\frac{e^2}{2T}\Gamma\sum_{i,j}P_{\rm eq}(N,i)f(\epsilon_{ij})\left|\sum_k \langle N+1, j|c_k^+|N,i\rangle\right|^2 \quad (18)$$

in which all the contributions of transition from $|N, i\rangle$ to $|N+1, j\rangle$ are summed by adding one electron on every possible level k. At low temperatures, $T \ll \epsilon = E(N+1,0) - E(N,0)$, only the ground states $|N,0\rangle$ and $|N+1,0\rangle$ can contribute and the conductance is expressed simply by

$$I = V\frac{e^2}{8T}\Gamma\frac{1}{\cosh^2(\epsilon/2T)}\left|\sum_k \langle N+1, 0|c_k^+|N,0\rangle\right|^2 \quad (19)$$

It is noted that the expression of the tunnel current involves the matrix elements between $c_k^+|N,i\rangle$ and $|N+1,j\rangle$. This means the current is suppressed at low temperature if transition from $|N,i\rangle$ to $|N+1,j\rangle$ does not occur just by adding one electron.

What suppresses the tunneling current? One possibility is the so-called spin-blockade effect proposed by Weinmann et al. [74–77]. If the ground states $|N,i\rangle$ and $|N+1,j\rangle$ respectively have spin S and S' and if $|S'-S| > 1/2$, one cannot change the total spin S into S' by adding spin 1/2. This results in a zero matrix element and the suppression of the current. This situation can occur when the single-particle levels are degenerate like in the shell structure in the circular QD or in the level crossings under magnetic field [78, 79]. As we considered previously, when p levels are almost degenerate near the Fermi energy, the total spin can be $S = p/2$ at most. Transition is prohibited from a state with three electrons having minimum total spin of 1/2 to a state with four electrons having maximum spin of 2. The spin of the ground state depends on the competition between the single-particle energy and the exchange energy, as discussed in Section 2.3, and total spin of the ground state does not always change by 1/2.

How can the spin-blockade effect be observed in experiment? One method is to measure the temperature dependence of the Coulomb blockade peaks. As temperatures increase, the excited states having nonzero matrix elements between $|N,0\rangle$ participate in the tunneling events and the current increases rapidly with temperature. This is in a sharp contrast to the normal $1/T$ dependence of the Coulomb blockade peak as seen in Eq. (19). Another method is to perform transport measurements in the nonlinear regime. Applying large source–drain voltage involves multilevels in the tunnel current through excited states. Evidence of the spin blockade has been obtained in the non-linear transport through GaAs QDs [80, 81]. Magnetotransport measurements have also provided indication of the spin-blockade effect in GaAs dots [81] and Si dots [82] having degenerate energy levels slightly split by the Zeeman effect. The spin-blockade effect at low temperatures is not always observed even when the condition $\Delta S > 1/2$ seems satisfied, as reported in ref. [82]. This problem deserves future study.

2.6. Kondo Effect in Quantum Dots

In the previous sections, we have treated source and drain electrodes as classical reservoirs that add electrons to or remove them from the QD incoherently, where electrons loose their quantum-mechanical phase memory during tunneling events. At extremely low temperatures, this treatment cannot be justified and a coherent coupling between electrons in the QD and leads should be taken into account. One consequence is the so-called Kondo effect.

In the 1930s, a peculiar phenomenon was found in the temperature dependence of the resistance of normal metals, such as copper, containing a dilute amount (below 0.1%) of magnetic impurities of iron or manganese [83–85]. The resistance decreased with temperature due to the reduction of phonon scatterings but increased upon cooling to very low temperatures. This anomalous behavior in resistance had been unresolved for a long time, but a crucial key to understanding this phenomenon was introduced by Kondo in 1964 [86].

The system is described by the Anderson model given by

$$\begin{aligned}\mathcal{H} &= \sum_{\mathbf{k}\sigma}\varepsilon_{\mathbf{k}}c_{\mathbf{k}\sigma}^+c_{\mathbf{k}\sigma} + \sum_{\sigma}\varepsilon_d n_{d\sigma} + Un_{d\uparrow}n_{d\downarrow} \\ &\quad + \sum_{\mathbf{k}\sigma}V\left(c_{\mathbf{k}\sigma}^+d_\sigma + d_\sigma^+c_{\mathbf{k}\sigma}\right)\end{aligned} \quad (20)$$

where $c_{\mathbf{k}\sigma}$ ($c_{\mathbf{k}\sigma}^+$) and d_σ (d_σ^+) are the annihilation (creation) operators of a conduction electron and a d-orbital electron with spin σ respectively, $n_\sigma = d_\sigma^+ d_\sigma$ is the number operator of the localized level with an energy ε_d measured from the Fermi energy, and V is the matrix element between states of the conduction electron and the d-orbital. In the strong coupling limit ($U \ll V$), the system is spin singlet $S = 0$. In the weak coupling limit ($U \gg V$), the number N and spin S on the localized level in the ground state are simply given by $(N,S) = (0,0)$ for $\varepsilon_d > 0$, $(N,S) = (1,1/2)$ for $\varepsilon_d < 0 < \varepsilon_d + U$, and $(N,S) = (2,0)$ for $\varepsilon_d + U < 0$.

Let us consider the weakly coupled regime $U \gg V$ and assume $\varepsilon_d < 0 < \varepsilon_d + U$. We can apply perturbation theory with respect to V, starting from the ground state of $d_\uparrow^+|F\rangle$ and $d_\downarrow^+|F\rangle$, where $|F\rangle$ is the state of conduction electrons filled up to the Fermi energy. The first-order process, which simply puts (removes) an electron in (from) the localized level, costs a large energy and can be neglected. The second-order process can be expressed by

$$\mathcal{H}'\frac{1}{E-\mathcal{H}_0}\mathcal{H}' \quad (21)$$

where $\mathcal{H}'$ is the fourth term in Eq. (20) and $\mathcal{H}_0 = \mathcal{H} - \mathcal{H}'$. By operating Eq. (21) to $d_\uparrow^+|F\rangle$ and $d_\downarrow^+|F\rangle$, one can obtain the effective interaction [87]

$$\begin{aligned}\mathcal{H}_{\rm eff} &= \sum_{\mathbf{k}\mathbf{k}'\sigma}\frac{V^2}{2}\left(-\frac{1}{\varepsilon_d} - \frac{1}{\varepsilon_d + U}\right)c_{\mathbf{k}\sigma}^+c_{\mathbf{k}'\sigma} \\ &\quad + \sum_{\mathbf{k}\mathbf{k}'\sigma\sigma'}2V^2\left(-\frac{1}{\varepsilon_d} + \frac{1}{\varepsilon_d + U}\right)c_{\mathbf{k}\sigma}^+c_{\mathbf{k}'\sigma'}\vec{\sigma}_{\sigma\sigma'}\cdot\mathbf{S}\end{aligned} \quad (22)$$

where $\vec{\sigma}$ is the Pauli matrix and $\mathbf{S}$ is the spin operator of the localized electron. The first term in Eq. (22) expresses normal scatterings independent of spins. The spin-dependent

scatterings in the second term represent so-called *s–d* exchange interactions with antiferromagnetic coupling when $\varepsilon_d < 0 < \varepsilon_d + U$. Kondo pointed out that higher Born scatterings between conduction electrons and the localized spin via antiferromagnetic interaction in Eq. (22) increase the scattering probability (or the inverse of relaxation time) below a characteristic temperature, resulting in a resistance increase. A sea of conduction electrons and the localized moment of spin in a magnetic impurity are coupled by the effective exchange interaction, forming a spin-singlet bound state. The localized moment of spin is screened by the so-called "Kondo cloud" of conduction electrons as if the localized spin disappeared. This many-body effect is called the Kondo effect and the characteristic temperature is the Kondo temperature.

The Kondo effect is a universal phenomenon which manifests itself when a localized state with a net spin couples with conduction electrons in the Fermi sea. A QD confining an unpaired electron of spin 1/2 coupled to leads, schematically shown in Figure 7, can be considered a Kondo system. This "mesoscopic Kondo effect" in a QD has been theoretically predicted [88–91]. First-order tunneling is prohibited by the Coulomb blockade effect as illustrated in Figure 7a because the addition of a second electron costs an energy of $\varepsilon_0 + U$, which exceeds the Fermi energies of the leads μ_L and μ_R. On the other hand, higher-order processes by co-tunneling allow a spin-flip on the dot, as shown in Figure 7c, via the intermediate virtual state depicted in Figure 7b. Successive spin-flip processes effectively screen the local spin on the dot leading to a macroscopically correlated, spin-singlet state. The Kondo temperature in this dot system is given by [92–94]

$$T_K = \sqrt{\frac{\Gamma U}{4}} \exp\left(\frac{\pi \varepsilon_0(\varepsilon_0 + U)}{\Gamma U}\right) \tag{23}$$

where ε_0 is the single-particle energy, U is the on-site Coulomb energy, and $\Gamma = \Gamma_L + \Gamma_R$ is the level broadening caused by the coupling between the dot and the leads. Below T_K, a resonant level ("Kondo peak") is induced near the Fermi energy in the density of states in the dot, and this level allows electrons to tunnel from the left to the right leads resonantly, even when the Coulomb blockade condition is satisfied.

Figure 7d schematically shows how normal Coulomb blockade oscillations change when the Kondo effect takes place. For $T > T_K$, the conductance oscillates with an equal spacing as in Figure 2 and its height is much smaller than $2e^2/h$, reflecting tunneling probabilities less than unity. Below T_K, an unpaired electron in the dot is screened by the conduction electron in the leads and the conductance approaches $2e^2/h$ in the so-called unitary limit where the transmission probability is unity due to a resonant tunneling. For an even number of electrons in the dot, when all the electrons have a pairing partner with an opposite spin, the Kondo effect does not occur and the usual Coulomb blockade effect suppresses the current through the dot.

Recently, the Kondo effect in QDs has been observed in many experiments [95–102]. As described in Section 2.1, lateral QDs have a tunable barrier formed by the gate-electrodes, and tunneling couplings between the dot and the leads are controllable. The conductance increase at valleys predicted in Figure 7d has been experimentally demonstrated in the lateral QDs [95–97]. To obtain ideal characteristics in the unitary limit like in Figure 7d, the barrier height must be low and symmetric ($\Gamma_L = \Gamma_R$). Van der Wiel et al. [99, 102] have observed $2e^2/h$ conductance in their lateral QD as shown in Figure 8. In Figure 8a, the valleys reach the maximum conductance value of $2e^2/h$. Two separate Coulomb peaks develop with narrowing peak spacing. The even–odd asymmetry of the temperature dependence of neighboring peaks is clearly seen. The zero-bias peak in the differential conductance around $V_{SD} = 0$ shown in Figure 8b reflects the Kondo resonance in the density of states at the Fermi energy.

The detailed aspects of the Kondo effect predicted in a QD have been investigated by theorists [103–114]. Here, we show examples calculated by a numerical renormalization group method [114], which gives a unified description of the temperature dependence of the Kondo effect in a single-site QD of an energy ε_d. The single-site approximation is justified when the single-particle energy spacing is much larger than the level broadening Γ. Figure 9 plots the conductance as a function of the single-particle level ε_d in the dot for different temperatures. When temperatures are higher than Γ, normal Coulomb blockade peaks can be seen near $\varepsilon_d \sim -U$ and 0. Decreasing temperatures $T \gtrsim \varepsilon_d$ makes the two peaks rapidly sharper and come closer together, while the valley between peaks has a weak temperature dependence and remains low. A further decrease of temperatures raises the valley up to the unitary value. This temperature dependence in the conductance at the peaks

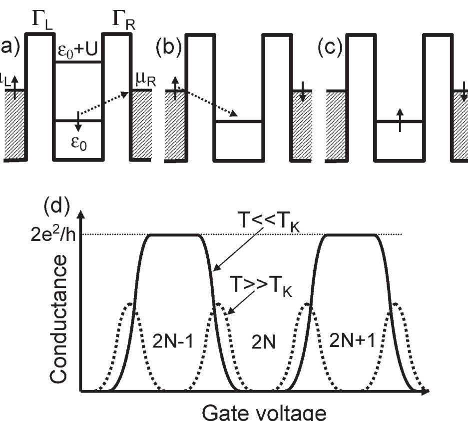

Figure 7. (a) Schematic of a quantum dot having single-site energy ε_0 and on-site Coulomb energy U. The dot is connected to the left and right leads by the tunneling probabilities Γ_L and Γ_R. The series (a)–(c) depicts the spin-flip of the electron at energy ε_0 due to a co-tunneling process via a virtual state shown in (b). (d) Schematic behavior of conductance oscillations as a function of the gate voltage. Above the Kondo temperature T_K, the Coulomb blockade oscillation has a periodicity of e/C_g with the peak heights smaller than e^2/h. In temperatures much lower than T_K, the conductance peak height reaches $2e^2/h$ when the number of electrons in the QD is odd, whereas the conductance is still suppressed for an even number of electrons.

and the valley comes from the characteristic temperatures $\widetilde{T}_K$ dependent on ε_d; $\widetilde{T}_K \sim \Gamma$ near the peaks ($\varepsilon_d \sim -U$ and 0), whereas, at the valley ($\varepsilon_d \sim -U/2$), $\widetilde{T}_K$ is comparable to $T_K = \sqrt{\Gamma U/4}\exp(-\pi\varepsilon_0(\varepsilon_0 + U)/\Gamma U)$, which is typically smaller than Γ. The calculation in Figure 9 not only reproduces the experimental observation in Figure 8 but also fits almost perfectly to the conductance curves measured in the experiment of Goldhaber-Gordon et al. [97].

In Figure 7d, we have assumed nondegenerate levels in the dot, where the total spin alternates between 0 and 1/2 according to even and odd numbers of electrons. The conductance oscillations have an even–odd parity below T_K. In real dots, this assumption is not always applied, and the higher levels can affect the Kondo effect. In general, the single-particle levels can be energetically degenerate, where the total spin is not necessarily the lowest due to Hund's rule, as we have seen in the previous subsection. Theorists have investigated the effect of multilevels in a Kondo system of QDs [108, 112, 115–121]. Inoshita et al. [108] have pointed out that the Kondo temperature is significantly enhanced in a multilevel QD compared to a single-level QD. The Kondo effect has been studied at the singlet–triplet transition in Zeeman splitting [117, 119] or the orbital effect [118, 120], where the level degeneracy enhances the Kondo temperature [118, 120] and the conductance peak for a two-level system approaches $4e^2/h$ in the unitary limit [112, 120, 122]. The Kondo effect without the even–odd parity has been observed in experiments [98, 100]. Sasaki et al. [98] have used a vertical QD having tunnel barriers thinner than in the circular QD shown in the previous subsection, in order to raise the Kondo temperature. They have observed the Kondo effect caused by high-spin states in the singlet–triplet transition where two adjacent levels cross in the presence of magnetic fields.

In coupled QDs, the splitting of Kondo resonant peaks has been observed, which reflects the energy difference between the bonding and antibonding states formed by the coherent superposition of the Kondo states of each dot [101]. The Kondo physics in the coupled QDs has been extensively studied by theorists [123–127]. The Kondo effect in QDs, as compared to that in metals, has revealed many fascinating aspects by means of tunable gate voltages or magnetic fields. Recently, the Kondo effect has been found in carbon nanotubes, where the unitary limit is achieved and the Kondo resonance for even numbers of electrons has also been observed [128]. The theoretical and experimental findings reviewed in this section have clearly proven the universality of the Kondo effect. Kondo physics will continue to be an important field in materials science.

2.7. Statistics of Coulomb Blockade Peak Spacings

So far, we have focused mainly on circular QDs with neither disorder nor anisotropic boundaries, where the Coulomb peak spacings have a regular distribution. However, Coulomb oscillations in typical QDs have random spacings, which reflect unintentional irregularities caused by disorder as well as the chaotic nature of electron trajectories. In QDs having a large number of electrons, very complicated mutual interactions also causes energy levels to fluctuate

randomly. This reminds us of the level statistics in the random matrix theory (RMT) used in analysis of the spectrum of complicated nuclei or metal clusters. For a review of RMT, see ref. [129]. In mesoscopic systems, RMT has been used to examine, for example, the universal conductance fluctuations in chaotic and diffusive metals, as reviewed in ref. [130]. In general, the energy distribution in the presence of randomness tends to obey certain statistics. In this subsection, we review the level statistics in the Coulomb blockade oscillations in QDs.

Let us consider the level statistics based on the CI model described in Section 2.3. We neglect exchange terms for simplicity. Without the spin degree of freedom, the CI model gives peak spacings $\Delta\mu = E_c + \Delta\varepsilon$ with the constant charging energy E_c and the single-particle-level spacing $\Delta\varepsilon$ characterizing the distribution. If one assumes the single-particle Hamiltonian is represented by a random matrix, the level distribution $P(s)$ of $s = \Delta\varepsilon$ is described by the Wigner–Dyson distribution: $P(s) = (\pi/2)s\exp(-\pi s^2/4)$ for the Gaussian orthogonal ensemble (GOE) in the presence of time-reversal symmetry and $P(s) = (32/\pi^2)s^2\exp(-4s^2/\pi)$ for the Gaussian unitary ensemble (GUE) in the presence of magnetic fields or magnetic impurities breaking the time-reversal symmetry. The level-spacing fluctuations are given by $\delta s = (\langle s^2\rangle - \langle s\rangle^2)^{1/2} = 0.53\langle s\rangle$ for the GOE, and $\delta s = 0.42\langle s\rangle$ for the GUE. This simplest model is called the CI-plus-RMT model (CI + RMT). When the spin degree of freedom is included in the CI model, two electrons with opposite spins occupy each level, and the spacing distribution has a bimodal behavior according to $\Delta\mu = E_c + \Delta\varepsilon$ for even numbers of electrons and $\Delta\mu = E_c$ for odd numbers of electrons. This model is the CI-plus-spin-degenerate-RMT (CI + SDRMT) model.

Experiments on the level statistics in Coulomb blockade oscillations have been carried out [131–135]. Sivan et al. measured the peak distribution in disordered GaAs and In_2O_{3-x} QDs and found unimodal Gaussian distributions with width $\delta s \sim (0.1 - 0.15)e^2/C \sim (2 - 3)\langle s\rangle$ which is larger than expected from RMT. By performing an exact diagonalization of the Anderson Hamiltonian, they showed that, as the on-site Coulomb interaction increases, the distribution approaches the Gaussian with width $\delta s \sim (0.1 - 0.2)e^2/C$, which is consistent with their experimental observation. Simmel et al. [132] have obtained similar results for lateral GaAs dots. Coulomb oscillations have also been measured in Si dots formed by the modulated gate technique in the metal–oxide–semiconductor field-effect transistor (MOSFET) geometry and the distribution with $\delta s \sim 0.06e^2/C$ has been obtained [134]. Patel et al. [133] have observed hundreds of clear Coulomb peaks in lateral QDs, as shown in Figure 10a. Like other experimental observations, these peaks have unimodal distributions fitted to Gaussian curves as shown in Figure 10b. However, the width of fluctuations is estimated as $\delta s \sim 0.019e^2/C$, which is much smaller than obtained in other experiments and is rather comparable to the single-particle-level spacing. The width becomes about 15% narrower by applying magnetic fields as seen in Figure 10c. The parameters obtained in four experiments are summarized in Table 1. Interaction parameter $r_s \sim 1$, where $r_s = \sqrt{1/(\pi a_B^{*2} n_{2DEG})}$ (n_{2DEG} is the electron

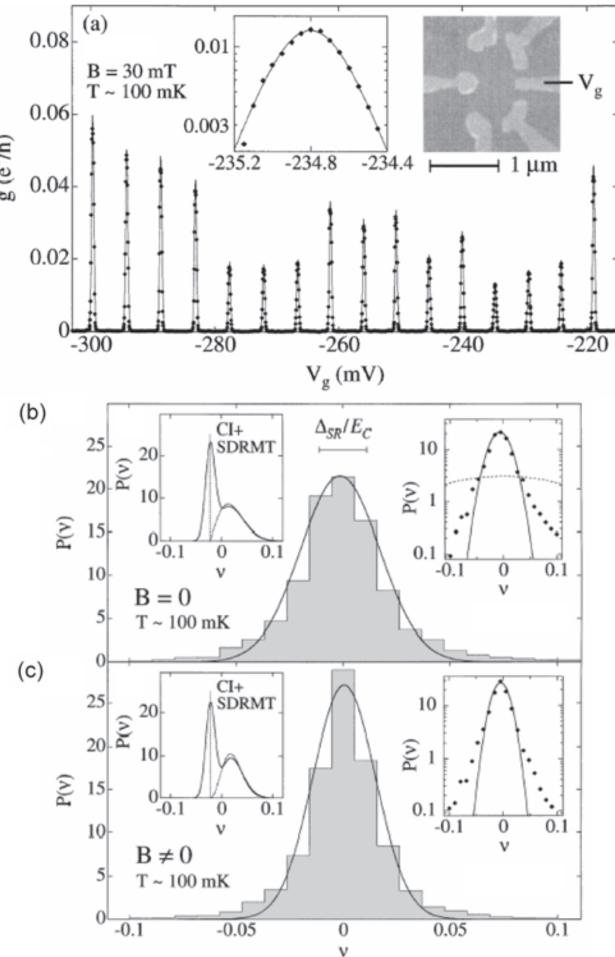

Figure 10. (a) Conductance peaks (diamonds) at $B = 30$ mT as a function of the gate voltage V_g for a lateral QD having a single-particle-level spacing of $\Delta = 14$ μV and charging energy $E_c = 460$ μV. Solid curve shows fits to a $\cosh^{-2}$ lineshape. Left inset: Detailed view of data and fit on a log-linear scale. Right inset: scanning electron microscope image of the device. (b), (c) Histograms of normalized peak spacing ν (bars) for (b) $B = 0$ and (c) $B \neq 0$ for three devices. Solid curves show fits to normalized Gaussian of width 0.019 (0.015) for $B = 0$ ($B \neq 0$). Data represent 4300 (10800) Coulomb blockade peaks with ~4300 (1600) statistically independent for $B = 0$ ($B \neq 0$). Horizontal bar indicates (spin-resolved) mean level spacing Δ_{SR}/E_c of three devices. Right inset: Plot of histogram (diamonds) and best fit Gaussian of width 0.13. Left inset: Dotted curves are CI + SDRMT peak spacing distributions; solid curves correspond to CI + SDRMT distributions convolved with Gaussian of width 0.009 averaged over three dots. density in 2D, and a_B^* is the effective Bohr radius) representing the strength of the Coulomb interaction at an average distance between the electrons relative to their kinetic energy. Besides the difference in the width of the distributions, all the experiments have shown unimodal distributions nicely fitted to Gaussian curves and no correlation between peak spacings and heights.

The experiments mentioned above have clearly indicated that the simple CI-plus-RMT model or its modified versions cannot properly describe the peak distributions. A lot

Table 1. Summary of parameters obtained in four experiments for Coulomb blockade oscillations in QDs.

	Sivan et al. [131]	Simmel et al. [132]	Patel et al. [133]	Simmel et al. [134]
Material	GaAs, In_2O_{3-x}	GaAs	GaAs	Si MOSFET

of theoretical calculations that take the electron–electron interactions into account have been performed [136–151]. Blanter et al. [136] have used a random phase approximation (RPA) to construct an effective screened Coulomb potential in finite geometries. They found that peak-spacing fluctuations are enhanced with respect to the RMT but still of the order of the mean level spacing Δ. This result cannot be directly compared with the experiments ($r_s \sim 1$), because the RPA is valid only in the high-density limit $r_s \ll 1$. A self-consistent Hartree–Fock approximation [137] has also obtained a slight enhancement $\delta s \sim 0.6\Delta$ for $r_s \lesssim 1$. Self-consistent Hartree–Fock methods have been applied in the low-density limit $r_s \gtrsim 1$ [143, 145, 146] and have shown that the peak distribution rapidly approaches Gaussian as r_s increases and its width is significantly enhanced compared to the noninteracting case. On the other hand, it has been pointed out that the effect of screened Coulomb interactions treated by the density functional theory [151] enhances the level fluctuations only slightly and the width is comparable to the single-electron-level spacing, which reproduces the experimental finding by Patel et al.

Why does the width of distributions differ in experiments? There are several possible reasons for that: First, the electrostatic coupling to external electrodes could affect the peak fluctuations. It has been pointed out on basis of a self-consistent calculations that spacings in addition spectra in QDs are reduced when QDs are coupled to the leads [78]. This indicates that we have to consider the screening effect of external electrodes to explain different experimental results. The thermal effect is also an important consideration. In the experiment of Simmel et al. [134], thermal energy was comparable to the single-particle-level spacing, where the thermal broadening reduces the peak spacings [133, 144]. Third, the dots used in the experiments are rather ballistic than diffusive, which requires an estimate of fluctuations based on correlation between wavefunctions in chaotic systems. Several calculations have shown that scars along periodic orbits can enhance peak spacing distributions [152, 153].

Recently, bimodal distribution of peak spacings has been obtained in a chaotic QD of GaAs, where interactions are weak ($r_s = 0.72$) [154]. The Coulomb blockade peaks show a pair correlation in both position and amplitude due to spin pairing. The distribution can be approximated by a modified bimodal Wignar–Dyson distribution composed of two components in the presence of spin splitting.

3. COUPLED QUANTUM DOTS (ARTIFICIAL MOLECULE)

In the previous section, we have seen that QDs act as artificial atoms and that Hund's high-spin states or Kondo resonance states, which have been observed in real atoms or metals, also emerge in the QD system in a tunable manner. In this section, we will consider two (or several) QDs coupled with each other electrostatically and/or by tunneling barriers. Such coupled QDs are called artificial molecules. When the tunneling coupling is small, the orthodox Coulomb blockade theory treated in Section 2.1 can be applied to electrostatically coupled QDs. Single-electron turnstiles [155, 156] and pumps [157, 158] in metallic dots are interesting devices having electrostatic interdot couplings. Lateral-type QDs have been the most widely used in the study of artificial molecules, in which gate voltages can tune the coupling strength between separate dots. It has been proposed that a coherently coupled QD can be used for a *qubit* (quantum bit, or two-level quantum system) in quantum computation [159]. Computation proceeds by a succession of coherent interactions between specific pairs of qubits. Quantum computation can be viewed as a coherent superposition of digital computations proceeding in parallel. This parallelism enables prime factoring, which has been viewed as intractable. Successful experimental coupling and entangling of quantum states in QD molecules has been reported [160], in which the coherent tunneling of an electron–hole pair (exciton) causes an energy splitting as a function of the separation between the dots.

3.1. Quantum Dot Molecules

In quantum dot artificial molecules, electrons can move between spatially separated dots, and electrostatic interaction strongly influences the distribution of charges. Transport spectroscopy in laterally coupled QDs has been studied in experiments [161–166] and theoretical calculations [167–171]. Waugh et al. [161] have reported on low-temperature tunneling measurements through coupled QDs by adjusting interdot coupling tuned by gates. When the tunneling coupling is small, the Coulomb blockade oscillations have the same peak spacing as in a single QD. As the conductance through the tunneling barrier increases, the conductance peaks split. When the tunnel conductance approaches e^2/h, the peak spacing is half as large as for a single QD, indicating that the two QDs have combined into a single

large QD with twice the gate capacitance. Similar peak splittings have been observed in vertically coupled QDs [166, 172, 173], which are separated by a thin barrier. The strength of coupling varies inversely with the barrier thickness and height, preserving the circular symmetry. By applying magnetic fields perpendicularly to the pillar in vertical QDs, the coupling strength can be modulated [174].

Multiple QDs can also be coupled by coherent tunneling. Coherent tunneling between coupled QDs has been experimentally observed [164, 173, 175–178], and many theories have investigated the coherent properties in coupled QDs [14, 17, 30, 179–197]. When the barrier thickness (or barrier height) is small and the coupling is strong, the QD molecule is regarded as a single QD; the shell structure and Hund's state have been observed in addition spectra of vertical double-dot systems with circular symmetry [172], which are in qualitative agreement with Hartree–Fock calculations [14]. Weak coherent coupling between two QDs recombines states into bonding and antibonding states, resulting in peak splitting of Coulomb oscillations.

Magnetic field effects have been observed in vertically coupled QDs [166, 198]. It has been found that the stability of the spin-polarized maximum-density droplet is considerably reduced compared to the single-dot system. Weak tunneling coupling splits the lowest Landau levels into bonding and antibonding levels, which are occupied by spin-polarized electrons in strong magnetic fields. The bonding (antibonding) state can be represented as a pseudospin-up (-down) state [199, 200]. This pseudospin (or isospin) representation has been used to describe double-layer systems in the quantum Hall regime under strong magnetic fields [201]. In this representation, a pair of electrons occupying the bonding and antibonding levels has zero pseudospin. As the magnetic field is increased further, electrons in the outer pseudospin-down orbital move to the pseudospin-up orbital one by one to relax Coulomb repulsion in strong magnetic confinement. This phenomenon is called the pseudospin-flip effect. An experimental attempt to observe this effect in vertical QDs has been made [166]. In QD molecules, the spin-blockade effect [188, 189, 191, 202] and pseudospin-blockade effect [195] have been discussed theoretically.

3.2. Electron Correlation in the Two-Site Hubbard Model

We have seen that a single-particle model, such as the CIE model or Hartree–Fock approximation, works very well in describing the addition spectra of single QDs having multilevels. When multiple QDs are coupled and electrons can move between spatially separated QDs, the electrons tend to avoid each other spatially and correlation effects become important. To examine this effect, let us consider a two-site Hubbard model where two electrons occupy one of two sites. Each site has a single-particle level $\varepsilon = 0$ and on-site Coulomb repulsion U. The transfer integral between two sites is given by t ($t > 0$) and the Hubbard Hamiltonian by $\mathscr{H} = -t\sum_\sigma (c^+_{1\sigma}c_{2\sigma} + c^+_{2\sigma}c_{1\sigma}) + U(n_{1\uparrow}n_{1\downarrow} + n_{2\uparrow}n_{2\downarrow})$. The possible six states for two electrons are expressed by $|\uparrow,\uparrow\rangle = c^+_{1\uparrow}c^+_{2\uparrow}|0\rangle$, $|\downarrow,\downarrow\rangle = c^+_{1\downarrow}c^+_{2\downarrow}|0\rangle$, $|\uparrow,\downarrow\rangle = c^+_{1\uparrow}c^+_{2\downarrow}|0\rangle$, $|\downarrow,\uparrow\rangle = c^+_{1\downarrow}c^+_{2\uparrow}|0\rangle$, $|\uparrow\downarrow,0\rangle = c^+_{1\uparrow}c^+_{1\downarrow}|0\rangle$, $|0,\uparrow\downarrow\rangle = c^+_{2\uparrow}c^+_{2\downarrow}|0\rangle$. It is easy to verify that the nonbonding states $|\uparrow,\uparrow\rangle$, $|\downarrow,\downarrow\rangle$ are eigenstates with eigenenergy $E = 0$ and total spin $S = 1$. The Hamiltonian on the basis of the remaining four states is given in the matrix form by

$$\begin{array}{c} \quad |\uparrow,\downarrow\rangle \ |\downarrow,\uparrow\rangle \ |\uparrow\downarrow,0\rangle \ |0,\uparrow\downarrow\rangle \\ \mathscr{H} = \begin{bmatrix} 0 & 0 & -t & -t \\ 0 & 0 & t & t \\ -t & t & U & 0 \\ -t & t & 0 & U \end{bmatrix} \begin{array}{l} \langle\uparrow,\downarrow| \\ \langle\downarrow,\uparrow| \\ \langle\uparrow\downarrow,0| \\ \langle 0,\uparrow\downarrow| \end{array} \end{array} \tag{24}$$

Diagonalizing this Hamiltonian, we obtain four solutions comprising eigenenergy, eigenstate, and total spin given by

$$\begin{array}{lll} E_{\rm GS} = \frac{U-\sqrt{U^2+16t^2}}{2} & \phi_{\rm GS} = \frac{1}{\sqrt{1+\alpha^2}}(\phi_{\rm covalent} + \alpha\phi_{\rm ionic}) & S=0 \\ E_1 = 0 & \phi_1 = \frac{1}{\sqrt{2}}(c^+_{1\uparrow}c^+_{2\downarrow} + c^+_{1\downarrow}c^+_{2\uparrow})|0\rangle & S=1 \\ E_2 = U & \phi_2 = \frac{1}{\sqrt{2}}(c^+_{1\uparrow}c^+_{1\downarrow} - c^+_{2\uparrow}c^+_{2\downarrow})|0\rangle & S=0 \\ E_3 = \frac{U+\sqrt{U^2+16t^2}}{2} & \phi_3 = \frac{1}{\sqrt{1+\alpha^2}}(\phi_{\rm covalent} - \alpha\phi_{\rm ionic}) & S=0 \end{array} \tag{25}$$

Here, $\alpha = (-U + \sqrt{U^2+16t^2})/4t$, the covalent state $\phi_{\rm covalent} = (c^+_{1\uparrow}c^+_{2\downarrow} + c^+_{2\uparrow}c^+_{1\downarrow})|0\rangle/\sqrt{2}$, and the ionic state $\phi_{\rm ionic} = (c^+_{1\uparrow}c^+_{1\downarrow} + c^+_{2\uparrow}c^+_{2\downarrow})|0\rangle/\sqrt{2}$. The $\phi_{\rm covalent}$ is also called the Heitler–London orbital. The ground-state wavefunctions and energies for $U/t > 0$ are denoted by $\phi_{\rm GS}, E_{\rm GS}$, and for the nth excited state by ϕ_n, E_n. The first excited state ϕ_1 is one of three nonbonding states with $E = 0$ and $S = 1$ having z-component of the spin $S_z = 0$. The parameter α represents the proportion of the ionic state with respect to the covalent state. For $U/t = 0, \alpha = 1$ and the covalent and ionic states contribute equally to the ground state. For $U/t \gg 1$, $\alpha \simeq 2t/U \ll 1$ and the proportion of the ionic state decreases with increasing Coulomb repulsion, which raises the total energy of the two electrons occupying the same site. The total energy of the ground state for $U/t \gg 1$ is given by $E_{\rm GS} \simeq -4t^2/U$. This dependence can also be deduced by performing a perturbation expansion with respect to t when $U \gg t$. In the unperturbed state for t=0, each site has one electron. When we turn on small $t > 0$ between two sites, the electron on one site can move to the other and go back when two electrons have opposite spins. This second-order process gives an energy decrease of about $-t^2/U$. This effective interaction is called kinetic exchange interaction. The nonbonding states $|\uparrow,\uparrow\rangle$, $|\downarrow,\downarrow\rangle$, $(|\uparrow,\downarrow\rangle + |\downarrow,\uparrow\rangle)/\sqrt{2}$ at $E = 0$ are equivalent to the state of two uncoupled sites, each having one electron with the same spin because, by the Pauli principle, an electron on one site cannot transfer to the other. As a result, the energy is independent of t and U.

The ground state properties of the two-site Hubbard model cannot be explained by a Hartree–Fock (HF) approximation. The thermal average of the number of electrons for this system is given by $\langle n_{i\sigma}\rangle = n/2$, where n is the average number of electrons per site. The HF approximation gives $\langle n_{i\uparrow}n_{i\downarrow}\rangle \to \langle n_{i\uparrow}\rangle\langle n_{i\downarrow}\rangle = n^2/4$, so that the Coulomb term $Un^2/2 = U/2$ is independent of t. The ground state is given by the bonding state filled by up- and down-spin electrons; that is, $\frac{1}{\sqrt{2}}(\phi_{\rm covalent} + \phi_{\rm ionic})$. This state corresponds to the weak interaction limit ($U = 0$ or $\alpha = 1$) in the exact ground state. The mean-field approximation fails to include

the correlation effect between electrons with opposite spin. This simple example clearly shows the essential role of correlation effects in coupled QDs, as will be discussed in the following section.

3.3. Ferromagnetic State in Quantum Dot Molecules

To see that electron correlations and magnetic properties are closely related, we consider two types of simple QD molecules, which we will call a Lieb molecule (Fig. 11a) and a triangular molecule (Fig. 11b). Omitting the Coulomb repulsion ($U = 0$) in the Hubbard model, we obtain the single-particle Hamiltonian

$$\begin{bmatrix} 0 & -t & -t & -t \\ -t & 0 & 0 & 0 \\ -t & 0 & 0 & 0 \\ -t & 0 & 0 & 0 \end{bmatrix} \mathbf{c} = E\mathbf{c} \quad \text{(Lieb molecule)} \tag{26}$$

$$\begin{bmatrix} 0 & -t & -t \\ -t & 0 & -t \\ -t & -t & 0 \end{bmatrix} \mathbf{c} = E\mathbf{c} \quad \text{(triangular molecule)} \tag{27}$$

It can be easily verified by substitution that the eigenvalues and eigenstates are given by $E = 0, 0, \pm\sqrt{3}t$, $\mathbf{c} = (0, 1, 0, -1)$, $(0, 0, 1, -1)$, $(\pm\sqrt{3}, 1, 1, 1)$ for the Lieb molecule and $E = -2t, t, t$, $\mathbf{c} = (1, 1, 1), (1, -1, 0)$, $(1, 0, -1)$ for the triangular molecule. The second and third lowest levels are doubly degenerate and $N = 4$ corresponds to half filling of these degenerate levels. Let four electrons interact with each other by the on-site Coulomb repulsion in these molecules. Diagonalizing the Hubbard Hamiltonian numerically, the ground states in both molecules have $S = 1$ high spin. Figure 12 plots the energy difference $\Delta E = E(S = 0) - E(S = 1)$ between the ground state ($S = 1$) and the first excited state ($S = 0$) as a function of U/t. This energy difference represents the effective exchange energy between electrons in the degenerate levels. For $U/t \lesssim 1$, $\Delta E \propto U$ in both types of molecules, because, from the Pauli principle, the on-site Coulomb repulsion between electrons in the low-spin state $S = 0$ raises the energy of order U, whereas it does not for the high-spin state $S = 1$. For $U/t \gg 1$, the energy difference behaves as $\Delta E \sim t^2/U$ for the Lieb molecule, and $\Delta E \sim t$ for the triangular molecule. The mechanism of this dependence is schematically shown in Figure 13. The effective interaction for the Lieb molecule is the antiferromagnetic kinetic exchange interaction, and the spins on the center site and on the end sites are in the opposite direction, which leads to the net spin of $S = 1$. On the other hand, the high spin in the triangular molecule is caused by a ferromagnetic ring exchange interaction of third order. In this process two electrons with the opposite spins cycle within the triangular sites, which gives an energy loss of order t and favors a parallel spin [203].

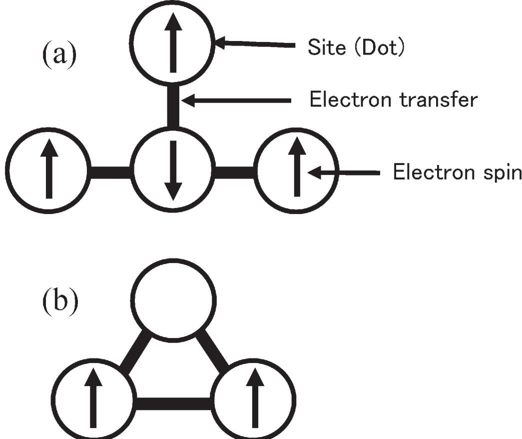

Figure 11. Schematics of quantum dot molecules. (a) A Lieb molecule and (b) a triangular molecule.

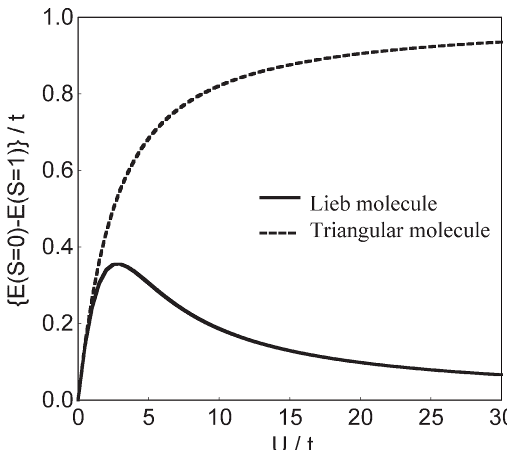

Figure 12. Calculated energy difference between the lowest excited state with spin $S = 0$ and the ground state with spin $S = 1$. Solid (dashed) line represents the Lieb (triangular) molecule.

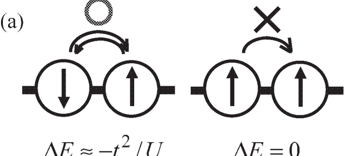

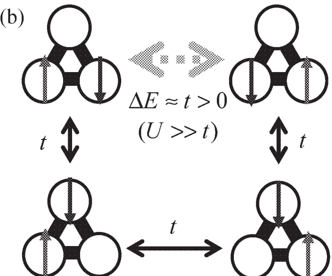

Figure 13. Effective exchange interaction for $U \gg t$. (a) Antiferromagnetic exchange interaction based on the second-order process of two electrons with opposite spins moving back and forth between two sites. (b) Ferromagnetic interaction based on the third-order process of two electrons cycling in triangular sites. When two electrons have opposite spins, this process raises their energy of order t, whereas it does not do so for two electrons with the same spin.

3.4. Magnetic Field Effect in Quantum Dot Molecules

In real molecules, the interatom distance a is very small and an extremely high magnetic field is necessary to induce magnetic field effects. In QD molecules, the magnitude of magnetic fields necessary to observe such effects is quite reasonable, because the interdot distance is typically $a = 10–1000$ nm. For example, one flux quantum h/e threading inside the triangular area $S = \sqrt{3}a^2/4$ in Figure 11b of $a = 10$ Å (100 nm) corresponds to $B \approx 10000$ T (1 T). Let us see what happens in the triangular QD molecule when it is threaded by an Aharonov–Bohm magnetic flux $\phi = BS/(h/e)$ in the triangle. The magnetic flux changes the phase of the transfer integrals as shown in Figure 14a. For $U = 0$, the tight-binding Hamiltonian is given by

$$\begin{bmatrix} 0 & -te^{\pi i\phi} & -t \\ -te^{-\pi i\phi} & 0 & -te^{\pi i\phi} \\ -t & -te^{-\pi i\phi} & 0 \end{bmatrix} \mathbf{c} = E\mathbf{c} \tag{28}$$

By solving this equation, the single-particle levels are given by $E = -2t\cos(2\pi\phi/3), 2t\cos\{2\pi(\phi \pm 1)/3\}$, where the doubly degenerate levels $E = t$ for $\phi = 0$ are lifted for $\phi > 0$. By taking into account the on-site Coulomb repulsion U and solving the Hubbard model for this molecule, we can show that the magnetic field induces a singlet–triplet transition for $N = 4$, as depicted in Figure 14b. The applied magnetic field splits the degenerate levels and the high-spin state is broken when the level splitting exceeds the exchange energy.

Magnetic field effects in several types of QD molecules have been discussed in refs. [185, 190, 204]. Yu et al. [185] used an extended Hubbard model to calculate addition spectra of linear chains and ring-shaped arrays of QDs and showed the doubly degenerate peak is split by the Aharonov–Bohm magnetic flux threaded inside the ring. Stafford et al. [190] discussed coherent resonant tunneling through a linear array of QDs in inhomogeneous magnetic fields and found a giant magnetoresistance caused by magnetic disorder. Kolehmainen et al. [204] employed the current spin-density-functional theory and discussed spin ordering in coupled QDs. They showed that four coupled dots with 40 electrons in a square or row have a ferromagnetic ground state.

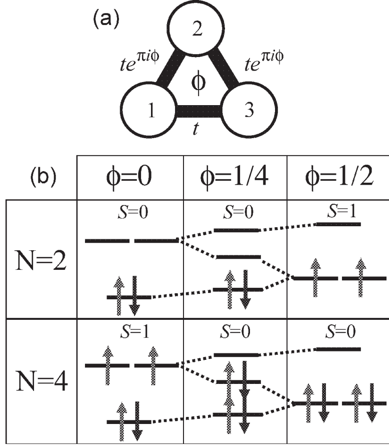

Figure 14. Magnetic field effect in triangular molecules. (a) ϕ is the magnetic flux threading the triangular area. (b) Schematic of energy levels as a function of the magnetic flux for $N = 2$ and 4. Applied magnetic flux lifts the degenerate levels, resulting in a spin-singlet–triplet transition.

4. QUANTUM DOT ARRAYS

In this section, we review the study of arrays of quantum dots. Here, we consider two types of dot arrays. One is an array of electrostatically coupled dots, where electron tunneling between dots occurs incoherently. This type of dot array is represented by a quantum dot cellular automaton. This device implementing Boolean logic functions can process and carry analog information. The other type of array is represented by a periodic lattice of dots in which coherent coupling between dots makes a band structure in the energy spectrum of electrons. This type is called a quantum dot superlattice. A wide range of lattice patterns is possible with tunable carrier concentration and coupling strength between dots. This enables us to achieve various correlation effects, such as ferromagnetism, in semiconducting nanomaterials.

4.1. Quantum Dot Cellular Automaton

Lent et al. have proposed a new device called a quantum dot cellular automaton (QCA) [205–209]. The QCA device consists of arrays of electrostatically coupled cells, each containing several coupled QDs. The electrons can tunnel between dots in the same cell but not between different cells. A basic cell consists of four dots in a square and is charged with two excess electrons. Coulomb repulsion makes these electrons arrange in one of two diagonal opposite positions, representing a binary logic state, 0 or 1. Long-range electrostatic Coulomb interaction provides an intercellular coupling between different cells. The overall state of the QCA device is determined by the boundary condition on edge cells, which act as the input channels. The QCA scheme can implement Boolean logic functions and perform general computational tasks [208]. When coupled cells interact with neighbors within a certain range, they can be viewed as an analog nonlinear (or neural) network [210].

Although the idea of QCAs seemed quite concrete and attractive, some of the proposals have been criticized by Bandyopadhyay [211–213] and Landauer [214]. Bandyopadhyay [213] argued that logic signals in the QCA device cannot propagate unidirectionally from the input to the output channel and the input bit cannot uniquely determine the output bit. To overcome this problem, Bandyopadhyay proposed an alternative type of logic architecture based on single-electron spin effects in QDs [213].

Experimental realization of QCA devices has been reported [215–222]. Orlov et al. [215] built a basic cell of QCAs consisting four metallic dots in Al/AlO_x/Al tunnel junctions and successfully achieved the polarization of two electrons by controlling an external gate voltage. Amlani et al. [220] demonstrated QCA majority gate operations in metallic QDs, where the inputs are driven by biased external electrodes and the output is detected by two single-dot electrometers.

In these devices, the polarization of bit cells is retained by the biased input electrodes and the electrostatic forces of neighboring cells. When the input polarization is switched, unidirectionality prevents the signal propagation. Lent et al. [223, 224] proposed a new type of QCAs which ensures unidirectionality. In the basic cell, three QDs are connected in series, where the middle dot acts as an interdot barrier between the top and bottom dots. By lowering or raising the bias to the middle dot, the tunneling between the two dots is allowed or suppressed. Whether the electron moves to the top or bottom dot depends on the input signal. Once the polarization is determined, it is retained (latched) after the input bias is removed. Orlov et al. [225, 226] experimentally demonstrated the clocked switching of a single electron in this type of QCA (see Fig. 15). They formed a QCA half-cell consisting of two QDs with an extra dot between them (Fig. 15a and b). Each dot of the device is capacitively coupled to a corresponding gate electrode (Fig. 15c), and the input signal is applied to the top and bottom gates. As demonstrated in Figures 15d–f, the clocking bias drives the charge state of the QCA half-cell. Although the clocked type of QCA can retain bit information much better than the original QCA scheme, a drawback arises in constructing the logic design: the number of clocked gates must increase with the number of cells, which may restrict scalability of the QCA logic architecture.

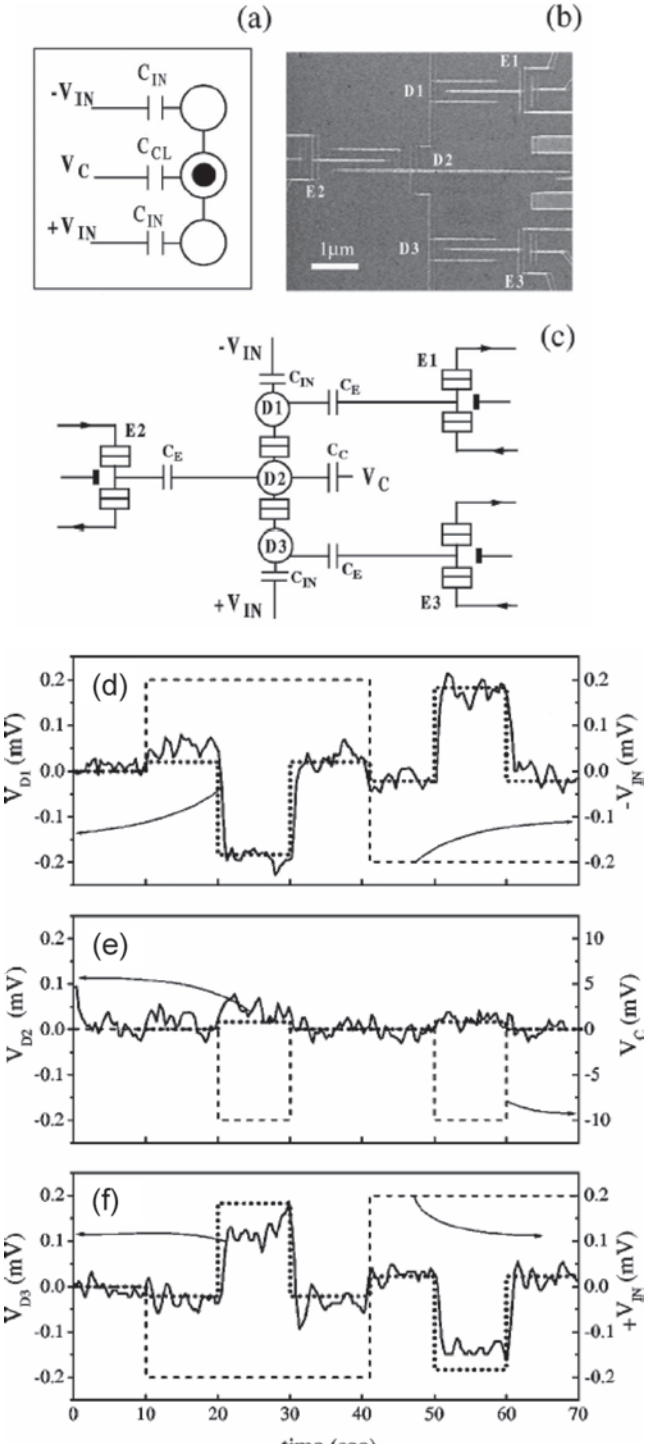

Figure 15. (a) Schematic of a QCA half cell. (b) Scanning electron microscopy image of the device utilizing $Al/AlO_x/Al$ tunnel junctions. (c) Schematic diagram of the experimental circuit. A single electron moves between the top (D1) and the bottom (D3) quantum dots through the middle dot (D2), which acts as a barrier and locks the electron in either D1 or D3 when it is biased. (d)–(f) Measured (solid lines) and calculated (dotted lines) responses to the input and clocking signals together with applied input signals (dashed lines) of the top (d), middle (e), and bottom (f) dot. 4.2. Quantum Dot Superlattices

Here, we focus on another type of QD array in which the coherent coupling between QDs forms a band structure in the energy spectrum. Kouwenhoven et al. studied the magnetotransport properties of an artificial one-dimensional (1D) crystal of 15 QDs defined in the 2DEG of GaAs/AlGaAs heterostructures by means of a split-gate technique [227]. They observed large oscillations with two deep dips enclosing 15 small oscillations. They argued that the larger oscillations correspond to large energy gaps of the 1D crystal of QDs and the smaller ones to the discrete levels in the miniband. Haug et al. [228] built linear chains of QDs consisting of one to four dots. Transport measurements of these devices show sharp resonant conductance peaks around threshold, which are attributed to the Coulomb charging and quantum confinement effects.

Phase transition [229–235], correlated electron transport [184, 190, 236–238], and addition spectra [185, 229, 239] in linear chains of coupled QDs have been theoretically studied. Stafford and Das Sarma [181] studied the addition spectra in a 1D array of QDs and obtained quantum phase transitions, such as the Mott–Hubbard metal–insulator transition. Ugajin [230–232] predicted a Mott–Hubbard metal–insulator transition driven by an external electric field. This effect provides a method of modulating collective excitations locally and can be applied to new field-effect devices.

Engineering of electronic and magnetic properties of a lattice of QDs has also been investigated [240–247]. Sugimura [240] theoretically proposed the possibility of magnetic ordered states in a semiconductor quantum dot array. Describing the GaAs/AlGaAs QD system by the one-band Hubbard model, he showed that magnetic orderings, such as ferromagnetism and antiferromagnetism, can be expected in

QD arrays. Khurgin et al. showed that exchange interactions between holes confined in arrays of strained $In_{1-x}Ga_xAs$ QDs (see Fig. 16) can lead to *ferrimagnetic* arrangement of magnetic moments. The ferrimagnetism is induced by coupling two neighboring QDs having different values of orbital angular momenta. The Curie temperature for QDs with thickness of $t_1 = 7$ nm and $t_2 = 3$ nm is of the order of 25 K (see Fig. 16d). Khurgin et al. also proposed a method of engineering ferroelectric arrays of coupled strained QDs [242].

Lattice structure and carrier concentration are essential factors determining the electronic and magnetic properties in solids. Carrier concentration in solids can be controlled by chemical or gate-induced doping [248, 249]. On the other hand, building a desired lattice of atoms is very hard, because the lattice structure is strictly determined by the atomic nature of constituent elements. The design of materials with desired lattice is possible by putting QD atoms on the lattice points and coupling the QDs with each other to form artificial crystals called quantum dot superlattices (QDSLs). Semiconductor fabrication technology enables us to form QDSLs in various patterns as we wish, including lattices not existing in nature. The electron concentration can be tuned by the gate voltages. Therefore, QDSLs are suitable for achieving various interesting effects, such as flat-band ferromagnetism [244–247], which have been considered unlikely to occur in semiconductors.

4.3. Flat-Band Ferromagnetism

It has been proved that the Hubbard model on specific types of lattice having a flat band exhibits ferromagnetism in the presence of on-site Coulomb interaction [203, 250–255]. The flat band is a dispersionless subband in the single-particle band structure. Figure 17 shows two examples of lattices having flat bands, where (a) is a Lieb lattice and (b) is a Kagome lattice. The Hubbard Hamiltonian for these lattices is

$$H = -t \sum_{(i,j)\sigma} c^{+}_{i\sigma} c_{j\sigma} - t' \sum_{\langle i,k\rangle\sigma} c^{+}_{i\sigma} c_{k\sigma} + U \sum_{i} n_{i\uparrow} n_{i\downarrow} \tag{29}$$

where t (t') is the transfer integral between the (next) nearest neighbor sites (i, j) ($\langle i, k\rangle$), U is the on-site Coulomb energy, $c^{+}_{i\sigma}(c_{i\sigma})$ is the creation (annihilation) operator of an electron with spin $\sigma = \uparrow$ or $\downarrow$ on site i, and $n_\sigma = c^{+}_{i\sigma} c_{i\sigma}$. The single-particle band diagrams calculated for $t' = U = 0$ are shown in Figure 18, where flat subbands can be seen. In the presence of on-site Coulomb repulsion, it has been mathematically proven that the Hubbard model exhibits flat-band ferromagnetism on the Lieb [250] and Kagome lattice [251] at zero temperatures. The mechanism of ferromagnetism in these lattices has already been explained in Figure 13. In the bipartite Lieb lattice, kinetic exchange interactions make the neighboring spins align in opposite directions (see Fig. 13a) and the different numbers of up- and down-spins result in *ferri*magnetism. The ferromagnetism in the Kagome lattice is caused by a ring exchange interaction of the third-order process cycling two electrons with the opposite spins within the triangular lattice of three sites (see Fig. 13b). When the next nearest neighbor transfer t' is included, the flat band is broken as shown in Figure 18. It is very important to know how t' affects the flat-band ferromagnetism, because the next nearest neighbor transfer t' is not negligible in QDSLs [247]. To include the effect of t', we consider a realistic potential in QDSL. The transfer and on-site Coulomb energies for QDSL are evaluated by assuming that electrons are

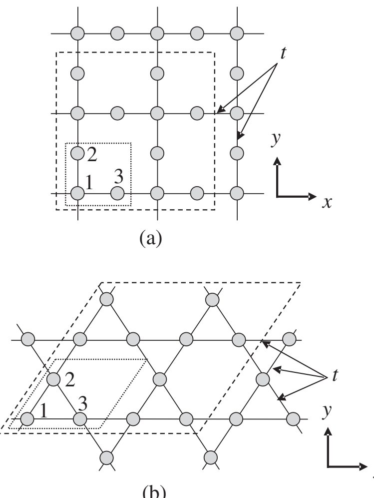

Figure 17. The Lieb lattice (a) and Kagome lattice (b). Solid lines represent the nearest neighbor transfer t. Dotted and dashed lines indicate one and 2×2 unit cell(s). A unit cell contains three sites $i = 1, 2, 3$.

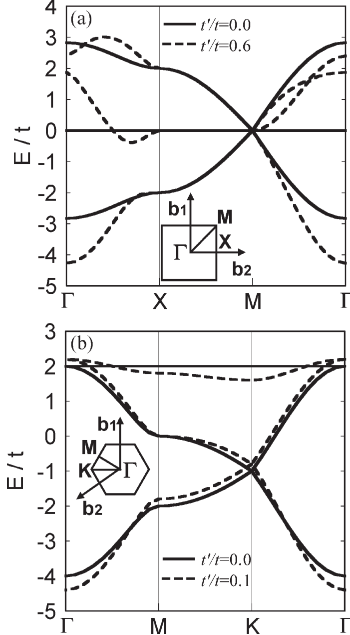

Figure 18. Single-particle band energy E for the (a) Lieb lattice and (b) Kagome lattice for the next nearest neighbor transfer $t' = 0$ (solid line) and $t' > 0$ (dashed line) calculated using the tight-binding approximation, where E and t' are normalized in units of the nearest neighbor transfer t. Insets: Brillouin zone. $\mathbf{b}_1$ and $\mathbf{b}_2$ are the reciprocal lattice vectors. Reprinted with permission from [247], H. Tamura et al., *Phys. Rev. B* 65, 085324 (2002). ©2002, American Physical Society.

confined in a two-dimensional potential [256] given by

$$V(\mathbf{r}) = \sum_i v(\mathbf{r} - \mathbf{R}_i),$$

$$v(\mathbf{r}) = \begin{cases} -\dfrac{1}{16} m^* \omega^2 a^2 [\cos(\pi x/a)\cos(\pi y/a)]^2 \\ \qquad \text{for } r < a/2 \\ 0 \qquad \text{for } r \geq a/2 \end{cases} \tag{30}$$

where m^* is the effective mass of an electron, ω is the confining oscillator frequency, $\mathbf{R}_i$ is the position of the ith dot, and a is the interdot distance. Noting that $[\cos(\pi x/a)\cos(\pi y/a)]^2 \simeq [(2r/a)^2 - 1]^2 \simeq 1 - 2(2r/a)^2$ for $r \ll a/2$, the "atomic" wave function localized in the potential $v(\mathbf{r})$ is given in a good approximation by

$$\phi(\mathbf{r}) = \frac{2}{\sqrt{\pi} d} \exp\left(-\frac{2r^2}{d^2}\right), \tag{31}$$

where $d = 2\sqrt{\hbar/m^*\omega}$ is the dot diameter.

The transfer and on-site Coulomb energies are given by

$$t(\mathbf{R}_i, \mathbf{R}_j) = -\int d\mathbf{r}\, \phi(\mathbf{r} - \mathbf{R}_i)\{-\hbar^2\nabla^2/2m^* + V(\mathbf{r})\} \cdot \phi(\mathbf{r} - \mathbf{R}_j) \tag{32}$$

$$U = \iint d\mathbf{r}_1\, d\mathbf{r}_2 \frac{e^2 |\phi(\mathbf{r}_1)|^2 |\phi(\mathbf{r}_2)|^2}{4\pi\varepsilon |\mathbf{r}_1 - \mathbf{r}_2|} = \frac{\sqrt{2\pi} e^2}{4\pi\varepsilon d} \tag{33}$$

where ε is the dielectric constant. Here, the nearest neighbor transfer t is calculated for $\mathbf{R}_i = (0, 0)$ and $\mathbf{R}_j = (a, 0)$ and the next nearest neighbor transfer t' for $\mathbf{R}_i = (a, 0)$ and $\mathbf{R}_j = (0, a)$ in the Lieb lattice and for $\mathbf{R}_i = (a, 0)$ and $\mathbf{R}_j = (a/2, \sqrt{3}a/2)$ in the Kagome lattice. For $d/a \lesssim 0.5$, t' is much smaller than t and negligible.

An exact diagonalization of the Hubbard Hamiltonian of 2×2 unit cells has been done using Eqs. (32) and (33) [247]. In realistic dot arrays formed by a negatively biased gate-electrode depleting the underneath 2DEG, the interdot distance is usually fixed and cannot be changed. By modifying the gate voltage, the dot diameter can be changed. To simulate this, we evaluate t, t', and U from Eqs. (32) and (33) for a fixed interdot distance and diagonalize the Hubbard Hamiltonian in Eq. (29) for a half filled flat band. Figure 19 plots the energy difference $\Delta E = E(S = 0) - E(S = 2)$ between the ground state with $S = 2$ and the lowest excited state with $S = 0$ as a function of dot diameter. This energy difference can be regarded as a qualitative estimate of the transition temperature of ferromagnetic and paramagnetic transition in a macroscopic sample. ΔE takes a peak around $d/a = 0.5 - 0.6$, where the effect of t' is negligible and ΔE is not affected by t'. Table 2 lists estimated ΔE's in units

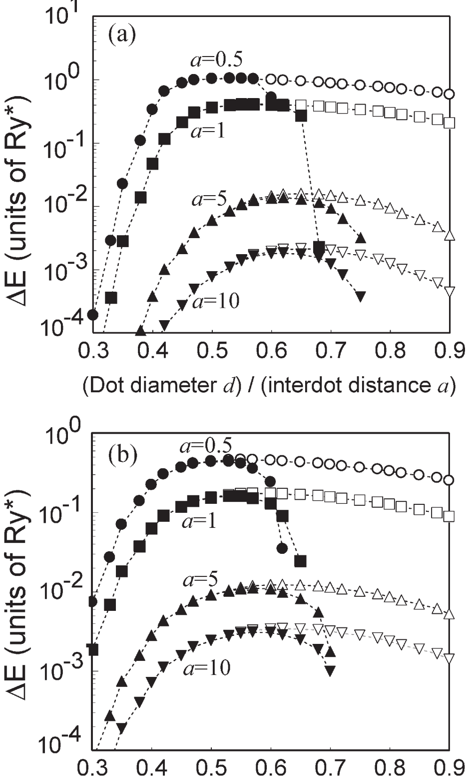

Figure 19. Energy difference $\Delta E = E(S = 0) - E(S = 2)$ as a function of dot diameter d for the (a) Lieb and (b) Kagome lattices for different interdot distances a in the dot model given in Eq. (30) represented by solid symbols. Open symbols represent the energy difference when we neglect the next nearest neighbor transfer t'. Energy and length are scaled in units of the effective Rydberg constant $Ry^* = 13.6\ \text{eV} \times (m^*/m_0)/(\varepsilon/\varepsilon_0)^2$ and the effective Bohr radius $a_B^* = 0.53\ \text{Å} \times (\varepsilon/\varepsilon_0)/(m^*/m_0)$, where m_0 and ε_0 are the mass of a bare electron and the dielectric constant in vacuum respectively. Reprinted with permission from [247], H. Tamura et al., *Phys. Rev. B* 65, 085324 (2002). ©2002, American Physical Society.

Table 2. Estimated energy difference $\Delta E = E(S=0) - E(S=2)$ (Kelvin) between the ground state with spin 2 and the lowest excited state with spin 0 for dot arrays of the kagome lattice of typical interdot distance $a = 5$, 10, 50, 100 nm and dot diameter $a/2$.

	ΔE (Kelvin) for Lieb Lattice				ΔE (Kelvin) for Kagome Lattice			
Distance	5 nm	10 nm	50 nm	100 nm	5 nm	10 nm	50 nm	100 nm
GaAs	76	26	0.5	0.06	31	11	0.6	0.2
InAs	90	43	3.5	0.6	45	19	1.7	0.5
Si	27	4.5	0.04	0.005	15	4.3	0.2	0.05

Note: We consider GaAs dots ($m^*/m_0 = 0.067$, $\varepsilon/\varepsilon_0 = 12.4$, $Ry^* = 6$ meV, $a_B^* = 10$ nm), InAs dots ($m^*/m_0 = 0.02$, $\varepsilon/\varepsilon_0 = 12.4$, $Ry^* = 1.8$ meV, $a_B^* = 34$ nm), and Si dots ($m^*/m_0 = 0.2$, $\varepsilon/\varepsilon_0 = 12$, $Ry^* = 19$ meV, $a_B^* = 3$ nm). *Source:* Reprinted with permission from [247], H. Tamura et al., *Phys. Rev. B* 65, 085324 (2002). © 2002, American Physical Society.

of Kelvin for dot arrays of various sizes and materials. We consider GaAs, InAs, and Si dots and assume $a = 2d$. For dots with a distance of 100 nm which is available within the present fabrication technology, ΔE is of the order of several hundreds milli-Kelvin and we can expect that ferromagnetism can be observed in the low temperature region. For dots of distance 5 nm, ΔE is as high as a few ten Kelvin.

Ideas for achieving flat-band ferromagnetism based on carbon networks [257, 258], graphite ribbons [259, 260], and Ga and As atomic wires [261, 262] have also been proposed. However, there has been no clear evidence for flat-band ferromagnetism in these materials. This is supposedly due to lattice distortion effects that would destabilize the ferromagnetism when the flat band is half filled [263]. In real materials, the number of valence electrons is determined in such a way that the crystal structure is stable. It follows then that unrestricted material design is difficult in general. The QDSL does not have such disadvantages and is suitable for achieving the flat-band ferromagnetism with tunable parameters.

One may think that a finite magnetization could not appear at finite temperatures in two dimensions because of the absence of long-range order described in the Mermin–Wagner theorem [264]. However, it should be noted that this theorem is applied in the thermodynamic limit. When a sample has a finite size smaller than the spin–spin correlation length, a finite magnetization can appear [247].

4.4. Quantum Wire Geometry for QDSLs

We discuss another implementation of the QDSL system. Schedelbeck et al. [265] have fabricated coupled QDs, each of which is formed in the intersection of three quantum wells, by using cleaved edge overgrowth [266] and demonstrated a coherent peak-splitting between the bonding and antibonding states in the photoluminescence spectrum. The area at the intersection is larger than the normal width of the wire, and the potential energy at each intersection in which a QD is formed becomes lower. In a similar way, an array of QDs is formed at the intersections in a network of quantum wires. Such a network geometry has been fabricated in GaAs wires by selective area growth techniques [267–270] and in Si wires by combining nanolithography and nanoetching techniques [271]. In the latter case, the widths of the Si quantum wires are less than 10 nm, which would provide much smaller QDs at intersections.

Recently, a QDSL implemented in a two-dimensional Kagome quantum wire network has been suggested and the possibility of flat-band ferromagnetism has been discussed [245]. InAs quantum wires are surrounded by $In_{0.72}Ga_{0.28}As$ barriers with a band offset of 0.21 eV, as schematically shown in Figure 20. The electronic band structure was calculated using first-principles calculations based on a local density functional as shown in Figure 21a, which is very similar to the band diagram calculated by the tight-binding approximation in Figure 18b. At 5/3 filling where the flat band is half filled, the charge density is well localized at the intersections of wires which form the Kagome lattice as seen in Figure 21b. A local spin-density-functional calculation reveals the ferromagnetic spin density at the intersections, as shown in Figure 22. This ferromagnetism can be turned off by changing the filling from 5/3 to 6/3 (or to 4/3). This wire network geometry is suitable for achieving strong potential modulations needed for creation of an effective Hubbard system in the QDSL.

4.5. Magnetic Field Effects in QDSLs

In Section 3.4, we explained that transfer integrals acquire the Peierls phase factor in magnetic fields, which splits degenerate levels in the triangular QD molecule. Magnetic fields significantly affect the band structure in QDSLs as well. The energy spectrum of the tight-binding model in magnetic fields has a self-similar (fractal) structure called the Hofstadter butterfly [272], which is obtained by solving the Harper equation [273]. Figure 23 shows the Hofstadter butterfly for the square lattice [274]. The Hofstadter butterfly of other lattices having a flat band has been studied

in ref. [275]. It is well known that the Hall conductance is in integer multiples of e^2/h when the Fermi level lies in a gap of the butterfly spectrum [276]. In Figure 23, the quantized values of the lowest Landau level are indicated in units of e^2/h. Experimental attempts have been done over the last couple of decades to find signatures of the Hofstadter butterfly [277–280]. Albrecht et al. [280] measured the quantized Hall effect of a 2DEG in the presence of a perpendicular magnetic field and a weak lateral periodic potential with square symmetry. They observed the expected quantized values when the Fermi level is in one of the minigaps in the Hofstadter butterfly diagram as shown in Figure 24. In real QDSLs, only primary gaps separating clusters of subbands will survive due to broadening induced by disorders and lattice imperfections.

Magnetic fields also affect the transport property of QDSLs, since they influence the many-body wavefunction of electrons in them. Stafford et al. [190] considered coherent tunneling through a 3×3 array of QDs and demonstrated a giant magnetoconductance effect. In finite magnetic fields, some Coulomb blockade peaks are strongly suppressed compared with those in a zero magnetic field, as shown in Figure 25. The interdot kinetic exchange interaction causes an antiferromagnetic spin-density-wave ground state in a zero magnetic field. When an external magnetic field is applied, the electron spins tend to align with the field to minimize the Zeeman energy and a transition occurs from the spin-density-wave ground state at $B = 0$ to a ferromagnetic state at some critical magnetic field. This spin-polarization transition causes the conductance suppression of the sixth peak at $B = 1.3$ T. The seventh peak at $B = 1.3$ T is caused by the spin-blockade effect explained in Section 2.5.

The effect of magnetic fields is especially interesting in the Kagome lattice, because the flat band in the Kagome lattice originates from the interference of wavefunctions, which is disturbed by the Peierls phase in magnetic fields. It has been shown that application of a perpendicular magnetic field destroys the flat-band ferromagnetism [246] and induces a ferromagnetic–paramagnetic transition when the Coulomb interaction is strong. When the Fermi level is in the flat band, the Kagome lattice acts as a band insulator in a zero magnetic field, because the dispersionless flat band has zero group velocity. When magnetic fields are applied, the flat band is destroyed and has dispersion, giving rise to a metal–insulator transition (or "a negative magnetoresistance"). When the flat band is half filled, the ferromagnetic–paramagnetic transition and the metal–insulator one occur

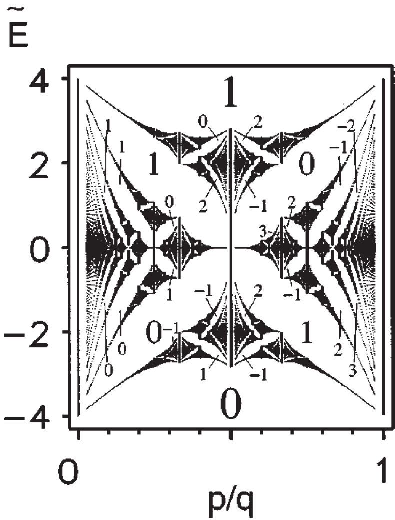

Figure 23. The scaled energy $\widetilde{E}$ versus inverse magnetic flux p/q (Hofstadter butterfly). The Landau band coupling is neglected. The numbers in the energy gaps are the quantized Hall conductances in units of e^2/h. For the Hall conductance in higher Landau bands, one has to add the Landau band index ν to these values. Reprinted with permission from [274], D. Springsguth et al., *Phys. Rev. B* 56, 2036 (1997). ©1997, American Physical Society.

simultaneously at a magnetic field when the Coulomb interaction is strong. The magnetic-field-induced metal–insulator transition in a 2D square lattice has also been discussed by An et al. [281]. These interesting phenomena can be observed in experiment under reasonable magnetic fields in QDSLs.

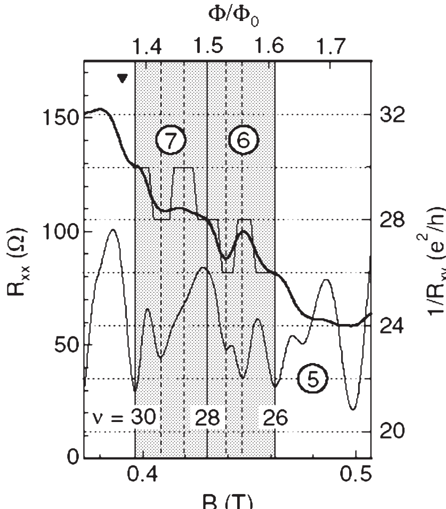

Figure 24. The longitudinal resistance R_{xx} and inverse Hall resistance, $1/R_{xy}$, for a 120 nm lattice at 50 mK near filling $\nu = 26$ to 30. Horizontal dotted lines indicate the quantized values of R_{xy}. The Hall conductance exhibits the 0–1–0–1 sequence in units of e^2/h when it is extracted by the contribution from the filled Landau levels $\nu e^2/h$. This is as expected when the Fermi level is in the right side of Hofstadter's butterfly (see Fig. 23). Reprinted with permission from [280], C. Albrecht et al., *Phys. Rev. Lett.* 86, 147 (2001). ©2001, American Physical Society.

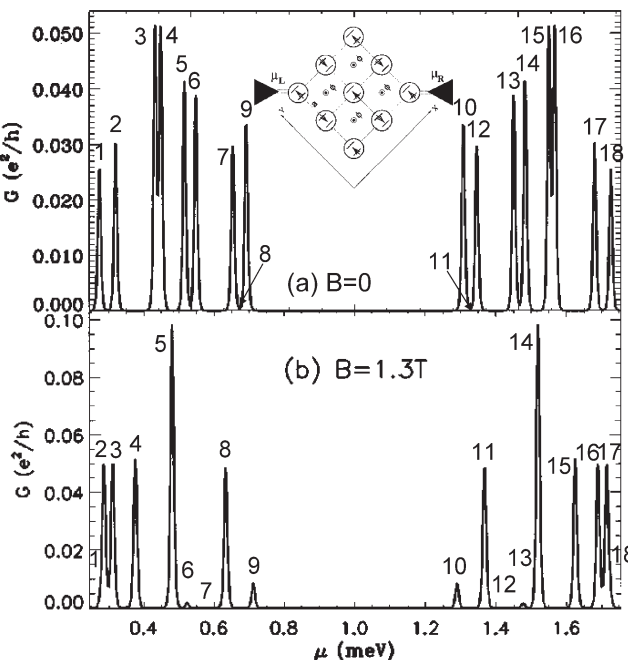

Figure 25. Conductance versus chemical potential μ through the 3×3 array of QDs at (a) $B = 0$ and (b) $B = 1.3$ T. Each peak is labeled by the number of electrons. The ground state (N, S, S_z) sequence for $B = 0$ is given by $(1, 1/2, 1/2) \rightarrow (2, 0, 0) \rightarrow (3, 3/2, 1/2) \rightarrow (4, 1, 1) \rightarrow (5, 1/2, 1/2) \rightarrow (6, 0, 0) \rightarrow (7, 1/2, 1/2) \rightarrow (8, 0, 0) \rightarrow (9, 1/2, 1/2)$, and for $B = 1.3$ T by $(1, 1/2, 1/2) \rightarrow (2, 1, 1) \rightarrow (3, 3/2, 3/2) \rightarrow (4, 2, 2) \rightarrow (5, 5/2, 5/2) \rightarrow (6, 2, 2) \rightarrow (7, 1/2, 1/2) \rightarrow (8, 1, 1) \rightarrow (9, 1/2, 1/2)$. The sixth peak at $B = 1.3$ T is strongly suppressed by the spin-polarization transition. The suppression of the seventh peak at $B = 1.3$ T is caused by the spin-blockade effect. 5. CONCLUSIONS

The advantage of using semiconductors to achieve ferromagnetism exists not only in making semiconducting "permanent magnets." As we mentioned, the controllability of the magnetic property by changing the electron filling and magnetic field will make dot lattices useful in electronic devices, such as memories, sensors, and magnetic heads, since they contain only semiconductor materials, such as Si and GaAs. Magnetic devices can be fabricated without using any magnetic elements, such as iron and manganese, which are incompatible with the conventional large-scale-integrated-circuit fabrication process.

Regarding QDSLs, one can expect research pursuing various correlation effects that have been predicted in mathematical models of lattice systems, other than the flat-band ferromagnetism. One of the most fascinating examples is high-temperature (high-T_c) superconductivity. High-T_c d-wave superconductivity in a repulsive Hubbard model has been predicted [282, 283]. Since the energy scale is a hundred times smaller than in conventional CuO_2 high-T_c superconductors ($T_c \sim 100$ K), the transition temperature of the superconductivity in semiconductor dot arrays should be quite low: the estimated transition temperature using the

prediction is $T_c \simeq 0.01t \sim 1$ K for $a = 2d = 10$ nm GaAs dots. It has been shown that, in other types of lattices, the transition temperature becomes much higher [284]. It would be very interesting if superconductivity (or at least the Kosterlitz-Thouless-Berezinskii transition) could be achieved in semiconductors.

Other types of lattice structures are also fascinating. One is the ladder structure constructed with oxide materials. This structure exhibits various interesting properties, such as the spin gap and superconductivity [285–287]. Optical properties of dot arrays deserve future study, since the large density of states in the flat band will significantly affect photoluminescence and laser characteristics [288].

GLOSSARY

Addition energy Energy necessary to add an extra electron to a quantum dot. It is the same as the chemical potential within the dot.

Artificial atom (molecule, crystal) Single (double, or lattice of) quantum dot showing the properties of real atom (molecule or crystal). Artificial crystal is also called quantum dot superlattice.

Constant interaction model Simple model to describe the Coulomb charging effect in a quantum dot. It is usually expressed by a Hamiltonian consisting of a single-particle energy and a classical charging energy.

Flat band A subband which does not have dispersion in a band diagram. Flat band is degenerate in energy, so the electron correlation becomes strong if the Fermi level is at the flat band.

Hofstadter butterfly Fractal band diagram when the tight-binding model is threaded by magnetic fields.

Spin blockade effect When the total spins of the initial (N) and the final ($N+1$) states in a quantum dot having N electrons are different by more than 1/2, the transition is forbidden and the tunneling current is suppressed.

ACKNOWLEDGMENTS

We have benefitted from extensive interactions with numerous colleagues and collaborators over the past years. We thank Tatsushi Akazaki, Hideo Aoki, Ryotaro Arita, David G. Austing, Yuichi Harada, Wataru Izumida, Takashi Kimura, Kazuhiko Kuroki, Kenichi Matsuda, Seigo Tarucha, and Masahito Ueda for collaborations and valuable discussions. We also thank Andreas Richter for critical reading of the manuscript. Some of the work reviewed here was supported by JPSJ under Contract RTF96P00203 and the NEDO International Joint Research Grant.

1. INTRODUCTION

Infrared (IR) detectors are important for numerous defense, commercial, and scientific applications. Infrared systems continue to demand detectors with the highest performance, highest operating temperature, and lowest cost. The current leading IR detector technology is HgCdTe [1–5]. However, this II–VI semiconductor material is extremely soft, leading to difficulties in materials growth and detector processing, which results in low yield and high cost. As a result, alternative detection schemes using bandgap engineering and more mature III–V semiconductor materials technologies have been pursued. One of these approaches is the strained-layer superlattice with a type-II band lineup [6–8] (e.g., InAs/InGaSb), which is predicted to have reduced Auger scattering rates that may lead to increased operating temperatures in comparison to HgCdTe. This promising technology is still in the developmental stage and requires complex material heterostructures. A second approach is the use of quantum-confined structures to detect IR radiation through optical absorption across intraband electronic states. The quantum well infrared photodetector (QWIP) [9] has shown success with this technique as demonstrated by its use in IR camera systems [10]. Unfortunately, QWIPs have not demonstrated performance comparable to HgCdTe due to fundamental performance limitations. An extension of the QWIP is the quantum dot infrared photodetector (QDIP), utilizing advantages of quantum confinement in three dimensions. QDIPs are predicted to outperform QWIPs due to their inherent sensitivity to normal incidence radiation and reduced phonon scattering. This review describes the operation of the QDIP; charts progress in materials growth, device design, fabrication, and testing; and outlines future directions for the detector technology.

2. OVERVIEW OF INTRABAND DETECTOR OPERATION

The concept of using quantum confinement in semiconductor heterostructures for infrared detection may be explained using basic principles of quantum mechanics. A quantum dot is analogous to the basic particle-in-a-box problem in three dimensions. For an infinite potential well, the solution to the time-independent Schrödinger equation yields the allowed energy states or eigenvalues

$$E_{n_x, n_y, n_z} = \frac{\pi^2\hbar^2}{2m^*}\left(\frac{n_x^2}{L_x^2} + \frac{n_y^2}{L_y^2} + \frac{n_z^2}{L_z^2}\right) \tag{1}$$

where n_i are quantum numbers and L_i are the dimensions of the potential well in the x, y, and z directions. The energy separation between the ground state and the first excited state for a cubic potential well with $L = L_x = L_y = L_z$ is given by

$$E_{1,1,2} - E_{1,1,1} = \frac{3\pi^2\hbar^2}{2m^*L^2} \tag{2}$$

The potential barriers in semiconductor heterostructures are finite and determined by the bandgap energy and alignment of the bands. For common III–V semiconductor material systems such as GaAs/AlGaAs, InGaAs/GaAs, and InGaAs/InP, the barrier height and well dimensions may be designed to produce an energy separation between confined states in the range of 0–1 eV, corresponding to wavelengths of interest for infrared detection: short-wave infrared (SWIR, 1–3 μm), mid-wave infrared (MWIR, 3–5 μm), long-wave infrared (LWIR, 8–12 μm), and very-long-wave infrared (VLWIR, >12 μm).

Bulk semiconductor photon detectors are based on interband optical absorption, where a photon is absorbed to create electron–hole pairs in the conduction and valence

bands. The photoexcited carriers are then extracted to create a current or voltage as the basis for the detection signal. Quantum-confined nanostructures may be utilized to detect photons using *intraband* optical absorption, where an electron (hole) in a confined conduction (valence) band state is promoted to a higher energy state. The photoexcited carrier may then be extracted as a photocurrent. In the case of both interband and intraband infrared photodetectors, these devices must operate at reduced temperatures since the energy level spacing corresponding to the desired infrared wavelength range is comparable to the thermal energy of the carrier at room temperature ($k_B T = 26$ meV). Thus, carriers may be thermally excited out of the quantum dot ground state in the absence of incident infrared radiation, contributing to large dark currents. The detection mechanism for QDIPs is illustrated in Figure 1. It should be noted that this detection scheme requires the presence of an electron (hole) in the conduction (valence) band, and doping is typically required to provide these carriers. The selection rules for electron–photon interactions are determined by the matrix element

$$|a \cdot p_{\mathrm{if}}|^2 = \left| \int \psi_{\mathrm{f}}^* p_a \psi_{\mathrm{i}} e^{ik \cdot r} \, d^3 r \right|^2 \quad (3)$$

where ψ_{i} and ψ_{f} are the wave functions of the initial and final electronic states, p_a is the momentum operator, and $e^{ik \cdot r}$ represents the incident photon. An optical transition is forbidden if this matrix element is 0. Therefore, in order for an optical transition to occur, a polarization component of the optical electric field must correspond to a direction of quantum confinement. For example, a semiconductor quantum well with confinement in the growth direction requires an electric field component in the growth direction. This implies that quantum wells are not intrinsically sensitive to normal-incidence photoexcitation. Despite this problem, QWIPs have demonstrated success using reflectors and gratings to couple infrared radiation with intraband transitions, though this intrinsically limits the quantum efficiency to 50%. Quantum dots provide quantum confinement in all directions, thus providing intrinsic sensitivity to normal-incidence photoexcitation and an inherent advantage over QWIPs.

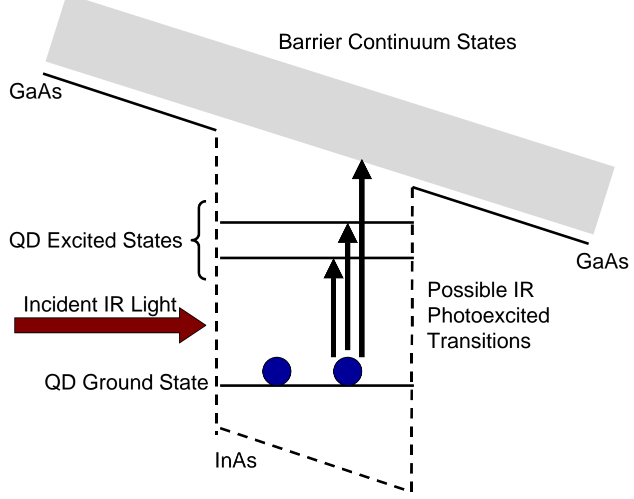

Figure 1. Illustration of intraband optical transitions in InAs/GaAs quantum dots that form the basis for QDIP detection.

Detectors based on intraband optical transitions are typically photoconductive in nature, where photoexcited carriers provide an increase in conductivity. These devices face challenges in extracting photoexcited carriers due to the inherent presence of the energy barriers used for quantum confinement. Ideally, the excited state for the optical transition should coincide with the top of the barrier for optimal carrier extraction. In practice, the excited state is significantly below the barrier and photoexcited carriers must be extracted by tunneling through the barrier or through thermionic emission. Detectors may also be designed using a single bound state, where absorption transitions are between the confined state and the continuum of states above the barrier energy.

3. EPITAXIAL GROWTH AND ELECTRONIC PROPERTIES OF QUANTUM DOT ENSEMBLES

Achieving nanoscale semiconductor heterostructures with excellent optical and electrical properties is a challenge. The realization of semiconductor quantum dots has been pursued for decades due to their potential applications in electronic and optoelectronic devices, including single-electron transistors, diode lasers, and infrared detectors and emitters. The development of epitaxial growth techniques, such as molecular beam epitaxy (MBE) and metal–organic chemical vapor deposition (MOCVD), has resulted in the routine ability to grow excellent quantum well materials with quantum confinement in the growth direction. Obtaining quantum confinement in the lateral direction is much more challenging. The most straightforward approach has been to pattern quantum well structures using lithographic and etching techniques [11, 12]. This method has not proven successful for device applications due to the inability to achieve high-quality interfaces after etching and regrowth. Growth on patterned substrates has also been investigated to provide lateral confinement using preferential growth on particular crystallographic planes [13–15]. This technique has been highly successful in producing quantum wire arrays and has proven to be an important technology for semiconductor diode lasers [16–18]. The preferential growth technique is limited in its ability to provide multiple layers of quantum dots, and both techniques are unable to provide high-density ensembles of quantum dots. The most successful approach to achieve multiple-layer, high-density, semiconductor quantum dot ensembles is the use of self-assembly techniques during epitaxial growth [19–25]. Strained-layer epitaxy in the Stranski–Krastanow growth mode has emerged as the premier method of forming quantum dot ensembles and has demonstrated success in a number of electronic and optoelectronic devices. All of the successful reports of QDIP operation use this technique to fabricate quantum dots. The epitaxial growth and electronic properties of self-assembled quantum dots using strained-layer epitaxy are described in the following discussion.

3.1. Epitaxial Growth

The surface morphology that evolves during epitaxial growth is determined by the relationship between the growth rate and the surface relaxation as the system is driven toward equilibrium by diffusion and kinetic processes. The surface profile is determined by the extent to which the surface atoms are mobile before incorporation into the underlying crystal lattice, which is under a driving growth flux. For unstrained systems, or systems with little strain, epitaxial growth is pseudomorphic, and growth occurs layer by layer. This growth mode is commonly referred to as the Frank–Van der Merwe growth mode. In a strained system, the minimum free-energy surface is not flat in all cases, but can have a three-dimensional form. Three-dimensional island growth may commence immediately (Volmer–Weber growth mode) or after initial layer-by-layer growth (Stranski–Krastanow growth mode [26]). The material deposited layer by layer in the Stranski–Krastanow growth mode is referred to as the wetting layer. The three-dimensional islands may have nanoscale dimensions where quantum confinement effects are observed. Several researchers have discovered that the highly strained growth of InAs on GaAs results in the Stranski–Krastanow growth mode [19–25], and three-dimensional islands of dimension less than 40 nm are formed. The driving forces for these self-assembled, three-dimensional quantum dots are elastic relaxation at the facet edges, renormalization of the surface energy of the facets, and interaction between neighboring islands via the substrate. This technique of self-assembling semiconductor nanostructures has proven to be a highly effective technique for fabricating dense ensembles of quantum dots with excellent electrical and optical properties. Self-assembled quantum dots have been achieved using MBE and MOCVD growth techniques in a number of semiconductor material combinations, including InGaAs/GaAs, InGaAs/InP, (In, Ga, Al)Sb/GaAs, InP/InGaP, and SiGe/Si. Self-assembled quantum dots also have been incorporated into a number of electronic and optoelectronic devices, including transistors, lasers, detectors, and modulators. A vast majority of QDIPs have used In(Ga)As/GaAs self-assembled quantum dots. Accordingly, we will primarily discuss the characteristics of QDIPs in this material system, though results from other materials are also discussed. For typical growth parameters used in MBE or MOCVD, an ensemble of dots with lateral sizes from 15 to 25 nm and heights from 5 to 8 nm are formed. The density of quantum dots is in the range of 10^9–10^{11} cm^{-2}. The typical size, shape, and density of self-assembled quantum dots used in QDIPs are shown in Figure 2.

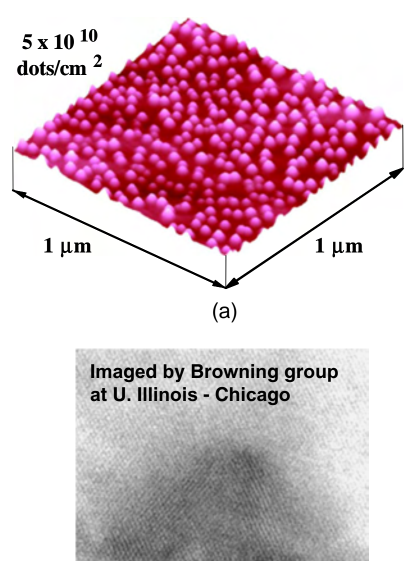

Figure 2. (a) Atomic force microscope and (b) cross-sectional transmission electron microscope image of self-assembled InAs/GaAs quantum dots illustrating characteristic size, shape, and density for QDIP applications.

3.2. Electronic Band Structure

The unique shape and strain distribution of self-assembled quantum dots leads to complexities in understanding the electronic band structure. The self-assembly technique results in an inhomogeneous distribution of quantum dot sizes. Each quantum dot in the ensemble demonstrates sharp atomic-like electronic states [27]. In the ensemble as a whole, however, there is an inhomogeneous distribution of electronic states that typically resembles a Gaussian distribution. Researchers have used a variety of theoretical and experimental techniques to gain an understanding of the band structure in individual and ensembles of quantum dots (QDs). The band structure of InAs/GaAs QDs has been calculated through modeling of the strain distribution and using an eight-band k.p model [28]. These calculations reveal a number of near-degenerate hole states and a few electron states for typical InAs/GaAs self-assembled QD dimensions. The photoluminescence spectra of self-assembled quantum dots reveal a number of excited-state interband transitions and agree with theoretical calculations [29–31]. For intraband detectors, it is desirable to experimentally verify the energy separation between electronic states within the conduction or valence band; however, it is difficult to distinguish these energy levels from the interband optical transitions probed in photoluminescence experiments. Electrical measurements such as capacitance spectroscopy [32] and deep-level transient spectroscopy [33] have been used to probe electronic states within the conduction or valence band. The fusion of the theoretical and experimental data provides a general picture of the band structure of self-assembled InAs/GaAs QDs, where a number of hole states with small energy separation, as well as single or multiple electron states, are observed. The energy separation between the ground electron state and an excited electron state (or the barrier) ranges from 50 to 500 meV [34–38], corresponding to the wavelengths of interest for infrared detection.

3.3. Intraband Optical Absorption

The absorption process requires the presence of a ground-state electron, where dopants have been incorporated into the heterostructure either by directly doping the quantum dots [39] or by modulation doping [40]. QDIP performance

has a distinct tradeoff between, and dependence on, quantum dot density and dopant concentration. As one would expect, the optimal dopant density corresponds to twice the QD areal density (i.e., just enough dopants to fill the ground states of the QDs). The dark current increases at higher dopant densities as dopants outnumber the electron states available in the QD ground state, providing additional "noise" carriers. At reduced dopant densities, there are fewer electrons in the QD ground state for absorption. The reduced absorption requires an increase in the number of QD layers for adequate detection. The optimal level for electron occupation is therefore the level required to fully occupy the ground state.

The primary wavelengths of interest for infrared detectors are less than 20 μm, corresponding to energy near 60 meV. The energy separation between electronic states in self-assembled quantum dots is on this order or larger for the conduction band, and much less than 60 meV for the valence band. As a result, devices based on intraband optical transitions in InAs/GaAs QDs thus far have exclusively used confined electron states in the conduction band. An understanding of intraband absorption is necessary to ascertain the suitability of self-assembled QDs for intraband detectors. The first report of intraband absorption in quantum dots was made by Pan et al. [41], where absorption was observed in the spectral range of 13–15 μm, corresponding to ground-state-to-excited-state optical absorption. Since then, intraband absorption has been reported for infrared wavelengths ranging from the MWIR to the VLWIR [42–44], where absorption peaks may be tuned by varying QD size through growth conditions or through modification of the barrier layer. The optical absorption spectral linewidths of the QDs are broadband and are determined by the size distribution of the QDs in the ensemble, where a typical spectrum is shown in Figure 3. QDIPs therefore have a tradeoff in absorption strength and broadband response for a given net QD volume. To illustrate, a perfectly uniform QD ensemble will have large peak absorption and a narrow absorption spectrum. A nonuniform QD ensemble will have reduced peak absorption, where the absorption response will be distributed in wavelength according to the electronic structure variation for differing QD sizes.

The intraband optical absorption shows the predicted intrinsic sensitivity to normal incidence excitation. The shape of self-assembled QDs resembles flattened pyramids or lenses, where quantum confinement is more significant in the vertical direction in comparison to the lateral direction. As a result, the intraband optical absorption is predicted to be more sensitive to in-plane polarization in comparison to polarization in the growth direction [45]. The significant decrease in intraband absorption for polarization in the growth direction has been reported [46, 47]. This polarization dependence has also been confirmed experimentally by measuring the change in peak absorbance at room temperature as a function of annealing time for in-plane ($\theta_{inc} = 0°$ to surface normal) and perpendicularly polarized ($\theta_{inc} = 65°$ to surface normal) light. The absorbance of a 70-layer InAs/GaAs quantum dot stack was obtained for various annealing times at a constant anneal temperature of 700 °C. As shown in Figure 4, in the unannealed case (anneal time = 0 min), absorbance is greater in the in-plane polarized case than in the perpendicularly polarized case, as predicted by theory. As the anneal time is increased, the in-plane polarized light absorbance decreases, while the perpendicularly polarized light absorbance increases. This result agrees with theoretical predictions since the dots become flatter and more like quantum wells as the anneal time is increased, allowing perpendicularly polarized absorbance to become dominant. This polarization dependence emphasizes the importance of realizing QDs with small lateral dimensions to obtain strong normal incidence sensitivity for IR detectors.

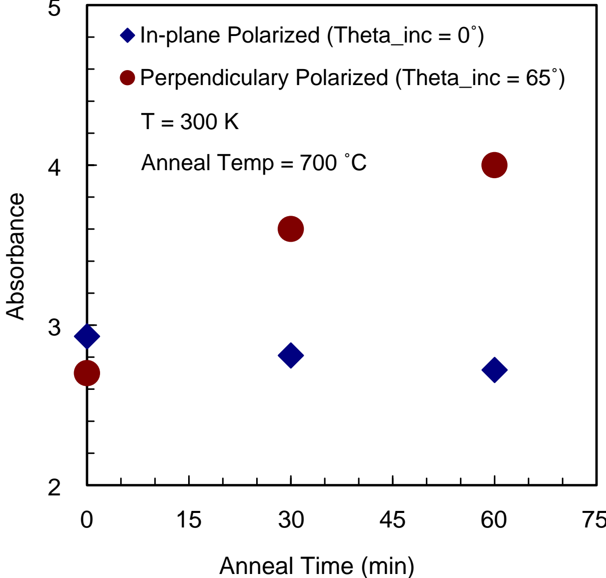

Figure 4. Room-temperature absorbance in 70-layer InAs/GaAs quantum dot stack as a function of anneal time for in-plane and perpendicularly polarized light.

3.4. Intraband Carrier Dynamics

Carrier excitation and relaxation processes play an integral role in intraband devices. Thermal excitation (generation and thermionic emission) is the principal mechanism governing dark current in an intraband detector. Relaxation of carriers reduces the efficiency of the detector, since a photoexcited carrier may relax into the ground state of a quantum dot before being collected as photocurrent. Once a carrier has been photoexcited by incident infrared radiation and has escaped a quantum dot, it can undergo several processes. The photoexcited carrier may drift in the electric field, be collected at a device contact as photocurrent, or relax into the ground state of the same quantum dot or a different one. The relaxation processes in an intraband device are analogous to minority carrier recombination in a photodiode; however, the carrier dynamics in quantum dots differ significantly from quantum wells.

The three-dimensional discrete nature of the QD electronic states suggests the existence of a "phonon bottleneck," where electron relaxation by a single phonon emission is suppressed. In contrast, the phonon process dominates carrier scattering and relaxation in quantum wells. Multiphonon events require a resonant condition, and therefore are typically slow for QDs (>1 ns). The suppression of phonon scattering in QDs suggests that carrier relaxation times will be significantly longer than in quantum wells. Recent investigations have demonstrated that Auger scattering [48] and electron–hole scattering [49] are responsible for interband carrier relaxation in QDs. Hole relaxation times measured by differential transmission spectroscopy (DTS) for In(Ga)As/GaAs QDs can be fast, less than 1 ps [50, 51], due to valence-band mixing, anisotropy, and high density of states. Electron relaxation times measured using the DTS technique show two time constants for relaxation from the excited state to the ground state [50, 51]. The short time constant ($\sim$7 ps) is believed to be governed by Auger, electron–hole, and multiphonon scattering, and the long time constant ($\sim$15–100 ps) by phonon-mediated processes. In quantum wells, electron relaxation processes are typically about 3 ps [52]. The DTS measurements described for QDs are performed under conditions where significant electron and hole densities are present. However, since the intraband detector is a unipolar device, there is a significantly reduced density of holes, which suppresses the Auger and electron–hole scattering processes and lengthens the electron relaxation time. The lengthened carrier relaxation times in self-assembled QDs are a desirable property for realizing efficient intraband detectors.

4. DEVICE FABRICATION AND CHARACTERIZATION

There are many possible heterostructure and device designs that have been used to fabricate QDIPs [53–64]. Therefore, the following section will discuss the most basic QDIP in order to understand the fundamental characteristics of the device and then briefly review various heterostructure and device designs to indicate the breadth of device possibilities.

The primary figures of merit for a detector are the dark current, spectral response, detectivity, quantum efficiency, and photoconductive gain. The dark current in a detector is the current flowing in the device in the absence of illumination. Dark current is a primary limitation in IR detectors where low incidence and corresponding low photocurrent are typical. The spectral response of a detector measures the photocurrent generated as a function of wavelength. The detectivity in a detector is a measure of the signal-to-noise ratio and represents a convolution of dark current and quantum efficiency, where the quantum efficiency represents the conversion of incident photons into an electrical signal. In a photoconductor, an analogous figure of merit to the quantum efficiency is the responsivity, given in amperes per watt (A/W) and representing the measured current for a given photon incidence. The photoconductive gain, also closely related to the quantum efficiency, is a measure of how many photoexcited carriers are generated for a single incident photon, and its value is based on the ratio of the carrier lifetime to the carrier transit time. After reviewing general QDIP characterization techniques, further description of these figures of merit and measured QDIP characteristics follow.

4.1. Device Heterostructure and Fabrication

QDIP devices are photoconductive in nature, where photoexcited carriers within the quantum dots provide a photocurrent and apparent increase in conductivity. QDIPs clearly have a resemblance to QWIPs in general operation and device structure; however, there are additional parameters unique to quantum dots that affect device performance. Essentially, QDIPs have more design parameters or "dials to turn," such as quantum dot size, shape, and density.

The common QDIP device heterostructure is an extension of QWIP devices, where a series of doped QD layers is placed between undoped barrier regions with doped contact layers at the device boundaries. Usually, InAs quantum dots are surrounded by GaAs barriers. IR detection requires a significant absorption volume to convert photons to electrons. Accordingly, QWIPs typically incorporate 10–50 quantum well layers. The small absorption volume of QDs also necessitates a large number of layers for adequate detection; however, the number of layers is typically limited by the ability to incorporate strain in the structure without generating dislocations. By calibrating the barrier region thickness to minimize the effect of strain from one dot layer to the next, QD layers can be repeated anywhere from 10 to 70 times without the propagation of dislocations.

In general, there are two device structures that have been studied, the lateral QDIP [56, 58, 59, 62] and the vertical QDIP [53–55, 57, 60, 61, 63, 64]. The device conduction band and heterostructure for the lateral and vertical devices are illustrated in Figure 5a and b, respectively. The lateral QDIP, which operates much like a field-effect transistor, conducts photocurrent through lateral transport of carriers across a high-mobility channel [62, 65]. AlGaAs barriers, which provide this high-mobility channel, are also necessary to modulation-dope the quantum dots. Since the major contributions to the dark current in lateral QDIPs are due to interdot tunneling and hopping conduction, these devices have demonstrated very low dark currents and high operating temperatures [56]. The vertical QDIP conducts photocurrent through vertical transport of carriers. In this case,

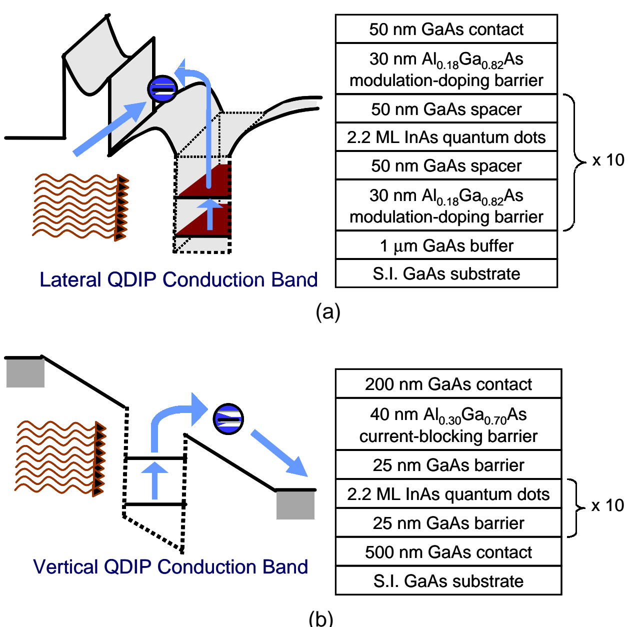

Figure 5. Schematics of QDIP conduction band and heterostructure designed for (a) lateral and (b) vertical detection.

the quantum dots are directly doped to provide free carriers during photoexcitation, and an AlGaAs barrier can be included in the vertical device to block dark current created by thermionic emission [66, 67].

For either type of device, fabrication typically consists of standard photolithography and wet-etching techniques. The lateral device requires a minimum of two lithography steps, the first for metal evaporation of two top contacts and the second for device definition by a mesa etch. The vertical device requires a minimum of three lithography steps: (1) metal evaporation of the top contact, (2) device definition by mesa etch around the top contact, and (3) metal evaporation of the bottom contact around the device mesa. An important advantage of QDIPs over QWIPs is the simpler device fabrication. QWIPs require the fabrication of random reflectors or gratings at the top of the detector in order to scatter normal-incidence light so that some portion will be laterally incident and thereby detectable by the QWIP. As discussed earlier, since QDIPs are inherently sensitive to normal-incidence light, no such processing is required. Most infrared detection applications require a two-dimensional format for imaging applications. Therefore, the vertical detection scheme in which arrays are illuminated from the top or backside and electrical contacts are placed correspondingly is typically used as opposed to the lateral detection scheme.

In addition to the typical InAs/GaAs QDIP, other III–V dot systems and heterostructures are being investigated for use as infrared detectors. In contrast to a typical QDIP with a series of symmetric and uniform layers, alternative material heterostructures may be designed to realize multicolor detectors [53]. In these structures, asymmetric barriers alter the response wavelength in differing bias directions to provide the capability for independent MWIR and LWIR response, depending on the bias conditions. As an example, InAs quantum dots embedded in strain-relieving InGaAs quantum wells are known as dot-in-a-well (DWELL) heterostructures. QDIPs using DWELLs not only permit greater control over detection wavelength tunability [68], but they have also demonstrated excellent device performance [69]. Devices containing an undoped active region of InAs quantum dots grown directly on AlGaAs with a GaAs cap layer have also demonstrated promising device performance [70]. Other III–V material systems under consideration include InAs/InAlAs QDs grown on InP [71] and InGaAs/InGaP QDs grown on GaAs [55]. Intraband transitions in the infrared have also been observed for the elemental semiconductor material system of Ge/Si quantum dots [72–74]. These boron-doped devices operate by the intraband absorption of infrared light by holes trapped in the quantum dot valence band. The device characterization of these Ge/Si QDIPs indicates they also may be an important technology for infrared detection [75–77]. A listing of reported QDIP results for various material systems and technologies is given in Table 1.

4.2. QDIP Characterization

Due to the large dark current present in all infrared photodetectors, QDIP properties must be measured at reduced temperatures (<300 K) by using a dewar or cryostat. Thus, QDIPs are usually mounted on a chip carrier, where contact is made with individual devices through gold wire bonds. The most straightforward detector measurement is the dark current as a function of bias voltage for various temperatures.

Spectral response measurements in QDIPs are often conducted at normal-incidence using a Fourier transform infrared (FTIR) spectrometer with a broadband (1–20 μm),

Table 1. Listing of QDIP results.

Quantum dot material	Barrier material	Growth technology	Device configuration	Ref.
InGaAs	GaAs	MBE	Vertical	[53, 54, 57, 58, 61, 64]
InGaAs	InGaP	MOCVD	Vertical	[55]
InGaAs	GaAs	MBE	Lateral	[56, 59, 62, 65]
InAs	InAlAs	MBE	Vertical	[60]
InGaAs	InGaAs/GaAs	MBE	Vertical	[63, 68, 69]
InGaAs	AlGaAs/GaAs	MBE	Vertical	[66, 67, 70]
InAs	InAlAs	MBE	Vertical	[71]
Ge	Si	MBE	Vertical	[75–77]

high-intensity source. Blackbody response measurements of QDIPs typically use a calibrated infrared photon source, such as a blackbody at a temperature anywhere from 500 to 800 K, to determine the absolute responsivity of the QDIP to normal-incidence IR radiation. In such a blackbody response measurement, the QDIP photocurrent signal and noise under illumination are measured with a fast Fourier transform (FFT) analyzer or a lock-in amplifier. A flat-band noise spectrum is desired because it indicates that the dominant noise mechanism is generation–recombination (GR) noise, as assumed in most theoretical calculations. The blackbody response measurement does not consider the wavelength of IR light that is detected; thus, spectral and blackbody responses are considered simultaneously to determine the detectivity and responsivity (quantum efficiency) at the peak wavelength response of the device.

The absolute responsivity may be determined by measuring the photocurrent induced by a calibrated blackbody source by

$$I_p = R_p \int R(\lambda) W(\lambda)\, d\lambda \tag{4}$$

where I_p is the photocurrent, R_p is the peak responsivity, and W is the blackbody power per unit wavelength at a given temperature. The responsivity shows a broadband response similar to the absorption spectra, corresponding to the inhomogeneous QD size distribution. In general, the spectral response, as shown in Figure 6, does not change significantly with bias. The peak responsivity, on the other hand, shows a clear dependence on bias, indicating the extraction process for photoexcited carriers. Typical values for peak responsivity at various temperatures are shown in Figure 7.

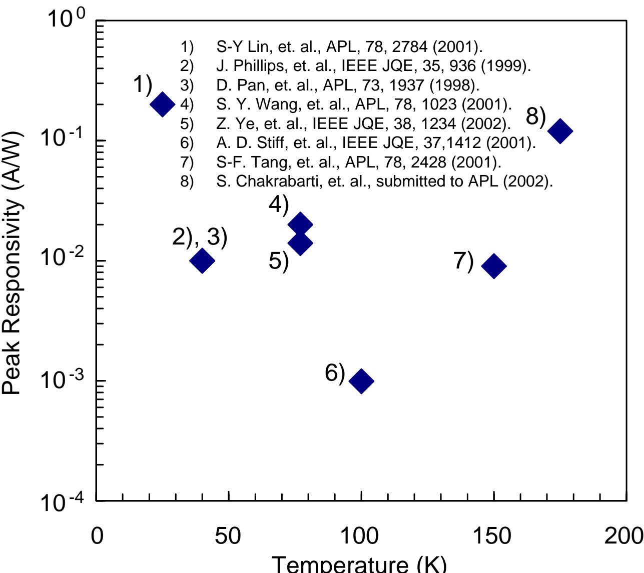

Figure 7. Peak responsivity as a function of temperature for several reported QDIP results.

4.3. Dark Current

Possible mechanisms for dark current in QDIPs include thermal generation, thermionic emission from QDs, interdot tunneling, and impact ionization [78]. Similar to QWIPs, the dominant mechanisms for dark current are suspected to be thermal generation and thermionic emission processes. To reduce dark current to sufficient levels, the devices are operated at cryogenic temperatures, as are all high-performance infrared photon detectors. A primary advantage predicted for QDIPs over QWIPs is the reduction of dark current due to reduced thermal generation in QDs versus QWs, as described in the above carrier dynamics section. A characteristic dark-current density–voltage curve for varying temperature in a vertical QDIP is shown in Figure 8. The asymmetry in the current–voltage curve is indicative of asymmetry in the device structure, which may stem from device structure (incorporation of barriers, nonuniform spacing

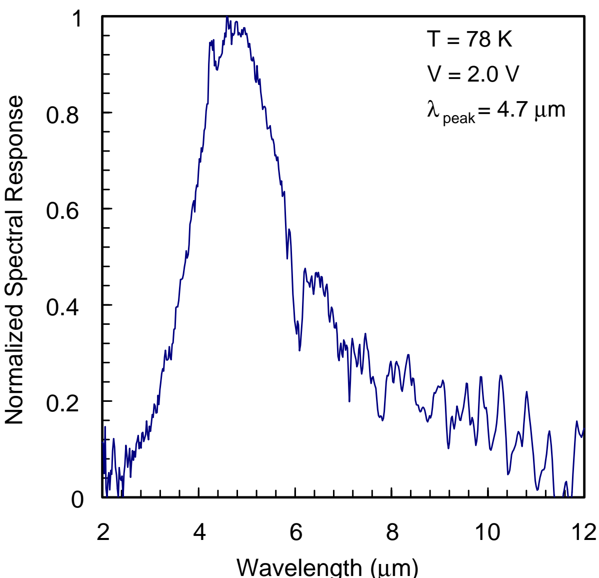

Figure 6. Spectral response of a vertical InAs/GaAs QDIP.

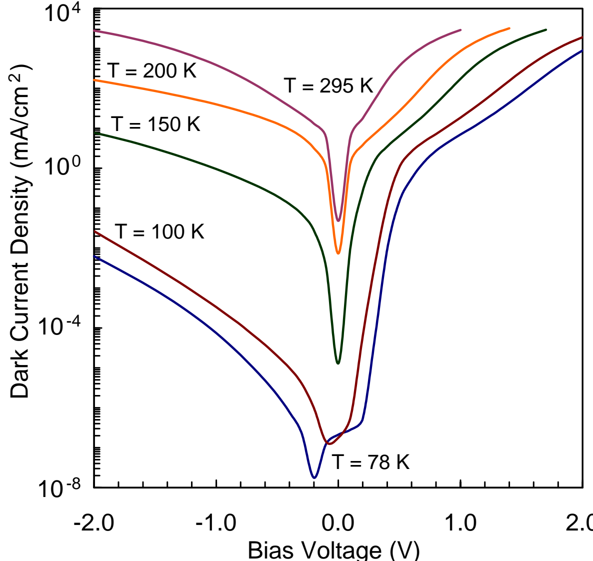

Figure 8. Temperature-dependent dark-current density–voltage characteristics for a vertical InAs/GaAs QDIP.

between QD layers), the QD shape, or doping nonuniformities. In addition to temperature dependence, the dark current shows a distinct dependence on energy separation or response wavelength correlating with the expected thermal generation processes. One of the inherent drawbacks with the typical photoconductor design is the larger dark current in comparison to a photodiode. As a result, QDIPs have been designed to incorporate higher bandgap barrier layers in the active region of the device and have demonstrated significant reductions in dark current [64].

4.4. Detectivity

A common figure of merit for detectors is the detectivity D^*, which reflects the signal-to-noise ratio independent of detector geometry and operation and is defined as

$$D^* = \frac{\text{Signal} \times \sqrt{\text{Bandwidth}}}{\text{Noise} \times \text{Incidance} \times \sqrt{\text{Area}}} \tag{5}$$

The value for detectivity is determined using calibrated blackbody response and dark-current noise measurements. Typical values for the peak detectivity are shown in Figure 9 for various temperatures.

4.5. Quantum Efficiency and Photoconductive Gain

The photocurrent in a photoconductive detector is given by

$$I_p = q\phi\eta g \tag{6}$$

where q is the charge of an electron, ϕ is the photon incidence, η is the quantum efficiency, and g is the photoconductive gain. The photoconductive gain is defined as the number of electrons flowing through the external circuit for each carrier generated in the device. This gain may be greater than 1 for the case where the carrier lifetime exceeds the transit time through the device. A direct determination of photoconductive gain or quantum efficiency requires a measurement of the product $\phi\eta$. This measurement is extremely difficult to do in practice due to optical reflection and the requirement to accurately determine absolute power levels. In practice, noise current measurements are typically used to determine photoconductive gain. In turn, the quantum efficiency is then inferred from photocurrent measurements.

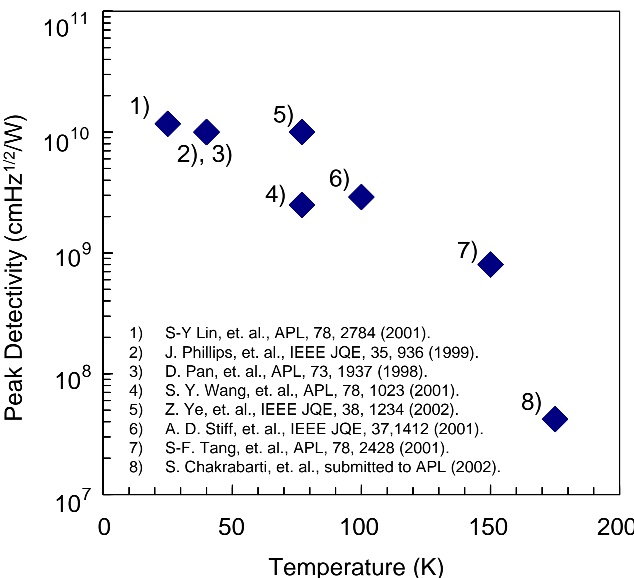

Figure 9. Peak detectivity as a function of temperature for several reported QDIP results.

In a QWIP, the commonly used expressions between gain and noise current were developed in the following manner. The mean carrier density flowing through a QWIP under steady state during time τ is given by n, where the mean density of captured and ejected carriers in a quantum well is given by

$$n_{ci} = n_{ei} = np_c \tag{7}$$

and p_c is the capture probability for a quantum well. This expression neglects tunneling between adjacent quantum wells. By the definition of g, the photoconductive gain is given by

$$g = \frac{n}{\sum n_{ei}} = \frac{1}{Np_c} \tag{8}$$

where N is the number of quantum wells in the device. Assuming that carrier generation and capture are statistically independent, the noise current may then be related to gain with the following expression

$$I_n^2 = 4qeIgB\left(1 - \frac{p_c}{2}\right) \tag{9}$$

Substitution of the relationship between gain and capture probability results in the following practical relationship

$$g = \frac{I_n^2}{4qIB} + \frac{1}{2N} \tag{10}$$

This relationship for gain in a photoconductor is commonly used to infer gain from noise current and dark current, where photoconductive gain is assumed to be equivalent to dark-current gain. This has been shown to be a good approximation for QWIPs.

For QDIPs, however, there are important fundamental differences, precluding the direct use of the QWIP photoconductive gain expression. In a quantum well, the presence of subbands provides a continuum of energy states for the capture and emission process, where state filling may be neglected under typical QWIP operation. In a QDIP, electron occupation in QD states governs the capture and emission process. Electron occupation in QD states in QDIPs with and without illumination differs significantly, and dark-current gain *does not* directly relate to photoconductive gain. The following simplified picture may be used to provide a revised expression for photoconductive gain in QDIPs. The capture and emission processes in steady state for a carrier density n are given by

$$n_{ei} = n_{ci} = n[p_{c1i}(1-m) + p_{c2i}] \tag{11}$$

where p_{c1i} and p_{c2i} are capture probabilities into the ground and excited QD states, respectively, and m represents the occupation probability for the QD ground state. Note that carrier relaxation processes between the QD ground and excited states are not explicitly represented in the previous expression, where these processes do not directly contribute to photocurrent or GR noise. These are also neglected in the QWIP analysis, and in the QDIP case will affect electron occupation in the QD states. The factor m is used to represent this relationship. The revised photoconductive gain expression is then given by

$$g = \frac{1}{N[p_{c1i}(1-m) + p_{c2i}]} \tag{12}$$

and the following relationship with noise current

$$g = \frac{I_n^2}{2qIB[2 + p_{c1}p_{c2}(1-m)]} + \frac{1}{N[2 + p_{c1}p_{c2}(1-m)]} \tag{13}$$

Note that gain cannot directly be determined without knowledge of the capture probability or occupation of the QD ground state. This analysis only accounts for state filling in the QD ground state, though filling of excited states may also significantly affect gain. For dark-current measurements, occupation of QD ground states should be significant, with $m \sim 1$. For illumination, occupation of QD ground states will be reduced due to photoexcitation, $m < 1$. The capture probabilities will be affected by the "fill factor" in the quantum dots and will change with electron occupation. The actual photoconductive gain predicted by the preceding analysis can be lower than the dark-current gain by approximately 30%. This analysis further suggests that the determination of the quantum efficiency (QE) of QDIPs in the current method of measurement is lower than the actual quantum efficiency (the real QE should be about 30% larger for the simulation given later). Note that the QDIP expressions reduce to the QWIP expressions when returning to a one-level versus two-level model for gain. Despite the differences between photoconductive gain in QWIPs and QDIPs, the expressions for QWIPs are currently being used to estimate gain and quantum efficiency from blackbody response and noise current measurements.

The quantum efficiency of QDIPs determined using the above technique has been generally low, approximately 1%, and has not come to equal that of QWIPs (~20%), suggesting that the size uniformity needs to be improved and/or the ability to increase the number of quantum dots in a detector is needed. The reduced quantum efficiency for QDIPs in comparison to QWIPs is consistent with the reduced QD peak absorption compared to quantum wells.

5. EVALUATION OF QDIP PERFORMANCE

The fundamental limitation for an IR detector is commonly referred to as the background limited performance (BLIP). This is the condition where the density of photogenerated carriers is equal to the density of carriers generated thermally. Kinch has made an excellent comparison for fundamental limitations in IR detector materials through analysis of the BLIP condition [79]. This analysis allows one to evaluate a materials technology independent of device configuration and examines the BLIP condition where photogenerated carriers are greater than thermally generated carriers in the material, given by

$$\eta\Phi\tau/t > n_{th} \tag{14}$$

where η is the absorption quantum efficiency, Φ is the photon flux, τ is the carrier lifetime, t is the material thickness in the direction of the incident photon flux, and n_{th} is the thermally generated carrier density. Using $\eta = \alpha t$, where α is the absorption coefficient in the material, we get the BLIP requirement $\Phi > n_{th}/\alpha\tau$ and obtain a normalized thermal generation rate [79]

$$G_{th} = n_{th}/\alpha\tau \tag{15}$$

This provides a simple technique for comparing differences between materials technologies for infrared detectors. The normalized thermal generation rate for a QDIP may be calculated using this technique, as described in [80]. A comparison of the normalized dark current for HgCdTe, QWIP, and QDIP, as obtained from the above equations is shown in Figure 10 for a bandgap energy of $E_g = 0.124$ eV corresponding to a cutoff wavelength of $\lambda_c \sim 10$ μm. Two cases for QDIPs are given in the figure: (1) The nonuniform case represents the typical QD size uniformity observed in current self-assembled QD ensembles, and (2) the uniform case represents a perfectly uniform QD ensemble. As can be seen from Figure 10, the performance of QDIPs is predicted to surpass that of QWIPs. In the case of dense QD ensembles with high size uniformity, QDIPs are predicted to rival and perhaps outperform HgCdTe.

These predictions agree with the theory reported by Ryzhii [81], where QDIPs were first proposed due to the following anticipated advantages over QWIPs: inherent sensitivity to normal-incidence radiation, low dark current,

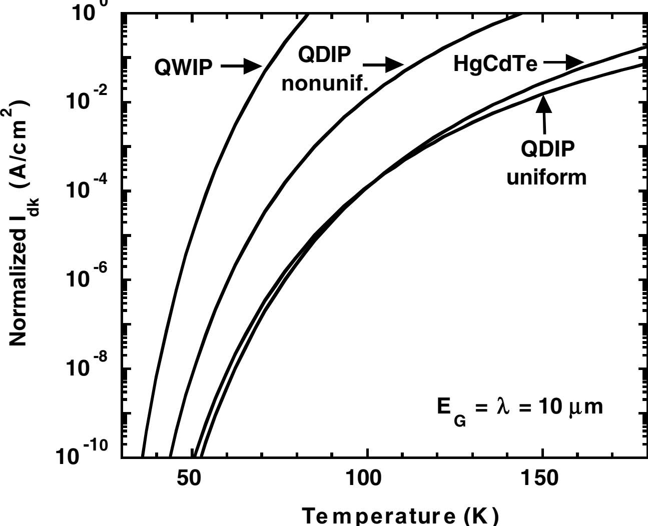

Figure 10. Normalized dark current for HgCdTe, QWIP, and QDIP detectors as a function of temperature for a peak response wavelength of 10 μm, using the analysis at BLIP outlined in the text.

inhibited carrier capture rates, and high photoconductive gain. This theory, however, considers somewhat idealized quantum dots in that the effect of inhomogeneous broadening resulting from the random size distribution in a QD ensemble is not considered. Such inhomogeneous broadening adversely affects actual device behavior. While the device characterization of QDIPs has demonstrated excellent, high-temperature performance, as discussed in Section 4, these devices have not yet yielded the same responsivity, quantum efficiency, or detectivity as QWIPs or as expected from theoretical calculations. Comprehensive theories have been developed to better understand the behavior of real devices [82–84]. In general, these theoretical models indicate that QDIP performance, in particular, the dark current and detectivity, can become comparable or superior to QWIP performance given the controlled growth of high-density, uniform QD ensembles composed of small dots in both the lateral and the growth directions.

6. CONCLUSION

III–V-based quantum dot infrared photodetectors are positioned to become an important technology in the field of infrared detection. Their inherent sensitivity to normal-incidence radiation, lower dark currents, higher operating temperatures, multispectral tunability, and mature processing techniques indicate that these devices could provide the type of high-resolution, low-cost, and high-yield imaging components required by the military and other highly sophisticated applications.

Excellent device performance has been demonstrated using QDIPs. Theoretical models predict that QDIPs should provide comparable performance to HgCdTe detectors and better performance than QWIPs, especially at elevated temperatures. However, QDIPs are not without disadvantages, and there are some challenges that must be overcome in order to take full advantage of this technology. The random growth process of self-assembled quantum dots adversely affects device performance due to the inhomogeneous broadening associated with the random distribution in quantum dot size. However, this problem can be resolved by the growth of dense, small quantum dot ensembles. Additionally, the quantum efficiency of these devices must be increased in order to improve the performance of QDIPs. Further study of MBE growth of self-assembled quantum dots, as well as more detailed modeling of realistic QDIP devices should aid in this development.

GLOSSARY

Dark current The external current that, under specified biasing conditions, flows in a photoconductive detector when there is no incident radiation.

Detectivity Detector figure of merit commonly used to characterize and compare the signal-to-noise ratio.

Epitaxy The growth of a thin layer on the surface of a crystal so that the layer has the same structure as the underlying crystal.

Long-wavelength infrared (LWIR) Typically referring to infrared wavelengths between 8 and 12 μm.

Mid-wavelength infrared (MWIR) Typically referring to infrared wavelengths between 3 and 5 μm.

Quantum dot infrared photodetector (QDIP) An infrared photon detector utilizing optical transitions between bound electronic states in the conduction or valence band of quantum dots.

Quantum efficiency In an optical detector, the ratio of the number of output quanta (electrons) to the number of input quanta (photons).

Quantum well infrared photodetector (QWIP) An infrared photon detector utilizing optical transitions between bound electronic states in the conduction or valence band of quantum wells.

Responsivity In a photodetector, the ratio of the electrical output to the optical input.

Short-wavelength infrared (SWIR) Typically referring to infrared wavelengths between 1 and 3 μm.

Very-long-wavelength infrared (VLWIR) Typically referring to infrared wavelengths longer than 12 μm.

1. INTRODUCTION

Recent years have witnessed the advancement of miniaturization techniques to such a sophisticated level that semiconductor structures with dimensions of a few hundred angstroms can be fabricated routinely. While this technology led to a reduction in feature sizes of conventional devices—for instance, deep submicron metal–oxide–semiconductor field effect transistors (MOSFETs)—it also made possible the realization of a whole new class of devices based on novel physical phenomena [1–3]. With the length scale of these devices approaching the de Broglie wavelength of carriers, electron motion is confined. This may be in one, two, or three dimensions with the corresponding systems being called quantum wells, quantum wires, and quantum dots (QDs), respectively. Therefore, electrons are confined to move in a plane in quantum wells, are confined to move along a line in quantum wires, and are mostly localized in QDs.

This chapter describes the electronical properties of QDs and addresses general modeling issues, mostly with the density functional formalism. After giving an introduction to the different QD systems in Section 2, we review in detail the phenomena of Coulomb blockade and single-electron charging in Section 3. The distinction is made between the classical regime discovered earlier in metallic QDs [4–6] and the quantum regime recently evidenced in semiconductor QDs [7–9]. The latter QDs are often called *artificial atoms* [10] because, as in real atoms, the electron energies are totally quantized and the total charge is restricted to an integer number of electrons. Section 4 describes the first experiment, carried out by Tarucha and co-workers, that evidences a shell structure in semiconductor vertical quantum dots (VQD) [11]. Through the observation of single-electron charging effects, shell filling in VQD was interpreted as governed by Hund's first rule, thereby manifesting single spin effects. However, it is worth emphasizing the differences between artificial atoms and their real counterparts as shown in Figure 1. In atoms, the attractive potential arising from the nucleus positive charge is central symmetric and varies as the inverse of the distance from the nucleus. In QDs, the confining potential depends on the way the nanostructure is fabricated. In many cases, the electron gas is strongly confined in one direction and subject to a more or less harmonic potential in the other two directions. Furthermore, while the nuclear charge is an integer number of positive elementary charges, the net attractive charge of a QD varies continuously by means of an external gate [10]. Sections 5 and 6 describe the physics background for our numerical model. In particular, the density functional formalism and the important concept of addition energy are introduced. In Sections 7 and 8, we present the results of simulations on cylindrical QDs, rectangular QDs, and electrostatically deformable QD structures, respectively. Section 7 discusses symmetric structures while Section 8 concentrates on the consequences of breaking this symmetry, structurally and electrostatically. Finally, Section 9 studies the electronic properties of double QDs, or *artificial molecules*.

Motivation for studies on QDs arises from the many possibilities they afford for investigation of many-body interactions in an atomlike setup. Whereas it is not possible to

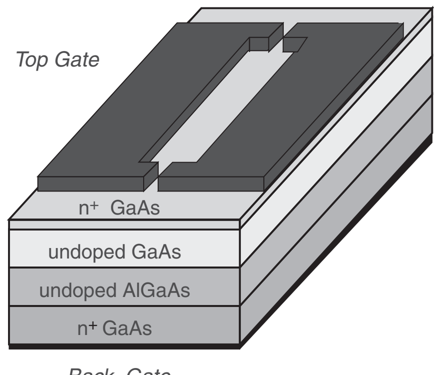

Figure 2. Schematic diagram of a PQD showing the gates and different material layers.

alter the nature and strength of the confining potential in atoms as they are fixed by the nuclear charge, it can be varied more freely in QDs. Furthermore, it is possible to populate the QD with an arbitrary number of electrons, corresponding to a specific atom in the periodic table. An additional important feature is that the length scale on which such phenomena occur is translated from the atomic dimensions (a few angstroms) to the mesoscopic dimensions (thousand angstroms), making the observations easier. All these factors and the many challenges that they pose to theorists have made the study of mesoscopic devices hugely popular in recent years. The interest from an engineering point of view comes from their many promising applications as optical memory elements, floating gate flash memory cells, lasers, photodetectors, current standards, etc. [12–16]. Moreover, with the emergence of quantum information, artificial molecules appear to be a very favorable ground to generate entangled states and therefore to be the core of quantum computers [17, 18].

2. QUANTUM DOTS

QDs are nanostructures electrostatically or structurally isolated from the outside in which electrons are confined. Typically QDs consist of a few hundreds to a few millions of atoms, but only a small number of electrons ($\leq$100) are free. Depending on electron confinement, it is possible to distinguish between planar QDs, vertical QDs, and self-assembled QDs.

2.1. Planar Quantum Dots

The first experiments with semiconductor QDs were made with planar structures by patterning several Schottky metal gates above the surface of a two-dimensional electron gas (2DEG) which isolates electrostatically a small region and form a planar quantum dot (PQD) [7, 19–25] (for a more exhaustive list see, e.g., [26]). An example of such structure is depicted on Figure 2. By applying a negative bias on the top gate, electrons are repelled and a small island is isolated at the center of the 2DEG, at the n^+GaAs/AlGaAs interface. A back gate allows one to change the dot confinement and thus the number of electrons inside the dot.

PQDs have two main characteristics. (i) The current flows in the 2DEG plane; (ii) the tunnel barrier are created electrostatically which has an advantage: their height is controllable. However, electrostatic barriers are weak (a few meV high) and thick ($\approx$100 nm). Moreover they have variable shape which is strongly influenced by the gate voltage. That makes PQDs quite sensitive to external perturbations.

2.2. Vertical Quantum Dots

In vertical quantum dots (VQDs), the zero-dimensional region is sandwiched vertically between a double resonant tunneling barrier made of heterostructure layers, and lateral confinement is achieved by a combination of deep mesa etching and electrostatic depletion [8, 9, 11, 27–37]. The dot confinement is controlled by a Schottky gate that is deposited on top of the mesa [30] or is wrapped around it [31]. VQD atomiclike properties were first evidenced by Ashoori, by capacitance spectroscopy measurements [8, 29, 30]. Later, in addition to the quantum features mentioned above, spin effects were clearly observed by Tarucha in experiments with a device similar to the one depicted in Figure 3 [9, 11, 31, 34, 35].

The main characteristics of VQD are: (i) the current flows vertically, perpendicularly to the 2DEG plane; (ii) the tunnel

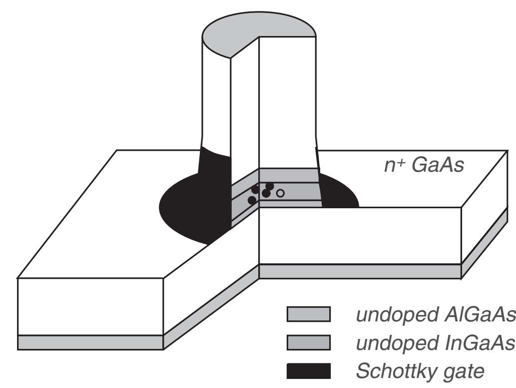

Figure 3. Schematic diagram of Tarucha's VQD. Adapted with permission from [11], S. Tarucha et al., *Phys. Rev. Lett.* 77, 3613 (1996). © 1996, American Institute of Physics.

barriers are high (>100 meV) and thin (≈10 nm) because they are due to the large bandgap material such as GaAs, but then, they are not electrically tunable. VQDs are therefore less sensitive to external fluctuations.

The most popular device made with PQDs and VQDs is the *single-electron transistor* (SET) in which the QD replaces the inversion channel of conventional MOSFETs [38]. Potential applications for SETs are metrology [39, 40], optical detectors [16], and ultradense digital logic circuits [15]. However, due to their high sensitivity to random background charges, SETs future is not clear [6].

2.3. Self-Assembled Quantum Dots

In PQDs and VQDs, electrostatic confinement leads typically to dimensions around 100 nm, and structural confinement is of the order of 10 nm. The eigenlevel separation of a rectangular box of such dimensions is about 1 meV. To prevent quantum effects from being smeared out by thermal fluctuations, experiments with PQDs and VQDs are conducted at very low temperature, typically below 1 K [7, 11].

When a few monolayers of InAs are grown on a GaAs substrate, the lattice mismatch between the two materials induces a strain which leads to the breakdown of a 2D layered structure and the emergence of randomly distributed self-crystallized islands called self-assembled quantum dots (SAQDs) on the GaAs substrate [41–44] (for a more complete list of references see, e.g., Jiang [45]). The confinement in SAQDs is determined by the conduction band offset between InAs and GaAs and is therefore much stronger than in PQDs and VQDs. This leads to pyramidal or lens-shape structures with sizes of approximately 100 Å. Pyramidal QDs are very promising structures for laser applications [46–49] because of their spectral purity, relative insensitivity to temperature, low current threshold, and high differential gain [50, 51]. However, they are relatively small to be addressed individually by electrical means, which constitutes an important drawback for electronic applications.

Even more promising candidates for room temperature devices are the so called "silicon nanocrystal s" which consist of 50 Å diameter spherical silicon particles embedded in silicon dioxide [52–55]. Here the eigenlevel separation is typically about 100 meV [56]. Several groups have fabricated flash memories based on nanocrystal s which surpass classical CMOS devices in terms of retention time and power consumption.

3. COULOMB BLOCKADE EFFECT AND SINGLE-ELECTRON TUNNELING

The ability to observe the single-electron charging effect relies essentially on the *Coulomb blockade effect* (CBE), which can be described as discrete changes in charging energy of an ultrasmall capacitor due to electrostatic interactions between electrons. We follow Likharev [6] and consider a small piece of conducting material called the *island* as being "somehow" isolated from its surrounding. Originally, the island is electrically neutral (Fig. 4a) and therefore, little work is required to bring an electron on the island. However, since the island is well isolated, after accepting the

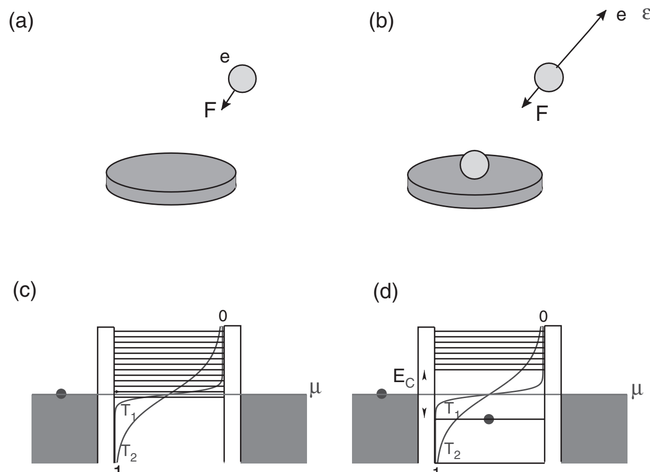

Figure 4. Principle of the CBE: spatial (a and b) and energetic (c and d), representation before (a and c) and after (b and d) the addition of a single electron as explained in detail in the text. Adapted with permission from [60], K. Likharev, *Proc. IEEE* 87, 606 (1999). © 1999, IEEE.

electron, the island charge becomes $-e$ (Fig. 4b). In order to add another electron on the island, one must then overcome the repulsive force originating from the electric field ε. The required energy is called the *charging energy* E_C. This situation is contrasted with a large conductor where charges are allowed to redistribute easily, and the individual electronic charges in the capacitor can be readily screened by polarizing charges in the system. Here, the island is a QD isolated from a reservoir by tunnel barriers and the injection of electrons is controlled by a gate capacitively coupled to the dot; that is, the electric field from the QD electrons can only be screened by adjusting the external control gate potential. If C is the effective capacitance between the dot and the reservoir, the charging energy is [6]

$$E_C = \frac{e^2}{C} \tag{1}$$

Although CBE was already observed in thin metallic films as early as 1950 by Gorter [4], single electronics gained popularity in the mid 1980s with the development of the so-called "orthodox theory" by Kulik and Shekhter [5] and Averin and Likharev [6]. This theory immediately supported by almost all experiments with metallic conductors. A theory similar to the orthodox theory, but taking into account level quantization in the dot, was later developed by Averin [57] and Beenakker [58].

3.1. The Coulomb Blockade Regime

It is worth mentioning that there is an visible contradiction between this classical picture—an integer number of electron N in the dot—and the quantum mechanical picture which associates to any observable an average value, here $\langle N \rangle$, and fluctuations with respect to this value, here the standard deviation $\langle \delta N \rangle$. In order to reconcile these two pictures, $\langle \delta N \rangle$ must be much smaller than 1. This criterion

is met if the average time $\langle\tau\rangle$ spent by the electron inside the dot is much larger than the charging time, $\Delta\tau > \hbar/SE$, where SE is the electron level broadening. In other words, the tunnel barriers must be opaque enough to prevent the electron from going back and forth between the dot and the reservoir. To quantify the opacity of the barrier by a resistance R, we use Thouless's argument [58]: let $i_e = e/\langle\tau\rangle$ be the current provided by one electron flowing across the barrier and let v_B be the bias allowing this current to flow. Then $R = v_B/i_e$. From Heisenberg uncertainty relation $\Delta\tau\,\delta E \geq \hbar$ and the condition for observation of CBE (i.e., $\langle\tau\rangle \gg \Delta\tau$ and $\delta E \ll ev_B$), we obtain

$$R \gg \frac{\hbar}{e^2} \tag{2}$$

$\hbar/e^2 \approx 4\ k\Omega$ is called the *quantum resistance*. When Eq. (2) is satisfied, it can be shown [26] that *cotunneling*—a two-electron process in which one electron from the lead tunnels into the dot while a second electron tunnels simultaneously from another state in the dot to the lead—can be neglected as well.

In the other regime (i.e., $R \leq \hbar/e^2$), when the barriers are too transparent (not high or wide enough), the electron wave function extends largely over the barriers and the electron cannot be treated as a localized particle. This regime corresponds to the *Kondo effect* [59] and is not treated here.

Moreover, CBE can only be observed if the charging energy is much larger than thermal fluctuations in the system. According to Likharev [60], $E_C \approx 100k_BT$ is a good condition for preventing CBE to be smeared out by thermal fluctuations. This situation is illustrated in Figures 4c and 4d where the Fermi–Dirac distribution has been superimposed on the energy levels inside the dot to account for thermal fluctuations at $T = T_1$ and T_2 ($T_1 < T_2$). When the dot is empty (Fig. 4c), an electron outside the dot can tunnel at both temperatures. When there is one electron inside the dot, the CBE creates a gap in the energy spectrum of the dot (Fig. 4d). At $T \leq T_1$, in the *Coulomb blockade regime* (CBR), there are no levels available to the electron outside the dot, and the conduction is suppressed. At $T = T_2$, thermal fluctuations make higher levels available to the outside electron, and the CBE is washed out.

In summary, the CBR can be characterized by these two criteria:

$$R \gg \frac{\hbar}{e^2} \qquad E_C \gg k_BT \tag{3}$$

3.2. Quantum Dot Statistics

A QD weakly coupled to a reservoir must be treated as a grand canonical system since, on one hand, the QD exchanges particles and energy with the reservoir and, on the other hand, the reservoir determines the temperature T and the electrochemical potential μ in the dot.

Under this framework, let $\{n_j\} = \{n_1, n_2, \dots, n_k, \dots\}$ be a dot configuration; that is, n_k represents the number of electrons occupying the many-body eigenlevel ε_k ($n_k = 0$ or 1 for fermions) and such that $\sum_k n_k = N$, the number of electrons in the dot. From Gibbs distribution, the probability for the dot to be in the configuration $\{n_j\}$ reads [61]

$$P(\{n_j\}) = \frac{1}{\Xi}\exp\left[-\beta\left(\sum_i n_i\varepsilon_i + U(N) - N\mu\right)\right] \tag{4}$$

where μ is the electrochemical potential of the reservoir measured with respect to the bottom of the conduction band, $\beta = (K_BT)^{-1}$, and Ξ is the grand partition function,

$$\Xi = \sum_{\{n_j\}}\exp\left[-\beta\left(\sum_i n_i\varepsilon_i + U(N) - N\mu\right)\right] \tag{5}$$

and where

$$U(N) = \int_0^{Ne}\phi(Q)\,dQ \tag{6}$$

is the electrostatic energy of the dot with ϕ being the potential difference between the dot and the reservoir.

To obtain the probability that the dot contains N electrons, we need to sum Eq. (4) over all configurations such that $\sum_k n_k = N$

$$P(N) = \sum_{\{n_j\},\,\sum_k n_k = N} P(\{n_j\}) \tag{7}$$

which can be rewritten

$$P(N) = \frac{1}{\Xi}\exp[-\beta(F(N) - \mu N)] \tag{8}$$

where $F(N)$ is the Helmholtz free energy

$$F(N) = -\frac{1}{\beta}\ln\left\{\sum_{\{n_i\},\,\sum_i n_i = N}\exp\left[-\beta\left(\sum_i n_i\varepsilon_i + U(N)\right)\right]\right\} \tag{9}$$

In order to derive a simple relation between the potential and the number of electrons in the dot at very low temperature, and following Beenakker [58], it is assumed that there is a dominant configuration $\{n_k\}$ in the summation so that $F(N)$ takes the simplified form

$$F(N) = \sum_i n_i\varepsilon_i + U(N) \tag{10}$$

The equilibrium configuration corresponds to the integer N that minimizes $F(N) - N\mu = \Omega(N)$, the grand potential. At very low temperature, either $P(N) \neq 0$ for one single value of N, which corresponds to a stable configuration in the dot, that is, there is no fluctuation allowed (Fig. 5a, b, d), or there are two nonzero values N and $N-1$ such that $P(N) = P(N-1)$ (Fig. 5c). According to Eq. (8), this leads to

$$\mu = F(N) - F(N-1) \tag{11}$$

which states that the electrochemical potential in the dot is equal to the electrochemical potential in the reservoir. Then, the number of electrons in the dot can fluctuate between N and $N-1$; the sequence $N-1 \to N \to N-1$ is allowed and corresponds to a single-electron tunneling event.

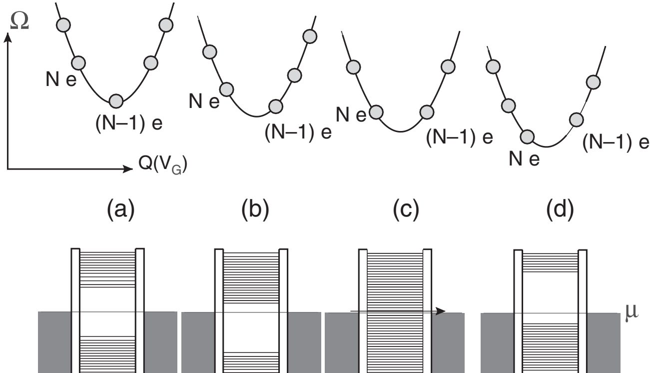

Figure 5. Illustration of single-electron tunneling and Coulomb blockade effect as the gate voltage V_G is swept. (a) The grand potential is minimized for $Q = (N-1)e$. The number of electrons in the dot is fixed, a gap is created in the energy levels, and tunneling is suppressed by CBE. (c) When the grand potential is minimized for $Q = (N-1/2)e$, the number of electrons can fluctuate between $N-1$ and N, the gap has vanished, and single-electron tunneling is allowed. (b) and (d) show intermediate situations. Adapted with permission from [10], M. Kastner, *Phys. Today*, 24, Jan (1993). © 1993, American Institute of Physics.

3.3. The Single-Electron Transistor

Single-electron transistors (SETs) are three terminal devices based on the CBE where the number of electrons inside a dot and the transfer of electrons one by one from a reservoir called the *source* to another reservoir called the *drain* through two series tunnel junctions is controlled by a *gate* [7]. They are schematically represented by Figure 6a, and the operation principle is similar to a MOSFET.

When the conditions (3) for CBR are satisfied, the tunnel junctions can be approximated by capacitors and the equivalent circuit for single electron transistor is shown in Figure 6b.

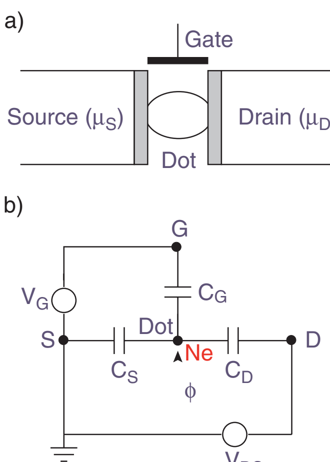

Figure 6. (a) Schematic diagram of a SET and (b) equivalent circuit in the CBR. Adapted with permission from [60], K. Likharev, *Proc. IEEE* 87, 606 (1999). © 1999, IEEE.

Solving the equivalent circuit, we find for the potential of the dot [62]

$$\phi = \frac{1}{C_\Sigma}\left(Ne - C_D V_{DS} - C_G V_G\right) \tag{12}$$

where C_G, C_S, and C_D are the gate, source, and drain capacitance, respectively, and $C_\Sigma = C_G + C_S + C_D$.

3.3.1. Linear Regime: Coulomb Oscillations

Here, we derive the condition for single-electron tunneling as a function of the gate voltage when the SET operates close to zero source-drain bias.

Using Eqs. (10) and (12) with $V_{DS} = 0$, the grand potential reads

$$\Omega(N) = \frac{(Ne)^2}{2C_\Sigma} - Ne\frac{C_G}{C_\Sigma}V_G + \sum_{i=1}^{N}\varepsilon_i - \mu N \tag{13}$$

and the condition (11) to observe single-electron tunneling becomes

$$\frac{(N-1/2)e^2}{C_\Sigma} - eV_G\frac{C_G}{C_\Sigma} + \xi(N) = \mu \tag{14}$$

where $\xi(N) = \sum_{i=1}^{N}\varepsilon_i(N) - \sum_{i=1}^{N-1}\varepsilon_i(N-1)$.

In summary, at equilibrium, as the gate voltage is swept continuously, there is alternation between Coulomb blockade and single-electron tunneling events. Typical experimental data of the current probed when a small bias ($\approx 150\,\mu$V) is applied between the source and the drain are shown in Figure 7. For each single-electron tunneling, a current peak or *Coulomb oscillation* (CO) is measured. It can be shown that the height of the CO is proportional to V_{DS} [58] and thus the small source-drain bias regime is usually called the *linear regime*.

The interval between two single-electron tunneling events reads

$$\Delta V_G = \eta^{-1}\left(\frac{e}{C_\Sigma} + \frac{1}{e}\left(\xi(N+1) - \xi(N)\right)\right) \tag{15}$$

since the electrochemical potential of the reservoir is insensitive to the fluctuations in the dot. The ratio $\eta = C_G/C_\Sigma$

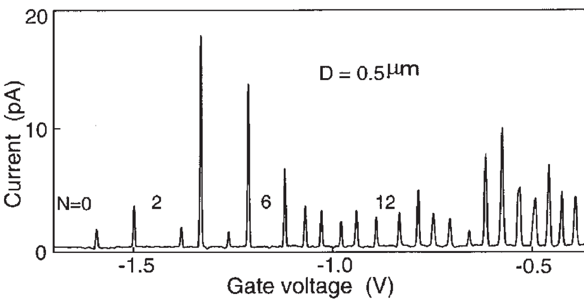

Figure 7. Coulomb oscillations as a function of the gate voltage for Tarucha's structure showing the irregular current peak spacing. Reprinted with permission from [11], S. Tarucha et al., *Phys. Rev. Lett.* 77, 3613 (1996). © 1996, American Institute of Physics.

can be seen as the gate efficiency if one notices that, all other quantities being unchanged,

$$\Delta\phi = \eta\Delta V_G = \left(\frac{e}{C_\Sigma} + \frac{1}{e}(\xi(N+1) - \xi(N))\right) \tag{16}$$

The quantity $E_a = e\Delta\phi$ is called the *addition energy* and its computation is a major issue of this work. It represents the amount of energy needed to add an electron in the dot. The addition energy is a very important parameter for single-electron devices, as crucial as the threshold voltage in MOSFETs.

If we set $C_Q(N) = e^2/(\xi(N+1) - \xi(N))$, Eq. (16) can be rewritten in terms of capacitances

$$\frac{1}{C(N)} = \frac{1}{C_\Sigma} + \frac{1}{C_Q(N)} \tag{17}$$

to introduce the dot capacitance $C(N)$, which consists of a classical contribution C_Σ depending only on the device geometry, that is, independent of N, a quantum contribution C_Q, highly dependent on N [63].

The addition energy (AE) is also defined in the literature as

$$E_a(N) \equiv \Delta_2(N) \equiv \mu(N+1) - \mu(N) \tag{18}$$

which can be understood by looking at Figure 8. The addition energy E_a can be thought of as the amount of energy provided by the gate to add an electron to the dot. This corresponds to the difference $\mu(N+1) - \mu(N)$, at constant V_G.

It is common to distinguish between the classical CBE, when the dot size is much larger than the de Broglie wavelength (Fig. 9a) and the quantum CBE, when the dot size is of the same order as the de Broglie wavelength (Fig. 9b).

3.3.2. Classical Limit

When the dot size is much larger than the de Broglie wavelength, the level spacing $\Delta\varepsilon \ll E_C$. Therefore, the second term of the right hand side of Eq. (15) can be safely neglected and the Coulomb oscillations are periodic, with period e/C_G: This is the classical limit as shown in Figure 10. The charging diagram that exhibits a staircase profile is also shown in this figure.

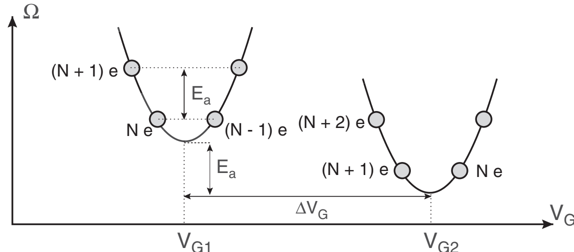

Figure 8. Grand potential Ω as a function of V_G at the transition between $N-1$ and N electrons in the dot (left curve) and the transition between N and $N+1$ electrons in the dot (right curve) that shows that the addition energy can be interpreted as the amount of energy provided by the gate in order to add an electron to the dot.

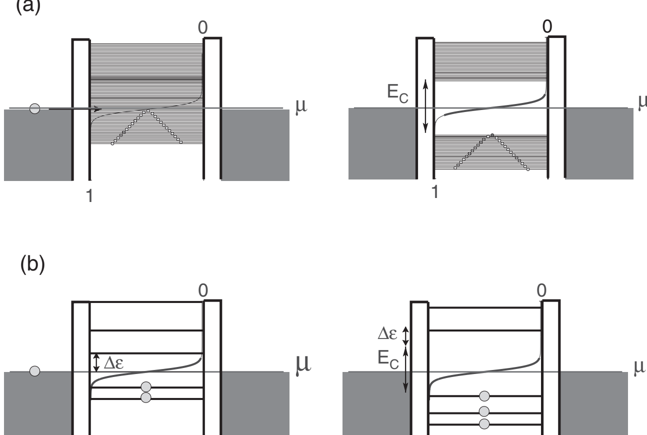

Figure 9. Illustration of the two CBRs: (a) When the dot size in much bigger than the de Broglie wavelength, the level spacing $\Delta\varepsilon$ is much smaller than the charging energy E_C which can be considered as the energy required to add an electron in the dot. (b) In smaller dots, $\Delta\varepsilon$ become of the order of E_C and can no longer be neglected in the calculations.

Based on an equation similar to (13), Averin and Likharev developed the "orthodox" theory where they used a master equation approach to derive the time evolution of $P(N)$ [6]. This theory was very successful in explaining single-electron effects in metal tunnel junctions where quantum effects such as discreteness of energy levels do not play an important role.

3.3.3. Quantum Limit

When the dot size is comparable to the de Broglie wavelength, electron energy quantization should be taken into account as shown in Figure 9b. In order to add an electron to the dot, not only does the classical charging energy have to be overcome but also $\Delta\varepsilon$, which is now comparable to E_C.

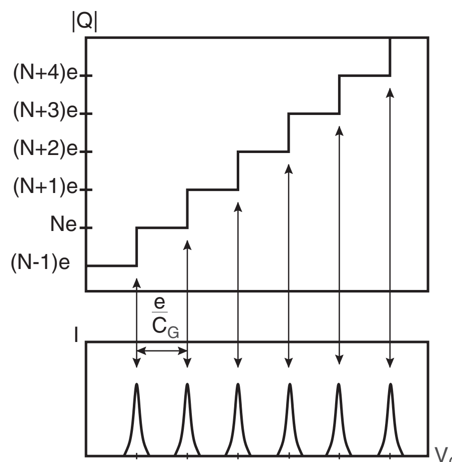

Figure 10. Coulomb staircase (top) and COs (bottom) as a function of the gate voltage V_G in the classical CBR, showing the periodicity e/C_G of the COs. Adapted with permission from [26], U. Meirav and E. Foxman, *Semicond. Sci. Technol.* 10, 255 (1996). © 1996, IOP Publishing.

In very small dots, $\Delta\varepsilon$ can even become the main contribution in ΔV_G and (15) reads $\Delta V_G \approx \xi(N+1) - \xi(N)$; that is, the COs are governed by the level spacing in the dot.

In this study, we consider QDs of intermediate sizes, for which no simplification of Eq. (15) is made. Moreover, the term $\xi(N+1) - \xi(N)$ hides a complicated many-body problem because the addition of a new electron in the dot takes into account a combination of electron–electron repulsion and exchange-correlation effects based on the occupation of quantum orbitals and electron spins. Therefore, this term can only be computed accurately by solving a many-body Schrödinger equation.

4. TARUCHA'S EXPERIMENT

The first reproducible experiments on single-electron charging effects with QDs in the quantum limit were achieved only recently by Tarucha and co-workers [9, 11, 35]. Figure 3 shows a schematic diagram of Tarucha's vertical QD [9, 11, 31, 33, 34]. The structure consists of an undoped 12 nm $In_{0.05}Ga_{0.95}As$ well and undoped $Al_{0.22}Ga_{0.78}As$ barriers of thickness 9 and 7.5 nm. This difference in the barrier thickness is required to facilitate accumulation of electrons in the dot in nonlinear transport. The inclusion of indium in the well is a major breakthrough to immune QD to fluctuations. In earlier devices, the well was made of GaAs [31]. However, to position the well bottom below the Fermi level, the AlGaAs barrier had to be doped, which increases the probability of dopant diffusion into the dot. The inclusion of indium in the well lowers the bottom of the conduction band and circumvents the drawbacks of delta doped AlGaAs barriers of earlier devices. The lead on the side of the thinner (thicker) tunnel barrier is made of n^+GaAs and is referred to as the source (drain). The doping is gradually reduced from the source (drain) to the double barrier heterostructure (DBH). The DBH is etched to a point below the DBH to form either a circular [9, 11, 31, 33–35, 64–66] or a rectangular [9, 32, 66, 67] mesa. A Schottky gate surrounding the mesa controls the number of electrons in the dot. The surrounding Schottky gate is another improvement with respect to other devices. In conventional planar technology, etching is performed to a point above the DBH and the Schottky gate is placed on top of the device. This innovation allows better control in pinching off the conducing channel [31].

Experimental measurements were made with samples cooled in a dilution refrigerator and the electron temperature was estimated to be about 0.2 K. A very small voltage is applied between the source and drain contacts and a current flowing through the dot is measured as the gate voltage is swept. The gate voltage raises or lowers the electrostatic potential of the dot relative to the source and drain. In order to observe COs, one should operate close to the zero source-drain bias for which tunnel barrier asymmetry mentioned above is irrelevant. Thus, when the source-drain bias is small, most of the time, the current is zero due to the Coulomb blockade but occasionally the Coulomb gap is lifted and current flows (i.e., the number of electrons in the dot oscillates between N and $N+1$), and current oscillations are observed as seen in Figure 7. Clearly, as N decreases, the current oscillations are more irregularly spaced. This was already observed by Dellow et al. [36] but was attributed to inhomogeneities in the dot. In contrast, in these experiments, the irregularities are systematic and depend on N, suggesting a mapping between the current peak interval and the energy level spacing in the dot. In order to confirm this idea, the addition energy, $\Delta\mu$, is measured as a function of N. From Eq. (16), $\Delta\mu = \eta\Delta V_G$, where ΔV_G is measured from the COs and η is deduced from the Coulomb diamonds of Figure 11 [11]. As shown in Figure 12a, the AE is unusually large for $N = 2, 6$, and 12, which suggests the influences of quantum effects in the AE spectrum of the QD.

5. THE MANY-BODY HAMILTONIAN OF ARTIFICIAL ATOMS

The electronic spectrum of N-electron QDs is computed by considering the many-body Hamiltonian

$$H = \sum_i H_{oi} + \sum_{i \neq j} H_{ij} \tag{19}$$

where H_{oi} is the single-particle Hamiltonian of the ith electron and

$$H_{ij} = \frac{e^2}{\epsilon |\mathbf{r}_i - \mathbf{r}_j|} \tag{20}$$

is the interaction Hamiltonian describing the Coulomb interaction amongst carriers. Here ϵ is the dielectric constant of the material. In the second term of Eq. (19), the sum is carried out on $i \neq j$ avoiding the interaction of carrier with themselves. Quite generally the Hamiltonian Eq. (19) is used for solving the Schrödinger equation for the many-particle energies and wavefunctions

$$E = E_N(1, 2, 3, \ldots, N) \tag{21}$$

$$\Psi = \Psi_N(\mathbf{r}_1, \mathbf{r}_2, \mathbf{r}_3, \ldots, \mathbf{r}_N) \tag{22}$$

which given the two-body interaction (20) can only be solved exactly for $N = 2$. In this section we will describe a natural approach toward the solution of this problem for a general number N of electrons by considering successive approximations.

5.1. Single-Particle Hamiltonian and Shell Structures

We start by considering a system of independent and 3D confined electrons in the conduction band. By neglecting the interaction H_{ij}, the Hamiltonian (19) is reduced to a sum of single particle Hamiltonians, each of the same form

$$H_{oi} = H_i = \frac{p_x^2 + p_y^2 + p_z^2}{2m^*} + V(\boldsymbol{r}) \tag{23}$$

Here we assume the electrons can be described with an effective mass m^*; p_x, p_x, p_x are the components of the electron momentum and $V(\boldsymbol{r})$ is the external potential which contains several contributions according to the confinement achieved in the quantum dot. We will also assume that the QD is realized by confinement of the electrons in an heterostructure quantum well along the z-direction and electrostatic confinement in the x–y plane. The latter confinement results usually from dopant atoms in neighboring semiconductor layers and from the fringing field of the metal electrodes on the semiconductor surfaces. This configuration is most commonly achieved in PQDs [7] and Tarucha's VQD structure [9], and results in a first approximation in a 2D parabolic potential in the x–y plane (Fig. 13). Confinement at the heterostructure along the z-direction is generally strong ($\approx$10 nm) with energy separation of the order of 50–100 meV, while the x–y planar confinement is much weaker with energy separation of the order of 1 meV over larger distances (>100 nm). In that case, the external potential is separable in a first approximation,

$$V(\boldsymbol{r}) = V_1(x, y) + V_2(z) \tag{24}$$

which results in the energy spectrum $\varepsilon_{\nu, n_x, n_y} = \varepsilon_\nu + \varepsilon_{n_x, n_y}$ with corresponding wavefunctions $\Psi_\nu(z)\,\Psi_{n_x, n_y}(x, y)$ where ε_ν (ε_{n_x, n_y}) is the spectrum resulting from the z-potential ($x - y$ potential). Hence, each value of the ν-quantum number gives a series of $x - y$ energy levels. At low temperature, given the large separation between the ε_ν energy states, only the first levels of the lowest series $\nu = 0$ are occupied by electrons. If one further assumes that the $V_1(x, y)$ potential is cylindrically symmetric, the $\nu = 0$ energy spectrum is written as

$$\varepsilon_{0, n_x, n_y} = \varepsilon_{0, n, l} = \varepsilon_0 + n\,\hbar\omega \tag{25}$$

where ω is frequency of the cylindrical parabolic potential. Here each n-level is $2n$-times degenerate with the factor 2 accounting for the spin degeneracy. The number n (=1, 2, 3, ...) is the radial quantum number and the number l (=0, ±1, ±2, ...) is the angular momentum quantum number. Hence the 2D cylindrical parabolic potential results in 2D orbitals supporting 2, 4, 6, 8, ... electrons which give rise to shell structures filled with 2, 6, 12, 20, ... particles, thereby creating a sequence of numbers which can be regarded as the 2D analogues of "magic numbers" in atomic physics.

In the absence of cylindrical or square symmetry, the parabolic potentials are characterized by two different frequencies, ω_x and ω_y, which lift the azimuthal degeneracy on the l-number of the 2D artificial atoms. Therefore electronic states are spin-degenerate only and determine a sequence of shell filling numbers 2, 4, 6, 8, ... of period or increment 2. Only when the ratio $K = \omega_x/\omega_y$ is commensurable does the sequence of filling numbers deviate from the period 2 and provide new sequences of numbers for particular combinations of the n_x and n_z quantum numbers in the case of accidental degeneracy.

5.2. Hartree–Fock Approximation and Hund's Rules

5.2.1. The Hartree–Fock Approximation

The natural extension of the atomic model for independent 3D confined electrons is the consideration of the Coulomb interaction between particles in the Hartree–Fock (HF) approximation. The HF scheme has the advantage of conserving the single-particle picture for the many-body state of the system by representing the total wavefunction as a

product of single-particle wavefunctions in a Slater determinant which obeys Fermi statistics. The main consequence of the HF approximation for the Coulomb interaction between particle is a correction of two terms to the single-particle energies derived from the H_o Hamiltonian;

$$\varepsilon_i = \varepsilon_{\nu,n,l} + \frac{e^2}{\epsilon}\sum_{j\neq i}\int \frac{\psi_j^*(\mathbf{r}')\psi_j(\mathbf{r}')\psi_i^*(\mathbf{r})\psi_i(\mathbf{r})\,d\mathbf{r}\,d\mathbf{r}'}{|\mathbf{r}-\mathbf{r}'|} - \frac{e^2}{\epsilon}\sum_{j\neq i}\int \frac{\psi_i^*(\mathbf{r})'\psi_j(\mathbf{r}')\psi_i(\mathbf{r})\psi_j^*(\mathbf{r})\,d\mathbf{r}\,d\mathbf{r}'}{|\mathbf{r}-\mathbf{r}'|} \tag{26}$$

where the first sum is the Hartree energy carried on all occupied j-states different from the i-state, irrespectively of their spins, and accounts for the classical repulsion between electrons. The second term is the attractive exchange interaction which occurs between carriers with parallel spins. In this scheme, the wavefunctions $\Psi_i(\mathbf{r})$ satisfy the HF integro-differential equation where the Coulomb interaction term depends upon all the other single-particle wavefunctions of the occupied states. The HF equation is therefore nonlinear and must be solved self-consistently for all wavefunctions of occupied states.

5.2.2. Hund's Rules

In atomic physics, the ground state of atoms can be approximated by first neglecting the electron–electron interaction and considering that individual electrons occupy a single-particle hydrogenic state (n, l, m). In this model, the total energy depends only on the radial quantum number n so that, for a given value of n, there are $2n^2$ degenerate eigenstates, including spin. In reality, however, electron–electron interaction lifts up these degeneracies so that the order of occupation is not arbitrary. Friedrich Hund devised a set of rules to identify the lowest energy electron configuration when such a "quasi-degenerate" set of levels has to be filled [68]:

1. *The configuration with the highest total spin S will have the lowest energy.*

   This rule relies on the fact that exchange between electrons of identical spin reduces the total energy of the configuration. Moreover, the Hartree energy of the configuration is reduced when an electron occupies a free orbital rather than an already partially occupied orbital since there is then less overlap between occupied orbitals.
2. *For a given total spin S, the term with the highest value of the total orbital angular momentum L will have the lowest energy.*

   The basis of this rule is that electrons with a high value of L (i.e., orbiting in the same direction) will meet less often than electrons with low value of L (i.e., orbiting in opposite directions), thereby reducing their Coulomb repulsion [68].
3. *For atoms with less (more) than half-filled shells, the level with the lowest (highest) value of the total angular momentum J will have the lowest energy*

   The origin of that rule is the spin–orbit coupling [68].

The orbitals of QDs studied here exhibit degeneracies due to circular rather than spherical symmetry. Therefore, the degree of degeneracy is reduced in QDs compared to real atoms so that only Hund's first rule needs to be invoked to resolve degenerate configurations.

5.2.3. Hund's First Rule in Quantum Dots

One of the important consequences of the HF approximation for interelectron interaction (20) is the prediction of spin effects in the shell filling of artificial atoms similar to Hund's rules in atomic physics. These effects are illustrated in the charging energy of a few electron QDs with cylindrical parabolic potential achieved in planar or vertical quantum structures. In Figure 14a, we show schematically the Coulomb staircase resulting from charging a QD with a few electrons as a function of the charging energy or voltage between the metal electrode or gate and the semiconductor substrate. The relative step sizes of the staircase represent the amount of energy needed to put an additional electron in the dot. The arrows on each step represent the spin of each individual electron on the successive orbitals during the charging process. The filling of the first shell (s-orbital with two electrons) consists of one electron with spin up followed by an electron with spin down. The step size of the spin-up electron measures the charging energy needed to overcome the Coulomb repulsion against the spin-down electron, which is just the Hartree energy between the two particles. The larger step size of the second (spin-down) electron is due to the fact that the charging of the third electron requires overcoming the Coulomb repulsion energy augmented by the energy to access the next quantized level, which is the first p-orbitals. The latter process starts the second shell filling with the third electron on either one of the degenerate $l = \pm 1$ orbitals of either spins (here we choose the $l = -1$ and the spin-up). At this stage, the configuration

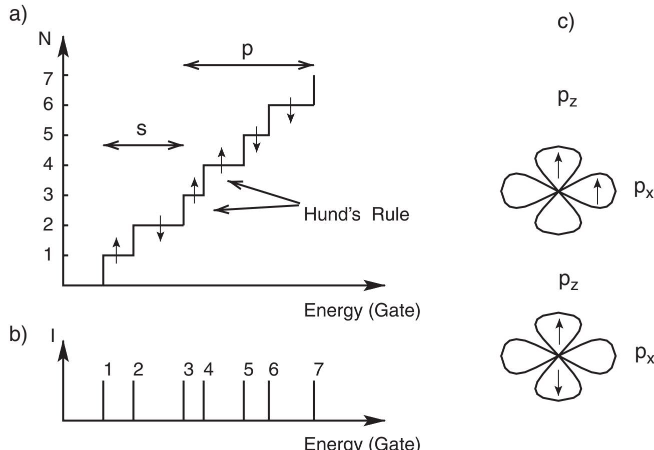

Figure 14. (a) Coulomb staircase as a function of the charging energy with the spin states of each electron. The horizontal two head arrows indicate the occupation of the s- and p-orbitals in the dot. (b) COs versus the charging energy. (c) 2D p-orbitals illustrating the two possible occupations of two electrons with parallel (top) and antiparallel spins (bottom). Reprinted with permission from [112], J.-P. Leburton and S. Nagaraja, "Optical Spectroscopy of Low Dimensional Semiconductor," NATO ASI Ser. E, Vol. 344, p. 235. © 1997, Kluwer Academic.

with the fourth electron on the $l = 1$ orbital with a parallel spin becomes more favorable because it minimizes the Hartree energy between orbitals of different quantum numbers and results in an attractive exchange energy between the two electrons (Fig. 14c). This is the reason the third step is smaller than the first and the second steps, requiring less energy and evidencing Hund's rule in the electron filling of the 2D artificial atom. The fourth step is wide because the addition of the fifth electron on either of the p-orbitals with $l = \pm 1$ must correspond to a spin-down electron which undergoes a repulsion from the two other p-electrons without benefitting from the exchange with them since its spin is antiparallel. Figure 14b shows the schematics of current peaks resulting from the single-electron charging of the QD which is obtained by differentiating the Coulomb staircase and which for the first two shells is consistent with the experimental data of Tarucha (Fig. 7).

Hence the HF approximation provides a reasonable picture of the contribution of electron–electron interaction and spin effects in the spectrum of quantum dots. However, it is well known from atomic physics and theoretical condensed matter physics that this approximation suffers from two important drawbacks which are the neglect of electron correlation and the fact that it overestimates the exchange energy. Moreover, it leads to a tedious solution of the self-consistent problem when involving a large number of electrons and makes it difficult to apply to quantum devices in accounting for the environment of heterolayers and doping as well as boundary conditions at the semiconductor interfaces with metal electrodes. Hence no single HF model to date reproduces one-to-one the absolute values of $E_a(N)$ actually observed in VQDs [66, 69–71]. Model calculations understandably but nevertheless include some arbitrary assumptions, typically a rigid or perfectly parabolic confinement, perfect circular symmetry, and the neglect of 3D effects [69, 72–74], which may not be completely realistic. In particular, it has been shown that maximal spin alignment still consistent with Hund's first rule can lead to different secondary maxima in the $0T$ third shell addition energy spectrum depending on the actual electronic configurations in realistic VQDs [71]. We argue that behavior which would widely be regarded as "anomalous" is a consequence of understandable many-body interactions and is strongly influenced by the exact profile of the 3D VQD confining potential. This issue is addressed in the following sections.

6. QUANTUM DOTS AS ELECTRONIC DEVICES

In order to investigate the effect of 3D geometry on the confining potential in the dot and describe its deviations from parabolicity, we model the CVQD as a cylindrical structure (Fig. 15) by taking into account macroscopic parameters, such as the doping of the source and the drain (N_D), the radius of the device (R), the pinning of the conduction band at the Schottky gate interface (ϕ_S), and the well width ($2z_i$), and include the effects of the third dimension.

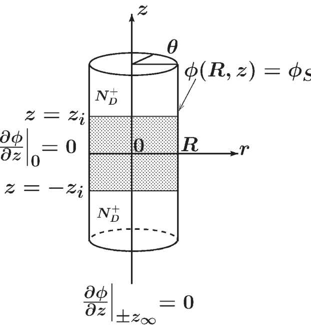

Figure 15. Cylindrical charge model for the cylindrical VQD structure with boundary conditions. N_D^+ is the ionized donor concentration, and (r, θ, z) are the cylindrical coordinates. 6.1. Potential Model

The model consists of an intrinsic region for $-z_i \leq z \leq z_i$ surrounded by two depleted regions for $|z| > |z_i|$, which extends up to $z = \pm z_\infty$ where it becomes neutral. The structure is assumed to be symmetric around $z = 0$, and the potential $\phi = \phi(r, z)$ does not depend on θ. The dot is also assumed to be empty of electrons in order to capture only the structural effects, as opposed to the many-body effects due to electron–electron interactions, on the confining potential. We obtain the confining potential ϕ by solving the 3D Poisson equation

$$\frac{\partial^2 \phi}{\partial r^2} + \frac{1}{r}\frac{\partial \phi}{\partial r} + \frac{1}{r^2}\frac{\partial^2 \phi}{\partial \theta^2} + \frac{\partial^2 \phi}{\partial z^2} = -\frac{\rho}{\epsilon} \tag{27}$$

where ρ is the charge density such as

$$\rho = 0 \qquad (-z_i < z < z_i)$$

and

$$\rho = qN_D^+ \qquad (|z| > z_i)$$

Here, ϵ is the dielectric constant. Since $z_{\pm\infty} \approx 300$ Å is much smaller than the source (drain)–DBH distance (4000 Å), the doping variation is neglected in this analytical model. The boundary conditions at $z = \pm z_\infty$ are such as the z-field is relaxed; that is, $(\partial\phi/\partial z)|_{\pm z_\infty} = 0$, and $\phi_S = \phi(R, z)$ is the Schottky barrier potential at the gate interface ($r = R$).

6.1.1. *Intrinsic Region* ($0 \leq |z| \leq |z_i|$)

We separate variables to solve Eq. (27) and find for the potential [71]

$$\phi(r, z) = \phi_S + \sum_n A_n J_0(\gamma_n r)(e^{-\gamma_n z} + e^{\gamma_n z}) \tag{28}$$

where $\gamma_n = \mu_n/R$ and μ_j is the jth zero of the zero order Bessel function of the first kind J_0.

6.1.2. N-*Doped Region* ($|z| > |z_i|$)

By using the same technique as above, we find

$$\phi(r,z) = \phi_S - K(R^2 - r^2) + \sum_n B_n J_0(\gamma_n r) \cdot e^{\gamma_n z_\infty}(e^{-\gamma_n(z-z_\infty)} + e^{\gamma_n(z-z_\infty)}) \tag{29}$$

where $K = qN_D^+/4\epsilon$. The constants A_n and B_n are determined by matching the values of ϕ and $\partial\phi/\partial z$ with the solutions found at $z = \pm z_i$, which yields

$$A_n = \frac{2KR^2}{\mu_n^2}\frac{J_2(\mu_n)}{J_1^2(\mu_n)}\frac{sh[\gamma_n(z_\infty - z_i)]}{sh[\gamma_n z_\infty]} \tag{30}$$

and

$$B_n = \frac{-2KR^2\, e^{-\gamma_n z_\infty}}{\mu_n^2}\frac{J_2(\mu_n)}{J_1^2(\mu_n)}\frac{sh[\gamma_n z_i]}{sh[\gamma_n z_\infty]} \tag{31}$$

so that the potential inside the dot can be rewritten

$$\phi(r,z) = \phi_s - \frac{qN_D^+R^2}{\epsilon}\sum_{n=0}\frac{sh[\gamma_n(z_\infty - z_i)]}{sh(\gamma_n z_\infty)} \cdot \frac{J_2(\mu_n)}{\mu_n^2 J_1^2(\mu_n)} J_0(\gamma_n r)\, ch(\gamma_n z) \tag{32}$$

By taking the limit $z \to 0$ in Eq. (32), we obtain the potential in the center of the dot. We make use of the power expansion of $J_0(x)$ and invert the summations to get the following expression;

$$\phi(r) = \phi_0 - \alpha\frac{qN_D^+}{4\epsilon}r^2 - \Lambda\left(\frac{r}{R}\right)r^4 \tag{33}$$

If we denote

$$C_n = \frac{sh(\gamma_n(z_\infty - z_i))}{sh(\gamma_n z_\infty)}\frac{J_2(\mu_n)}{J_1^2(\mu_n)} \tag{34}$$

which is simply a structure factor depending on the problem geometry, the first term

$$\phi_0(V_G, N_D^+) = \phi_S(V_G) - \frac{qN_D^+R^2}{\epsilon}\sum_n\frac{C_n}{\mu_n^2} \tag{35}$$

represents the potential in the bottom of the dot that depends on the applied gate voltage V_G. The second term is the harmonic term with the form factor $\alpha = \sum_n C_n$. We notice that this term does not scale directly with the dot radius R, nor V_G. However, there is a hidden dependence on these factors through the α-parameter that is a function of R, z_i and z_∞, as shown in Figure 16. Our model predicts a weak dependence on the radius of the structure R (Fig. 16a) but a strong dependence on z_i and z_∞ (Fig. 16b and c). In plotting the R-dependence of the α-factor, we use $z_i = 175$ Å, according to device geometry, and $z_\infty \approx 350$ Å, which is extracted from the solution of our numerical model presented hereafter. The weak dependence on R is not surprising since the solution of the 2D harmonic oscillator (2DHO) is only a function of the doping level. The z_i-dependence can be understood by noticing that, by increasing the width of the intrinsic ($\rho = 0$) well, the field density, and thus the potential curvature in the longitudinal direction (z) decreases. In Figure 16b, we use $R = 2500$ Å, and we keep the depleted region $z_\infty - z_i$ constant at 200 Å in order to maintain the charge constant. The z_∞-dependence of α (here $R = 2500$ Å and $z_i = 175$ Å) is strong because the variation of z_∞ implies a significant change in the charge of the depleted region, which, via the Poisson equation, results in a strong variation of the electrostatic potential curvature. It is worth emphasizing that Figure 16c reflects the 3D nature of the potential variation, with correlation between its curvature along the radial and the longitudinal directions. Figure 17 shows that the 2D harmonic oscillator (dotted curve) model, with a spring constant $K = qN_D^+/4\epsilon$, overestimates the real potential curvature compared with 3D models. This is consistent with the z_i-dependence of the α factor previously obtained since the 2D harmonic oscillator picture can be considered as the limit for $z_i \to 0$ of the 3D problem (Fig. 16b). In practical problems, K is a fitting parameter

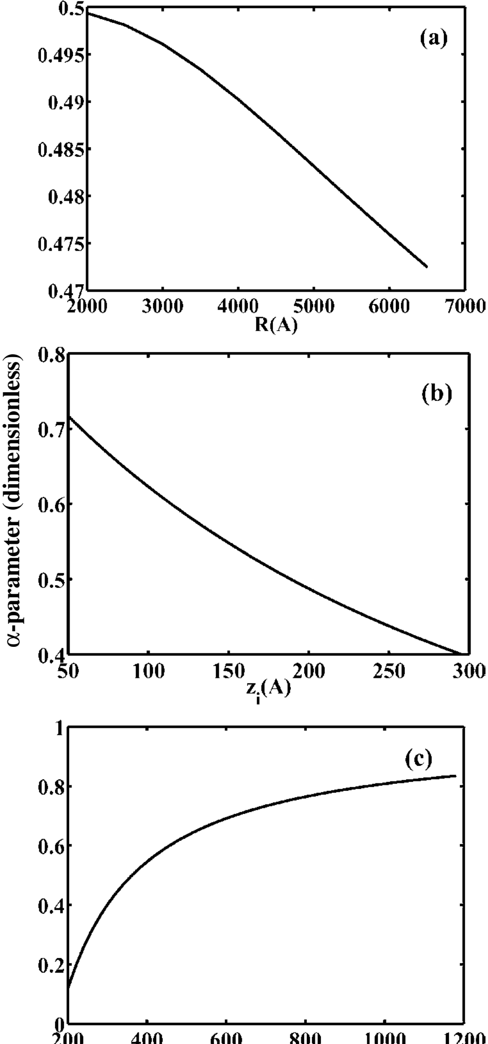

Figure 16. Variation of the form factor α as a function of (a) the dot radius R ($z_i = 175$ Å, $z_\infty \approx 350$ Å), (b) the well width $2z_i$ ($R = 2500$ Å, $z_\infty \approx 350$ Å), (c) the extension of the depletion width z_∞ ($R = 2500$ Å, $z_i = 175$ Å) in the vertical direction.

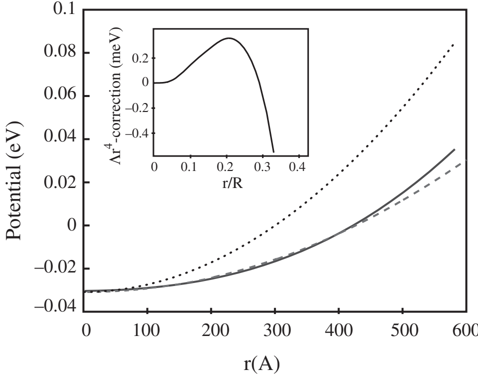

Figure 17. Comparison between the profiles of the conduction band edge ($z = 0$) computed from self-consistent simulations (solid) and from our 3D cylindrical charge model (dashed). The dotted curve shows a parabolic potential with $K = qN_D/4\epsilon$. The inset shows the Λr^4-correction to the harmonic potential as a function of r/R, where R is the dot radius.

[66, 75] fudged with a power variation of n, the electron density, but then it loses its physical meaning since it is unrelated to any of the nanostructure parameters.

The last term in Eq. (33) is the 3D correction to the "quasi-2D" parabolic potential with

$$\Lambda\left(\frac{r}{R}\right) = \frac{qN_D^+}{4\epsilon R^2}\sum_{n=0}^{\infty} C_n \sum_{l=0}^{\infty}(-1)^{l+1}\frac{\mu_n^{2l+2}}{2^{2l+2}[(l+2)!]^2}\left(\frac{r}{R}\right)^{2l} \tag{36}$$

We point out that, while retaining the cylindrical symmetry, this term is structure (N_D^+, C_n) and geometry (R) dependent; it is not necessarily negligible, growth with r/R, and could be positive or negative since J_2 oscillates with μ_n. The correction $\Lambda\, r^4$ is plotted as a function of (r/R) in the inset of Figure 17. It is seen that the correction is small but not negligible at short distance from the origin.

6.2. 2D Eigenstates Analysis

Since the effective dot radius is much smaller than R, the $\Lambda\, r^4$-correction can be treated as a perturbation of a parabolic potential in the quantum mechanical problem of the determination of the eigenvalues and the eigenfunctions in the QD [76]. Hence, we consider the actual xy-potential profile to be given by

$$\phi(r, \theta) = \phi_{\text{osc}}(r) + W(r, \theta) \tag{37}$$

where $\phi_{\text{osc}}(r) = \phi_0 - Kr^2$ is the harmonic potential of Eq. (33) and W is a perturbation which contains the Λ-correction term and, for the sake of generality, depends on r and θ (Fig. 15b). If the confining potential ϕ retains cylindrical symmetry, one can state that

1. ϕ commutes with the two-dimensional angular momentum operator $(\hbar/i)(\partial/\partial\theta)$. Therefore, H and H_0 have the same eigenfunctions $|n, l\rangle$.
2. $|n, l\rangle$ and $|n, -l\rangle$ can be generated from one another by rotation; that is, if $\mathbf{R}$ is a rotation operator with z axis, $\mathbf{R}|n, -l\rangle = |n, l\rangle$. Therefore, $|n, l\rangle$ and $|n, -l\rangle$ have the same energy $\varepsilon_{n,|l|}$.

Thus, as long as the perturbation is small with respect to $\hbar\omega$, the shell structure in VQD is preserved. However, within a shell, degeneracy is partially lifted, and subshell levels, characterized by identical absolute values in their quantum number l, emerge.

When the cylindrical symmetry is broken by, for instance, the electron occupation of non-s-orbitals, deviations from the circular shape of the dot, and/or potential fluctuations arising from the long range Coulomb interaction of ionized donors in GaAs, the eigenlevels are, in general, no longer degenerate.

7. FULL SCALE SIMULATION OF QUANTUM DOTS

Beyond the HF approximation, the density functional theory is extremely powerful in predicting with relative accuracy the electronic properties of atomic systems, and even of large ensemble of atoms. It is therefore well suited for computing the electronic spectra of QDs and artificial atoms in the nanostructure environment [77–81]. Moreover, like the HF approximation, it has the advantage of retaining the single-particle picture for the wavefunctions in the system.

In simulating quantum devices, it is often useful to partition the device into regions of different confinements. Hence, the eigenenergies and the eigenstates are computed numerically in each region based upon the degree of quantization and the 3D electrostatic potential computed from the Poisson equation. The wavefunctions are then assembled using the appropriate occupation probabilities to generate a 3D charge density throughout the device. If the quantum device contains 2DEG regions, the adiabatic approximation can be used by assuming the Schrödinger equation to be separable into vertical (z) and transverse components (x, y). This approximation assumes that the vertical component of the wavefunction responds instantaneously to the variation of the transverse potential. Since the longitudinal wavefunctions generally exhibit a propagating nature, they are cast as plane waves to enhance the performance of our code. In quasi-2D leads, therefore, the quantum mechanical problem breaks down into solving the 1D Schrödinger equation in slices down the x–y plane of the 2D region. The use of plane waves in 2D regions results in an incomplete treatment of evanescent leakage and reflection in regions where propagating states impinge on the barriers. The plane wave approximation could be justified, however, when in the calculation of charge densities, the counting of occupied propagating states is of interest rather than rigorously calculating quasi-bound energies.

7.1. The Local Spin Density Approximation Hamiltonian

In the envelope function–effective mass approximation, the Kohn–Sham equations, one for spin up (↑) and one for spin down (↓), read

$$H^{\uparrow}(\mathbf{r})\psi_m^{\uparrow}(\mathbf{r}) = \varepsilon_m^{\uparrow}\psi_m^{\uparrow}(\mathbf{r}) \qquad H^{\downarrow}(\mathbf{r})\psi_m^{\downarrow}(\mathbf{r}) = \varepsilon_m^{\downarrow}\psi_m^{\downarrow}(\mathbf{r}) \tag{38}$$

where ε_m and ψ_m are the corresponding eigenenergies and eigenstates of the Hamiltonians $H^{\uparrow}$ and $H^{\downarrow}$:

$$H^{\uparrow(\downarrow)}(\mathbf{r}) = -\frac{\hbar^2}{2}\nabla\left[\frac{1}{m_n^*(\mathbf{r})}\nabla\right] + E_c + \mu_{xc}^{\uparrow(\downarrow)}(n, \zeta) \quad (39)$$

The conduction-band edge energy $E_c(\mathbf{r})$ is given by $E_c(\mathbf{r}) = -e\,\phi(\mathbf{r}) + \Delta E_c$, where ΔE_c is the band offset between different materials. The electrostatic potential $\phi(\mathbf{r}) = \phi_H(\mathbf{r}) + \phi_{\text{ions}}(\mathbf{r})$, where $\phi_H(\mathbf{r})$ is the Hartree potential equivalent to the second term in Eq. (26) and ϕ_{ions} is the potential resulting from ionized donors and acceptors present in the nanostructure, is the solution of the 3D Poisson equation

$$\nabla \cdot (\epsilon(\mathbf{r})\nabla\phi(\mathbf{r})) = e(n(\mathbf{r}) - N_D^+(\mathbf{r}) + N_A^-(\mathbf{r})) \quad (40)$$

which is solved self-consistently with the stationary Kohn–Sham equations. In the above equation, we allow for the position dependence of the effective mass m^* and the dielectric constant ϵ; $n(\mathbf{r})$, $N_D^+(\mathbf{r})$, and $N_A^-(\mathbf{r})$ are electron, ionized donor, and ionized acceptor densities respectively. Exchange and correlation are self-consistently incorporated into the model using the Kohn–Sham density-functional method [82]. This approach accounts for high-order electron–electron interaction by adding a correction to the Hartree potential,

$$\mu_{xc}(n) = \frac{d}{dn}[n\varepsilon_{xc}(n)] \quad (41)$$

where $\varepsilon_{xc}(n)$ is the exchange-correlation energy per electron derived from the local electron density n which can be expressed in terms of the Slater exchange energy and the Perdew–Zunger parametrization of the correlation potential [83]. The effect of exchange is predominant in the localized QD region, where the conduction band is altered by as much as 1 meV. In the local spin density approximation (LSDA) formulation, the exchange correlation energy is a function of the spin polarization $\zeta = (n^{\uparrow} - n^{\downarrow})/n$, where $n^{\uparrow}$ ($n^{\downarrow}$) is the spin up (down) electron density. Here, we use Perdew and Wang's formulation [84].

7.2. Electron Equilibrium Statistics

The electron density in the dot containing N electrons reads

$$n(\mathbf{r}) = \sum_i f(\varepsilon_i|N)|\psi_i(\mathbf{r})|^2 \quad (42)$$

where $f(\varepsilon_i|N)$ is the probability that the eigenlevel ε_i is occupied, knowing that there are N electrons in the dot. In general, $f(\varepsilon_i|N)$ is not equivalent to the Fermi–Dirac factor [58] but has to be determined by filtering out from (7) those particular configurations for which ε_i is occupied,

$$f(\varepsilon_i|N) = \frac{1}{P(N)} \sum_{\{n_j\},\, \sum_k n_k = N,\, n_i = 1} P(\{n_j\}) \quad (43)$$

The computation of Eq. (43) is a combinatorial problem that becomes rapidly insurmountable, even with powerful computer resources. Fortunately, in the Coulomb blockade regime, that is, when the level spacing $\Delta\varepsilon_i$ is much larger than the thermal fluctuation k_BT, for N electrons in the dot, the first N eigenlevels are certainly occupied. The electron density in the QD thus reads

$$n(\mathbf{r}) = n^{\uparrow}(\mathbf{r}) + n^{\downarrow}(\mathbf{r}) = \sum_{i=1}^{N_{\uparrow}} |\psi_m^{\uparrow}(r)|^2 + \sum_{i=1}^{N_{\downarrow}} |\psi_m^{\downarrow}(r)|^2 \quad (44)$$

where $N_{\uparrow} + N_{\downarrow} = N$ is the number of electrons in the dot.

7.3. Bulk Region

In regions where quantum effects are negligible, all the quantities of interest are obtained under the Thomas–Fermi approximation. The electron density reads

$$n(\mathbf{r}) = N_c \frac{2}{\sqrt{\pi}} F_{1/2}(\eta_c(\mathbf{r})) \quad (45)$$

where

$$\eta_c(\mathbf{r}) = \frac{-q\phi(\mathbf{r}) + \Delta E_c(\mathbf{r})}{k_BT}$$

which sets up the Fermi level E_F as the zero energy (i.e., $-q\phi = E_C - E_F$). $F_{1/2}$ is the Fermi integral,

$$F_{1/2}(\eta) = \int_0^{\infty} \frac{\xi^{1/2}\,d\xi}{1 + e^{\xi-\eta}} \quad (46)$$

and

$$N_c = 2\left(\frac{2\pi m_n k_B T}{h^2}\right)^{3/2} \quad (47)$$

is the electron effective density of states where m_n is the electron density of states effective mass. For nondegenerate semiconductors, Eq. (45) reduces to the Boltzmann factor

$$n = N_c\, e^{\eta_c} \quad (48)$$

However, at very low temperature, a semiconductor is always degenerate and the Fermi integral (46) cannot be simplified. Here, we use the rational function approximation proposed by Aymerich-Humet and Millan [85],

$$F_{1/2}(\eta_c) \approx \left(\frac{3/2\ 2^{3/2}}{\left(2.13 + \eta_c + (|\eta_c - 2.13|^{12/5} + 9.6)^{5/12}\right)^{3/2}} + \frac{2}{\sqrt{\pi}} e^{-\eta_c}\right)^{-1} \quad (49)$$

which in the worst case shows a 0.5% relative error $(\Delta F_{1/2}/F_{1/2})$ [86].

The dopant statistics for dilute donors and acceptors read

$$N_D^+ = \frac{N_D}{1 + g_D\ e^{(E_F - E_D)/k_BT}} \qquad \text{(donors)} \quad (50)$$

$$N_A^- = \frac{N_A}{1 + g_A\ e^{(E_A - E_F)/k_BT}} \qquad \text{(acceptors)} \quad (51)$$

where N_D and N_A, N_D^+ and N_A^-, E_D and E_A are the donor and acceptor concentrations, ionized concentrations, and energy levels, respectively. g_D and g_A are coefficients

depending on the semiconductor species. This statistic relies on the assumption that the wavefunction of a dopant in a piece of semiconductor is very similar to the first ground state in an hydrogen atom and is given by

$$\psi(\mathbf{r}) = (\pi a_B^3)^{-1/2} e^{-\mathbf{r}/a_B} \tag{52}$$

where a_B is the effective Bohr radius

$$a_B = \frac{4\pi\hbar^2\epsilon_d}{m_d e^2} \tag{53}$$

and ϵ_d is the semiconductor dielectric constant. At low impurity concentrations, the impurity density of states can be approximated by delta functions (see Fig. 18a). As the doping is increased, this simple picture is no longer appropriate. The orbitals of adjacent impurities begin to overlap so that impurity energy levels smear with each other in such way to create an impurity band (Fig. 18b). At even higher doping levels, the center of the impurity band distribution moves toward the conduction band minimum and the ionization energy diminishes considerably. Finally, at a certain doping level, the conduction and impurity bands merge, leaving a zero effective ionization potential (Fig. 18c). The set of additional states below the conduction band is traditionally referred to as the *band-tail*.

The precise determination of band-tailing in semiconductors was first treated semiclassically by Kane [87] and later quantum mechanically by Halperin [88]. The complete implementation of these models would be computationally too expensive. We only retain the two main consequences of band-tailing: (i) the bandgap of the semiconductor is narrowed and (ii) all the impurities are ionized, as opposed to what would be predicted by the simple model of isolated impurities. We use the results established by Jain and Roulston to compute the bandgap narrowing in our model [89].

7.4. Boundary Conditions

Boundary conditions for the electrostatic potential ϕ are established by imposing Dirichlet conditions at the source, drain, and lateral surfaces of the device. At the source and drain, a flat band condition is assumed and ϕ is set up such that the net charge is zero in these regions. An equivalent way to express neutrality is to impose zero electric field (i.e., a Neumann boundary condition). Both approaches were successfully tried, but the latter is favored in the finite element method since homogeneous Neumann boundary conditions

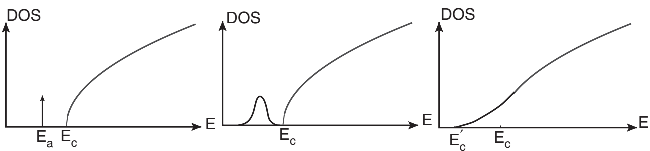

Figure 18. Variation of the density of states as a function of energy for a *n*-doped semiconductor. (a) For nondegenerate semiconductors, the donor levels are localized at E_a, in the forbidden gap; (b) for degenerate semiconductors, the orbitals of neighbor impurity overlap and their interaction lead to the formation of an impurity band; (c) for highly degenerate semiconductors, the donor band merges with the conduction band E_c.

are automatically taken into account. Along lateral surfaces, the Schottky barriers heights ϕ_s are strongly influenced by surface chemistry, so we use the experimental data of Grant et al. [90] and Best [91]. On the gated surfaces, the Schottky barriers are modified by $\phi_s - V_G$, where V_G is the gate bias.

Boundary conditions for the Kohn–Sham equation are imposed by assuming vanishing wavefunctions on any surface of the device. Since the QD is much smaller than the physical dimensions of the device, the wavefunctions vanish already before reaching those boundaries. In the direction perpendicular to the heterointerfaces, we allow wavefunctions to leak into the source and drain regions. However, this leakage is not taken into account for the computation of the charge in the source and drain regions where it is computed entirely using the Thomas–Fermi approximation in that region. This is a good approximation since it does not affect the charge within the dot and is too small compared to the bulk charge in the source and drain regions.

7.5. Conduction Band Profiles

Figure 19c shows the variation of the effective conduction band edge $E_c(\mathbf{r})$, including many-body effects, at $x = A$, B, C, and D (Fig. 19a) and at $y = 0$ (center) along the growth (z) direction for $N = 2$ electrons in a 4000 Å diameter VQD structure. Although the overall picture is not at all symmetrical with respect to a vertical line drawn at the center of the well, the central region, as shown in the inset, is perfectly symmetrical, which explains that simulations on a simpler domain were qualitatively in good agreement with experimental results [63, 66, 70]. The central InGaAs dot region (4105 Å $\leq z \leq$ 4225 Å) is defined by the 180 meV AlGaAs double barrier. The lower energy gap of InGaAs (1.448 eV) compared to the energy gap of GaAs (1.519 eV) results in the bottom of the well being, 35 meV lower than the source and drain regions. Therefore, electrons are confined in the 120 Å wide InGaAs region. The portion of curve A on the right of the barrier shows a steplike behavior which results in two different pinnings of the conduction band under the gate and at the exposed surface, respectively.

Figure 19d shows, for the same structure, the variation of the conduction band edge along the x direction, that is, perpendicular to the growth direction, along the lines E and F (in the bulk), G (underneath the gate), H (in the InGaAs well), and I (in the AlGaAs barrier). None of these curves is parabolic at all, but, as we will see, the bottom of the conduction band in the dot region is almost parabolic.

In the analytical potential model, we have already pointed out the weak potential dependence with respect to radius of the structure. This is confirmed by our simulations and is shown in Figure 20a for structures with diameter $d =$ 2000, 5000, and 8000 Å. For $0 \leq r \leq 1000$ Å, the conduction band profile of each structure is almost identical so that the effective size of the dot is practically independent of the size of the structure.

According to our experience, a variation in the gate shape or length has an impact only on the threshold voltage V_{th} of the structure as shown in Figure 20b. Indeed, in a structure with a shorter gate, the fringing fields are more important than in a structure with a larger gate so that a more negative bias is required to empty the dot. As predicted by

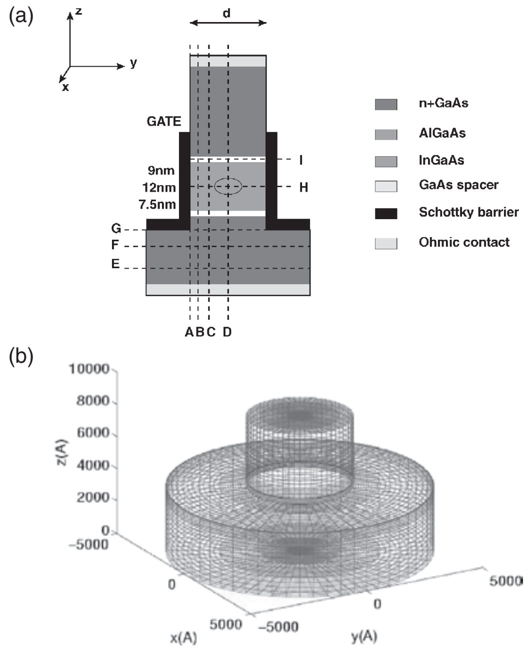

Figure 19. (a) Schematic diagram of a cylindrical vertical quantum dot tunneling heterostructure showing the different semiconductor layers. The quantum dot, represented with the oval, lies in a 12 nm wide quantum well ($In_{0.05}Ga_{0.95}As$) surrounded by two potential barriers ($Al_{0.22}Ga_{0.78}As$) whose thickness are 7.5 nm on the source side and 9 nm on the drain side. (b) Finite element mesh. (c) Conduction band edges along the z-direction at $x = 0$ along the lines A, B, C, and D in (a). (d) Conduction band edges along the x-direction at $y = 0$ along the lines E, F, G, H, and I in (a).

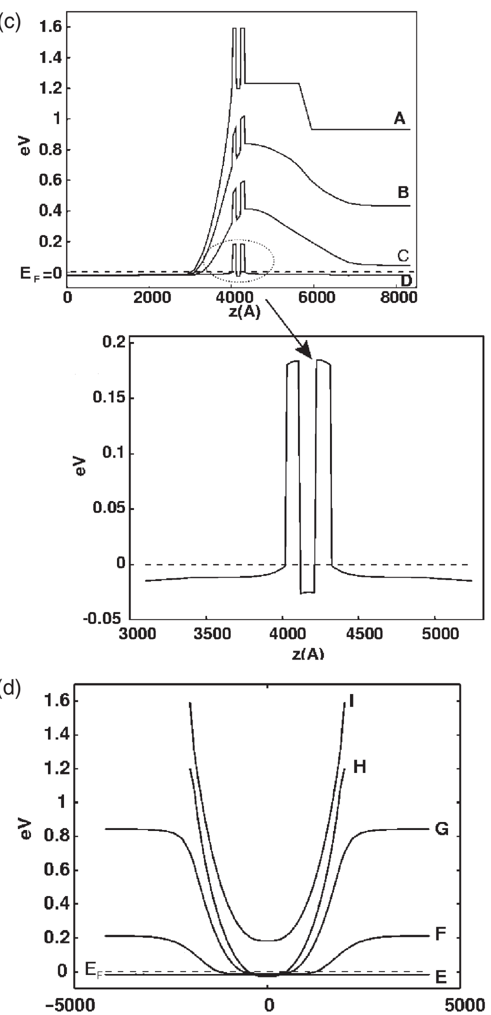

Figure 19. Continued.

the analytical model [Eq. 35], the threshold voltage varies linearly with the ionized donor concentration in the bulk N_D^+. Figure 20c shows that V_G varies almost linearly with N_D^+. It also shows a comparison between the self-consistent (SC) results, our 3D analytical model, and the 2DHO model. The slope of the curve predicted by our 3D model is in remarkable agreement with the SC results and is a clear improvement over the 2D model. There is, however, a 250 mV difference between the values predicted by the analytical model and the SC data because the analytical model does not consider the quasi-neutral region of the structure. Figure 20d shows the dependence of the confining potential on the ionized donor concentration. In practice, however, the range of doping concentration itself depends on the size of the structure. When device diameter is small, low doping concentration produces a confining potential that hardly confines anything. If device diameter is large, a too high doping concentration would make it impossible to pinch the dot off.

Figure 21 shows the variation of the conduction band edge $E_c(\mathbf{r})$ along the x direction, at $y = 0$ in the QD, for N varying from 0 to 20; that is, -1.7 V $< V_G < -0.61$ V. It is seen that when the dot is empty, the conduction band profile is almost parabolic, but as the gate voltage is varied, thus increasing the number of electrons in the dot, the bottom of the conduction band flattens, due to increasing Coulomb repulsion (Hartree potential) amongst charge carriers. The inset shows that the minimum of the conduction band edge $E_c(\mathbf{r})$ in the dot is not a monotonic function of the number of electrons N but oscillates as a combined influence of the attractive ion potential ϕ_{ION} and V_{xc}, and the repulsion between electrons ϕ_H.

7.6. Electronic Structure of Vertical Quantum Dots

The first 45 single-particle eigenlevels and the profile of the wave functions along the radial direction are shown in Figure 22, for $N = 2$. The confining potential is drawn on dashed lines. The corresponding xy (or $r\theta$) contour plots are shown in Figure 23, in agreement with the statements of Section 6.2. Although the shell structure is maintained, each shell is split into various subshells. In general, if one starts numbering shells at $n = 0$, the nth shell contains $n+1$ states. The even numbered shells ($n = 2j$) split into j twofold degenerate subshells plus one s state; the odd numbered shells ($n = 2j+1$) split into $j+1$ twofold degenerate subshells. Figure 23 shows that the levels in the shell number

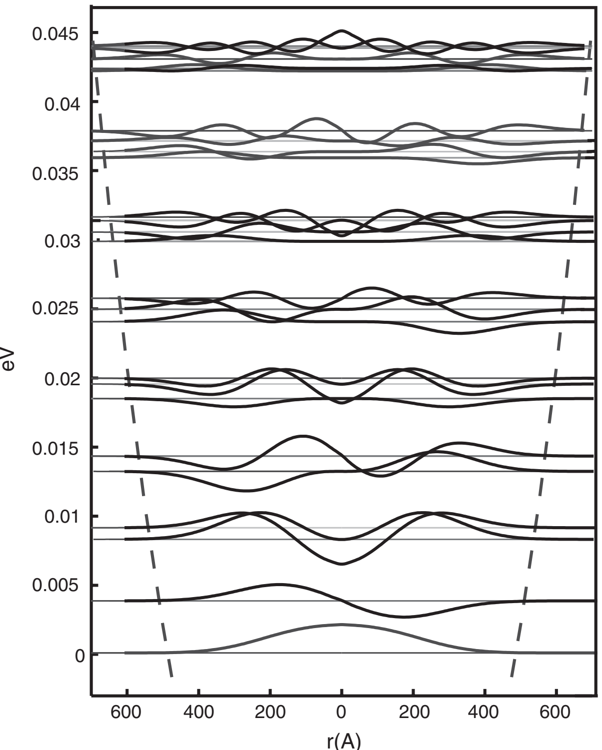

Figure 22. First 45 eigenlevels and radial projection of the eigenfunctions in the confining potential (dashed line).

j are obviously characterized by the quantum numbers (n, l)

$$(0, \pm j), (1, \pm(j-2)), \ldots, (j/2, 0) \qquad j \text{ even} \quad (54)$$

$$(0, \pm j), (1, \pm(j-2)), \ldots, ((j-1)/2, \pm 1) \qquad j \text{ odd} \quad (55)$$

It must be noticed that, inside a shell, the subshells are ordered in descending order of $|l|$.

7.7. Single-Electron Charging

Because the QD is weakly coupled to the source and drain, electrons are completely localized in the dot. At equilibrium, and for a given bias, as mentioned in Section 3.2 the integer number of electrons N minimizes the grand potential of the system Ω. In order to determine N, at equilibrium two approaches may be considered:

- The first method involves the computation of Ω for several values of N in order to find its minimum. This task is readily simplified by considering that the number of electrons in the dot lies around twice the number of eigenlevels below the Fermi level. Only a few values of N are considered. In $\Omega(N) = F(N) - N\mu$, the Helmoltz free energy $F(N)$ now reads

$$F(N) = \sum_{i=1}^{N} \varepsilon_i - \frac{1}{2} \iint \frac{q^2}{4\pi\epsilon_0\epsilon_r} \frac{n(\boldsymbol{r})\, n(\boldsymbol{\rho})}{|\boldsymbol{r} - \boldsymbol{\rho}|}\, d\boldsymbol{r}\, d\boldsymbol{\rho} + E_{xc}[n(\boldsymbol{r})] - \int n(\boldsymbol{r}) V_{xc}[n(\boldsymbol{r})]\, d\boldsymbol{r} \qquad (56)$$

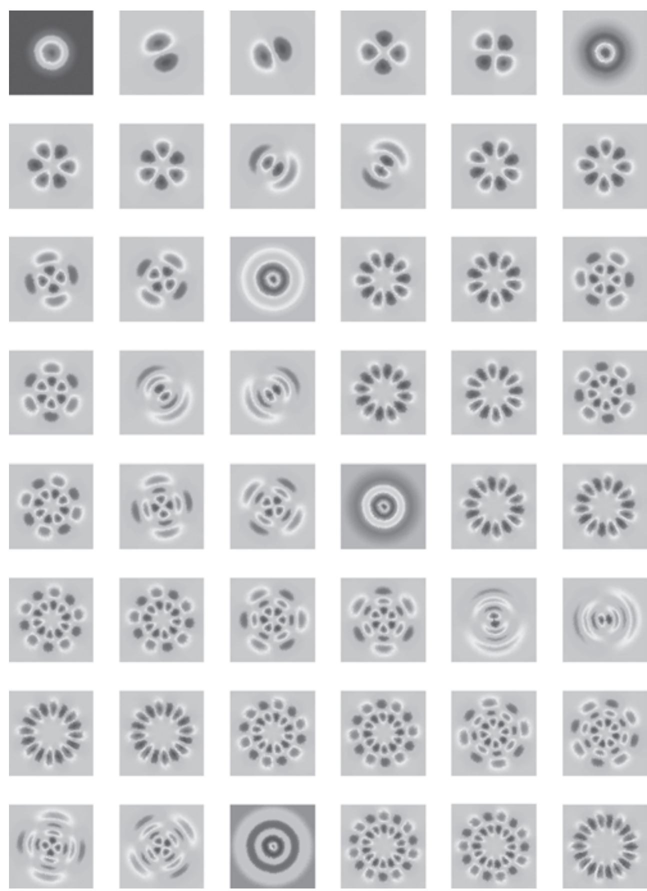

Figure 23. Eigenfunction contour plots for the first nine shells.

where E_{xc} and V_{xc} are the exchange and correlation energy and potential, respectively. In Eq. (56), the second term with the factor 1/2 on the right hand side avoids double counting in the Coulomb interaction energy [82] and the third and fourth terms on the right hand side take exchange and correlation contributions into proper account [82]. This method is computationally tedious because of the double integral in Eq. (56) and will be avoided whenever possible.

- The second method relies on the physical significance on the Kohn–Sham equation eigenvalues [92]

$$\varepsilon_i = \frac{\partial E_T}{\partial n_i} \tag{57}$$

where E_T is the total energy of the dot and n_i is the occupancy of the single-particle level ε_i. Then, if ε_i is a linear function of n_i, it is easy to show that [92] (*Slater formula*)

$$E_T(N+1) - E_T(N) = \int_0^1 \varepsilon_{\text{LUO}}(n)\, dn \approx \varepsilon_{\text{LUO}}(1/2) - E_F \tag{58}$$

where E_F is the Fermi energy and ε_{LUO} is the lowest unoccupied orbital eigenvalue. Hence, upon populating ε_{LUO} with 0.5 electron, a stable configuration of N electrons is achieved in the dot if $E_T(N+1) > E_T(N)$ [i.e., if the integral in Eq. (57) is positive]; otherwise there are $N+1$ electrons. Calculations by Fonseca et al. [93] have established the validity of this approximation in self-assembled InAs/GaAs QDs. Here, we will present a method to test the validity of this approach.

7.8. Computation of the Addition Energy

In this section, we apply Eq. (57) to the particular case where the single-particle eigenlevels ε_i are linear functions of both n_i and V_G. We then show that the AE has a very convenient geometrical interpretation.

By definition,

$$E_a = \mu(N+1) - \mu(N) \tag{59}$$

$$\mu(N) = E_T(N) - E_T(N-1) \tag{60}$$

where E_a is the AE, E_T is the total energy, and $\mu \equiv E_F$ is the chemical potential. Thus, using (58), (59), and (60), we get

$$\begin{aligned} E_a &= \mu(N+1) - \mu(N) && (61)\\ &= (E_T(N+1) - E_T(N)) + (E_T(N) - E_T(N-1)) && (62)\\ &= \varepsilon^{N}_{\text{LUO}}(1/2) - \varepsilon^{N-1}_{\text{LUO}}(1/2) && (63) \end{aligned}$$

Therefore (see Fig. 24),

$$E_a = \left(V_G^{N+1} - V_G^{N}\right) tg(B) \tag{64}$$

if we assume that for N electrons, $\varepsilon_{\text{LUO}} = \varepsilon_{i+1}$, and for $N-1$ electrons, $\varepsilon_{\text{LUO}} = \varepsilon_i$. Here, the upper script of ε gives the total number of electrons in the system and the number between brackets gives the occupancy of a single-particle level.

Let us now assume that ε_i is linear function of both n_i and V_G,

$$\varepsilon_i(n_i, V_G) = an_i + bV_G + c \tag{65}$$

Obviously from Slater's formula, we must have

$$\varepsilon_i^N(n_i, V_G) = an_i + b(V_G - V_G^{N+1}) - a/2 \tag{66}$$

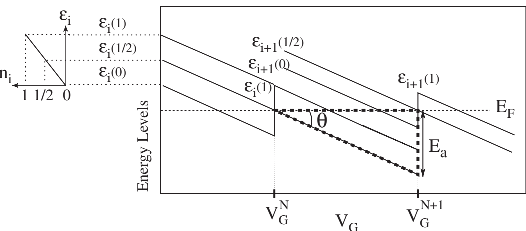

Figure 24. Schematic of the energy spectrum in the gate voltage interval corresponding to successive charging of two electrons. Single-particle energies $\varepsilon_i(n_i)$ are represented with the level index (i) and its electron occupation n_i. E_F and E_a are the Fermi level and the AE, respectively. θ is the slope of the variation of the eigenlevel as a function of the gate voltage. Side: variation of the eigenlevels $\varepsilon_i(n_i)$ as a function of their occupation number n_i.

Thus,

$$\varepsilon_i^N(n_i, V_G^{N+1}) = an_i - a/2 \tag{67}$$

and

$$\int_0^1 \varepsilon_i^N dn_i = \int_0^1 (an_i - a/2)dn_i = \left[\frac{an_i^2}{2} - \frac{an_i}{2}\right]_0^1$$
$$= 0 = \varepsilon_i^N(1/2, V_G^{i+1}) \tag{68}$$

which confirms Slater's rule. Moreover, using Eq. (67),

$$\varepsilon_i^N(1, V_G^{i+1}) = a/2 \qquad \varepsilon_i^N(0, V_G^{i+1}) = -a/2 \tag{69}$$

as illustrated on Figure 24. It is therefore possible to test the validity of Slater's formula in particular by doing a simulation at $V_G = V_G^{i+1}$ and populating ε_i with 0, 1/2, and 1 electron and checking if the shift of ε_i is symmetric with respect to E_F.

7.9. Electron Densities in Vertical Quantum Dots

Figure 25 shows the evolution of the electron density $n(\boldsymbol{r})$ in the xy plane as N increases from 2 to 30. Each subplot corresponds to a filled 2D shell. Each density profile can be understood from Figure 23 which shows the contour plots of the eigenfunctions where the electron density is equal to the summation of the square of the wavefunctions over the occupied states. Hence, for two electrons in the dot, that is, one electron of each spin on the s state (Fig. 25a), the electron density has one lobe and a maximum at the center, which is in agreement with the first wavefunction of Figure 23. When the p-orbitals are filled (i.e., $N = 6$), the maximum has moved on a ring around the center (Fig. 25b) since the two p states have a node at the center and two maxima 250 Å away from it (second and third wavefunction in Fig. 23). When the third shell is completely filled (i.e., $N = 12$), the maximum of $n(\boldsymbol{r})$ moves back to the center, but the crown is still present, although further away from the center (Fig. 25c). This is consistent with the third, fourth, and fifth wavefunctions in Figure 23: the fifth wavefunction shows a maximum at the center while the third and fourth ones have their maximum 280 Å away from it. When the fourth shell is filled (i.e. $N = 20$), the maximum of the electron density moves back again at the periphery (Fig. 25d) since all wavefunctions of this shell have their maximum at the periphery.

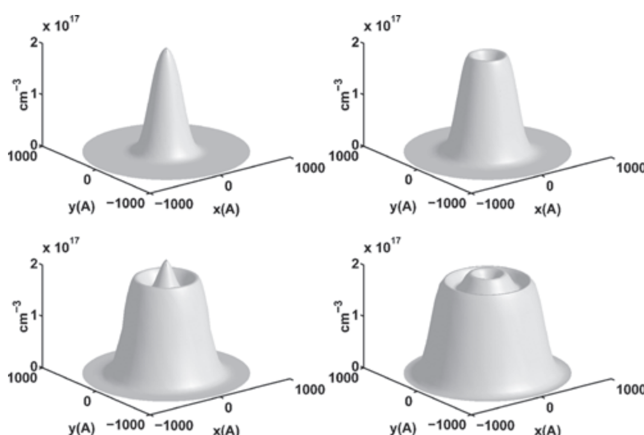

Figure 25. Electron density profile in the xy plane for (a) 2, (b) 6, (c) 12, and (d) 20 electrons in the dot. Adapted with permission from [81], P. Matagne et al., *Comput. Modeling Eng. Sci.* 1, 1 (2000). © 2000, Tech. Science Press.

Figure 26 shows the electron concentration, $n(\boldsymbol{r})$, in the xz plane at $y = 0$, for $N = 20$. The effect of the different types of confinements is evident in the figure: Along the z-direction, the electrons in the dot are squeezed into a thin layer whereas in the x-direction, the concentration profile is more spread out and exhibits four lobes, which result from the contributions of the occupied excited states The only lobe along the z-direction indicates that only the ground z-state (i.e., $n_z = 0$) is occupied, if we label the states as (n_x, n_y, n_z) where n_x, n_y, and n_z are the number of nodes in the x, y, and z directions respectively.

7.10. Shell Charging Analysis

Figure 27 shows the single-particle eigenspectrum for the first 10 orbitals in the CVQD as a function of the gate voltage V_G as obtained from the 3D computational model. Because of their spatial symmetry and spin degeneracy, the orbitals are grouped into four sets of levels which when occupied by electrons will form the first four shells. The upper horizontal scale indicates the number of electrons in the QD on a particular range of V_G. On the vertical axis, the Fermi level is taken as the reference at zero. Below $V_G = -0.62$ V, all levels are empty and decrease monotonically with V_G as the potential energy is lowered.

The variation of all eigenlevels ε_i is piecewise linear with respect to V_G. At each transition from N to $N + 1$ electrons, each curve $\varepsilon_i(V_G)$ is discontinuous with an upward shift. This is a manifestation of the Coulomb blockade effect: when a new electron enters the dot, it induces an upward shift of the whole spectrum because of the sudden increase of the total electrostatic energy in the dot due to Coulomb interaction. Here, the first electron entering the dot occurs for $V_G = -0.62$ V. It must be noticed that the higher the shell being populated, the smaller the shifts, that is, the smaller the charge increment. Unlike in orthodox Coulomb

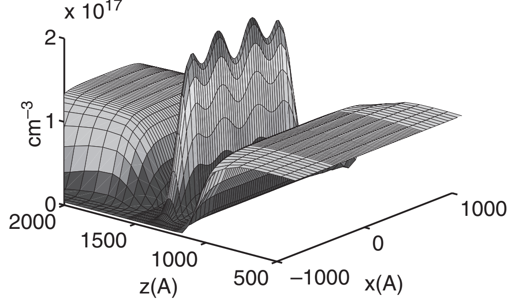

Figure 26. Electron concentration in the xz plane (growth direction) at $y = 0$ for 20 electrons in the dot. Reprinted with permission from [81], P. Matagne et al., *Comput. Modeling Eng. Sci.* 1, 1 (2000). © 2000, Tech. Science Press.

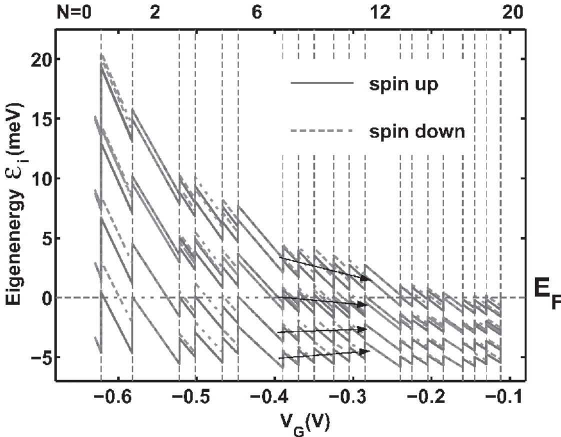

Figure 27. Energy spectrum of the first four sets of eigenlevels (solid curves: spin up, dotted curves: spin down) as a function of the gate voltage V_G (bottom horizontal axis) and number of electrons N (top horizontal axis). E_F is the Fermi level.

blockade experiments [6], ΔV_G, the voltage increment for adding an electron in the dot, takes very unequal values, irregularly distributed over the range of V_G, because of the influence of the quantization and quantum many-body effects during the charging of the dot. ΔV_G is large for $N = 2, 6$, and 12 (i.e., after the complete filling of each shell) because, in addition to the energy required to overcome the electrostatic repulsion of the electrons already present in the dot, an energy contribution is needed to lower the next orbital below the Fermi level for admitting the next electron.

We note that in the interval between the addition of two electrons, $\varepsilon_i(V_G)$ decreases monotonically with V_G because the overall potential energy of the system decreases as the gate voltage is made more positive. This behavior is different from the results of Nagaraja et al. [80] whose model did not account for individual spin states. In that case, the single-particle eigenvalues were tangential to the Fermi level during the charging of the whole orbital.

During the charging process over the whole gate voltage range (-0.62 V $< V_G < -0.082$ V), the four sets of levels (shells) remain well separated, which indicates that the shell structure is preserved. However, as predicted by the analytical model (Section 6), the degeneracy of levels belonging to the same shell, even when nonoccupied (i.e., second, third, fourth sets of levels for -0.522 V $< V_G < -0.447$ V), is partially lifted.

Another interesting feature appears by considering the overall energy variation of the different shells during a single shell charging. For instance, for -0.39 V $< V_G < -0.285$ V (i.e., during the third shell charging), the average energy of the two lower full shells is higher at the end of the charging process than at the beginning. This is easily seen by drawing a line joining the middle of each discontinuity segment. For the two lower shells, the slope is positive, which indicates an overall energy repulsion among these shells. For the third filling shell, the slope is slightly negative, which means that the attractive energy of the gate field is just sufficient to overcome the electron repulsion energy. Finally, for the upper empty shell, the slope is negative because, free of electron repulsion, the eigenstates only experience the attractive effect of the gate.

We also notice the decrease of the intershell energy separation as V_G increases, as observed experimentally [11]. This effect is generally interpreted as due to the Coulomb interaction between high energy electrons with extended wavefunctions which weakens the confining potential. However, our analytical model reveals that, in CVQDs, there is in addition a pure *3D geometrical effect* that enhances the level collapse when V_G increases *even if the dot is empty*. Indeed, from Eq. (34), the quadratic term α in the potential depends on the depletion region extension z_∞. As z_∞ decreases when V_G is made more positive, so does α (Fig. 16). Therefore, as V_G is swept, we expect the oscillator frequency to decrease and, thereby, the shell separation. This effect is at the origin of the renormalization of the harmonic oscillator frequency by the fourth root of the electron density; that is, $\omega \propto 1/n^{1/4}$, in models based on pure 2D parabolic confining potential [66, 75]. This $n^{-1/4}$ renormalization was justified to keep the electron concentration constant during charging of the dot, which is readily obtained in our simulations.

Addition energy measurements are the clearest way to evidence the shell structure in CVQDs. Figure 28 shows the variation of the addition energy with respect to the number of electrons N, as measured in Tarucha's experiment (dashed) and as computed in our simulations for three different confining potentials $\omega_1 > \omega_2 > \omega_3$ that correspond to 50, 30, and 20 meV conduction band offset ΔE_c between GaAs and InGaAs, respectively. The band offset variation is not unreasonable due to the fact that the GaAs conduction band edge with a doping density of 10^{17}/cm^3 is simply not well defined and this can result in an impurity fluctuation at the well edge ($z = z_i$). Figure 28 shows a very pronounced peak for $N = 2, 6$, and 12 reminiscent of the shell structure in the experimental curve as well as in the simulation curves for $\omega = \omega_1$ and ω_2. For $\omega = \omega_3$, the confining potential is so weak that the shell structure begins to vanish. In this case, charging the second shell ($N = 2$) requires less energy than overcoming the repulsive energy generated by the first electron ($N = 1$) so that $E_a(1) < E_a(2)$. In the experimental curve, there are also secondary peaks for $N = 4, 9$, and 16. These peaks are interpreted as the manifestation of Hund's rule with parallel spin alignment for a

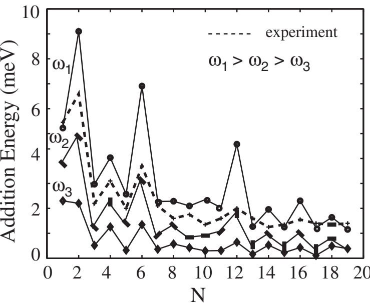

Figure 28. Comparison between computed addition energy spectra (solid) for three different confining potentials $\omega_1 > \omega_2 > \omega_3$ and the experimental spectrum [11] (dashed) as a function of the number of electrons. Notice that, by definition, $E_a(N) = E_F(N+1) - E_F(N)$, so that a value for $N = j$ in this figure refers to the energy needed to add the $(j+1)$th electron in the dot.

half-filled shell [9, 11, 34, 35]. In the simulation curve, we clearly obtain the peaks at $N = 4$ and $N = 16$, but not the peak at $N = 9$, and we have other secondary peaks at $N = 8$, 10, 14, and 18.

7.11. Spin Sequence in Vertical Quantum Dot Charging

If Hund's rule governs the filling of the second shell, then, necessarily, the addition energy spectrum will exhibit a peak at $N = 4$ surrounded by two minima at $N = 3$ and $N = 5$, as described in Section 5.2. Hence, the third and fourth electrons, with parallel spins (↑), access the empty $|0, \pm 1, \uparrow\rangle$ orbitals, maximize the exchange interaction, and induce a minimum for $N = 3$. For $N = 4$, the fifth electron, occupying the $|0, 1, \downarrow\rangle$ state, is the only ↓-electron in the second shell, with no additional exchange; that is, $E_a(4) > E_a(3)$. For $N = 5$, the sixth electron in the $|0, -1, \downarrow\rangle$ state induces exchange between the sixth and the fifth electron, which lowers $E_a(5) < E_a(4)$, leading to a peak for $N = 4$.

The idea that the peak at $N = 9$ is the manifestation of Hund's rule originates from the 2D circular oscillator model where the three states of the third shell are degenerate.

In this case, the filling sequence would be

$$L^S = 2^{1/2} \to 2^1 \to 0^{3/2} \to 2^1 \to 2^{1/2} \to 0^0 \tag{70}$$

where $L(S)$ is the total angular momentum (total spin), and leads to the configuration $1s^2\ 2p^4\ 3d^2\ 3s^1$, by adopting a terminology similar to atomic physics for representing the electronic orbitals. Here, the $|1, 0, \uparrow (\downarrow)\rangle$ (s-like) state is occupied before the $|0, \pm 2, \uparrow (\downarrow)\rangle$ (d-like) states to maximize the total orbital angular momentum. Consequently, the addition energies for $N = 7$ and 8 are low, since the exchange interaction is maximized. In addition, $|1, 0, \uparrow\rangle$ and $|0, \pm 2, \uparrow\rangle$ overlap weakly, which reduces the (repulsive) Hartree energy E_H. For $N = 9$, the same argument as for $N = 4$ applies; that is, the tenth electron is the first ↓-electron of the third shell (no exchange-correlation) that sits on an already occupied orbital (large Hartree), producing a peak for $N = 9$. However, it was demonstrated earlier (Section 6.2) that the accidental degeneracy between the $\varepsilon_2^{1,2}$ and ε_2^3 is lifted in CVQDs so that the actual configuration depends on the antagonistic action of the exchange energy and the $|1, 0\rangle$-$|0, \pm 2\rangle$ level separation E_λ.

If E_x is the exchange energy between two spin-parallel electrons, one in the $|1, 0\rangle$ state and one in a $|0, \pm 2\rangle$ state, that, for the present structure, is effectively 0.3–0.4 meV for $N = 8$ [94], three situations, shown sequentially in Figure 29, are predicted at $0T$ depending on the value of E_λ:

1. $E_\lambda \leq 0.2$ meV ($E_\lambda \ll E_x$) for which 3D effects and Coulomb repulsion interactions practically cancel each other. Then, the three levels of the third shell are practically degenerate, and $E_a(N)$ initially shows a peak at $N = 9$ and a clear dip at $N = 7$. The state occupation sequence going from $N = 7$ to 12 is $L^S = 2^{1/2} \Rightarrow 2^1 \Rightarrow 0^{3/2} \Rightarrow 2^1 \Rightarrow 2^{1/2} \Rightarrow 0^0$. The second electron in the third shell with parallel spin prefers to sit on the $|1, 0\rangle$ state rather than on the available $|0, -2\rangle$ state because of the weaker Coulomb repulsion (top inset of Fig. 29a). However, this sequence is quickly broken as soon as the accidental degeneracy between the $|1, 0\rangle$ and $|0, \pm 2\rangle$ states is slightly lifted, to be replaced by the new sequence $L^S = 2^{1/2} \Rightarrow 0^1 \Rightarrow 0^{3/2} \Rightarrow 2^1 \Rightarrow 0^{1/2} \Rightarrow 0^0$ where the weaker Coulomb (Hartree) interaction between two electrons in the $l = 0$ and $l = 2$ states cannot compensate for the level splitting (bottom inset of Fig. 29a). Nonetheless, the spectral shape, like in Figure 29a for $E_\lambda = 0.11$ meV, may change very little. Hence, negative nonharmonicity arising from 3D effects is critical to offset the influence of Coulomb interactions for achieving this configuration.
2. 0.2 meV $< E_\lambda <$ 0.6 meV ($E_\lambda \sim E_x$) for which the sequence (inset of Fig. 29b is the same as the final sequence in a) with Hund's first rule is still being fulfilled ($S = 3/2$ for $N = 9$). However, placing the third electron in the third shell on the $|1, 0\rangle$ state that is now much higher than the two $|0, \pm 2\rangle$ states requires the non-negligible energy E_λ, and this can noticeably increase $E_a(8)$ (see Fig. 29b for $E_\lambda(7) = 0.35$ meV). The fourth electron in the third shell with antiparallel spin, deprived from gain in energy due to the exchange interaction, still falls on one of the two $|0, \pm 2\rangle$ states, and so $E_a(9)$ can be reduced. Still with a clear dip at $N = 7$, $E_a(N)$ may show a peak at $N = 8$, and not $N = 9$, with a magnitude depending on the difference between E_λ and E_x.
3. $E_\lambda > 0.6$ meV ($E_\lambda > E_x$), for which the third shell splits into two distinct subshells of four and two electrons. One then expects a peak at $N = 8$ for maximum spin alignment ($S = 1$) within the lower subshell, a situation similar to that for the second shell peak at $N = 4$ (i.e., Hund's first rule). There is also a peak at $N = 10$ because of the presence of the non-negligible gap between the two subshells. $E_a(N)$ for $E_\lambda(7) = 0.65$ meV, and the new filling sequences are shown in Figure 29c.

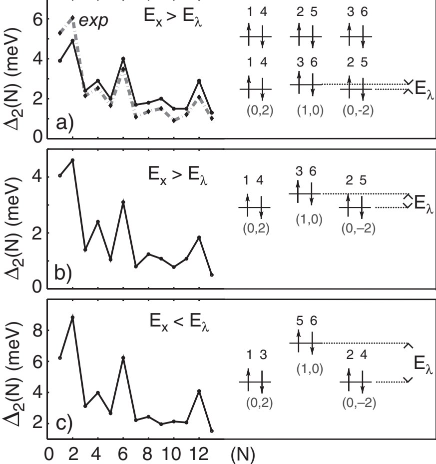

Figure 29. Addition energy spectra computed by 3D DFT versus N, for three ranges (a), (b), and (c) of nonparabolic potential energy, E_λ. Insets schematically show the filling sequences for the third shell. Bold dotted-dash trace in (a) gives $E_a(N)$ for a 0.54 μm device discussed in detail in the text. 7.12. Magnetic Field Analysis

In order to determine the spin filling sequence within a shell, a magnetic field parallel to the current flow is applied. Level splitting is observed according to the Darwin–Fock model [95],

$$E_{n,l} = (2n + |l| + 1)\hbar\left(\frac{1}{4}\omega_c^2 + \omega_0^2\right)^{1/2} - \frac{1}{2}l\hbar\omega_c \qquad (71)$$

where $\hbar\omega_c$ is the cyclotron energy. Theoretical calculations and experimental results are shown in Figure 30a and b respectively. Theoretical calculations predict that levels with positive l shift downward and levels with negative l shift upward. Figure 30b shows the variation of the current oscillations as a function of N for B varying from 0 to $8T$. Assuming a mapping between Figure 30a and b, the electrons must therefore undergo transitions in their quantum numbers. For example, at $0.4T$, the fourth electron goes from $|0, -1\rangle$ to $|0, 1\rangle$ and the fifth electron goes from $|0, 1\rangle$ to $|0, -1\rangle$. This suggests that at $B < 0.4T$, shell filling can be predicted by Hund's rule: up to half shell filling, all electrons have parallel spins; more electrons can only be added with antiparallel spins. At $B > 0.4T$, Hund's rule breaks down because the splitting between levels originally degenerate at $B = 0T$ becomes larger than exchange between electrons of parallel spin.

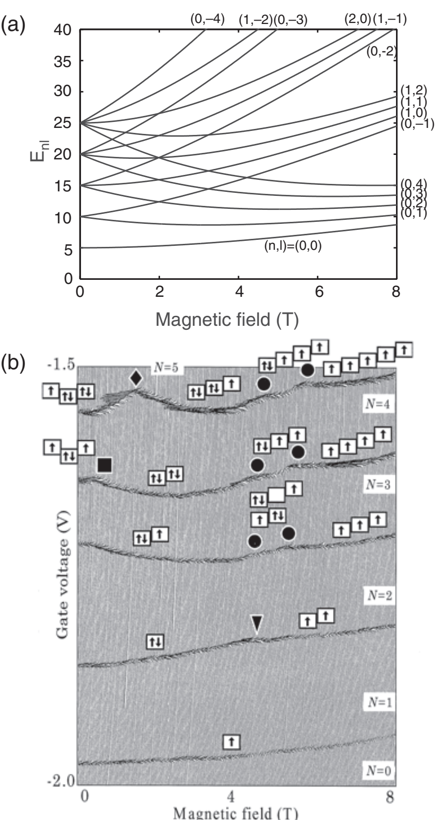

Figure 30. Single-particle energy levels as a function of the magnetic field (a) theoretical (Darwin–Fock model), (b) experimental data. Reprinted with permission from [35], L. P. Kouwenhoven et al., *Science* 278, 1788 (1997). © 1997, American Assoc. Adv. Sci.

Figure 31 shows experimental $0T$ third shell spectra for four VQDs. Applying an arbitrarily small bias ($<100\ \mu$V) between the source and drain, V_d, the spacings between the Coulomb oscillation peaks on sweeping V_g are measured to an accuracy of better than 2%, which reflect directly $E_a(N)$ [71]. For easy comparison, we actually show the peak spacings normalized by the peak spacing for $N = 6$, that is, $E_a(N)/E_a(6)$. We start our analysis with the topmost trace in Figure 31. The AE spectrum of this 0.5 μm device is shown in full in Figure 31b of ref. [11], and principal peaks at $N = 2, 6, 12$, and 20 are clear. The secondary peak at $N = 9$ has been widely interpreted as due to Hund's first rule ($S = 3/2$), apparently indicating that the three single-particle levels of the third shell are quasi-degenerate as depicted in Figure 31a. We cast doubt on whether this simple interpretation is so clear-cut. First, the weak magnetic ($B-$) field dependence close to $0T$ of the 7th to the 12th Coulomb oscillation peaks appears to show just regular pairing (Fig. 2 of ref. [11]), surprisingly implying the sequence $L^S = 2^{1/2} \Rightarrow 4^0 \Rightarrow 2^{1/2} \Rightarrow 0^0 \Rightarrow 0^{1/2} \Rightarrow 0^0$.

Second, $E_a(7)$ is larger than expected when we look at Figure 31a. Both observations bare the hallmark of the presence of small (possibly but not exclusively elliptic) deviations from the circular shape of the fabricated VQD (e.g., due to potential fluctuations arising from long range Coulomb interactions of ionized donors in the doped GaAs), which can lift the degeneracy of all third shell 3s and 3d states. Because the secondary peak in $E_a(N)$ at $N = 4$ can be demonstrated to be due to Hund's first rule ($S = 1$) [11], the deviation from the circular symmetry (κ) is of the order of 10% [66]. Nonetheless, the half-shell peak at $E_a(9)$ does not always guarantee maximum spin alignment ($S = 3/2$). Trace

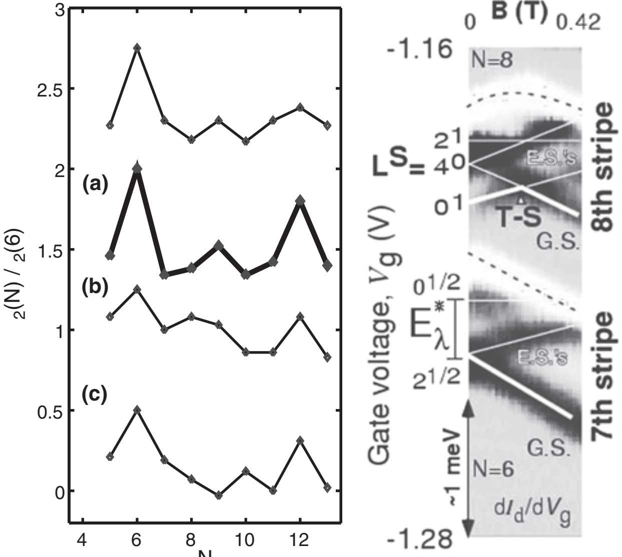

Figure 31. Left panel: Experimental $0T$ third shell $E_a(N)/E_a(6)$ spectra for four VQDs. Traces are shifted vertically for clarity. Right panel: Grey scale plot shows the weak B-field dependence of the seven- and eight-electron ground and first few excited states of the 0.54 μm device whose $E_a(N)$ spectrum is shown as the bold trace in Figure 29a. (a) in Figure 31 is crucial. $E_a(N)$ for this 0.54 μm device is shown in Figure 31a (bold trace). Principal peaks at $N = 2, 6, 12$, and 20 are clear, and the general shape is in good agreement with the theoretical trace. The secondary peak here at $N = 9$ can be demonstrated to be due to Hund's first rule ($S = 3/2$ at $N = 9$). We make this interpretation because: (i) the weak B-field dependence close to $0T$ of the 7th to the 12th peaks reveals clear deviations from regular pairing (Figure 2 of [94]), and (ii) there is a clear dip in $E_a(N)$ at $N = 7$. In Figure 31, we also show dI_d/dV_g in the V_g–B plane for a weak B-field applied parallel to the current (I_d) for the same mesa showing the 7th and 8th current stripes ($V_d \gg 1$ mV) so the width of each stripe is equivalent to an energy $\gg 1$ meV. Positive (negative) dI_d/dV_g is black (white). The lower (upper) edge of the each stripe is black (white). Features within these stripes provide information about the ground state (G.S.) and first few excited states (E.S.) [35] of the 7 and 8 electron systems. For each stripe, the G.S. (E.S.) is marked with a thick (thin) white line at (above) the lower edge. From the $B = 0T$ dependence, we can identify the quantum numbers, L^S, of these many-body states. For $N = 7$, the G.S. (first E.S.) corresponds to the 1st third shell electron entering a $3d$ ($3s$) state at $0T$. For a small B-field, the $L^S = 2^{1/2}$ G.S. splits because the $|n, l\rangle = |0, \pm 2\rangle$ states split. We do not claim that the dot inside this mesa is perfectly circular. Nevertheless, it is sufficiently circular that within our measurement resolution these two states appear degenerate at $0T$ ($\kappa \sim 0\%$). From the separation, E^*_λ, between the $2^{1/2}$ G.S. and $0^{1/2}$ E.S., an estimate for the effective value at $N = 7$ of the subthird shell splitting at $0T$ yields $E_\lambda(7) \sim 0.26$ meV [94]. For $N = 8$, the 2nd third shell electron initially enters the $|0, -2\rangle$ state so the $0T$ G.S. is $L^S = 0^1$, a spin-triplet consistent with Hund's first rule [11, 94]. This electron can only go into the $|1, 0\rangle$ state if E_λ is much smaller than that deduced. The 4^0 singlet E.S. splits for a small B-field, again because the $|0, \pm 2\rangle$ states split. At about $0.2T$, there is a triplet–singlet (T–S) transition in the $N = 8$ G.S. Based on Figure 29, for this near-ideal artificial atom, the filling sequence for the six electrons to enter the third shell is $L^S = 2^{1/2} \Rightarrow 0^1 \Rightarrow 0^{3/2} \Rightarrow 2^1 \Rightarrow 0^{1/2} \Rightarrow 0^0$.

With principal peaks at $N = 2, 6$, and 12, experimental trace (b) ($d = 0.5$ μm) of Figure 31 most resembles the situation of Figure 29b. This trace has a prominent peak at $N = 8$ and a clear dip at $N = 7$ ($\kappa \sim 0$–10%). The key point here is that this spectrum also bares the signature of three parallel spin filling up to $N = 9$, and this is not in violation of Hund's first rule.

Lastly, experimental trace (c) ($d = 0.54$ μm) of Figure 31 reflects the situation depicted in Figure 29c. $E_a(N)$ again reveals principal peaks for $N = 2, 6$, and 12. The peak at $N = 10$ is clear, but there must be a non-negligible splitting of the $|0, \pm 2\rangle$ states. This splitting reduces the effect of exchange between two parallel spin electrons, increasing $E_a(7)$ and reducing $E_a(8)$. The $B = 0T$ dependence of second and third shell Coulomb oscillation peaks reveals barely noticeable deviations from regular pairing. The dot is therefore probably deformed to an extent that puts κ just below that required to induce the $N = 4$ T–S transition, namely $\sim$20% [66].

The different ways electrons fill shells depend sensitively on the 3D nature of the VQD confinement, including small deviations from perfect parabolicity and circular symmetry, and the resulting complex Coulomb interactions between electrons. We have focused on the third shell, for which a clear dip at $N = 7$ followed by a peak at $N = 8$ or 9 is the signature of maximum spin alignment at half-shell, but without loss of generality we have shown that: (i) maximal spin alignment does not guarantee a peak at half-shell filling (conversely a half-shell peak does not always mean maximum spin alignment), and (ii) a particular spin filling sequence does not result in a unique addition energy spectrum. Finally, the model discussed here is very relevant for the general subject of electrostatics in any confined interacting electron system. The third shell of an artificial atom is a particularly good test for this realistic approach.

It is now possible to suggest an interpretation for the peak at $N = 16$ in the fourth shell. Since the accidental degeneracy between the $\psi_3^{1,2}$ and $\psi_3^{3,4}$ states is lifted in the CVQDs (see Section 6.2)—here, the spacing between the two subshells is about 1.5 meV—the filling sequence predicting the four spin alignment up to $N = 16$, as shown in Figure 32a, seems unlikely. As for $N = 10$, the peak at $N = 16$ results from the excess energy needed to access the second subshell in the fourth shell as shown in Figure 32b which also depicts the ordering sequence obtained in our density functional theory-based simulations and for which the addition energy spectrum shows a jagged curve with alternative peaks and minima for even and odd numbers of electrons, respectively (Fig. 28). In this sequence, the secondary peaks at $N = 14$ and $N = 18$ result from the fulfillment of Hund's rule with two parallel spins at midoccupation within each subshell. In order to explain the experimental spectrum with a single peak at $N = 16$, we again consider the complete lifting of degeneracy caused by external static perturbations as illustrated in Figure 32c. The minima at $N = 14$ and $N = 18$ are then due to the filling of two empty states $|0, -3\rangle$ and $|1, -2\rangle$. The intermediate values at $N = 13, 15$, and 19 result from the Coulomb repulsion due to the filling of the already occupied states $|0, 3\rangle$, $|0, -3\rangle$, and $|1, -2\rangle$, respectively. The maximum at $N = 16$, in this scenario, is also due to the energy increment needed to access the second subshell, made of the $|1, 2\rangle$ and $|1, -2\rangle$ orbitals.

8. ASYMMETRICAL SINGLE QUANTUM DOTS

The confining potential of a QD can be altered either structurally, by etching mesas of various shapes, or electrostatically, by patterning several independent gates on a square VQD and applying different voltages at the gates.

8.1. Rectangular Quantum Dots

Experiments performed on rectangular structures lead to the conclusion that the shell structure that would be observed from addition energy measurements in a square or cylindrical VQD is disrupted [9].

For this reason, we consider a rectangular vertical QD shown in Figure 33. The material sequence is identical to the cylindrical structure investigated in the previous chapter with

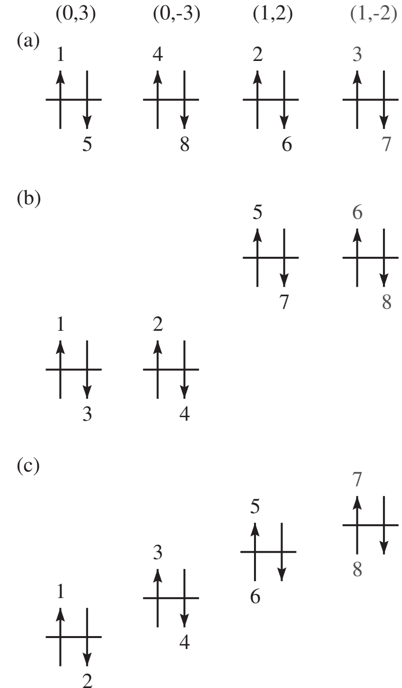

Figure 32. Schematic possible sequences for the filling of the fourth shell. (a) In a 2D circular oscillator with four degenerate levels and four spin alignment. (c) Total lifting of degeneracy leading to the usual pairing sequence $\uparrow \downarrow$.

the vertical confinement realized in the InGaAs well. In-plane confinement is achieved by applying a negative bias on a Schottky gate wrapped around the rectangular pillar, as in the cylindrical structure. The aspect ratio δ of the rectangle is $S = W/D = 1.4$ ($W \cdot D = 7000$ Å $\cdot$ 5000 Å).

Using a simple model of an anisotropic harmonic oscillator whose eigenstate reads

$$\varepsilon_{n_{xy}} = \hbar\omega_x\left(n_x + \frac{1}{2}\right) + \hbar\omega_y\left(n_y + \frac{1}{2}\right) \qquad n_x, n_y = 0, 1, \ldots \tag{72}$$

since $\omega_x \neq \omega_y$, there is no reason to expect systematic degeneracies due to spatial symmetry as was the case for the cylindrical structure. Depending on the aspect ratio, only accidental degeneracies may arise.

In Figure 34, we observe level crossings when charging the dot. Level crossings are pointed by arrows and labeled A, B, C, D, and E. For example, at the transition $N = 2 \longrightarrow 3$ electrons, the third and fourth eigenlevels switch, as well as the seventh and eighth eigenlevels. In order to be able to identify the eigenlevels, we need to look at the eigenfunctions. As seen in Figure 35, n_x, the quantum number associated with the larger dimension, changes faster than n_y, the quantum number associated with the smaller dimension. This implies that the aspect ratio of the dot increases with the number of electrons, as the gate is made more positive. This is confirmed by Figure 36 which shows equipotential in the xy plane for $N = 0, 5$, and 10 electrons at $V_G = -1.887$, -1.726, and -1.579 V, respectively. At the center of Figure 36b and c, we can even see how the equipotentials are influenced by the eigenfunctions. The fact that the eigenlevel sequence depends on the number of electrons can be explained easily. For $N = 0$ already, due to the aspect ratio of the QD, the quantum number n_x changes faster than n_y so that the electrons occupy orbitals that extend more in the x-direction than in the y-direction (Fig. 35a).

However, level crossings are observed even if the dot is empty, by solely varying the gate voltage, which is unexpected. Besides, one would expect that high order wavefunctions would be more sensitive to the outer equipotentials that follow more closely the rectangular shape of the device, and consequently have a smaller aspect ratio than inner equipotentials whose shapes are more elliptic. The alteration of the eigenlevel sequence is actually the combination of the many-body effect described above and a three-dimensional effect that can be understood by looking at Figure 37 that shows equipotentials in xz and yz planes, for $V_G = -1.887$ V and $V_G = -1.579$ V, $N = 0$ in both cases. The changes in

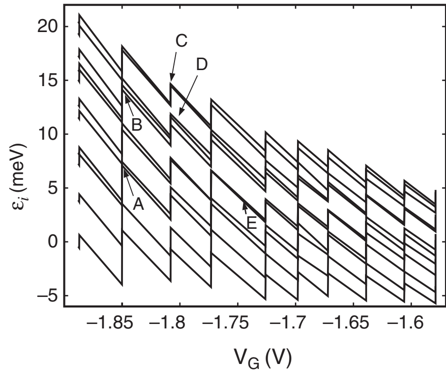

Figure 34. Eigenlevel spectrum ($\uparrow$) for the rectangular quantum dot. The arrows A, B, C, D, and E indicate level crossings.

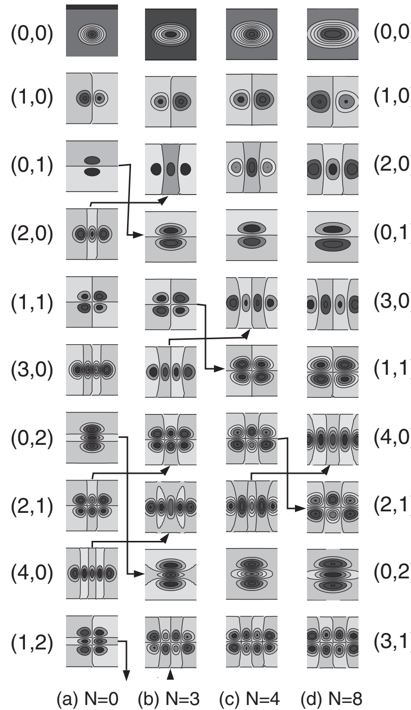

Figure 35. Eigenvector (↑) contour plots for a rectangular VQD as N varies from 0 to 8, showing the alteration of the eigenlevel sequence due to the electrostatic deformation of the confining potential.

the potential profile outside the dot are carried over inside the dot. This effect can also be explained by Eq. (34): the depletion in the bulk influences the curvature of the potential in the dot. Here, however, since the field is stronger in one direction, the rate of change is different along x than along y, which enhances the effect.

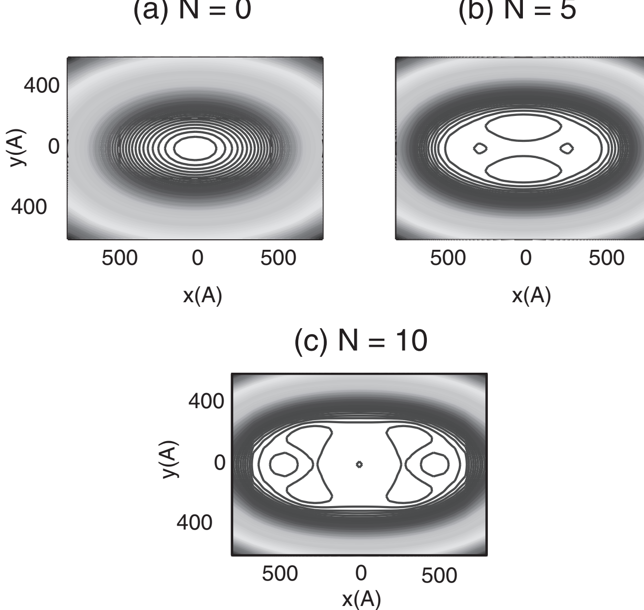

Figure 36. Potential contour plots in the xy plane for $N = 0$, 5, and 10, respectively, showing that the QD aspect ratio increases with N.

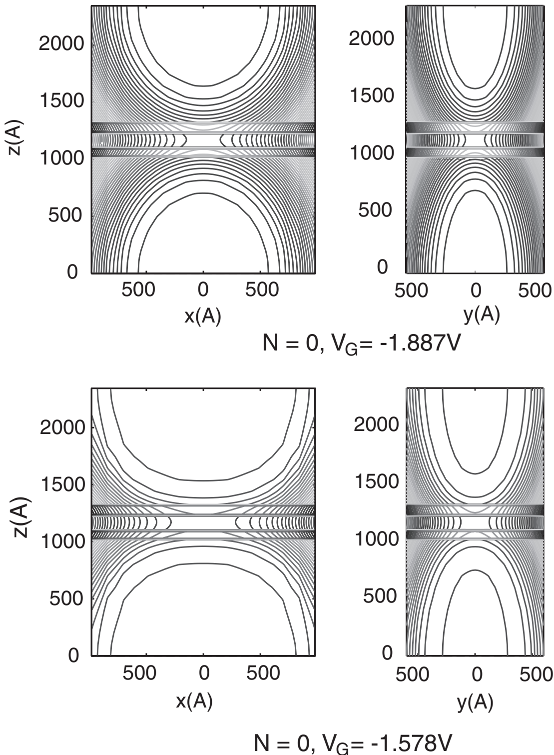

Figure 37. xz potential contour plot for $N = 0$ at $V_G = -1.887$ V and $V_G = -1.578$ V showing that, in addition to the many-body effect, there is a geometrical effect that modifies the potential curvature of the dot.

Figure 38 shows the comparison between the addition energy spectra of a cylindrical QD and a rectangular QD. By comparing Figure 38 to Figure 34, the differences between the two spectra are easily explained. The peak at $N = 2$ is considerably reduced, because, in the rectangular QD with $L = 7000$ Å, the second shell is closer to the first shell than for the 5000 Å diameter cylindrical QD. Hence, the confirmation of Hund's rule fulfillment is rather a matter of how deep the minima are rather than how high the peaks are in the addition energy spectrum as seen for $N = 3$. The rectangular QD has a second shell with only one spatially nondegenerate level whose filling involves no exchange. The

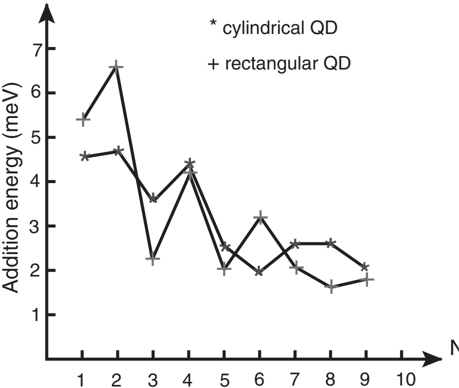

Figure 38. Addition energy spectrum comparison between the cylindrical (+) and the rectangular (∗) QD.

addition energy for $N = 3$ is therefore much larger for the rectangular QD than for the cylindrical QD. The peaks exhibited by both structures for $N = 4$ have two completely different origins. For the rectangular QD, the increase in addition energy stands for the access of a new shell while for the cylindrical QD, it is due to the maximization of the Hartree contribution and minimization of exchange when a shell is half filled plus one electron. For $N = 7$, there is a minimum in the rectangular QD addition energy spectrum because the third shell is half filled and the exchange is maximized, then an increase for $N = 8$ to reach the fourth shell, etc .... The main consequence of the modification of the eigenlevel sequence is that electrons might undergo level transition. Although it is not observed here—the crossings occur at empty level—it will certainly do at a later stage.

Austing et al. studied experimentally and theoretically the charging of rectangular QDs with aspect ratios (δ) varying from 1 to 3.2 [66]. A similar theoretical study has also been performed by Lee et al. [96], for $1 \leq \delta \leq 2$. Both works assume an a priori, lateral CP given by $V_{\text{ext}} = \frac{1}{2}\omega^2(\delta x^2 + \frac{y^2}{\delta})$ and show that, for ellipticity factor $\delta > 1.2$, the shell structure is almost completely destroyed and the total spin sequence is strongly altered. Unsurprisingly, all that was described so far is confirmed by our simulations. But, in addition, we found that the eigenlevel sequence changes when the dot is filled with electrons and the gate is made more positive.

Finally, Figure 39 shows a two-electron configuration for $\delta = 3$ and 5, respectively. In the first case, the attractive confining potential still dominates the electrostatic repulsion and the electrons are in the center of the dot. In the second case, we have the opposite situation where the electron–electron repulsion dominates and the electrons are now clearly localized on each side of the dot.

8.2. Electrostatically Deformable Quantum Dots

Since ideal features are very sensitive to the electrostatic potential confining the electrons [66, 71, 96], Tarucha and co-workers investigated a square VQD with four independent gates [32, 67, 97] that causes deformation of the lateral potential by acting differently on each gate. The interest in this study was to analyze the influence of the spatial distortion of the lateral confinement on the atomiclike properties of the VQD. Evidence of the deformation of the confining potential (CP) was deduced from measurements of the source-drain current peak spacing, which arises from single-electron tunneling between Coulomb blockade regimes, as a function of the gate voltages. In particular, it was found that the peak spacings were more separated when fewer gates were operated, evidencing different CPs for different gate voltage sequences.

Figure 40 shows a schematic view of a 4GVQD with 0.8 μ side length similar to the device investigated by Tarucha et al. [32]. The material sequence of this QD is the same as for the cylindrical QD. The top view (Fig. 40) reveals the four independent Schottky gates A, B, C, D with corresponding voltages V_A, V_B, V_C, and V_D.

Figure 41 shows the source-drain current peak spacing as a function of the gate voltage V_G and the number of electrons, N, inside the dot for two different gate voltage sequences. Each peak, schematically represented by a vertical arrow, corresponds to an additional electron in the dot. The arrow orientation indicates the spin polarity. The peak height is arbitrary since our model does not compute the transport properties. For each sequence, the total spin S as a function of N in the dot is shown on the inset. In Figure 41a, the VQD is pinched off with the four gates at $V_G = -2.98$ V. Then, the four gates are interconnected and swept continuously from -2.98 to -2.73 V to charge 13 electrons in the dot (symmetric charging). If ΔV_G^i denotes the incremental gate voltage required to add the ith electron in the dot, the large gaps ΔV_G^3, ΔV_G^7, and ΔV_G^{13} reflect the shell structure of the orbitals proper to the quasi-parabolic confining potential of a symmetrical structure [11, 70, 81]. For $N = 4$ and 9, $S = 1$ and 3/2, respectively; that is, the dot is fully polarized at half occupied shells because these configurations are more favorable with electrons of parallel spins (exchange energy is maximized) and orthogonal orbitals (Hartree energy is minimized) [71]. In Figure 41b, the two opposite gates A and B are kept at constant voltage $V_A = V_B = -2.73$ V and V_C and V_D are swept backward until the dot is empty again at $V_G = -3.24$ V (asymmetric charging). We first notice that the gate voltage swing with two acting gates is almost exactly twice the gate voltage swing for four acting gates, reflecting the fact that the strength of four gates is twice that of two gates, which confirms the experiments [67]. This effect can also be noticed by observing that the separation between individual peaks

is larger when only two gates are swept. In this respect, it is interesting to compare ΔV_G^j and ΔV_G^k, where the $j-1$th and jth electrons belong to the same shell, whereas the $k-1$th and kth belong to different shells. In Figure 41a and b, $\Delta V_G^k > \Delta V_G^j$ (i.e., the shell structure is preserved even in the asymmetric charging). However, the ratio $\Delta V_G^k/\Delta V_G^j$ is smaller in the asymmetric configuration which indicates that the shell structure is weaker when the CP loses symmetry. As seen in the inset of Figure 41b, the total spin of the dot reveals orbitals filling successively with electrons of antiparallel spins. Indeed, due to the CP deformation, the degeneracies inside a shell are gradually lifted and, at some point, sequential state filling with antiparallel spin electrons becomes more favorable because exchange between electrons does not compensate any more for the degeneracy lifting between occupied levels.

Figure 42 shows the equipotential contours in the x–y plane of the dot, for $N = 12$ at $V_G = -2.73$ V (Fig. 42a), when the dot is still uniformly biased, and for $N = 0$ and $V_C = V_D = -3.25$ V (Fig. 42b), after the asymmetric bias has been applied. In both cases, the very dense equipotentials on the four sides of the plots denote the proximity of the gates. In Figure 42a, the contours are circular at the center and become square at the periphery while in Figure 42b, they become slightly elliptic in the center, which reflects the fact that the electric field is now stronger in the x-direction than in the y-direction. The deformation is weak though, as shown in Figure 42c where the equipotential is drawn at the Fermi level before (solid line, $N = 12$) and after deformation (dashed line, $N = 0$). The area spanned by the Fermi contours reflects the effective size of the QD. Since the solid (dashed) contour corresponds to $N = 12$ ($N = 0$), it simply shows that the QD expands while filled with electrons. It is also worth noticing that, at $T = 0$ K, the electronic properties are mainly determined by the confining potential at the Fermi level, which explains why large square and circular QDs have almost identical electronic properties, as already reported by Kumar [98]. The aspect ratio of the dot after deformation is $\delta = 1.08$, for gate voltage swing ratio of $\Delta V_G = 0.49/0.25 = 1.96$, which shows that we cannot expect to obtain large deformations in electrostatic deformable dots as opposed to rectangular dots where δ, determined by the geometric aspect ratio, is arbitrarily fixed.

Figure 43 shows the contour plots of the first six eigenfunctions as a function of the number of electrons in the case of asymmetric voltage sweep. The upper-most row corresponds to $N = 12$, before deformation ($V_A = V_B = V_C = V_D = -2.73$ V), and the lower-most row corresponds to $N = 0$ ($V_A = V_B = -2.73$ V, $V_C = V_D = -3.24$ V), that is, the strongest deformation. Intermediate rows show the progressive transformation from circularly confined orbitals to elliptically confined orbitals as N varies from 12 to 0. Before deformation, the first orbital is a s-like state according to atomic physics and constitutes the first shell. The second and third orbitals are p-like and form the second shell. The fourth and fifth d-like orbitals and the sixth s-like orbital form the third shell. In general, all the orbitals are less spread out for $N = 0$ than for $N = 12$ because, as mentioned above, the dot has shrunk.

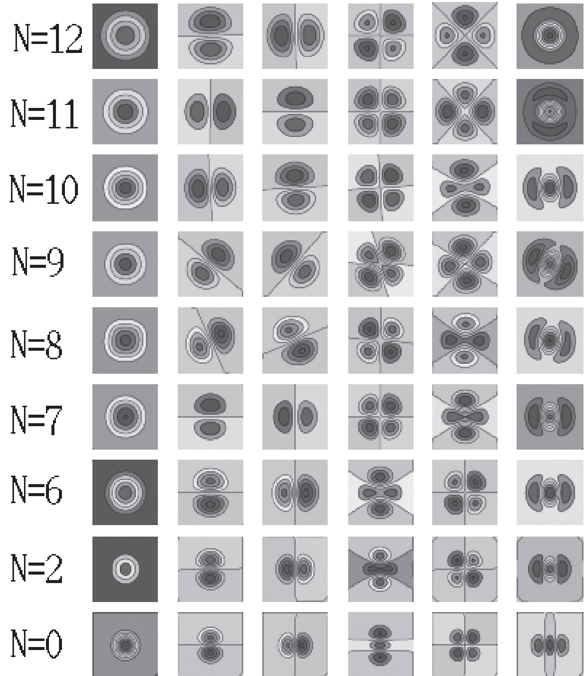

Figure 43. Wavefunction contour plots for the first three shells (first shell: first column, second shell: second and third column, third shell: fourth, fifth, and sixth column) of a 4GVQD. From top row to bottom row, N varies from 12 to 0; V_C and V_D are swept from −2.8 to −3.24 V. V_A and V_B are help at −2.73 V. Reprinted with permission from [113], P. Matagne and J.-P. Figure 44. (a) Theoretical AE spectra of 4GVQD for the symmetric charging (dashed) and the asymmetric charging (solid) as a function of the number of electrons. (b) Comparison between computed AE spectrum (solid) of the asymmetric 4GVQD and the experimental spectrum [11] of a symmetric VQD (dashed) as a function of the number of electrons. Notice that, by definition, $E_a(N) = E_F(N+1) - E_F(N)$, so that a value for $N = j$ in this figure refers to the energy needed to add the $(j+1)$th electron in the dot. Reprinted with permission from [113], P. Matagne and J.-P. Leburton, *Phys. Rev. B* 65, 1553 (2002). © 2002, American Institute of Physics.

The first orbital is very weakly affected by the deformation. From $N = 12$ to $N = 8$, the two p-states do not show any particular favored orientation. Physically, as long as they are degenerate, all linear combinations of the original eigenfunctions are equally valid solutions. Numerically, the orientation of the two degenerate wavefunctions is mainly influenced by the mesh. On the contrary, from $N = 7$ to $N = 0$, V_A and V_B are now substantially different than V_C and V_D so that the states are no longer degenerate and align according to the symmetry axis of the dot. The third shell orbitals (last three columns) show the most spectacular transformations, that is, from circular state symmetry with principal and azimuthal quantum number $(n, l) = (0, 2)$, $(0, -2)$, and $(1, 0)$ to rectangular state symmetry with quantum numbers $(n_x, n_y) = (0, 2)$, $(1, 1)$, and $(2, 0)$ states, respectively. One also notices the crossing between the fourth and fifth eigenlevels at the transition $N = 7 \longrightarrow 6$.

Various addition energy spectra (AES) are shown in Figure 44. Figure 44a shows a comparison between the theoretical AES corresponding to the symmetric charging (dashed line) and the AES corresponding to the asymmetric charging (solid line). The symmetric and asymmetric AES have similar global features. First, there are large peaks at $N = 2, 6$, and 12 due to the shell structure, which reflects the energy contribution needed to lower the next orbital below the Fermi level for admitting the next electron, in addition to the energy required to overcome the electrostatic repulsion of the electrons already present in the dot. These peaks are approximately 0.5 meV lower in the asymmetric AES though, since the intershell spacing is reduced in this configuration. Second, there are secondary peaks at $N = 4$, which has been so far explained in term of Hund's rule (HR) [11, 70]: the third and fourth electrons, with parallel spins (↑), access empty p-like orbitals, maximize E_{xc}, and minimize E_H, inducing a minimum for $N = 3$. For $N = 4$, the fifth electron with antiparallel spin sits on an already occupied state, which increases E_H. Moreover, this electron is the only ↓-electron in the second shell, with no additional exchange interaction; thus, $E_a(4) > E_a(3)$. For $N = 5$, the sixth electron sits on an already occupied orbital sharing exchange interaction with the fifth electron, which lowers $E_a(5) < E(4)$, leading to a peak for $N = 4$. This explanation applies, of course, to the symmetric AES (solid curve, Fig. 44a), which demonstrates that HR is a necessary condition for observing a peak at $N = 4$. However, it is not a sufficient condition since the asymmetric AES (dashed curve, Fig. 44a) also exhibits a peak at $N = 4$, and, as shown before, HR is not fulfilled for asymmetric charging (inset of Fig. 41b). The peak is weaker, however, since there is no exchange between the third (fifth) and four (sixth) which increases the addition energy for $N = 3$ and $N = 5$. Moreover, the fifth electron sits now on an unoccupied orbital, which reduces the addition energy for $N = 4$. For the symmetric charging, there is also a secondary peak for $N = 9$ which, with a dip at $N = 7$, reflects three parallel spins in the third shell

[71, 99]. This peak is not present in the asymmetric AES, which shows that, due to symmetry breaking, levels are more randomly distributed inside the third shell. In summary, secondary peaks in the energy spectrum are not necessarily the signature of parallel spin alignment.

Figure 44b shows a comparison between the theoretical asymmetric charging (solid) and the experimental AES of a circular device [11]. The striking feature here is that the asymmetric AES follows very closely the experimental AES of the cylindrical structure. The asymmetric AES is actually closer to the experimental AES than the symmetric AES, in particular for the third shell charging. This agreement is not fortuitous since it was recently demonstrated that the peak structure in the experimental curve [11] reflects a sequence of alternate spins in the filling of the third shell [71], similar to the sequence achieved in the theoretical asymmetric charging. This observation leads us to conclude that real VQDs are probably never completely symmetric.

Based on the observations above, and on the fact that the total energy of the dot is spin dependent, we investigate the possibility of changing the spin polarization by deforming the dot electrostatically (Fig. 45). Here, we assume that the first shell is completely filled, and we exclusively focus on filling the second shell, which consists of two degenerate p-like states, each of them being twofold spin degenerate. Let us call them $\psi_x^\uparrow$, $\psi_x^\downarrow$, $\psi_y^\uparrow$, $\psi_y^\downarrow$ with eigenvalues $\varepsilon_x^\uparrow$, $\varepsilon_x^\downarrow$, $\varepsilon_y^\uparrow$, $\varepsilon_y^\downarrow$, respectively. Let us assume that, with $N = 3$, $\varepsilon_x^\uparrow$ is occupied. Now, let us increase the four gates positively until the fourth electron enters the dot. By using the same argument as above, as long as the orbitals are degenerate, the energetically most favorable configuration for $N = 4$ is achieved with the occupation of $\varepsilon_y^\uparrow$ with the fourth electron, as predicted by HR. As soon as the fourth electron is in the dot, $V_C = V_D \equiv V_Y$ is made more negative and $V_A = V_B \equiv V_X$ is made more positive to confine electrons stronger along the x- than along y-direction, while keeping $N = 4$ constant. Figure 45 shows the evolution of $\varepsilon_x^\uparrow$, $\varepsilon_y^\uparrow$, and $\varepsilon_y^\downarrow$ with respect to $\Delta V_G \equiv V_X - V_Y$. When $\Delta V_G = 0$, the dot is spatially symmetric; hence, $\varepsilon_x^\uparrow = \varepsilon_y^\uparrow$ and $\varepsilon_x^\downarrow = \varepsilon_y^\downarrow$. The dot is spin polarized, however, and the exchange energy between $\uparrow$-electrons lowers $\varepsilon_x^\uparrow$ and $\varepsilon_y^\uparrow$ with respect to $\varepsilon_x^\downarrow$ and $\varepsilon_y^\downarrow$. Another interpretation of the gap between $\varepsilon_x^\uparrow$, $\varepsilon_y^\uparrow$ and $\varepsilon_x^\downarrow$, $\varepsilon_y^\downarrow$ is given by the Coulomb blockade that should be overcome to populate the empty orbitals. Let us mention that $\varepsilon_x^\downarrow$, which is equal to $\varepsilon_y^\downarrow$ for $\Delta V_G = 0$ and runs parallel to $\varepsilon_x^\uparrow$, is not shown for clarity, since it is never occupied. As V_X (V_Y) is made more positive (negative), the confining potential along y (x) is weaker (stronger), ε_y (ε_x) are shifted down (up), and the energy separation $\varepsilon_x^\uparrow - \varepsilon_y^\uparrow$ grows linearly. It must be noticed that the rate of decrease of ε_y is larger than the rate of increase of ε_x because ΔV_Y should be smaller than ΔV_X in order to maintain four electrons inside the dot. Otherwise, if $\Delta V_Y = \Delta V_X$, the three-electron configuration is more favorable. For $V_G < V_G^S$, $\varepsilon_x^\uparrow$ is smaller than $\varepsilon_y^\downarrow$, and the parallel spin configuration, schematically shown in inset (a) of Figure 45, is favored with respect to the configuration shown in inset (b), because the attractive exchange interaction between electrons sitting on $\psi_x^\uparrow$ and $\psi_y^\uparrow$ is larger than the energy separation $\varepsilon_x^\uparrow - \varepsilon_y^\uparrow$. At $V_G = V_G^S$, $\varepsilon_x^\uparrow - \varepsilon_y^\uparrow = 0.15$ meV exactly offsets the exchange energy between the two parallel spin electrons with wave functions $\psi_x^\uparrow$ and $\psi_y^\uparrow$. For $V_G > V_G^S$, $\varepsilon_x^\uparrow$ is larger than $\varepsilon_y^\downarrow$; that is, the exchange interaction between parallel spin electrons is no longer capable of overcoming the energy separation $\varepsilon_x^\uparrow - \varepsilon_y^\uparrow$, and the $\psi_y^\downarrow$-state becomes energetically more favorable than the $\psi_x^\uparrow$-state. Thus, through electrostatic deformation, it is possible to control the spin polarization of a 4VGQD.

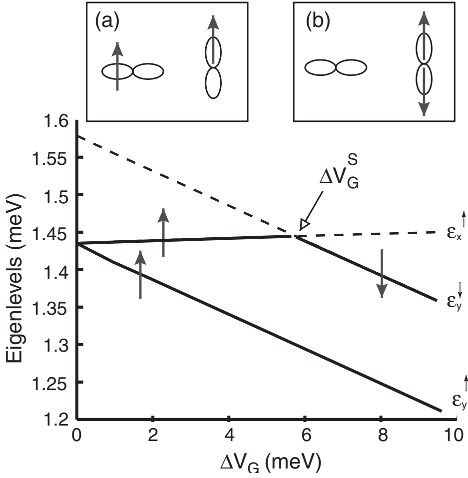

Figure 45. Variation of the single-particle eigenlevels of the second shell $\epsilon_x^\uparrow$, $\epsilon_y^\uparrow$, and $\epsilon_y^\downarrow$ as a function of $\Delta V_G \equiv V_X - V_Y$ ($X = A, B$; $Y = C, D$). A solid (dashed) eigenlevel is connected to an occupied (empty) orbital. For $\Delta V_G < \Delta V_G^S = 5.8$ meV, two parallel electron spins sit on the orbitals associated with $\epsilon_x^\uparrow$ and $\epsilon_y^\uparrow$ so that the favored configuration is shown in the top left inset (i.e., a triplet state). For $\Delta V_G > \Delta V_G^S$, two antiparallel electron spins sit on the orbitals associated with $\epsilon_y^\uparrow$ and $\epsilon_y^\downarrow$ so that the favored configuration is shown on the top right inset (i.e., a singlet state) ($S = 0$). 9. DOUBLE QUANTUM DOTS—ARTIFICIAL MOLECULES

While a single QD displays features characteristic of an atom, an array of QDs coupled through tunnel junctions shows many similarities to molecules and is therefore also called an *artificial molecule*. Just as in molecules, electron states (in coupled QDs) can couple to form covalent states that are delocalized over the entire array, making it possible for an occupying electron to tunnel between the various dots without being localized to any [100, 101]. These *bonding states* are lower in energy than the constituent dot states by an amount that is equivalent to the binding energy of the molecule. For instance, a two-dot system may be compared to a diatomic molecule. Such artificial molecules provide an advantage in that the number of electrons in the coupled dot, equivalently the constituent "atoms" in the periodic table, may be varied by varying a external potential. Different molecular analogs can be realized by varying the size of the dots, simultaneously or independently, and their number of electrons. Furthermore, in the case of coupled PQDs the vibrational motion of a molecule may be simulated by driving such an array between weak and strong tunneling regimes.

Most of the experimental [101–103] and theoretical studies [104–109] on coupled dots have so far been on linear arrays of PQDs, with the exception of some recent work on vertically coupled SADs [75, 93]. In particular, Ruzin et al. [106] studied the Coulomb blockade structure for two nonidentical dots using the activation-energy approach. Stafford and Sharma [107] and Klimeck et al. [108] have used a Mott–Hubbard approach with and without interdot capacitances to determine the many-body wavefunction for an array of dots. More recently Golden and Harpen [109] have studied the problem of Coulomb blockade peak splitting in the weak and strong coupling limits to explain the experimental data in [110]. Partoens and Peeters [75] studied the ground state of two vertically coupled QDs as a function of the interdot distance to explain an experiment performed by Tarucha et al. [64]. Here, we will focus on a planar double quantum dot (DQD) structure because this configuration provides an easy way to control the coupling between the dots electrostatically [111].

9.1. Double Quantum Dot Structure

The schematic of the double dot is shown in Figure 46. It consists of an inverted GaAs–$Al_{0.3}Ga_{0.7}As$ heterostructure which confines the electrons to a 2D gas at the interface. In our model, the simulated structure consists of a 22.5 nm layer of undoped $Al_{0.3}Ga_{0.7}As$ followed by a 125 nm layer of undoped GaAs, and finally an 18 nm GaAs cap layer. The cap layer is uniformly doped to 5×10^{18} cm^{-3} so that the conduction band edge is just above the Fermi level at the GaAs cap layer–undoped GaAs boundary. The inverted heterostructure is grown on a GaAs substrate and charge control is achieved by varying the voltage on the back gate V_{back}. We assume a negligible voltage drop across the substrate; hence, we apply V_{back} directly to the bottom of the $Al_{0.3}Ga_{0.7}As$ layer. The two dots are defined by energizing the 10 metallic gates shown in Figure 46b, with the coupling between them varied by means of the voltage V_t on the tuning gates. Electron charging of the two dots is possible through tunnel injection from the adjacent two-dimensional regions through the 35 nm opening between the opposite stubs. The tuning gates, besides demarcating the two dots, also control the extent to which the two dots are coupled.

Figure 47a shows the total potential for the empty double-dot in the plane of the heterointerface for $V_t = -0.67$ V obtained by LSDA-based computer simulations. The two dot regions are visible as depressions in the region 4000 Å $\leq x \leq$ 8000 Å and 2500 Å $\leq y \leq$ 4200 Å. The potentials in the dots are parabolic at low energy as seen more clearly in Figure 47b, which shows the potential along $x-$, the direction of coupling of the two dots for two values of V_t. For $V_t = -0.67$ V, hereafter referred to as the weak-coupling regime, the interdot barrier (Δ_{67} in Fig. 47) is 4 meV, while for $V_t = -0.60$ V (i.e., the strong coupling regime), the

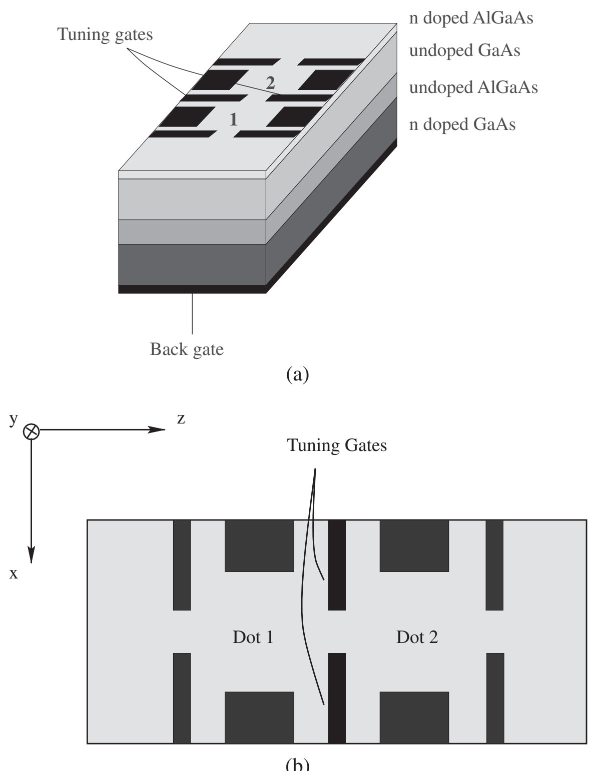

Figure 46. The double dot system: (a) layer structure of the double dot, and (b) schematic representation along the x–y plane. The gate stub voltage is −1.2 V and the gate pad voltage is −0.40 V. Figure 47. Potential profile for the empty double dot (a) in the plane of the heterointerface, and (b) along y in the weak (dashed line), $V_t = -0.67$ V, and strong (solid line), $V_t = -0.60$ V, coupling regimes. The corresponding interdot barriers, Δ_{67} and Δ_{60}, are seen to be 4 and 3 meV, respectively. Reprinted with permission from [111], S. Nagaraja et al., *Phys. Rev. B* 60, 8759 (1999). © 1999, American Institute of Physics.

interdot barrier (Δ_{60} in Fig. 47) is reduced to 3 meV. The entire double-dot is bounded by 14 meV tunnel barriers at the source and drain ends. Confinement along the vertical y-direction is provided by a combination of the band offset of 255 meV between the GaAs and $Al_{0.3}Ga_{0.7}As$ and a large vertical electrostatic field, $F_y \simeq 35$ kV/cm, in GaAs. This results in the separation between energy levels along y of 30–40 meV, much greater than that in the x–y plane, which is of the order of 1 meV. This large level separation results in only the ground state (along the z-direction) being occupied at low temperatures. All the results present correspond to $T = 0.25$ K.

9.2. Electronic Structure and Charging Effect in Double Quantum Dots

Figure 48 shows the schematic of the lowest four states with their wavefunctions in the double dot for $V_t = -0.67$ V and $V_t = -0.60$ V. For both values of V_t the ground states in the individual dots are 1s type and form a degenerate pair. However, the first excited states, which are p_x- and p_y-like, are degenerate for weak coupling (i.e., $V_t = -0.67$ V), whereas for strong coupling ($V_t = -0.60$ V), the p_x-like states couple to form symmetric (bonding) and antisymmetric (antibonding) states which are lower in energy than the p_y-like states as seen in Figure 48. This reordering of the states has an important bearing on the spin polarization of the double-dot system, as shall be fully explained later.

9.2.1. Weak Coupling

Figure 49a shows the *Coulomb staircase* indicating the variation of the number of electrons in the dot with V_{back} at $V_t = -0.67$ V. For $V_{\text{back}} = 0.9769$ V, $\epsilon_{\text{LAO}}(0.5)$ is just negative, implying that the dot can accept one electron in the lowermost 1s state. At this point no distinction is made as to whether Dot 1 or Dot 2 or both are occupied since, in our model, the two dots are identical from the electrostatic and quantum mechanical points of view. The dots are decoupled quantum mechanically, since the leakage of the 1s wavefunctions into the adjacent dot is negligible, and electrostatically, since the distance between the two electron distributions is large, and the resulting Coulomb repulsion, screened by the high dielectric constant of GaAs ($\epsilon_{\text{GaAs}} = 13.2$), is negligible, or at least weak enough to be overcome by less than 0.1 mV change in V_{back} (which is the minimum increment in V_{back} considered in this work). Thus both dots can be charged simultaneously with an electron each, resulting in N jumping from zero to two. Also, the orientation of the individual spins of the two electrons does not matter; we choose both electrons to be ↑. This simultaneous (double) charging persists as long as the two dots are isolated. However, as V_{back} is increased to 0.9804 V, when the next charge degeneracy point occurs, even though Dots 1 and 2 are identical in all respects, only one of them can be charged (with a ↓ electron), but not both. This is due to the fact that charging, say, Dot 1 first increases the total Coulomb repulsion experienced by the incoming electron to Dot 2; that is, electrostatic coupling is established between the dots prior to any appreciable quantum mechanical coupling. Overcoming this repulsion requires a 0.1 mV increment in V_{back}, resulting in the termination of double charging, and is evident as a narrow step for $N = 3$. At $V_{\text{back}} = 0.9805$ V, Dot 2 also can be charged with a ↓ electron increasing N to 4. At this point the double-dot is spin unpolarized and the 1s ground states of both the dots are completely filled with two electrons (↑↓) each. The next available states for occupation are the p_x and p_y states in each of the dots which are above the ground state by $\simeq$1 meV. These states are almost degenerate; the slight splitting of the states caused by the nonisotropicity of the two-dimensional parabolic confining potential in the x–y plane is very small ($\simeq 10^{-6}$ eV). Though

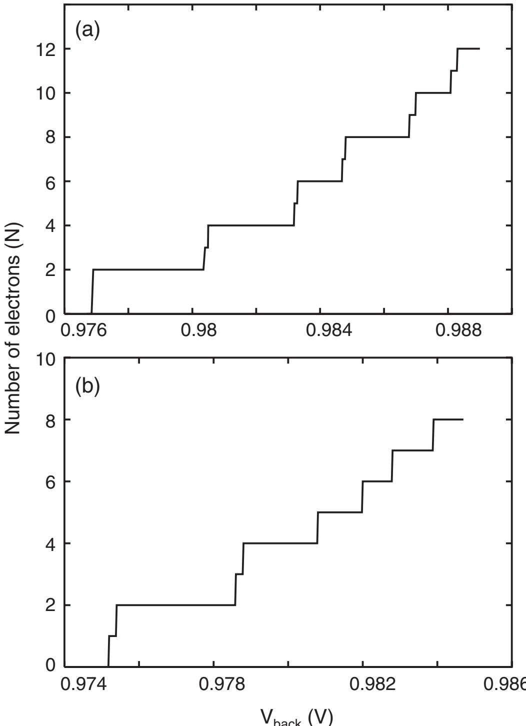

Figure 49. Coulomb staircase diagram for (a) $V_t = -0.67$ V, where the transitions that do not follow Hund's rules are shown in dashed lines, and (b) $V_t = -0.60$ V. Reprinted with permission from [111], S. Nagaraja et al., *Phys. Rev. B* 60, 8759 (1999). © 1999, American Institute of Physics.

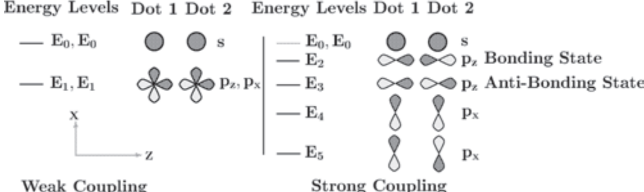

Figure 48. Schematic representation of the lowest six states in the empty double dot in the weak ($V_t = -0.67$ V) and the strong ($V_t = -0.60$ V) interdot coupling regimes. In the former the p_z- and p_x-like states are shown together since they are degenerate within each dot and are decoupled from the corresponding states in the other dot. The reordering of these single-particle states due to increased interdot coupling is also seen. The shaded areas denote the positive portion of the wavefunctions. Reprinted with permission from [111], S. Nagaraja et al., *Phys. Rev. B* 60, 8759 (1999). © 1999, American Institute of Physics.

either of the two states could be occupied we choose to occupy the p_x state since it is slightly lower in energy than the p_y state by $\simeq 10^{-6}$ eV. Even though the leakage of the p_x state into the interdot barrier is greater than that of the 1s state, it is still not coupled to the corresponding p_x state of the adjacent dot to form a bonding state. Consequently, charging of the two p_x states proceeds in the same manner as done for the $N = 2$ to $N = 3$ and $N = 3$ to $N = 4$ electrons. The charging of the dot with the fifth electron occurs at $V_{\text{back}} = 0.9832$ V, where we choose to occupy the p_x state of Dot 1 with an $\uparrow$ electron. Subsequent occupation of the p_x state of Dot 2 with an $\uparrow$ electron ($N = 5$ to $N = 6$ transition) occurs at $V_{\text{back}} = 0.9833$ V, the 0.1 mV increment in V_{back} being required to overcome the Coulomb repulsion due to the fifth electron. It must be noted that the sixth electron occupying p_x state in Dot 2 is also of $\uparrow$ spin, which makes the double-dot spin polarized. This configuration is energetically favorable due to the attractive nature of the exchange interaction between the two $\uparrow$ electrons in the p_x states of Dots 1 and 2. The unpolarized configuration, where the sixth electron (in p_x state of Dot 2) is of spin $\downarrow$ is less favourable and occurs at a slightly higher value V_{back} (0.98335 V) (dashed curve in Fig. 49a). Likewise, occupying the p_y state of Dot 1 with a spin $\uparrow$ electron, thereby increasing N to 7, occurs at a lower voltage than occupying the p_y state of Dot 1 with a $\downarrow$ electron or completely filling the p_x state of Dot 1. This is again a demonstration of Hund's first rule. Similarly, the eighth electron of $\uparrow$ spin occupies the p_y state of Dot 2 at $V_{\text{back}} = 0.9848$ V, requiring a 0.1 mV increment in V_{back} after the p_y state in Dot 1 has been occupied. As before, this 0.1 mV increase in V_{back} is required to overcome the Coulomb repulsion due to the p_y electron in Dot 1. The double-dot at this state is spin polarized with six $\uparrow$ and two $\downarrow$ electrons. The ninth through twelfth electrons (of $\downarrow$ spins) now complete the partially occupied p_y and p_x states in Dots 1 and 2, at $V_{\text{back}} = 0.9868$, 0.9870, 0.9881, and 0.9883 V, thereby reverting the double-dot to a zero spin state. A feature that is conspicous over the $N = 9$ to $N = 12$ range is the increasing interaction between the electrons occupying similar single-particle states in the two dots, as evident in the 0.2 mV increment in V_{back} for $N = 9 \rightarrow N = 10$ ($\downarrow$ electrons in the p_x states of Dots 1 and 2) and $N = 11 \rightarrow N = 12$ transitions, compared to the 0.1 mV increment for the $N = 5 \rightarrow N = 6$ and $N = 7 \rightarrow N = 8$ transitions. This is a consequence of increasing leakage of the wavefunctions into the adjacent dot and the center of the charge distributions in the two dots moving toward each other. Experimental investigations of Waugh et al. [110] on arrays of two and three coupled dots confirm our findings.

9.2.2. Strong Coupling

Figure 49b shows the Coulomb staircase diagram for $V_t = -0.60$ V. The interdot coupling in this case is stronger than in the previous one ($V_t = -0.67$ V), which enhances the leakage of the 1s states into the interdot barrier, thereby increasing quantum mechanical as well as electrostatic couplings between the dots. The increase in electrostatic coupling between the dots (quantum mechanical coupling, although present, is still negligible for s states), expectedly, terminates double charging and charging proceeds sequentially from $N = 1$ ($V_{\text{back}} = 0.9752$ V) to $N = 2$ ($V_{\text{back}} = 0.9754$ V). The increase in interdot electrostatic interaction is evident from the 0.2 mV increment required to charge Dot 2 with a $\downarrow$ electron after Dot 1 has been charged with an $\uparrow$ electron. This increment in V_{back} as may be observed from Figure 49a is more than the interaction between the third and fourth electrons that go to complete the 1s states in Dots 1 and 2 for $V_t = -0.67$ V. The $N = 2 \rightarrow N = 3$ transition occurs at $V_{\text{back}} = 0.7586$ V and the $N = 3 \rightarrow N = 4$ transition at $V_{\text{back}} = 0.9788$ V. The four electrons occupy the two 1s states in Dots 1 and 2. The p_x states which are the lowest available for occupation couple strongly to form symmetric and antisymmetric states akin to *bonding* and *antibonding* states in molecules. A consequence of strong interdot coupling is that for states including p_x, and for higher states, the double-dot appears as a single dot about twice as long along the x-direction as along the y-direction. These lead to a reordering of states in the eigenenergy spectrum, as the states with increasing n_x (number of nodes along x-direction) get closer and move below the p_y state. Thus, the fifth through eighth electrons occupy sequentially the p_x bonding and antibonding states. This is to be contrasted with the partial filling of the p_y and p_x states, for $V_t = -0.67$ V, by the fifth through eighth electrons, which create a spin polarized state with a net polarization $S = 2\hbar$. It is thus clear that an increase in the interdot coupling drives the double-dot from a spin polarized to an unpolarized state. Also, the Coulomb staircase steps assume a more uniform width for $N > 4$ as charging proceeds similar to a single QD.

A complete transformation of the two-dot system into a single large dot requires a de-energizing of the tuning gates (i.e., $V_t = 0$ V), a case that has not been considered in this work. However, from the cases considered so far, it can be extrapolated that the separation of the peaks would be maximum and equal to e/C_T, where C_T is the capacitance of the single large dot. This corresponds to the case in Figure 2d in the work of Waugh et al. [110].

Figure 50 shows the variation of the spin $\uparrow$ and $\downarrow$ electron densities at the GaAs/$Al_{0.27}Ga_{0.73}As$ interface for $V_t = -0.60$ V, along the x-direction for $N = 3, 5$, and 8. Figure 50a shows the variation for $N = 3$, a spin polarized state with two $\uparrow$ and one $\downarrow$ electrons. The two $\uparrow$ electrons occupy the 1s states in Dots 1 and 2, respectively, while the $\downarrow$ electron occupies the 1s state in Dot 1. Consequently, the two electron densities have a 1s type distribution in the two dots. Since the two dots are identical the electron distributions in them are identical. In reality, however, a very small voltage is applied between the drain and source to facilitate electron tunneling injection into the two QDs. This does result in a breaking of symmetry between the two dots and might lead to a small differences between the two electron distributions. The electron densities in the interdot barrier region ($z \simeq 6000$ Å) are small as the coupling of the 1s states is weak for this value of V_t. However, as N increases the stronger electron–electron interaction induces a lowering of the barrier, an increase in the leakage of the wavefunctions, and an increase in the electron densities in the barrier. This is seen in Figure 50b for $N = 5$; the dot is still spin polarized with three $\uparrow$ and two $\downarrow$ electrons. The two $\downarrow$ and two $\uparrow$ electrons occupy the 1s states of Dots 1 and 2, respectively, while the third $\downarrow$ electron occupies the p_z bonding state that gives the jagged profile to the $\downarrow$ electron concentration, as

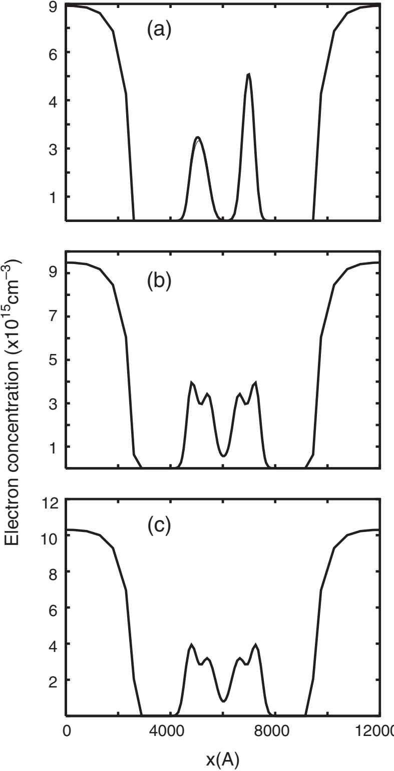

Figure 50. The variation of the electron spin ↑ (solid) and the ↓ (dashed) electron densities at the GaAs/$Al_{0.27}Ga_{0.73}$ interface along the length of the double dot for (a) $N = 3$, $V_{back} = 0.9786$ V, (b) $N = 5$, $V_{back} = 0.9808$ V, and (c) $N = 8$, $V_{back} = 0.9839$ V. Resolution of spin is confined to the dot region only (i.e., $3000 \leq z \leq 9000$ Å). The tuning voltage $V_t = -0.60$ V. Reprinted with permission from [111], S. Nagaraja et al., *Phys. Rev. B* 60, 8759 (1999). © 1999, American Institute of Physics.

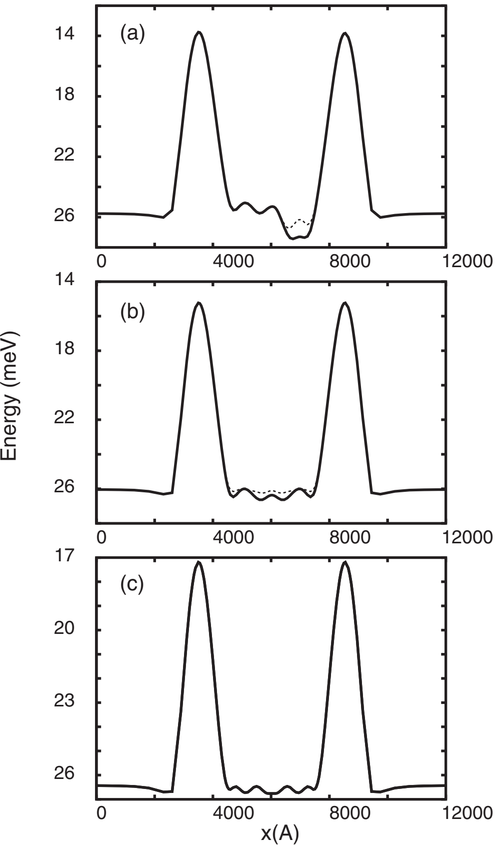

Figure 51. The variation, along $z-$, of the effective potential energy at the GaAs/$Al_{0.27}Ga_{0.73}$As interface for the spin ↑ (solid) and the ↓ (dashed) electrons for (a) $N = 3$, $V_{back} = 0.9786$ V, (b) $N = 5$, $V_{back} = 0.9808$ V, and (c) $N = 8$, $V_{back} = 0.9839$ V. The tuning voltage $V_t = -0.60$ V. Reprinted with permission from [111], S. Nagaraja et al., *Phys. Rev. B* 60, 8759 (1999). © 1999, American Institute of Physics.

seen in the figure. Figure 50c shows the variation for $N = 8$. This is a spin unpolarized state with four ↑ and four ↓ electrons. These fill completely the two 1s states in Dots A and B and the p_x state. Hence, the two (↑ and ↓) distributions look identical.

It is also seen in Figure 50 that the peak electron densities decrease with increasing N. This apparent anomaly can be explained by noting that as more electrons are added to the dot, the volume of the dot increases (in the plane of the interface where the confinement is the weakest). Consequently, the electron density spreads out in the x–y plane while the height of the distribution decreases. This is manifest in the figure as an increase in the width electron distribution.

Figure 51 shows the variation of the effective potential energy for the up and down spin electrons at the GaAs/$Al_{0.27}Ga_{0.73}$As interface for $V_t = -0.60$ V, along the x-direction, for $N = 3$, 5, and 8. The profile for $N = 0$ is similar to that shown in Figure 47 but the height of the interdot barrier is lower at 3 meV. In a spin polarized state the effective potential for ↑ electrons is different from that for the ↓ electrons, since $\mu_{xc}(\mathbf{r})$ for each of them is different. In the $N = 3$ case shown in Figure 51a the higher ↑ density leads to a larger $\mu_{xc}^{\uparrow}(\mathbf{r})$, which, being attractive, lowers the net electron–electron interaction energy. This also leads to the interdot barrier seen by the ↑ electrons to be slightly higher than that seen by the ↓ ones. When N increases to 5, as in Figure 51b, the large ↑ density in the barrier region and the resulting $\mu_{xc}^{\uparrow}(\mathbf{r})$ leads to a drastic reduction in the barrier height. The potential energy profile for the ↑ electrons then resembles a single large dot, instead of a coupled dot. In contrast, for the ↓ electrons whose density in the barrier is small, the potential energy is characteristic of a coupled-dot system. With a further increase in N to 8 (four each of ↑ and ↓ electrons), as in Figure 51c, the profiles for the ↑ and ↓ electrons are identical. The interdot barrier separation is extremely small and is barely noticeable in the figure. A feature that is evident in Figure 51, typical of electrostatically defined dots, is the decrease in confinement with increasing N. The barrier at the source and drain ends decreases from $\simeq$15 meV for $N = 0$ to about 9 meV for $N = 8$.

The variation of interdot coupling by varying V_t is comparable to the vibration of a diatomic molecule. Weak coupling (a large negative V_t) is comparable to the situation wherein the distance between the atoms is large, and strong coupling when the distance is a minimum. Thus by varying V_t the level crossing as a function of separation between the artificial atoms in the molecule can be studied. From the Coulomb staircase diagrams of Figure 49a and b and the ensuing discussions it is seen that a lowering of the interdot

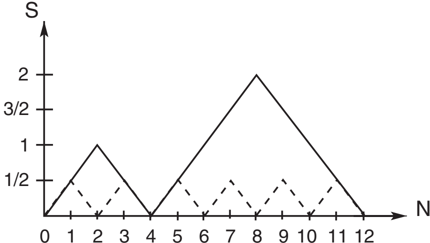

Figure 52. Variation of the total electron spin S in the double dot with N for $V_t = -0.67$ V (solid line), $V_t = -0.60$ V (dashed line). Adapted with permission from [111], S. Nagaraja et al., *Phys. Rev. B* 60, 8759 (1999). © 1999, American Institute of Physics.

barrier results in a reordering of the single-particle levels, thereby transforming the double-dot (for $N = 8$) from a spin polarized to an unpolarized state. The variation of total spin with the number of electrons in the dot in the weak ($V_t = -0.67$ V) and strong ($V_t = -0.60$ V) coupling regimes is illustrated in Figure 52. For weak coupling the total spin of the dot increases in steps of $\hbar/2$ between $N = 5$ and $N = 8$ as the p_x and p_z states in Dots 1 and 2 get charged with an electron each of $\uparrow$ spin, which is an illustration of the familiar Hund's rule in atomic shell filling. For strong coupling such a spin polarization of the dot is precluded by a lifting of degeneracy of the p_x and p_y states, and the total spin is never greater than $\hbar/2$. We would like to draw attention to the fact that for $V_t = -0.67$ V the total spin is seen to be $\hbar$ for $N = 2$ (Fig. 52). This, however, does not imply that the double dot is spin polarized, but rather that since the dots are electrostatically decoupled the spins of the two electrons are not correlated in any way. Though in reality there may be a weak interaction between the two electrons, such an interaction is not observable within the resolution of our model, and our choice of the two electrons being of parallel spin is incidental.

GLOSSARY

Addition energy Amount of energy required to overcome Coulomb blockade and add an electron in a quantum dot.

Artificial molecule Coupled quantum dot structures that exhibit molecular properties due to the quantum nature of the electronic motion.

Coulomb blockade Suppression of conductance through a QD due to electrostatic interactions between electrons.

Quantum dot (QD) Electronic structure in which electrons are completely confined in the three directions of space. Confinement can be electrostatic or structural. When the size of the confining region is comparable to the electron de Broglie wave length, QDs exhibit full quantum behavior: three dimensional energy quantization with orbital motion, shell structure, typical to atoms. For these reasons, QDs are often called artificial atoms.

Quantum well Material structure consisting of heterojunctions that creates a potential well in which electrons are trapped, so their motion is restricted onto a plane parallel to the interface of the two materials.

Quantum wire Material structure in which electrons are confined in two dimensions of space so their motion is restricted to move along a line.

Single electron charging Ability to control the charging of an ultra-small capacitor by one electron at a time due to Coulomb blockade.

Single electron devices Devices based on Coulomb blockade in conjunction with tunneling of single-electron from externally controlled reservoirs.

Single-electron transistor Three-terminal quantum dot device based on the Coulomb blockade effect, in which single electron transfer from a reservoir called the source to another reservoir called the drain is executed through two series tunnel junctions and controlled by a electric gate.

1. INTRODUCTION

Nanotechnology has shown its powerful ability to control electron behavior in a potential well, and the size of the potential well is of the order of the wavelength of the electron wave function [1, 2]. In this quantum mechanical regime, the electron properties depend strongly on the shape of the potential well. The most intensively studied system is the semiconductor quantum well, which consists of three semiconductor layers, one narrow bandgap material layer (called quantum well) sandwiched between two wide bandgap material layers (potential barriers, or just barriers). The potential barriers confine the electrons in the quantum well, and the energy band structure of the confined electron in the quantum well is made of discrete energy sublevels along the confinement direction. The energy positions of the sublevels are determined by the thickness of the quantum well (quantum well width) and the difference between the energy bandgaps of the quantum well and barrier materials (i.e., the height of the potential barrier). In one application of the quantum well system, the inter-sublevel energy is tuned to match the energy of the incident infrared photon [3, 4]. An electron originally occupying one sublevel can then transit to another sublevel by absorbing one infrared photon. This is the core physical nanostructure for infrared detection. Up to now, the quantum well in infrared detection has been one of most successful nanotechnology applications. With the reverse process of absorption, one designs the quantum well in such a way that the electron transits from one sublevel to another by emitting a photon, and with this we are in the field of light emitter and laser.

Infrared detector technology has been well developed based on narrow bandgap materials, like InSb and $Hg_{1-x}Cd_xTe$ [5]. Due to the high performance and flexibility in the infrared detection application, $Hg_{1-x}Cd_xTe$-based infrared detector technology has been studied extensively in the past 30 years. The infrared response of $Hg_{1-x}Cd_xTe$ is based on the interband transition, that is, from the valence band to the conduction band (Fig. 1a). The transition energy (i.e., the energy band gap, E_g) is determined by the mole fraction of Cd atoms, x, in $Hg_{1-x}Cd_xTe$. In such a detection system, the response wavelength can be easily adjusted from 1 to 20 μm. After absorbing the infrared photons, photogenerated electrons and holes transport in opposite directions either in an external electrical field when the device is biased in the photoconductive mode, or in a built-in electric field in the photovoltaic mode. The photoconductive detector is based on the resistance variation due to the increased density of conduction carriers excited from the valence band by the interband transition after absorbing infrared photons. Such a photoconductive operation mode has been widely used for the infrared detectors of $Hg_{1-x}Cd_xTe$.

Since the response time of the $Hg_{1-x}Cd_xTe$ photoconductive detector is normally in the region of 10^{-4} to 10^{-6} second, an image frame from a medium size image format of 256 × 256 pixels takes about 0.1–1 second, whereas the time interval between image frames should be less than 0.01 second when shooting moving objects. A focal plan

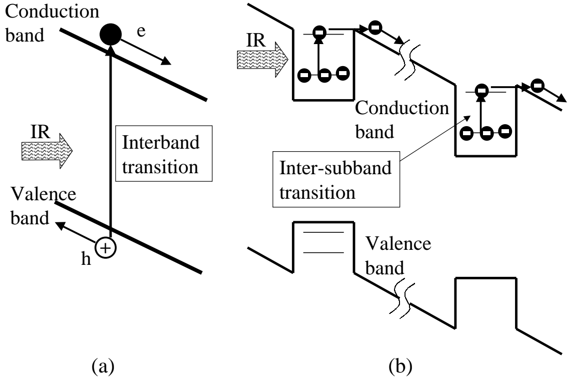

Figure 1. Optical transitions in infrared detection systems. (a) $Hg_{1-x}Cd_xTe$; (b) quantum well infrared photodetector. Interband transition is used for infrared detection in $Hg_{1-x}Cd_xTe$ material, while the QWIP system utilizes the inter-subband transition.

array (FPA) device has therefore been developed to replace the two-dimensional scanner. In such a system, the mechanical scanner is replaced by an electrical scanner fulfilled by a readout circuit, which can be well fabricated by the commercial microelectronic foundry. The integration time for one pixel in the FPA device is now extended to the time duration of the image frame. With this, the image recording speed can be high (e.g., more than 100 frames per second). A spin-off advantage of the electrical readout circuit in the FPA device over the mechanical scanner is the much reduced weight of the detection system, and the reduction can be more than 50%. At present, the infrared technology is mainly based on the FPA technology.

However, the dark current in the $Hg_{1-x}Cd_xTe$ photoconductive detector is normally rather high, which limits the FPA applications. A high dark current of one pixel in a FPA device easily saturates the capacity of the readout circuit in the photoconductive operation mode. Meanwhile, a FPA device consists of a huge number of sensors which are monolithically integrated in one semiconductor chip. A high dark current from one pixel means a huge dark current in the semiconductor chip, which can destroy easily the device. Thus, the $Hg_{1-x}Cd_xTe$ FPA system cannot work in the photoconductive mode, even if the fabrication process of a photoconductive sensor is rather simple and the sensor exhibits very high detectivity and responsibility.

To avoid the large dark current, the photovoltaic mode was developed. In this mode, the dark current is almost zero under the zero external bias condition. The photon excited carriers are swept out by the built-in electric field in the *pn* junction. With the photovoltaic operation mode, very large format FPAs (e.g., 2048 × 2048) have been demonstrated from the *pn* junctions of narrow bandgap semiconductors including InSb and $Hg_{1-x}Cd_xTe$. For long wavelength applications, the 256 × 256 format FPA device has already been commercialized. Up to now, the most widely used infrared FPA devices have been based on InSb and $Hg_{1-x}Cd_xTe$.

However, with the breakthrough of $Hg_{1-x}Cd_xTe$ based FPA device technology, one finds that the yield of the device is still too low, especially for very large format FPA devices. The infrared detectors always work at low temperature at about 77 K, but they are processed at room temperature. The temperature change degrades the device performance caused by the thermal expansion induced defects originating from the interface between the substrate and the $Hg_{1-x}Cd_xTe$ film. Moreover, due to the thermal instability and the material growth difficulties of the $Hg_{1-x}Cd_xTe$ material, the cost is rather high. This strongly limits the $Hg_{1-x}Cd_xTe$ FPA device application.

Since 1980, the infrared detector based on the intersubband transition in quantum well systems, called the quantum well infrared photoconductor (QWIP), has been studied and developed intensively.

By inter-subband transition, one can utilize wide bandgap materials like GaAs for infrared detection [3, 4, 6–20]. As shown in Figure 1b, the photoexcited electrons have a much higher mobility compared to ground-state carriers, which are basically not mobile due to the quantum confinement of the quantum well. This large difference in the mobilities forms the principal infrared photoconductive signal in the QWIP material. Quantum well systems based on wide bandgap III–V materials are much more mature in both the system fabrication and the device processing as compared to narrow bandgap $Hg_{1-x}Cd_xTe$ material. Up to now, most research and commercialization effects have been concentrated on the multiple quantum well system of GaAs/AlGaAs. This quantum well system has an almost perfect lattice match, which makes a good interface between the quantum well material and barrier material (very low density of interface states). Excluding silicon, the compound semiconductor of GaAs is the best developed material among the commonly used semiconductors. By combining the GaAs semiconductor technology and nanotechnology through optimization of the quantum well structure, the QWIP will show its advantages with its low cost, high stability, very large format FPA, easy wavelength extension (especially for the wavelengths longer than 12 μm), easy multicolor integration, and easy monolithic integration of the readout circuit with infrared sensor technology. Figure 2 shows thermal images of a man taking a glass in hand taken by a 128 × 1 linear array and a hand by a 64 × 64 QWIP FPA with a cutoff wavelength of 9 μm. A huge number of research papers have been published since 1985. The number becomes saturated in 1997; from then the commercialization project of the QWIP has focused on the optimization of the device performance.

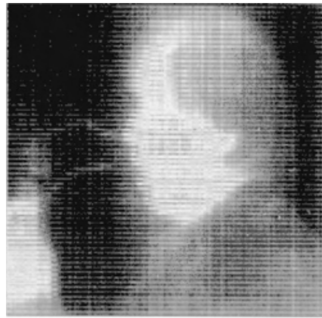

Figure 2. Thermal images of a man with a glass in his hand taken by a 128 × 1 linear array and a hand taken by a 64 × 64 QWIP FPA with a cutoff wavelength of 9 μm.

2. MOLECULAR BEAM EPITAXY TECHNOLOGY FOR QWIP MATERIAL

The quantum well is the core for the infrared detector operation. Conventional infrared detector materials of HgCdTe and InSb utilize inter-band transitions for photon excitation, whereas the QWIP utilizes the inter-subband optical transitions. In HgCdTe and InSb, the optimized material size is of micrometer order determined by the diffusion length of photoexcited carriers and surface-state induced energy band bending. The subband alignment in the QWIP is directly determined by the quantum well width and barrier height, so that both the infrared response wavelength and responsibility are determined by the energy separation between the ground state and first excited state and the energy position of the excited state with respect to the barrier height. A one monolayer change in the quantum well width can significantly affect the QWIP performance. Due to this sensitive condition, almost all QWIP materials are grown by the molecular beam epitaxy (MBE) technique. For the most widely used QWIP material of lattice-matched GaAs/AlGaAs quantum wells, the MBE process has been very well developed. Meanwhile, by using the MBE method one can control the doping profile in the nanometer scale. Therefore the MBE process can in principle grow all kinds of desired quantum well structures for QWIP applications. And normally MBE provides better control over the quantum well potential profile than is observed in the metal-organic chemical vapor deposition method [21].

As we will see in Section 2.2 the best alignment of the subband in quantum wells for the QWIP application is that the first excited state is at the quasi-bound condition. In this case, the photoexcited electrons are easily driven by an external bias. For this, the quantum well structure, namely the quantum well width and barrier height, is to be precisely controlled. During the material growth, the reflection high energy electron diffraction (RHEED) specular intensity oscillation is one of the best monitoring methods.

A typical MBE material growth chamber consists of effusion cells with shutters, a RHEED gun with an electron beam detection fluorescent screen, an ionization gauge for source flux detection, a gate valve to separate the growth chamber and the sample load chamber, a main shutter, and a view port. The effusion cells contain different sources for QWIP material growth, including Ga, Al, and As for quantum well structure growth and Si for *n*-type doping in GaAs material. The RHEED equipment is used to monitor the growth speed and material surface reconstruction. The sample holder in the center of the chamber keeps the (001) GaAs substrate rotating and heated. A typical GaAs substrate temperature for QWIP material growth is about 600 °C. All the effusion cells and substrate holder heater are well controlled by the electrical power with a temperature stability which is better than 0.2 °C, so that a homogeneous QWIP material is guaranteed for the FPA (which will be discussed later) device fabrication. For the QWIP FPA device, the homogeneity of the sample structure is much more critical than that of any other conventional infrared material.

The RHEED measurement is normally in the forward configuration and the energy of the electron beam is in the range of 5–40 keV. The de Broglie wavelength of such electrons ranges from 0.17 to 0.06 Å. The incident angle between the direction of the electron beam and the substrate surface is 1–3°. The penetration length of the electron beam into the GaAs substrate is limited within several atomic layers. In this way, the roughness of the growth surface is clearly reflected by the RHEED pattern. Basic properties of the RHEED pattern are explained by the kinetic theory of the electron diffraction [22]. For a flat growth surface, the lattice can be approximated as a two-dimensional grating which results in a RHEED diffraction pattern in the form of parallel lines. When the surface is deposited with lattice islands in the nanometer scale, the islands act as a three-dimensional grating so that diffraction points will be generated in the RHEED pattern [23–25].

For the GaAs substrate used for the QWIP material growth, the (001) orientation is used. The surface of the (001) GaAs can be either a Ga-rich surface or an As-rich surface. The two surfaces have different surface reconstructions. The Ga-rich surface, which has a 4×2 reconstruction, is to be avoided in QWIP materials. Instead, the As-rich surface with a 2×4 reconstruction is utilized. A high As-atom partial pressure can protect the MBE growth surface against the Ga-rich surface. However, a too high As-atom partial pressure will degrade the migration of Ga atoms on the growth surface, resulting in the generation of lattice islands. In order to grow a high-quality quantum well structure, a layer by layer growth mode is preferred to keep the growth surface flat. Thus the conditions of the MBE growth are very critical so that one has an As-rich surface and, at the same time, a balanced As-atom partial pressure. Obviously, the transition point in the RHEED pattern from 2×4 to 4×2 reconstruction is a good reference condition for the As-atom partial pressure.

The RHEED specular intensity shows a clear oscillation of the intensity during the MBE growth. This oscillation has been used to measure the epitaxy growth rate [26] and to control both the composition and layer thickness in semiconductor superlattice [27]. Moreover, the atom diffusion on the surface [28, 29], growth mechanism [30, 31], and doping behavior [32] have been also studied by the oscillation measurement. The RHEED intensity oscillation period corresponds to the growth time of one atomic layer, that is, one layer of Ga–As atoms along the (001) direction, and its thickness is 2.83 Å. This oscillation behavior is characteristic in the two-dimensional growth mode [33]. We can directly correlate the RHEED intensity with the roughness of the growth surface: A flat surface will result in a high reflectivity, while a rough surface will decrease the specular intensity due to the increased diffusion reflection. Starting at a flat growth surface, the electrons of the RHEED beam are largely reflected into the special specular points. With a constant flux of molecular beams, the anion and cation atoms combine randomly on the growth surface, so that the local growth rates vary. Since the atomic layer step of the (001) GaAs substrate is 2.83 Å, which is much longer than the de Broglie wavelength 0.1–0.2 Å of the electron beam used in the RHEED, the combined Ga–As atoms which are randomly distributed make the originally flat surface "rough." The RHEED electrons are reflected and the electron densities on the special RHEED specular points

decrease. When half of the growing surface becomes occupied by the islands, the degree of roughness reaches its maximum, and the RHEED specular intensities reach their minimum [34]. Further growing of the surface reduces the isolated island density and a complete flat surface gradually emerges. The degree of the surface roughness becomes small, and enhanced RHEED specular point intensities are expected. The completion of the new flat surface thus forms a period of the RHEED intensity oscillation. Normally, a new layer will start to grow before an old one is complete so that gradually the growing surface will consist of several different atomic layers, which decreases the RHEED specular intensity oscillation amplitude.

In general, it is observed from the RHEED intensity oscillation that the QWIP material growth is in the two-dimensional mode. The RHEED oscillation period provides us the absolute growth rate with a precision on the scale of one subatomic layer. Thus, with the help of RHEED intensity oscillation, we can grow the quantum well structure with a layer thickness precision of 1 Å required for the optimized QWIP device operation.

In order to have a high integrity QWIP, a high carrier mobility in the $Al_xGa_{1-x}As$ barrier region is also required, which means a very pure material growth condition. During the material growth, the wall of the MBE growth chamber is normally cooled down to 77 K to prevent foreign atoms or molecules from the chamber wall. And the background pressure should be lower than 10^{-11} Torr. In addition, adsorbed atoms or molecules on the substrate surface should be eliminated. This is done by degassing the substrate at 150, 260, and 370 °C separately for several minutes in a buffer chamber. After that, the substrate is heated to about 580 °C to evaporate the oxidation layer under the protection of As flux. At this moment, the RHEED pattern will change from the amorphous-structure-induced ringlike pattern to the crystal-structure-induced linelike pattern. Finally, the substrate will be heated at 620 °C for about 20 minutes to evaporate other remaining impurity atoms.

2.1. Growth of $Al_xGa_{1-x}As$/GaAs Heterostructure

Unlike all other conventional materials of infrared detector applications, the QWIP system contains a lot of heterointerfaces between GaAs and $Al_xGa_{1-x}As$ layers. Up to now, among all heterostructure semiconductor materials, the GaAs/$Al_xGa_{1-x}As$ system is the best developed in terms of the MBE growth technology. Such a mutual structure has established an excellent basis to industrialize the QWIP materials. Moreover, the system is also used to test and evaluate new epitaxy technologies [35].

The first step to grow GaAs/$Al_xGa_{1-x}As$ heterostructure is to obtain a correct Al composition x. This is done by adjusting the fluxes of Ga and Al sources (i.e., P_{Ga} and P_{Al}). Since the adsorption coefficients of Ga and Al on the GaAs substrate are almost identical, we can approximate the ratio between Al and Ga molecular beam fluxes as their composition ratio of $x/(1-x)$. In the MBE growth process, the flux ratio is determined by the partial pressures measured by the ionization gauge using the equation

$$\frac{J_{Al}}{J_{Ga}} = \frac{P_{Al}\eta_{Ga}}{P_{Ga}\eta_{Al}}\sqrt{\frac{T_{Al}M_{Ga}}{T_{Ga}M_{Al}}} \tag{1}$$

where J_{Ga} and J_{Al} are the Ga and Al fluxes, η_{Ga} and η_{Al} represent the relative sensitivities of the ionization gauge to Ga and Al, T_{Ga} and T_{Al} are the temperatures of the effusion cells, and M_{Ga} and M_{Al} are the Ga and Al atomic weights.

However, this is only the first approximate adjustment of the Al composition. A fine tuning of the composition x is to be achieved by the RHEED specular intensity oscillation measurement. Even for a small Al composition change of $x = 0.02$, the difference in the oscillation periods is unambiguous after 10 oscillation periods. From the oscillation periods of GaAs and $Al_xGa_{1-x}As$ materials (e.g., $\tau_{GaAs} =$ 1548 ms and $\tau_{Al_xGa_{1-x}As} = 1517$ ms), we can determine the composition x:

$$x = 1 - \frac{\tau_{Al_xGa_{1-x}As}}{\tau_{GaAs}} = 0.02 \tag{2}$$

The quantum well width of quantum well is normally equal to 4–5 nm for long wavelength QWIP applications. One atomic layer change means a fluctuation of 6% in the quantum well width. A large quantum well width fluctuation degrades the device performance. There have been extended works on the study of the quantum well interface quality using photoluminescence (PL) spectra and transmission electron microscopy [36]. Since the migration mobility of Ga on the growing surface is larger than that of Al, GaAs-stopped and AlGaAs-stopped surfaces shall have different roughness sizes. Two type of interfaces are expected; one is called the normal interface formed by $Al_xGa_{1-x}As$ grown on GaAs, and the other is the inverse interface which is formed by GaAs grown on $Al_xGa_{1-x}As$. Normally, interface growth pause is used to improve the interface flatness. There are four possible ways: (A) growth pause at the two interfaces of quantum well; (B) growth pause only at the normal interface; (C) growth pause only at the inverse interface; and (D) without any growth pause. At 77 K, the PL linewidths from types A and B are about 4 meV, while they are about 12 meV when types C and D are used. In addition, the quantum wells in the QWIP have to be heavily doped by Si at a level of about 1×10^{18} cm^{-3}. The PL lines of interband transitions from these doped quantum wells are about 22 meV wide when the samples are grown by type A; growth pause type D results in a 39 meV wide PL line.

2.2. Si Doping in Quantum Wells

Shallow impurity doping is another key point in obtaining high quality QWIP materials. In QWIP materials, impurities are normally doped in quantum wells (i.e., the GaAs layers), and Si and Be are used as n- and p-type doping impurity atoms, respectively. The Si atoms are the best shallow donors among IV group elements like Ge and Sn [37]; they can result in an electron concentration as high as 1.8×10^{19} cm^{-3} in GaAs-based materials [38]. As an element in group IV, Si can be either a donor having an ionization

energy of 5.8 meV or an acceptor with an ionization energy of 35 meV in the GaAs material. During the Si doping process in GaAs, there are two possible reactions,

$$\begin{aligned} \mathrm{Si}_{(g)} + V_{\mathrm{Ga}} &\longleftrightarrow \mathrm{Si}_{\mathrm{Ga}}^{+} + e \\ \mathrm{Si}_{(g)} + V_{\mathrm{As}} &\longleftrightarrow \mathrm{Si}_{\mathrm{As}}^{-} + h \end{aligned} \tag{3}$$

where the label (g) represents the gas phase, V_{Ga} and V_{As} are the vacancies of Ga and As, $\mathrm{Si}_{\mathrm{Ga}}^{+}$ and $\mathrm{Si}_{\mathrm{As}}^{-}$ are the cation and anion of Si occupying Ga and As lattice positions, respectively, and e and h are electron and hole.

In the MBE material growth process, the flux ratio of As and Ga sources, $J_{\mathrm{As}}/J_{\mathrm{Ga}}$, determines the behavior of Si in GaAs to be either a donor or an acceptor [39, 40]. If the flux ratio is small, the GaAs surface will be Ga-rich with a (4×2) reconstruction. More Si atoms will occupy the As vacancies. The epilayer becomes p-type. With the increase of the flux ratio, the GaAs surface will change its reconstruction from (4×2) to (3×1) and finally to As-rich (2×4). The Si atoms then mainly occupy the Ga vacancies, resulting in an n-type epilayer. As described previously, the QWIP material should be grown in the As-rich (2×4) reconstruction surface condition; thus the Si doping will mainly result in n-type epilayers.

Increasing the doping concentration to 1×10^{18} cm^{-3}, the impurity scattering will dominate the free electron mobility [40]. Thus, the Si atoms are normally doped in the central parts of quantum wells; the barriers are undoped. In this way, the Si impurities are constrained inside the quantum wells to avoid possible diffusion of Si into the AlGaAs barriers where Si can induce deep levels. Meanwhile, this will also strongly suppress the scattering of photoexcited carriers, since the photoexcited carriers transport mainly in the barriers.

3. PHYSICAL MODEL

3.1. General Consideration of Optical Transition

Figure 3 shows the typical heterostructure of the QWIP system. Denoting the electronic state by its quantum number k, the photon state by photon energy $\hbar\omega$, and photon density by n_{ph}, the absorption rate between two electronic states k_i and k_j is [41]

$$W_{ji}(\hbar\omega) = \frac{\pi\hbar^2 e^2 n_{\mathrm{ph}}}{m_0^2 \omega\epsilon} |\langle k_j | \boldsymbol{a} \cdot \nabla | k_i \rangle|^2 \delta[E(k_i) - E(k_j) + \hbar\omega] \tag{4}$$

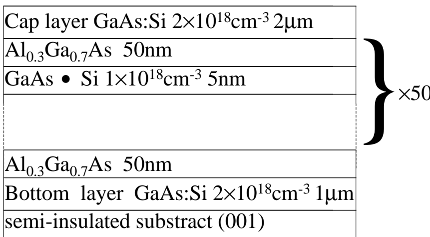

Figure 3. The layer structure of a typical QWIP with a response wavelength of 8 μm.

where $|k_i\rangle$ and $E(k_i)$ are the wave function and eigenvalue of state k_i, respectively. The net absorption rate (per unit time) of the system in a photon field is calculated by

$$W(\hbar\omega) = \sum_{ji} W_{ji}(\hbar\omega)\{f[E(k_i)] - f[E(k_j)]\} \tag{5}$$

where $f[E(k_j)]$ and $f[E(k_i)]$ are occupations of the final and initial electronic states, introduced here due to the Pauli exclusion principle (the initial state occupied and the final state empty).

Considering a beam of photons traveling along the z-axis, we can write the continuity equation for the photon density as

$$\frac{dn_{\mathrm{ph}}(\hbar\omega, z)}{dt} = \frac{\partial n_{\mathrm{ph}}(\hbar\omega, z)}{\partial t} - \frac{\partial[v n_{\mathrm{ph}}(\hbar\omega, z)]}{\partial z} \tag{6}$$

where the first term on the right side of the above equation represents the absorption rate of photons and the second term represents the photons leaving due to the photon current. At the steady state of $dn_{\mathrm{ph}}(\hbar\omega, z)/dt = 0$,

$$n_{\mathrm{ph}}(\hbar\omega, z) = n_0(\hbar\omega) e^{-\alpha(\hbar\omega)z} \tag{7}$$

which defines the absorption coefficient $\alpha(\hbar\omega)$. Since

$$\frac{\partial n_{\mathrm{ph}}(\hbar\omega, z)}{\partial t} = -W(\hbar\omega) \tag{8}$$

we have

$$\begin{aligned} \alpha(\hbar\omega) = \sum_{ij} \frac{\pi\hbar^2 e^2}{m_0^2 v\omega\epsilon} |\langle k_j | \boldsymbol{a} \cdot \nabla | k_i \rangle|^2 \delta(E_j - E_i - \hbar\omega) \\ \times \{f[E(k_i)] - f[E(k_j)]\} \end{aligned} \tag{9}$$

We now begin to calculate the optical absorption when a semiconductor quantum well sample is illuminated. By defining the growth direction of the sample as the z-axis and the plane perpendicular to this direction as the xy-plane, the Hamiltonian is

$$H = -\frac{\hbar^2 \nabla^2}{2m^*} + V(z) \tag{10}$$

in the effective-mass approximation, where m^* is the effective mass and $V(z)$ is the quantum well potential energy. By solving Eq. (10), one can easily get the energy states of ground state and the first excited state. However, the measured absorption line positions can differ from this simple prediction due to different physical effects, including nonparabolic band structures in the z-direction [42–47] and Coulomb interactions [48, 49]. For typical QWIP materials, all of these effects will not shift the absorption peak position by more than 10%. In general they are neglected in the first-order approximation, whereas they should be included in practical device simulations.

The interaction between the incident radiation and the electron is $e\hbar\boldsymbol{A} \cdot \nabla/m^*$ for an incident light of $\boldsymbol{A} = \boldsymbol{A}_0 e^{-i\omega t}$ [41]. Since H is translation symmetric in the xy-plane, the wave function can be expressed as

$$\Phi_{j\boldsymbol{k}}(\boldsymbol{r}) = \phi_j(z) u(\boldsymbol{r}) e^{i\boldsymbol{k}\cdot\boldsymbol{b}} \tag{11}$$

where $u(\boldsymbol{r})$ is the Bloch function and $\boldsymbol{r} = (\boldsymbol{b}, z)$. For all values of j, $u(\boldsymbol{r})$ is identical, since only intra-band transitions among sublevels are involved in the photodetector. $u(\boldsymbol{r})$ can be well approximated as $\boldsymbol{k}$-independent. $\boldsymbol{k}$ and $\boldsymbol{b}$ are the wave vector and coordinate in the xy-plane, respectively. $\phi_j(z)$ is the envelope function and is normalized in the z-direction. Between ground sublevel $|\Phi_{0\boldsymbol{q}}\rangle$ and excited ones, it is easy to show that

$$\left\langle \Phi_{jk} \left| \frac{e\hbar}{m^*} \boldsymbol{A} \cdot \nabla \right| \Phi_{0\boldsymbol{q}} \right\rangle = \delta_{\boldsymbol{k},\boldsymbol{q}} \frac{e\hbar A_z}{m^*} \left\langle \phi_j \left| \frac{\partial}{\partial z} \right| \phi_0 \right\rangle \tag{12}$$

Equation (12) indicates the momentum conservation in the xy-plane, and the transition is between the envelope functions in the z-direction.

Moreover, the most important result indicated by Eq. (12) is the condition of the optical coupling: The coupling of a radiation with the carriers inside a quantum well structure is not possible at a normal incident condition (the light propagates along the sample growth direction so that the component of its vector potential along this direction, A_z, is zero). This has been clearly observed experimentally [50–52]. Optical coupling is therefore a necessity in many practical quantum-well-based photodetector devices. The Bruster angle incidence, 45 degree facet waveguide coupling, and grating coupling are the most frequently used optical coupling methods.

The probability of an electron optically excited from the ground sublevel to sublevel j becomes

$$W_j = \int \frac{2d\boldsymbol{q}}{(2\pi)^2} \left| \frac{e\hbar A_z}{m^*} \left\langle \phi_j \left| \frac{\partial}{\partial z} \right| \phi_0 \right\rangle \right|^2 \frac{2e^2\Gamma}{\hbar(\hbar^2\Omega_j^2 + \Gamma^2)} \times \left[f(E_{0\boldsymbol{q}}) - f(E_{j\boldsymbol{q}}) \right] \tag{13}$$

where we have replaced the energy conservation of $\delta(E_j - E_i - \hbar\omega)$ by the lifetime Γ of electrons in excited states.

3.2. Optical Coupling

As a good example, we consider a typical QWIP material structure for long wavelength detection. The QWIP is n-type and has an optical active layer consisting of 50 periods of $Al_{0.3}Ga_{0.7}As$–GaAs multiple quantum wells (MQWs) along the z-direction. Each $Al_{0.3}Ga_{0.7}As$ barrier is 500 Å thick and the GaAs well is 50 Å thick. The GaAs layer is Si-doped at a level of 5×10^{17} cm^{-3}. Doping levels in the cap and bottom layers are 2×10^{18} cm^{-3}. From the I–V characterization of the QWIP device, the current density is about 0.25 mA/cm^2 at the saturation level.

The active Γ electrons are described by an effective mass of $m^* = 0.067m_0$ in GaAs layers and $0.091m_0$ in $Al_{0.3}Ga_{0.7}As$ barriers, where m_0 is the free electron mass. The conduction band offset is $0.65 \times 1.247x$ eV between $Al_xGa_{1-x}As$ and GaAs.

Due to the isotropic effective mass of the Γ electrons, normal incident photon absorption is not possible, as discussed in the previous section. A component of the optical electric field along the QWIP growth direction, A_z, is required. To utilize Γ electrons, diffraction gratings are used as one of the optical coupling methods. Electron–photon coupling, by Eq. (12), is achieved normally by a two-dimensional optical grating. A typical diffraction grating structure consists of $2a \times 2a$ rectangular apertures, or circular apertures with radius a periodically arranged on the optical pixel, at distance b from each other. The depth of the apertures is denoted as h. Figure 4 shows the scanning electron microscope (SEM) pictures of such an optical grating.

The QWIP structure is not exactly nonconductive. However, the current density at normal device working conditions is very low so that the approximation of nonconduction with respect to the electromagnetic field is acceptable. When analyzing unpolarized infrared radiation, the vector nature of the wave amplitude will not be important, so that we can assume that we are dealing with a scalar amplitude function $\psi(\boldsymbol{r})$ which is a solution to the wave equation of [53]

$$\nabla^2\psi_{\text{ph}} + 4\pi^2k^2\psi_{\text{ph}} = 0 \tag{14}$$

for purely elastic diffraction, where $2\pi k = \sqrt{\epsilon\mu}\omega$ is the wave number. By Huygen's principle and considering a light source far away from the diffraction plane XY, the optical wave function for the refractive diffraction grating defined by its reflection coefficient $q(X, Y)$, which is perpendicular to the direction of radiation incidence, becomes [54, 55]

$$\psi_{\text{ph}}(x, y, R) = \iint q(X, Y) \frac{e^{-i2\pi kr}}{r} cr \times \left[\left(\frac{1}{r} + i2\pi k \right) \cos\,\theta - i2\pi k \right] dX\,dY \tag{15}$$

$r^2 = (x - X)^2 + (y - Y)^2 + R^2$, R is the distance from the observation plane xy to the diffraction grating plane XY, and θ is the angle between the z axis and vector $\boldsymbol{r}$.

From the calculated electric field as shown in Figure 5 for a quarter of a QWIP sensor with typical square apertures, one can observe a periodic behavior of optical field ψ in the xy-plane which is determined by the wavelength of the incident radiation. Such periodicity is expected when considering a one-dimensional grating structure so that the oscillation factor becomes $e^{-i2\pi kr} = e^{-i2\pi kx}e^{i2\pi kX}$. This is very much like the so-called near-field effect extensively applied to the surface properties [56].

Knowing the distribution of the optical field, we can calculate the amplitudes of different optical plane waves propagating in different directions. The optical field can be expressed as

$$\psi_{\text{ph}}(x, y, z) = e^{i2\pi kz} + \sum_{\boldsymbol{k}} t_{\boldsymbol{k}} e^{i2\pi(\boldsymbol{k}cdot\boldsymbol{b} - k_z z)} \tag{16}$$

Figure 4. SEM pictures of a typical optical grating.

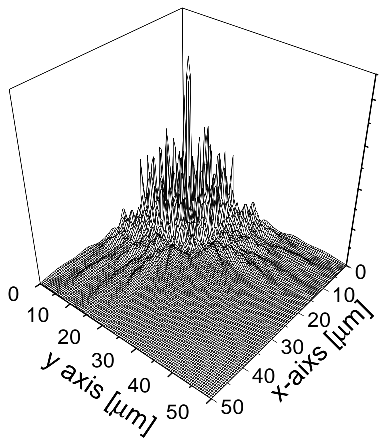

Figure 5. Intensity distribution of the optical field of 10 μm from square diffraction apertures. Reprinted with permission from [276], Y. Fu et al., *J. Appl. Phys.* 84, 5750 (1998). © 1998, American Institute of Physics.

where $\boldsymbol{r} = (\boldsymbol{b}, z)$, $e^{i2\pi kz}$ is the original incident radiation propagating along the z-direction, and $t_{\boldsymbol{k}}$ is the amplitude of the plane wave propagating along the $-z$-direction with wave vector $\boldsymbol{k} = (k_x, k_y)$ in the xy-plane after diffraction. Since we consider only elastic scattering, $k_x^2 + k_y^2 + k_z^2 = k^2$.

The diffraction grating is to be designed for large values of $t_{\boldsymbol{k}}$ corresponding to small values of k_z. The larger these amplitudes, the larger the effective optical strength to excite optical transitions, and thus a larger optical coupling between the incident photons and active electrons in the QWIP. Defining the effective strength of the diffracted radiation along the z-direction which can absorbed by the Γ-electrons in the GaAs quantum well as $\langle |A_z|^2 \rangle = A^2 B/2$, where A is the amplitude of the incident infrared radiation and the factor of $1/2$ is due to the unpolarization of the incident radiation, the value of the B parameter for the grating structure described above is 0.66. Similar results were reported earlier based on the EM mode approach [57].

Based on these design rules for diffraction grating, many different grating structures have been studied, including linear gratings [58, 59], two-dimensional (2D) periodic gratings [57, 60, 61], random reflectors gratings [62, 63], and quantum grid structure [64–67]. By the random reflectors, more passes of infrared light are achieved by the randomly roughened reflecting surface. So the absorption is efficiently enhanced. The minimum feature sizes of random reflectors for the FPA with cutoff wavelengths at 15 and 9 μm are about 1.25 and 0.6 μm, respectively [68, 69]. Combined with a AlGaAs waveguide structure or a thinned substrate, the two-dimensional periodic grating can enhance the detector responsivity by a factor of 2–3 with respect to the standard 45° polished facet illumination device [57, 60]. The so-called corrugated structure also shows its efficient optical coupling. In these structures, linear V-grooves are chemically etched to create a collection of angled facets within a single detector pixel in the FPA device [70, 71]. A general concept of utilizing microlenses was also achieved by monolithic integration. The responsivity is increased by a factor of 2.7 at a response wavelength of 15 μm [72].

3.3. Dark Current and Photocurrent

Dark current is one of key sources of the detection noise [73, 74], which determines the detectivity of the detector. A simple physical model was proposed for an order-of-magnitude estimation [75]. Another model was called the 3D carrier drift model where the three-dimensional electron density on the top of the barriers is estimated by taking into account the drift contribution while the diffusion process is neglected [76]. There was also the so-called emission-capture model which give adequate results for a quite extended range of applied fields [77–79]. A self-consistent drift-diffusion model was proposed in 1995 [80, 81]. This model was used to calculate the QWIP dark current by self-consistently solving the Poisson equation, the continuity equation for electrons in barriers, and the rate equations for electrons in the quantum wells. The self-consistent emission-capture model was also proposed, in which a nonuniform electric field is self-consistently determined by the Gauss law [82]. For the ultrafast electron transport properties, the semiclassical Monte Carlo model was advantageous [83]. Even with such intensive study on the modeling of dark current, a fundamental model is still missing for proper simulation and optimization of a realistic QWIP device, in which a thick barrier and a thin quantum well put the electron transport mechanism in the regime between a complete ballistic transport and a complete drift diffusion [4].

Distributed effects of external bias across the system recently began attracting attention [84–91]. Since the barrier regions are normally undoped and, in general, the carrier concentration in the barrier region can be neglected, the electric field there can be well approximated as constant, as assumed in many theoretical analyses [92, 93]. The electric field in each quantum well is negligible as compared with the ones in the barriers because of the high density of free carriers and the coincidental spatial distributions of electrons in the quantum well with the doped impurities [18].

Figure 6 shows a very small occupation probability $f(E_k)$ of excited states E_k above the barriers (the AlGaAs conduction bandedge is zero). On the other hand, the electron transport from one quantum well to the next quantum well

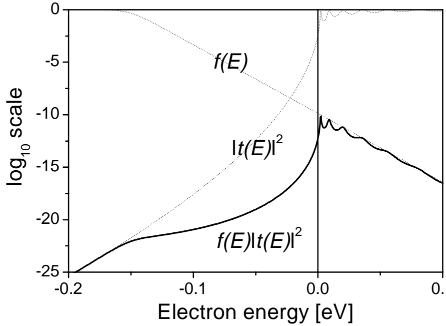

Figure 6. Occupation probability and transmission from one quantum well to the next as functions of the electron energy in the z-direction (the wave vector in the xy-plane is zero). $L = 2.9$ Å, $E_0 = -0.158$ eV, $E_f = -0.151$ eV at 77 K. Reprinted with permission from [277], Y. Fu et al., *J. Appl. Phys.* 87, 511 (2000). © 2000, American Institute of Physics.

is in the context of coherent wave transmission [94, 95],

$$\phi_k(z) = e^{ikz} + re^{-ikz} \tag{17}$$

in the quantum well that emits the electron wave, and

$$\phi_k(z) = t_k e^{ikz} \tag{18}$$

in the quantum well that collects the transmission wave. Here the QWIP is not biased. $\hbar^2 k^2/2m^* = E_k$. The transmission probability $|t_k|^2$ as a function of E_k is plotted in Figure 6, showing that due to the thick barriers the escape of carriers occupying the ground state E_0 in one quantum well to the next is almost impossible. By the complex eigenvalue approach it was concluded [20] that the lifetime of the electrons in the localized ground state E_0 is rather long so that these carriers have a rather small rate to escape to the adjacent wells through barriers.

By Figure 6 it is observed that in the QWIP system, thermal excitation dominates. In other words, the dark current consists of mainly thermally excited carriers over the barriers. It is also reconfirmed here that the current density is rather low so that the approximation of the quasi-equilibrium state is well established (we have used such an approximation by introducing the Fermi level E_f). The approximation of the nonconductive QWIP system when discussing the propagation of the electromagnetic field is also established due to this low conduction current.

It is concluded that electrons in one quantum well transmit to other spatial regions (adjacent quantum wells and contacts) via thermal activation above the barrier (forming the dark current); they become photoexcited to excited states above the barrier by absorbing the incident infrared radiation (forming the photocurrent). The current density has been modeled as $J = ev_d n'$ [92, 93, 96, 97], where v_d is the carrier drift velocity:

$$v_d = \mu F_z \left[1 + \left(\frac{\mu F_z}{v_s} \right)^2 \right]^{-1/2} \tag{19}$$

v_s is the saturation drift velocity ranging from 0.1×10^6 to 5×10^6 cm/s, μ is the low-field carrier mobility (2000 $\text{cm}^2/\text{V} \cdot \text{s}$ for n-type AlGaAs QWIPs), and F_z is the electric field intensity in the barrier region induced by the external bias. The density of mobile carriers n' in the quantum well consists of two parts, $n' = n'_{\text{th}} + n'_{\text{ph}}$, where n'_{th} is the carrier density due to the thermal excitation

$$n'_{\text{th}} = \int_{E_z \geq 0} \frac{2\, dk\, d\boldsymbol{k}}{(2\pi)^3} f(E_{\boldsymbol{k},k}) \tag{20}$$

It is easy to see that, in general, the optical transition probability is very small so that the carrier distribution of the ground state is almost unchanged. The photon excitation is

$$n'_{\text{ph}} = n_0 \int \langle |A_z(\hbar\omega)|^2 \rangle d(\hbar\omega) \int \frac{2dk}{2\pi} \left| \left\langle \phi_k \left| \frac{e\hbar}{m^*} \frac{\partial}{\partial z} \right| \phi_0 \right\rangle \right|^2 \times \frac{\Gamma}{(E_k - E_0 - \hbar\omega)^2 + \Gamma^2} \tag{21}$$

where n_0 is the carrier density occupying the ground state (E_0, ϕ_0).

The device operation of the QWIP is in photoconductive mode. It is similar to the extrinsic semiconductor [98]. Unlike conventional photoconductors, the incident photon is only absorbed in the quantum well region by the intersubband transition, so the absorption region is much narrower than the inactive barrier region. This difference causes the dependence of photoconductive gain to depend on the number of quantum wells [99]. The photoconductive gain is defined as the number of electrons flowing through the external circuit for each photon absorbed. The magnitude of optical responsivity is determined by both quantum efficiency and photoconductive gain [100, 101].

3.4. Boundary Conditions of Continuum States

We consider the multiple quantum well structure in the form of $V[z + n(d_B + d_W)] = V(z)$, where

$$V(z) = \begin{cases} \Delta E_c & -d_W/2 - d_B \leq z < -d_W/2 \\ 0 & -d_W/2 \leq z < d_W/2 \\ \Delta E_c & d_W/2 \leq z < d_W/2 + d_B \end{cases} \tag{22}$$

n is an integer, d_B is the AlGaAs barrier width, and ΔE_c is the barrier height. There is one localized state confined in the GaAs quantum well and its boundary conditions are unambiguous so that the corresponding wave function is zero deep inside the AlGaAs barriers. It is consistent numerically with other theoretical considerations, for example, the complex eigenvalue approach [20, 102–104]. Carriers occupying the localized state are thermal-excited as well as photoexcited to the extended continuum states above the barrier. Theoretically there exist three types of boundary conditions for these extended states. In early works [105–108], the GaAs quantum well and its adjacent two AlGaAs barriers were approximately embedded in an infinitely high barrier media, which is denoted as a box approximation. Because of the infinitely high barrier at the two ends, extended states above the AlGaAs barrier become discrete and are denoted as E_i, $i = 1, 2, \ldots$. Knowing the wave functions it is then easy to calculate the optical matrix element of $\langle \phi_i | \partial/\partial z | \phi_0 \rangle$.

However, due to the consideration of the carrier transport in the QWIP under normal device working conditions, we must envisage the conduction of both the thermal-excited and photoexcited electrons from one quantum to the next one. We first consider the running wave

$$\psi_{\text{running}}(z) = \begin{cases} e^{ikz} + re^{-ikz} & z < -d_W/2 \\ Ae^{iqz} + Be^{-iqz}: & -d_W/2 \leq z < d_W/2 \\ te^{ikz} & z \geq d_W/2 \end{cases} \tag{23}$$

for $E > \Delta E_c$. Here

$$\frac{\hbar^2 q^2}{2m^*} = E - \Delta E_c \qquad \frac{\hbar^2 k^2}{2m^*} = E \tag{24}$$

The third alternative is the transport of the excited continuum states in the Bloch wave form

$$\psi_{\text{Bloch}}(z) = u(z) e^{iKz} \tag{25}$$

where $u(z) = u[z + n(d_W + d_B)]$ accounts for the periodic boundary conditions of the GaAs/AlGaAs multiple quantum wells.

Knowing the optical matrix elements, the optical absorption spectra are easily calculated and numerical results are presented in Figure 7. Fine structures were observed experimentally in QWIPs consisting of multiple quantum wells, whereas single-quantum-well QWIPs display simple spectra [11]. Figure 7 suggests the Bloch-state boundary conditions as the most proper ones for continuum states in characterizing QWIPs consisting of multiple quantum wells (the discrepancy between the theoretical and experimental spectra at low wavelength range can be the result of the complicated conduction band structure at higher electron energies, where the simple effective mass approximation is not valid). The boundary conditions of running waves are definitely proper for QWIPs consisting of a single quantum well or only a few quantum wells, as demonstrated by the tunneling effect experimentally [109].

3.5. Alloy Scattering and Carrier Mobility

Recently, researchers have been interested in the application of quantum well intermixing techniques [110, 111] to modify energy levels of heterosystems. Ion implantation using materials such as Si [112] and As [113] and then further encapsulation by a dielectric layer such as SiO_2 and Si_3N_4 have been proven to be rather effective.

Figure 8 shows dark current spectra from annealed and ion-implanted QWIP samples. Note that the dark current increases by nearly a factor of 2 after proton implantation while it is almost unchanged after annealing. Theoretically it is expected that due to the ion implantation and annealing, the Al atoms diffuse from barrier regions into well regions. The bottom of the quantum well is lifted up and the width of the quantum well is effectively reduced so that subband energies of carriers are increased.

We continue considering the QWIP system consisting of 50 periods of 50-nm-$Al_{0.3}Ga_{0.7}As$/5-nm-GaAs. Generally speaking, due to the surface kinetic processes, a certain degree of GaAs and AlGaAs intermixing is inevitable at the heterointerface [114]. The intermixing is enhanced by postgrowth treatments [110–113, 115–118]. The GaAs/AlGaAs heterointerfaces are described by the degree of the Al interdiffusion [119–121]

$$x(z) = \frac{x_0}{2}\left[2 + \mathrm{erf}\left(\frac{z - d_W/2}{2L}\right) - \mathrm{erf}\left(\frac{z + d_W/2}{2L}\right)\right] \quad (26)$$

where x_0 is the initial Al concentration in the barrier, d_W is the quantum well width, L is the diffusion length, and erf is the error function. The center of the well is located at $z = 0$.

The Al diffusion length is determined by matching the peak positions of the theoretical absorption and experimental photocurrent spectra. Numerical results of the Al diffusion length are listed in Table 1. It is concluded by fitting the peak positions that the Al diffusion length increases from 2.9 to 6.5 Å when the dose of ion implantation increases up to 2.5×10^{15} cm^{-3}. In addition to the redshift of the absorption peak we have observed an increased absorption intensity following the increase of the Al diffusion length. It is due to the increased coupling between the ground state and excited states when the energy separation between them decreases. However, the photocurrent decreases experimentally following the increased H^+ dose.

On the other hand, the density of thermally excited carriers increases by a factor of 4.6 when L increases from 2.9 to 6.5 Å, while experimentally the dark current increases by a factor of only 2. It must thus be concluded that we have to take into account the microscopic mechanism (which has reduced the carrier lifetime) when studying the carrier transport property. Postgrowth processes enhance various scatterings so that the lifetime of carriers at excited states is reduced, and the absorption coefficient is therefore decreased. The concept of carrier lifetime is introduced for steady states. In studying the carrier transport we consider

Table 1. Numerical values of physical quantities.

H^+ dose [10^{15} cm^{-3}]	0	2.5	Exp.
Diffusion length L [Å]	2.9	6.5	
Peak absorption coefficient	24.75	34.61	
n'_{th} [10^7 cm^{-3}]	6.875	31.978	
Carrier mobility	0.82139	0.32895	
Dark current	1	1.8	2.0
Peak photocurrent	1	0.56	0.65

unperturbed electronic states and the transport properties of carriers occupying these states are perturbed by various scattering centers. At the normal QWIP device working temperature of 77 K, alloy scattering is expected to be dominant in GaAs/AlGaAs-based materials. Phonon and impurity scatterings are limited due to the low device working temperature and spatially localized doping profile.

We consider a ternary compound $A_xB_{1-x}C$, where the mole fraction x of atom A varies along the sample growth direction (z-direction) so that $x = x(z)$. Now the potential energy $V(\boldsymbol{r})$ for the one-electron Schrödinger equation is divided into a virtual crystal part

$$V_0(\boldsymbol{r}) = \sum_{\boldsymbol{a}} [xV_A(\boldsymbol{r}-\boldsymbol{a}) + (1-x)V_B(\boldsymbol{r}-\boldsymbol{a})] \tag{27}$$

and a random potential part

$$V'(\boldsymbol{r}) = \sum_{\boldsymbol{a}} c_a [V_A(\boldsymbol{r}-\boldsymbol{a}) - V_B(\boldsymbol{r}-\boldsymbol{a})] \tag{28}$$

where $V_A(\boldsymbol{r}-\boldsymbol{a})$ and $V_B(\boldsymbol{r}-\boldsymbol{a})$ are periodic atomic potentials of compound AC and BC. $c_{\boldsymbol{a}}$ is a random function which is defined only at lattice site $\boldsymbol{a}$,

$$c_{\boldsymbol{a}} = \begin{cases} (1-x) & \text{for an A atom at } \boldsymbol{a} \\ -x & \text{for a B atom at } \boldsymbol{a} \end{cases} \tag{29}$$

The total scattering rate of state $\boldsymbol{ik}$ [122] is

$$M(\boldsymbol{ik}) = \Delta^2[1 - f(E_{ik})] \int [1 - x(z)]x(z)|\phi_i(z)|^4\, dz \tag{30}$$

The velocity relaxation time associated with alloy scattering is

$$\frac{1}{\tau(\boldsymbol{ik})} = \frac{2\pi\Delta^2}{\hbar}[1-f(E_{ik})] \int [1-x(z)]x(z)|\phi_i(z)|^4 dz \tag{31}$$

The above expression reduces to the ones of Ando [123] and Bastard [124] when the alloy composition is constant in the barrier region. It further reduces to the one of bulk material when the alloy composition is constant in the whole sample (e.g., see [125]).

The mobility μ_z along the z-direction determined by the alloy scattering then becomes

$$\mu_z = \frac{e}{n'} \int \frac{2d\boldsymbol{K}}{(2\pi)^3} \tau(\boldsymbol{K}) v_z^2(\boldsymbol{K}) \frac{\partial f(E_{\boldsymbol{K}})}{\partial E_{\boldsymbol{K}}} \tag{32}$$

where $\boldsymbol{K} = (\boldsymbol{k}, k)$, and $\boldsymbol{k}$ is the wave vector in the xy-plane. $\hbar v_z = \partial E_{\boldsymbol{K}}/\partial k$. Increasing L from 2.9 to 6.5 Å (corresponding to the H^+ dose of 2.5×10^{15} cm^{-3}), the calculated mobility decreases from 0.82 to 0.33, a factor of 2.5. We then expect an increasing factor of $31.978 \times 0.33/(6.875 \times 0.82) = 1.8$ in the dark current, which agrees very well with Figure 1 in Section 1, where a factor of about 2.0 has been observed. For the photocurrent, it is 0.56–0.65. Detailed data are listed in Table 1.

4. PROCESSING OF INFRARED PHOTODETECTORS

An infrared FPA device consists of two parts. The first one is the sensor array which is used to convert the infrared radiation into the electrically readable signal. In a QWIP, this signal is the photocurrent. The second part of the QWIP is the electrical circuit array, also called the readout circuit (ROC), which is used to transfer the electrically readable signals generated in very pixels of the array in a series manner. Such a signal transferring mode is very convenient for further data acquisition technology. Normally, the infrared sensor array is hybridized with the readout circuit by indium bumps. This hybridization method is very efficient to improve the total FPA performance, with the combination of the best infrared sensor array and the very well developed silicon based integrated circuit technology. The disadvantage of the hybridization method is its complexity during device processing. A brief description of the QWIP FPA device is schematically shown in Figure 9. The up contact layer of the QWIP material is also used for fabricating the optical grating to couple the infrared (IR) radiation with the inter-subband transition, while the bottom contact layer is a common electrode of the FPA device. By the hybridization method, the QWIP sensor array is connected with the Si readout circuit to form a QWIP FPA. The IR radiation is introduced to the system from the back side of the QWIP material.

A typical QWIP material for long wavelength infrared detection has 50 periods of quantum well and barrier sandwiched between two n^+-GaAs contact layers. Each period consists of one 4.5-nm-thick quantum well and one 50-nm-thick $Al_{0.3}Ga_{0.7}As$ barrier. The quantum wells are doped with Si at a level of about 5×10^{17} cm^{-3}. The contact layers are doped at a level of 1×10^{18} cm^{-3} for ohmic contact. Such a material structure can be further optimized for specific device application requirements. There are two basic considerations in designing a QWIP FPA device: (1) matching the quantum well width and barrier height with the detecting wavelength and (2) increasing the doping concentration to enhance the absorption coefficient within the limit of

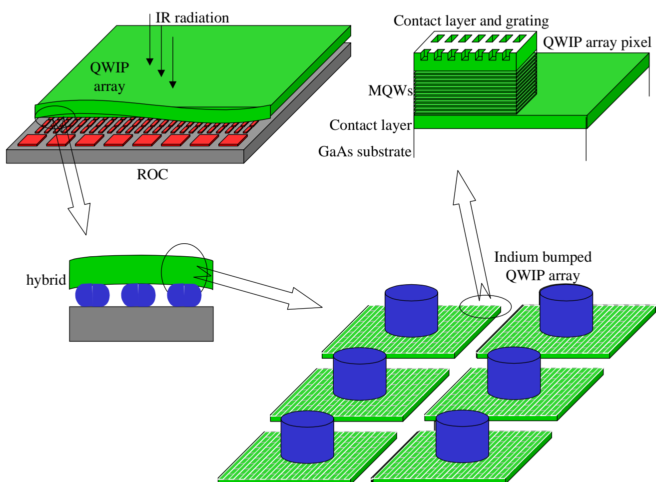

Figure 9. Schematic presentation of the QWIP FPA device.

the dark current that should be acceptable by the readout circuit.

A detailed device process is described schematically by Figure 10. Unlike the single infrared detector fabrication, special attention concerning the uniformity of all pixels in the FPA is to be emphasized in the FPA fabrication. Almost every step will introduce some nonhomogeneous factors. For example, the first step in the process is to fabricate the optical grating on all pixels in Figure 10 to couple the infrared radiation with the inter-subband transition in the quantum wells. The nonhomogeneity in the grating fabrication will result in different optical coupling efficiencies in different pixels. The second step is to make the mesa for all pixels. Both the wet etching and dry etching can be used to create a square mesa with a typical size from 30×30 to 50×50 μm^2. Any fluctuation in the mesa etching process among different pixels will induce different mesa surface states. These surface states will in turn induce different dark currents. In order to make a good ohmic contact between the In bump and the GaAs contact layer, the alloying between the GaAs contact layer and an AuGeNi/Au alloy metal is to be made, on which the In bump is evaporated. The In bump is typically a cylinder with a diameter of about 10–20 μm and a height of 10 μm. Using these In bumps the QWIP array is hybridized with the readout circuit. In a very large FPA format, fluctuations in the In bump diameter and height will affect the electric connection property between the QWIP array and the readout circuit. If an optical pixel is not properly connected with the readout circuit, a blind point appears in the FPA. Finally the QWIP array is mechanically thinned to release the thermal expansion mismatch between the GaAs based material and Si material. A thin QWIP array is also preferred so as to avoid optical cross-talking and to enhance the multi-reflection-induced infrared radiation absorption. At this moment, the QWIP FPA device process is completed.

For the destination application, the device is packaged into a cooling Dewar at a temperature of about 77 K. Normally

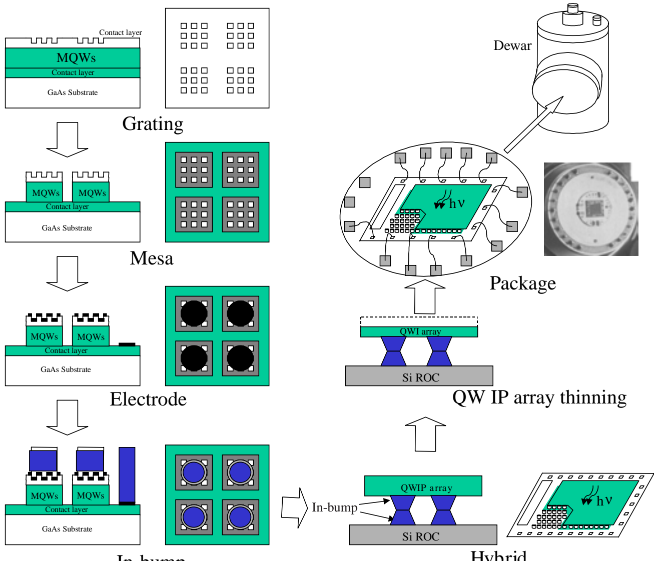

Figure 10. Schematic description of QWIP FPA device process steps.

for the same response wavelength, the dark current of the QWIP detector increases much faster than that of a HgCdTe detector with temperature because of the thermal contact. The packaging process should be much more careful to ensure perfect thermal contact between the QWIP chip and the cooling head.

One important aspect in the FPA fabrication is the optical coupling efficiency. A detailed electromagnetic wave modeling about the light coupling mechanism in the QWIP has been developed [126]. Optical gratings with different spacings were used to match the two-color QWIP device at 4.8 and 9.4 μm [127]. A corrugated QWIP structure was also proposed by chemically etching linear V-grooves through the detector active region, where normal incident light is modified through internal reflections for optical absorption so that the coupling efficiency of the structure does not depend on the wavelength or the grating size [128]. High coupling efficiency was obtained by random reflectors in a very long wavelength (15 μm) infrared QWIP 128×128 FPA device [129], and the prism–film coupler concept was also proposed, which can turn the incident electric field from parallel polarization to perpendicular polarization with respect to the quantum well layer surface, thereby increasing dramatically the absorption coefficient [130]. Direct optical coupling in inter-subband transitions utilizes the AlGaSb multiple-valley quantum-well material, where strong normal-incidence electron absorption can be achieved using asymmetrically stepped quantum wells in contrast to rectangular wells [131].

5. DEVICE DEVELOPMENT

In 1982, a GaAs/GaAlAs quantum well structure was proposed as a potentially new type of infrared photodetector for 3–5 and 8–10 μm bands [132]. Up to now, there has been very extended progress on both the common QWIP structures and some new structures based on the inter-subband transitions.

5.1. *n*-Type QWIPs

Many *n*-type QWIP device structures have been investigated, including bound-to-bound, bound-to-continuum, bound-to-quasibound, bound-to-bound miniband, bound-to-continuum miniband, and bound-to-miniband structures [133–141]. The first bound-to-bound state QWIP was reported at an absorption peak at 10.9 μm and a net absorption of 5% [133]. An increased barrier thickness structure was used to reduce the dark current [134]. Similar to the bound-to-bound QWIP structure, a bound-to-continuum QWIP was realized by decreasing the quantum well width so that the energy position of the first excited state is higher than the barrier height. This makes the photoexcited electrons free to move away from the quantum well. A detectivity of 3×10^{10} cm$\sqrt{\text{Hz}}$/W at 68 K with a cutoff wavelength of 10 μm was reported [135]. In order to improve the QWIP performance, a bound-to-quasibound structure was designed to further reduce the dark current [136]. In this structure

the first excited state is placed exactly at the well top. The bound-to-bound miniband QWIP was experimentally demonstrated in the response wavelength range from 3.6 to 6.3 μm [137], using the superlattice miniband to replace the discrete sublevel in the single quantum well. A square step barrier at the end of superlattice was used to reduce the ground state miniband tunneling dark current [138]. By placing the excited state miniband in the continuum levels, one can improve the transportation ability of photoexcited electrons. This kind of QWIP has been demonstrated in the 5–9 μm spectral range [139]. Finally the bound-to-miniband structure has shown its excellent long wavelength infrared images in a 256×256 FPA camera [141]. The structure consisted of two bound states; the higher energy level is resonant with the ground state miniband in the superlattice barriers. For the thermal infrared image and thermal infrared imaging spectrometer applications, a broadband QWIP in the 6–20 μm spectral range has been developed [142]. Such a detector has been mated to a 640×480 multiplexer.

5.2. *p*-Type QWIPs

The valence band structure is normally much more complicated compared to the conduction band structure due to the nonparabolic and anisotropic effects and the valence subband mixing effects. However, the complications result in the direct absorption of the normal incident IR radiation by the *p*-type material-based QWIPs. These *p*-type QWIPs have thus been introduced and studied [143–146]. The electronic structure and wave functions of the quantum wells have been calculated by the 8×8 envelope-function model to study the photoresponse as a function of the quantum well width, alloy concentration, polarization, and temperature [147]. The dark current behavior has also been studied [148], and the noise was attributed to a number of fluctuation noises associated with generation and recombination of holes from and to the quantum-well bound states and the extended valence-band states [149].

InGaAs/GaAs, InGaAs/InP, InGaAs/AlGaAs, and GaAs/GaInAsP MQWs have very good detectivities in the middle IR wavelength region [150–159]. AlGaAs/GaAs and AlGaAs/InGaAs MQWs grown on (311) GaAs have also been investigated for *p*-type QWIP device applications [160]. The GaAs/AlGaAs *p*-type QWIP device has been systematically studied as far as operation performance as a function of the barrier height and the quantum well width [161, 162]. The photoresponse of the detector ranges from 1.4 to 15 μm [163]. By aligning the first heavy hole subband as the ground state and the second light hole subband in resonance with the top of the barrier, the detector shows a background-limited operation temperature of 100 K for the 3–5 μm response [164]. The optimum two-dimensional doping density obtained for this structure is in the range of $(1\text{–}2) \times 10^{12}$ cm^{-2} [165]. A resonant cavity can increase the absorption efficiency of the *p*-type GaAs/AlGaAs quantum-well peak absorption by 25% [166]. It was also found that a QWIP with three wells of $In_{0.25}Ga_{0.75}As$ of different thicknesses (4.5, 5.5, and 6.2 nm) and an undoped GaAs barrier (40 nm thick) shows a broadband IR detection in the range of 7–14 μm [167]. A very long wavelength detection with a peak response at 19.2 μm has also been demonstrated by the *p*-type compressively strained $In_{0.27}Ga_{0.73}As/Al_{0.15}Ga_{0.85}As$ QWIP [168]. The detectivity of 5.9×10^{10} cm$\sqrt{\text{Hz}/\text{W}}$ at the peak wavelength of 8.1 μm and operation temperature 77 K was obtained [169]. More recently, the *p*-type GaAs/GaInP QWIPs show background-limited performance up to 120 K, while the *p*-type GaInAsP/GaInAsP QWIPs exhibit a rather broadband response window of 2.5–10 μm [170].

5.3. QWIP Light Emitting Device

An innovative concept of frequency up-conversion based on QWIP devices has been proposed [171, 172]. The conversion of the middle infrared radiation into near infrared or visible radiation utilizing inter-subband transitions in the QWIP and interband transitions in the light emitting device (LED) has been demonstrated. A large area QWIP is covered by a near infrared LED to fulfill the frequency up-conversion. The up-converted photons generated by the detection of longer wavelength infrared radiations were collected by a Si charge coupled device, resulting in the up-converted image from the infrared source image [172–174]. Recently, a large pixelless thermal imager based on the up-conversion technique has shown its temperature resolution of 1 K by converting a mid-infrared (9 μm) scene to a near-infrared (0.82 μm) emission image [175]. A multicolor infrared photodetector based on this up-conversion concept has been achieved. A remarkable selectivity of the device has been achieved between wavelengths of 9.1 and 4.85 μm by bias voltage adjustment [176].

5.4. Multicolor QWIP

With the development of the IR technology, the integrated multicolor detector is very advantageous in increasing the target recognition capability. The multicolor, especially having response wavelengths in two atmosphere windows, 3–5 and 8–12 μm, is of great interest. Very extended works on multicolor QWIP devices have been published. There are two typical methods for multicolor detection. One is the voltage tuning method based on the Stark effect of the confined electron states; the other is based on multistack MQWs in the QWIP structure [177–186]. Theoretically, it was observed that a strong Stark effect can tune the response wavelength from 2.9 to 4.2 μm by an electric field variation of 90 to -90 kV/cm [187, 188], and from 7.4 to 14 μm when the electric field changes from 60 to -60 kV/cm [189, 190]. Experimentally a response wavelength tuning from 8.2 to 9.1 μm and 10.8 to 11.5 μm was demonstrated [183].

In the simplest structure, one can electrically tune the response wavelength of a GaAs/AlGaAs asymmetric step quantum well from 8.5 to 13.5 μm [191]. In the multistack MQW structure, the wavelength tuning behavior is determined by both the dc resistance and the dynamic resistance of individual detectors [180, 181, 184, 192, 193]. A structure with four stacks of MQWs for four different detection wavelengths at 4.7, 8.5, 9.0, and 12.3 μm has been fabricated from InGaAs/AlGaAs and GaAs/AlGaAs systems [194].

Recently, a two-color QWIP device has also been demonstrated based on electron transfer between two asymmetric

coupled quantum wells under an applied bias [195, 196]. The intermixing technology in the nanostructure of quantum wells has also shown its potential application of the multicolor detection [197–201].

5.5. Photovoltaic Quantum Well Detector

Similar to the HgCdTe materials, a quantum well photoconductive device has a much larger dark current than the photovoltaic (PV) device, so that the PV device is more suitable in FPA device applications to match with the external readout circuit. Unlike the conventional PV device with the *p–n* junction, an asymmetric nanostructure is used in the quantum well device to generate the necessary built-in field. Many types of structures have been used, including AlGaAs/GaAs and InAs/GaInSb superlattice structures [202–204], modulation doping [205], nanosize AlAs layers induced asymmetric structures [206–209], asymmetric quantum well structures [210], and double-barrier quantum wells [211–216]. A structure consisting of graded barrier between three quantum wells also shows the PV effect [217]. A MQW structure operating in a photovoltaic detection mode with an intrinsic event discrimination capability has also been developed, and the device shows a peak responsivity of 0.4 A/W and a detectivity of 6.0×10^{11} Jones [218]. The dynamic process of the photoexcited carrier was also studied, both theoretically [219] and experimentally, by infrared pulse excitation [220–222]. In order to enhance the PV effect, a four-zone structure was proposed, where every period of the active region consists of an excitation zone, a drift zone, a capture zone, and a tunneling zone [223]. The PV structure was also combined with a PV structure for a two-color device application [224–226].

5.6. High Frequency Response Detectors

Infrared communication needs a very fast response infrared detector. Like optical communication at the wavelength of 1.3–1.5 μm, operation frequencies in the range of GHz are strongly required. For the CO_2 laser based communication, a GHz frequency response detector at the wavelength of 10.6 μm becomes the key device. For conventional infrared detectors, such a high frequency requirement does not impose any problems since the lifetime of photoexcited carriers is rather long. The QWIP device can also operate at such a high GHz response frequency, since the lifetime of photoexcited carriers is about 5 ps [227]. By the optical heterodyne detection technique, an experiment with an intermediate operation frequency up to 26.5 GHz was reported [228]. Furthermore, by combining the conventional heterodyne experimental method with an additional microwave excitation, a frequency separation of two infrared beams up to 82.16 GHz has been achieved [229]. Moreover, theoretical and experimental works focused on the high frequency capability of QWIP are useful for specific applications [230–234].

5.7. FPA Devices

For FPA device applications, the QWIP device should be matched with the external readout circuit electrically. To achieve this, optimization and trade-off of the QWIP operation parameters, including responsivity, dark current, dynamic resistance, noise current, optical gain, and detectivity, are very important and, at the same time, rather complicated [235]. The dark current is one of the key parameters, which should be reduced as much as possible from the viewpoint of perfectly matching the QWIP arrays with the readout circuit. An infrared hot-electron transistor was proposed

Table 2. Optical transition structures of quantum well infrared photodetectors.

Optical transition	Material	Advantage	Disadvantage	Ref.
Bound–bound	GaAs/AlGaAs	high absorption, low dark current	low responsibility, normal incident absorption forbidden	[133, 134]
Bound–continuum	GaAs/AlGaAs InGaAs/InAlAs InGaAs/InP GaInAsP/InP GaAs/GaInP GaAs/AlInP InGaAs/GaAs	high responsibility	low absorption, high dark current, normal incident absorption forbidden	[135, 261–271]
Bound–quasibound	GaAs/AlGaAs	high responsibility, high absorption, low dark current	normal incident absorption forbidden	[136]
Bound–bound miniband	GaAs/AlGaAs	low dark current, low noise, good for very long wavelength response	low responsibility, normal incident absorption forbidden	[137, 138, 272, 273]
Bound–continuum miniband	GaAs/AlGaAs	high responsibility	high dark current, normal incident absorption forbidden	[139]
Bound–miniband	GaAs/AlGaAs, GaAs/AlGaAs/InGaAs	high responsibility, low dark current	normal incident absorption forbidden	[140, 141, 274, 275]
p-Type	GaAs/AlGaAs InGaAs/InP	normal incident absorption	low responsibility, high dark current	[143–158] [159, 161, 162] [166–170]

Table 3. Device structures of QWIPs.

Device structure	Material	Advantage	Disadvantage	Ref.
QWIP-LED	GaAs/AlGaAs, GaAs/InGaAs	optical readout, pixelless for FPA	fabrication complex	[171–176]
Multicolor QWIP	GaAs/AlGaAs, GaAs/InGaAs/AlGaAs	two-color or multicolor detection	fabrication complex	[177–190, 192–201]
Photovoltaic QWIP	GaAs/AlGaAs	low dark current	low resposibility	[202–226]
High frequency response QWIP	GaAs/AlGaAs	very fast response	low responsibility	[227, 228, 230–234]
QWIP FPA	GaAs/AlGaAs	good for infrared technology application	fabrication complex	[235–244, 246, 247]

to reduce the dark current [236]. For other conventional QWIP structures, a low-bias current should be used [237, 238]. Recently, the feasibility of monolithic integration of QWIP with the readout circuit on the same GaAs/AlGaAs material was demonstrated, where a charge storage capability of 2×10^7 electrons in a 50×50 μm^2 area was obtained [239].

As a single device for high temperature operation (>70 K), the HgCdTe material is better than the QWIP material due to the fundamental limitations associated with inter-subband transitions. However, the QWIP is advantageous in the fabrication of large format FPAs due to its high impedance, fast response time, long integration time, and low power consumption [240]. The 128×128 QWIP FPAs at 7.7 μm have been shown to have a high performance at 78 K [241]. For long wavelengths, the FPAs with 256×256 and 640×512 pixels have been demonstrated to have a noise equivalent temperature difference $NE\Delta T$ of only 10 and 20 mK, respectively [242]. A similar result was also reported from a 640×480-pixel single-color FPA, which has a $NE\Delta T$ of 30 mK at 60 K operation temperature [243]. A very useful two-color array for both mid- and long wavelength was reported having a FPA format of 256×256 [243]. Moreover, a 640×480 format monolithically integrated 8–9 and 14–15 μm two-color QWIP FPA was reported [244].

In the practical applications of QWIP FPAs, the 256×256 handheld QWIP long wavelength infrared camera has shown its various possible applications in science, industry, and medicine fields. The hot spots, which are not normally visible, have been clearly revealed in QWIP cameras. The QWIP cameras are perfect fire surveillance devices [245], and the volcanic observation feature (with a temperature variation from 300 to 1000 °C) demonstrates the wide dynamic range of the QWIP [246]. In medical applications, the sensitivity of the QWIP revealed arterial plaque inside a heart [247]. The excellent $1/f$ noise performance of the QWIP FPA operating at 35 K has been successfully used in the slow scan strategy, which is often required in infrared observation from space [245].

6. CONCLUSIONS

Quantum well technology is a typical and a major one-dimensional nanotechnology. With this, one is able to control the electron behavior in semiconductors. For quantum well infrared photodetector applications, detector key parameters can be adjusted from the nanoscale of atomic monolayers to optimize the infrared detection. Tables 2 and 3 list important aspects of the QWIP materials and devices. This novel QWIP will be an important member in the infrared detector family in the very near future. Meanwhile, the QWIP detector performance can be further optimized and new device concepts have been reported based on deeper theoretical investigation and the advancing MBE material growth technology. It has been clearly shown that the commercialization of the QWIP has been very successful due to its maturation of the GaAs based material and related device process technology. Moreover, the intensive research on the QWIP in the past 20 years has greatly improved its IR detecting ability, which is now almost identical to the typical IR materials of HgCdTe and InSb. Current and future research activities concentrate on the normal incident response, dark current reduction, high temperature operation, very long wavelength detection, very large format FPA devices, and monolithic integration. It has been suggested that by further increasing the electron confinement (e.g., to work with quantum dots), higher detector operation temperature and normal incidence absorption coefficients can be achieved [248–258]. The QWIP material grown on Si substrate has also shown its high application potential [259], and special structures have been proposed to reduce the dark current [260].

GLOSSARY

Focal plan array (FPA) An FPA consists of either a one-dimensional or a two-dimensional array of QWIPs sensor. The optical response is fulfilled by the QWIP sensor. Then the electrical signal from the QWIP sensor is picked up by the readout circuit in one by one mode.

Infrared photodetector A device converts that the infrared photon into an electric signal which is ready for use.

Multicolor QWIP One type of QWIP device. With this device, more than one wavelengths can be selectively detected. The electric field can tune the detection wavelength due to the Stark effect in asymmetric quantum well structures. Or one can simply stack QWIP structures with different response wavelengths together during material growth and then pick out the detection signal separately.

Photovoltaic quantum well detector Similar to a normal QWIP device, but a built-in electrical field is created in

the quantum well region by the asymmetric quantum well structure design. Then the photoexcited carrier will be driven by the built-in field and result in the electrical signal without external bias.

Quantum well infrared photodetector (QWIP) Energy sublevels form in the multiple GaAs/AlGaAs quantum wells. Electrons at low-energy sublevels (normally confined in the GaAs quantum wells) absorb infrared photons and then jump to high-energy sublevels (in the AlGaAs barriers), forming a photocurrent in an external bias induced electric field.

1. INTRODUCTION

With the advancements in modern growth techniques such as molecular beam epitaxy and MOVPE, the addition of quantum wells within semiconductor devices has expanded considerably over the past decade. For instance, quantum well infrared photodetectors (QWIPs) [1, 2] rely upon a series of uncoupled quantum wells to detect light by exciting a bound electron into the continuum of states above the quantum well. Self-electro-optic effect devices [3, 4] use a quantum well to enhance carrier confinement and an electric field to produce the quantum confined Stark effect for optical switching.

Upon the application of an electric field, the quantum well is no longer a closed system but becomes an open system [5–7]. This changeover from a closed system to an open system results in a continuum of states arising below the band offset where, at zero electric field, there would exist no states [7]. Moreover, the states above the conduction band offset are also modified with applied electric field. It is this modification of the states that is known as the redistribution of the density of states [5–7] and occurs in both position and energy within a biased quantum well. Furthermore, as there is a redistribution in the density of states below the band offset, there exists a finite probability of the particle lying at those states. Therefore, the wavefunctions for these states are different than the zero field wavefunctions.

The present treatment also questions the validity of the use of the free particle group velocity for a quasi confined system. Traditionally, the free particle group velocity, $\hbar k_z/m^*$, has been used in calculating the current through a quantum structure. However, it has already been shown that for double barrier resonant tunneling structures [5, 6], the local group velocity is a function of position and energy and in only very special cases is the quantity equal to $\hbar k_z/m^*$. The field dependence of the local group velocity when averaged over position, by taking into account the redistribution of the density of states [7], approaches $\hbar k_z/m^*$ only for conduction well above the band offset energy.

The importance of these effects resulting from a perpendicular electric field upon a quantum well will be demonstrated through the calculation of the escape rate of an electron from a biased quantum well [8, 9], the absorption coefficient of a two quantum well QWIP as well as the dark currents for a QWIP. Furthermore, the electron–polar optical phonon interaction is also addressed in terms of the escape rate [10], capture rate, and the general scattering rates.

The determination of the dark current [1, 11] and the escape rate [8, 9] requires the computation of the current density that in turn requires parameters such as carrier concentration, carrier velocity, and the knowledge of the density of states. Furthermore, the calculation of the absorption coefficient [1, 12–21] and the electron–phonon scattering rates [22] requires the knowledge of the matrix elements

between the initial and final state wavefunctions. However, for open systems, the normalization of the wavefunction forces one to use complicated numerical techniques such as the density matrix approach [23] or the Wigner function [24]. A simple calculation of the wavefunctions can be easily achieved by the transfer matrix approach [25] or through Airy functions [25]. However, these methods are (a) not suitable for self-consistent calculations, (b) require the wavefunctions to be artificially boxed normalized, and (c) are error prone.

Over the last several years, quantum wells have been incorporated into semiconductor devices to enhance carrier confinement. A large number of these semiconductor devices [1–4, 26–28] also utilize an electric field applied perpendicular to the quantum well which modifies the electron's dynamics within the quantum well. The characteristics of these devices depend to a large extent on the rate at which carriers escape from the quantum well, the absorption of light, and the interactions between electrons and phonons. For instance, the dark current in quantum well infrared detectors and multiple quantum well avalanche photodiodes has been attributed to the electrons escaping the quantum well [29, 30] while exciton saturation [31, 32] has been linked to the rate at which both the electrons and holes escape the quantum well. However, efforts in modeling such devices as SEEDs and QWIPs have lagged behind the advancements in the growth and fabrication techniques. This has especially been demonstrated through the electron–phonon interaction within a quantum well which has traditionally been linked to the broadening in the absorption spectrum [33] and excitonic peaks [34] as well as the dark currents [35, 36] in QWIPs and SEEDs.

The calculation of the carrier escape time was first reported by Schneider and von Klitzing [32] using thermionic emission to explain their experimental study of carriers escaping a biased quantum well. This model addressed only over the barrier conduction with a transmission coefficient of unity. However, the use of this simple thermionic emission model proved to be inadequate in explaining the experimental results of Cavailles et al. [37] for the escape of both the electrons and holes from a biased quantum well. Also pointed out by Cavailles et al., lack of agreement between the experimental and theoretical results at low electric fields may be due to the sudden change from the two-dimensional (2D) density of states to the 3D density of states. Moss et al. [38] introduced the concept of tunneling through a full width at half maximum (FWHM) calculation and the uncertainty principle in order to theoretically explain the results obtained by Cavailles et al.; however, the Moss et al. treatment provided only a qualitative understanding of the experimental data. Nelson et al. [39] also reported the measurement of photocurrent from a single quantum well. However, in order to explain their experimental results, an adjustable recombination time parameter was introduced to the escape time, which included both tunneling and thermionic emission components of current, to relate the experimental work to the theoretical work.

As electron transport from a biased quantum well can either be through a thermionic current, transport over the barrier, or through a tunneling current, transport through the barrier. The calculation of the current proceeds by integrating over all energies the product of the particle's group velocity, the density of states, the occupation probability, and the transmission coefficient. However, the previously discussed models apply the infinite quantum well density of states [38] to calculate the escape time even though the energy levels are calculated for a finite quantum well. Moreover, as stated previously, in the presence of an electric field the density of states is redistributed in energy as well as position; therefore, the infinite well density of states is an approximation that cannot be justified upon the application of an electric field. In addition, the calculation of the carrier velocity must be based upon the proper density of states where the simplified group velocity of $\hbar k_z/m^*$ cannot be justified [40]. Also, proper partitioning between the thermionic emission and the tunneling current needs to be accounted for which results from the redistribution of the density of states.

The calculation of the electron–phonon scattering rate within a quantum well is critical to understanding the broadening in the absorption spectrum, the capture rate, and the escape rate. Lam and Singh [35] calculated the thermalization of carriers within a biased quantum well through the absorption of a phonons. Ferreira and Bastard [41] and Zhu et al. [42] calculated the scattering rates of electron–phonons in biased and unbiased quantum wells. Zhu et al. included the effects due to confined phonons. Hernandez-Cabrera et al. [43] considered the escape of carriers through a time dependent investigation of the electron–phonon interaction, whereas Feldmann et al. [44] addressed the escape of carriers via a phonon interaction from shallow quantum wells and Shorthose et al. [45] investigated the escape of electrons via phonon assisted tunneling. However, none of the previous studies of the electron–phonon interaction within a quantum well accounted for the redistribution of the density of states when an electric field is applied. Therefore, Section 4 will address the effects of the redistribution of the density of states in the calculation of the general electron–polar optical phonon scattering rate for both emission and absorption of phonons as a function of applied electric field as well as the capture rate and the escape rate due to an electron–phonon interaction.

Determining the performance of quantum well devices requires knowledge of the transport of carriers in and around the quantum well. For instance, the gain [22, 47, 48] and dark currents [1, 29] of a quantum well infrared photodector as well as the modulation bandwidth of quantum well laser [49] are strong functions of the rate at which carriers are captured into the quantum well. Extensive investigation [50–70] over the last decade has theoretically predicted and experimentally verified capture times on the order of femto- [57, 58] to picoseconds [58–60] with an oscillatory behavior [62–69] as a function of quantum well widths. However, these studies [50–68] have been for a flat conduction band which is essential for the operation of quantum well lasers but not for quantum well infrared photodetectors, the quantum well solar cell, or the self-electro-optic device. Furthermore, Vinter et al. [70] studied a specially designed quantum structure under bias by impedance spectroscopy; the theoretical explanation yielded a weaker dependence on the field than the experimental results.

Theoretical calculation of the absorption coefficient for a QWIP [1, 12–21] that explains experimental results has yet to be achieved. Previous calculations of the absorption coefficient [14–20] introduced a dephasing time into the transition rate to account for the broadening in the absorption spectrum. The dephasing time is determined experimentally by measuring the FWHM of the absorption spectrum. This results in a theoretical model which is dependent upon experimental results, making the design of QWIPs difficult. Furthermore, a comparison between the theoretical and experimental magnitudes of the absorption coefficient is usually done on a normalized scale, eliminating any error that may occur between theoretical calculations and experiment results

The dephasing time introduced in the transition rate has been attributed to the scattering [37] of electrons by phonons [14, 21], interface roughness [21], and impurities [21] within the quantum well. Furthermore, band nonparabolicity [19], carrier lifetimes [14, 15, 17], and k_z dependence on k_t [21] have also been attributed to the broadening where k_z and k_t are the wavevectors in the perpendicular (z) and transverse directions, respectively. However, as stated by Sizov and Rogalski [12] and Manasreh et al. [16], the broadening in the experimental absorption coefficient can be different than the theoretical broadening associated with excited state lifetimes, nonparabolicity, inhomogenity of the layers, and phonon interactions. However, none of the previous works have investigated the redistribution of the density of states as a possible source of broadening in the absorption coefficient of a biased quantum well. Since the transition rate of an electron from a bound state to a continuum state is a function of the number of final states through the matrix elements as well as a summation over final states [46], the absorption coefficient is broadened as a result of the redistribution of the density of states. An important implication of the redistribution of the density of states is that the states above the quantum well in a multiple quantum well system are correlated even in the presence of wide barriers. This correlation further affects the redistribution of the density of states, thereby affecting the absorption calculation of single wells especially in the presence of other quantum wells. This effect is enhanced in the presence of an applied electric field.

Quantum well infrared photodetectors with a high detectivity over a varying range of wavelengths [1, 11, 13, 71] have been achieved over the last several years. The range of the wavelength at which the sensitivity peak occurs varies depending upon the size of the conduction band offset as well as the quantum well width. However, variations in the quantum well width are limited to a small range since a higher detectivity occurs when there exists one bound state within the quantum well and a virtual bound state just above the conduction band offset. Therefore, any changes in the location of the sensitivity peak mainly occurs by varying the conduction band offset. However, as previously demonstrated by Levine et al. [11], decreasing the conduction band offset increases the dark currents.

Theoretical calculations of the dark currents have been performed by Levine et al. [1, 11] where the dark current was attributed to the current tunneling out of the quantum well as well as the thermionic emission current above the quantum well. The agreement between theory and experiment was achieved by varying sample parameters to match the experimental results. Liu [13] has also addressed the dark currents by calculating the current exiting a quantum well. His calculation incorporated the capture of electrons into the quantum well since the current exiting a quantum well must equal the current entering the quantum well under steady state conditions.

Considering that a QWIP is fabricated in an n^+–i–n^+ structure [1, 11, 13, 71] and assuming that the current exiting the quantum well is equal to the current captured by the quantum well under steady state [13], dark current must result from the contact or n^+ regions. Furthermore, as the transmission coefficient for an electron exiting a single quantum well is not a strong function of the barrier width and the number of quantum wells, the results of Levine et al. [1, 11] will not change for increasing barrier widths or varying number of quantum wells. Liu et al. have incorporated the barrier width into the dark currents through a transit time calculation, resulting in the dark current being inversely proportional to the barrier width. However, if the dark currents decreases with increasing barrier width, the experimental result of Liu [13] is self-contradictory. Therefore the variation in the dark currents as a function of barrier width and number of quantum well must arise from some other mechanisms.

2. INFLUENCE OF A PERPENDICULAR ELECTRIC FIELD UPON A QUANTUM WELL

Upon the application of an electric field perpendicular to a quantum well, the quantum well becomes tilted (Fig. 1) changing the density of state the group velocity and the wavefunction of the electron. The effects of an applied electric field on the energy dependence of the density of states and the wavefunction for a symmetric quantum wells are investigated within this section.

The redistribution of the density of states is calculated by using the method of the logarithmic derivative of the

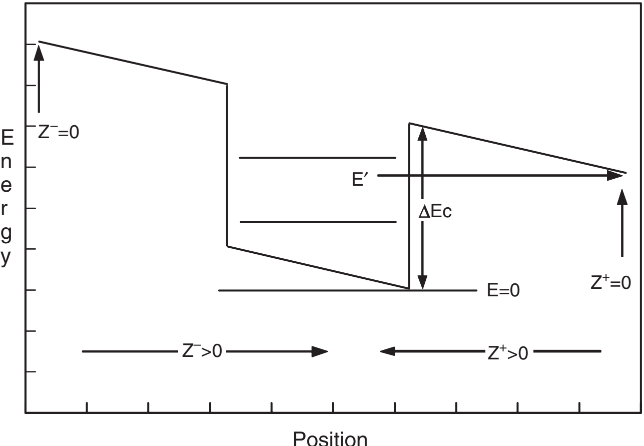

Figure 1. Symmetric quantum well under the influence of an applied electric field.

wavefunctions [5–7]. It is demonstrated that there exist discrete states as well as a continuum of states between the bottom of the quantum well to the conduction band offset which depends upon the applied field and the quantum well itself [7].

After the redistribution of the density of states is obtained, the average local velocity of electrons as well as the electron's wavefunction is calculated within a biased quantum well. Considering that the distribution of electrons within a quantum well is a function of position as well as energy, the average local velocity (group velocity) deviates from the free particle group velocity of $\hbar k_z/m^*$. A comparison between $\hbar k_z/m^*$ and the average local group velocity is made for energies both above and below the band offset as a function of applied electric field, band offset, and quantum well width.

The single electron Schroedinger equation in the effective mass approximation can be written as [46]

$$-\frac{\hbar^2}{2}\frac{d}{dz}\left(\frac{1}{m^*(z)}\frac{d\varphi(E_z, z)}{dz}\right) + (V(z) - E_z)\varphi(E_z, z) = 0 \tag{1}$$

where $V(z)$ is the potential energy which includes all externally applied fields, E_z is the z-directed carrier energy, $m^*(z)$ is the effective mass at position z, $\hbar$ is the reduced Planck's constant, and $\varphi(E_z, z)$ is the envelope function at energy E_z and position z. Using the substitution

$$G(E_z, z) = (2\hbar/jm^*(z))[\varphi'(E_z, z)/\varphi(E_z, z)] \tag{2}$$

Eq. (1) can be rewritten as [5–7]

$$\frac{d}{dz}G(E_z, z) = -j\left[\frac{m^*(z)}{2\hbar}G(E_z, z)^2 + \frac{4}{\hbar}[V(z) - E_z]\right] \tag{3}$$

where $j = \sqrt{-1}$ is the complex number and $G(E_z, z)$ is known as the logarithmic derivative of the wavefunction.

By discretizing both in energy (ΔE) and in position (Δz) (i.e., for a piecewise continuous potential profile), Eq. (3) can be solved to yield

$$\begin{aligned} G^{\pm}(E_z, z_i) &= G_{oi}\frac{G(z_{i-1})\cosh(\xi_i\Delta z) \mp G_{oi}\sinh(\xi_i\Delta z)}{G_{oi}\cosh(\xi_i\Delta z) \mp G(z_{i-1})\sinh(\xi_i\Delta z)} \\ &= G_R^{\pm}(E_z, z_i) + jG_I^{\pm}(E_z, z_i) \end{aligned} \tag{4}$$

where $G_{oi} = 2\xi_i\hbar/jm^*(z_i)$, $\xi_i = j\sqrt{(2m^*(z_i)/\hbar)/(E - V(z_i))}$, and $\Delta z = z_i - z_{i-1}$. The positive and negative signs indicate the direction of the calculation of $G^{\pm}$; for G^+ the calculation proceeds from negative to positive values of z and vice versa for G^-.

Once the logarithmic derivative of the wavefunction in both the positive and negative directions is known for all positions and energies [Eq. (4)], the one-dimensional (1D) density of states can be calculated as a function of position and energy by [5–7]

$$g_{1D}(E_z, z) = \text{Im}\left[\frac{j8/\pi\hbar}{G^+(E_z, z) - G^-(E_z, z)}\right] \tag{5}$$

The energy dependence [5–7] of $g_{1D}(E_z, z)$ can be obtained by integrating over distance, eliminating the position dependence, as

$$\langle g_{1D}(E_z)\rangle = \frac{1}{L_{\text{well}}}\int_0^{L_{\text{well}}} g_{1d}(E_z, z)dz \tag{6}$$

where L_{well} is the length of the quantum well. The total three dimensional density of states is calculated by convolving the 1D density of states with the 2D density of states. As shown in Eq. (7), this integration is trivial due to the delta function in energy:

$$\begin{aligned} g_{3D}(E'') &= \frac{m^*}{\pi\hbar^2}\int_0^{\infty} dE_t \int_0^{E''} \langle g_{1D}(E_z)\rangle dE_z\, \delta(E - E_t - E_z) \\ &= \frac{m^*}{\pi\hbar^2}\int_0^{E''} \langle g_{1D}(E_z)\rangle dE_z \end{aligned} \tag{7}$$

As shown in Figure 1, there exists an energy, the tunneling energy, below which the transmission of an electron out of the quantum well is practically zero. Since the energies below E', the tunneling energy, are still bounded, the density of states below E' is the usual quantum well density of states for a finite quantum well. This results in the total three-dimensional density of states within a biased quantum well as

$$g_{3D}(E'') = \sum_{\substack{n \\ E_n < E'}} \frac{m^*}{\pi^2\hbar^2}(k_{zn} - k_{z(n-1)}) + \frac{m^*}{\pi\hbar^2}\int_{E'}^{E''} \langle g_{1D}(E_z)\rangle dE_z \tag{8}$$

where

$$k_{zn} = \sqrt{\frac{2m^*E_n}{\hbar^2}} \qquad k_{z0} = 0$$

As stated previously, once the logarithmic derivative is known for all positions and all energies [Eg. (4)], the local group velocity can be calculated. Following the method in [5–7, 46], the local group velocity, $v_g^{\pm}(E_z, z)$, is one-half the real part of $G^{\pm}(E_z, z)$, where the positive (negative) sign indicates a positive (negative) velocity. The average local velocity is obtained by averaging the number of electrons at positive E_z with the local velocity over position as

$$\langle v_g^{\pm}(E_z)\rangle = \frac{\int_0^{L_w} n_{1d}(E_z, z)v_g^{\pm}(E_z, z)\, dz}{\int_0^{L_w} n_{1d}(E_z, z)\, dz} \tag{9}$$

where $n_{1d}(E_z, z)$ $\{=f(E_z)g_{1D}(E_z, z)\}$ is the number of carriers at position z and energy E_z and obtained by multiplying the Fermi distribution function by the one-dimensional density of states.

For the calculation of the scattering rates later addressed in this chapter, the wavefunction of the electron is required. The wavefunctions can be calculated by Eqs. (3) and (4) as

$$\varphi(z, E_z) = \exp\left[\int_0^z \zeta(z', E_z)\, dz' + \int_0^z \beta(z', E_z)\, dz'\right] \tag{10}$$

where

$$\begin{aligned} \zeta(E_z, z) &= -[m^*(z)G_R^+(E_z, z)]/2\hbar \quad \text{and} \\ \beta(E_z, z) &= i[m^*(z)G_I^+(E_z, z)]/2\hbar \end{aligned} \tag{11}$$

The structure considered is a symmetric quantum well consisting of 200 Å AlGaAs barriers and a 100 Å GaAs

quantum well. The concentration of Al is 20%, yielding a conduction band offset of 0.1621 eV and effective masses of 0.084 for AlGaAs and 0.067 for GaAs.

The energy levels and tunneling energy are plotted as a function of the applied electric field in Figure 2. As seen from the graph, the tunneling energy decreases and the energy levels increase with increasing electric field. The energy reference for the energy levels is the lowest possible energy within the quantum well.

The 1D density of states is plotted in Figure 3 as a function of energy with applied electric field as a parameter. Since both of the energy levels are below the tunneling energy when the electric field is below 20 kV/cm, the 1D densities of states are delta function spikes, as shown in Figure 3a. Also shown in Figure 3a is the existence of states between the upper most energy level and E_c. As was stated before, this is a result of the system being unbounded for energies greater than the tunneling energy when an electric field is applied. Figure 3a also shows the virtual bound states which occur above the conduction band offset (dotted vertical line), E_c. As the electric field is increased to 30 kV/cm, only the upper energy level is above the tunneling energy. This creates a spreading in the 1D density of states around the upper energy level as shown in Figure 3b. However, the spreading of the density of states is not limited to a small area around the energy level but is continuous to E_c and is more pronounced compared to the 20 kV/cm case. Also shown in Figure 3b are the virtual bound states which are becoming less defined and shifting to a higher energy. Increasing the electric field further results in the spreading of the density of states for the virtual bound states. The uppermost energy level eventually shifts above E_c, and there is an increase in the number of states between the energy levels as well as above the upper most energy level. This is demonstrated in Figure 3c–e for electric fields of 50, 100, and 140 kV/cm. The spreading out of the 1D density of states and the shifting of energy peaks suggests that as the electric field is increased, the quantum well loses the steplike characteristics of the zero field density of states and approaches the 3D density of states for bulk. This will be discussed further in the next paragraph.

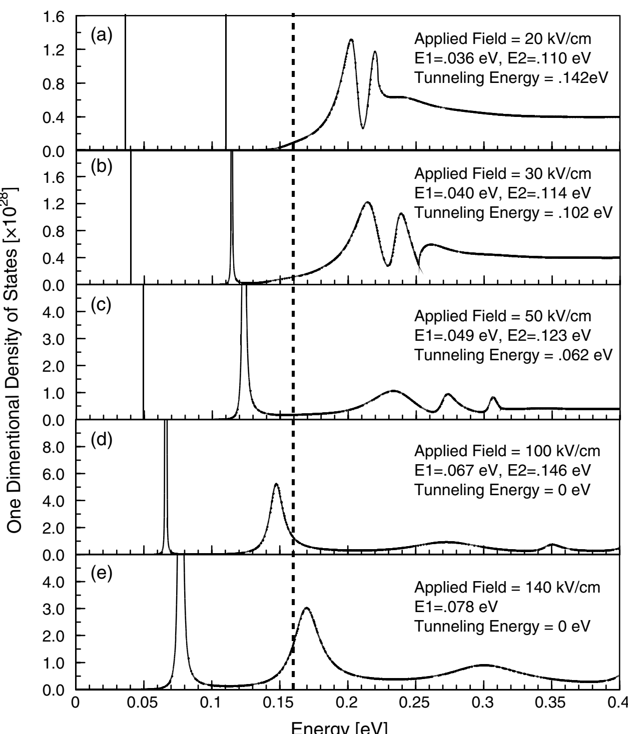

Figure 3. One-dimensional density of states for a symmetric quantum well as a function of energy and applied electric field. Reprinted with permission from [46], K. R. Lefebvre, Electron Dynamics in a Biased Quantum Well, Ph.D. Dissertation, University of Connecticut, Storrs, CT, 1997.

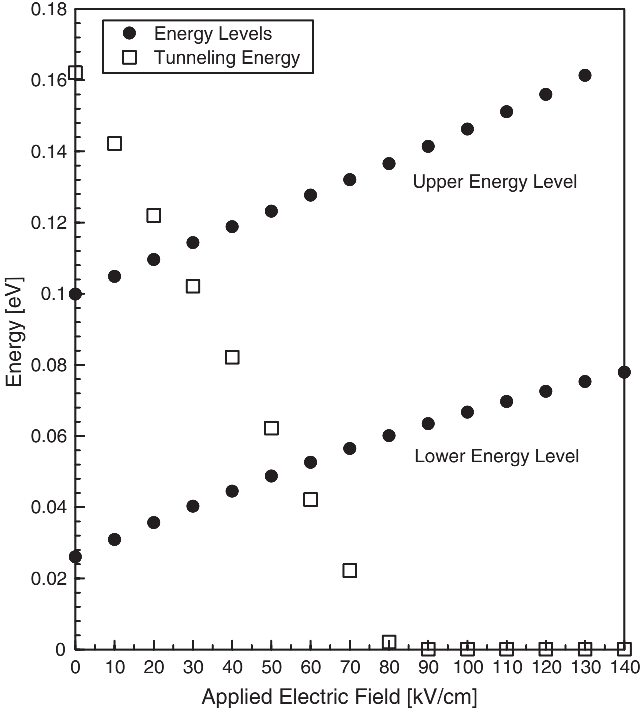

Figure 2. Energy levels and tunneling energy for a symmetric quantum well as a function of applied electric field. Reprinted with permission from [46], K. R. Lefebvre, Electron Dynamics in a Biased Quantum Well, Ph.D. Dissertation, University of Connecticut, Storrs, CT, 1997.

In Figure 4, the 3D densities of states are plotted as a function of energy for electric fields of 0, 20, 50, 90, 110, and 140 kV/cm. As shown in Figure 4a, at low fields where the tunneling energy is greater than the upper most energy level, the 3D density of states for 20 kV/cm resembles the zero electric field case except for the energy shift and a slight curvature occurring between the upper most energy level and E_c. At energies above E_c, the 3D density of states follows the bulk density of states except for slight oscillations due to the virtual bound states. However, as the electric field is increased and the tunneling energy falls below the upper most energy level, the steplike function of the density of states becomes more bulklike as shown in Figure 4b and c. Eventually the density of states will lose the steplike characteristics of the zero field density of states as the applied electric field is progressively increased. This is demonstrated in Figure 5 where the 3D density of states is plotted for electric fields of 100 and 200 kV/cm verses energy on a semilog scale.

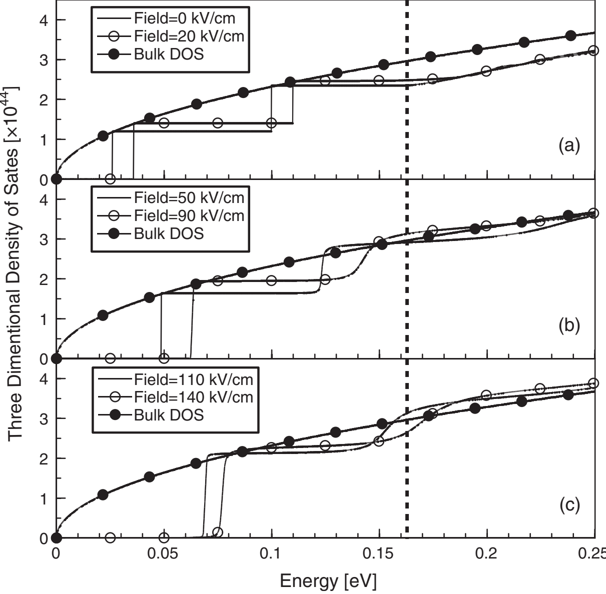

Figure 4. Three-dimensional density of states for a symmetric quantum well as a function of energy and applied electric field [46].

The calculation of the wavefunction [Eq. (10)] is shown in Figure 6 for an AlGaAs/GaAs system with an electric field of 0 kV/cm, 20% Al, a conduction band offset of 0.1621 eV, a quantum well width of 100 Å, and a barrier width of 200 Å. As shown in Figure 6, there exist two energy levels.

As previously demonstrated, there exist states from the tunneling to the band offset. If states exist then these states must have a wavefunction. This is demonstrated in Figure 7 where an electric field of 100 kV/cm is applied.

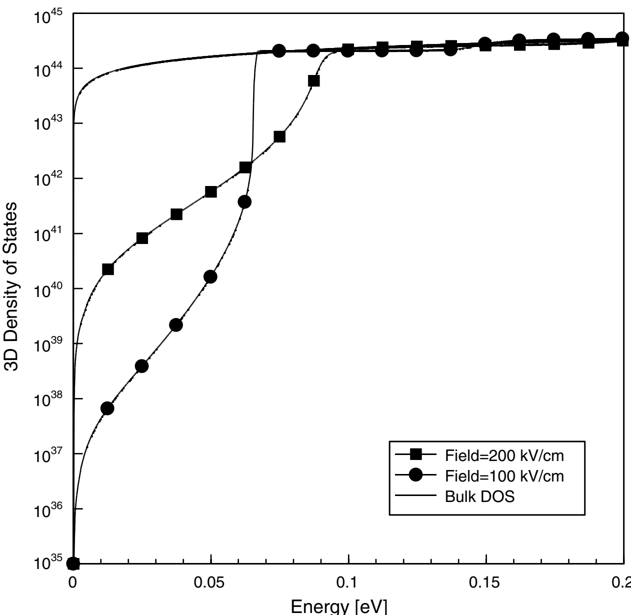

Figure 5. Three-dimensional density of states for a symmetric quantum well as a function of energy and applied electric fields of 100 and 200 kV/cm. Reprinted with permission from [46], K. R. Lefebvre, Electron Dynamics in a Biased Quantum Well, Ph.D. Dissertation, University of Connecticut, Storrs, CT, 1997.

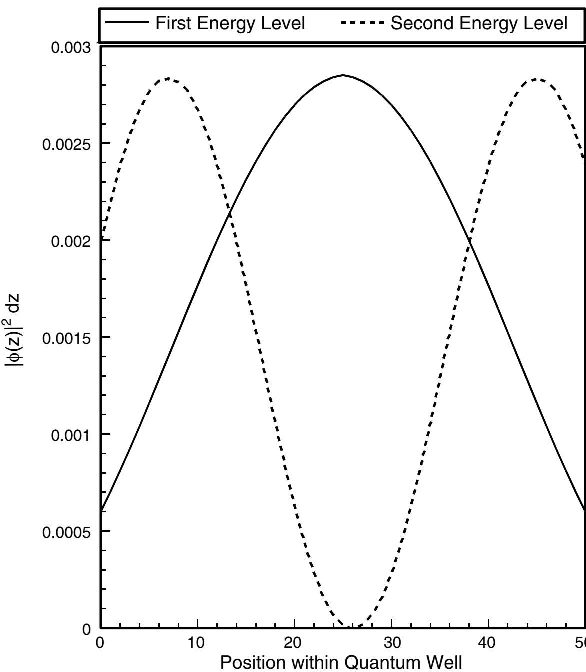

Figure 6. The wavefunctions for the first and second energy level at zero bias.

As demonstrated, the wavefunctions of the first and second energy levels shift toward the lower portion of the quantum well (inset of Fig. 7). Also, as the energy increases from the first energy level (66 meV) toward the second (161 meV), the first energy level must transform into the second. This is demonstrated for selected energies between the first and second energy level.

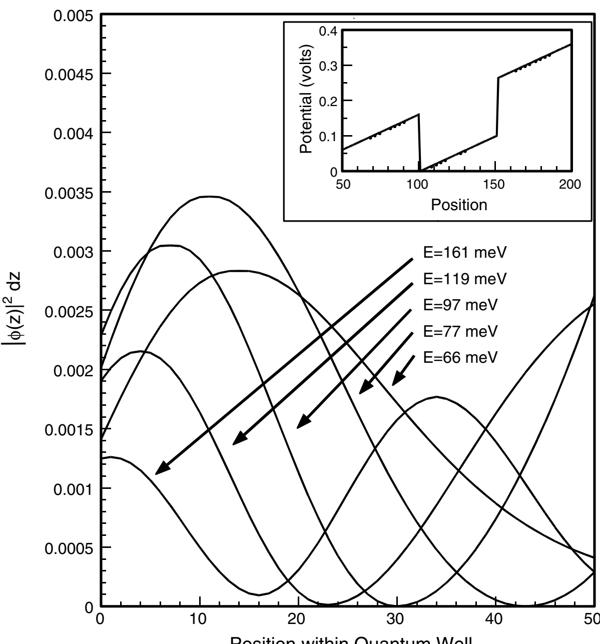

Figure 7. The wavefunctions for the first (66 meV) and second (161 meV) energy level along with the wavefunctions for selected energies between the first and second energy levels at 100 kV/cm.

3. ELECTRON ESCAPE TIME FROM A QUANTUM WELL

The current exiting a quantum well as a result of a z-directed electric field is the sum of two components (Fig. 8): the thermionic emission component (J_{th}) and the tunneling component (J_{tu}). The thermionic emission component is the current above the conduction band offset (E_c) while the tunneling component is the current below the conduction band offset. The total current is a combination of two oppositely propagating current components: J^+ along the positive z-direction and J^- along the negative z-direction [46],

$$J_{\text{tot}} = [J_{\text{tu}} + J_{\text{th}}]^+ + [J_{\text{tu}} + J_{\text{th}}]^-$$

$$[J_{\text{tu}} + J_{\text{th}}] = \frac{2e}{(2\pi)^2}\left[\begin{array}{l} \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} dk_x dk_y \\ \times\left[\frac{1}{2\pi}\int_{\text{tu}} f(E)\langle v_g^{\pm}(E_z)\rangle D^{\pm}(E_z) dk_z^{\text{tu}}\right] \\ +\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} dk_x dk_y \\ \times\left[\frac{1}{2\pi}\int_{\text{th}} f(E)\langle v_g^{\pm}(E_z)\rangle D^{\pm}(E_z) dk_z^{\text{th}}\right] \end{array}\right] \tag{12}$$

where $f(E)$ is the Fermi distribution function, E_z is the energy corresponding to the wavevector in the z-direction, $\langle v_g^{\pm}(E_z)\rangle$ are the effective carrier velocities in the positive and negative z-directions, $D^{\pm}(E_z)$ is the transmission coefficient, and e is the elemental electron charge.

The integration over k_z for the tunneling current is between $\pm k_{\text{tu}}$ to $\pm k_c$ where $\pm k_{\text{tu}}$ is the z-directed wavevector associated with E' (the energy at which carriers can first tunnel out of the quantum well [$E' = (\hbar k_{\text{tu}})^2/2\text{m}^*$]: Fig. 8) and $\pm k_c$ is the wave vector associated with the energy of the conduction band offset [$E_c = (\hbar k_c)^2/2m^*$]. The integration over k_z for the thermionic emission current is from $\pm k_c$to ± 8, where the upper sign corresponds to the positive k_z integration and the lower sign is for the negative k_z integration. Assuming parabolic energy bands and converting the integrals over k into integrals over energy, we obtain the total current,

$$J_{\text{Tot}} = \frac{em^*}{2\pi\hbar^2}\left[\begin{array}{l} \int_0^{\infty} dE_t \int_{kz>0}^{E} f(E)\langle v_g^{+}(E_z)\rangle D^{+}(E_z)\langle g_{1\text{D}}(E_z)\rangle dE_z \\ +\int_0^{\infty} dE_t \int_{kz<0}^{E} f(E)\langle v_g^{-}(E_z)\rangle D^{-}(E_z)\langle g_{1D}(E_z)\rangle dE_z \end{array}\right] \tag{13}$$

where $\langle g_{1\text{D}}(E_z)\rangle$ is the effective 1D density of states [Eq. (6)], E_f is the Fermi level, $\hbar$ is the reduced Planck's constant, m^* is the effective mass, and E_t is the energy in the transverse direction.

For a given carrier concentration, the Fermi level is obtained by solving

$$n_{\text{tot}} = \sum_i \int_{E_i}^{E'} g_i(E_z) f(E) dE + \int_{E'}^{\infty} g_{3\text{D}}(E_z) f(E) dE_z \tag{14}$$

where $g_i(E_z)$ is the finite well density of states, E_i is the ith energy level below E' with a corresponding wavevector k_{zi} and $k_{z0} = 0$ and $g_{3\text{D}}(E_z)$ is the 3D density of states which is calculated by Eq. (7).

Calculation of the carrier escape time that includes the proper partitioning of the thermionic emission and tunneling components of the current is obtained by considering the total number of carriers that are able to traverse the barrier. Rearranging the usual current equation ($J = qnv = qnL/\tau$), the escape rate can be calculated as

$$\frac{1}{\tau} = \frac{1}{\tau_{\text{un}}^{2\text{D}}}\beta + \frac{1}{\tau_{\text{un}}^{3\text{D}}}(1-\beta) \tag{15}$$

where $\tau_{\text{un}}^{2\text{D}}(=en_{2\text{D}}L_w/J_{\text{tu}})$ is the unweighted tunneling time, $\tau_{\text{un}}^{3\text{D}}(=en_{3\text{D}}L_w/J_{\text{th}})$ is the unweighted thermionic emission escape time, $\beta(=n_{2\text{D}}/n_{\text{tot}})$ is the partitioning factor, and $n_{3\text{D}}$, $n_{2\text{D}}$ are the carrier concentrations above and below E_c. According to this equation the thermionic emission and the tunneling mechanisms provide two parallel paths for carrier escape. Moreover, the partitioning of carriers in the 2D and 3D parallel paths depends upon the applied bias and the structure of the quantum well as well as the redistribution of the density of states.

The theoretical calculations are compared to the experimental work of Cavailles et al. [37] for a quantum well consisting of 200 Å AlGaAs barriers and a 96 Å GaAs well. The composition of Al is 40% and 20% yielding an asymmetric quantum well with conduction band offsets of 0.3242 and 0.1621 eV respectively (Fig. 8). The measurement of

the escape time was performed by a pump–probe method where the pumping laser produces approximately 10^{22} m^{-3} electrons within the quantum well [37] and the probing laser detected any changes in the sample at a later time with respect to the pumping laser. The material parameters used are from [8, 9, 37] and are shown in Table 1 for convenience [46].

The calculation of the electron escape time as a function of applied electric field is shown in Figure 9 (open squares). Experimental results (solid circles) [37] are also shown on the same plot and show excellent agreement with the present model. Also shown in Figure 9 is theoretical results of Moss et al. [38] (solid diamonds) which demonstrate the general trend of decreasing escape time as the electric field increases.

Three distinct regions can be identified by comparing the individual escape times (tunneling and thermionic emission) to the total escape time as shown in the inset of Figure 9: (1) a thermionic emission dominated region, (2) a tunneling dominated region, and (3) a combination tunneling and thermionic emission region. At low electric fields, the electron escape time is dominated by the thermionic emission component, whereas at high electric fields the electron escape time is tunneling dominated. At intermediate electric fields the determination of the escape time is decided by the partitioning of current/charge between the thermionic emission and tunneling components.

To better understand the role of the two current components, the ratios of the individual current components to the total current are plotted as a function of electric field in Figure 10. It is apparent that the thermionic emission component is dominant at lower bias as is evident from the ratio of J_{th}/J_{tot} whereas at high fields, J_{tu}/J_{tot} dominates. At low electric fields, the tunneling particles experience a rectangular barrier attributing to an extremely small transmission coefficient and a large tunneling energy (E' is close to E_c) resulting in a negligible tunneling current. However, for the same range of electric fields, over the barrier transport with a transmission coefficient of approximately unity contributes largely toward the total current. As the electric field increases, the barriers and the quantum well become more triangular corresponding to an increase in the transmission coefficient as well as a reduction in the tunneling energy. By reducing the tunneling energy as well as increasing the transmission coefficient, the number of carriers within the quantum well that are able to participate in J_{tu} increases, resulting in a rapid rise in J_{tu} as the electric field increases as shown in the inset of Figure 10. However, since the transmission coefficient above E_c is approximately unity and the effective velocity is approximately constant as the field increases, the steady increase in J_{th} as the electric field increases arises from an increase in the number of

carriers above E_c. Therefore, as the electric field increases, J_{tu} overcomes J_{th} and eventually becomes the dominant current at high electric fields.

The increasing function of J_{th} in Figure 10 can also be explained by considering the product of $\langle\langle v_{3D}\rangle\rangle$ and n_{3D} ($\langle\langle v_{3D}\rangle\rangle$ is the local group velocity averaged over position as well as energy) which yields J_{th} as shown in Figure 11. Since the rate of increase in n_{3D} is greater than the rate of decrease in $\langle\langle v_{3D}\rangle\rangle$, J_{th} shows a steady increase with applied bias. n_{2D}, on the other hand, is much larger than n_{3D} and is a very weak function of the applied electric field. This attribute of n_{2D} along with the rapid increase in $\langle\langle v_{2D}\rangle\rangle$ results in a sharply increasing tunneling current, J_{tu}, with applied bias. Though J_{th} and J_{tu} both increase with increasing electric field, J_{tu} increases faster, becoming the major component of current at higher bias. This switch over from thermionic emission dominance to tunneling dominance for this structure occurs at around 50 kV/cm.

The calculation of the escape time based upon $\tau_{un}^{3D}(=qn_{3D}L_w/J_{th})$ and $\tau_{un}^{2D}(=qn_{2D}L_w/J_{tu})$ is not complete as carrier partitioning is not accounted for. The carrier partitioning, which is also implicit in the Moss et al. treatment, yields the correct escape time by writing it as $\tau^{-1} = \beta/\tau_{un}^{2D} + (1-\beta)/\tau_{un}^{3D}$. In Figure 12, the unweighted escape times are shown. As observed, the unweighted thermionic emission escape time always dominates, as $\langle\langle v_{3D}\rangle\rangle$ is greater than $\langle\langle v_{2D}\rangle\rangle$. Also shown in Figure 12 is the partitioning factor, β, which is close to unity for the structure considered. The weighted tunneling time ($\tau_{wt}^{3D} = \tau_{un}^{3D}/(1-\beta)$) is much greater than $\tau_{un}^{3D}$and can become comparable or even greater than the weighted tunneling time ($\tau_{wt}^{2D} = \tau_{un}^{3D}/\beta$).

The importance of using the proper quantum mechanical group velocity as well as the continuous density of states is shown in Figure 13. In Figure 13 the escape time has been calculated using $\hbar k_z/m^*$ for the group velocity, including the redistribution of the density of states (solid triangles) and excluding the redistribution of the density of states (solid circles). As observed, the electron escape time is overestimated when the redistribution of the density of states is not accounted for. Also to be noticed is that the curvature of the electron escape time is opposite the experimental results when the redistribution in the density of states has been excluded; a similar situation is observed in the Moss et al. [38] calculations.

For completeness, the hole escape time is shown in Figure 14 is included. Included in the hole escape time figure are the experimental results of Cavailles et al. as well as the previously reported theoretical results of Moss et al. The theoretical escape time for holes also shows excellent agreement with the experimental results with similar plateaus in regions. In the present calculation for holes, the heavy hole masses (m_{hh}/m_o) of 0.734, 0.284, 0.454, and 0.415 and the light hole masses (m_{lh}/m_o) of 0.596 and 0.222 are used. These hole masses are obtained by fitting parabolas to the calculated band structures in [75]. The use of the data that were reported for a slightly different structure may explain the discrepancy between the experimental and the theoretical results.

Comparison between the Moss et al. work and the experimental results for the holes demonstrates large discrepancies. The large discrepancy can be attributed to the use of the conventional hole effective mass, discrete density of states, FWHM calculation for the tunneling

times, and $\hbar k_z/m$ for the group velocity. This is demonstrated in Figure 14 where the escape time for holes has been calculated using this theory with the effective masses given by Moss et al. (open circles). As demonstrated, an improvement in the hole escape time results from using the present formulation.

4. ELECTRON–POLAR OPTICAL PHONON INTERACTION WITHIN A BIASED QUANTUM WELL

4.1. Electron–Polar Optical Phonon Interaction within an Unbiased and Biased Quantum Well

The calculation of the absorption (abs) and emission (ems) rates of phonons begins with Fermi's golden rule [46],

$$\frac{1}{\tau_{\substack{\text{abs}\\ \text{ems}}}(E_i)} = \frac{2\pi}{\hbar}\sum_{\bar{k}_f}\sum_{\bar{q}} |\langle\Psi_f|H_{ep}|\Psi_i\rangle|^2(1-f(E_f)) \times \delta(E_f - E_i \pm \hbar\omega) \tag{16}$$

where Ψ is the wavefunction in three dimensions for the initial (i) and final (f) states, E_i and E_f are the energies of the states Ψ_i and Ψ_f, $f(E_f)$ is the Fermi distribution, k_f is the final state wavevector, q is the phonon wavevector, and $\hbar\omega$ is the energy of the polar optical phonon. The positive sign in the conservation of energy ($\delta(E)$) is for the emission of a phonon while the negative sign is for the absorption of a phonon.

Assuming bulk phonons within the quantum well and neglecting screening, the interaction Hamiltonian, H_{ep}, is the Frölich Hamiltonian [46],

$$H_{ep} = \left[\frac{e^2\hbar\omega}{2V}\left[\frac{1}{\varepsilon_\infty} - \frac{1}{\varepsilon_o}\right]\right]^{\frac{1}{2}} \left(N_q + \frac{1}{2} \pm \frac{1}{2}\right)^{\frac{1}{2}} \left(\frac{1}{q}\right) \times \left[a_q^+ e^{-i\bar{q}\cdot\bar{r}} + a_q e^{i\bar{q}\cdot\bar{r}}\right] \tag{17}$$

where a_q is the annihilation operator, a_q^+ is the creation operator, q is the phonon wavevector, r is the position vector, e is the elemental charge, N_q is the phonon occupation number, and ε_∞ and ε_o are the high frequency and static dielectric constants, respectively.

The wavefunctions can be decomposed into transverse and perpendicular components as shown in

$$\Psi_{i,f}(r) = \frac{1}{\sqrt{V}} e^{i\bar{k}_{ti,tf}\cdot\bar{r}_t}\, \varphi_{zi,zf} \tag{18}$$

The perpendicular component ($\varphi_{zi,zf}$) is the bound (or quasi bound when an electric field is applied) particle wavefunction in the z-direction and the transverse component ($e^{i\bar{k}_{ti,tf}\bullet\bar{r}_t}$) is the free particle wavefunction parallel to the quantum well. Also, $k_{ti,tf}$ is the initial (final) wavevector in the transverse direction and r_t is the position vector. The

decomposition of the initial and final wavevectors into transverse and perpendicular components simplifies the calculation of the matrix elements, $\langle\Psi_f|H_{ep}|\Psi_i\rangle$ which yield

$$\langle\Psi_f|H_{ep}|\Psi_i\rangle = \frac{1}{V}\left[\frac{e^2\hbar\omega}{2V}\left[\frac{1}{\varepsilon_\infty}-\frac{1}{\varepsilon_o}\right]\right]^{\frac{1}{2}}\left(N_q+\frac{1}{2}\pm\frac{1}{2}\right)^{\frac{1}{2}} \times\left(\frac{1}{q}\right)\delta_{\bar{k}_{ti}\mp\bar{q}_t,\bar{k}_{tf}}\int_0^{L_w}\varphi_{zf}^* e^{\mp iq_z}\varphi_{zi}\,dz. \quad (19)$$

The upper sign corresponds to emission while the lower sign corresponds to absorption. The z component of the wavefunctions will be addressed later.

Using the properties $\delta(aE)=a^{-1}\delta(E)$ and $\delta((E-E_1)(E-E_2))=|E_1-E_2|^{-1}(\delta(E-E_1)+\delta(E-E_2))$, the conservation of energy and momentum in the transverse direction, as in Eqs. (16) and (19), can be combined [10] to solve for the momentum in the transverse direction as

$$\delta(E_f-E_i\pm\hbar\omega)\delta_{\bar{k}_{ti}\mp\bar{q}_t,\bar{k}_{tf}} = \frac{2m^*}{\hbar^2}\frac{1}{|Q_t^+-Q_t^-|}[\delta(q_t-Q_t^+)+\delta(q_t-Q_t^-)] \quad (20)$$

where for the absorption of phonons

$$Q_t^\pm = -k_{ti}\cos\phi\pm\sqrt{(k_{ti}\cos\phi)^2-\left(k_{zf}^2-k_{zi}^2-\hbar\omega\frac{2m^*}{\hbar^2}\right)} \quad (21)$$

and for the emission of phonons

$$Q_t^\pm = k_{ti}\cos\phi\pm\sqrt{(k_{ti}\cos\phi)^2-\left(k_{zf}^2-k_{zi}^2+\hbar\omega\frac{2m^*}{\hbar^2}\right)} \quad (22)$$

where the angle ϕ is between the initial wavevector and the phonon wavevector in the transverse direction.

As stated in Section 2, upon the application of an electric field perpendicular to the quantum well (along the z-direction), there exists a finite probability for the electrons within the quantum well to tunnel through the triangular barrier for energies greater than E'. However, for energies below E', the system is bounded and the density of states is the usual steplike function. Therefore, for the final states greater than E', the summation over the final states can be converted into an integral over energy, whereas for energies below E', the summation over final states remains. Using Eqs. (17)–(22), Eq. (16) can be rewritten (we have dropped the subscripts abs and ems for convenience) as

$$\frac{1}{\tau(E_i)} = \beta\iiint|M_{k_z q_z}|^2\frac{\langle g_{1\mathrm{d}}(E_{zf})\rangle}{|Q_t^+-Q_t^-|} \times\left[\frac{Q_t^+}{(Q_t^+)^2+q_z^2}+\frac{Q_t^-}{(Q_t^-)^2+q_z^2}\right]dq_z\,d\phi\,dE_{zf} \quad (23)$$

where

$$\beta = \frac{2m^*}{\hbar^3}\frac{L_w e^2\hbar\omega}{(2\pi)^4}\left[\frac{1}{\varepsilon_\infty}-\frac{1}{\varepsilon_o}\right]\left(N_q+\frac{1}{2}\pm\frac{1}{2}\right) \times(1-f(E_i\mp\hbar\omega))$$

for final states where the energy is greater than E' and

$$\frac{1}{\tau(E_i)} = \beta\sum_{k_{zf}}\iint|M_{k_z q_z}|^2\frac{1}{|Q_t^+-Q_t^-|} \times\left[\frac{Q_t^+}{(Q_t^+)^2+q_z^2}+\frac{Q_t^-}{(Q_t^-)^2+q_z^2}\right]dq_z\,d\phi \quad (24)$$

where

$$\beta = \frac{2m^*}{\hbar^3}\frac{e^2\hbar\omega}{(2\pi)^3}\left[\frac{1}{\varepsilon_\infty}-\frac{1}{\varepsilon_o}\right]\left(N_q+\frac{1}{2}\pm\frac{1}{2}\right) \times(1-f(E_i\mp\hbar\omega))$$

for final states in the region is below E'. Here $M_{k_z q_z} = \int_0^{L_w}\varphi_{zf}^* e^{\mp iq_z}\varphi_{zi}dz$ while the limits on the q_z and ϕ are determined by requiring the quantity beneath the radical in Eqs. (21) and (22) be positive.

The conversion of the k_{tf} summation into an integral over the final energy, E_{tf}, introduces the effective 1D density of states, $\langle g_{1\mathrm{D}}(E_z)\rangle$, into the scattering rate. Calculating the effective (1D) density of states is performed as in Section 2, Eqs. (1)–(6).

The calculation of the scattering rate, which is a function of the initial energy, can be extended to calculate the average scattering rate of phonons. The average total scattering rate is calculated by averaging $\tau_{\mathrm{tot}}^{-1}(E_{zi})(=\tau_{\mathrm{abs}}^{-1}(E_{zi})+\tau_{\mathrm{ems}}^{-1}(E_{zi}))$ over the number of carriers at that energy as shown in Eq. (24),

$$\left\langle\frac{1}{\tau}\right\rangle = \frac{\int\tau_{\mathrm{tot}}^{-1}(E_i)g_{3\mathrm{d}}(E_i)f(E_i)\,dE_i}{\int g_{3\mathrm{d}}(E_i)f(E_i)dE} \quad (25)$$

where $f(E)$ is the Fermi function and $g_{3\mathrm{d}}(E_i)$ is the 3D density of states calculated from the convolution of the effective 1D density of states $\langle g_{1\mathrm{D}}(E_z)\rangle$ and the 2D density of states [Eq. (23)].

The system under consideration consists of a single quantum well with AlGaAs barriers and a GaAs quantum well. The composition of Al is 20% producing a band offset of 0.1621 eV and a barrier effective mass of $0.0836\mathrm{m}_0$. Also, the applied electric field ranged between 0 and 70 kV/cm.

The phonon absorption, emission, and total scattering rate are plotted as a function of initial energy and applied electric field in Figure15a–d. Consider first the absorption rate (solid curves). At zero electric field (Fig. 15a) the absorption rate is zero for initial energies below the first energy level, due to a lack of initial states. With increasing initial energy, a step occurs in the absorption rate arising from the availability of initial states corresponding to the first energy level (E_1). For this structure, the separation between the two energy levels ($E_2-E_1=77$ meV) is greater than $\hbar\omega$ (36 meV); therefore, the absorption rate is determined purely by intrasubband absorption. As the initial energy is increased, there is a steady rise in the absorption rate until the initial energy equals $E_2-\hbar\omega$. Once the initial energy equals $E_2-\hbar\omega$, another step in the absorption rate results signifies that both intrasubband and intersubband scattering can occur. Further increase in the initial energy again produces a steady rise in the absorption rate

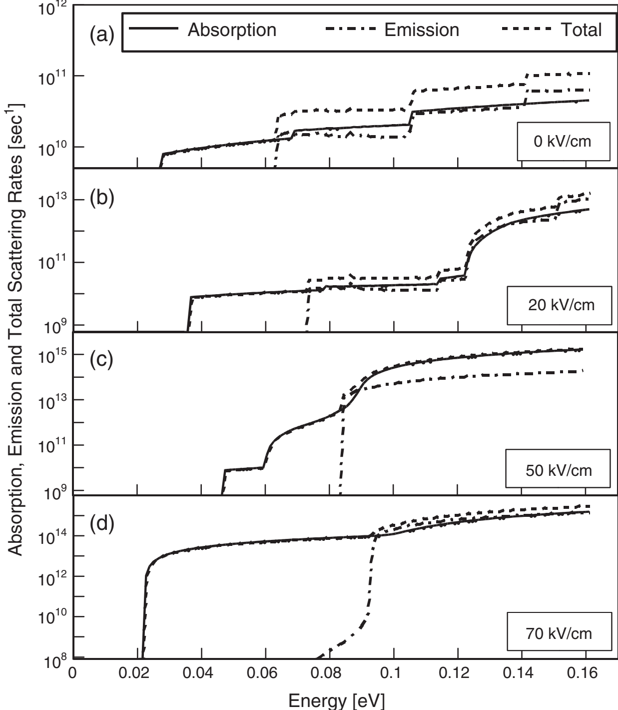

Figure 15. The electron–phonon scattering rates as a function of initial energy and the electric field as a parameter. Reprinted with permission from [10], K. R. Lefebvre and A. F. M. Anwar, *IEEE J. Quantum Electron*. 35, 216 (1999). © 1999, IEEE.

until the initial energy equals the second energy level. At the second energy level, a step occurs in the absorption rate as a result of an increase in the initial states. It is worth noting that if the assumption that the first energy level is the only initial state in the k_z direction and not including the second energy level, the step resulting from an increase in the initial states once the second energy level is reached (from the initial energy equaling the second energy level) would not exist in the absorption rate.

For the emission rate (dashed dotted curve) at zero electric field, the first step in the emission rate occurs when the initial energy is above the first energy by an amount equaling $\hbar\omega$. As the initial energy is further increased, there exists a slight decrease in the emission rate due to the transverse phonon wavevector increasing with an increase in initial energy and the scattering rate being inversely proportional to the transverse phonon wavevector. As the initial energy increases further another step results when the initial energy equals E_2, increasing the number of initial states which the electron can scatter from. Another step in the emission rate occurs when the initial energy equals $E_2 + \hbar\omega$ as a result in an increase in the final states of the scattered electron. The slight downward slope in the emission rate disappears since once the second energy level is reached due to the increase in the number of initial states. The total scattering rate (dashed curve) is the combination of the absorption and emission rates and demonstrates characteristics of both curves as expected.

In Figure 15b, the electric field is increased from 0 to 20 kV/cm for the phonon absorption and emission rates. As in the zero field case both the emission and absorption rates exhibit the steplike function. However, as mentioned before, the electric field redistributes the density of states above the point where the transmission coefficient becomes appreciable ($E' \sim 122$ meV for 20 kV/cm). For completeness, this is demonstrated in Figure 16a–d where the 1D density of states is plotted as a function of energy and applied electric field. With increasing electric field, the 1D density of states expands below the band offset and a spreading around the energy levels occur. Applying this knowledge to the phonon absorption and emission rates, the extra step which occurs around 122 meV corresponds to the point where the transmission is appreciable (E'). The gradual increase in the absorption and emission rates is a result of the continuous nature of the 1D density of states. Another difference between the zero field scattering rates and the 20 kV/cm scattering rates is the shift in the steps toward higher energies.

Increasing the electric field further (Fig. 15c) to 50 kV/cm demonstrates evidence of a second energy level in the absorption rate; however, the smoothing effect is more pronounced than in the previous cases. As before, the first step in the absorption curve is due to the first energy level while the second step is a result of E'. However, there exists a flattening in the absorption curve resulting from the large energy separation (>36 meV) between E' and the peak in the 1D density of states (Fig. 16c). As the initial energy is increased further to around 90 meV, the absorption rate turns up rapidly which is 36 meV from the peak in the 1D density of states. Any further increase in energy results in

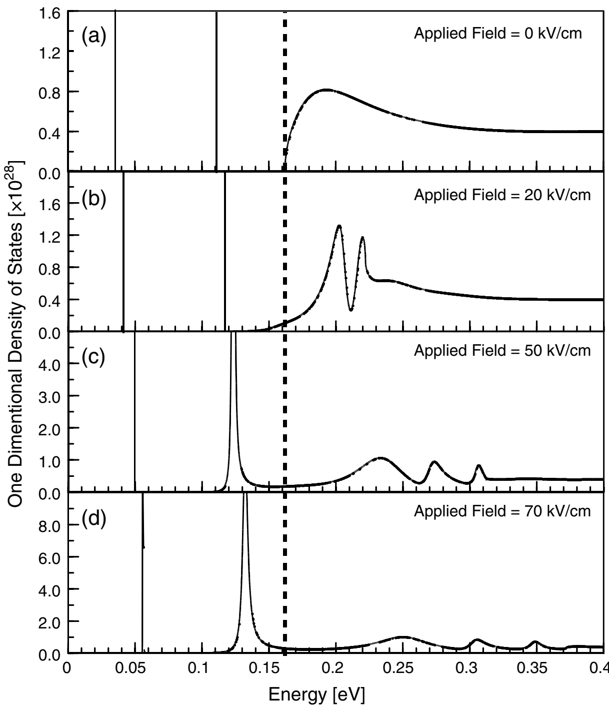

Figure 16. The effective one-dimensional density of states as a function of energy and applied electric field where the vertical dotted line is the band offset. Reprinted with permission from [10], K. R. Lefebvre and A. F. M. Anwar, *IEEE J. Quantum Electron*. 35, 216 (1999). © 1999, IEEE.

the gradual increase in the absorption rate as demonstrated previously. The rate at which electrons emit phonons for the 50 kV/cm case begins at 36 meV above the first energy level, as has been demonstrated before, and increases gradually with increasing energy. A further increase in the electric field to 70 kV/cm (Fig. 15d) shows a switch in the emission rates from turning on at higher energies to turning on at a lower energy. This is a result of E' falling well below the first energy level ($E' \sim 20$ meV), implying that the quantum well is almost completely unbounded. The spreading in the 1D density of states is more dramatic for the second energy level (Fig. 16d), resulting in a smoother transition in the absorption rate from the first step to the second step.

The average total scattering rate is shown in Figure 17a function of applied electric field along with the energy difference between the energy level, E', and $\hbar\omega$. which demonstrates a direct correlation between the average scattering rate and the energy separation. At electric fields of 10 and 40 kV/cm, there is a peak in the average scattering rate which occurs at a point where there is a minimum in the energy separation. As shown in Figure 17 at 40 kV/cm both energy levels are within $\hbar\omega$ from E', resulting in a sharp rise in both the emission and absorption rates. This is also demonstrated for the 20 kV/cm case (Fig. 15b), except that only the second energy level is within $\hbar\omega$ from E'.

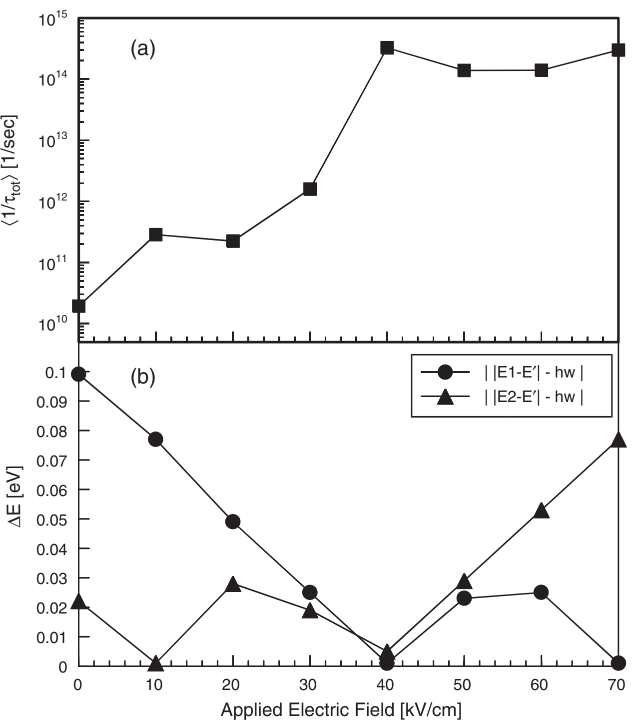

Figure 17. (a) The average electron–phonon scattering rate as a function of applied electric field. (b) The comparison between the energy level separation E_T and $\hbar\omega$. Reprinted with permission from [10], K. R. Lefebvre and A. F. M. Anwar, *IEEE J. Quantum Electron.* 35, 216 (1999). © 1999, IEEE.

4.2. Electron Escape via a Polar Optical Phonon Interaction and Tunneling from a Biased Quantum Wells

The escape rate of electrons due to a phonon interaction as a function of initial energy is calculated by first order perturbation as [46]

$$\frac{1}{\tau_{\text{abs}}(E_i)} = \frac{2\pi}{\hbar}\sum_{\bar{k}_f}\sum_{\bar{q}} |\langle \Psi_f|H_{ep}|\Psi_i\rangle|^2 \times (1-f(E_f))\,\delta(E_f - E_i - \hbar\omega) \quad (26)$$

the parameters for Eq. (26) are defined in Section 4.2.1 and only the upper sign is used in Eqs. (16) and (19).

Combining the conservation of energy and momentum in the transverse direction and solving for q_t, as in Eqs. (16) and (17) [10], yields

$$\delta(E_f - E_i - \hbar\omega)\delta_{\bar{k}_{ti}-\bar{q}_t,\bar{k}_{tf}} = \frac{2m^*}{\hbar^2}\frac{1}{|Q_t^+ - Q_t^-|} \times [\delta(q_t - Q_t^+) + \delta(q_t - Q_t^-)] \quad (27)$$

where

$$Q_t^{\pm} = -k_{ti}\cos\phi \pm \sqrt{(k_{ti}\cos\phi)^2 + \left(k_{zf}^2 - k_{zi}^2 - \hbar\omega\frac{2m^*}{\hbar^2}\right)} \quad (28)$$

and ϕ is the angle between the initial wavevector (k_{ti}) of the particle and the phonon wavevector (q_t) in the transverse direction.

The redistribution of the density of states can by included into the scattering rate calculation by converting the k_{zf} summation into an integral as the final energy, E_{zf}, introduces the effective 1D density of states, $\langle g_{1D}(E_z)\rangle$. The 1D density of states can be calculated as in Section 2. Equation (26) now may be rewritten as

$$\frac{1}{\tau(E_i)} = \beta \iiint |M_{k_z q_z}|^2 \frac{\langle g_{1d}(E_{zf})\rangle}{|Q_t^+ - Q_t^-|} \times \left[\frac{Q_t^+}{(Q_t^+)^2 + q_z^2} + \frac{Q_t^-}{(Q_t^-)^2 + q_z^2}\right] dq_z\, d\phi\, dE_{zf} \quad (29)$$

where

$$\beta = \frac{2m^*}{\hbar^3}\frac{L_w e^2\hbar\omega}{(2\pi)^4}\left[\frac{1}{\varepsilon_\infty} - \frac{1}{\varepsilon_o}\right](N_q)(1 - f(E_i + \hbar\omega))$$

Here $M_{k_z q_z} = \int_0^{L_w} \varphi_{zf}^* e^{-iq_z z}\varphi_{zi}\, dz$ while the limits on ϕ are determined by requiring the quantity beneath the radical in Eq. (28) be positive. The limits on the E_{zf} integration are from the top of the conduction band offset to infinity since we are considering the transition of an electron from a state below the conduction band offset to a state above the conduction band offset.

Since the tunneling rate is a function of the z-directed energy, the transition rate due to phonons needs to be converted to only a function of E_z. The calculation of the scattering rate, which is a function of the initial energy, into a

function of only E_z can obtained by the averaging scattering rate of phonons over the transverse initial states as

$$\left\langle \frac{1}{\tau(E_{z_{ti}})} \right\rangle = \frac{\int \tau^{-1}(E_i) f(E_{ti}) dE_{ti}}{\int f(E_{ti}) dE_{ti}} \tag{30}$$

where $f(E_{ti})$ is the Fermi function. Just as in Eq. (30), the average scattering rate is calculated by averaging $\langle \tau^{-1}(E_{z_{ti}}) \rangle$ over the number of electrons at E_{zi} as

$$\left\langle \frac{1}{\tau} \right\rangle = \frac{\int \langle \tau^{-1}(E_{zi}) \rangle \langle g_{1d}(E_{zi}) \rangle f(E_{zi}) dE_{zi}}{\int \langle g_{1d}(E_{zi}) \rangle f(E_{zi}) dE_{zi}} \tag{31}$$

The structure simulated is a symmetric $Al_xGa_{1-x}As/GaAs$ system with a 100 Å quantum well and 240 Å barriers. An Al mole fraction of $x = 20\%$ is used, resulting in a band offset of 0.1621 eV and two energy levels with a separation greater than the polar optical phonon energy, $\hbar\omega$ (0.036 eV). The electron's effective mass in the quantum well is $0.067m_0$ while the electron's effective mass in the barrier material is $0.084m_0$ with m_0 being the free electron mass. The two competing processes for carrier escape out of a quantum well are tunneling and phonon interaction. As demonstrated in Figure 18, tunneling is related to a spatial dislocation of the carrier whereas phonon interaction modifies the carrier's energy. The carriers that are assisted by phonons to move from within the quantum well to continuum are eventually swept away by thermionic emission. It should also be pointed out that the energy at which the transmission coefficient becomes appreciable for an electron tunneling out of the quantum well is denoted as E' as shown in Figure 18, implying that any electrons with a z-directed energy above E' and below E_c (conduction band offset) can participate in the tunneling current.

In Figure 19, the electron transition rate via a phonon interaction is plotted as a function of initial energy in the z-direction for an applied bias of 10 kV/cm. The damped oscillatory behavior of $1/\tau$ shows a peak for energies within the quantum well followed by a dip. This behavior is explained in the context of the density of states. For completeness, in Figure 20, the 1D density of states is plotted as a function of E_z. As demonstrated in Figure 20, there exist states (initial states) between the upper most energy level and the band offset as well as a virtual bound state above the band offset (final states). The initial states below the band offset allow phonon induced transitions to the final states above the band offset, creating the peak in the phonon transition rate. It should be mentioned that such a transition is only possible due to the redistribution of the states in the presence of an applied electric field. The existence of states below the band offset but above the upper most energy level make possible a phonon assisted electron transition with k_t equal to zero even though the difference between the band offset and the upper most energy level is greater than $\hbar\omega$. This is demonstrated in the inset of Figure 19 where the phonon induced transition rate has been plotted as a function of E_z for $k_t = 0$. This is unlike previous calculations where if the difference between the band offset and the energy level is greater than $\hbar\omega$, the transition of an electron from the below the band offset to above the band offset via a phonon is only possible with finite k_t.

The damped oscillatory behavior of $1/\tau$ is not only due to the redistribution of the density of states, the matrix elements also play a role as is evident from Figures 21 and 22. In Figures 21 and 22, the transition rate and the density of states are plotted as a function of E_z for an applied field of 20 kV/cm. As shown from Figure 22, at an electric field of 20 kV/cm, the first virtual bound state lies beyond $E_c + \hbar\omega$. Therefore, the dip followed by the hump in $1/\tau$ (Fig. 21) is not due to the redistribution of the density of states but is a result of the matrix elements between the initial and final states. This observation is justified in the inset of Figure 21 where $1/\tau$ follows the 1D density of states and is obtained by forcing the matrix elements to a constant.

Further increasing the electric field to 50 kV/cm (Fig. 23) modifies the $1/\tau$ and density of states vs E_z curves considerably. As evident from the density of states plot, a bound state exists at 0.122 eV and there are no virtual bound states within $E_c + \hbar\omega$. The small hump at $E_z = 0.122$ eV results from a phonon assisted transition from the bound state to the continuum states below the band offset. In the absence of any states between the bound states and the band offset such a transition would be impossible and is attributed to the field induced redistribution of the density of states. Increasing E_z to 0.126 eV, a phonon assisted transition from within the well to the continuum is possible. Though $1/\tau$ increases sharply at 0.126 eV, the magnitude, when compared to Figures 19 and 21, is less and is due to the lower number of final states.

An electron in a biased quantum well experiences two competing processes: a change in energy due to a phonon assisted transition or a change in position via tunneling out of the quantum well. In Figure 24, the two competing processes, the phonon assisted electron transition time, $\langle\langle\tau_{\text{ph}}\rangle\rangle$, and the electron tunneling time, $\langle\langle\tau_{\text{tun}}\rangle\rangle$, are plotted as a function of applied electric field. The calculation of the tunneling times has been performed by the method of Anwar et al. in [6, 7]. As is evident, at low electric fields, phonon assisted transitions dominate over tunneling; however, with increasing electric field, tunneling dominates. To clearly understand the process, the scattering times as a function of energy, E_z, are plotted for an applied field of 50 kV/cm in Figure 25. For energies around 0.12 eV, the density of states reaches a maximum value where, from Figure 25, tunneling dominates. At higher energies, though phonon scattering time is large, the number of carriers at these energies is negligible, making its contribution insignificant toward the escape time calculation.

The dominant transport mechanism responsible for carrier transport, that mainly contributes toward escape, is a strong function of conduction band offset and width of the quantum well. In Figure 26, the phonon assisted electron transition time and the tunneling time are compared by plotting the probability of tunneling $[(1/\tau_{\text{tun}})/(1/\tau_{\text{tun}} + 1/\tau_{\text{phon}})]$ as a function of applied field for quantum well widths of 40, 70, and 100 Å and band offsets of 0.1621 eV (dashed line—20% Al) and 0.2 eV (solid line—30% Al). Starting with the 20% Al cases, for electric fields greater than 20 kV/cm the probability of tunneling is larger than the probability of a transition due a phonon interaction. For small electric fields (<20 kV/cm), there exists a virtual bound state within $\hbar\omega$ of the band offset, increasing the number of final states for phonon absorption and the probability of phonon absorption. However, with increasing electric field, the virtual bound state increases in energy beyond $\hbar\omega$ above E_c, reducing the number of final states and the probability of phonon absorption. For electric fields not exceeding 40 kV/cm the energy difference between E' and E_c is less than $E_c - \hbar\omega$ (see Fig. 18). This implies that the number of electrons available, with energy E_z, to absorb a phonon

is equal to the number of electrons available for tunneling. However, for electric fields greater than 40 kV/cm, $E_c - E'$ is greater than $E_c - \hbar\omega$, implying that the number of electron available, with energy E_z, for tunneling is greater than the number for phonon absorption. Furthermore, not only is the number of electrons available important in the removal of an electron from a quantum well; the transmission coefficient is an important parameter for tunneling while the number of final states is important for phonon absorption, both of which change with applied electric field. It is worth noting that the dip which occurs in the 70 Å quantum well between 60 to 80 kV/cm arises from an increase in the number of final states above E_c, increasing the probability of phonon absorption. However, as $E_c - E'$ is much greater than $E_c - \hbar\omega$, the effects of phonon absorption on the probability of tunneling is small. It should also be pointed out that for electric fields below 40 kV/cm the probability of tunneling decreases with increasing well width for the same electric fields. This results from the virtual bound states residing closer to E_c with increasing well width as well as being broader for larger quantum well widths, resulting in a higher probability of phonon absorption.

As the well width increases, the energy levels are located deeper in the well while the virtual bound states are located closer to the band offset at low electric fields. Therefore, with increasing well width, a larger electric field is required to move the virtual bound state above $E_c + \hbar\omega$, making the transition due to phonons more probable over a larger range of electric fields for larger well widths as shown in Figure 26. However, by increasing electric field even further, tunneling overcomes phonon absorption since there are more electrons available for tunneling than phonon absorption. This is the same situation for the case of the 30% Al composition except that the virtual bound states are broader, yielding an even larger range of electric fields where phonon transition is more probable for the 40 and 70 Å quantum wells. However, as see by Figure 26, the 100 Å quantum well, 30% Al composition demonstrates unique characteristics. This results from the 100 Å quantum well beginning with three energy levels in the well, one close to the top and two much deeper within the well, for electric fields below 20 kV/cm and the existence of a virtual bound state within $\hbar\omega$ of the band offset, producing a high probability of phonon absorption for small electric fields. However, as the electric field increases above 20 kV/cm, the probability of phonon absorption increases rapidly creating the dip in the probability of tunneling. This results from the upper most energy level being within the quantum well for small electric fields but residing above E_c within increasing electric field. This increases the probability of phonon absorption rapidly, decreasing the probability of tunneling. As the electric field is increased further, the virtual bound states exists beyond $E_c + \hbar\omega$ which reduces the probability of phonon absorption. This occurs around 80–90 kV/cm resulting in the sharp upswing in the probability of tunneling.

The temperature dependence on the competing escape times is demonstrated in Figure 27 where of the probability of tunneling is plotted for the 20% Al case as a function of electric field, quantum well width, and temperatures of 300 and 77 K. As one would expect, with decreasing temperature both the tunneling rate and the phonon scattering rate would increase. This is indeed the case and is demonstrated in Figure 27, where the individual scattering rates for the 40 Å quantum well have been plotted as a function of electric field and temperature. As is demonstrated in Figure 27, the tunneling rate has a stronger temperature dependence than the phonon scattering rate, making the probability for tunneling at the 77 K less than 300 K even though both interactions increase with decreasing temperature.

4.3. Dynamics of Electron Capture into a Biased Quantum Well

An electron residing above the conduction band offset of a quantum well can be captured within the quantum well by emitting a polar optical phonon. The rate at which this transition can occur is calculated by first order perturbation theory as [10]

$$\frac{1}{\tau(E_{zi})} = \frac{2\pi}{\hbar} \sum_{\bar{k}_f} \sum_{\bar{q}} |\langle \Psi_f | H_{ep} | \Psi_i \rangle|^2 (1 - f(E_f)) \times \delta(E_f - E_i + \hbar\omega) \tag{32}$$

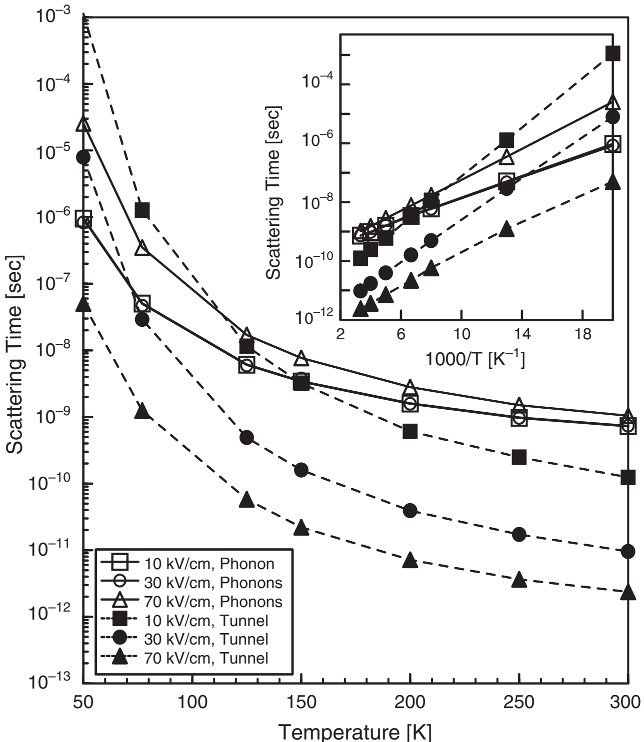

Figure 27. Scattering times as a function of temperature and electric field. Reprinted with permission form [46], K. R. Lefebvre, Electron Dynamics in a Biased Quantum Well, Ph.D. Dissertation, University of Connecticut, Storrs, CT, 1997.

where the parameters for Eq. (32) are defined in Section 4.2.1.

As stated previously, the application of an electric field perpendicular to a quantum well creates an open system, producing a continuum of states below the conduction band offset. The range of energies below the conduction band offset that becomes continuous varies as a function of electric field, a larger region of continuum with increasing electric field. If the final k_z states are within the continuum region, the summation over final k_z states can be converted over to an integral over final energy, E_z, states as

$$\frac{1}{\tau(E_{zi})}=\frac{2\pi}{\hbar}\frac{V}{(2\pi)^3}\int_{E'}^{E_c}\int_0^{\infty}\sum_{\bar{q}}|\langle\Psi_f|H_{ep}|\Psi_i\rangle|^2(1-f(E_f))$$
$$\times\,\delta(E_f-E_i+\hbar\omega)\langle g_{1\mathrm{d}}(E_{zf})\rangle dk_t\,dE_{zf} \qquad (33)$$

where the parameters for Eq. (33) are defined in Section 4.2.1. However, if the final energy, E_z, states are below E', the summation over final k_z states remains. The effective one-dimensional density of states is calculated by the method in Section 2.

Separating the wavefunctions into a transverse component ($e^{i\bar{k}_{ti,tf}\bullet\bar{r}_t}$) and a z-component ($\varphi_{zi,zf}$), the matrix elements, $\langle\Psi_f|H_{ep}|\Psi_i\rangle$, become

$$\langle\Psi_f|H_{ep}|\Psi_i\rangle=\frac{1}{V}\left[\frac{e^2\hbar\omega}{2V}\left[\frac{1}{\varepsilon_\infty}-\frac{1}{\varepsilon_o}\right]\right]^{\frac{1}{2}}(N_q+1)^{\frac{1}{2}}\left(\frac{1}{q}\right)$$
$$\times\,\delta_{\bar{k}_{tf}-\bar{q}_t,\bar{k}_{ti}}\int_0^{L_{\mathrm{well}}}\varphi_{zf}^{*}e^{+iq_z}\varphi_{zi}\,dz \qquad (34)$$

where e is the elemental charge, N_q is the phonon occupation number, ε_∞ and ε_o are the high frequency and static dielectric constants, φ_z is the initial (i) and final wavefunction (f), and $\delta_{\bar{k}_{tf}-\bar{q}_t,\bar{k}_{ti}}$ is the conservation of momentum in the transverse direction.

Combining the conservation of energy and momentum in the transverse direction, as in Eqs. (33) and (34) [10], yields

$$\delta(E_f-E_i\pm\hbar\omega)\delta_{\bar{k}_{ti}\mp\bar{q}_t,\bar{k}_{tf}}$$
$$=\frac{2m^*}{\hbar^2}\frac{1}{|Q_t^+-Q_t^-|}\Big[\delta(q_t-Q_t^+)+\delta(q_t-Q_t^-)\Big] \qquad (35)$$

where

$$Q_t^{\pm}=-k_{tf}\cos\phi\pm\sqrt{(k_{tf}\cos\phi)^2+\left(k_{zf}^2-k_{zi}^2+\hbar\omega\frac{2m^*}{\hbar^2}\right)} \qquad (36)$$

and the angle ϕ is between the final wavevector and the phonon wavevector in the transverse direction.

Combining Eqs. (33), (35), and (36) yields the capture rate as a function of initial energy,

$$\frac{1}{\tau(E_{zi})}=\beta\iiint|M_{k_zq_z}|^2\frac{\langle g_{1\mathrm{d}}(E_{zf})\rangle}{|Q_t^+-Q_t^-|}$$
$$\times\left[\frac{Q_t^+}{(Q_t^+)^2+q_z^2}+\frac{Q_t^-}{(Q_t^-)^2+q_z^2}\right]dq_z\,d\phi\,dE_{zf} \qquad (37)$$

where

$$\beta=\frac{2m^*}{\hbar^3}\frac{L_{\mathrm{well}}e^2\hbar\omega}{(2\pi)^4}\left[\frac{1}{\varepsilon_\infty}-\frac{1}{\varepsilon_o}\right](N_q+1)(1-f(E_i-\hbar\omega))$$

and $M_{k_zq_z}$ is the matrix elements.

The average capture rate can be calculated by averaging the capture rate over the number of electrons at E_{zi} as

$$\left\langle\frac{1}{\tau}\right\rangle=\frac{\int\langle\tau^{-1}(E_{zi})\rangle\langle g_{1\mathrm{d}}(E_{zi})\rangle f(E_{zi})dE_{zi}}{\int\langle g_{1\mathrm{d}}(E_{zi})\rangle f(E_{zi})dE_{zi}} \qquad (38)$$

where the integral over energy is from E_c to infinity.

An AlGaAs/GaAs single quantum well is utilized to demonstrate the electron capture rate for a biased quantum well as a function of quantum well width and conduction band offset. The parameters used in this calculation are shown in Table 2. Figure 28 demonstrates the capture of an electron by the emission of a polar optical phonon into a biased quantum well where, as stated previously, E' is the energy at which the transmission coefficient becomes appreciable.

In Figure 29, the capture rate is plotted as a function of z-directed energy above the conduction band offset (initial energy) for electric fields between 0 and 50 kV/cm. The conduction band offset (E_c) and the quantum well width

Composition of Al	20% Al	30% Al
Band offset	0.1621 eV	0.2432 eV
Quantum well m^*	$0.067m_0$	$0.067m_0$
Barrier m^*	$0.0836m_0$	$0.092m_0$
Phonon energy	0.036 eV	0.036 eV

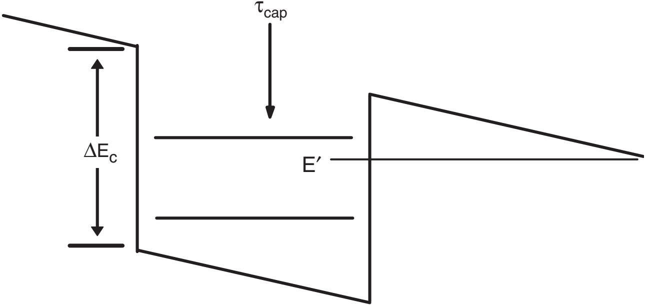

Figure 28. Energy band diagram for a quantum well with an applied electric field.

are 0.1621 eV and 100 Å, respectively. The vertical line in Figure 29 represents the energy $\hbar\omega$ above band offset. Since the bound energy levels are at least 36 meV below the band offset, the capture rate for the zero field case (▼) decreases with increasing initial z-directed energy as demonstrated in Figure 29. For a bound state removed from the band offset by $\hbar\omega$, an electron capture requires that the initial and final transverse wavevectors are nonzero for zero electric field. However, through an application of an electric field, the requirement of a tranverse momentum is relaxed for the capture of an electron and is demonstrated in Figure 29 for electric fields greater than zero.

Increasing the electric field to 10 kV/cm (◯), the capture rate for energies below 0.185 and above 0.198 eV is similar to the zero electric field case. However, for energies between 0.185 and 0.198 eV, the capture rate deviates away from the zero electric field case. This is a result of the applied electric field redistributing the final states below the band offset, creating a continuum of states below E_c. The point at which the continuum of energies below the band offset begins will be defined as E'. This is demonstrated in Figure 30 where the redistribution of the density of states is plotted, for completeness, as a function of energy and applied electric field. Through an increase in the number and location of final states, the capture rate increases in an energy range where, for zero electric field, the capture rate would be less. Furthermore, for an electric field greater than zero there exists a capture rate when the final transverse momentum equals zero and the difference between the eigenenergies and E_c is greater than $\hbar\omega$. This is demonstrated in the inset of Figure 29 where the capture rate is plotted as a function of E_z and electric fields when the momentum in the transverse direction is zero for the final states (k_{tf}). For an electric field of 10 kV/cm, the capture rate for $k_{tf} = 0$ resides in the energy range between 0.185 and 0.198 eV since electrons in this energy range can emit a phonon and be captured into the states between 0.15 eV and E_c (0.1621 eV) as shown in Figure 29 and in the inset of Figure 29.

Increasing the electric field further redistributes the states below E_c (Fig. 30) and widens the range of initial energies where a transverse final momentum is not required for a transition. This is demonstrated in Figure 29 (and inset) where the energy range $\hbar\omega + E'$ to $\hbar\omega + E_c$ expands, broadening the plateau in the capture rate which occurred for the 10 kV/cm case. It is also worth mentioning that $E_c + \hbar\omega$ occurs at 0.198 eV, implying that if there is any transition due to phonon emission, it must occur with a final transverse momentum and is demonstrated by a sharp drop in

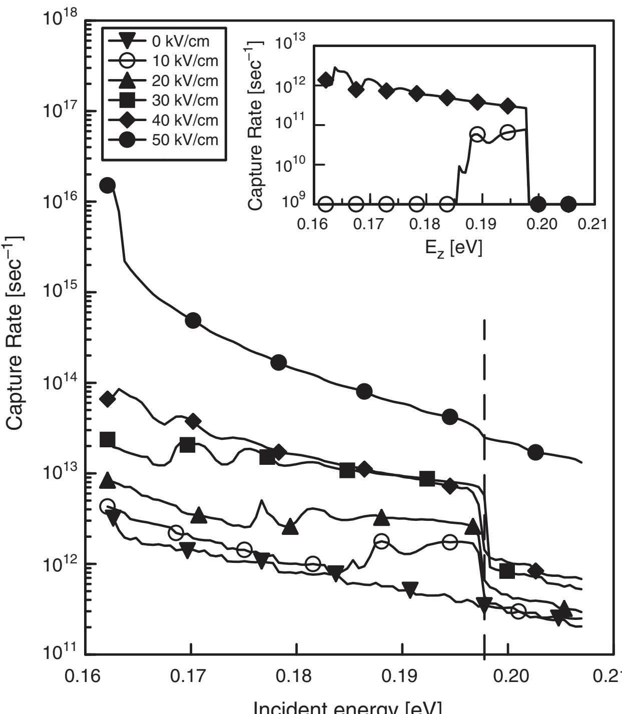

Figure 29. Capture rate as a function of incident energy and the capture rate as a function of z-directed incident energy in the inset.

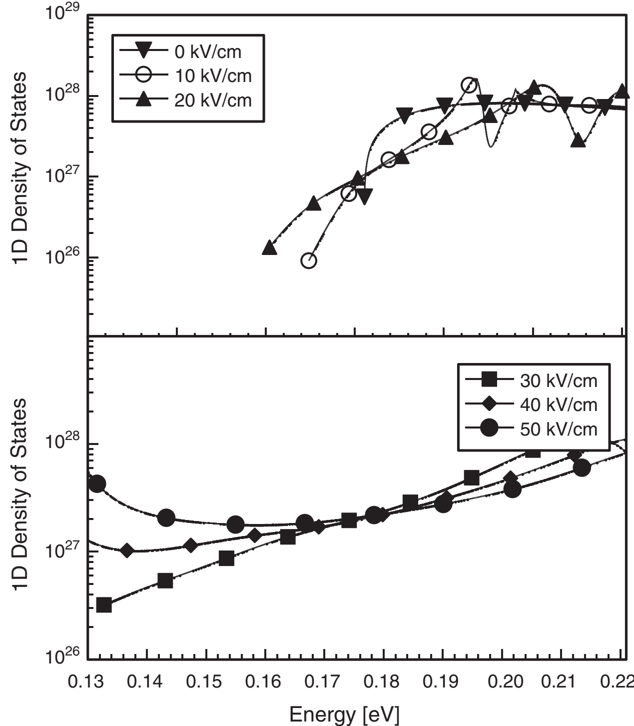

Figure 30. One-dimensional density of states as a function of energy and electric field.

the capture rate at 0.198 eV in the inset of Figure 29. In addition, the gradual rise in the capture rate for increasing electric field arises from an increase in the total number of final states (transverse and z-directed) as the electric field increases.

Increasing the band offset to 0.2434 eV (30% Al) produces an eigenenergy within $\hbar\omega$ from E_c. This allows transitions to occur when the transverse momentum is equal to zero for any electric fields. This is demonstrated in Figure 31 where the capture rate is plotted as a function of initial energy with the applied electric field as a parameter for $E_c = 0.2434$ eV. The sharp peak in the capture rate (~0.265 eV for zero electric field) is a result of the final state eigenenergy being within $\hbar\omega$ from E_c. The inset in Figure 31 is the capture rate when $k_{tf} = 0$ for various electric fields and as a function of energy. It is worth mentioning that unlike the 20% Al ($E_c = 0.1621$ eV) case, the capture rate for the 30% Al case does not generally increase with increasing electric field. This can also be explained in the context of the redistribution of the density of states which is plotted in Figure 32 as a function of energy for $E_c = 0.2434$ eV and for various applied electric fields. As the electric field increases, the density of states of the upper most energy level spreads and shifts in energy as well as reduces in magnitude. All of these combined result in a shift in the peak of the capture rate to a higher energy, a broadening in energy, as well as a reduction in magnitude for the energies around the peak.

As previously mentioned, it has been demonstrated that the capture rate oscillates with increasing quantum well width when the electric field equals zero. This is still the case for nonzero electric fields. This is demonstrated in Figure 33 where the average capture time is plotted as a function

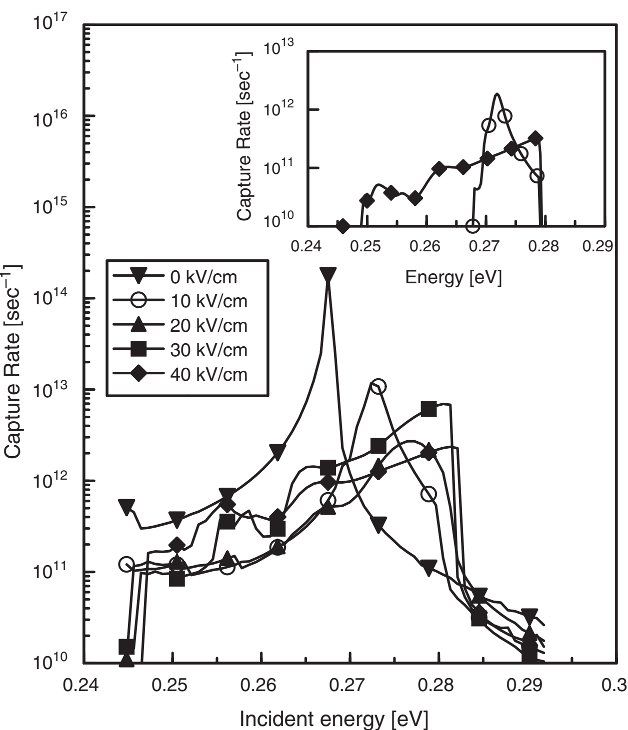

Figure 31. Capture rate as a function of incident energy for a band offset of 0.2434 eV.

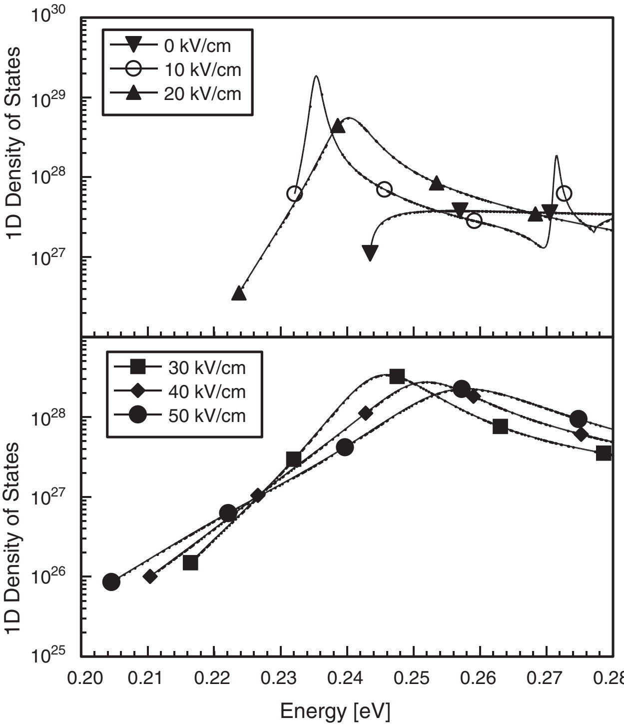

Figure 32. One-dimensional density of states as a function of electric field and energy for a band offset of 0.2434 eV.

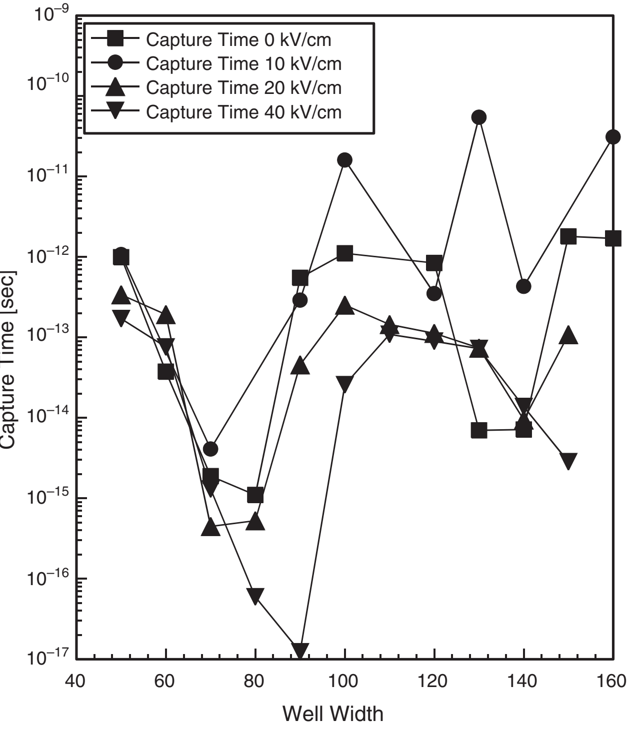

Figure 33. Average capture time as a function of quantum well width and electric field.

of quantum well width with the applied electric field as a parameter. As demonstrated by Figure 33, with increasing quantum well width and increasing electric field, the oscillatory nature dampens out, resulting from the redistribution of the density of states.

5. DENSITY OF STATES INDUCED ABSORPTION LINE BROADENING OF A BIASED QUANTUM WELL

The transition rate for an electron at initial states Ψ_i and final state Ψ_f is [46]

$$W_{if} = \frac{2\pi}{\hbar} |\langle \Psi_f | H_{\text{int}} | \Psi_i \rangle|^2 (1 - f(E_f)) f(E_i) \times \delta(E_f - E_i - \hbar\omega) \tag{39}$$

where E_i (E_f) is the initial (final) energy of the electron, H_{int} is the interaction Hamiltonian, $f(E)$ is the Fermi function, and $\hbar\omega$ is the energy of the photon. The interaction Hamiltonian is calculated by applying perturbation theory to the interaction between electrons and electromagnetic radiation [46]:

$$H_{\text{int}} = \frac{i\hbar e}{mc} \bar{A} \cdot \bar{\nabla} \tag{40}$$

Assuming z-polarized light, Eq. (40) can be written as

$$H_{\text{int}} = \frac{i\hbar e A_0}{2mc} \frac{d}{dz} \tag{41}$$

where e is the elemental charge, m is the free electron mass, c is the speed of light, $\hbar$ is the reduced Plank's constant, $i = \sqrt{-1}$, and A_0 is the vector potential. This reduces the matrix elements to

$$\langle \Psi_f | H_{\text{int}} | \Psi_i \rangle = \frac{1}{V} \frac{i\hbar A_0}{2mc} \delta_{\bar{k}_{ti}, \bar{k}_{tf}} \int_0^{L_w} \varphi_{zf}^* \frac{d}{dz} \varphi_{zi} \, dz \tag{42}$$

where the initial (i) and final (f) state wavefunctions have been separated into a z-component (φ_z) and a transverse component (φ_t) which results in a conservation of momentum in the transverse direction, $\delta_{\bar{k}_{ti}, \bar{k}_{tf}}$ V is the crystal volume and L_w is the length of the quantum well.

Absorption coefficient, α_{abs}, is defined as $\hbar\omega$ times the number of transitions per unit volume per unit time and divided by the incident power,

$$\alpha_{\text{abs}} = \frac{1}{V} \sum_{\bar{k}_f} \sum_{\bar{k}_i} \frac{2\mu c}{n_r \omega^2 A_0^2} \hbar\omega W_{if} \tag{43}$$

where n_r is the refractive index and μ is the permeability.

Combining Eqs. (39)–(42), using the conservation of momentum and energy and converting the final state summation into an integral, Eq. (42) can be written as

$$\alpha_{\text{abs}}(\hbar\omega) = \frac{e^2 c\mu\hbar^2 |\sin\,\theta|^2}{\omega\, m^2 n_r} \sum_{k_{zi}} \int k_{ti} \langle g_{1\text{d}}(E_{zi} + \hbar\omega)\rangle |M_z|^2 \times (1 - f(E_i + \hbar\omega)) f(E_i)\, dE_{ti} \tag{44}$$

where θ accounts for the incident angle of the light, M_z are the matrix elements, and $\langle g_{1\text{d}}(E_{zi} + \hbar\omega)\rangle$ is the effective one-dimensional density of states.

Converting the k_{zf} summations into an integral over the final energy, E_{zf}, introduces the effective 1D density of states, $\langle g_{1\text{d}}(E_{zf})\rangle$, into the absorption rate. The effective (1D) density of states is obtained by the method of Section 2 where $V(z)$ not only includes the conduction band potential energy and any externally applied fields but also incorporates the effects of the transverse momentum upon the z-directed wavefunction [70].

The structure investigated is the one used by Levine [2] and consists of two 40 Å GaAs quantum wells with 500 Å AlGaAs barriers. The composition of Al is 30% yielding a band offset of 0.2431 eV. The effective masses for electrons in the barriers and quantum wells are $0.092m_0$ and $0.067m_0$, respectively, where m_0 is the free electron mass. One bound energy level exists within the quantum well at 82 meV for a 25 kV/cm electric field while a virtual bound state exists at 260 meV.

In Figure 34, the calculation of the responsivity [$R \sim (1 - \exp(-2\alpha l))$] [1] of the two quantum well system is compared to the experimental two quantum well [1] system and shows excellent agreement. The responsivity of the individual wells is also shown in Figure 34 where the peaks in the responsivity of the individual wells occur at different wavelengths and are discussed later. The availability of states due to the redistribution of the one-dimensional density of states (see Fig. 35) around the band offset but above the bound energy level accounts for the excellent fit above 6 μm. For wavelengths below 6 μm, the theoretical calculations show

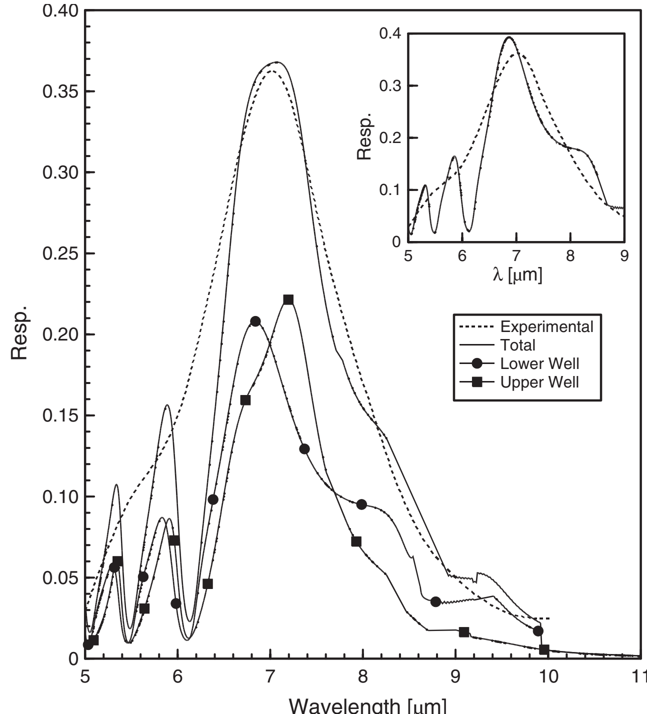

Figure 34. The calculated (solid line) and the experimental (dashed line) responsivity for the two quantum well QWIP. The inset is the responsivity of only the lower quantum well as a function of wavelength.

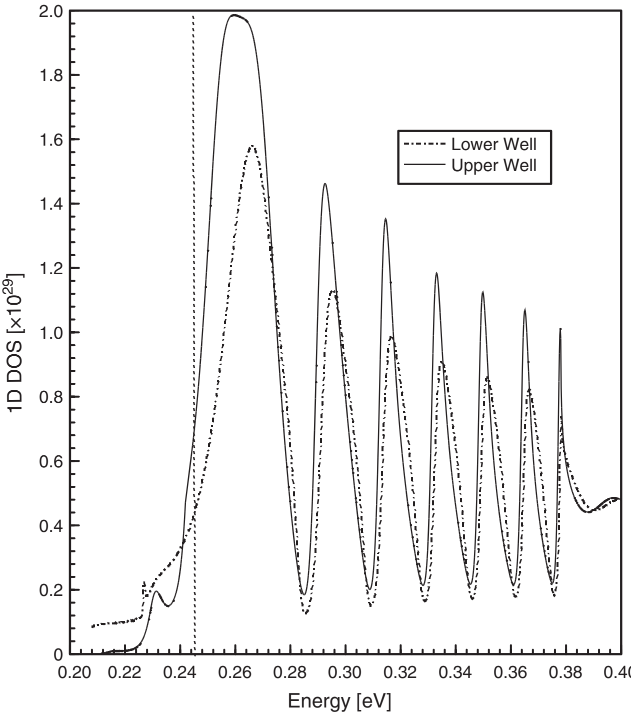

Figure 35. The one-dimensional density of states for the upper (solid) and lower (dashed–dotted) quantum wells. The vertical line is the conduction band offset.

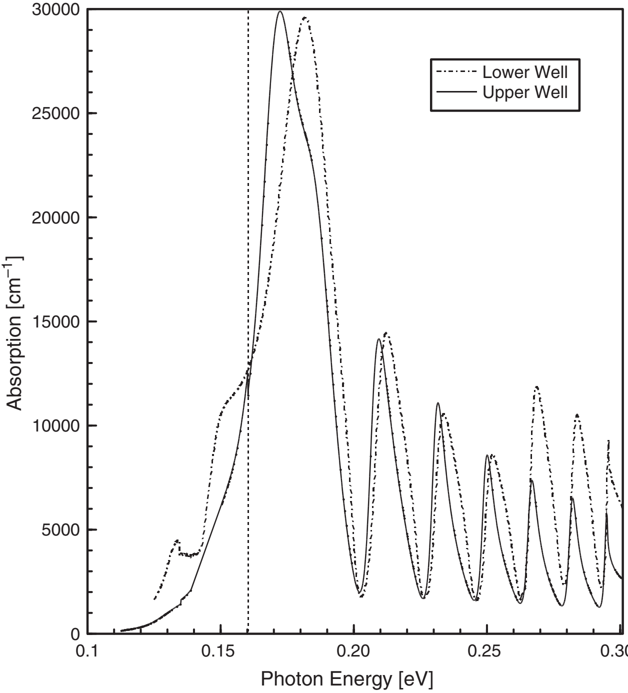

Figure 36. The absorption coefficient of the upper (solid) and lower (dashed–dotted) quantum well as a function of photon energy.

oscillatory behavior and is attributed to the nature of the one-dimensional density of states due to the virtual bound states above the band offset. This oscillatory behavior of the one-dimensional density of states, as shown in Figure 35, results from simulating an abrupt heterojunction. However, upon fabrication, the heterojunction loses its abruptness resulting in a slightly graded junction which would suppress the oscillatory nature of the 1D density of states. Furthermore, the incorporation of other scattering mechanisms (i.e., phonons, interface roughness) will also smooth out the oscillation wavelengths below 6 μm.

Figure 35 also shows the density of states of the two wells separately. As is evident, the presence of one quantum well, though separated by a large barrier, redistributes the other's density of states. This behavior affects the absorption characteristics and the responsivity as shown in Figures 35 and 36. In Figure 36, the absorption coefficient of the combined two quantum well system is shown along with the absorption coefficient of the individual quantum wells. In comparing Figures 35 and 36, it is seen that the absorption coefficient is a strong function of the density of states. Moreover, the existence of states below the band offset (vertical line in Fig. 35) but above the bound energy level results in the transition of an electron to these states. This is demonstrated in Figure 36, where there exists an absorption coefficient for states which lie below the band offset (the vertical line in Fig. 36 represents the energy difference between the energy level and the band offset). It is worth noting that if one claims that the densities of states are identical for both wells, the peak in the responsivity curve would be shifted and the broadening would be reduced as shown in the inset of Figure 34 where the responsivity is plotted using only the absorption coefficient of the lower well.

Furthermore, if the effects upon the wavefunction in the z-direction from changes in k_t are neglected, the broadening would be less and the peak in the responsivity would shift. This is demonstrated in Figure 37 where the responsivity is plotted as a function of wavelength when the effect of k_t upon the wavefunction is not accounted for. However, as shown in Figure 37, the broadening has not been drastically reduced, implying that the broadening in the absorption spectrum and the responsivity mainly results from the redistribution of the density of states and not due to scattering mechanisms or the effects of k_t upon the wavefunction.

6. DARK CURRENTS IN MULTIPLE QUANTUM WELL INFRARED PHOTODETECTORS

The dark current arising from the n^+ regions consists of a positive z-directed and a negative z-directed current where z is perpendicular to the quantum wells. The total current is the summation of the two components where each component is calculated by integrating over all k-space the local velocity ($v_g(E, z)$), the transmission coefficient ($D(E_z)$), and the Fermi function ($f(E)$) at the edge of the n^+ regions as [46]

$$J_{\text{tot}} = J^+ + J^- = \frac{2q}{(2\pi)^2} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} dk_x \, dk_y \times \left[\frac{1}{2\pi} \int f(E) v_g^{\pm}(E_z) D^{\pm}(E_z) \, dk_z \right] \tag{45}$$

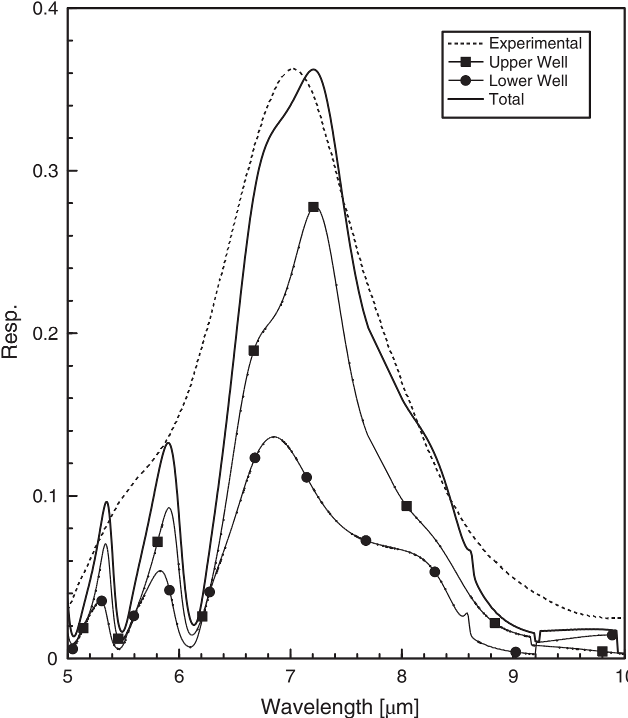

Figure 37. The responsivity as a function of wavelength for the two quantum well QWIP when the k_z dependence on k_t is not accounted for.

where q is the elemental charge and k is the wavevector in the x, y, and z direction.

Since the local velocity and the transmission coefficient are a function of the z-directed energy, the k_z integral is converted to an integral over energy (as well as the k_x and k_y integrals), E_z, as

$$J_{\text{tot}} = \frac{qm^*}{2\pi\hbar^2} \times \left[\int_0^\infty dE_t \int_{\substack{0 \\ kz>0}}^\infty f(E) v_g^+(E_z) D^+(E_z) g_{1\text{D}}(E_z) dE_z + \int_0^\infty dE_t \int_{\substack{0 \\ kz<0}}^\infty f(E) v_g^-(E_z) D^-(E_z) g_{1D}(E_z) dE_z \right] \tag{46}$$

where $g_{1\text{D}}(E_z)$ is the 1D density of states at the edge of the n^+ regions and E_t is the energy in the transverse direction (x and y).

The calculation of the 1D density of states proceeds as in Section 2. The calculation of the transmission coefficient [5–8] is obtained from the logarithmic derivative of the wavefunction by subtracting the square of the reflection coefficient at the edge of the n^+ region as

$$D^\pm(z_i, E_z) = 1 - \left| \frac{G^\pm(z_i, E_z) \mp G_{oi}}{G_{oi} \mp G^\pm(z_i, E_z)} \right|^2 \tag{47}$$

The QWIPs investigated are the same as those reported by Liu [13] with the system parameters summarized in Table 3 and an energy diagram shown in Figure 38.

Table 3. System parameters for QWIP.

Number of wells	Aluminum composition	Length of well	Length of barrier
4	26%	60 Å	254 Å
8	28%	60 Å	254 Å

In Figure 39, experimental dark current [13] is plotted as a function of applied bias for QWIPs with four and eight quantum wells. On the same graph, theoretical plots are also shown. It is observed that dark current is independent of the number of quantum wells contrary to the common belief. Transport in any structure is controlled by (a) the transmission coefficient, (b) the local velocity, and (c) density of states. In Figure 40, where the transmission coefficient, local velocity, and 1D density of states are plotted as a function of electron energy, for both four and eight quantum well systems, for a band offset of 0.216 eV. The plot suggests that the current is independent of the number of quantum wells as the parameters themselves do not change appreciably. As shown in the figure, there exist minibands of high transmission above the band offset separated by minibands of low transmission regions. The only difference in the transmission coefficient between the four well system and the eight well system is that the transmission coefficient between the minibands is smaller for the eight well system than the four well system. However, since the transmission coefficient of valleys for both systems is several orders of magnitude less than unity, there is a negligible difference between the four and eight well system. Moreover, a comparison of the local velocity and the density of states between the two systems also does not demonstrate any significant change.

However, a slight change in the growth parameters, namely, the band offset or the doping, makes a noticeable difference in the magnitude of dark current as is shown in Figure 39. It was pointed out in the table provided by Liu [13] that the Al concentration in the barrier region of the four and eight quantum well systems are 26% and 27%, respectively. The dark current for the eight well system (dashed–dotted line) is smaller than the four well system (dashed line). This results from the conduction band offset being larger for the eight well system, resulting in a smaller number of electrons participating in the current even though the peaks of the velocity and transmission coefficient are broader than the four well system, and is shown in Figure 41.

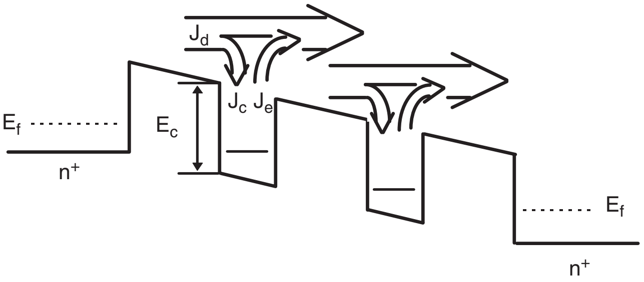

Figure 38. Energy diagram of a biased multiple quantum well n^+–i–n^+ systems demonstrating the origin of the dark currents.

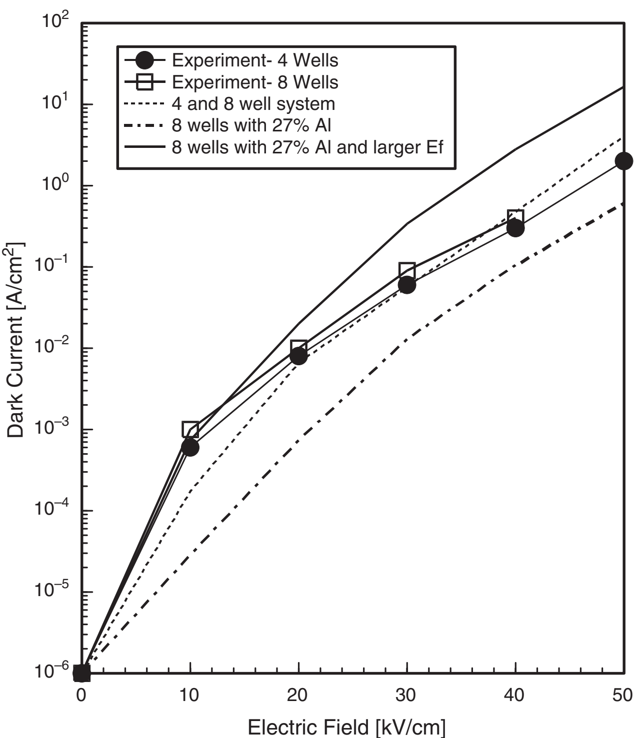

Figure 39. Comparison between the calculated and experimental dark current.

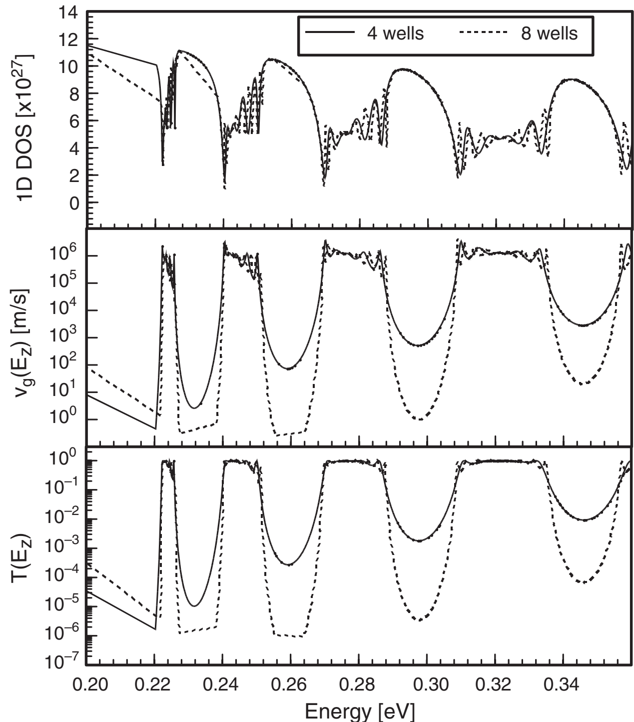

Figure 40. The velocity, density of states, and transmission coefficient for a four and eight quantum well system for Al compositions of 26%.

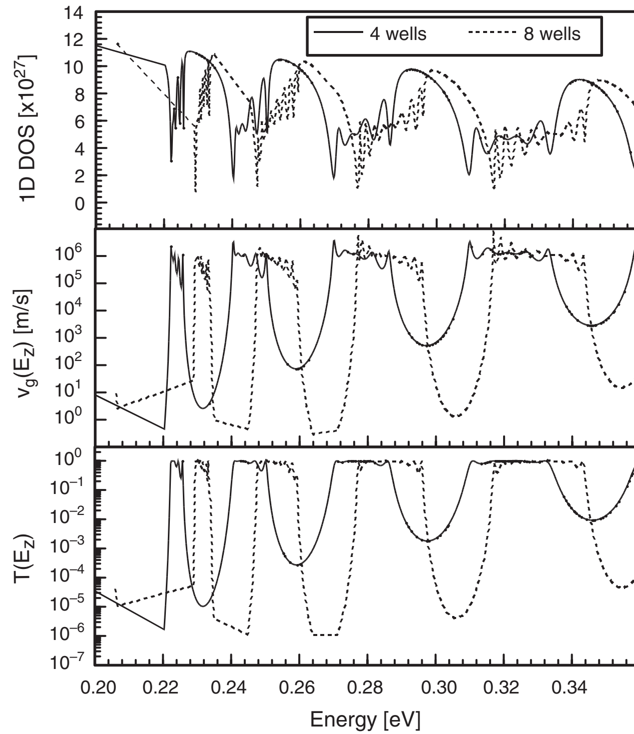

Figure 41. The velocity, density of states, and transmission coefficient for a four and eight quantum well system for Al compositions of 26% and 27%, respectively.

The experimental determination of the dark currents for the four and eight well system shows that the eight well system has a higher dark current. This can be attributed to the 10% uncertainty in the n^+ doping level as pointed out by Liu [13]. Incorporating the variation in n^+ doping level, the dark currents for the eight well system can become larger than the four well system. This is also demonstrated in Figure 39, where an increase in the dark current for the eight quantum well system (solid line) system is obtained by adjusting the Fermi level to 0.03 eV above the four well Fermi level. The increase in the dark current of the eight well system reported by Liu [13] may therefore be attributed to the difference in the donor doping level and not to the number of quantum wells.

GLOSSARY

Metalorganic vapor phase epitaxy (MOVPE) The reactor where the layered structures using different materials are grown. MOVPE growth is preferred by industry over MBE (molecular beam epitaxy) or LPE (liquid phase epitaxy) as it provides high throughput and lower cost per device while maintaining the quality especially for large wafers.

Quantum well (QW) A quantum well is like a well where a particle can be trapped. Layers made by using different semiconductor materials may result in the trapping of carriers (electrons, holes) in a particular layer. The trapped carriers and confined and are restricted to make certain movements or move in certain directions. The presence of QWs has resulted in modern electronic devices such as high

electron mobility transistors (HEMTs), heterojunction bipolar transistors (HBTs) and photonic devices such as QWIPs.

Quantum well infrared photodetector (QWIP) QWIPs operate based upon the bound to quasi-bound transition in a quantum well. It has been demonstrated in focal panel arrays in high resolution infrared cameras.

Self electro-optic device (SEED) An optically bistable device used in optical switching. An external voltage is applied to shift the wavelength of the onset of absorption, thereby, controlling the intensity of transmitted light.

1. INTRODUCTION

1.1. Semiclassical Theory of the Raman Scattering from a Molecule

In this section a simplified description of the Raman effect is presented, with the aim of providing readers who have no experience in the field with the basic physical concepts and equations, which may allow a discussion of some peculiar aspects of the Raman response of nanostructured materials or (more generally) of chemical compounds on the order of nanometers. For a comprehensive treatment of the Raman effect the reader can refer to books and reviews listed in the References [1–3].

Several concepts needed to understand the phenomenon of inelastic scattering of light observed when a material is irradiated with a monochromatic beam can be rather easily introduced starting from a classical approach. According to this scheme, we describe scattered light in terms of the fluctuating polarization field originating in the material and radiating the Raman light. In this section the material is described as the simplest case of an isolated molecule.

The intensity I (or time-averaged power per unit solid angle) radiated by an oscillating electric dipole $\mathbf{p}$ induced in a molecule by the electric field $\mathbf{E}^I = E^I\mathbf{e}^I$ of the incident radiation beam of frequency ω^I, along a direction making an angle θ with the axis of the dipole is given by classical electrodynamics [4] as

$$I = \frac{(\omega^S)^4 p^2 \sin^2(\theta)}{32\pi^2\epsilon_0^2 c^3} = \frac{(\omega^S)^4 |\mathbf{e}^S \cdot \mathbf{p}|^2}{32\pi^2\epsilon_0^2 c^3} \tag{1}$$

where $\mathbf{e}^S$ is the polarization unit vector of the emitted radiation. Due to quantized rotovibrational motion, the molecule polarizability $\boldsymbol{\alpha}$ is modulated at some internal frequencies ω_k (see below) and thus the induced electric dipole oscillates at frequencies ω^S which can be different from ω^I.

The expression for the (time-dependent) induced dipole of a molecule can be written, in very general terms, as a Taylor series in the field $\mathbf{E}$

$$p_\varrho = \sum_\sigma \alpha_{\varrho\sigma} E_\sigma + \frac{1}{2}\sum_{\sigma\tau}\beta_{\rho\sigma\tau} E_\sigma E_\tau + \frac{1}{3!}\sum_{\sigma\tau\upsilon}\gamma_{\rho\sigma\tau\upsilon} E_\sigma E_\tau E_\upsilon + \cdots \tag{2}$$

where p_ϱ is the ρth Cartesian component of the induced dipole and $\alpha_{\rho\sigma}, \beta_{\rho\sigma\tau}, \gamma_{\rho\sigma\tau\upsilon}$ are the elements of the (second rank) polarizability tensor and of the first and second hyperpolarizability tensors, respectively.

Raman scattering originates by the first term of this expression, namely, from molecular polarizability fluctuations; while in an isolated molecule the fluctuations are purely quantum mechanical effects, in a system of molecules in thermal equilibrium one also has to take into account thermodynamic fluctuations [5]. In the following we consider the expression (2) approximated to the first term, linear in the field. The time dependence of $\mathbf{p}$ is determined both by the time dependence of the tensor involved and from the time dependence of the electric field $\mathbf{E}$ of radiation. Combining the above formulae we obtain

$$I = \frac{(\omega^S)^4 |\mathbf{e}^S \cdot \boldsymbol{\alpha} \cdot \mathbf{e}^I|^2}{32\pi^2\epsilon_0^2 c^3}(E^I)^2 \tag{3}$$

The polarizability tensor $\boldsymbol{\alpha}$ is indeed a function of the nuclear coordinates. Neglecting rotations, for a vibrating molecule this dependence can be expressed in terms of the

All rights of reproduction in any form reserved.

set of all vibrational normal coordinates of the molecule $\{Q_k\}$ according to the relationship

$$\alpha_{\rho\sigma} = (\alpha_{\rho\sigma})_0 + \sum_k \left(\frac{\partial \alpha_{\rho\sigma}}{\partial Q_k}\right)_0 Q_k + \frac{1}{2}\sum_{kl}\left(\frac{\partial^2 \alpha_{\rho\sigma}}{\partial Q_k \partial Q_l}\right)_0 Q_k Q_l + \cdots \quad (4)$$

where the index 0 indicates the values at equilibrium geometry of the molecule in its electronic ground state. In the electric harmonic approximation we can write

$$\alpha_{\rho\sigma} = (\alpha_{\rho\sigma})_0 + \sum_k \alpha'_k Q_k$$

neglecting the higher order anharmonic terms in (4). The quantity $\boldsymbol{\alpha}'_k = (\partial \alpha_{\rho\sigma}/\partial Q_k)_0$ is called the derived polarizability tensor. According to the expressions above we can explicitly describe the time dependence of the fluctuating induced dipole resulting from the kth normal mode of vibration of the molecule irradiated by a plane monochromatic electromagnetic wave of frequency ω^I

$$\mathbf{p}_k = \boldsymbol{\alpha}_0 \mathbf{E}^I \cos(\omega^I t) + \boldsymbol{\alpha}'_k \mathbf{E}^I Q_{k0} \cos(\omega_k t + \delta_k)\cos(\omega^I t) + \cdots \quad (5)$$

Simple algebraic manipulation of the above equation allows us to identify three different contributions to $\mathbf{p}_k$ oscillating at different frequencies:

$$\mathbf{p}_k = \mathbf{p}(\omega^I) + \mathbf{p}(\omega^I - \omega_k) + \mathbf{p}(\omega^I + \omega_k) \quad (6)$$

$$\mathbf{p}(\omega^I) = \boldsymbol{\alpha}_0 \mathbf{E}^I \cos(\omega^I t) \quad (7)$$

$$\mathbf{p}(\omega^I \pm \omega_k) = \boldsymbol{\alpha}_k^{\mathrm{Raman}} \mathbf{E}^I \cos[(\omega^I \pm \omega_k)t + \delta_k] \quad (8)$$

$$\boldsymbol{\alpha}_k^{\mathrm{Raman}} = Q_{k0}\boldsymbol{\alpha}'_k$$

The dipole moment in Eq. (7) describes the elastic scattering of light (taking place at the same frequency as that of the exciting beam) called Rayleigh scattering. The fluctuating dipole moments in Eq. (8) are associated with inelastic Raman scattering. These random dipoles radiate two different monochromatic components oscillating, respectively, at lower frequency $\omega^I - \omega_k$ (Stokes line) and at higher frequency $\omega^I + \omega_k$ (anti-Stokes line) with respect to the frequency of the incident beam. The emission of the Raman light is a random process as it depends on the normal coordinate $Q_k = Q_{k0}\cos(\omega_k t + \delta_k)$, a function of time and of the random variables Q_{k0} and δ_k, the amplitude and the initial phase of a quantum harmonic oscillator obeying Bose–Einstein statistics [5].

Considering the Raman scattering from a polyatomic molecule (N atoms with $3N$-6 vibrational normal modes), we would expect to observe (at least in principle) $3N$-6 lines at negative frequency shifts with respect to the Rayleigh line (Stokes Raman spectrum) and $3N$-6 lines at positive frequency shift (anti-Stokes Raman spectrum). Usually the Raman spectrum is recorded in the Stokes region (see below) and Raman intensities are plotted versus Raman shifts, measured as wave numbers (units of cm^{-1}). In fact the number of Raman transitions which can be observed can be lower than that predicted by dynamics: indeed if the molecule has some symmetry selection rules may be active.

The simple derivation illustrated above holds in the hypothesis of strict electrical and mechanical harmonicity: the effect of anharmonicity is the appearance of lines at frequency shifts corresponding to near multiples of the fundamental vibrational frequencies (overtones) and at frequencies which are the sum or difference of fundamental vibrational frequencies (combination lines). Raman transitions corresponding to overtones and combination bands are usually referred to as second order Raman spectra.

According to Eqs. (8) and (3) we can state that the intensity of a Raman line (and thus the possibility of observing Raman scattering at a given frequency shift) is determined by the (i) vibrational dynamics of the molecules (i.e., normal vibrations and their frequencies: Q_k, ω_k); (ii) values of the Raman tensors $\boldsymbol{\alpha}'_k$; and (iii) orientation of the molecule with respect to the polarization directions of both the incident and scattered light beams.

This last point is important both in the discussion of the symmetry of the normal vibration responsible for Raman scattering and in the determination of the orientation of the molecule with respect to a space fixed reference system.

Analysis of (ii) can be further developed according to the following logical steps.

(a) Determination of the symmetry selection rules is done. The analysis of the molecular symmetry allows us to select (among the $3N$-6 molecular normal modes) those Q_k modes with $\boldsymbol{\alpha}'_k \neq 0$. This can be done without any specific knowledge of any numeric value of $\boldsymbol{\alpha}'_k$. For fundamental Raman transitions the selection rules can be easily stated: Q_k is Raman active if at least one element (uv) of the polarizability tensor fullfils the requirement $\Gamma_1 \subset \Gamma(Q_k) \otimes \Gamma(\alpha_{uv})$, where Γ_1 is the totally symmetric representation.

(b) The intrinsic intensity of a Raman allowed transition at ω_k (large or small Raman cross section) is determined by the electrical properties of the molecule considered (molecular polarizability and the extent of its change during the normal mode motion). Based on experimental findings it is usually accepted that Raman transitions associated with totally symmetric normal modes are stronger than those associated with vibrations belonging to non totally symmetric species.

(c) According to the simple classical theory illustrated in this section it is impossible to discuss one of the most important issues of Raman scattering. Raman intensities depend on the dispersion behavior of the Raman tensor while varying the frequency of the exciting electromagnetic wave (incident photon energy). Factors which determine this behavior are intimately related to the electronic structure of the molecule (material) and can be explicitly considered only in the frame of a quantum theory of Raman scattering [6–8]. The study of the evolution of the Raman spectrum with the exciting photon energy is of great importance, since it can give specific insight into the electronic properties of the material.

(d) A special case related to what is illustrated in (c) is the occurrence of resonance enhancement of a Raman line [6–9], when a suitable exciting energy is used matching the energy gap between energy levels

(usually the gap between the ground state and one selected electronic excited state) of the material. Resonance effects are responsible for a huge enhancement of Raman cross sections (which is often very selective for specific normal vibrations).

1.2. Raman Scattering in Extended Media

Many nanostructures can be thought as the assembly of elementary molecular units (conceptual bottom-up approach) and the scheme of the preceding section can be naturally extended. Yet, in some cases, a conceptual top-down approach is more convenient and the nanostructure is seen as a limited portion of an otherwise perfect infinite crystal. To this purpose we now generalize the classical theory of Raman scattering from single molecules in such a way that it can be applied to extended media and also to Brillouin scattering (inelastic light scattering from acoustic excitations). For the sake of simplicity we restrict ourselves to the case of optically isotropic solids (e.g., amorphous bodies or cubic crystals). Both Raman and Brillouin scattering can be treated introducing the instantaneous anisotropic dielectric susceptibility of the medium around the frequency ω^I, the tensor

$$\chi_{ij} = \chi\delta_{ij} + \delta\chi_{ij} \tag{9}$$

χ is the usual time-independent isotropic susceptibility, while the tensor $\delta\chi_{ij}$ is the anisotropic fluctuating part of the susceptibility due to the presence of phonon excitations modulating the optic response of the body. The corresponding fluctuating part of the dielectric constant is simply

$$\delta\epsilon_{ij} = \epsilon_0\delta\chi_{ij} \tag{10}$$

while the usual isotropic dielectric constant is $\epsilon = \epsilon_0(1+\chi)$. When the body is irradiated, there is a fluctuating part of the polarization vector radiating the scattered electromagnetic waves. This fluctuating continuous volume density of electric dipoles can be written as $\delta P_i = \delta\epsilon_{ij}E_j$ (in the following, the summation convention over repeated indexes is understood). Here

$$E_j = E_j^I + E_j^S \tag{11}$$

is the sum of the incident field and of the scattered field. Using the linearity of Maxwell equations the scattered electric field $\mathbf{E}^S$ radiated by the source $\partial\delta P_i/\partial t$ can be computed by means of first order perturbation theory (Born approximation), that is, assuming

$$\delta P_i \approx \delta\epsilon_{ij}E_j^I = \epsilon_0\delta\chi_{ij}E_j^I \tag{12}$$

The above equation is justified by the smallness of both the scattered field and $\delta\epsilon_{ij}$: in this way the excess polarization is seen as driven only by the incident electric field $\mathbf{E}^I$. Following the same scheme used above for molecules, it turns out that δP_i oscillates at the frequencies $\omega^S = \omega^I \pm \omega_\alpha$ as the time dependence of $\delta\epsilon_{ij}$ is $e^{-i\omega_\alpha t}$, where ω_α is one of the vibrational eigenfrequencies of the whole body, that is,

$$\delta\epsilon_{ij} = \epsilon_0\delta\chi_{ij}(\mathbf{r}|\boldsymbol{\alpha})e^{-i\omega_\alpha t} \tag{13}$$

$\delta\chi_{ij}(\mathbf{r}|\boldsymbol{\alpha})$ represents the space-dependent part of $\delta\chi_{ij}$ when only one normal mode of frequency ω_α is active. Solving the radiation problem in the far field approximation, as it is appropriate for most Raman and Brillouin scattering experiments, we find the fundamental formula [11]

$$\mathbf{E}^S(\mathbf{r},t) \approx \Re\left\{-\frac{E_0 e^{i(\mathbf{k}^S\cdot\mathbf{r}-\omega^S t)}}{4\pi\epsilon_r r}\mathbf{k}^S \times (\mathbf{k}^S \times \mathbf{G}_\alpha)\right\} \tag{14}$$

In the above equation the observation point $\mathbf{r}$ is at distance r from the scattering portion V of the irradiated crystal. The origin of the coordinate system is inside the scattering volume scanned by vectors $\mathbf{r}'$ and the direction of the vector $\mathbf{r}-\mathbf{r}'$, which is the same as that of the vector $\mathbf{k}^S$, has been confused with that of vector $\mathbf{r}$. The vector scattering integral $\mathbf{G}$ is given by the key expression

$$\mathbf{G}_\alpha = \int_V (\delta\boldsymbol{\chi}(\mathbf{r}'|\boldsymbol{\alpha}) \bullet \mathbf{e}^I)e^{-i\mathbf{Q}\cdot\mathbf{r}'}\,d\mathbf{r}' \tag{15}$$

where $\bullet$ denotes the product of a second rank tensor by a column vector generating again a column vector. The transferred wave vector $\mathbf{Q}$ is defined as

$$\mathbf{Q} = \mathbf{k}^S - \mathbf{k}^I \tag{16}$$

where $\mathbf{k}^S$ and $\mathbf{k}^I$ are the wave vectors of the incident and of the scattered photons, respectively. Equations (14) and (15) express the scattered electric field as a function of the random variables $\delta\chi_{ij}$. At thermodynamic equilibrium the thermal average $\langle\mathbf{E}^S\rangle_{th} = 0$ because $\langle\delta\chi_{ij}\rangle_{th} = 0$, but the mean square $\langle|\mathbf{E}^S|^2\rangle_{th}$, which depends on the finite mean square value of the phonon normal coordinate buried in $\delta\chi_{ij}$, does not vanish.

The measured outcome of any inelastic light scattering experiment is the power spectrum $S_{E^S}(\omega)$ of the scattered light, which is computed as

$$S_{E^S}(\omega) = \int_{-\infty}^{\infty}\langle E^S(t+\tau)E^{S*}(t)\rangle_{th}e^{i\omega\tau}\,d\tau \tag{17}$$

where $E^S = \mathbf{E}^S\cdot\mathbf{e}^S$ is the complex amplitude of the scattered field projected along a given analyzed polarization direction perpendicular to $\mathbf{k}^S$.

Defining

$$\delta\boldsymbol{\chi}_{\mathbf{Q}}^{\alpha} = \int_V \delta\boldsymbol{\chi}(\mathbf{r}'|\alpha)e^{-i\mathbf{Q}\cdot\mathbf{r}'}\,d\mathbf{r}' \tag{18}$$

as the Fourier transform of index $\mathbf{Q}$ of the spatial part of the susceptibility tensor fluctuation and using some straightforward manipulations, the power spectrum of the scattered light can be written as

$$S_{E^S}(\mathbf{Q},\omega) = \frac{|E_0|^2(\omega^S)^4}{8\pi\epsilon_r^2c^4r^2}\left\langle|\mathbf{e}^S\cdot\delta\boldsymbol{\chi}_{\mathbf{Q}}^{\alpha}\bullet\mathbf{e}^I|^2\right\rangle_{th} \times \delta[\omega-(\omega^I+\omega_\alpha)] \tag{19}$$

for anti-Stokes scattering. For Stokes scattering one has just to replace $\omega^I+\omega_\alpha$ with $\omega^I-\omega_\alpha$ in the argument of the delta function. In all practical applications the delta function is substituted by a Lorentzian line shape centered at $\omega^I\pm\omega_\alpha$ with a FWHM related to the lifetime of the phonon

and to instrumental and opacity broadening. Introducing the Raman susceptibility $\delta(\boldsymbol{\chi}_{\mathbf{Q}}^{\alpha})/\partial\xi_\alpha$ with respect to the amplitude ξ_α of normal mode α, Eq. (19) can be rewritten as

$$S_{E^S}(\mathbf{Q},\omega) = \frac{|E_0|^2(\omega^S)^4}{8\pi\epsilon_r^2c^4r^2}\left|\mathbf{e}^S\cdot\frac{\partial(\boldsymbol{\chi}_{\mathbf{Q}}^{\alpha})}{\partial\xi_\alpha}\bullet\mathbf{e}^I\right|^2\langle\xi_\alpha^*\xi_\alpha\rangle_{th} \times \delta[\omega-(\omega^I+\omega_\alpha)] \qquad (20)$$

Standard second quantization arguments [12] show that

$$\langle\xi_\alpha^*\xi_\alpha\rangle_{th} = \frac{\hbar}{2\omega_\alpha}n \qquad (21)$$

Again the above formula can also be applied to Stokes scattering provided $\omega^I+\omega_\alpha$ is replaced with $\omega^I-\omega_\alpha$ and n with $n+1$, where

$$n = \left(e^{\frac{\hbar\omega_\alpha}{k_BT}}-1\right)^{-1} \qquad (22)$$

is the Bose–Einstein statistical factor. Because of the statistical weight the Raman Stokes intensity is always higher than the anti-Stokes one and often only the Stokes signal is recorded.

In the case of a crystal the normal modes of vibration are lattice waves (or Bloch waves [13] called optic and acoustic phonons). As a consequence of space periodicity (translational invariance of the crystal) the mode eigenfrequencies $\omega_\alpha(\mathbf{q})$ of a given phonon branch α are periodic functions of the phonon wave vector $\mathbf{q}$ in the extended zone scheme [13], that is, $\omega_\alpha(\mathbf{q}+\mathbf{g}_i)=\omega_\alpha(\mathbf{q})$ for any reciprocal lattice vector $\mathbf{g}_i$. It is important to stress that the phonon wave vector $\mathbf{q}$ is, strictly speaking, a good mode label only for ideal crystals. Yet in real cases $\mathbf{q}$ also keeps a physical meaning for systems exhibiting a sufficient degree of long-range translational order (see the confinement theory below). In the limit $\mathbf{q}\to\mathbf{0}$ $\omega_\alpha(\mathbf{q})$ of acoustic phonons goes linearly to 0, the group velocity $\partial\omega_\alpha(\mathbf{q})/\partial\mathbf{q}$ becoming identical to the corresponding sound speed $\mathbf{v}_\alpha$. For optic phonons instead $\omega_\alpha(\mathbf{q})$ goes to a finite value $\omega_\alpha(\mathbf{0})$ (typically in the range of 100–4000 cm^{-1}) with a vanishing group velocity. While scattering from crystal optic phonons is still called Raman scattering, as for single molecules, scattering from acoustic phonons is called Brillouin scattering (see below).

If the phonon-induced susceptibility fluctuations are due to lattice waves, the main result one gets is that one-phonon scattering occurs only for $\mathbf{q}=\mathbf{Q}$ and $\mathbf{Q}\approx\mathbf{0}$ due to the low photon momentum transfer, in the visible or in the infrared, with respect to zone boundary wave vectors. The argument goes as follows. In a crystal with a basis, the basis atoms of cell $\mathbf{n}$ in the lattice position $\mathbf{r}_\mathbf{n}$ form a molecule with polarizability $\boldsymbol{\alpha}_\mathbf{n}$. Thus the crystal susceptibility fluctuation due to all individual polarizability fluctuations $\delta\boldsymbol{\alpha}_\mathbf{n}^\alpha$ caused by a phonon ($\alpha\mathbf{q}$) can be written as

$$\delta\boldsymbol{\chi}(\mathbf{r}|\alpha) = \sum_\mathbf{n}\delta\boldsymbol{\alpha}_\mathbf{n}^\alpha\delta(\mathbf{r}-\mathbf{r}_\mathbf{n})$$

Computing the Fourier transform in Eq. (18) we obtain

$$\delta\boldsymbol{\chi}_\mathbf{Q}^\alpha = \sum_\mathbf{n}\delta\boldsymbol{\alpha}_\mathbf{n}^\alpha e^{-i\mathbf{Q}\cdot\mathbf{r}_\mathbf{n}}$$

Because $\delta\boldsymbol{\alpha}_\mathbf{n}^\alpha$ is a Bloch wave with wave vector $\mathbf{q}$

$$\delta\boldsymbol{\alpha}_\mathbf{n}^\alpha = \delta\boldsymbol{\alpha}_0^\alpha e^{i\mathbf{q}\cdot\mathbf{r}_\mathbf{n}}$$

we get

$$\delta\boldsymbol{\chi}_\mathbf{Q}^\alpha = \delta\boldsymbol{\alpha}_\mathbf{0}^\alpha\sum_\mathbf{n}e^{-i(\mathbf{Q}-\mathbf{q})\cdot\mathbf{r}_\mathbf{n}} = \frac{1}{V}\delta\boldsymbol{\alpha}_\mathbf{0}^\alpha\sum_i\delta(\mathbf{Q}-\mathbf{q}-\mathbf{g}_i)$$

Due to the extremely low photon momentum (with respect to zone boundary wave vectors), we can assume $\mathbf{Q}\approx\mathbf{0}$. Thus only the optic phonons with $\mathbf{q}\approx-\mathbf{g}_i$ do contribute to Raman scattering in a crystal. These phonons have frequencies $\omega_\alpha(\mathbf{q}\approx-\mathbf{g}_i)=\omega_\alpha(\mathbf{q}\approx\mathbf{g}_i)=\omega_\alpha(\mathbf{q}\approx\mathbf{0})$. As the group velocity of optic phonons at small $\mathbf{q}$ is negligible we can put $\omega_\alpha(\mathbf{q}\approx\mathbf{0})=\omega_\alpha(\mathbf{0})$. This marks an important difference with respect to coherent Brillouin scattering and incoherent Raman scattering. In fact, in the case of Brillouin scattering, $\mathbf{q}$ is small but cannot be put exactly equal to $\mathbf{0}$ in the linear dispersion relationship of acoustic phonons: this would correspond to a rigid translation of the lattice as a whole.

Introducing the normal mode expansion for the displacement $\mathbf{u}\binom{p}{\mathbf{0}}$ of atom p of the basis, composed of s atoms, of the cell in $\mathbf{0}$:

$$u\begin{pmatrix}p\\\mathbf{0}\end{pmatrix} = \frac{1}{\sqrt{Nm_p}}\sum_{\mathbf{q}\alpha}\xi_\alpha(\mathbf{q})\mathbf{e}(p|\mathbf{q}\alpha)e^{i\mathbf{q}\cdot\mathbf{r}_p}$$

we can express $\partial\boldsymbol{\alpha}_\mathbf{0}^\alpha/\partial\xi_\alpha(\mathbf{0})$ as

$$\frac{\partial\boldsymbol{\alpha}_\mathbf{0}^\alpha}{\partial\xi_\alpha(\mathbf{0})} = \frac{1}{\sqrt{Nm_p}}\sum_{p=1,s}\frac{\partial\boldsymbol{\alpha}_\mathbf{0}^\alpha}{\partial\mathbf{u}\binom{p}{\mathbf{0}}}\bullet\mathbf{e}(p|\mathbf{0}\alpha)$$

where the $\mathbf{e}(p|\mathbf{0}\alpha)$ are the polarization eigenvectors of the basis excited by phonon $(\mathbf{0}\alpha)$. Now the power spectrum of the anti-Stokes Raman signal can be obtained from Eq. (19) just summing up over all phonons $(\mathbf{0}\alpha)$ with eigenfrequencies $\omega_\alpha(\mathbf{0})$, obtaining the fundamental result: $S_{E^S}(\mathbf{0},\omega)$ is proportional to

$$\sum_\alpha\left|\mathbf{e}^S\cdot\left[\sum_{p=1,s}\frac{\partial\boldsymbol{\alpha}_\mathbf{0}^\alpha}{\partial\mathbf{u}\binom{p}{\mathbf{0}}}\bullet\mathbf{e}(p|\mathbf{0}\alpha)\right]\bullet\mathbf{e}^I\right|^2 \times\langle\xi_\alpha^*(\mathbf{0})\xi_\alpha(\mathbf{0})\rangle_{th}\delta[\omega-\omega^I-\omega_\alpha(\mathbf{0})]$$

The quantity

$$\left|\mathbf{e}^S\cdot\left[\sum_{p=1,s}\left(\partial\boldsymbol{\alpha}_\mathbf{0}^\alpha/\partial\mathbf{u}\begin{pmatrix}p\\\mathbf{0}\end{pmatrix}\right)\bullet\mathbf{e}(p|\mathbf{0}\alpha)\right]\bullet\mathbf{e}^I\right|^2$$

governs the first order Raman selection rules in crystals [13, 214] through their symmetry properties combining the point-group symmetry of the basis with the translations group of the lattice [14]. In particular, the Raman tensor of odd-parity phonons in centrosymmetric crystals must vanish. In this case only even-parity phonons with $\mathbf{q}=\mathbf{0}$ can be Raman active.

To treat disordered bodies and finite size crystalline bodies (isolated nanocrystals and nanocrystalline systems), it is worth (see below) further generalizing the above formalism, using the fact that the square modulus of the Fourier

transform of some function $f(\mathbf{r})$ equals the Fourier transform of the autocorrelation function of the same function $\langle f(\mathbf{r})f(\mathbf{r}')\rangle$. In this way the Raman spectrum of a generic extended medium can be written in terms of direct space–direct time dependence of fluctuations as [43]

$$S_{E^S}(\mathbf{Q},\omega) \propto \Im \int d\mathbf{r} \int d\mathbf{r}' \int dt \langle \delta\chi(\mathbf{r},t)\delta\chi(\mathbf{r}',0)\rangle_{th} e^{[-i\mathbf{Q}\cdot(\mathbf{r}-\mathbf{r}')-i\omega t]} \quad (23)$$

where, for the sake of simplicity, we dropped the tensorial notation.

The function $S_{E^S}(\mathbf{Q},\omega,)$ is called the dynamic structure factor, its $\omega = 0$ value being the static structure factor, governing elastic light scattering. The experimental investigation of the dynamic structure factor can be performed with different techniques depending on the time scale (i.e., frequency range). For frequencies in the range of some gigahertz, which is typical of Brillouin spectroscopy, interferometric techniques (Fabry–Perot interferometers) are necessary [14]. Higher frequencies, typical of Raman spectroscopy, require the use of diffraction gratings (monochromators).

As we have seen, the ingredients which determine the Raman spectrum are the normal modes of vibration (either molecular vibrations or optic phonons) and the derived polarizability tensors (with respect to normal modes).

Our discussion is organized according to the following questions.

- How are normal vibrations of a material affected by the confinement within material domains of a size of a few nanometers?
- How is the polarizability tensor affected? That is, how are Raman selection rules affected? How is dispersion behavior and/or resonant behavior affected?

In the following section we try to extract some answers to these questions. Some quite general predictions can be given (and also suitable formalisms can be used) if specific models for the description of nanostructures are developed: for this reason we need to introduce a classification of nanostructures, based on their peculiar structural characteristics.

2. CLASSES OF NANOSTRUCTURES

The vibrational dynamics and the sequence of Raman transitions of a periodic (infinite) system (crystal) are subjected to rules (and give rise to a formalism, i.e., that of phonons) determining a spectroscopic behavior deeply different from that of single molecules. On the other hand, nanostructures can be considered objects which occupy an intermediate position between a perfect, ideally infinite crystal and a giant molecule.

Thus it is useful to group nanostructures according to a similarity criterion with respect to either a crystal (in this case the nanostructure is seen as a very little crystal and the solid state physics approach is the suitable starting point for its description) or to a molecule (in this case the nanostructure can be seen as a very large molecule and the molecular approach is better).

As this classification is necessarily too rigid, a bridge between the two different approaches can be conveniently built in same specific cases.

We propose the following classification, based on pure geometrical properties.

1. **Nanoobjects.** These objects must necessarily be regarded as (large) molecular entities, which cannot be correlated to a parent crystal with higher perfection characteristics (first of all, large enough to be thought as infinite). Molecular normal modes and molecular point symmetry rule their Raman response. According to this definition clusters (e.g., fullerenes) are nanoobjects.
2. **Nanocrystals.** These objects can be obtained cutting a finite portion from an infinite crystal. This ideal procedure finds several examples in reality, for example, by ball milling crystalline materials can be reduced to a powder made of small crystallites of few nanometers in size. Moreover, in a large crystal, due to the presence of structural defects, translational order can also be lost over relatively few cells: in this case the material can be described as formed by crystalline subunits of reduced dimensions. Defected graphites are often regarded as assembly of finite size domains with the same structure of a graphite sheet.

   A specific example in which nature directly provides us with nanocrystals is the case of (semi)crystalline polymers where single crystals are born in forms of lamellae with a characteristic thickness of few nanometers.

   The relevant point characteristic of nanocrystals is the fact that they can be set in correspondence with a parent crystal (which can exist in reality, as in the case of Ge crystals described below, or which exist only ideally, as in the case of a polymer). This fact allows us to start from the phonon formalism for the treatment of the vibrational problem.
3. **Special nanostructures.** In this class we collect materials which, according to their geometry, would be classified as nanoobjects, but which, at least in some respect, can be also related to an ideal parent crystal. Carbon nanotubes belong to this class. Their structure can be described as originating by cutting and rolling a piece of matter from a single graphite sheet. A very long nanotube can be regarded as a graphite portion which has been confined in two dimensions (the radial and the tangential ones), giving rise to a one-dimensional 1D crystal. On the other hand, the rolling of the sheet gives rise to an object which is unique from the structural point of view (it is not a strip, but really a tube, which is even characterized by a given chirality) with respect to the parent crystal.

3. GENERAL CONSIDERATIONS ON VIBRATIONAL DYNAMICS AND RAMAN SCATTERING OF NANOSTRUCTURES

In this section we discuss the general criteria (relative to vibrational dynamics and spectroscopic selection rules) which can be derived for the three classes of nanostructures considered above.

1. Vibrational dynamics of nanoobjects must be treated on the usual basis of molecular dynamics (nanoobjects are indeed molecules in all the points of view). In this case selection rules are dictated by the point group symmetry of the molecule and can be derived applying the usual procedure described for molecules. Notice that, in the case of a very large object (made by N atoms) with low symmetry, at least in principle, all $3N$-6 vibrational modes can be observed in the Raman spectrum at spectral shifts corresponding to their eigenfrequencies.

   Also, when nanoobjects are assembled to form solid aggregates (e.g., crystals, as in the case of fullerite, made assembling C_{60} fullerenes in a f.c.c. lattice) their molecular nature still dominates and practically governs their spectroscopic behavior. This is especially true when intermolecular bonds are relatively weak (van der Waals interactions), as usually happens in molecular crystals. An exception to this rule seems to be the f.c.c. solid C_{20} in which interstitials carbon atoms could create stiff covalent bridges between different cluster units [28].

   The case of nanoobjects does not require any further discussion at this level. A detailed example is given in Section 5.1, where the Raman spectrum of C_{60}, the most famous fullerene, is described and commented upon.
2. In the treatment of the vibrational dynamics of nanocrystals one can start from the hypothesis that their normal modes would be described on the basis of the phonons of the parent perfect crystal. This hypothesis drastically reduces the complexity of the mathematical problem and has several immediate consequences.
   - The normal vibrations (of the nanocrystal) are described as stationary waves which can be easily built as a combination of two phonons of the parent perfect crystal traveling in the opposite directions, characterized by wave vectors **q** and −**q**, respectively.
   - According to this model, the vibrational frequencies of the normal modes obtained from the phonons of wave vector **q** are identical to those lying on the vibrational dispersion curves of the parent crystal (at the same **q**).
   - The choice of the suitable subset of **q** values is determined by boundary conditions dictated by the finite size, as in the case of the electromagnetic standing waves characteristic of a cubic cavity of edge length L. In the simplest case of a 1D crystal [15] this leads to the relationship $q = \pi j/L = j/(N + 1)d$, j being an integer ranging from 1 to N and N the number of unit cells of size d contained in $L = d(N + 1)$ (see Fig. 1). The 3D case is similarly treated.

Since in nanocrystals the translational symmetry is broken, all the frequencies selected with the procedure described above can (in principle) be observed in the Raman spectrum. However, selection rules determined by the point symmetry of the nanocrystal (thought of as a unity) will determine the activity of each normal mode.

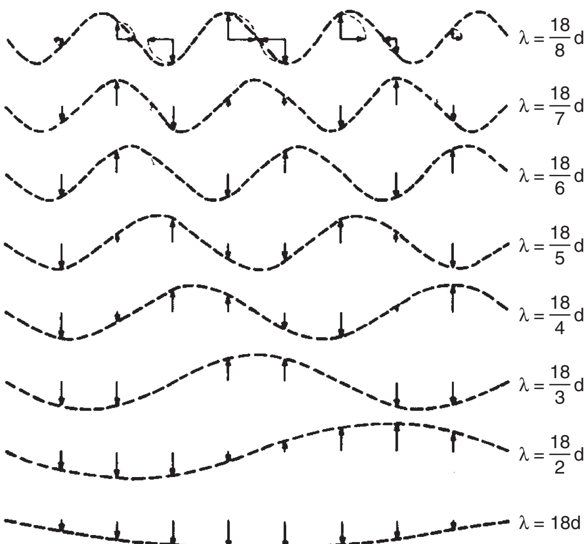

Figure 1. Longitudinal vibrations of a linear chain of eight point masses with fixed ends. The real displacements of the masses can be obtained by turning the vectors by 90° clockwise, as indicated for the mode with $\lambda = 18/8\ d$.

Under this point of view the finite size of a nanocrystal can be regarded as a very peculiar kind of defect of the parent crystal. As a consequence of the geometrical confinement, we can predict, as for any other kind of defect, the activation in the Raman (and/or infrared) spectrum of $q \neq \mathbf{0}$ phonons of the parent crystal. In a limiting case where the point symmetry of the nanocrystal is low we would expect that features observed in the Raman spectrum should be directly related to the density of phonon states, as is true to a first approximation for amorphous solids [29]. This is indeed what one expects for sufficiently large nanocrystals, where the spacing $\Delta q = 2\pi/(N+1)d$ between allowed $q's$ is small. However, in the simplest cases also, the experimental findings are often quite different from this ideal expectation.

The breakdown of the translational $\mathbf{q} = \mathbf{0}$ selection rule is usually effective only in the activation of phonons near to the zone center ($\mathbf{q} \approx \mathbf{0}$ phonons). This can easily be realized considering the simplest case of normal modes of a one-dimensional crystal: these modes can be classified according to the number of "nodes" of the associated stationary wave (Fig. 1).

The mode with the longest λ (lowest $q = 2\pi/\lambda$) allowed ($\lambda = 2L$) is characterized by two nodes at the boundaries (end of the chain): in this case the phase difference between amplitudes of vibration for atoms belonging to different repeating units of the chain is always less than π. As a result the contribution to the change of total polarizability by each unit sums up to that of the others (i.e., the effect is cooperative, by each unit). Modes with higher q values are described as an amplitude wave with more than two nodes. In this case we have several pairs of units along the chain which vibrate with the opposite phase, giving rise to contributions to the total polarizability which cancel each other. This mechanism of cancellation is more and more efficient as the number of nodes increases and as the dimension of the crystal increases.

On this basis it can easily be realized that for a relatively large nanocrystal only phonons in a narrow range of q values near zone center will be seen in the Raman spectrum. Another consideration must be added about confinement (for details see the case of small 3D Ge nanocrystals, quantum dots, as illustrated in Section 5.3.1). Confined phonons can be thought of as the application of an envelope factor to a plane wave. This amplitude modulation makes the phonon wave function significantly different from 0 only in a space region of linear size a. Thus a very general, though rough, evaluation of the size $|\Delta\mathbf{q}|$ of wave vector space involved is easily deduced from the uncertainty principle as $2\pi/a$, where a could be the nanoparticle radius. As $\mathbf{q}$ scans a volume $\approx|\Delta\mathbf{q}|^3$ around $\mathbf{q} \approx 0$, provided the group velocity of crystal phonons is significantly different from 0, one can observe the Raman contribution of several phonons leading to inhomogeneous broadening of the Raman line. If the group velocity is negative, one observes an average red shift; if it is positive, an average blue shift. In this way inhomogeneous broadening and either red or blue shifts are distinctive marks of vibrational confinement effects. Yet special interpreting care must be assumed, because small shifts in the Raman line can also be due to internal stresses via anharmonic effects.

Due to the extreme flatness of the optical phonon dispersion curves of polymers, it is practically impossible to reveal the small thickness of polymer lamellae by inspection of Raman bands corresponding to vibrational transitions which belong to optical branches. However, in the case of normal modes belonging to acoustic branches, new frequencies can be revealed. This is the case of longitudinal accordion motions, whose frequencies give reliable information about the dimension of the polymer lamellae (see Section 5.4).

4. CONFINEMENT EFFECTS

In Section 3 we have described the effect of confinement in nanocrystals solely as a pure geometrical constraint: all relevant dynamic properties were thought to remain the same as in the parent crystal and finite size boundary conditions ruled out the $\mathbf{q} = \mathbf{0}$ rule activating a whole set of wave vectors.

Unfortunately this first approximation shows some weakness in many cases. This can be ascribed to the following points:

(i) *Effects due to change in the vibrational potential energy* (*and then in vibrational force constants*). This effect is usually found in systems characterized by long-range interactions. It is the case of organic materials containing conjugated π electrons, with an electronic structure strongly sensitive to the delocalization path available (and then to the size of the crystal).

As a consequence, one finds a continuous change in the values of some force constants often accompanied by an increase in the distance of interaction as a function of the size of the crystal itself. The signature of this phenomenon in the Raman spectrum is a frequency shift of some characteristic Raman bands with respect to the frequency value of the parent crystal.

Systematic frequency and intensity dispersion of the strongest Raman active modes has been observed for linear polyenes with increasing chain length [18] (see Fig. 2). These frequencies do not reach the limit of the $q = 0$ phonon of polyacetylene, which can be estimated by extrapolation from the frequency trend observed for polyenes of increasing length. On the other hand, probing a polyacetylene sample [20] (see Fig. 3) with different exciting laser lines one can sweep through the range of energy gaps of polyacetylene. Thus by resonance it is possible to probe the poly-dispersity in conjugation lengths of a given sample (see Section 5.4).

The frequency dispersion observed in the case of polyenes cannot be simply explained considering the fact that normal modes of finite size chains (polyenes) correspond to polyacetylene phonons with small (but finite) q values. Due to the large frequency shifts observed, this would imply having very steep optical phonon branches (near $q = 0$) for the parent crystal. For this reason a change in some relevant force constant (a softening of the relevant force constant while increasing the chain length) has been

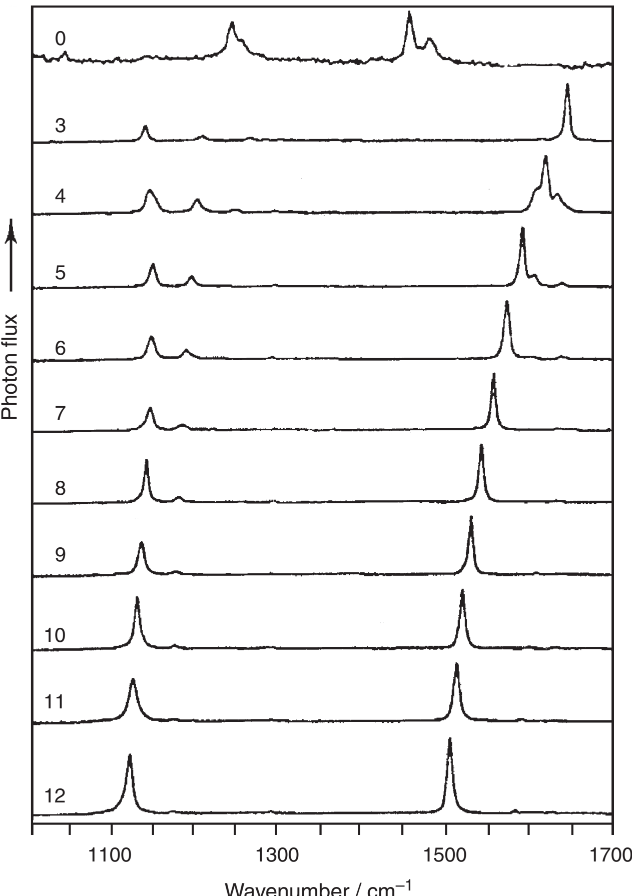

Figure 2. Raman spectra of t-butyl-capped polyenes $N = 3$–12 is the number of C=C bonds in the chain. $\lambda_{exc} = 647.1$ nm. The top spectrum is that of di (t-butyl) that is, $N = 0$ [18]. proposed [16, 17, 19] in order to explain the observed phenomena.

(ii) *Structural relaxation infinite size crystal domains*. In the case of polyenes mentioned above it is possible to follow the effect of the changes in the electronic structure (due to the presence of conjugated π electrons) with chain length or conjugation length, also considering the ground state nuclear geometries. Theoretical calculations [21] of polyenes of different and increasing size show that the degree of bond alternation (i.e., the value of the difference between the equilibrium bond length of adjacent CC bonds along the polyene chain) decreases as the chain length increases, as a consequence of the larger delocalization of the p_z electrons. According to this trend one would expect that in the infinite crystal (polyacetylene) a perfect equalization of the CC bonds should be reached, thus making polyacetylene, a metal. However, due to the Peierls instability [22, 23] in the 1D crystal, this does not happen and the parent crystal keeps a structure similar to that of the oligomers (polyenes) with a sequence of quasi-simple and quasi-double bonds. The dimerization parameter is determined by the strength of the Peierls instability.

However, structural relaxation infinite size domains can bring much more drastic effects. This can be realized, for instance, if one compares the equilibrium nuclear geometry of graphite with that of molecular graphites [24] (very large polycyclic aromatic hydrocarbons (PAHs) [25]) (see Fig. 4). In Section 5.5 the Raman behavior of these molecular materials will be described and compared with that of graphite. What is relevant for the present discussion is the fact that the ground state geometries of PAHs do not show the presence of equalized CC bonds, as happens in the case of graphite. Theoretical predictions [24] indicate that PAHs start to show an equalized structure (but only in the very inner region) only when a very large size (about 10 nm of diameter) is reached. PAHs can be grouped according to three different canonical structures (Fig. 5). All the PAHs experimentally available belong to the all-benzenoid family, where the bonds are arranged in aromatic rings (sextets of short CC bonds) linked each other by longer CC bonds. According to these findings it can be concluded that the parent crystal of molecular graphites is not an infinite graphite sheet (with all CC bonds of identical length, two C atoms per hexagonal unit cell), but a 2D crystal with a relaxed structure, whose unit cell contains six C atoms arranged according to the same topology as graphite, but showing CC bonds of two classes, with different equilibrium bond length (Fig. 6). This fact has very important implications in the discussion of normal modes of PAHs in terms of the phonons of graphite.

Indeed a superlattice (with a threefold cell) has to be introduced as a reference lattice for PAHs (seen as nanocrystals cut from an infinite graphene sheet). The definition of this superlattice, implies that phonon dispersion curves obtained for a 2D graphite must be looked at after a zone folding procedure, following the introduction of a new reciprocal lattice. In Figure 7 it can be seen that this procedure brings K points of the first Brillouin zone (BZ) of graphite to coincide with

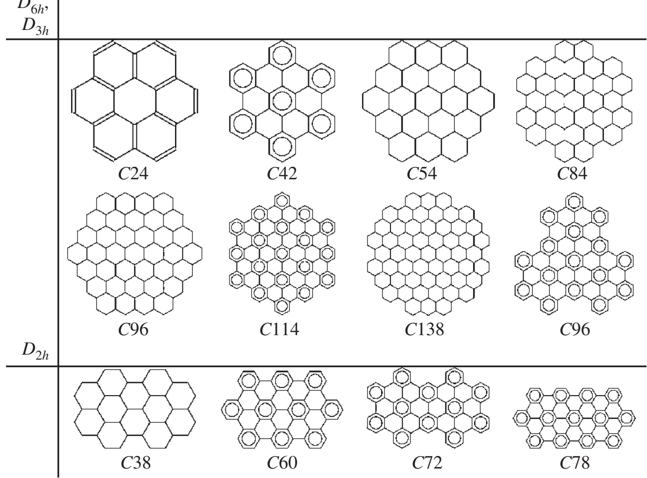

Figure 4. Structure of some PAH molecules. $C_{42}H_{18}$, $C_{114}H_{30}$, $C_{96}H_{30}$, $C_{60}H_{22}$, $C_{72}H_{26}$, and $C_{78}H_{26}$ are experimentally available thanks to the new synthetic route developed at Max Planck Institut of Mainz (D) [25].

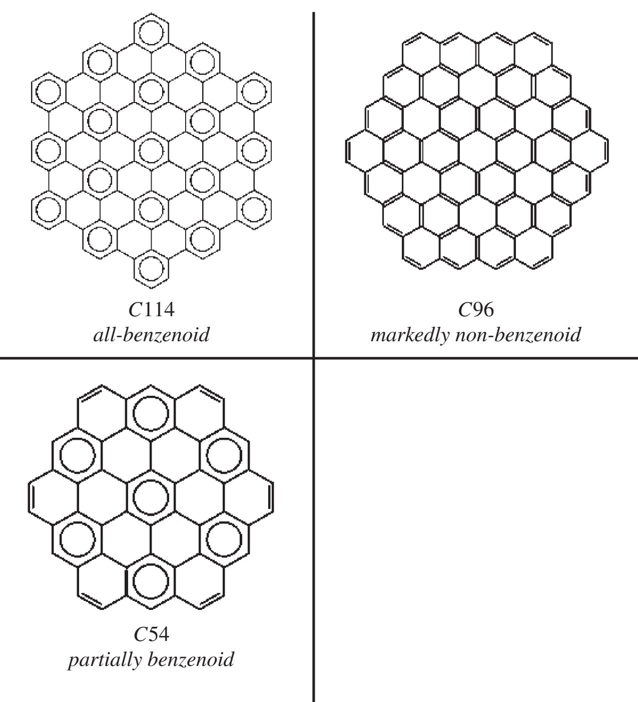

Figure 5. Schematic representation of the three classes of PAHs identified according to the ground state optimized geometry.

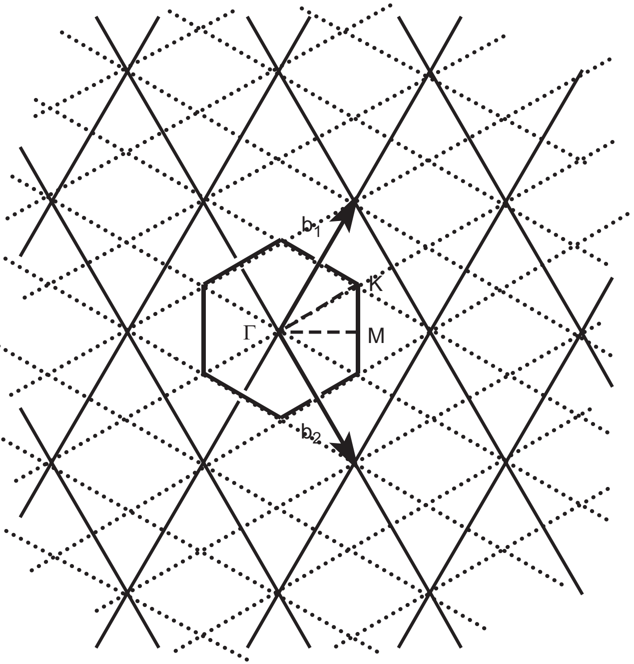

Figure 7. Reciprocal lattice of the supercrystal of Figure 6 (dotted lines). The reciprocal lattice and the first Brillouin zone of a perfect 2D lattice of graphite are shown (solid lines).

nodes ($\mathbf{q} = \mathbf{0}$ points) of the reciprocal lattice of the superlattice [26].

According to this finding we expect (see Section 5.5) that large molecular graphites show strong Raman transitions for those normal vibrations corresponding to graphite phonons with wave numbers $\mathbf{q} \approx \mathbf{0}$, where $\mathbf{q}$ is read according to the suitable reciprocal lattice (i.e., that of a threefold superlattice). As a consequence both phonons near Γ and near K points of the first BZ of graphite are predicted to be potentially active in the Raman spectrum.

This is what indeed happens in the case of large PAHs where two strong bands appear in the Raman spectrum which can be set in correspondence with the one Raman active optical phonon of 2D graphite at Γ point (the so-called G band) and to the totally symmetric phonon at K point (D band).

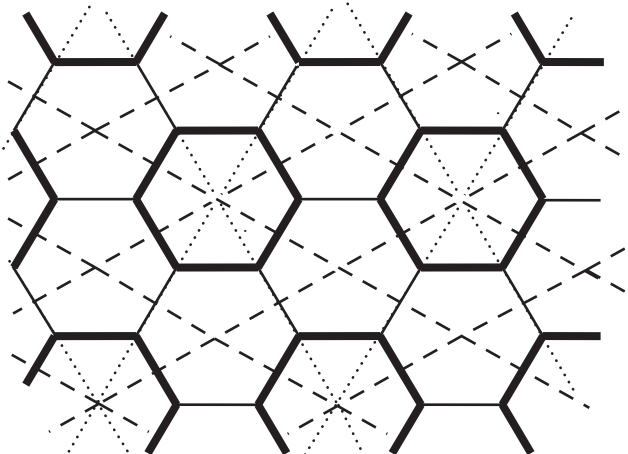

Figure 6. Perfect 2D graphite lattice (dashed lines) and superlattice (dotted lines) corresponding to the parent crystal of molecular graphites, showing an all-benzenoid structure.

The results obtained by the study of molecular graphite have been extrapolated to the case of disordered graphites and microcrystalline graphite in order to explain the activation of the D band in these materials [27] (see Section 5.5 for a discussion and comparison with different approaches).

The concept of zone folding is a quite general procedure which allows us to make use of the dynamics (and phonon dispersion curves) obtained for a given crystal structure in order to study systems characterized by different topologies and symmetries, but which are expected to keep the same (or a very similar) dynamic interactions (force constants) between atoms.

The frequencies of the active phonons of carbon nanotubes have indeed been predicted with success by this technique [109]. As expected, several ($q \neq \mathbf{0}$) points of the first BZ of a 2D graphite lattice are brought to coincide with Γ point, after zone folding is applied (Fig. 8). What is important is the fact that a given nanotube (characterized by a given diameter and a given chirality) requires the definition of its own superlattice: as a consequence the activation of different graphite phonons for nanotubes with a different structure can be predicted.

It can immediately be seen that this approach can be extremely useful for a structural diagnosis (in terms of tube diameters, chirality, and even distribution of these parameters) by Raman spectroscopy on nanotube samples (see Section 5.5 for a discussion).

Kataura, "Topics in Applied Physics, Vol. 8, Carbon Nanotubes: Synthesis, Structure, Properies and Applications" (2001). © 2001, Springer-Verlag.

(iii) *Resonance effects*. As mentioned in the Introduction the dispersion behavior of the Raman intensity with the energy of the exciting laser line is a very important phenomenon, most of all for low band gap materials.

From a formal point view and similarly to the case of phonons, for the description of electronic states in nanostructures the band theory (as developed for an infinite perfect crystal) is also no longer exact. However, one expects to find discrete energy levels (which merge in a continuum of states as the size of the crystal increases) which approximately lie on the dispersion electronic branches of the parent crystal. This allows us to make use of the known electronic structure of the parent crystal in order to discuss effects due to interactions between phonons and electronic excited states.

According to this idea it is possible to predict important effects observed in the Raman spectra of nanostructures, as the resonance enhancement of scattering from $\mathbf{q} \neq \mathbf{0}$ phonons activated by the confinement (see ii above).

As an example, we can quote the case of graphites: in order to explain the activation of the *D* line in microcrystalline and nanocrystalline graphites, Thompsen and Reich [104] proposed a very elegant treatment based on a double resonance effect responsible of the very strong activation of a specific $\mathbf{q} \neq \mathbf{0}$ phonon. In the Thompsen model the use of the electronic band structure of graphite is explicitly introduced.

Moreover, the lowering in the dimensionality in going from graphite to nanotubes gives rise to Van Hove singularities in the density of electronic states. The implication of this phenomenon is remarkable: the intensity behavior of the Raman spectrum of nanotubes as a function of the exciting laser cannot be explained without the introduction of the concept of resonance enhancement by interaction with electronic states corresponding to these singularities [109, 116].

(iv) *End or surface effects*. When one considers finite size crystals it is immediately realized that the lack of a perfect translational invariance does not consist only in the fact of having a finite number of cells: while approaching the crystal boundaries unit cells cannot be considered identical due to effects of the (near) surface. When this effect is strong (i.e., it is a long-range effect) a perturbation of the vibrational potential can take place in the whole nanocrystal and possibly also changes in the nuclear equilibrium structure.

However, in all the cases (both in the presence or in the absence of long-range interactions) atoms lying at the surfaces have to be considered defects which probe an environment different than that probed by the atoms which belong to the bulk.

The case of polymers is meaningful: in any linear chain, for chemical reasons, end groups are chemically and structurally different from those of the central units. For instance polyethylene (chemical formula $(CH_2)_n$) can end on either side by methyl (CH_3) groups or by vinyl groups ($CH{=}CH_2$). Vinyl groups are also the ends of polyenes and polyacetylene (chemical formula $(CH)_n$).

As a consequence of the presence of end defects in polymers we expect to find specific signals in the vibrational spectra: characteristic group frequencies corresponding to normal modes localized on end atoms can indeed be detected in the case of relatively short chains. These signals are easily detectable in the infrared (they are routinely used for an estimate of the average chain length in low-molecular-weight polymers); however, they can be detected via Raman scattering only when the ratio between the number of end and bulk groups is high.

It is indeed an usual finding that in the Raman spectra collective vibrations are intrinsically much more active than localized modes.

5. SPECIFIC NANOSTRUCTURES

5.1. C_{60}: The Bucky Ball

Since the discovery of the main (most stable) fullerene, the C_{60} molecule (or cluster), also called the buckminsterfullerene (or bucky ball) [30–34], the detection and the study of its vibrational fingerprints has attracted a great deal of interest both from the experimental and the theoretical point of view. Due to the large number of papers that have appeared in the literature, it is a difficult task to give, in a necessarily short paragraph, a comprehensive summary of the work done on this subject during the last 15 years. For this reason, the reader interested in an overview of all the relevant aspects is referred to some books and specifically to chapters dealing with the spectroscopy of fullerenes [35–37].

The following discussion has merely the aim of pointing out some of the most relevant aspects of the Raman spectrum of (C_{60}) and its interpretation.

C_{60} can be described (with respect to its spectroscopic behavior) as a nanoobject. In other words, it is really a

molecule and the concepts of molecular spectroscopy can be applied to the interpretation of its vibrational spectra with success.

The structure of an isolated C_{60} unit is that of a closed carbon cage (fullerene), with the point group symmetry of a regular truncated icosahedron. C atoms in the cage are bounded together in an highly symmetrical arrangement of pentagonal (12) and hexagonal (20) rings (Fig. 9). The C atoms belonging to pentagonal rings are connected by longer (single) bonds ($R_{CC} = 1.455$ Å) and C atoms shared by adjacent hexagons are connected by shorter (quasi-double) bonds ($R_{CC} = 1.391$ Å) [38].

According to I_h point group symmetry, the structure of the representation in the vibrational space of C_{60} is

$$\begin{aligned}\Gamma_{vib} &= \Gamma_{vib}^{Raman} + \Gamma_{vib}^{infrared} + \Gamma_{vib}^{inactive}\\ \Gamma_{vib}^{Raman} &= 2A_g + 8H_g\\ \Gamma_{vib}^{infrared} &= 4F_{1u}\\ \Gamma_{vib}^{inactive} &= 3F_{1g} + 4F_{2g} + 6G_g + A_u + 5F_{2u} + 6G_u + 7H_{2u}\end{aligned} \tag{24}$$

According to this description we can immediately make some observations.

1. The very high symmetry of the molecule implies that the vibrational transitions which can be detected in vibrational spectra are few with respect to the number of degrees of freedom of the molecule. The vibrational degrees of freedom of an isolated C_{60} are 174, but they correspond to 46 different frequencies, due to the high degeneracy of some symmetry species (e.g., modes of H species have a degeneracy of 5). Moreover, among these 46 frequencies, only 4 are active with respect to infrared absorption and 10 are Raman active. On this basis we expect to obtain relatively simple Raman and infrared spectra from samples of C_{60}.
2. Another consequence of the high symmetry of the molecule is the fact that all normal modes of C_{60} involve the molecule as a whole (all C atoms are displaced during each normal mode). By virtue of this fact we expect that frequencies are strongly sensitive to the characteristic structure of C_{60} (on the whole): in this sense vibrational spectra are expected to behave as is usual in molecular vibrational spectroscopy as fingerprints of that specific molecule, with that specific structure.

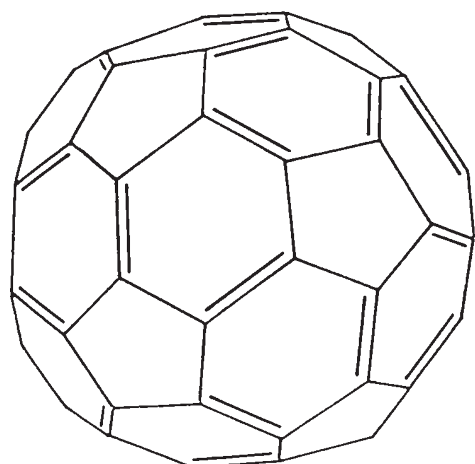

Figure 9. Sketch of the structure of buckminsterfullerene, C_{60}.

One of the first Raman experiments on purified C_{60} have been reported by Bethune et al. [39]. Spectra (see Fig. 10) have been taken by a micro-Raman from a C_{60} film deposited on a suprasil slide by a C_{60} solution.

According to these spectra the 10 Raman active fundamental transitions of C_{60} were clearly identified. Among these, the strongest lines at 1470 and 496 cm^{-1} have been assigned to the two A_g modes, according to their behavior in polarized Raman spectra.

In the same paper [39] vibrational spectra of C_{70} (the other abundant fullerene) are reported. In the case of C_{70}, due to the lower symmetry of the molecule, infrared and Raman spectra show a drastic increase in the number of observed frequencies. No coincidences of the frequencies of the main lines are found with observed frequency values of C_{60}. These last observations strongly support statements 1 and 2 above. On the other hand they make clear that Raman and infrared spectra of C_{60} provide evidence that C_{60}

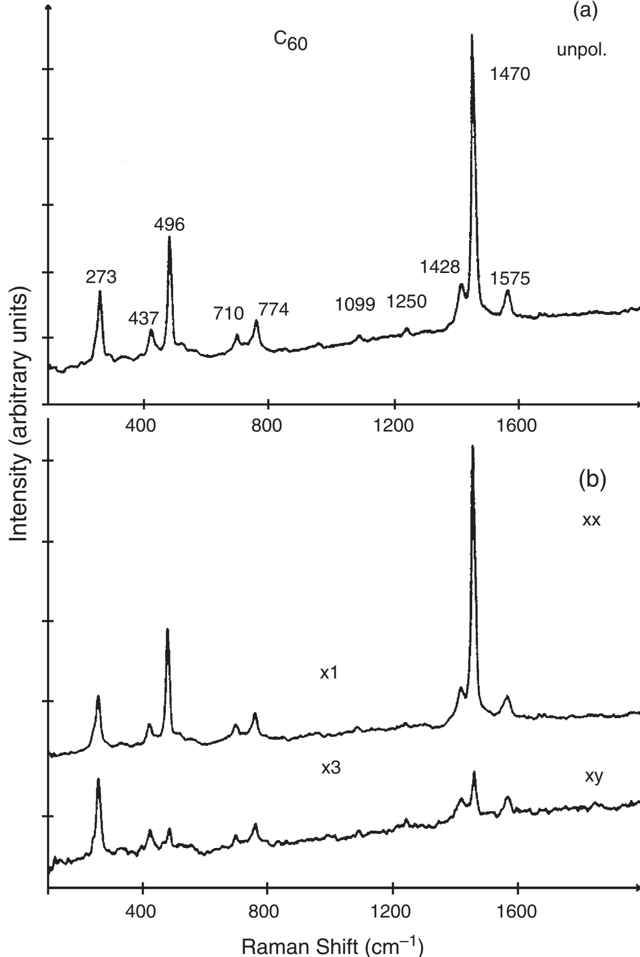

Figure 10. Raman spectra of a film of purified C_{60} on a suprasil substrate. (a) Unpolarized; (b) polarized. Reprinted with permission from [39], D. S. Bethune et al., *Chem. Phys. Lett.* 179, 181 (1991). © 1991,

belongs to the I_h symmetry group and that vibrational spectra can be safely used for the detection of C_{60} in unknown samples.

The identification and the vibrational assignment of C_{60} transitions proposed by Bethune et al. [39] were supported by theoretical predictions obtained by Stanton and Newton [40]. Theirs is only one of the many papers that has appeared in the literature dealing with the theoretical prediction of vibrational frequencies of C_{60}. In the more recent calculations, the accuracy of the results has been raised in such a way that the discrepancies found between computed and experimental frequencies are of the order of few wave numbers.

According to our opinion, two points have to be stressed regarding the development of theoretical models for the study of C_{60} vibrational dynamics.

(i) The possibility of obtaining reliable results is strongly influenced by the level of the theory used (which in turns depends on the available computational resources). In a recent paper by Schettino et al. [41]. DFT calculations using B3-LYP exchange and correlation functional and a large (6–31G*) basis set have been performed, thus reproducing the experimental frequencies of C_{60} with very good accuracy, with a single scaling factor (0.98) on the calculated frequencies. On the other hand, semiempirical methods based on suitable Hamiltonians have been shown to give excellent results. The use of an updated QCFF/PI Hamiltonian developed by Negri and Orlandi [42] made if possible to obtain an accuracy very close to that already reached by first principle calculations, at a fraction of the computational cost.

(ii) The choice of the best theoretical models and the critical comparison of the different approaches is based on the availability of as many experimental data as possible. In this respect the case of fullerene presents the problem that few vibrational frequencies give observable transitions. The problem of obtaining information about silent frequencies has been partially solved with the help of neutron scattering [33] data and partially making use of accurate data from C_{60} crystals and chemically substituted C_{60}.

As suggested at point ii, the difficulty arising from the lack of information about the frequencies of the inactive transitions can be overcame by some suitable molecule modification which lowers the symmetry of the molecule itself. A technique widely used in molecular spectroscopy is (asymmetric) chemical substitution with isotopes.

In the case of C_{60} nature itself provides a way to observe a C_{60} molecule with a lowered molecular symmetry. This happens when C_{60} molecules pack together into a fullerite crystal. I_h symmetry is not compatible with any crystal space group: in its low-temperature crystalline phase C_{60} forms a closely packed f.c.c. lattice with T_d symmetry.

As mentioned in Section 3, however, the interactions between pairs of C_{60} molecules in the crystal are weak: as a consequence the intramolecular vibrations are expected and found to be very weakly perturbed by such interactions and the Raman and infrared spectra of fullerite show a pattern which can be interpreted on the basis of the vibrations (and symmetry) of the single isolated molecule. On the other hand, the symmetry lowering of the molecular surrounding in the crystal causes (at least in principle) a breakdown of the Raman (or infrared) selection rules: weak transitions, corresponding to the silent frequencies of the isolated species, have been detected. Data from vibrational spectra of fullerite have been used by Schettino et al. [41] and Negri and Orlandi [42] for comparison with the predicted results.

According to these last observations, we can conclude that when the nanostructured materials (e.g., fullerite) are made by weakly interacting nanoobjects characterized by high symmetry, we can obtain from the Raman spectrum information essentially related to the molecular nature of the object (namely, its shape, symmetry, and intramolecular potential). On the contrary, relatively little information can be derived about the superstructure (molecular arrangement and interactions). On this subject we refer the reader to Eklund et al. [36] where a thorough discussion of optical phonon modes and their symmetry classifications in solid (fullerite) and doped C_{60} is presented.

5.2. 3D Nanocrystalline Materials

We have seen that the differential cross section for spontaneous light scattering $d^2\sigma/d\Omega d\omega_s$ is proportional to the dynamic structure factor $S_{E^S}(\mathbf{Q}, \omega)$. We now follow Nemanich et al. [43] and assume that in the presence of confinement effects also the susceptibility fluctuations are related to the phonon displacements $u(\mathbf{r}, t)$ to linear order by

$$\delta\chi_{ij} = A_{ij}u(\mathbf{r}, t) \tag{25}$$

In this way $S(\mathbf{Q}, \omega)$ (we drop the index E_S) becomes directly proportional to a phonon displacement autocorrelation function (see Eq. (23)).

In the case of nanocrystalline materials characterized by dimensions of particles or domains comparable with phonon wavelength, the description of the elementary excitations with (modulated) plane waves (Bloch waves) is no more justified. A wave packet whose spatial dimension is comparable to the crystallite size must be used: this introduces a spread or uncertainty in wave vectors. This uncertainty will be larger for smaller domain sizes because the wave packet becomes more localized in real space. Since the phonon dispersion curves are in general not flat, new frequencies will be introduced in the Raman spectra when contributions from phonons with wave vectors $\mathbf{q}$ significantly different from 0 start to play a role [44].

In general, assuming that the size reduction does not modify the phonon dispersion curves of the periodic reference system (parent crystal) and does not change the other Raman selection rules, Raman lines, now resulting from both $\mathbf{q} = \mathbf{0}$ and $\mathbf{q} \neq \mathbf{0}$ individual contributions, will exhibit an overall shift and asymmetrically broaden, the nature of the changes and the critical size where these changes take place depending on the dispersion curve of the material and on the intrinsic phonon lifetimes.

We can assume that phonons of the same branch of different **q** in small crystallites have a correlation function as in a perfect infinite crystal given by

$$\langle u^*(\mathbf{r}, t)u(\mathbf{r}', 0)\rangle_{th} = \frac{1}{V}\sum_{\mathbf{q}}\langle u^*(\mathbf{q})u(\mathbf{q})\rangle_{th} e^{[i\mathbf{q}\cdot(\mathbf{r}-\mathbf{r}')+i\omega(\mathbf{q})t]} \tag{26}$$

where $\omega(\mathbf{q})$ are the intrinsic phonon dispersion curves. Thus [43] $S(\mathbf{Q}, \omega,)$ can be written as

$$S(\mathbf{Q}, \omega,) = \left(\frac{N}{V^2}\right)\frac{1}{V}\sum_{\mathbf{q}}|A_{ij}(\mathbf{q})|^2\delta(\omega-\omega(\mathbf{q}))\langle u^*(\mathbf{q})u(\mathbf{q})\rangle \times |F(\mathbf{Q}-\mathbf{q})|^2 \tag{27}$$

where N is the number of crystallites in the volume V and F is a integral restricted to a single crystallite:

$$F(\mathbf{Q}-\mathbf{q}) = \int e^{i(\mathbf{Q}-\mathbf{q})\cdot\mathbf{r}}\, d\mathbf{r} \tag{28}$$

then $S(\mathbf{Q}, \omega,)$ can be written as

$$\frac{N}{V^2}\left(\frac{n(\omega)+1}{\omega}\right)\frac{1}{V}\sum_{\mathbf{q}}C(\mathbf{q}, \omega)|F(\mathbf{Q}-\mathbf{q})|^2 \times \frac{\Gamma_{1/2}/4\pi}{[\omega-\omega(\mathbf{q})]^2+(\Gamma_{1/2}^2/4)} \tag{29}$$

where all coefficients are grouped in a single collective matrix element $C(\mathbf{q}, \omega)$, the boson occupation numbers have been introduced and a phonon lifetime has been included as a Lorentzian broadening $\Gamma_{1/2}$.

For a large crystal $F(\mathbf{Q}-\mathbf{q})$ becomes a delta function and the spectrum becomes, in general, a sum (over active phonon branches at Γ) of weighted Lorentzians; on the other extreme, for very small structures, the system can be considered amorphous and the whole phonon density of states becomes visible: the spatial integration will be limited to the local atomic environment and all the excitations can contribute to the scattering.

In the intermediate case, where crystallites of a few nanometers in diameter must be considered, the choice of $F(\mathbf{Q}-\mathbf{q})$ should be based on physical considerations to motivate a specific phonon confinement function.

For example, Nemanich and co-workers [43] have considered a confinement function for boron nitride microcrystals of the form

$$F(\mathbf{Q}-\mathbf{q}) = \prod_{i=x,y,z} 2\sin[(q_i-Q_i)L_i/2]/(q_i-Q_i) \tag{30}$$

Due to size distribution, this function should be more appropriately replaced with a Gaussian function. In reality a direct connection between the confinement function and the microscopic structure of the crystallites is not straightforward. Numerical fits of the experimental results are used to find the best confinement function. With this information the mean size of the crystallites can be extracted; however, this quantity can be exactly determined only for a single size ensemble of particles or if the size distribution and the phonon dispersion curves are known exactly.

5.3. Semiconductor Nanoparticles

Group-IV-based structures, consisting of Ge and Si nanocrystals embedded in matrices or free standing, exhibit visible photoluminescence that is sensitively dependent upon the particle size and size distributions. Despite considerable efforts having been concentrated on the characterization of these nanocrystalline systems and on their electronic structures, many aspects remain to be clarified. The confinement of elementary excitations in semiconductor nanocrystals has a strong influence on photoluminescence behavior and more generally on linear and nonlinear optical properties. For an unambiguous characterization of the role played by structure and dimensions in determining the quantum confinement effects, it is necessary to prepare well-characterized nanostructures and to be able to follow their evolution along the different steps of the synthetic routes.

Raman scattering is particularly suitable for the characterization of semiconductor low-dimensional systems: it is nondestructive, it can be applied to systems embedded in transparent matrices, and it can also be used for *in-situ* measurements with a lateral resolution of 1 μm. As we have already discussed, in many instances, a theory has been developed that successfully explains the observed spectra in terms of the structural properties of the particles. The effect of confinement on the phonon density of states can be quantitatively related to the size and distribution of the particles, making Raman scattering a powerful tool for the characterization of assemblies of semiconductor nanoparticles. Despite its potentiality a word of caution is in order concerning the different factors affecting the phonon density of states and hence the Raman spectra. As we discuss in more detail in the following, the interaction of the particles with the host matrix, the oxidation of the surface, the coexistence of different amorphous and crystalline phases in the same particle, and the size distribution of the particles can affect the Raman response. It is then difficult to disentangle the different contributions to the modification of the phonon density of states of a reference crystalline bulk system and to what extent confinement effects are the only responsible cause of the observed spectra features. This implies that an independent determination of the size distribution and of the structure of the particle and of their degree of crystallinity is highly desirable for a correct interpretation of the Raman spectra and an identification of the confinement effects.

5.3.1. Germanium Nanoparticles

Ge nanostructures embedded in different matrices have been extensively studied by Raman spectroscopy. A wide variety of techniques have been used to produce Ge nanocrystals, including gas evaporation [45, 46], rf magnetron sputtering [47–49, 238, 50], chemical vapor deposition [51], chemical reduction of metastable $Si_{1-x}Ge_xO_2$ [52–55], molecular and cluster beam deposition [56–58], oxide reduction in zeolite [59], inorganic solution phase synthetic routes [60] and ion implantation and annealing [61]. These techniques have to meet several requirements for the production of samples which can be unambiguously characterized: (i) Production of single sized particles or assemblies

of particles with a well-defined size distribution and (ii) control of the crystalline state of the particles and of their interaction with the embedding matrices.

The production of Ge nanocrystals embedded in a matrix such as SiO_2 is obtained by chemical reduction, precipitation, and annealing of the $Si_xGe_yO_z$ phase [52–55]. The influence of the host matrix on the structure of the embedded clusters is still an open question. The crystalline structure, the coexistence of amorphous and crystalline phases, and the nature of the interfaces are very difficult to characterize over macroscopic regions of the sample. X-ray scattering, TEM, and HRTEM analysis are usually employed for the determination of size distribution and for checking the crystalline structure of nanoparticles [46, 62]. In principle, with these techniques information about the structure and dimension of a particle can be achieved independently; however, an extrapolation over the entire sample is not always straightforward.

Raman scattering has been used as a diagnostic tool for the determination of size distribution; however, since Raman spectra are expected to be quite sensitive not only to quantum confinement, but also to disorder, strain, or in general to interface peculiarities and structural characteristics of the system, it is mandatory to have an independent way to characterize the crystalline nature of the particles and their size distribution. On the other hand the same problem is encountered in the study of the confinement effects themselves, since the size distribution and the interaction with the matrix can introduce effects which render the interpretation of the spectra in terms of confinement very difficult [46].

For bulk crystalline Ge, the Raman spectrum can be assigned to the $\mathbf{q} \simeq 0$, Γ_{25}^{+} optic phonon exhibiting a Lorentzian line at 300 cm^{-1} with an intrinsic width of $\approx$3 cm^{-1} [14, 57]. The $\mathbf{q} \simeq 0$ selection rule is a consequence of the full translational symmetry of a crystalline sample. In the presence of phonon confinement in the nanoparticles, the Raman intensity can be written as a superposition of Lorentzians centered at $\omega = \omega(\mathbf{q})$. This produces a symmetric broadening and red shift of the Raman line. In particular the red shift is caused by the fact the in germanium ω is a decreasing function of $|\mathbf{q}|$. Since it is very difficult to produce samples characterized by identical particles, the size distribution of the particles must be taken into account. This introduces a further asymmetry in the line which can be described by

$$I(\omega) \propto \int_0^\infty \rho(R) R^3 \, dR \int_0^1 \exp\left(-\frac{q^2 R^2}{4}\right) \times \frac{\Gamma/2\pi}{[\omega - \omega(q)]^2 + (\Gamma/2)^2} d^3 q \tag{31}$$

where the size distribution $\rho(R)$ should be measured independently [46].

Different authors used Raman spectroscopy to characterize the Ge particles in SiO_x matrices and to follow the change in size distribution due to thermal annealing. Kobayashi and co-workers produced an SiO_2/ncGe/SiO_2 structure [55] by depositing a Ge layer on a SiO_2 film and annealing it at a temperature between 1100 and 1300 K for 1 h in a dry O_2 ambient. Due to rapid diffusion of oxygen molecules through the Ge grain boundaries, the Ge become crystallized and embedded in the SiO_2 during high-temperature oxidation. Raman spectroscopy has been used to determine the size of Ge nanocrystals as a function of the annealing temperature. The Raman spectrum of the as-deposited amorphous Ge is characterized by a broad shoulder peaked around 270 cm^{-1}. The annealing, inducing a crystallization of the amorphous phase, causes the appearance of the phonon peak at 300 cm^{-1} and the disappearance of the shoulder. The asymmetric peak obtained at 1300 K has been fitted to obtain the average size of the particles.

Paine and co-workers performed Raman spectroscopy on $S_{1-x}Ge_x$ alloys oxidized and annealed under various conditions to promote the formation of Ge nanoparticles [52]. This work indicates that larger average particle size can be obtained with longer annealing times and higher temperatures. It should be remarked that no frequency shift of the Raman peak is observed contrary to the prediction of the theory. Samples deposited by rf sputtering in a glassy SiO_2 matrix and subsequently annealed showed a similar behavior, with, however, a shift of the peak position [238].

A systematic study of the growth of Ge nanocrystals in SiO_2 matrices by Raman spectroscopy and electron microscopy has been performed by Fuji and co-workers [48]. Rf cosputtering and annealing were employed to produce Ge nanoparticles. The dependence of the Raman spectra upon annealing temperature is similar to that of Kobayashi et al. [55], showing a crystallization for temperature higher than 900 K. The size distribution of Ge nanocrystals has been determined by HRTEM analysis and used to calculate the Raman spectra following the phonon confinement relation. They have found a qualitative agreement; however, the peak frequencies of experimental spectra are much lower than the calculated ones and no shift of the Raman peak is observed.

The discrepancies in the Raman shifts in apparently similar samples are difficult to account for. A possible explanation is the deviation of the lattice constant from the bulk value caused by cluster surface–matrix interaction. Fortner and co-workers have demonstrated the influence of the near-surface dangling bonds and of the bond–angle disorder on the phonon density of states [49].

Besides the particle–matrix interaction, several other factors can affect Raman response: Fujii and co-workers have suggested that the presence of compressive stress exerted by the matrix on the clusters can compensate for the downward shift of the Raman peak. However, no direct evidence for the existence of the stress has so far been provided. The coexistence of amorphous and crystalline phases in the same particle can also induce a departure of the Raman behavior from that predicted by a too naive theory taking only confinement into account. The effects of size distribution should also be taken into account explicitly. As already discussed the width of the Raman peak is determined from both homogeneous broadening caused by the phonon confinement and inhomogeneous broadening caused by size distribution. A strong size dependence of the peak frequency should indicate that the inhomogeneous broadening is nonnegligible.

In order to minimize the interaction of particles with host matrices, free particles can be grown from gas phase and in colloidal suspension [45, 60]. Hayash et al. [45] produced

oxidized germanium microcrystals by gas condensation and characterized by TEM and electron diffraction. Very small clusters show Raman spectra and electron diffraction typical of amorphous systems; a transition to crystalline structure is observed for relatively large sizes. The effect of surface should play an important role in determining the vibrational spectra.

In the case of colloidal suspensions of Ge nanocrystals, Raman spectra showed broadened bulk Ge features with virtually no dependence of the peak position on the particle dimensions. In order to reconcile the prediction of the phonon confinement model with TEM observations, Heath et al. [60] used a bulk homogeneous line width of the bulk peak of ≈1.85 cm^{-1} and proposed a very small amount of lattice contraction as the origin for the absence of frequency shift.

Raman spectroscopy of germanium nanoparticles has been performed in conjuction with TEM characterization and optical absorption measurements [46]. The samples were grown by an evaporation–condensation self-organization technique that allows obtaining particles with a truncated sphere shape, a size dispersion of $\sigma/R \le 20\%$ (R is the average radius), and with the possibility, in addition, of controlling their average radii in a range from about 1 up to 10 nm [186]. Samples are prepared by deposition of Ge vapor on amorphous Al_2O_3 substrates. The partially wetting character of the substrate and the high-temperature deposition allow the formation of particles with regular sizes and the minimization of interaction with the matrix and reduction of stresses.

The particle size distribution $\rho(R)$ has been obtained by TEM analysis and could be introduced to fit the Raman spectra. A deviation from the theory has been observed for the lowest size values. This can be due to a strong influence of the surface (dangling bonds and bond angle disorder [48, 49]); instrumental correction of TEM observations, needed to obtain the size distribution, tends to underestimate the percentage of larger particles with a high Raman cross section in favor of the more numerous smaller particles with a low cross section.

The relevance of confinement effects in the observed Raman spectra is confirmed by optical spectra which show a good crystallinity of particles, suggesting that matrix effects can be neglected. The coupling of different techniques allows us to distinguish different contributions affecting the vibrational spectra of small particles [46].

5.3.2. Silicon Nanoparticles

Technological interest has stimulated the study of silicon micro- and nanocrystals showing electronic and vibrational confinement [44, 63, 64]. More recently, a renewed interest has been motivated by the characterization of porous silicon, which promoted the use of Raman scattering as a technique for the determination of the size distribution of nanoparticles considered as building blocks of porous mesostructures.

Raman spectroscopy has been also used to characterize different silicon-based systems showing different degrees of order and crystallinity and ranging from amorphous silicon to polycrystalline and microcrystalline silicon obtained by laser annealing or ion implantation [44]. The Raman spectrum of crystalline silicon is characterized by a Γ_{25}^{+} optical phonon at 521 cm^{-1} with a natural width of ≈3.5 cm^{-1} [67]; in amorphous silicon the $\mathbf{q} \simeq 0$ selection rule does not apply and the Raman spectrum resembles the phonon density of states with a broad bump centered around 480 cm^{-1}. Samples characterized by incomplete or incipient crystallization show a Raman spectrum which is somehow intermediate between the two extreme cases. A broadening and red shift of the 521-cm^{-1} peak is observed together with the appearance of a broad feature around 480 cm^{-1} [63].

Microcrystalline silicon films, characterized by grain size of the order of a few tens of nanometers, show similar behavior, with the line shape and red shift of the 521-cm^{-1} line depending on the crystallite size.

Several authors interpreted the observed features in terms of a relaxation of the $\mathbf{q} \simeq 0$ vector selection rule and of the presence of confinement effects [44, 63, 64]. As in the case of germanium many experiments have shown that for microcrystalline samples a broadening and a red shift of the 521-cm^{-1} Raman peak is observed and those features that depend on the crystalline domain dimensions. Fauchet and Campbell [44] showed that phonon confinement theory can successfully be used to explain the Raman spectra of small silicon crystals and their dependence on crystalline size and shape. Considering spherical microcrystallites, Campbell and Fauchet have investigated the influence of the choice of the confinement factor $W(\mathbf{r}, L)$, the anti-Fourier transform of a generalization of the $F(\mathbf{Q})$ factor in Eq. (30) $W(\mathbf{r}, L) = F^{-1}\{F(\mathbf{Q})\}$ on the quality of the fit between theory and experiments. They have considered three types of functions:

$$W(\mathbf{r}, L) = \frac{\sin(2\pi r/L)}{2\pi r/L} \tag{32}$$

$$W(\mathbf{r}, L) = \exp(-4\pi^2 r/L) \tag{33}$$

$$W(\mathbf{r}, L) = \exp(-8\pi^2 r^2/L^2) \tag{34}$$

The first confinement function was chosen in analogy with the ground state of an electron confined to a hard sphere, the phonon amplitude being 0 at the boundary. Equation (33) can be written as $\exp(-\alpha r)$ and it has been chosen in analogy with a wave in a absorbing medium. Equation (34) can be written as $\exp(-\alpha r^2/L^2)$ (in agreement with [43, 63]). Equation (34) is found to lead to a good agreement with the experiments when the phonon is confined very strongly to the microcrystal. On this basis Raman spectroscopy can be applied for the characterization of silicon nanocrystalline systems.

A detailed study of silicon microcrystallites has been reported by Iqbal and Vepřek [64]. Microcrystalline silicon films have been prepared by chemical transport in a DC hydrogen plasma at low pressure; by varying the substrate temperature the dimensions of the crystalline domains have been varied. A shift and broadening of the Γ_{25}^{+} phonon peak together with the appearance of a second broad component around 480 cm^{-1} is observed. This component could be correlated with the feature observed in amorphous silicon. The origin of the amorphouslike feature has been related to a surfacelike mode involving Si–Si shearing motion of the Si surface groups [64]. Hayashi and Yamamoto [241] reported amorphouslike Raman spectra for silicon clusters smaller than 100 Å, in contrast with TEM measurements showing

that very small clusters present a crystalline structure. These discrepancies were tentatively attributed to surface effects: the amorphous contribution should be due to the outer disordered shell of the clusters surrounding a crystalline core.

It is known that below a crystallite size of ~3 nm silicon becomes thermodynamically unstable with respect to the amorphous phase [64]; it is thus reasonable to expect that when very small clusters are present they can contribute to the onset of the amorphouslike Raman spectrum. A size distribution extending toward small sizes may account for the observed features without invoking the presence of high-energy surface modes. An independent determination of the size distribution would improve the understanding of the different contributions to Raman spectra.

Raman scattering has been used to characterize SiO_2 films with embedded Si mesoscopic particles [241], very small clusters with diameters ranging from 10 to 1 nm have been produced by cosputtering and postannealing, as observed in germanium. The dimensions of the particles did not allow the use of TEM to determine in an independent way the size distribution. This prevented a quantitative determination of the size and of the structure of the clusters.

5.4. Nanomaterials in One Dimension: The World of Relevant Nanosized Molecular Sticks

A large class of organic chain molecules occurring in nature, or synthesized in the laboratory, develops anisotropic and directional interactions along the molecular backbone yielding systems whose equilibrium structure consists of long straight chains with a remarkable structural rigidity. On the whole, the intramolecular forces are larger than those which glue them together in the supramolecular clusters, which may reach, sometimes, a tridimensional crystalline order. Such world of one-dimensional nanosized objects cannot be neglected, especially since vibrational spectroscopy in general and Raman spectra in particular provide a tool for the understanding of their structural and dynamic properties which are directly connected with their extremely relevant functions in nature or in material science in general. As will be shown, phonon confinement does take place in these one-dimensional molecular sticks and can be nicely and relatively easily revealed by Raman spectroscopy, which becomes a unique probe of the structure and dynamics of these systems.

The world of chain molecules is very wide and includes (i) natural and synthetic linear polymers which need to be considered in this review since they are able to self-organize in crystalline lamellae with nanoscale thickness (Fig. 11 [65]) and (ii) long linear molecules which again self-organize in mesoscopic or crystalline lamellae [65]. The physics of the lamellar organization of such molecular nanosticks is still matter for extensive studies to which Raman scattering and other techniques (which probe their vibrational motions through infrared spectroscopy, inelastic neutron scattering, etc.) can substantially contribute.

A prototypical case of lamellar organization is that encountered when the process of self-organization of very long polymer chains takes place with the folding of the polymer chain into shorter segments (with lengths between 5 and 25 nm) and their tridimensional packing, which yields a large lamella (Fig. 11) (for a thorough discussion see Wunderlich [65]). The stacking of these lamellae, more or less free or bound to each other through tie molecules, is the basis for further self-assembling into various kinds of morphological architectures (Fig. 12) which determine the physicomechanical properties of any polymeric material. The important

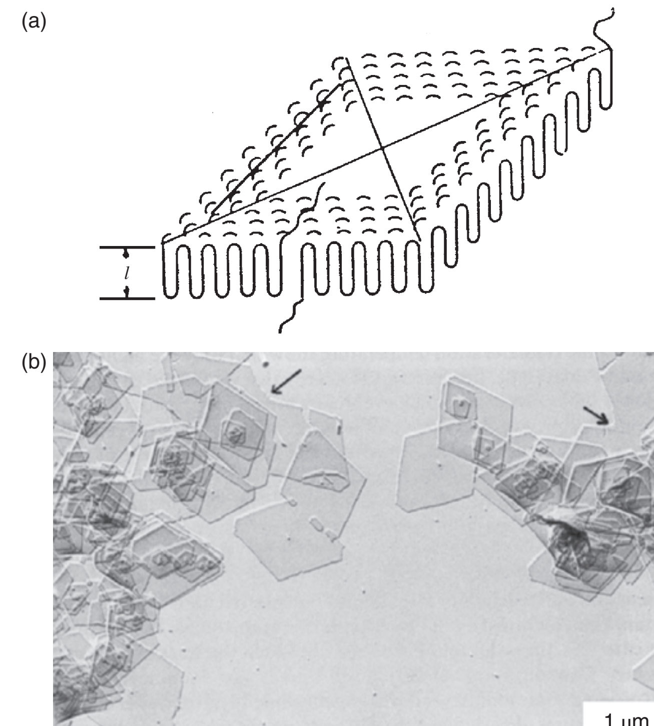

Figure 11. (a) Sketch of a polyethylene lamellar crystal the vertical lines represent segments of the molecular chains which fold at the surface. (b) Trasmission electron micrograph of single crystals (lamellae) of polyethylene, cystallized from a diluite solution.

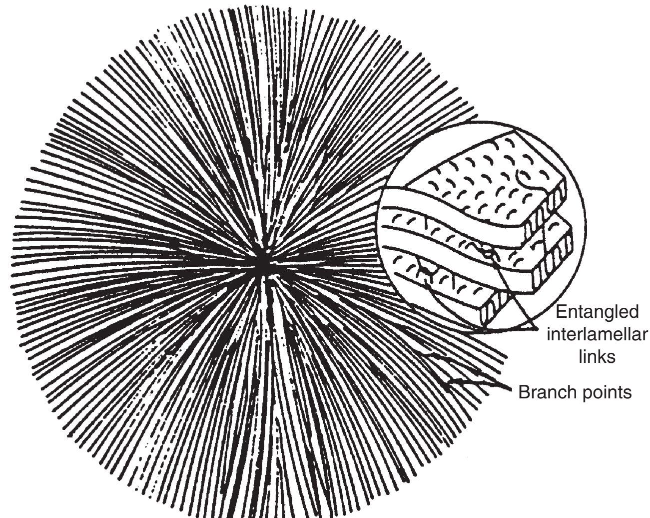

Figure 12. Polymer spherulite (grown from the melt). In the magnified section a stack of lamellae is shown.

concept in the physics of the organized soft matter consisting of regular polymer chains is the ubiquitous lamellar self-organization of molecules. The length of the segments, their topological distribution throughout the lamella (reached by suitable chain reentry as a consequence of some energetically plausible process of chain folding (see Fig. 11), and their local and/or collective mobility need to be precisely known).

The main concept underlying the treatment of the vibrational dynamics of segmented polymer chains is that the folding decouples the vibrations of each segment, thus allowing spectroscopic analysis of each segment as an isolated entity. The atoms forming the fold do perform their peculiar and characteristic vibrations (defect modes) which are fully localized in the fold itself [66] and need not considered or discussed in this review.

A second nonnegligible case of lamellar organization is found in nature when finite chain molecules of nanometric length self-organize in mesoscopic or crystalline lamellae, some of which are able to perform functions essential in the life of living organisms. The simplest case is the lamellar organization of the molecules of *n*-hydrocarbons with the general formula $CH_3{-}(CH_2)_n{-}CH_3$. In systems where the stacking of the lamellae has taken place small angle X-ray scattering experiments indicate the existence of long-range periodicities. When interchain packing is perfect wide angle scattering indicates short-range crystalline order inside the lamella, while the surface of the lamella may be ordered and/or disordered depending on the (temperature-dependent) molecular mobility of the chain. From spectroscopy [67, 68], STM experiments [69, 70], and numerical simulations by molecular mechanics [71] it has been shown that on the molecular scale the process of melting of such systems starts first with the generation of a surface disorder (surface melting) which proceeds into the lamella until the binding interchain forces of the ordered lamella have to yield to the incoming geometrical disorder (Fig. 13 [67]).

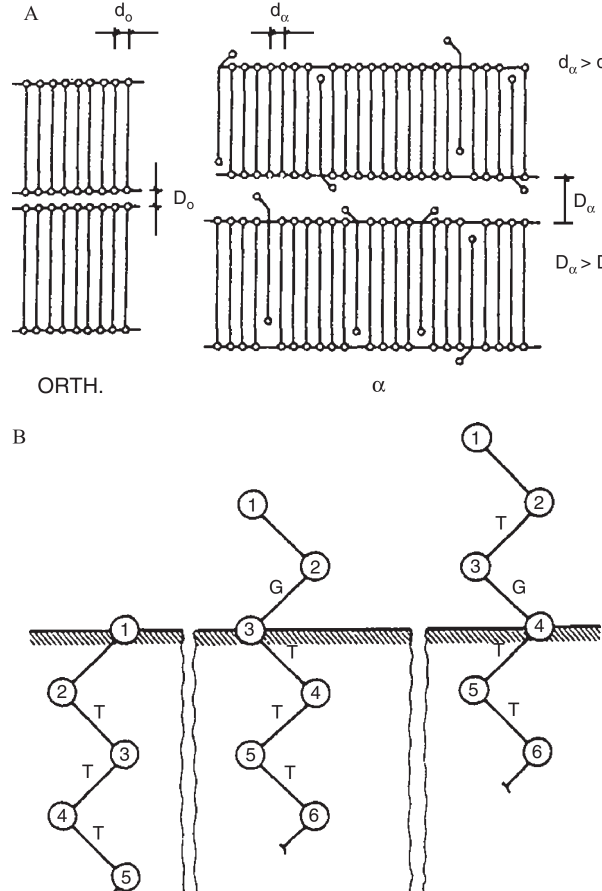

Figure 13. Sketch of the mechanism of phase transition of *n*-dodecane. (A) Schematic overall view; (B) detail on a molecular level.

The problem of order/disorder in conformationally flexible molecules self-organized into nanosized lamellae is basic in biological systems which perform essential functions in living organisms. First is the case of the intermolecular lamellar organization of long chain fatty acids or alcohols with the general formula $CH_3{-}(CH_2)_n{-}X$, where $X = -COOH$ or $-CH_2OH$. These molecules can also double their length because they can form dimers through the hydrogen bonding of the carboxylic or hydroxylic heads (e.g., $CH_3{-}(CH_2)_n{-}COOH \cdots HOOC{-}(CH_2)_n{-}CH_3$, Fig. 14).

If these kinds of molecules are tied as esters to phosphoric acids and derivatives the class of phospholipids is generated; such systems are universally found in all living cells and play a role essential in life, thanks to their hydrophilic or hydrophobic properties. The thickness of the membrane, the relative concentrations of straight sticks vs disordered matter (with a well-defined geometry) as function of temperature, ionic strength, attack by an external agent (e.g., a molecule of antibiotics), etc., are basic questions which can be answered by Raman spectroscopy studies of the phonons confined in such nanosized one-dimensional systems organized as lamellae (Fig. 15, [72]).

The list of other cases of nanosticks of relevance in the basic and applied science of nanomaterials could become longer (Langmuir–Blodgett films, monomolecular films deposited onto metallic surfaces relevant in microelectronics, soaps, lubricants, detergents), thus showing the relevance of the physics of nanosized soft matter at the molecular level studied through vibrational Raman spectroscopy.

In this chapter we will summarize the background concepts which may be applied and generalized to many other cases.

Let us first consider the phonon dispersion curves of a linear chain of polyethylene in its perfect conformational

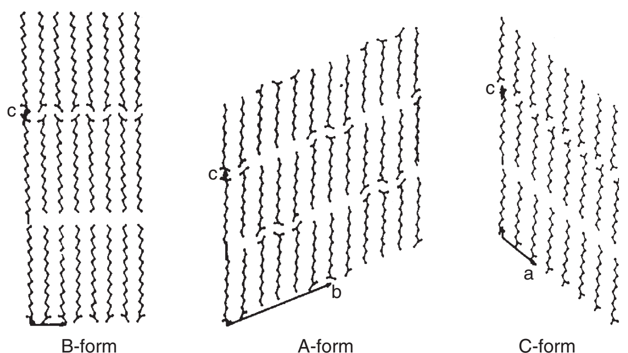

Figure 14. (A–C) Crystal form of fatty acids with an even number of carbon atoms.

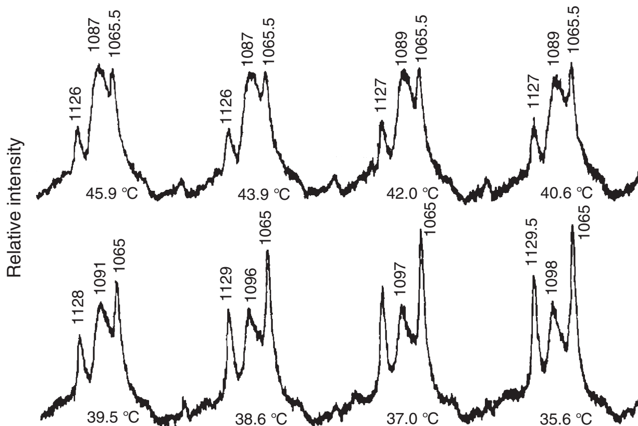

Figure 15. Alteration in the intensities of the bands attributed to the skeletal C–C stretching modes as a function of the temperature for a multilamellar dispersion of dipalmitoyl phosphatidylcholines (chain of 16 C atoms). structure (i.e., with a geometry corresponding to its absolute energy minimum) considered, so far, in the vacuum. The translational repeat unit of polyethylene as a 1D crystal consists of $N = 6$ masses associated with two equivalent chemical units (two CH_2 groups). The dynamics, group theory analysis, and optical selection rules can be and have been worked out in detail. We expect $3N$ phonon branches in the dispersion relation given by

$$M^{-1}(q)F(q)L(q) = L(q)\Lambda(q) \tag{35}$$

which represents the q-dependent (18×18) dynamic problem in terms of Cartesian coordinates [73, 74], where the matrix M^{-1} is the inverse masses tensor, $F(q)$ is the q-dependent tensor containing Cartesian harmonic force constants, $L(q)$ is the matrix made by the q-dependent Cartesian eigenvectors, and $\Lambda(q)$ the diagonal matrix of the frequency parameters $\lambda^s(q) = [(\nu^s(q))^2/4\pi^2c^2]$; the index s labels the sth phonon dispersion curve $\nu^s(q)$.

Since the vibrational harmonic force field for a chain of sp^3 carbon atoms (valence force field) is well known, highly reliable phonon dispersion curves are available and are routinely used (Fig. 16 [75]). It should be pointed out that consideration of a tridimensional crystalline system leaves the intramolecular potential practically unaltered, while it turns on weak intermolecular van der Waals type interactions which act only as small and often negligible perturbations of the phonons of the isolated chain (Fig. 17 [76]). This concept, which has been verified from both experiments and calculations for very many molecular systems, can be extended to all the "mesosticks" we are considering in this review and our discussion proceeds always referring to "single chains" with the only proviso that since for all polymer chains the single chain model neglects interchain forces it cannot describe the rotational (libration) motion about the chain axis, that is, the chain rotation about its axis is free. It follows that (i) while for tridimensional crystals we have the three acoustic branches (with a finite slope at $q = 0$ in the Brillouin zone), the single chain model adds an extra zero

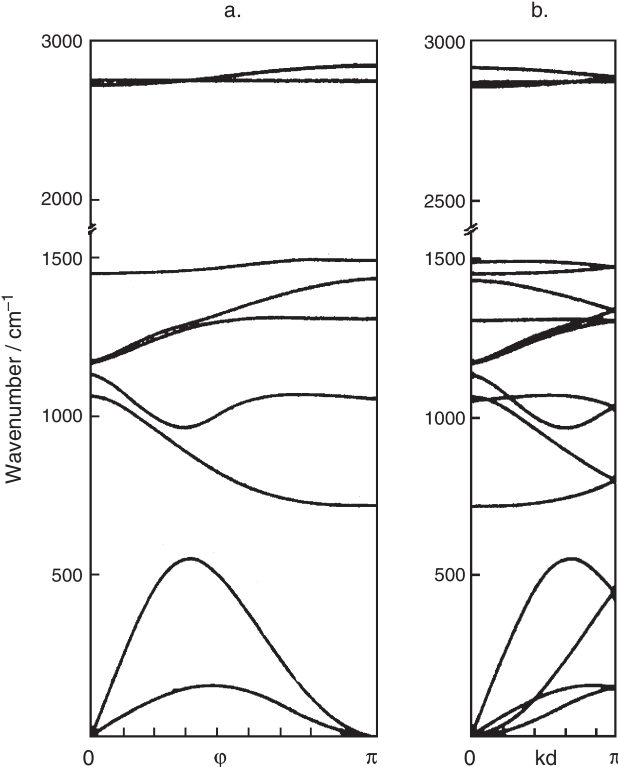

Figure 16. Phonon dispersion curves of a single polyethylene chain.

frequency (free rotation); (ii) the slope at $q = 0$ of the acoustic branches corresponding to the two "transversal" modes are wrong and the derived singularities near $q = 0$ in the density of vibrational states have no physical meaning. On the contrary, the longitudinal acoustic branch is fully reliable and gives the correct description of the low-frequency longitudinal accordion modes observed in the Raman spectra of nanosticks (see below).

A great contribution to the study of the physics of classical polymers and of the derived shorter nanoscopic chain segments was given as early as 1963 by Snyder and Shachtschneider (S, S) [77], who studied in detail the dynamics of polyethylene and of many shorter nanosized molecular models. If N is the number of atoms in the translational repeat units of polyethylene $3N$ are the branches in the phonon dispersion relations and $3N - 4$ are the nonzero phonon frequencies at Γ in terms of the single chain model.

For the sake of conciseness let us consider the longitudinal vibrations of a linear chain of n masses, each at a distance d, joined by weightless elastic springs; its standing waves can be characterized by the phase shift between vibrational amplitudes of adjacent units.

$$\varphi_j = q_j d \tag{36}$$

$$\varphi_j = \frac{\pi j}{n} \quad j = 0, 1, 2, \ldots (n-1) \tag{37}$$

$$\varphi_j = \frac{\pi j}{n+1} \quad j = 1, 2, \ldots n \tag{38}$$

where Eqs. (37) and (38) refer to a chain with free or fixed ends, respectively. Since in the case of polymers the

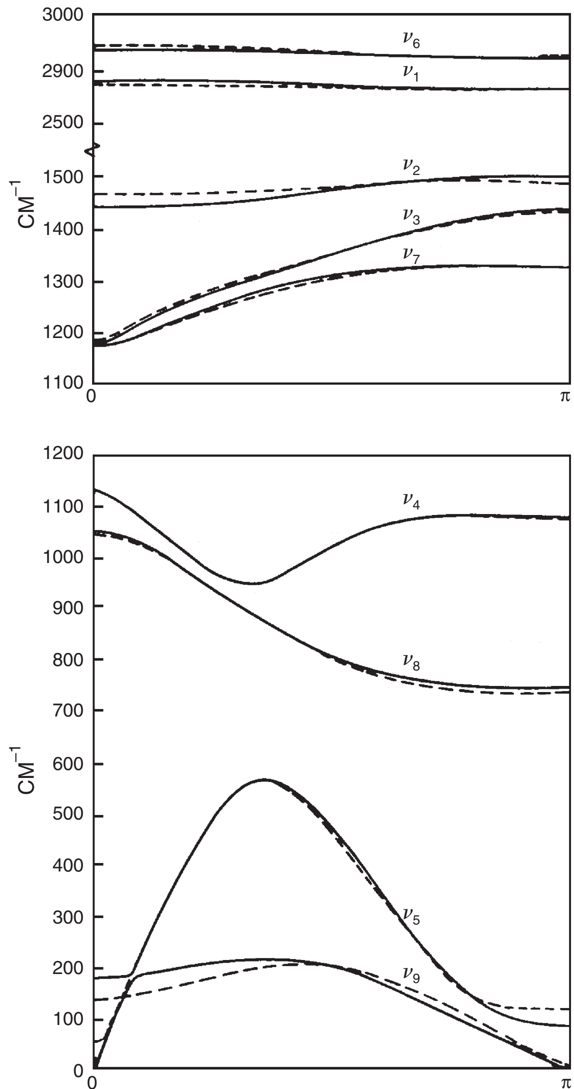

Figure 17. Phonon dispersion curves for crystalline (3D) polyethylene.

translational repeat unit is formed by several smaller chemical units related by a symmetry operation (e.g., through a screw axis if the polymer forms a helix), phonons are usually described with the phase shift between chemical units. For instance, in the case of polyethylene φ describes the amplitude shift between two adjacent CH_2 units. S,S showed experimentally (and later by dynamical calculations) that the vibrations of long chain hydrocarbons, tending to and reaching polyethylene, could be labeled in terms of the phase shift φ. Band progressions are observed mostly in infrared, with increasing intensity toward the $q = 0$ phonons of the infinite 1D crystal. For long chains, it can be shown that the finiteness of the chain does not give enough intensity to most of the $q \neq 0$ phonons to be observed in the Raman spectra and only $q \approx 0$ phonons are observed for most of the model molecules; the only exception are the phonons in the band progression for the longitudinal acoustic branch where all $q \neq 0$ gain remarkable intensities, with the lowest frequency components being the strongest line in the Raman spectra of each model molecule. From the spectroscopically observed (in infrared (IR) and or Raman) band progressions, experimental phonon dispersion curves were constructed. Only very recently has the new technology in inelastic neutron scattering [78] experiments the reaching of spectroscopic results similar to those obtained much earlier by S,S.

The dynamics of nanosized molecular sticks cannot avoid consideration of the so-called "end group modes," which derive by the fact that chain ends are different (in terms of masses and of force constants) from the repeat chemical units which make up the finite molecular entity. The number of end modes (not their location in the spectrum) can be predicted by Ledermann's theorem, which states that if in a Hermitian matrix the elements of r rows and their corresponding columns are modified in any way whatever, the number of eigenvalues which lie in any given interval cannot increase or decrease by more than $2r$ [79]. The locations of the end modes in the class of n-alkanes studied by S,S were analytically predicted with the method of the "transfer matrix" [80]. The present availability of powerful computers and of suitable algorithms for the construction of the dynamic matrices for each nanosized molecular stick of any chemical nature provides a quick and easy way to calculate and to describe the nature of all normal modes, including the end group modes. It has to be remarked that for chains made up of sp^3 carbon atoms the interactions between neighboring chemical units are very short range, reaching at most the second neighbor. It follows that for long nanosized sticks even if the size of the secular determinant to be solved becomes enormous the matrix is a typical band matrix consisting of a diagonal and a few codiagonals, while all other elements are 0 (the band width increases with the increasing of the molecular complexity of the chain). The numerical solution of the dynamic problem becomes extremely fast even for huge systems [74].

From the experimental viewpoint, in the case of chain segments with increasing length where the force field is not modulated by chain length (i.e., the numerical value of r is very small because long-range electronic interactions do not take place) end group modes are few and can be easily located in the spectrum because their relative intensity decreases when the number of repeat units in the chain increases.

The easy and unquestionable observation in the Raman spectra of finite molecular chains of phonons which lie on the longitudinal acoustic branch of the corresponding infinite polymer chain opens the way to further relevant and unique characterizations. Such vibrational modes are commonly referred to as "longitudinal accordion modes" (LAM) [81, 82] and correspond to stationary vibrational waves with one or more nodes along the chain backbone. For n-alkane molecules (n even), if j is the number of nodes, because of symmetry, only modes with odd j are Raman active and the Raman intensity strongly decreases when j increases. LAM-1 has received most of the attention since it gives rise to the strongest line in the Raman spectrum, thus becoming a very useful spectroscopic probe (Fig. 18). Mizushima and Shimanouchi [81] have shown that if a segment of a trans-planar polymethylene molecule is represented by an elastic rod of length l, density ρ, and Young modulus E, the LAM-1

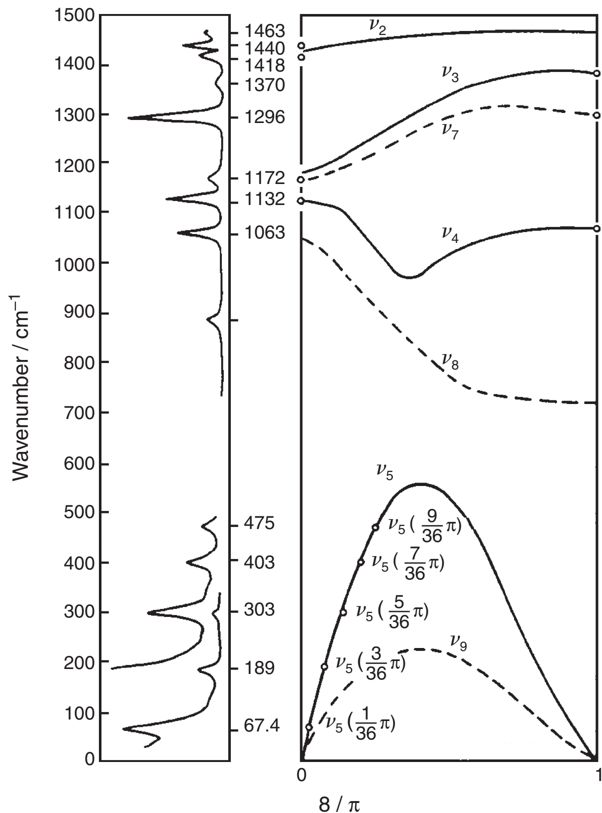

Figure 18. Frequency versus phase difference curves for acoustic (LAM) vibrations of a polymethylene chain with the corresponding observed Raman.

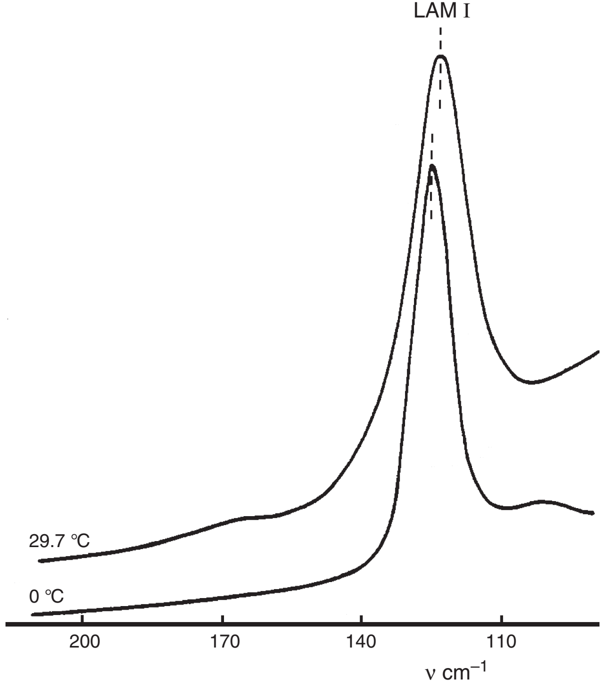

Figure 19. LAM band from the Raman spectrum of n-nonadecane at 0±C (orthorombic) and 29.7°C (α phase). Reprinted with permission from [67], G. Zerbi et al., *J. Chem. Phys.* 75, 3175 (1981). © 1981, American Institute of Physics.

frequency [cm^{-1}] can be related to l by

$$\nu(LAM1) = \frac{1}{2lc}\sqrt{\frac{E}{\rho}} \tag{39}$$

Once the numerical values of E and ρ are known for a given polymer the length l of the nanosized molecular sticks (which are chemically similar to that of the parent polymer) can be immediately derived from the observation in the Raman of their ν(LAM-1). On the other hand, if a sequence of several LAM-j modes can be experimentally observed for a given finite chain, part of the acoustical branch can be fitted on the experimental data and the elastic modulus of the polymer can be derived.

The same concepts form the basis of a recent study [83], in which the frequency behavior of the transverse acoustic modes (TAM) of polyacetylene has been predicted with a simple, classical model. In this model the molecular chain is represented by a continuous elastic beam with a flexural rigidity value extrapolated from *ab initio* computed TAM frequencies of polyenes of increasing length (ranging from C_4H_6 to $C_{22}H_{24}$).

LAM modes have been used in structural determinations of many nanosized molecular segments. A few interesting cases are quoted here as meaningful examples.

From what has been stated above the existence of straight nanosized sticks in a given material is relevant information in soft matter physics. Figure 19 shows the contribution of LAM spectroscopy to the study of phase transition (orthorhombic → pseudo-hexagonal → melt) of n-nondecane (taken as a prototype of a class of molecules) [67]. At $T < 0$ °C ν(LAM-1) = 124.5 cm^{-1} assures that n-nonadecane has 19 carbon atoms in a transplanar geometry, near $T = 27.78$ °C ν(LAM-1) = 123.2 cm^{-1} the chain is still straight, but the weak surface interactions at either end of the chain (interlamellar forces) further weaken, at $T > 32$ °C the nanostick collapses in a "disordered" structure and LAM-1 disappears, leaving a broad scattering near 220 cm^{-1}.

The nature of such broad scattering (observed in practically all systems consisting of long CH_2 chains in the liquid phase) has been the a center of attention for quite a while, suggesting that the material in the liquid phase may not consist of fully structurally collapsed and randomly coiled chains, but a nonnegligible fraction may consist of a distribution of short, but still straight segments. Statistical thermodynamics has been strongly involved in such studies. The observed broad scattering may result from the convolution of the LAM-1 transitions of short and "stiff" hydrocarbon segments. This view has refueled the relevant issue of the local order in amorphous polymers or systems with long alkyl residues in terms of short- or long-range reorientational correlations which may determine the process of crystallization. A contribution to these studies again comes from Raman LAM spectroscopy of short hydrocarbon chains, which provide evidence of short straight segments in liquid hydrocarbons as long as C_{12} [84, 85] thus supporting the idea that the model of nematiclike structure for liquid n-alkane melts is not applicable, while indications are collected

from LAM of the existence of weak orientational correlations characterized by a short correlation length and/or of a pretransitional ordering of very short segments as seeds of crystallization [85], in agreement with numerical simulations [71].

LAM has also contributed greatly to the study of the folding of polymer chains during the formation of lamellae. As early as 1978 Snyder and Scherer [86] were able to modify the existing Raman spectrometers in order to reach extremely small Raman shifts (reaching 3 cm^{-1}) for the recording of LAM modes of specimens of polyethylene as solid state extruded or as bulk-crystallized materials. From the shape of the observed LAM-1 scattering the authors were able to obtain a quantitative distribution of lengths of straight chain segments associated with polymer lamellae (Fig. 20).

The use of Raman LAM spectroscopy for tackling structural and dynamic problems of complex biologically relevant nanosized molecular sticks has required the development of a simplified theoretical approach. Indeed it has been observed experimentally that heavy substituents at either end of chain molecules (e.g., monolayer comblike systems biochemically very common), weak or strong interactions between molecular chains facing each others in finite systems (e.g., hydrogen-bonded heads in fatty acid dimers), and interlamellar forces in crystals critically affect both LAM frequencies and intensities. A simplified model of coupled oscillators has been developed and applied to many cases offered by nature [87]. The theoretical results drastically modify the way experimental LAM frequencies and intensities have to be interpreted. The first direct consequence of such treatment is that the previous belief (based on a wrong interpretation of LAM modes) that the chains of fatty acids were not planar, but conformationally distorted had to be dismantled since evidence of fatty acid dimers as straight sticks has been unambiguously offered [87]. Finally, the coupled oscillator model has been extended to "composite" nanosized chain molecules, that is, linear chains made up of segments of different chemical natures (hence with different mechanical and optical properties) linked together. A classical case is that of semiflouorinated *n*-alkanes of the general formula $F(CF_2)_n - (CH_2)_mH$, with $m = n$ in the range 7 to 12 and with $n = 12$ and m raging from 1 to 20, produced and experimentally studied by Twieg and Rabolt [88] and interpreted by Minoni and Zerbi [89].

After the first synthesis of polyacetylene [90] (in this discussion we always refer only to *trans*-polyacetylene, hereafter indicated as PA) and after the discovery that it can be transformed in a highly conducting material by suitable doping [91] the interest of pure and applied chemistry, physics, and technology has grown dramatically and has branched out in many directions, including molecular electronics and photonics [92]. Actually, because of its poor chemical stability PA has been set aside and replaced by chemically more stable and workable oligomers and polymers of pyrrole, thiophene, paraphenylene vinylene, and many others.

The physical phenomenon which forms the basis of all these studies is that PA (and the many derivatives and homologues which have been produced) is a prototypical polymer molecule made up of carbon atoms in sp^2 hybridization. The p_z orbitals are delocalized along the molecular backbone, thus forming again a one-dimensional crystal. In the previous sections we have stressed that all polymers or short molecules considered were made up of carbon atoms in sp^3 hybridization, with the consequence that intramolecular interactions are short range and intermolecular forces are weak and almost negligible. In the case of polyconjugated polymers and short oligomers, because of delocalization, the HOMO–LUMO bandgap decreases substantially (thus changing colour of the material), the electronic interactions turn on the so-called Peierls distortion, strong electron/phonon coupling takes place, and intramolecular forces may extend long distances.

It is beyond the scope of this chapter to review the chemistry and physics associated with the existence of delocalized π electrons in polyconjugated polymers, again taken as 1D

crystals and in short molecular segment (oligomers) where both phonons and electrons become localized [16, 93]. As a conceptual continuation of the discussion started with chains and nanosticks made by sp^3 carbon atoms we feel obliged to point out that in polyconjugated systems with sp^2 carbon atoms all physical properties are conjugation length (CL) dependent. Since our present interest is Raman scattering of nanosized molecular chains we feel it necessary to focus on a few properties of the Raman spectra of these materials.

First is the observation that the Raman spectrum of a sample of PA is extremely simple, and similarly the spectra of nanosized polyene chains (ranging from polyenes to carotenoids etc.) show almost the same spectral pattern of two strong bands which shift by changing CL. It becomes obvious that if the electronic properties of these systems are CL dependent the molecular force field also changes with CL together with the derived dynamic and spectroscopic properties. We then expect a frequency dispersion and intensity dispersion of the Raman spectrum in terms of CL, as indeed is observed in various samples of PA and in very many nanosized chains of molecular models (see Figure 2).

Of particular interest is the observation for several polyconjugated materials of an extremely strong Raman transition (showing frequency and intensity dispersion with CL) in the range of 1600–1450 cm^{-1} which has been accounted for in terms of a collective totally symmetric vibrational mode which involves the in-phase stretching of all C=C bonds and the in-phase shrinking of all C—C bonds. These modes have been variously described in terms of the “dimerization coordinate” or the “effective conjugation coordinate” and form the basis for understanding the electronic properties and dynamics of the whole class of polyconjugated linear chains oligomers and polymers [16]. Since the mode probes the whole molecular chain it can be taken as a characteristic signal of each nanosized segment of a certain length.

Using these concepts, from Raman spectra of polyacetylene samples, bimodal or trimodal distribution of segment lengths has been derived [95].

5.5. Carbon-Based Nanostructured Materials

There are very many materials made of only carbon atoms, which show relevant deviations (from the viewpoint of structure and properties) from the two main allotropic forms of carbon, namely, graphite and diamond. Among carbon nanomaterials we find molecular objects with a well-defined structure and point symmetry (this is the case of fullerenes and other carbon clusters) and materials which can still be described starting from some parent structure (graphite or diamond), by the introduction of structural defects (for instance, the loose of the three-dimensional order as in turbostratic graphites, or the drastic lowering of the crystals size, as in micro- and nanocrystalline graphites). Sometimes the structural similarity with a parent, perfect crystal is restricted to very a short-range order, as in the case of amorphous carbons: here graphitic islands (characterized by a finite number of condensed hexagonal carbon rings) develop and increase their size (the characteristic diameters range from of a few to 10^1 nm) upon thermal treatment.

A very special case is that of carbon nanotubes, which can be regarded as nanoobjects but which obey a physics which can be written starting from concepts and calculations already developed for the case of a 2D graphite lattice.

5.5.1. Disordered Graphites

Under this name we can group a very wide family of materials (ranging from amorphous carbons, microcrystalline graphites, and graphite fibers to whiskers). All these materials are characterized by the presence of a nonnegligible number of sp^2 carbons which give rise to islands which can be correlated (in terms of structure and also in terms of their Raman response) to an ideally perfect crystal of graphite.

The Raman spectra of many carbon materials containing a variable number of sp^2 structures have been extensively studied [96–102, 155, 187]. Their first order spectra show two main signatures: first, a band located at about 1580 cm^{-1}, which is known as the graphite (G) band, since it is the only intense feature observed in the first order Raman spectrum of highly ordered, crystalline graphite. The second band (D band) appears at about 1350 cm^{-1} and is a characteristic feature of disordered samples of graphite (e.g., nanocrystalline and microcrystalline graphites) and amorphous carbon materials containing sp^2 graphitic islands.

In Figure 21 the first order Raman spectrum of a variety of disordered graphitic samples is shown. As can be immediately observed the different samples show

- Relatively modest frequency shift in the two main lines.
- A wide range of values of the intensity ratio between the two main lines. The ratio I_D/I_G ranges from the theoretical value for a perfect graphite crystal ($I_D/I_G = 0$) to values $I_D/I_G > 1$.
- Band shapes and especially bandwidths show sample dependence.

The fundamental experiments made by Póksic et al. [97] on microcrystalline graphites and those performed by Ferrari and Robertson [98] and Robertson and O’Reilly [99] on films of amorphous carbons showed a clear resonance behavior and frequency dispersion of the D line with respect

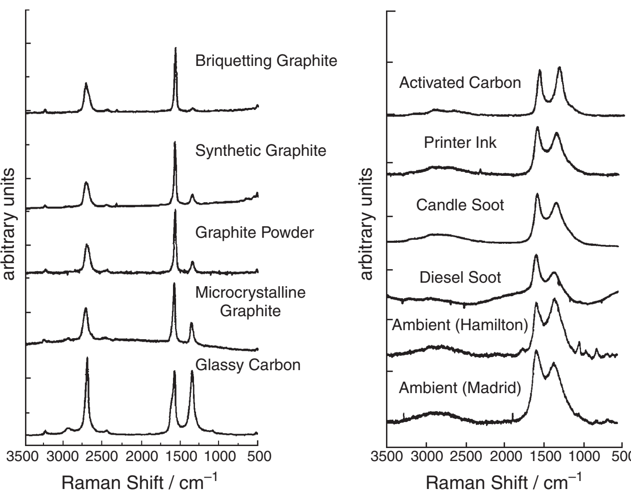

Figure 21. (Left) Raman spectra of commercial samples of graphitic materials. (Right) Raman spectra of “disordered” samples of various origins. Reprinted with permission from [101], R. Escribano et al., *Vibrational Spectrosc.* 26, 179 (2001). © 2001,

to the energy of the exciting laser line used in the Raman experiments. This behavior is illustrated in Figure 22.

Other peculiar features can be identified in Raman spectra of graphites, namely, that in several samples a second component in the high-frequency side of G band (referred as the G′ band) arises and several features ascribed to second order Raman spectra (overtones or combination bands) can be detected. All these features show a more or less marked sample dependence.

In what follows we restrict ourselves to the main features in the first order Raman spectrum of graphitic materials, namely, to the G and D lines.

The presence of the G band can be immediately related to the existence of structures like graphite in the samples. It corresponds to the only symmetry allowed phonon transition in the Raman spectrum of a perfect two-dimensional graphite lattice (the E_{2g} phonon at Γ point in the first Brillouin zone of graphite). This line is indeed the only one observed in the first order Raman spectrum of graphite crystals of high perfection (e.g., HOPG, highly oriented pyrolytic graphites). It is commonly accepted in the literature that the G line in disordered samples corresponds to the excitation of the same vibrational mode as in HOPG, confined into a finite size graphite domain. The small frequency shifts observed for this line in different samples can be ascribed to intrinsic changes in the force field (atom–atom interactions). Moreover, it can also be rationalized as due to the mere effect of the geometrical confinement which is well recognized in solid state physics, namely, the activation of phonons characterized by wave vector **q** different from **0**, in a narrow range around $\mathbf{q} = \mathbf{0}$ (see point 2, Section 3).

On the contrary, the understanding of the physical mechanism lying behind the activation of the D band has been, and is presently, a matter of debate in the literature.

A point is generally accepted, namely, the fact that the appearance of the D line is due to a transition corresponding to a $\mathbf{q} \neq \mathbf{0}$ graphite phonon which is activated by the presence of "disorder" in the sample. Independently of the kind of disorder, the measure of the intensity of the D line has been used by several authors to obtain an estimate of the degree of disorder. An empirical linear correlation

between the intensity ratio and the inverse of the crystal planar domain size L_a has been observed by Nemanich and Solin [187]. This correlation has been used for evaluating the average size of the graphite domains in both microcrystalline graphites and amorphous carbons. More recently, thanks to the systematic work of Ferrari et al. on several samples of amorphous carbons it was definitely shown that the I_D/I_G parameter does not follow a monotonic law as a function of L_a. It increases systematically in a regime were graphite domains of a few nanometers are present, thus reaching a maximum and than decreasing in samples with larger graphite domains (e.g., microcrystalline graphites). Moreover, it is now clear that the crystal size is not the only factor which determines the intensity of the D line: suitably induced defects (e.g., by ion irradiation [102]) have been shown to contribute to enhancement of the D line cross section. Other experiments reported by Wang et al. [103] showed that the D line intensity is independent of the crystalline size.

Despite the general agreement about the existence of a correlation between disorder and the D line, there are at least two fundamental problems which have to be clarified: (i) to explain the selectivity of the phenomenon and (ii) to give a description (e.g., in terms of structural parameters) of the nature of the defects responsible for activation.

The breaking of spectroscopic selection rules (by virtue of disorder) brings us (at least in principle) to the activation of the whole phonon density of states. What is surprising in this case is the fact that only one phonon (or a distribution of phonons in a very narrow range of energies) is activated by disorder. Moreover, the simpler explanation in terms of correspondence of the observed Raman frequency with a peak of the phonon density of states must be dismissed based on the observed frequency shift (Fig. 22) of the D line with excitation energy. Indeed a peak in VDOS lies definitely at a fixed frequency. All these observations are at the basis of the model proposed by Thompsen and Reich [104], which explains the appearance of the D line as due to a double resonant process involving (1) the creation of an electron–hole pair at the **k** point of the graphite BZ for a particular laser energy E_1 matching the energy difference between valence and conduction band at **k**; (2) the scattering of the electron to a state in a second band by a phonon with the proper phonon quasi-momentum; (3) the recombination of the electron assisted by elastic scattering from lattice defects.

Both processes 1 and 2 are affected by resonance behavior (double resonance). The model developed by Thompsen and Reich [104] has been analytically worked out, giving rise to equations which predict in a quantitative way, the experimentally observed dispersion relation of the D line frequency with respect to the energy of the exciting laser line (Fig. 22) [97].

An alternative interpretation of the origin of the D line in graphitic materials has been proposed [24, 26, 106] based on a molecular approach. This approach is built on the spectroscopic data obtained from a wide series of samples of PAHs. Very recently a new synthetic route has been developed [25, 107] and PAHs of very large size have become available. These large polycyclic aromatic hydrocarbons can be considered molecularly defined graphitic clusters, such as

those present in defected graphite samples and other carbon materials. Molecularly defined objects can indeed be investigated in order to provide explanations for some not yet well understood experimental behaviors observed for disordered carbon materials containing nanosized sp^2 domains.

Interestingly, the experimental spectra of PAHs [24, 26, 106] are also characterized by a few bands in approximately the same G and D regions (Fig. 23). This is expected, given the similarity of their structure to that of graphitic islands, and offers the advantage of using molecules with a well-known dimension and structure to probe defects of similar size and structure in carbonaceous materials.

To assess quantitatively the correlation experimentally found between the Raman bands of graphite and the Raman active modes of PAHs, we carried out a quantum–chemical study of vibrational force field and Raman intensities of PAHs of different sizes and symmetries [24, 26]. These calculations, performed at the BLYP/6-31G level of theory, confirmed the idea (earlier developed on the basis of classical vibrational dynamics calculations) that this correlation is due to the strong polarizability changes associated with two peculiar [182] collective vibrational displacements, characteristic of a graphitic cluster, namely, R^- and A vibrations.

The Raman active modes of PAHs in the 1600-cm^{-1} region correspond to vibrational eigenvectors with a large projection on the vibrational coordinate R^- and give rise to the G band. In a similar way the normal modes (usually two or three) giving rise to strong Raman transitions in the D band region show a large content of the vibrational coordinate A. In the case of a perfect two-dimensional crystal of graphite the vibrational coordinates R^- and A correspond to two phonons of the crystal: the only Raman active $\mathbf{q} = \mathbf{0}$ E_{2g} phonon and the totally symmetric A'_1 phonon at $\mathbf{q} = \mathbf{K}$ [26].

In Figure 24 the nuclear displacements associated with these phonons are shown and compared with the computed eigenvectors of a large PAH ($C_{114}H_{30}$). The eigenvectors displayed for $C_{114}H_{30}$ have been selected on the basis of their very large Raman cross sections.

The analysis in terms of local contributions to Raman intensities clarifies the origin of the large Raman cross section for the few bands at about 1300 cm^{-1}, observed (and calculated) for all the PAHs examined. It is shown that the values of the local stretching polarizability tensors ($\partial\alpha/\partial R_{cc} = \alpha'$ parameters) can be used as a very sensitive probe of the character of CC bonds in PAH molecules. More specifically, in the case of "all-benzenoid" PAHs, they allow easy identification of the presence of aromatic sextets. Moreover, the α' correlate with the equilibrium bond lengths that results from quantum–chemical calculations of equilibrium structure. This lies in the peculiar electronic structure of PAHs, which is induced by the confinement of

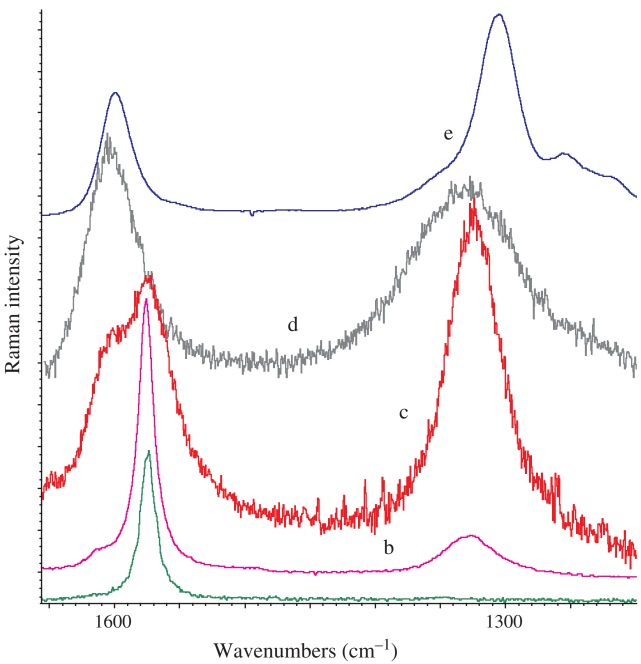

Figure 23. Raman spectra of different graphitic materials: (a) HOPG graphite ($\lambda_{exc} = 632.8$ nm); (b) disordered graphite ($\lambda_{exc} = 632.8$ nm); (c) multiwall nanotubes ($\lambda_{exc} = 632.8$ nm); (d) pyrolitic graphene sheet ($\lambda_{exc} = 632.8$ nm); (e) a D_{6h} PAH molecule containing 222 carbon atoms ($\lambda_{exc} = 632.8$ nm). Samples d and e were kindly provided by Professor K. Müllen [25].

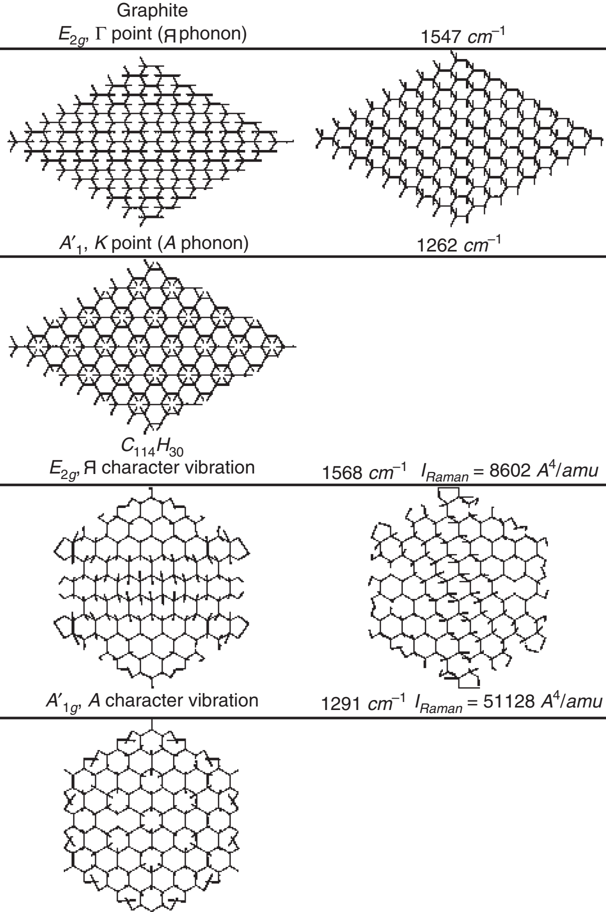

Figure 24. (Upper panels) Nuclear displacements associated to R^- and A phonons of a perfect two-dimensional lattice of graphite. (Lower panels) Comparison with selected normal modes of $C_{114}H_{30}$, as obtained from BLYP/6-31G calculations.

the π electron system into a finite size domain. This electronic structure is strongly affected by the molecular topology and it is reflected by the nuclear equilibrium geometry, characterized by nonequivalent CC bonds which can be described according to the canonical structures commented on in Section 4, point ii.

The relevant fact is that the existence of nonequivalent CC bonds (and, correspondingly, nonequivalent α' parameters) in PAHs is essential for the activation of normal modes in the D band region.

If these ideas are extended to the rationalization of the Raman spectra of carbon materials containing nanosized clusters of condensed aromatic rings, we have to conclude that in these cases the confinement of π electrons also induces a structural relaxation (like that described in Fig. 5), with respect to the structure of a perfect graphite crystal with all the CC bonds perfectly equivalent. The spectroscopic signature of this relaxation is just the appearance of the D line in the Raman spectrum. It must be noted that several years ago, Tuistra and Koenig [96], based on a simple symmetry consideration, proposed that the D line observed in disordered graphites was correlated to a totally symmetric phonon corresponding to the A mode sketched in Figure 24.

The success of the molecular approach consists in the fact that it makes it possible (1) to clearly identify the quasi-phonon involved in the Raman process as the A mode and (2) to describe the effect of disorder in terms of a well-defined structural relaxation, which is in turn correlated with effects of confinement of the π electrons. Effects of this kind can certainly be induced both by the presence of finite size graphitic domains and by the presence of edges, as in nanocrystalline graphites.

Moreover, as in the model of Thompsen and Reich [104], the molecular approach indicates that the appearance of the D line is a resonance phenomenon. It has indeed been shown (both experimentally and by means of theoretical calculations) that Raman intensity enhancement of the D band occurs in PAHs [27, 106].

In conclusion, we stress that the interpretation of the Raman spectra of materials containing graphitic domains of small size has been done with the help of models which, at first sight, may appear very different or even incompatible. However, both the models mentioned in this section make it possible to rationalize several experimental features and shine new light on the nature of nanostructured carbon materials. The challenge for future research is to find a bridge between the different approaches and to clarify the limitations, potentialities, and complementarities of the different points of view.

5.5.2. Carbon Nanotubes

Since their discovery [108] carbon nanotubes have attracted the interest of both theoretical and applied researchers due to their very peculiar physics and consequently to the many possible applications foreseen for these materials (e.g., in the fields of nanoelectronics, sensors, and energy storage).

Raman spectroscopy is a widely used technique for the structural diagnosis and study of electronic properties of carbon nanotubes. Among other things, vibrational spectra are useful for the identification in experimental samples of different nanotubes (characterized by different structures and properties). This is probably the reason for the large number of publications which have appeared in the literature in the last 10 years dealing with the prediction and interpretation of the vibrational spectra of carbon nanotubes. Due to the amount of literature on the subject we are forced to refer the reader interested to a deeper discussion to some selected reviews which contain a wide bibliography on the subject [109, 110].

A first classification of carbon nanotubes is based on the fact that they can be described as either made by a single (rolled) graphite sheet (single wall nanotubes, SWNT) or consisting of several concentric cylindrical graphite layers imbedded one inside the other (this configuration is traditionally called the "Russian-doll" model, and these nanotubes are referred as multiwall nanotubes, MWNT).

The interpretation of the Raman behavior of SWNT has now reached, thanks to the many experimental and theoretical works, a consistent set of reliable conclusions. On the contrary, the study of the spectroscopic behavior of MWNT presents much more complicated theoretical issues and has not yet reached the same degree of maturity. For this reason we deal in the following with just the case of SWNT.

The structure of a given SWNT can be specified in terms of the tube diameter and the chirality. These concepts are conveniently expressed in terms of a proper chiral vector $\mathbf{C}_h = n_1\mathbf{a}_1 + n_2\mathbf{a}_2$ defined on the honeycomb lattice (see Fig. 25) and by a translation vector $\mathbf{T}$ which is in turn determined by the choice of the two integers, n_1, n_2. Accordingly, the pair (n_1, n_2) is the only information needed in order to fully specify the structure of the tube. The importance of the knowledge of nanotube structure consists mainly in the fact that it determines the electronic structure (and then the electrical behavior) of the tube: while varying (n_1, n_2) one can obtain a 1D metal or a semiconductor (and the energy gap value can be tuned by selecting (n_1, n_2)).

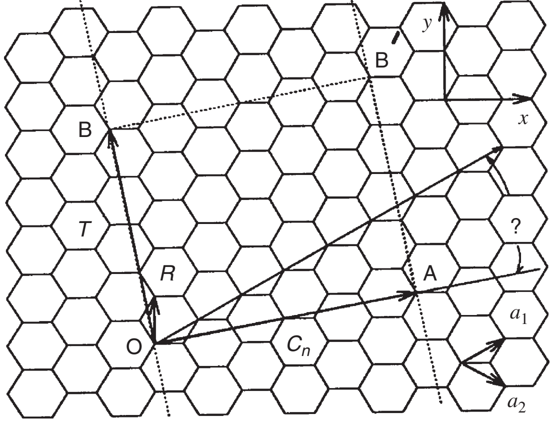

Figure 25. The unrolled honeycom lattice of a nanotube. Connecting sites O and A and sites B and B′ a nanotube can be constructed. C_h (the chiral vector) and T (translational vector) are indicated. The rectangle OAB′B defines the unit cell of a (4, 2) nanotube. Reprinted with permission from [109], R. Saito and H. Kataura, "Topics in Applied Physics, Vol. 8, Carbon Nanotubes: Synthesis, Structure, Properies and Applications" (2001). © 2001, Springer-Verlag.

Since the length of carbon nanotubes is usually between 10^2 and 10^3 nm, while diameters are of the order of 10 nm, the treatment of the electronic and vibrational properties of a single tube can be performed on the simplified hypothesis that they are infinite in the direction of the tube axis. This allows the avoidance of the explicit description of the nanotubes edges. However, as an example of a structurally well-defined nanotube end, in Figure 26, SWNTs are shown where each end of the cylinder is capped with half a fullerene.

Raman spectra of bundles of SWNT and, more recently, from isolated nanotubes [111] have been reported in the literature.

In Figure 27 [112] the first order Raman spectra recorded with different exciting laser lines for a purified SWNT sample are shown.

Despite the higher number of $\mathbf{q} = \mathbf{0}$ phonons of carbon nanotubes with respect to those of graphite, symmetry selection rules determine the activation of relatively few phonons in the Raman spectra.

The most important observed Raman features are the following: (1) the radial breathing mode (RBM), whose frequency varies according to the diameter of the tube; (2) the tangential G band (derived from the graphite $\mathbf{E}_{2g}$ Raman mode) in the range of 1550–1605 cm^{-1}; and (3) the "disordered induced" D band at about 1350 cm^{-1} and its second order harmonic (G′ band) at about 2700 cm^{-1}.

Another very relevant point is the fact that the Raman intensities of a given nanotube are strongly enhanced by resonance phenomena. Resonance effects are determined by matching between the laser energy and the energy of electronic transitions between Van Hove singularities in the valence and conduction bands. As already stressed, this is peculiar to one-dimensional structures.

The different locations of Van Hove singularities for SWNTs characterized by different diameters and chiralities offer the way to obtain (by suitable tuning of the laser energy) Raman spectra arising from nanotubes of a selected structure. This effect is clearly shown in Figure 27, where frequency dispersion of the main lines is observed while varying the excitation energy.

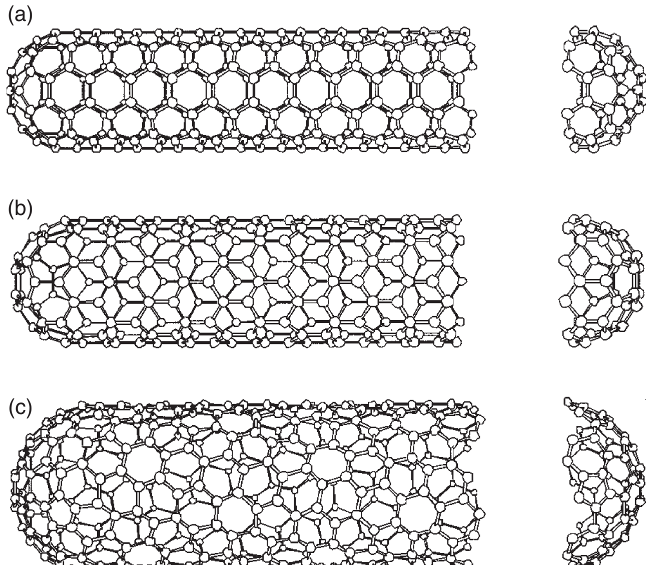

Figure 26. Schematic models for single-wall nanotubes capped with hemispherical fullerene-like caps: (a) armchair nanotube; (b) zigzag nanotube; (c) chiral nanotube.

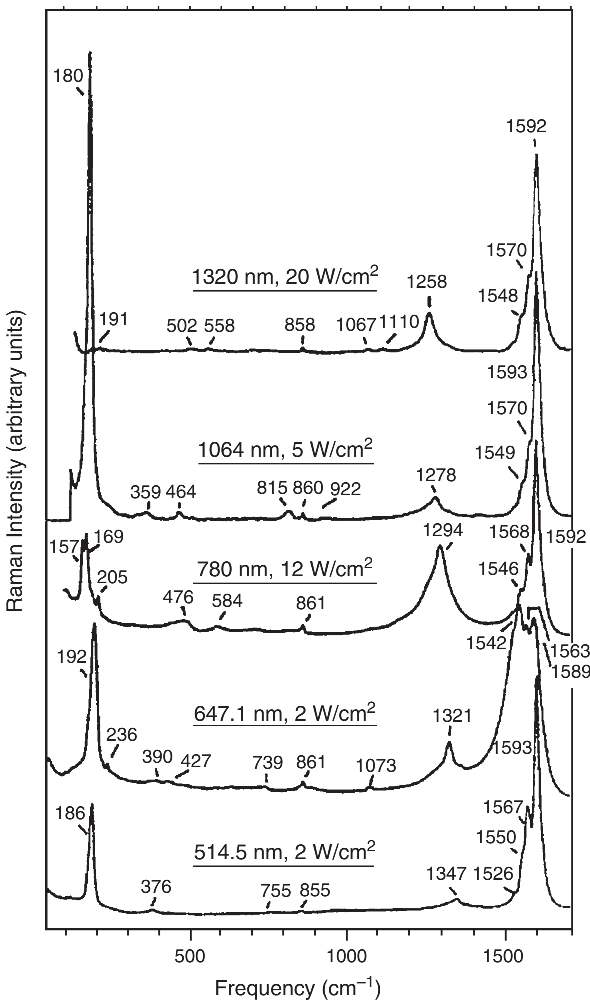

Figure 27. Experimental Raman spectra of purified single-wall carbon nanotubes excited at five different wavelengths; the laser wavelength and power density for each spectrum are indicated in the figure. Reprinted with permission from [110], M. S. Dresselhaus and P. C. Eklund, *Adv. Phys.* 49, 705 (2000). © 2000, Taylor & Francis.

The dispersion of the frequency of RBM has been reproduced by both empirical force constants [113] and *ab initio* calculations on model structures: these calculations showed a linear dependence of its value on the inverse of the tube diameter. Accordingly, the relationship ν (cm^{-1}) $= 248/d_t$ has been proposed for the practical determination of SWNT diameters from the Raman frequency of RBM.

As for the G band, the most dramatic features are the characteristic differences between the G bands for metallic and semiconducting nanotubes, as shown in Figure 28. The rationalization of these findings not only requires the description (frequency prediction by vibrational dynamics) of the Raman active phonons for a given (n_1, n_2) tube, but also calls for the understanding of the Raman intensity and line shape associated with the Raman transitions. These two features strongly depend on the characteristic electronic

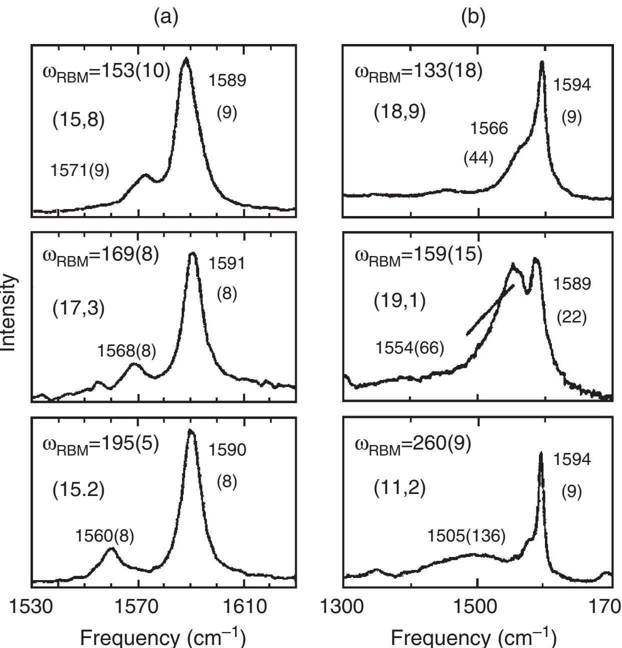

Figure 28. Profiles of the G band spectra for three semiconducting (a) and three metallic (b) nanotubes whose indices (n, m) are determined by their RBM spectra. Frequency values and line widths (in parentheses) are indicated in the figure. Reprinted with permission from [111], M. S. Desselhaus et al., *Carbon* 40, 2043 (2002). © 2002, Elsevier.

structure of the tube considered (see [111] for a discussion) and are the specific signature of the strong electron–phonon coupling in SWNTs.

As for the case of graphitic materials (see Section 5.2) the origin of the D band in Raman spectra of nanotubes is still ascribed to a double resonant mechanism [111] activated by the presence of disorder. In the discussion of the behavior of the D line in nanotubes, the existence of Van Hove singularities is explicitly taken into account in the treatment by Kürti et al. [116], giving rise to phenomena which are described by the authors as triple resonances.

The experimental study of the G band behavior and of the D line activation for nanotubes shines light on the fact that each (n_1, n_2) nanotube is characterized by its own unique electronic structure and that the strong coupling between electrons and phonons determines its Raman response. Conversely, the theoretical models developed in order to give a reasonable description of these interactions and to accurately predict the observed spectroscopic behavior are essential, at least for the following reasons: (i) developing the correct correlation for structural diagnosis (e.g., assignment of Raman lines to the corresponding (n_1, n_2) tube); (ii) extracting (from spectra) information about the electronic structure; and (iii) for a challenging test of different levels of theories and computational methods.

Point iii requires some comment. As mentioned in Section 2, the simplest way to treat the vibrational dynamics of nanotubes consists in applying the zone folding methods to the phonon dispersion curves obtained for an infinite graphite sheet. This technique has been followed by several authors who obtained in a relatively quick way good insight into the interpretation of SWNT Raman spectra. On the other hand, a more detailed comparison of the predictions with experimental data revealed nonnegligible weakness in the method. The main drawback of the zone folding treatment can be briefly summarized in the following two points.

1. The description of some modes of nanotubes cannot be made correctly on the basis of the nuclear displacements characteristic of the corresponding phonon of the graphene sheet (see Fig. 29). This happens, for instance, for the radial breathing mode of the nanotubes, which is put in correspondence with the out-of-plane acoustic mode of the graphene sheet (Fig. 29a). This last mode corresponds to a vanishing frequency (pure translation of the sheet) in the limit $\mathbf{q} \to \mathbf{0}$. It is immediately realized that the RBM of the nanotube is an optical mode, which does involve both the graphite out-of-plane (radial) force constants and the in-plane (tangential) force constants. As another example, nanotube modes exist for which the correct nuclear displacements can be obtained only by mixing of in-plane and out-of-plane modes of graphite (Fig. 29b), which cannot mix by reason of symmetry in the case of a graphene sheet.
2. Another problem arises from the fact that a force field transferred from graphite may be intrinsically different (different values of force constants) from the real field of a nanotube. This can happen for at least two reasons: (a) the curvature of the nanotube surface can modify, in principle, all radial and tangential force constants and (b) the presence of a finite sequence of CC bonds along the circumference of the tube is certainly responsible for confinement effects of the π electrons and of the resulting change in the intramolecular potential.

In a recent paper by Dubay and Kresse [117] state of the art calculations of phonon dispersion relations for nanotubes are presented and all the relevant references are quoted.

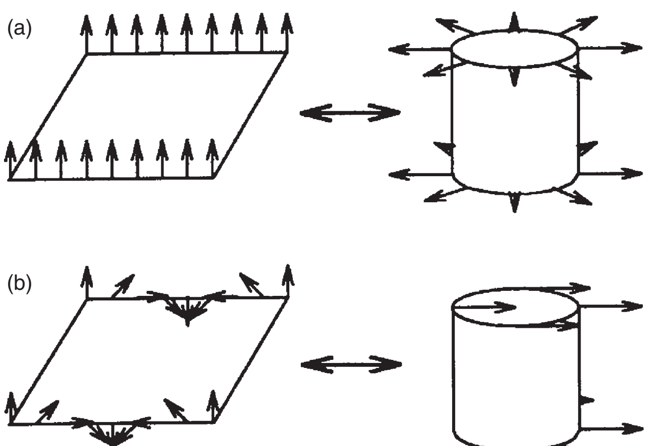

Figure 29. (a) The out-of-plane acoustic mode at $K = 0$ (left) in a single layer of graphite gives rise to a radial breathing mode in the carbon nanotube with nonzero frequency (right); (b) an acoustic mode of the nanotube corresponds to a linear combination of both in-plane and out-of-plane graphene modes. Reprinted with permission from [110], M. S. Dresselhaus and P. C. Eklund, *Adv. Phys.* 49, 705 (2000). © 2000, Taylor & Francis.

In this paper, accurate calculations for the phonon dispersion relations of single wall armchair (n, n) and zigzag (n, 0) nanotubes based on density functional theory are reported. The results are compared to those predicted by the zone folding procedure applied to graphite phonon dispersion branches as obtained with a consistent theoretical treatment at the same level of theory. According to this study an appreciable softening of the longitudinal A_1 mode in metallic nanotubes has been found with respect to frequency value obtained by the simple zone folding procedure: this effect has been correlated to a precise electronic mechanism taking place in metallic nanotubes.

5.5.3. Carbynes

Nanostructured carbon films produced by supersonic cluster beam deposition have been studied by *in-situ* Raman spectroscopy [135]. Raman spectra show the formation of an sp^2 solid with a very large fraction of sp-coordinated carbyne species showing a long-term stability under ultrahigh vacuum. Distinct Raman contributions from polyyne and cumulene species have been observed. The long-term stability and the behavior of carbyne-rich films under different gas exposures have been characterized showing different evolution for different sp configurations. These experiments confirm theoretical predictions and demonstrate the possibility of easily producing a stable carbyne-rich pure carbon solid. The stability of the sp^2–sp network has important implications for astrophysics and for the production of novel carbon-based systems.

Linear carbon chains with sp hybridization are considered fundamental constituents of the interstellar medium [118, 119]. They are abundant in circumstellar shells [118] and their presence can account for many features of the diffuse interstellar bands [118, 119]. The efforts to synthetise and study these species in the laboratory stimulated the discovery of C_{60} [120]. Several gas phase studies of carbon clusters with linear or cyclic structure have suggested that they can be elemental building blocks of three-dimensional fullerenes and nanotubes [121].

The sp carbon chains can present alternating single and triple bonds (polyyne) or only double bonds (polycumulene) [122]. Theoretical calculations suggest that polycumulenes are less stable than polyynes [122, 123]. Both species are characterized by an extremely high reactivity against oxygen and a strong tendency to interchain cross-linking [124], thus rendering the direct observation of a pure carbyne-assembled solid still a major challenge. Isolated carbynic species have been investigated in the gas phase in order to determine their geometry [121, 125]; their electronic and vibrational structure has been studied for non-interacting clusters embedded in matrices of cold rare gases [126].

The sp carbon chains have also been proposed as the elemental building blocks of a carbon allotrope called carbyne [124]. The carbyne story is very controversial: the first claims of direct observation of carbyne date from the sixties [124, 127]; however, up to now, no firm and unambiguous evidence of the existence of this allotrope has been provided [124]. Experimental results, mainly based on crystallographic recognition supporting the identification of crystalline carbyne, have been the object of strong criticism up to a complete rejection of the carbyne concept [124, 128].

Although the occurrence of crystalline carbyne is still a matter of debate, carbyne-rich or carbynoid solids have been produced by synthetic strategies mainly based on chemical routes. These include oxidative coupling reactions, dehydrohalogenation of polymers, polycondensation reactions of halides, electrochemical reductive carbonization, and condensation of end-capped chain molecules produced in the gas phase [129, 132]. In these systems polyyne chains, assembled together, are preserved against cross-linking and chemical decomposition by the presence of metal-based species and molecular groups terminating and separating the chains.

A different approach to the synthesis of carbyne is the high-temperature and high-pressure treatment of carbon-based materials. Resistive heating of graphite or high-energy laser or ion irradiation of carbon have been suggested as possible methods to produce carbynoid materials [133]. However, no definitive confirmation of the validity of these methods has yet been reported.

Raman spectroscopy is one of the techniques of choice for the study of carbon-based materials and for the identification of carbyne [124, 134]. The presence of a Raman band at roughly 2100 cm^{-1}, generated by the carbon triple bond, is admitted to be one of the strongest arguments in favor of the presence of carbynes [124, 131]. Raman spectra of carbynoid materials are characterized by G and D bands in the range of 1200–1700 cm^{-1} as in amorphous carbon and by the presence of the band in the 2100-cm^{-1} region [124, 131]. For carbyne-rich materials this band should have an intensity comparable to or even greater than the amorphous contribution.

Raman spectra from chemically stabilized carbynoid systems are reported in the literature, but due to the high reactivity and fast aging of the carbyne species, no Raman spectra are reported for pure carbon systems.

Ravagnan et al. [135] it have shown that it is possible to produce nanostructured carbon films rich in carbyne species by depositing pure carbon clusters from a supersonic beam. These films have been characterized by *in-situ* Raman spectroscopy determining the contribution to the spectra coming from the polyyne and cumulene species.

Cluster-assembled carbon films have been previously characterized *ex-situ* by Raman spectroscopy [139]. The films have an amorphous structure with a main sp^2 hybridization character. The G and D features reveal a substantial amount of distortion of bond lengths and angles [140]. A weak peak at about 2100 cm^{-1} was observed. Due to the high reactivity of carbyne this peak could be attributed to the residual presence of a primeval larger carbynoid population. Although an attribution based solely on *ex-situ* data cannot be considered definitive.

Figure 30 shows the comparison between the *ex-situ* and *in-situ* Raman spectra of two films deposited under the same conditions. The G and D bands are almost identical, whereas the peak at 2100 cm^{-1} has dramatically increased in intensity in the *in-situ* spectrum (we will refer to it as the C peak). This peak has a remarkably strong intensity and appears to be structured and composed of a main broad peak at about 2100 cm^{-1} and a weaker shoulder centered around 1980 cm^{-1}, as evidenced by a two-Gaussian fit. The relative C peak intensity, expressed by the ratio between its

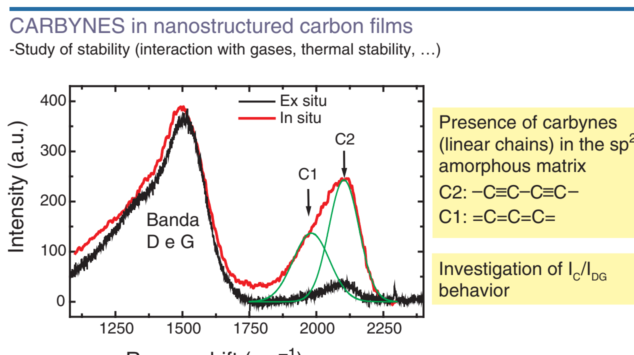

Figure 30. Raman spectra of nanostructured carbon films deposited by a supersonic cluster beam, measured *ex-situ* (gray) and *in-situ* in UHV conditions (red). For the second spectra we have indicated the two fitting curves identifying the cumulene (left) and polyyne (right) contributions.

integrated intensity and the D–G band integrated intensity (IC_{rel} = IC/ID, G) is roughly 45%.

Raman spectra confirm the formation of a carbynoid material with a substantial presence of sp linear structures among an sp^2-hybridized disordered network, although it is not possible to quantify the number of *sp*-hybridized C atoms, since the Raman cross section of this kind of vibration is unknown. Compared to other carbynoid systems reported in the literature the C peak at 2100 cm^{-1} presents a low-frequency shoulder at 1980 cm^{-1}. This is caused by the presence of both cumulenic and polyynic chains coexisting in the film and giving spectral contributions at different frequencies [141]. The broadening of the two components can be ascribed to the sp chain length distribution and to disorder [124].

These observations show that a carbyne-rich material can be formed by assembling carbon clusters at very low energies without high temperature and high pressure or chemical reactions inducing carbyne formation from polymers or hydrocarbons.

The experimental results reported here provide new elements for the interpretation of the carbyne puzzle and are of relevance for areas where carbon clusters play an important role, such as the composition of the interstellar medium and the existence of new allotropic forms of carbon. Low-energy cluster beam deposition in an oxygen-free environment appears to be a viable technique for the production of a pure carbon nanostructured material extremely rich in carbynoid species. The unexpectedly high stability of polyyne and cumulene species interacting with each other and with a fullerenelike type of clusters once deposited [138] suggest the existence of a cluster–cluster reaction mechanism leading to the formation of networks where the sp bonds are stabilized. These networks composed of sp^2 and sp linkages may be a disordered analogue of a new phase of carbon called graphyne and theoretically predicted by Baughman et al. [143]. The doping of this material with alkali metals or stabilizing molecular groups may lead to the observation of novel structural and functional properties in these systems.

The gas phase chemical models of interstellar clouds take into account the presence of different carbon nanoparticles, such as carbyne, fullerenes, and polycyclic aromatic hydrocarbons [118, 144]. These species are related by very complex reaction pathways to produce and destroy one species from another. Cluster–cluster interaction can produce large carbonaceous grains where carbyne species are present and stable.

5.6. Raman Scattering from Confined Acoustic Modes

5.6.1. Nanoparticles

As described in the preceding sections, the confinement of optical phonons in small particles can be studied by Raman spectroscopy. Raman scattering from confined acoustic phonons can also be observed and it can be used for the determination of particle size. Duval and co-workers have reported low-frequency Raman bands in nucleated cordierite glass [145]. The size of the particles has been determined by X-ray scattering and electron microscopy and the position of the low-frequency Raman peaks as a function of the inverse of particle diameter is reported in Figure 36. An analysis of Raman peak intensity and polarization have suggested the existence of a spherical source of scattering. This observation, together with the linear dependence of the Raman line shift from the inverse of nanocrystallites dimensions, suggested that vibrational surface modes of the particles are responsible for the observed Raman scattering [145].

A model that can account for the observed low-frequency scattering describes the nanocrystal embedded in matrices as an homogeneous elastic body of spherical shape vibrating elastically. Lamb [146] Tamura and Ichinokawa [147], and Fujii et al. [148] have theoretically studied the vibrational eigenfrequencies of a homogenous elastic sphere with a free surface (i.e., the eigenfrequencies of the confined acoustic modes). Two equations determining the spectrum are derived:

$$j_{l+1}(\eta) - \frac{l-1}{\eta} j_l(\eta) = 0 \tag{40}$$

$$2\left[\eta^2 + (l-1)(l+2)\left[\frac{\eta j_{l+1}(\eta)}{j_l(\eta)} - (l+1)\right]\right]\frac{\xi j_{l+1}(\xi)}{j_l(\xi)} - \frac{\eta^4}{2} + (l-1)(2l+1)\eta^2 + [\eta^2 - 2l(l-1)(l+2)] \times \frac{\eta j_{l+1}(\eta)}{j_l(\eta)} = 0 \tag{41}$$

where η and ξ are nondimensional eigenfrequencies and l is an angular momentum quantum number. The first equation describes, with $l \geq 1$, a torsional mode and the second, with $l \geq 0$, a spheroidal mode [148]. The torsional modes are vibrations without dilatation, which is instead present in spheroidal modes. The eigenfrequencies corresponding to different angular momentum quantum numbers can be written as

$$\eta_l^t = \frac{\omega_l^t d}{2v_t} \tag{42}$$

where ω_l^t is the angular frequency of the lth torsional mode, v_t is the transverse sound velocity, and d the diameter of the particle. For the spheroidal modes the eigenfrequencies are

$$\eta_l^s = \frac{\omega_l^s d}{2v_t} \tag{43}$$

$$\xi_l^s = \frac{\omega_l^s d}{2v_l} \tag{44}$$

where v_t is the transversal sound velocity.

With the above equations one can calculate the eigenvalues belonging to angular momentum $l\eta_{\text{ln}}^t$ and η_{ln}^s ($n+1$th eigenvalues). By introducing the transverse and longitudinal sound velocities with $n=0$, the Raman peak frequencies of the torsional and spheroidal modes can be reproduced by fitting the dimension of the crystallites d.

This model has been applied to different systems starting from the observation of Duval and co-workers [143]. Fujii et al. measured the low-frequency Raman spectra of small silver particles embedded in SiO_2; the agreement between theory and experiment is reasonable for particles with an average size $d \leq 40$ Å. This has been attributed to the fact that particles with a small average size have a narrow size distribution, whereas the growth of large particles cannot avoid a wider size distribution. Size distribution cannot be taken into account in the model [148]. Another possible reason for the discrepancy between experiments and calculations could be the effect of particle shape. The deviation from spherical shape can cause changes in the vibrational frequencies and Raman selection rules. TEM micrographs show that large particles have irregular shapes.

For Ag crystallites in SiO_2, the effect of the matrix seems to be negligible. This is true if the elastic properties of the matrix are very different from those of the particles. In this case the clusters can be considered under free surface boundary conditions. The assumption that the nanocrystal is a homogeneous elastic body is valid for Ag nanocrystals as small as 3 nm. For very small nanocrystals, the continuous assumption is not justified and lattice dynamics calculations should be performed [148].

The low-energy Raman scattering from silver particles in alkali halides was also investigated by Mariotto et al. [149]. From the energies of the observed modes the shape and dimensions of the particles were deduced. A good agreement with small angle X-ray scattering characterization of the samples has been found.

Films assembled by LiF clusters with diameters between 10 and 5 nm have been characterized by Raman spectroscopy [150, 151]. Bulk LiF does not show first order Raman scattering; the selection rules are relaxed in small crystallites because of the uncertainty of the phonon wave vector. The Raman spectra of LiF clusters show several sharp lines located between 28 and 1492 cm^{-1}. In particular two lines at 28 and 42 cm^{-1} have been attributed to localized acoustic vibrations of the clusters [151]. The interpretation of the origin of the other peaks observed at higher frequencies has been discussed in terms of surface optical modes. The role of size distribution and of cluster–cluster interaction in the film needs further investigation to be clarified.

Quasi-free silicon clusters deposited onto a porous silicon matrix also show low-frequency Raman lines that can be attributed to surface acoustic modes and to their combinations [152]. The clusters in porous silicon are only weakly bound and touching each other so that although the matrix is of the same material as the clusters, surface effects should not be suppressed. Comparison between theory and experiments suggests that surface modes are Raman active.

Low-frequency Raman scattering has also been used to detect acoustic modes in metallic nanocrystals and their behavior as a function of temperature for sizes in the confinement regime, giving new information about melting of the particles. The eigenfrequencies of the acoustic modes are in agreement with theoretical calculations of vibrations in a sphere. Approaching the nanoparticle melting temperature [153] the acoustic modes of the particles are progressively softened and damped; a sudden change in the mode frequency and damping is detected just below the previously measured melting temperature and is explained in terms of surface premelting; no acoustic peaks can be detected after melting. A broad central peak, whose intensity increases with temperature, was detected. The coupling of the particle acoustic modes with relaxing degrees of freedom, through a damping process also involving the matrix–particle interaction, produces overdamped fluctuations in dielectric function, thus explaining the observed behavior.

5.6.2. Nanotubes

As discussed above, SWNTs are formed by warping a single graphitic layer to form a seamless cylindrical object [155]. Their expected very high strength-to-weight ratio has stimulated an enormous interest in view of applications as reinforcement fibers in composite materials, high-strength cables, actuators, etc. [155, 160, 162, 163]. The quasi-static elastic properties of SWNTs (e.g., Young modulus) have been estimated by observing their bending with AFM [164] or their freestanding room-temperature bending vibrations with TEM [159, 163]. With these methods problems arise from the lack of precision in determining the SWNT diameter, length, temperature, and vibrational frequency [159] and the tendency of SWNTs to form bundles complicates the analysis. A Young modulus of the order of $E = 1.25$ TPa was found, even though, in the vibrating rod model, this quantity is related to a ill-defined quantity, the thickness of the tube walls. Moreover, different theoretical approaches have been proposed to model a SWNT with an elastic continuum model [159], or by *ab initio* calculations [156, 157, 160, 161] and the predicted Young moduli are scattered over a large interval. It is still a matter of speculation whether the curvature modifies the original properties of the graphene sheet [159, 165–168], since the Young modulus of SWNT's appears to be systematically higher than the in-plane elastic modulus of graphite, and no precise comparison could be made between SWNTs and MWNTs (see, e.g. [169, 170]). The higher value of their Young modulus could be attributed to an increased strength due to the wrapping [159] (stiffening of the graphite sheets is predicted for a radius lower than 0.5 nm [171]).

Bottani et al. [172] present the measurement by inelastic light scattering of confined longitudinal acoustic modes

(with a wavelength of the order of hundreds of nanometers) in aligned SWNT, whose dispersion relations depend on the 2D elastic constant of the tube walls, that is, of a single warped graphite sheet. This is a dynamic measurement, in contrast with AFM (static) and TEM (dynamic, flexural modes at lower frequencies). So far no direct dynamic measurement of these modes has been reported, even though theoretical calculations have been attempted. The analyzed sample is a freestanding film of pure SWNTs aligned in the plane of the film. Tubes are present in bundles or ropes (100–1000 tubes), with a preferential orientation.

The SWNT diameter was evaluated to be in the range of 12–14 Å by measuring the frequency of the breathing radial mode at about 170–180 cm^{-1} in the Raman spectrum, which is inversely proportional to the radius of the tube [155]. Raman spectroscopy also confirmed the pure SWNT nature of the samples. The absence of scattering for a scattering plane perpendicular to the tube direction confirmed the relative vibrational independence of the tubes and that the composite material is not an effective medium in which acoustic waves can propagate in all directions, at least at the scale of laser excitation wavelength λ_0. Nevertheless, the interaction between adjacent nanotubes probably plays some role and makes the theoretical description based on an isolated cylindrical shell only a first approximation to the problem of acoustic phonon propagation in this kind of material.

Depending on tube length compared to λ_0, the inelastic photon scattering from the acoustic excitations of a nanotube can be a new type of coherent line Brillouin scattering or an incoherent, Raman-like inelastic scattering by confined acoustic phonons (typically in the range of 0–10 cm^{-1} $\equiv$ 0–300 GHz [180]). The authors computed the scattering intensity going beyond the rod approximation and modeled the SWNT as an elastic cylindrical surface in the membrane approximation, i.e., as a 2D elastic object. This 2D model allows only dynamic 2D stress conditions and the nanotube elastic constants have the dimensions of force per unit length. Though the membrane approximation would be inadequate to describe strong bending modes of long tubes, it is precise enough to compute those normal modes along the tube axis, which have a frequency in the range of 1–300 GHz and are thermally excited. These modes are the only ones responsible for the scattering described here. The authors assumed that a surface elasto-optic effect couples the light to the tube thermal phononic strains which are then expanded in normal coordinates. This coupling produces a fluctuating surface polarization density that radiates the Stokes and anti-Stokes scattered photons. The computation has been carried out for the backscattering geometry.

The elasto-optic coupling [177] can be described by introducing the fluctuating part of the 2D dielectric susceptibility of the nanotube surface, the tensor $\delta\boldsymbol{\chi}$ whose three independent components (by symmetry arguments similar to those used for determining the strain tensor) are related to membrane displacements in cylindrical coordinates x, r, φ by the equations

$$\delta\chi_{xx} = \frac{K}{1-\xi^2}\left[\frac{\partial u_x}{\partial x} + \xi\left[\frac{\partial u_\varphi}{R\partial\varphi} - \frac{u_r}{R}\right]\right];$$

$$\delta\chi_{\varphi\varphi} = \frac{K}{1-\xi^2}\left[\xi\frac{\partial u_x}{\partial x} + \frac{\partial u_\varphi}{R\partial\varphi} - \frac{u_r}{R}\right];$$

$$\delta\chi_{x\varphi} = \left[\frac{K}{2(1+\xi)}\frac{\partial u_x}{R\partial\varphi} + \frac{\partial u_\varphi}{\partial x}\right] \tag{45}$$

where u_x, u_φ, and u_r are the longitudinal, radial, and tangential displacements, respectively, R is the tube radius, and K and ξ are the components of the 2D elasto-optic tensor $\mathbf{K}$ (having the same symmetry as the elastic constant tensor which, in turn, has only two independent components for a sixfold symmetry surface). Assuming traveling waves (W represents the normal coordinate and $q_\parallel$ the wave vector)

$$[u_x \quad u_\varphi \quad u_r] = \frac{1}{2}W[u_0 \quad v_0 \quad w_0]\exp i(q_\parallel x - \omega t + m\varphi) + c.c. \tag{46}$$

and using the elastodynamic equations of a cylindrical membrane we find the dimensionless eigenfrequencies (E_{2D} is the 2D surface Young modulus and ν is the Poisson ratio):

$$\Omega^2_{m,q_\parallel,j} \equiv (\rho_{2D}/E_{2D})(1-\nu^2)R^2\omega^2_{m,q_\parallel,j} \tag{47}$$

where j is a branch index. For an infinitely long tube the above traveling waves are the appropriate solution; for tubes of finite length L the proper boundary conditions affect the form of the solution and the corresponding frequencies, unless $L \gg 2\pi/q_\parallel$.

In our case, since $(R/\lambda_0) \ll 1$, the computation of the intensity of the light scattered from a single tube reduces to [177]

$$I(\omega) \approx \omega_0^4 \sum_{m,\mathbf{q}_\parallel,j} I_{m,\mathbf{q}_\parallel,j}\,\delta(\omega - \omega_0 \pm \omega_{m,q_\parallel,j}) \tag{48}$$

where the contribution of each normal mode $I_{m,\mathbf{q}_\parallel,j}$ is given by

$$I_{m,\mathbf{q}_\parallel,j} = \left\langle\left|\int_S e^{iQ_\parallel x}(\mathbf{e}^S \bullet \delta\boldsymbol{\chi} \bullet \mathbf{e}^I)_{m,q_\parallel,j}\,dS\right|^2\right\rangle_{th} \tag{49}$$

where S is the tube surface and $Q_\parallel$ is the component of the scattered wave vector parallel to the tube direction; in backscattering $\mathbf{Q} = \mathbf{k}_s - \mathbf{k}_i = -2\mathbf{k}_i$. An analysis of the above equations shows that only the longitudinal modes with $m = 0$ contribute to inelastic scattering with nonvanishing intensity, provided $Q_\parallel \neq 0$ (i.e., there must be a nonvanishing component of the transferred wave vector, i.e., a scattering plane not perpendicular to the SWNT orientation). In this case the scattered light remains polarized. When the tube length L is much longer than λ_0, the above equation gives

$$I_{m,q_\parallel,j} \propto \delta(Q_\parallel - q_\parallel) \tag{50}$$

In this case (infinite tube, i.e., length $L \gg \lambda_0$) the scattering would be a coherent line Brillouin scattering and only one longitudinal wave (determined by the selected value of $q_\parallel$) would contribute to the measured spectrum (see the surface Brillouin scattering below). The cross section is significant only if the parallel wave vector is conserved ($Q_\parallel = q_\parallel$), and

this conservation would produce a strong dependence of the peak position on the incident angle θ_i (dispersion of the modes) that was not observed. Instead the θ_i dependence of the peak position turned out to be negligible. This was interpreted taking into account that the free mean SWNT length in the samples was of the order of 1 μm or less ($L \approx \lambda_0$), and the tubes cannot be considered infinite with respect to the propagation of the modes selected by the scattering technique used. Assuming clamped ends boundary conditions, as suggested by AFM images, all longitudinal modes with $m = 0$ (stationary waves in this case) turn out to contribute to scattering, due to confinement effects when $L \approx \lambda_0$. The name usually given to this kind of scattering is low-frequency Raman scattering (e.g., in the case of scattering from vibrational eigenmodes of small spheres see [180]). This is the case with the inelastic scattering here reported. In Bottani et al. [172] a more detailed model for the description of the vibrational dynamics of the tubes was used (Donnel theory, see [178, 179]) and applied to a thin shell (thickness $h \ll R$), which considers the finite length L of the tube and takes into account shear forces and torques not belonging to the shell surface. Imposing clamped ends boundary conditions ($u_x = u_\varphi = u_r = du_x/dx = 0$), the normal modes can be written as

$$\begin{aligned} u_x &= u_0[-\sin(\mu/R)(L/2-x) + k\sinh(\mu/R)(L/2-x)] \\ &\quad \times \cos m\varphi \cos \omega t \\ u_\varphi &= v_0[\cos(\mu/R)(L/2-x) + k\cosh(\mu/R)(L/2-x)] \\ &\quad \times \sin m\varphi \cos \omega t \\ u_r &= w_0[\cos(\mu/R)(L/2-x) + k\cosh(\mu/R)(L/2-x)] \\ &\quad \times \cos m\varphi \cos \omega t \end{aligned} \tag{51}$$

The eigenmodes are characterized by a reduced wave vector $\mu = n(\pi/L)R$, with $n = 1.506, 3.5, 5.5, 7.5, \ldots$. The corresponding dimensionless eigenvalues can be written as in Eq. (47) and numerically computed.

It is found again that only longitudinal modes with $m = 0$ contribute to scattering, provided $Q_\parallel \neq 0$. Longitudinal modes with different values of n contribute to the scattered intensity with relative weights given by the above mentioned computation. The authors assumed $\rho_{2D} = 7.6 \cdot 10^{-7}$ kg/m^2 (surface density in SWNTs is assumed to be the same as that in graphite), $R = 6 \cdot 10^{-10}$ m (as obtained by Raman measurements), and Poisson's ratio $\nu = 0.2$ [160]. The dispersion relation of the longitudinal modes turns out to depend only very weakly on ν. Spectra corresponding to different tube lengths (0.5–1.5 μm) have then been convoluted. The 2D Young modulus being the only unknown, its value can be estimated to be the one that best reproduces the measured frequency position of the scattering features. The best correspondence between the computed and the measured peak positions is obtained for $E_{2D} = 110$ N/m. This value is of the same order of magnitude as the C–C atomic force constant computed for a graphite plane [182]. If one considers the thickness of a graphite layer, this corresponds to a Young modulus for an ideal isolated graphitic plane of the order of 1 TPa.

6. BRILLOUIN SCATTERING

6.1. Bulk and Surface Acoustic Waves and their Phonons

Bulk Brillouin scattering of laser light is the inelastic coherent scattering of a photon in a material from a long-wavelength traveling acoustic phonon. If instead the acoustic phonons are localized in nanostructures with sizes of $\delta < \lambda = 2\pi/|\mathbf{k}^I|$, λ being the photon wavelength, then the scattering from an ensemble of independent separated nanostructures is incoherent and it is better referred to as low-frequency Raman scattering (see the sections above on nanoparticles and nanotubes). To save space the reader is referred to Sandercock [206] for a detailed description of the experimental setup. Particularly interesting is the hybrid case of surfaces, thin films, and multilayers in which phonon localization can occur only in the depth z direction, while free propagation with wave vector $\mathbf{q}_\parallel$ takes place parallel to the surface in the (x, y) plane (surface Brillouin scattering). In view of the wavelength of the excitations involved, the vibrational dynamics responsible for every type of Brillouin scattering can be treated in the continuum elastodynamic approximation [195].

6.2. Bulk Waves

The elastodynamic equations can be written in terms of the dynamic displacement field $\mathbf{u} = \mathbf{u}(\mathbf{r}, t)$ mapping the equilibrium $\mathbf{r}$ configuration into the istantaneous dynamic configuration $\mathbf{r}' = \mathbf{r} + \mathbf{u}(\mathbf{r}, t)$, where $\mathbf{r}$ spans all the undeformed volume of the material. In the simplest case of a homogeneous isotropic body these equations read

$$\frac{\partial^2 \mathbf{u}}{\partial t^2} = v_t^2 \boldsymbol{\nabla}^2 \mathbf{u} + (v_l^2 - v_t^2)\boldsymbol{\nabla}(\boldsymbol{\nabla} \cdot \mathbf{u}) \tag{52}$$

where

$$v_l = \sqrt{\left(B + \frac{4}{3}\mu\right) \Big/ \rho}$$

is the longitudinal sound velocity and $v_t = \sqrt{\mu/\rho}$ is the transverse sound velocity. ρ is the mass density and B and μ the bulk and shear moduli, respectively [195]. Remembering that the most general deformation process is the superposition of a simple dilation $\mathbf{u}_l$ and of a simple shear $\mathbf{u}_t$, one is tempted to try a solution of the type $\mathbf{u} = \mathbf{u}_l + \mathbf{u}_t$, with $\boldsymbol{\nabla} \times \mathbf{u}_l = 0$ and $\boldsymbol{\nabla} \cdot \mathbf{u}_t = 0$. The second condition is identical to that holding for electromagnetic waves in a vacuum. This trick works perfectly (instead anisotropic materials require a more complex treatment [198]), leading to two decoupled wave equations for $\mathbf{u}_l$ and $\mathbf{u}_t$:

$$\frac{\partial^2 \mathbf{u}_l}{\partial t^2} = v_l^2 \nabla^2 \mathbf{u}_l \quad \text{and} \quad \frac{\partial^2 \mathbf{u}_t}{\partial t^2} = v_t^2 \nabla^2 \mathbf{u}_t \tag{53}$$

The fundamental bulk solution of Eq. (52) is then the superposition of three independent monochromatic plane waves, one longitudinal (LA) and two (mutually perpendicular) transverse (TA_1, TA_2), of the type

$$\mathbf{u}_\alpha = \Re\left\{Q_{\mathbf{q}\alpha} \mathbf{e}_{\mathbf{q}\alpha} e^{i[\mathbf{q}\cdot\mathbf{r} - w_\alpha(\mathbf{q})t)]}\right\} \tag{54}$$

where $\mathbf{q}$ is the wave vector, α is a branch index ($\alpha = l, t_1, t_2$), $Q_{\mathbf{q}\alpha}$ is the complex amplitude of the normal coordinate $\xi_\alpha(\mathbf{q}) = Q_{\mathbf{q}\alpha} e^{-i\omega t}$, and $\mathbf{e}_{\mathbf{q}\alpha}$ is a polarization unit vector ($\mathbf{e}_{\mathbf{q}l} \| \mathbf{q}$; $\mathbf{e}_{\mathbf{q}t} \perp \mathbf{q}$). Moreover: $\boldsymbol{\omega}_l(\mathbf{q}) = v_l|\mathbf{q}|$ and $\boldsymbol{\omega}_{t_1,t_2}(\mathbf{q}) = v_t|\mathbf{q}|$. The above classical description can be translated into the language of quantum mechanics of the systems of independent harmonic oscillators: the quanta of the fields $\mathbf{u}_\alpha$ are the long-wavelength acoustic phonons whose possible energies are

$$E_n(\mathbf{q}\boldsymbol{\alpha}) = \left(n_{\mathbf{q}\alpha} + \frac{1}{2}\right)\hbar\boldsymbol{\omega}_\alpha(\mathbf{q}) \tag{55}$$

with $n_{\mathbf{q}\alpha} = 0, 1, 2, 3, \ldots$.

6.3. Surface Waves

The prototypes of surface acoustic waves (SAWs) are Rayleigh waves (for a treatment of Rayleigh waves following the lines of the above section see [195]). When the medium is semi-infinite (let us assume the $z = 0$ plane is the surface, the medium is below it: $z < 0$) the translational symmetry is broken in the direction perpendicular to the surface. This produces new facts: (a) the reflection of bulk phonons (in general with branch conversion) and (b) the existence of surface waves [195, 199]. The simplest case of type (a) is that of a transverse (TA) bulk phonon propagating in the sagittal (xz) plane with wave vector $\mathbf{q} = q_\| \hat{\mathbf{e}}_x + q_\perp \hat{\mathbf{e}}_z$ polarized in the horizontal y direction (a shear horizontal phonon: SH) and impinging on the surface. If the surface is not subjected to external forces, applying the boundary conditions, one finds that the surface acts as a perfect acoustic mirror and that the parallel wave vector $q_\|$ of the reflected phonon is identical to that of the incident phonon. Then from the dispersion relation for TA phonons, we get

$$q_\perp = \sqrt{\frac{\omega^2}{v_t^2} - q_\|^2} \tag{56}$$

That is, once $q_\|$ is fixed, there is a lower frequency threshold $\omega_t = v_t q_\|$ for the existence of SH bulk phonons. Above this frequency the spectrum is continuous. If the incident phonon is either a longitudinal or a transverse one but polarized in the incidence plane (shear vertical, SV), there is both a longitudinal and a transverse phonon reflected at different angles; the parallel wave vector $q_\|$ is always conserved in the reflection. For the longitudinal components to be true bulk phonons the threshold is $\omega_l = v_l q_\| > \omega_t$. Otherwise the corresponding partial wave is evanescent in nature. The region of the continuous spectrum between ω_t and ω_l is that of the mixed modes. What happens in the spectral region $\omega < \omega_t$ when the polarizations are only L and SV? For a given $q_\|$ there exists a unique surface wave (the Rayleigh wave). In other words, there also exists a discrete spectrum with a single eigenvalue, $\omega_R = v_R q_\|$. Putting $\omega_R = \xi v_t q_\|$, v_R is found taking the sole real root of an algebraic sixth order equation in ξ resulting from the insertion of a linear combination of partial waves (one L and one SV) of the type

$$\boldsymbol{\psi}_\alpha(z|\omega_R, q_\|) = Q_{\mathbf{q}\alpha}\mathbf{e}_{\mathbf{q}\alpha} \exp(-\kappa_\alpha z) \exp[iq_\|(x - v_R t)] \tag{57}$$

in the boundary conditions and in (52). Considering the possible values of Poisson's ratio $\nu = (3B - 2\mu)/2(3B + \mu)$ [195], numerical computation shows that ξ can vary between 0.874 and 0.955 and that a good approximation is

$$v_R \simeq \frac{0.862 + 1.14\nu}{1 + \nu} v_t \tag{58}$$

Both the SV and the L components of a Rayleigh wave are nondispersive waves traveling parallel to the surface. Both waves decay exponentially with depth as $\exp(-\kappa_\alpha z)$, with

$$\kappa_t = q_\| \sqrt{1 - \frac{v_R^2}{v_t^2}} \quad \text{and} \quad \kappa_l = q_\| \sqrt{1 - \frac{v_R^2}{v_l^2}} \tag{59}$$

showing that the penetration (localization) depth $\delta_\alpha = \kappa_\alpha^{-1}$ is of the order of the wavelength $\lambda = 2\pi/q_\|$. This result, together with the existence of the transverse threshold, separating the discrete from the continuous spectrum, is a general feature of acoustic surface waves physics even in the presence of overlayers or of a more complex layered subsurface structure. In the general case the transverse threshold depends on the transverse sound velocity of the substrate material.

6.4. Layered Subsurface Structures: More General Surface Waves

The most compact way to face the case of a layered subsurface structure is followed generalizing the treatment of the previous paragraph to an elastic half space ($z \leq 0$) whose density ρ and elastic constants B and μ are functions of the depth z. Rigorously this method would imply again deriving the propagation equation which would take a form different from Eq. (52) [200–203]. For our limited purposes one can just think of the same Eq. (52) but with z-dependent coefficients. Excluding the case of very sharp interfaces between adjacent layers, this is also a tenable and useful approximation (for the alternative, standard approach, see, e.g. [204]).

Once we have found the surface wave spectrum of a layered structure by means of any numeric method, a very useful set of spectral functions can be constructed: the layer-projected phonon densities of LPPDS states. For given $q_\|$ and polarization α, considering the whole set of eigenfunctions of Eq. (52) together with all their boundary conditions,

$$\varphi_{n\alpha}(z|\omega_{n\alpha}, q_\|) \exp[iq_\| x - \omega_{n\alpha}(q_\|)t] \tag{60}$$

The spectral functions are defined as

$$g_\alpha(\omega, q_\||z) = \sum_n \langle|\varphi_{n\alpha}(z|\omega_{n\alpha}, q_\|)|^2\rangle_{th} \delta(\omega - \omega_{n\alpha}(q_\|)) \tag{61}$$

where $\langle\cdots\rangle_{th}$ is the thermal average and the summation is over the entire spectrum thought of as discrete. The continuous part of the spectrum can be made discrete using a slab approximation [200]. In a layered surface structure the Rayleigh wave is not the only true surface wave corresponding to a unique discrete eigenvalue and other surface waves, more or less confined in single or multiple layers, corresponding to several $\omega_{n\alpha}(q_\|)$, can exist (Sezawa, Stonley, and Love waves [204]). The contour lines of a smoothed

version of a specific $g_\alpha(\omega, q_\parallel|z)$ in the ω, z plane give a vivid and direct image of phonon localization [205]. The function $g_\alpha(\omega, q_\parallel|0)$ is the surface-projected phonon density of states which plays a major role in surface Brillouin scattering from opaque materials [205].

6.5. Volume Brillouin Scattering

The scattering kinematics can be described in a quite direct and intuitive picture. For the sake of simplicity we consider both the incident $(\mathbf{k}^I, \omega^I)$ and the scattered $(\mathbf{k}^S, \omega^S)$ photons only inside the medium. While a single acoustic phonon $(\mathbf{q}, \omega_\alpha = v_\alpha|\mathbf{q}|)$ is propagating within the material its periodic strain field sets up an anisotropic modulation of the otherwise isotropic dielectric susceptibility χ (Eq. (68)). This adiabatic modulation is viewed as a traveling diffraction grating by the incident electromagnetic wave. Then the scattering kinematics can be explained by the familiar wave concepts of Bragg reflection and Doppler shift. Equivalently, in the quantum language, the scattering process must obey the laws of conservation of momentum (wave vector) and energy. In the transition from the initial photon state $(\mathbf{k}^I, \omega^I)$ to the final (scattered) photon state $(\mathbf{k}^S, \omega^S)$

$$\mathbf{k}^S - \mathbf{k}^I = \pm\mathbf{q} \tag{62}$$

$$\omega^S - \omega^I = \pm\omega_\alpha(\mathbf{q}). \tag{63}$$

In Eqs. (62) and (63) the plus sign stands for the so-called anti-Stokes events, when a phonon is annihilated in the process and the scattered photon is more energetic, having gained energy from the medium, while the minus sign corresponds to the so-called Stokes events, when a new phonon is created in the process and the scattered photon is less energetic, having transferred energy to the medium. In the classical wave picture, Eq. (63) represents the Doppler shift of an electromagnetic wave dynamically diffracted by an elastic wave moving either in the direction of vector $\mathbf{q}$ or in the direction of vector $-\mathbf{q}$ with the same absolute sound velocity. To see how Brillouin inelastic scattering may be viewed as a Bragg reflection of the incident wave, let us consider Eq. (63) with the aid of the dispersion relations for photons $\omega^I = c|\mathbf{k}^I|$ and $\omega^S = c|\mathbf{k}^S|$ and phonons:

$$\frac{|\mathbf{k}^S| - |\mathbf{k}^I|}{|\mathbf{q}|} = \frac{v_\alpha}{c} \tag{64}$$

The order of magnitude of the ratio v_α/c could be typically 10^{-5} so that $|\mathbf{k}^S| \approx |\mathbf{k}^I|$. Because the energy of a photon is $c\hbar|\mathbf{k}|$ the scattering is quasi-elastic. Taking this into account and squaring Eq. (62) one easily obtains

$$2|\mathbf{k}^I|\sin(\phi/2) = |\mathbf{q}| \tag{65}$$

where ϕ is the scattering angle. The above equation can be given the form of Bragg law

$$2d\sin(\theta) = \lambda \tag{66}$$

$\theta = \phi/2$ being the Bragg angle. The grating spacing d is equal to the phonon wavelength $2\pi/|\mathbf{q}| = 2\pi v_\alpha/\omega_\alpha|$ and $\lambda = \lambda_0/n$ is the wavelength of the incident photon in the medium, while λ_0 is the corresponding quantity in a vacuum. From the above considerations it turns out that the measurement of the Brillouin shift $\Delta\omega = |\omega^S - \omega^I| = \omega_\alpha$ in a fixed scattering geometry (e.g., backscattering with $\phi = \pi$) leads to the possibility of measuring the sound velocity v_α, provided the index of refraction of the medium n is known, by means of the formula

$$v_\alpha = \frac{\lambda_0|\Delta\omega|}{4\pi n\sin(\phi/2)} \tag{67}$$

Equations (62) and (63) are only necessary conditions for the scattering events to take place. To have complete information one must compute the intensity of the scattered wave, or the elasto-optic scattering cross section. Once this is done, particular selection rules appear in connection with the scattering angle and the polarizations of both photons and phonons and their relative orientations with respect to the scattering plane (defined by the vectors $\mathbf{k}^I$ and $\mathbf{k}^S$); moreover, in the case of crystalline bodies, the dependence of v_α on the phonon propagation direction (elastic anisotropy) must be taken into account.

In the following we restrict ourselves to the case of optically isotropic solids. The key ingredient of bulk Brillouin scattering theory is the instantaneous anisotropic dielectric susceptibility of the medium around the frequency ω^I, the tensor

$$\chi_{ij}(\mathbf{r}, t) = \chi\delta_{ij} + \delta\chi_{ij}(\mathbf{r}, t) \tag{68}$$

where χ is the usual time-independent isotropic susceptibility, while the tensor $\delta\chi_{ij}(\mathbf{r}, t)$ is the anisotropic fluctuating part of the susceptibility due to the presence of thermal phonons. Then the fluctuating part of the polarization vector radiating the scattered waves can be written as $\delta P_i = \epsilon_0\delta\chi_{ij}E_j$, ϵ_0 being the vacuum dielectric constant. Here $E_j = E_j^I + E_j^S$ is the sum of the incident field and of the scattered field. Using the linearity of Maxwell equations, the scattered electric field E^S can now be computed by means of first order perturbation theory (Born approximation [207]):

$$\delta P_i \approx \epsilon_0\delta\chi_{ij}E_j^I \tag{69}$$

The above equation is justified by the smallness of both the scattered field and $\delta\chi_{ij}$. So far the treatment is analogous to that of Raman scattering in extended media. In the case of acoustic phonons the coupling between sound and light (the elasto-optic effect) can be written in terms of two elasto-optic constants a_1 and a_2 as

$$\epsilon_0\delta\chi_{ij} = a_1 e_{ij} + a_2\varepsilon_{ll}\delta_{ij} \tag{70}$$

and the phonon strains are very small. Sometimes a_1 and a_2 are written in terms of the Pockels coefficients p_{ij} as $a_1 = -\epsilon^2(p_{11} - p_{12})$ and $a_2 = -\epsilon^2 p_{12}$ [195, 206]. For a cubic crystal three independent coefficients are necessary to express the elasto-optic coupling. In Eq. (69) δP_i oscillates at the frequency $\omega^S = \omega^I \pm \omega_\alpha(\mathbf{q})$ because E_j^I is proportional to $e^{i\omega^I t}$ and $\delta\chi_{ij}$, being proportional to the strain field of a bulk phonon (see Eq. (54)), and oscillates as its normal coordinate $\xi_{\boldsymbol{\alpha}}(\mathbf{q}) = Q_{\mathbf{q}\boldsymbol{\alpha}}e^{\pm i\omega_\alpha(\mathbf{q})t}$ does. Solving the radiation problem (the Maxwell equations with a source proportional to

$\partial(\delta P_i)/\partial t$ [207]), the scattered electric field can be obtained. Once this is known the spectral intensity of the scattered light is computed as the power spectrum $S_{E^S}(\omega)$, which is essentially the measured outcome of a Brillouin scattering experiment:

$$S_{E^S}(\omega) = \int_{-\infty}^{\infty} \langle E^S(t+\tau)E^{S*}(t)\rangle_{th} e^{i\omega\tau}\, d\tau \tag{71}$$

where $E^S = E^S \cdot \mathbf{e}^S$ is the complex amplitude of the scattered field projected along a given analyzed polarization direction $\mathbf{e}^S$ perpendicular to $\mathbf{k}^S$. An explicit computation gives [208]

$$S_{E^S}(\mathbf{Q}, \omega,) \propto \frac{|E_0^I|^2}{\lambda_0^4} |\mathbf{e}^S \cdot \delta\boldsymbol{\chi}_{\mathbf{Q}} \bullet \mathbf{e}^I|^2 \langle |\xi_\alpha(\mathbf{q})|^2\rangle_{th} \times \delta[\omega - (\omega^I + \omega_\alpha(\mathbf{q}))] \tag{72}$$

for anti-Stokes scattering. For Stokes scattering one has just to replace $\omega^I + \omega_\alpha(\mathbf{q})$ with $\omega^I - \omega_\alpha(\mathbf{q})$ in the argument of the delta function. In the classical limit, valid for Brillouin scattering, $\langle |\xi_\alpha(\mathbf{q})|^2\rangle_{th} \propto k_B T/\omega_\alpha^2(\mathbf{q})$. In all practical applications the delta function is substituted by a Lorentzian line shape centered at $\omega^I \pm \omega_\alpha(\mathbf{q})$ (Brillouin doublet) with a FWHM related to the lifetime of the phonon and to instrumental and opacity broadening [206]; $\mathbf{e}^I$ is the polarization of the incident electric field. In Eq. (72)

$$\delta\boldsymbol{\chi}_{\mathbf{Q}} = \int_V \delta\boldsymbol{\chi}(\mathbf{r}')e^{-i\mathbf{Q}\cdot\mathbf{r}'}\, d\mathbf{r}' \tag{73}$$

is the Fourier transform of index $\mathbf{Q}$ of the spatial part of the susceptibility tensor fluctuation, the transferred wave vector $\mathbf{Q}$ being always defined as

$$\mathbf{Q} = \mathbf{k}^S - \mathbf{k}^I \tag{74}$$

Because the bulk phonon wave function (54) is a plane wave $\propto e^{i\mathbf{q}\cdot\mathbf{r}}$, computing $\delta\boldsymbol{\chi}_{\mathbf{Q}}$ we get

$$\delta\boldsymbol{\chi}_{\mathbf{Q}} \propto \int_V e^{-i(\mathbf{Q}-\mathbf{q})\cdot\mathbf{r}'}\, d\mathbf{r}' \propto \delta(\mathbf{Q}-\mathbf{q}) \tag{75}$$

that is, the wave vector conservation (62). The fact that $\mathbf{Q}$ must be equal to the phonon wave vector $\mathbf{q}$ to have a peak in the spectrum is typical of Brillouin scattering by bulk phonons in transparent materials. The partial relaxation of this rule in the case surface waves and/or of opaque media is one of the most characteristic points in the theory of surface Brillouin scattering [206]. Summarizing the main results that can be obtained from a detailed analysis of Eqs. (72), (18), and (70) (a) the light scattered by transverse phonons is completely depolarized; (b) there is no scattering by transverse phonons polarized in the scattering plane; (c) the intensity of scattering from transverse phonons goes to 0 in back scattering; (d) scattering by longitudinal phonons is fully polarized, that is, keeps the polarization of the incident wave.

6.6. Surface Brillouin Scattering

Surface Brillouin scattering (SBS) became a practical spectroscopic technique about 30 years ago due to the great progress made in Fabry Perot interferometry by Sandercock [206]. Because the formal theory of surface Brillouin scattering is rather complex and usually involves cumbersome computations both of the phonon density of states and of the scattering cross section [205], qualitatively only the main characteristic conclusions that can be drawn from Eq. (18) are outlined here. First of all, the finite penetration depth of light in the material (e.g., about 1000 nm in Si and only a few nanometers in Al at $\lambda_0 = 514$ nm, the typical wavelength of an argon laser) profoundly modifies the wave vector conservation law (62).

The skin depth of the light being δ, the effective scattering volume is limited in the direction z perpendicular to the surface within a length of the order of δ that can be less than the light wavelength $\lambda \approx |n\mathbf{k}^I|^{-1}$. We can then define a complex transferred wave vector $\mathbf{Q} = Q_\parallel \hat{\mathbf{e}}_x + (Q_\perp - i\delta^{-1})\hat{\mathbf{e}}_z$ to be used in Eq. (18). Moreover, taking into account that the phonon wave function of a true surface wave is proportional to

$$e^{iq_\parallel x} \sum_n b_n e^{-\kappa_{\alpha n} z}$$

with κ_α of the same magnitude as $q_\parallel$, from Eq. (18) it is found that

$$\delta\boldsymbol{\chi}_{\mathbf{Q}} \propto \delta(Q_\parallel - q_\parallel) \sum_n \frac{b_n}{\kappa_{\alpha n} + \delta^{-1} + iQ_\perp} \tag{76}$$

Due to the absence of $q_{\perp n}$ in the imaginary part of the denominator, only parallel wave vector conservation can occur even in the case of very low opacity. Introducing θ_i as the incidence angle and θ_s as the angle (positive in the clockwise direction) between the outgoing surface normal and the scattering direction and considering that $Q_\parallel = \pm q_\parallel$, we find

$$|\mathbf{k}^I|(\sin\theta_s - \sin\theta_i) = \pm q_\parallel \tag{77}$$

which is the fundamental kinematic relation of SBS. In backscattering, as $\theta_s = -\theta_i$, we obtain

$$\omega_{n\alpha} = v_{n\alpha}\frac{4\pi}{\lambda_0}\sin\theta_i \tag{78}$$

where $\omega_{n\alpha}$ is the Brillouin shift of a surface peak, $v_{n\alpha}$ is the phase velocity of the surface phonon responsible for the SBS event, and $q_\parallel = (4\pi/\lambda_0)\sin\theta_i$ is the allowed wave vector. Then, in backscattering, the SBS peak shifts of nondispersive SAWs (e.g., the Rayleigh wave) scale as the sine of the incidence angle, while the volume BS peak shifts of bulk phonons (Eq. (67)) do not depend on the angle. If the subsurface structure is not homogeneous but layered the surface waves are dispersive and $v_{n\alpha} = v_{n\alpha}(q_\parallel)$ in a nontrivial way for each different type of surface phonon [205]. The measurement of the dispersion relations is an effective way to measure the elastic constants of the surface once the density is known. The elasto-optic coupling is not the only SBS channel. A second scattering mechanism, the ripple effect,

can be operative if the phonons have a shear vertical polarization component [206]. In fact these phonons modulate the instantaneous shape of the free surface. The dynamically corrugated surface, depending on its reflectivity, scatters the incident light and, due to the Doppler effect, there appear scattered photons with frequencies shifted from ω^I. It turns out that the ripple scattering cross section is proportional to the power spectrum of the u_z displacement field computed at the surface ($z = 0$) and, thus, to $g_{SV}(\omega q_\parallel|0)$, the SV surface-projected phonon density of states [205, 208].

6.7. Thin Films and Multilayers: Localization of Surface and Pseudo-Surface Acoustic Phonons in Buried Layers

We have also seen that acoustic phonons, as optic phonons, can be confined (partially or totally) in limited regions of space in 3D and 2D. Here we focus our attention on 1D localization of surface acoustic phonons which can be measured by surface Brillouin scattering spectroscopy: in practice, this means phonon frequencies between 1 and 200 GHz. The characteristic length scale of such collective excitations falls in the range of a few hundreds of nanometers, a scale typical of VLSI microelectronics. In the particular case of shear horizontal (SH) surface acoustic phonons, the wave equation governing their displacement field produces a spectral problem showing strong analogies with the 1D quantum mechanics of spinless electrons. This case will be treated first.

The spectrum of long-wavelength surface acoustic phonons in opaque or semiopaque materials has been extensively investigated by means of Brillouin light scattering. Most of the studies have dealt with surface acoustic phonons polarized in the sagittal plane, defined by the surface phonon propagation wave vector, $\mathbf{q}_\parallel$, and the surface normal. For this type of excitation, light scattering occurs through the surface ripple and volume elasto-optic effect and the Brillouin scattering cross section, which depends on both these mechanisms, can show strong interference effects [218]. Until 1994 [200, 201] the case of SH phonons, that is, transverse phonons polarized in the plane of the surface perpendicularly to the sagittal plane, had received little attention, at least from the experimental point of view. Although a great deal of acoustic and geophysics literature exists about shear horizontal surface elastic waves [210] and although the corresponding mathematical treatment is easier than that needed to treat sagittal waves, SH thermal waves (phonons) have been considered sources of surface Brillouin scattering in a very limited number of papers and only in the case of supported films.

SH waves being polarized parallel to the surface, the mechanism of their interaction with the light is only the volume elasto-optic effect and no interference phenomena coming from scattering of the thermal surface ripple (as in the case of sagittal modes) can appear in the spectrum.

Calculations of Brillouin scattering cross sections for SH surface acoustic modes (in the discrete part of the spectrum these modes are called Love modes) have been performed by Bortolani et al. [220], by Albuquerque et al. [221], and Mayer [222], who performed a full quantum-mechanical computation of the cross section for dielectric layered media on a metallic substrate, but at that time these authors could not compare their theoretical predictions with any experimental data.

To our knowledge there are only two reported experimental works on the detection of SH surface acoustic phonons using Brillouin scattering. The first was conducted by Bell et al. [223] in Nb/Cu superlattices on a sapphire substrate. Those authors performed their measurements by detecting the tails of the acoustic modes in the sapphire substrate and gave no evidence of SH acoustic modes in the continuum part of the spectrum.

The second, by Bottani et al. [200], announced the observation of SH surface acoustic modes in both the discrete and continuum parts of the spectrum in silicon on insulator (SOI) structures (see Fig. 31). There the theory was limited to the computation of the LPPDS for the SH polarization and the Brillouin cross section was not evaluated.

Thin buried oxide (a-SiO_x) layers (BOX) have been prepared in recent years in crystalline silicon wafers by different techniques. Particularly interesting is the case of SOI-SIMOX structures (silicon on insulator structures obtained by separation of implanted oxygen techniques) analyzed by Ghislotti and Bottani [201].

In that paper the authors investigated surface Brillouin scattering in a silicon on insulator structure composed of a silicon dioxide layer buried in a Si(001) substrate. The structure was produced by low-dose oxygen implantation and subsequent high-temperature treatment of a Si(001) wafer.

The thicknesses of the buried oxide L and of the top silicon layer d were measured by cross-sectional transmission electron microscopy to be, respectively, either 110 and 350 nm, as in Bottani and Ghislotti [200], or 80 and 360 nm. Observations were conducted for phonons propagating both along $\langle 100 \rangle$ and $\langle 110 \rangle$.

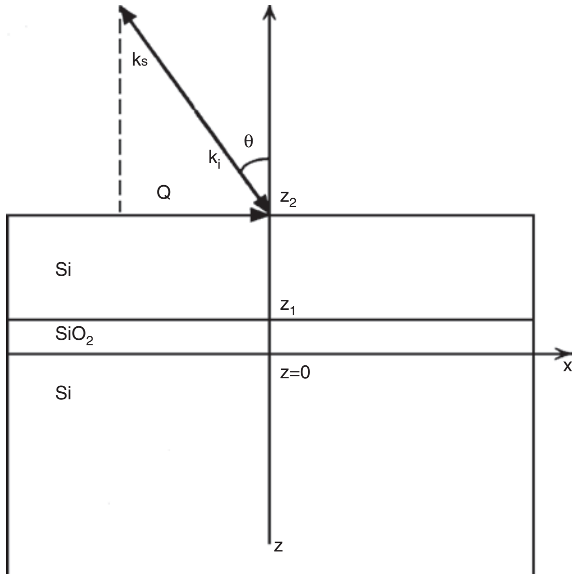

Figure 31. Silicon on an insulator structure: sample geometry and scattering configuration. The x axis is parallel to the surface phonon propagation wave vector, and the z axis is normal to the surface. Reprinted with permission from [177], P. Milani and C. E. Bottani, "Handbook of Nanostructured Materials and Nanotechnology" (Hari Singh Nalwa, Ed.) (2000). © 2000, Elsevier.

As far as acoustic phonon localization is concerned, the key physical point is that the buried layer has lower sound velocities than silicon: thus either the BOX or the Si–SiO_x bilayer acts as an acoustic wave guide for surface phonons with respect to the bulk Si substrate and depth-dependent confinement effects can be detected.

As the treatment of SH localization is the easiest one still showing quite general characteristics, we treat it in great detail and just briefly discuss the sagittal phonon case at the end. In this way the general features of surface Brillouin scattering, summarized in the introductory part, are fully exemplified.

(i) We discuss the spectrum of surface SH phonons in the SOI-SIMOX structure presenting the LPPDS for SH polarization.
(ii) We show the fluctuating polarization vector field P_y produced by elasto-optic coupling when SH phonons modulate the dielectric function of the medium. The knowledge of P_y implies the computation of the incident p-electric field transmitted in the body.
(iii) The theoretical results are compared with the experimental Brillouin spectra and an extension is made to sagittal phonons and their confinement behavior.

6.7.1. The Layer-Projected Spectral Density of SH Phonons

We assume that the vacuum–Si(001) interface coincides with the $z = 0$ plane and that the z axis points downward in the medium. The first Si/SiO_2 interface is at $z = d$ and the second SiO_2/Si interface is at $z = L + d$. For SH waves propagating along any direction parallel to the $y = 0$ plane (which is both the sagittal and the scattering plane in the experiments) the relevant displacement field component is then u_y. In particular Love waves, that is, true SH surface waves belonging to the discrete spectrum and exponentially decaying in the Si substrate, propagate along the x direction. We consider only $\langle 100\rangle$ and $\langle 110\rangle$ propagation directions for which the sagittal motion is decoupled from the SH one. The wave equation for u_y when the x axis coincides with the $\langle 100\rangle$ direction is written as

$$\rho(z)\frac{\partial^2 u_y}{\partial t^2} = C_{44}(z)\frac{\partial^2 u_y}{\partial x^2} + \frac{\partial}{\partial z}\left[C_{44}(z)\frac{\partial u_y}{\partial z}\right] \qquad (79)$$

where the functions $\rho(z)$ and $C_{44}(z)$ take within each layer the constant value of the mass density and C_{44} elastic constant of the corresponding material.

Since the system is translationally invariant in the x direction parallel to the surface, we introduce the $(\omega, q_\parallel)$ Fourier component of the u_y SH displacement field, the parallel wave vector $\mathbf{q}_\parallel = q_\parallel \hat{\mathbf{e}}_x$, as

$$u_y(\omega, q_\parallel; x, z, t) = \xi(\omega, q_\parallel)\phi_y(\omega, q_\parallel, z)\exp[i(q_\parallel x - \omega t)] \qquad (80)$$

where $\xi(\omega, q_\parallel)$ is the normal coordinate of the SH phonon $(\omega, q_\parallel)$. Introducing (80) in the wave equation (79) we obtain the self-adjoint Liouville equation [226]

$$\frac{d}{dz}\left[C_{44}(z)\frac{d\phi_y(\omega, q_\parallel, z)}{dz}\right] + [\rho(z)\omega^2 - C_{44}(z)q_\parallel^2] \times \phi_y(\omega, q_\parallel, z) = 0 \qquad (81)$$

The mode z profiles $\phi_y(\omega, q_\parallel, z)$ are the real eigenfunctions of Eq. (81) corresponding to the real eigenvalues $\omega^2 = \omega^2(q_\parallel)$, the SH phonon eigenfrequencies. The $\phi_y(\omega, q_\parallel, z)$s play, in the continuum model adopted here, the same role of the polarization unit vectors in lattice dynamics. A similar Liouville equation is obtained for the $\langle 110\rangle$ case substituting $\frac{1}{2}[C_{11}(z) - C_{12}(z)]$ to $C_{44}(z)$ as the multiplying coefficient of $q_\parallel^2$ in (81).

Using a slab approximation [224] to solve the above spectral problem (in this way the whole spectrum becomes discrete) we impose the normalization conditions [226]

$$\int_0^h \rho(z)\phi_y^2(\omega, q_\parallel, z)\, dz = 1 \qquad (82)$$

the slab thickness being $h \gg L + d$.

Also, we assume stress-free boundary conditions which are written in terms of the vanishing of the z derivatives of the mode profiles at both the slab outer surfaces

$$\left(\frac{d\phi_y(\omega, q_\parallel, z)}{dz}\right)_{z=0} = \left(\frac{d\phi_y(\omega, q_\parallel, z)}{dz}\right)_{z=d} = 0 \qquad (83)$$

Together with (82) and (83) Eq. (81) constitutes a well-posed singular (at least in the case of sharp interfaces) Sturm–Liouville eigenvalue problem [227] with strong analogies with 1D quantum mechanics.

In principle the spectrum of SH long-wavelength acoustic phonons in a semi-infinite (when the slab thickness d goes to infinity) layered medium is the union of a discrete and a continuous part. The latter starts at the transverse threshold of the Si substrate $\omega_t = c_t q_\parallel$, where c_t is the shear horizontal sound velocity of Si in the appropriate propagation direction. In fact, at fixed $q_\parallel$, only for $\omega > \omega_t$ the partial plane waves in the unbounded Si substrate have a real perpendicular wave vector $q_\perp = (\omega^2/c_t^2 - q_\parallel^2)^{1/2}$ as it must be for a nondecaying bulk wave. Thus, strictly speaking, only the discrete eigenvalues correspond to true surface modes or Love waves (bounded states or resonances). Yet in the continuous spectrum (where the mode profiles are not decaying in the substrate, corresponding to SH bulk waves reflecting at the surface) one can also find considerable structure of surface character or pseudo-Love waves (quasi-resonances or pseudo-surface modes). These last vibrational states share some formal properties with virtual states in the continuum found in quantum scattering theory.

The adoption of the slab approximation produces only a discrete spectrum but the (still infinite but now numerable) eigenfrequencies separate into two classes: a limited number of eigenvalues with $\omega < \omega_t$ still correspond to the Love waves, while all the other eigenvalues tend to accumulate from above toward ω_t and build a quasi-continuous spectrum provided the slab is sufficiently thick. It is then possible to compute the density of phonon states and to simulate in this way the true continuous spectrum of a semi-infinite medium.

The more or less surface character of these collective excitations can be judged from inspection of the LPPDS for the SH polarization

$$g_{yy}(\omega, q_\parallel | z, z') = \sum_\alpha \sqrt{\rho(z)\rho(z')}\,\phi_y(\omega_\alpha(q_\parallel), q_\parallel, z) \times \phi_y(\omega_\alpha(q_\parallel), q_\parallel, z')\delta[\omega - \omega_\alpha(q_\parallel)] \qquad (84)$$

computed for $z = z'$

$$g_{yy}(\omega, q_\parallel|z, z) = \sum_\alpha \rho(z)\phi_y^2(\omega_\alpha(q_\parallel), q_\parallel, z)\delta[\omega - \omega_\alpha(q_\parallel)] \quad (85)$$

Although in general $g_{yy}(\omega, q_\parallel|z, z')$ in the case of Brillouin light scattering is not directly related to the cross section as it is instead in the case of low energy electron surface scattering [224], this quantity is, in any case, useful in investigating the surface localization of the phonon modes (see below).

Introducing the retarded and advanced Green functions of Eq. (81) $G_{yy}(\omega \mp i\epsilon, q_\parallel; z, z')$ as the solutions of the nonhomogeneous equation

$$\frac{d}{dz}\left[C_{44}(z)\frac{dG_{yy}}{dz}\right] + \left[\rho(z)(\omega \mp i\epsilon)^2 - C_{44}(z)q_\parallel^2\right]G_{yy} = \delta(z - z') \quad (86)$$

with the same boundary conditions as for the ϕ_y, a smooth representation $\bar{g}_{yy}(\omega, q_\parallel|z, z)$ of the LPPDS for SH phonons can be obtained as

$$\bar{g}_{yy}(\omega, q_\parallel|z, z) = \frac{\rho(z)}{2\pi i}[G_{yy}(\omega - i\epsilon, q_\parallel; z, z) - G_{yy}(\omega + i\epsilon, q_\parallel; z, z)] \quad (87)$$

Once a sufficiently high number of eigenfrequencies and eigenfunctions of Eq. (81) has been obtained numerically [200] the Green functions can be computed by means of the spectral expansion [226]

$$G_{yy}(\omega \mp i\epsilon, q_\parallel; z, z) = \sum_\alpha \frac{\phi_y^2(\omega_\alpha(q_\parallel), q_\parallel, z)}{(\omega \mp i\epsilon)^2 - \omega_\alpha^2(q_\parallel)} \quad (88)$$

6.7.2. Electromagnetic Wave Equations for the Incident and Scattered Fields for p–s Scattering

Neglecting thermal fluctuations silica and crystalline silicon have isotropic dielectric properties. The perturbation caused by long-wavelength acoustic phonons can be accounted for by means of an istantaneous anisotropic susceptibility (see above), a second order tensor the components of which are linear functions of the fluctuating elastic strains. Because of dispersion a simple constitutive law relating the polarization vector **P** to the electric field can be written only for monochromatic components. Taking into account the linearity of Maxwell equations and the smallness of thermal elastic strains the electromagnetic problem can be solved by first order perturbation theory (the Born approximation in scattering theory) [218].

At 0th order (neglecting the fluctuating part of the susceptibility and thus the scattered field) the electric field $\mathbf{E}^{\omega_0}(x, z)$ transmitted in the medium can be conveniently computed in terms of the y component of the magnetic induction field $B_y^{\omega_0}(x, z) = e^{i(k_\parallel x)}B(z)$, where $k_\parallel = (2\pi/\lambda)\sin\theta_i = (\omega_0/c)\sin\theta_i$ is the component parallel to the surface of the wave vector of the incident wave [228]. $B(z)$ satisfies the ordinary differential equation

$$\frac{d}{dz}\left(\frac{1}{\epsilon(z)}\frac{dB}{dz}\right) + \left(\frac{\omega_0^2}{c^2} - \frac{k_\parallel^2}{\epsilon(z)}\right)B = 0 \quad (89)$$

where $\epsilon(z)$ is the z profile of the complex relative dielectric function of the structure at frequency ω_0. In the ideal case $\epsilon(z)$ has a finite jump at each interface where the continuity of $B(z)$ and $\epsilon^{-1}(z)(dB/dz)$ is imposed and keep a constant value in each layer. In particular in the vacuum $(z < 0)$ above the surface $B(z) = (E_0/c)(e^{i(k_\perp z)} - r_p e^{-i(k_\perp z)})$, E_0 being the electric field amplitude of the incident p wave, $k_\perp = (\omega_0/c)\cos\theta_i$ is the component perpendicular to the surface of the wave vector of the incident wave and r_p the reflection coefficient. Once $B(z)$ has been computed $E_x^{\omega_0}(x, z)$ and $E_x^{\omega_0}(x, z)$ can be obtained as [228]

$$E_x^{\omega_0} = -i\frac{c^2}{\omega_0\epsilon(z)}\frac{\partial B_y^{\omega_0}}{\partial z} = -i\frac{c^2}{\omega_0\epsilon(z)}\frac{dB}{dz}e^{i(k_\parallel x)} \quad (90)$$

$$E_x^{\omega_0} = i\frac{c^2}{\omega_0\epsilon(z)}\frac{\partial B_y^{\omega_0}}{\partial x} = -\frac{c^2 k_\parallel}{\omega_0\epsilon(z)}B(z)e^{i(k_\parallel x)} \quad (91)$$

Now the next step is to compute the fluctuating part of the polarization vector in the medium. The first order result in perturbation theory is

$$P_i^{\omega_s} = \epsilon_0(\epsilon(z) - 1)E_i^{\omega_s} + \epsilon_0\delta\chi_{ij}(\omega_0| \pm \omega_\alpha(q_\parallel))E_j^{\omega_0} \quad (92)$$

In the above equation $\epsilon(z) - 1 = \chi(z)$ is the unperturbed isotropic susceptibility in the absence of phonons (because $\omega_\alpha(q_\parallel) \ll \omega_0$ we assume that $\epsilon(z|\omega_0 \pm \omega_\alpha(q_\parallel)) \approx \epsilon(z|\omega_0) = \epsilon(z)$ and $\delta\chi_{ij}(\omega_0| \pm \omega_\alpha(q_\parallel))$, the anisotropic fluctuating part of the susceptibility due the excitation of a single SH $(\omega_\alpha(q_\parallel), q_\parallel)$ phonon mode. The second term in the r.h.s. of Eq. (14) is responsible for the radiation of the Brillouin light, that is, of the scattered field $\mathbf{E}^{\omega_s}$ at frequencies $\omega_s = \omega_0 \pm \omega_\alpha(q_\parallel)$.

Taking explicitly into account the elasto-optic coupling one finds that the part of the fluctuating polarization vector radiating the scattered field has only one component $(P_y^{\omega_s})_R$ which can be written in terms of the fluctuating thermal elastic strains

$$u_{yx} = (1/2)[\partial u_y(\omega_\alpha, q_\parallel)/\partial x]$$

and

$$u_{yz} = (1/2)[\partial u_y(\omega_\alpha, q_\parallel)/\partial z]$$

as [200]

$$(P_y^{\omega_s})_R = \epsilon_0 k_{44}(z)[u_{yx}(\omega_\alpha, q_\parallel)E_x^{\omega_0} + u_{yz}(\omega_\alpha, q_\parallel)E_z^{\omega_0}] \quad (93)$$

for $\langle 100\rangle$, and as

$$(P_y^{\omega_s})_R = \epsilon_0\left[\frac{1}{2}(k_{11}(z) - k_{12}(z))u_{yx}(\omega_\alpha, q_\parallel)E_x^{\omega_0} + k_{44}(z)u_{yz}(\omega_\alpha, q_\parallel)E_z^{\omega_0}\right] \quad (94)$$

for ⟨110⟩, where the $k_{ij}(z)$ are the z profiles of the relevant elasto-optic coefficients. Thus Brillouin scattering of an incident p electromagnetic wave of a pure SH phonon produces a scattered s electromagnetic wave, that is, scattering rotates the polarization of 90°.

With the source of Eqs. (4.15) and (4.16) the radiation problem can be solved and the Brillouin cross section computed.

6.7.3. Experimental Results and Discussion of SH Phonon Localization

A Brillouin spectrum taken along ⟨100⟩ at $\theta = 40°$ is presented in Figure 32. Only fully depolarized light was measured (p–s scattering). Two peaks are clearly visible: they were identified as being due to scattering from SH acoustic modes. If only fully polarized light (p–p scattering) were measured a third different peak of sagittal character, due to the Rayleigh wave propagating at the free surface, would be observed alone in the same spectral region (see below [232, 233]). Only the elasto-optic coupling mechanism gives contribution to the p–s cross section.

The solid line in Figure 32 is the calculated p–s Brillouin differential cross section convoluted with a Gaussian of FWHM of 200 MHz to simulate the finite experimental spectral resolution. In the calculation the authors used the dielectric (ϵ), elastic (C_{ij}), and elasto-optic constants of bulk Si and SiO_2. The Si constants are $\epsilon = 18.5 + 0.52i$, $C_{11} = 166$ GPa, $C_{12} = 63.9$ GPa, $C_{44} = 79.6$ GPa, $K_{11} = 53.2$, $K_{12} = 25.0$, $K_{44} = 23.4$, $\rho = 2330$ kg^{-3}. The SiO_2 constants are $\epsilon = 2.16$, $C_{11} = 78.5$ GPa, $C_{44} = 31.2$ GPa, $K_{11} = -0.55$, $K_{44} = 0.345$, $\rho = 2200$ kg^{-3}. The theory does not contain any free parameter.

The experimental spectra show an increase in the magnitude of the lower frequency peak relatively to the higher one for decreasing incidence angles. This is in agreement with the calculated intensities and can already be explained by the analysis of plots of the LPPDS as a function of depth and frequency computed at the same angles of incidence (see below).

In Figure 33 a contour plot of $g_{yy}(\omega, q_\parallel|z, z)$ is shown for a parallel wave vector $q_\parallel \approx 0.0157$ nm^{-1}. Since in a surface Brillouin scattering event the total parallel wave vector of the photon–phonon system is conserved and these experiments where conducted in backscattering (see above), $q_\parallel = (4\pi/\lambda)\sin\theta_i$, where $\lambda = 514.5$ nm was the wavelength in a vacuum of the incident photon and θ_i the incidence angle. In the case of Figure 33 this corresponds to $\theta_i = 40°$. Inspection of Figure 33 shows clearly the nature of the guided mode of the Love wave below ω_t. The mode is highly localized within the silica buried layer whose transverse sound velocity is lower than that of silicon. Also clearly visible is the pronounced surface character of the pseudo-mode in the continuum above ω_t. In Figure 34a the surface-projected SH phonon density of states $SPPDS = g_{yy}(\omega, q_\parallel|0, 0)$ is shown for four different values of θ_i (or $q_\parallel$). It can be seen that the Love wave tends to become less confined in the silica layer for small $q_\parallel$ (its surface intensity increases), while the pseudo-Love wave has the highest surface intensity for $\theta_i \approx 40°$. In Figure 34b $g_{yy}(\omega, q_\parallel|z, z)$ is shown for $z = 400$ nm about in the middle of the silica layer. Only the peaks corresponding to the Love wave are clearly visible. One can see the increasing of the peak amplitude as $q_\parallel$ increases: the mode becomes more and more confined (guided) in the silica layer.

Figure 35 shows the mean square value of $(P_y^{\omega_s})_R$ corresponding to $\theta_i = 40°$ when either the Love mode is excited (the first phonon eigenvalue: the unique in the discrete spectrum for our geometry) or the pseudo-mode in the continuum at a frequency corresponding to the second peak in Figure 32.

Although the Love wave is essentially a wave guided in the silica buried layer, it is evident that the source of the Brillouin light is mainly located in the subsurface Si layer. This is due to the fact that the k_{44} elasto-optic coefficient of Si is much bigger than the corresponding quantity of silica

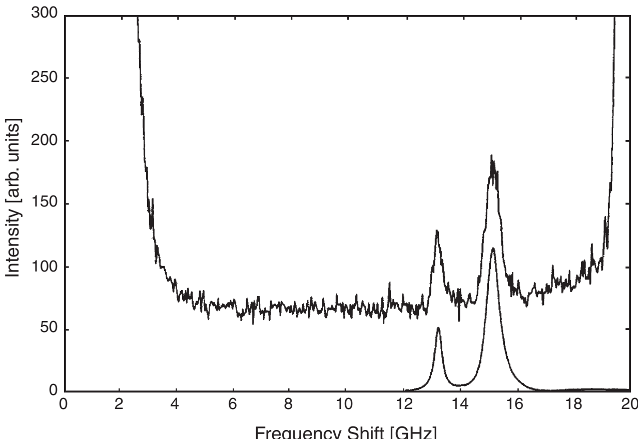

Figure 32. Measured p–s Brillouin anti-Stokes spectrum (top line) and theoretical p–s cross section (bottom line) along ⟨100⟩ for $\theta_i = 40°$. The peak tail immediately at the right of 0 shift belongs to the laser line, while that growing near 20 GHz is due to an instrumental ghost of the interferometer. Figure 35. Mean square polarization radiating the Brillouin light vs z at the frequency of the Love (full line) and of the pseudo-Love (dashed line) waves for $\theta_i = 40°$ and propagation direction $\langle 100 \rangle$. It is seen that the source of the Brillouin light is confined in the top Si layer immediately below the surface. Reprinted with permission from [177], P. Milani and C. E. Bottani, "Handbook of Nanostructured Materials and Nanotechnology" (Hari Singh Nalwa, Ed.) (2000). © 2000, Elsevier.

(see above) and because the incident electric field transmitted in the medium is maximum there. This is even more true for the pseudo-Love wave (in the continuous spectrum) the mode profile of which has a strong surface character. The exponential vanishing of the source for $z \to \infty$ in the Si substrate is simply explained in terms of the vanishing of $B(z)$ due to absorption and leads to the conservation of only the parallel total wave vector in the scattering integral (see below).

The theory presented above was generalized by Bottani and Caporali [202] and by Caporali et al. [203] to include the effect of smooth interfaces and, more in general, of layers with nonuniform acousto-optic properties.

6.7.4. Experimental Results and Discussion of SV and L Phonon Localization

The buried oxide and the bilayer made by top silicon and buried oxide (as well as any other system with similar acoustic properties) can also partially confine (localize) sagittal phonons visible in a p–p scattering experiment. Here the phenomenology is richer for, even along a high symmetry direction, the propagation of such phonons must be described with a two-component displacement vector (u_x, u_z) obeying a system of coupled wave equations. This rules out the analogy with simple scalar 1D quantum mechanics and requires a specific treatment of the spectral problem. The u_x component has a longitudinal (L) character, while the u_z component has a shear vertical (SV), transverse, character. Among sagittal pseudo-surface phonons a special role is played by the HFPSW (high-frequency pseudo-surface wave), or LR (longitudinal resonance), in the continuous spectrum and by the Rayleigh and Sezawa phonons in the discrete spectrum. The LR is a pseudomode of L character propagating along a free surface with a phase parallel velocity $\omega_{LR}/q_\parallel = v_L$ coinciding with the longitudinal bulk velocity. If the surface has a slower overlayer the LR tends to be confined in the overlayer and is called the longitudinal guided mode. The SOI-SIMOX structures have a bilayer on the top of the silicon wafer and the buried oxide is slower than both top and bulk silicon. This produces quite intricate Brillouin spectra in the continuum. The Rayleigh phonon is a true surface wave of both SV and L character. It exists beneath pure free surfaces and also survives in the presence of an overlayer: in this case it is called a modified Rayleigh wave. If the overlayer is slower than the substrate other guided true surface phonons can exist at higher frequencies: they are called Sezawa waves. We notice that for the SH polarization there are no true surface waves beneath pure free surfaces below the transverse threshold: a slower overlayer is required for their existence (the modified Love waves; see above). In SOI-SIMOX structures a mixing of Rayleigh and Sezawa waves can take place, giving rise to peculiar Brillouin spectra even in the discrete. The theory of Brillouin scattering from sagittal surface waves in buried oxides is due to Byloos et al. [231], while the first experiments are due to Nizzoli et al. [232] and Ghislotti et al. [233]. Figures 36 and 37 show experimental spectra and theoretical cross sections

Figure 36. (a) Anti-Stokes Brillouin spectra for different incidence angles taken along ⟨100⟩ in p–p polarization. (b) Theoretical cross sections evaluated at the same incidence angles. at various incidence angles and for different BOX thicknesses. The localization of the observed phonons is shown for both SV and L polarization in Figure 38 by means of the spectral function LPPDS. In this figure it is evident that each mode (phonon) has a peculiar localization behavior: the confinement is more prominent in the top overlayer, or in the buried oxide, or in the substrate. This observation suggested the idea of using the measured dispersion relationships of each mode to get space-resolved information on real imperfectly layered structures. For a general review of Brillouin scattering in supported films the reader is invited to consult Nizzoli and Mills [215]. In the case of buried layers the space-selective propagation properties of surface acoustic phonons were used by Ghislotti et al. [234] and Beghi et al. [235] to detect the presence of silicon inclusions in the BOX and to measure their concentration in a completely nondestructive way. The results were confirmed by TEM.

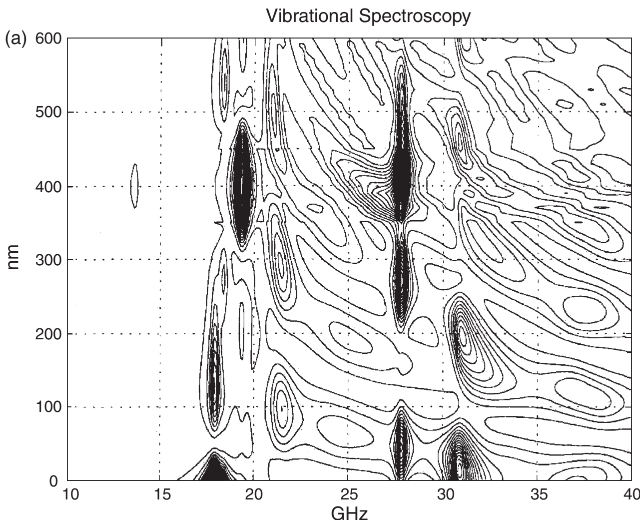

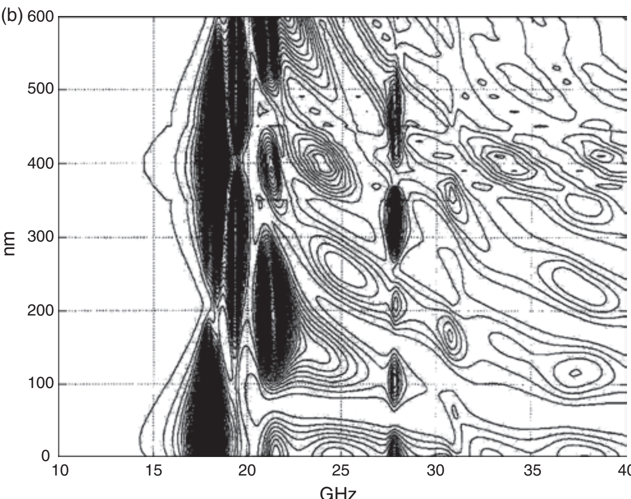

Figure 38. LPPDS for sagittal phonons of a SOI-SIMOX structure: the buried oxide layer is situated between 350 and 450 nm of depth. (a) Longitudinal polarization; (b) shear vertical polarization. When examining the ability of surface Brillouin scattering to measure local elastic constants of thin films two major observations are in order. First, the quality of the results depends strongly on the independent knowledge of the film density. Second, the thickness of the film must be known. To keep the whole procedure completely nondestructive Beghi et al. made an integrated use of Brillouin scattering, X-ray reflectivity, and high-resolution X-ray diffraction [205]. In this way it was possible to measure with great precision the small effect of alloying low Cu and Ni concentrations in a thin Au film on silicon. It is in any case worth noting that, for films with a thickness less than 1 μm, surface Brillouin scattering is the only nondestructive technique that can be used to measure the elastic properties of the film.

6.8. Surface Melting in Nanoparticle Films

The abrupt change in velocity in surface acoustic waves in thin films of amorphous SiO_x containing nanometer-scale β-Sn crystals has been shown to be directly associated with the size-dependent melting of the nanoparticles, thus confirming preliminary experiments. High-resolution thin film powder diffraction using synchrotron radiation has shown that the abrupt red shift in the Brillouin spectra satellites occurs at the same temperature as the melting of the nanoparticles, evident for the loss of the Bragg peaks. Effective medium theory has been used to explain the origin of the anomaly. A central peak in the Brillouin spectrum, the intensity of which showed a maximum at the melting temperature, can be interpreted in terms of overdamped fluctuations in the dielectric function. The melting temperature as a function of particle size is in agreement with theoretical predictions. No evidence of strain could be found the X-ray diffraction profiles, the *a* and *c* axis thermal expansion coefficients being the same as those in bulk tin [236, 237].

6.9. Carbon Mesostructures

Experimental characterization and theoretical modeling of cluster-assembled materials have to face the problem of cluster coalescence and of their organization in structures spanning length scales from the nanometer up to the micrometer. The different structures in which the precursor clusters are organized need experimental probes sensitive to the different length scales typical of intracluster and intercluster interactions. For carbon-based materials, as we have already discussed, Raman spectroscopy can be used for characterization on a nanometer scale [193]. In order to study the organization of clusters on a scale of hundreds of nanometers, which is the typical scale of thermally excited long-wavelength acoustic phonons, Brillouin light scattering was used for the first time by Bottani et al. [209]. Films of graphite, polycrystalline diamond, diamondlike a-C:H, C_{60} (fullerite), and phototransformed C_{60} have also been studied by Brillouin scattering [193]. Normally SBS is applied to homogeneous compact films with perfect (atomically flat) surfaces and buried interfaces [205]. Particularly challenging is instead the attempt to get and interpret Brillouin spectra of films with a rough surface and/or a granular or

porous structure. The extraction of the elastic properties of these systems from the spectroscopic data can be based only partially on what is known in the case of good films and a complete theory is still lacking. Bulk and surface Brillouin scattering- signals have been obtained from films characterized by a complex structure from the atomic to the hundreds of nanometers level, showing that this technique can also be used for nanostructured materials with irregular surfaces. Bulk and shear modulus of the material have been determined giving information on the acoustic properties on a mesoscopic scale. This allows us to infer the nature of the bonding between the carbon aggregates.

Thick films (thickness, $\geq 1\ \mu$m) and thin films (down to a thickness of 20 nm) have been examined. The results depend strongly on the presence (or the absence) of a beam focalizer selecting (or not) only clusters of small size for deposition [210].

6.9.1. Films Grown by an Unfocused Beam

In thick films only damped bulk acoustic phonons with a typical wavelength λ_{ph} of the order of 170 nm have been detected. This indicates that for a length $d \geq \lambda_{ph}$ the film bulk can be modeled as a continuum [196] with approximate translational invariance and effective elastic constants, although structural disorder at smaller scales scatters the phonons significantly. The presence of a rather strong central peak in the spectra could be ascribed to nonpropagating (overdamped) or confined vibrational excitations, probably connected with different characteristic correlation lengths less than d. The most damped bulk acoustic phonons could be coupled to the confined modes by a relaxation mechanism. The surface phonons could be almost overdamped if not already replaced by surface fractons or by localized cluster modes [211]. Instead in thinner films, notwithstanding the high degree of surface roughness, which increases with film thickness, intense surface peaks can be detected up to a critical thickness of the order of 200 nm (Fig. 39). To make the SBS spectrum measurable the films must be grown on a ultrasmooth high-reflecting substrate to maximize the buried interface ripple scattering [212].

Bottani, "Mechanical Properties of Low Dimensional Carbon Structures," "Nanostructured Carbon for Advanced Applications" (G. Benedek, P. Milani, and V. G. Ralchenko Eds.). 2001. © 2001, Kluwer Academic.

6.9.2. Films Grown by a Focused Beam

Films with a completely different nanostructure, more compact and with a smoother surface, can be grown using the focalization device. Typical spectra of a focalized thick film (1 μm) are shown in Figure 40. The study of a thick film with respect to a thin film gives an advantage: we can consider the film a semi-infinite medium and so the nature and the characteristics of the acoustic waves propagating in the system are not affected by the thickness (often not known with enough accuracy) and thus by the presence of the substrate.

Figure 40 shows the Brillouin spectra of a focalized thick film taken at two different angles of incidence, $\theta_i = 50°$ and $\theta_i = 70°$. The shift in the first two peaks scales with θ_i: both peaks belong to the surface spectrum. The first peak corresponds to a Rayleigh phonon (RW) and the second, the LR, is a general feature of the continuous spectrum whose shift scales as $v_l 4\pi \sin\theta_i/\lambda_0$. The LR is a so-called pseudo-surface phonon. It is a wave packet of bulk phonons with a strong surface localization of the longitudinal polarization behaving as a surface wave. Because of its longitudinal character it gives no contribution to ripple scattering. The third peak is due to a longitudinal bulk phonon whose shift is independent of θ_i and scales as $v_l 4\pi n/\lambda_0$. In the small inset boxes the fit of the $\theta_i = 50°$ spectrum is shown: the numerical simulation of the scattering total cross section (line) is superimposed to the experimental points in the right box, while in the left one the RW peak (discrete spectrum) was fitted separately with a pseudo-Voigt function. These spectra are interesting mainly for the high intensity and small width of the Rayleigh peak, never observed before in cluster-assembled carbon films. This feature supports the conclusion that long life acoustic phonons can propagate along the film surface; in other words, at a mesoscopic scale of observation this film appears as a homogeneous elastic continuum

and the relatively low surface roughness, acting as surface structural disorder, introduces only a small acoustic damping factor without hindering the phonon propagation (as in the case of nonfocalized films). This fact is consistent with a smooth surface film of compact material made of close-packed small clusters and it is important in comparison with the results of BS experiments on the deposited without beam focalization in which the surface roughness increases as the film thickness. These findings are confirmed measuring the SBS spectra of films of increasing thickness. The results are shown in Figure 41.

Here distinct surface peaks are clearly visible for thickness in the range of 50–400 nm. Measuring the dispersion relations of the surface phonons the elastic constants of the films can be estimated. The best results are obtained for the Young modulus E, as demonstrated by a detailed sensitivity analysis [213]. Using for the density ρ values coming from X-ray reflectivity [205] (all values are in the range 1–1.3 g/cm^3) the found elastic constants are, typically, of the order $c_{11} = 5.4$ GPa, $c_{44} = \mu = 2.5$ GPa, $E = 4.6$ GPa, $B = 1.9$ GPa, and $\nu = 0.1$. These values are comparable to those obtained from the thin films (thickness of about 100 nm or less) deposited with an unfocused beam [200]. In particular, they are near the values of the harder of this thin film series. The comparison with diamond elastic constants indicates a very soft and highly deformable material with a shear modulus (for shear between graphene planes) near that of graphite. These results can be compared with Raman measurements [208] which point out the mainly sp^2 carbon bonding present in the disordered granular structure of the films on a nanometer scale. Yet the film material is not elastically identical to nanocrystalline graphite: in fact the values of B (and, consequently, ν) are significantly different.

1. INTRODUCTION

Raman spectroscopy is a realisation of inelastic light scattering. This implies that upon irradiation of a sample with monochromatic light the scattered light contains components with a characteristic frequency shift. This effect is due to the generation or annihilation of an elementary excitation (e.g., a lattice vibration) in the sample. It was predicted by Smekal (1923) and was first observed by Raman, Landsberg, and Mandelstam (1928). The first experiments were carried out using focused sunlight and filters and relied on the visual observation of color changes in the scattered light.

The Raman effect is an inherently weak effect, typically below 10^{-10} of the intensity of the exciting light. Therefore, in the early years, limited light source intensity and stability and the cumbersome detection of weak signals made Raman spectroscopy extremely difficult. It was not until the 1960s that the modern Raman renaissance started. This revival was triggered by the availability of commercial visible laser light sources (ion lasers with a series of laser lines at fixed wavelengths, and soon afterward also frequency-tunable lasers) and computer-controlled novel spectrometers with sensitive detection systems (photomultipliers, and more recently diode arrays and charge coupled devices).

In this way its sensitivity was substantially enhanced, and meanwhile Raman spectroscopy has achieved the ability to detect single monolayers (e.g., at surfaces and interfaces) and quantum dots, which are the focus of this chapter. The enhanced sensitivity also opened the path to a strongly improved lateral resolution: micro-Raman spectroscopy.

The main reason for the widespread utilization of Raman spectroscopy is its ability to analyze a broad variety of different sample properties. It is used, for example, for the identification of materials, to study their chemical composition, crystalline perfection, crystallographic orientation, strain, doping, and intermixing, as well as carrier-depleted layers and electric fields at surfaces and interfaces. The study of all these aspects essentially relies on the lattice dynamics. The eigenfrequencies, frequency broadening, and Raman scattering efficiencies of the vibrational eigenmodes are characteristically influenced by the properties listed above.

The analysis of all these properties is performed in a nondestructive way and without the requirement of a special sample preparation. The information depth can by tuned by applying different excitation wavelengths, allowing one to derive information from the sample surface as well as from deeper regions and interfaces. It will be shown below that this technique even can be applied for *in-situ* online analysis during epitaxial growth.

A general survey of theory and experiments of Raman scattering is given in various books and articles (e.g., [1–3]). A very detailed description of the achievements in light scattering in solids is presented in a series of eight volumes, edited by Güntherodt and Cardona [4]. It comprises, for example, a review on Raman scattering from surface phonons [5]. Moreover, it should be noted that besides its widespread application for research purposes, Raman spectroscopy also has revealed its broad potential for industrial applications [6].

The first part of this review of Raman spectroscopy on II–VI semiconductor interfaces and nanostructures (Sections 2 to 4) deals with general aspects required for appreciating

the discussion of interfaces and nanostructures in the second part (Sections 5 and 6). The general part starts with a brief survey of the fundamentals of Raman spectroscopy in Section 2 and a description of the experimental equipment (Section 3). Subsequently, Section 4 contains the discussion of the detection of bulk crystal lattice properties by Raman spectroscopy, with special emphasis to crystalline perfection and orientation, composition of mixed compounds, and the effects of doping and strain, which are relevant aspects for the analysis of interfaces and nanostructures.

In the second part of this review, first the consequences of size restriction by interfaces are discussed for single interfaces and (multi)-quantum wells in Section 5.

For single interfaces, first vibrational modes of interfaces are treated: chemical vibrational modes due to the specific interface bonds, as well as dielectric vibration modes due to the different dielectric constants of adjacent materials. The second single-interface phenomenon which can be studied by Raman scattering is electronic band bending due to charge trapping or exchange at interfaces of doped materials.

For multiple-layer systems such as (multi)-quantum wells and superlattices, qualitatively new phenomena are discussed:

(i) confined optical phonons, which give Raman spectroscopic access to the whole Brillouin zone;
(ii) folded acoustic phonons, which enable Raman scattering from the acoustic branch.

Section 6 deals with chemically produced dots, etched quantum wires, and dots, as well as self-organized dots. Common items of interest for all these systems are chemical composition, strain effects, and local strain gradients. Furthermore, essential properties are the average dot size and the size homogeneity, which also can be addressed by Raman spectroscopy. When studying these aspects, for very small dots also confinement effects have to bes considered.

In addition, quantum dot Raman studies of various items of fundamental physics are discussed, such as the size dependence of the electron–hole exchange interaction in the exciton, and the extension of the electronic wavefunctions beyond the nanostructure edges. Numerous examples are presented from binary, ternary, and quaternary II–VI compounds (e.g., ZnSe, $ZnSe_{1-x}S_x$, $Zn_{1-y}Mg_ySe_{1-x}S_x$, $Cd_xZn_yMg_{1-x-y}Te$), from interfaces between different combinations of II–VI compounds (e.g., ZnSe/BeTe, CdSe/BeTe, CdTe/ZnTe), as well as II–VI/III–V interfaces (e.g., ZnSe/GaAs and CdTe/InSb), and from various II–VI nanostructure systems (e.g., ZnCdSe/ZnSe wires, CdS, CdSe, and CdS_xSe_{1-x} dots, and fractional CdSe monolayers), produced with the different techniques mentioned above.

2. FUNDAMENTALS OF RAMAN SPECTROSCOPY

In this section the description of the theory of Raman scattering is confined to a brief treatment of its fundamentals, followed by several selected aspects, which are of direct relevance for its application to surfaces, interfaces, and quantum dots. Such aspects are, for example, symmetry-induced selection rules, resonant Raman scattering, analysis of intermixing, strain, and doping.

The fundamentals of the Raman scattering process can be described either by a macroscopic theory, based on the concept of a generalized dielectric susceptibility (see Section 2.1), or by a microscopic quantum-mechanical theory, based on electron–photon and electron–phonon coupling (see Section 2.2).

2.1. Susceptibility Theory

In the Raman scattering process a frequency shift of the scattered light with respect to the incident light occurs. The reason for this peculiar optical behavior of the sample can be of various natures, for example, a lattice vibration [mostly optical phonons: longitudinal-optical (LO) or transverse-optical (TO)], a lattice vibration coupled to a collective electronic excitation (plasmon–LO–phonon mode), etc.

The inelastic scattering of light can be described phenomenologically by a generalized dielectric susceptibility $\chi(\omega_i, \omega_s)$, which is also called the transition susceptibility. It connects the incident electric field $\mathbf{E}_{i\beta}(\omega_i)$ with the resulting polarization $\mathbf{P}_{s\alpha}(\omega_s)$,

$$\mathbf{P}_{s\alpha}(\omega_s) = \varepsilon_0 \chi_{\alpha\beta}(\omega_i, \omega_s)\mathbf{E}_{i\beta}(\omega_i) \tag{1}$$

where α and β denote the directions of the fields. It is the modulation of this susceptibility by, for example, a lattice vibration, which induces the inelastic light scattering. In the quasi-static approximation the susceptibility is defined for every instantaneous atomic displacement, and the modulation of $\chi(\omega_i, \omega_s)$ by lattice vibrations can be described by a Taylor series in terms of vibration normal modes j with amplitude Q_j, wavevector $\mathbf{q}_j$, and angular frequency ω_j [2]:

$$\chi_{\alpha\beta}(\omega_i, \omega_s) = \chi^0_{\alpha\beta}(\omega_i, \omega_s) + \chi^1_{\alpha\beta}(\omega_i, \omega_s) + \chi^2_{\alpha\beta}(\omega_i, \omega_s) + \cdots \tag{2}$$

where

$$\chi^0_{\alpha\beta}(\omega_i, \omega_s) = \chi^0_{\alpha\beta}(\omega_i)$$

$$\chi^1_{\alpha\beta}(\omega_i, \omega_s) = \sum_j Q_j \cdot \left(\frac{\partial \chi_{\alpha\beta}(\omega_i, \omega_s)}{\partial Q_j}\right) + \sum_j Q_j \cdot q_j \cdot \left(\frac{\partial^2 \chi_{\alpha\beta}(\omega_i, \omega_s)}{\partial Q_j\, \partial q_j}\right) + \sum_{j,\gamma} Q_j \cdot E_\gamma \cdot \left(\frac{\partial^2 \chi_{\alpha\beta}(\omega_i, \omega_s)}{\partial Q_j\, \partial E_\gamma}\right) + \cdots$$

$$\chi^2_{\alpha\beta}(\omega_i, \omega_s) = \sum_{j,j'} Q_j Q_{j'} \cdot \frac{1}{2}\left(\frac{\partial^2 \chi_{\alpha\beta}(\omega_i, \omega_s)}{\partial Q_j\, \partial Q_{j'}}\right) + \cdots$$

where E_γ is the component of a possible static electric field as an external perturbation. The main contribution comes from the first term χ^0, which represents the susceptibility of the unperturbed static crystal; this term leads to elastic light scattering with $\omega_s = \omega_i$, also denoted as Rayleigh scattering.

The subsequent terms represent the inelastic light scattering. The term χ^1 describes first-order Raman scattering (i.e., scattering from a single phonon). This scattering may occur due to the phonon-induced lattice deformation Q (first term of χ^1) or the simultaneous occurrence of symmetry-reducing effects, such as a finite phonon wavevector q (second term of χ^1) or, for example, the presence of a static electric field (third term of χ^1). The term χ^2 describes the two-phonon processes. The partial derivatives of the susceptibility in Eq. (2) constitute the Raman tensors, which will be elucidated below. The frequency values of the scattered light, which originates from the susceptibility term χ^1, are obtained from Eqs. (1) and (2):

$$\omega_s = \omega_i \pm \omega_j(\mathbf{q}_j) \tag{3}$$

Thus, the shift of the angular frequency of the light equals the angular frequency of the lattice vibration.

2.2. Microscopic Theory

In the quantum-mechanical model, the light frequency shift in the inelastic scattering process is explained in terms of an energy difference between the scattered photon and the incoming one. This difference occurs due to the creation or annihilation of an elementary excitation (e.g., a phonon) in the sample.

For the first-order phonon scattering, energy conservation reads

$$\hbar\omega_s = \hbar\omega_i \pm \hbar\omega_j(\mathbf{q}_j) \tag{4}$$

where the minus sign stands for the creation of a phonon and the plus sign for the phonon annihilation. The first scattering process is called a Stokes process, whereas the latter is denoted as an anti-Stokes process. Similar to the energy conservation, the wavevectors $\mathbf{k}_i$ of the incident laser photon and $\mathbf{k}_s$ of the scattered photon inside the sample are correlated by the momentum conservation law

$$\hbar\mathbf{k}_s = \hbar\mathbf{k}_i \pm \hbar\mathbf{q}_j + \hbar\mathbf{G} \tag{5}$$

where $\mathbf{G}$ is a reciprocal lattice vector.

Many solid-state applications of Raman spectroscopy deal with opaque materials, which implies experiments in backscattering geometry: the direction of the scattered light is approximately antiparallel to the incident one. In this case, the value of the phonon momentum in the Stokes process is given by

$$q_j = \frac{1}{c_0}[n(\omega_i)\omega_i + n(\omega_s)\omega_s] \tag{6}$$

The refractive index values of the II–VI compounds which are in the focus of this chapter are in the range between 2 and 3. Then the backscattering experiments with the available visible laser wavelengths yield scattering wavevectors in the range $q = 6$–$8 \cdot 10^5$ cm^{-1}. The reciprocal lattice vector $|\mathbf{G}|$ is of the order of 10^8 cm^{-1} and therefore the scattering process takes place near the center of the first Brillouin zone. The optical phonons of the materials of interest here show a negligible dispersion in this wavevector range, resulting in a well defined phonon frequency in the Raman spectrum, independent of the exciting wavelength. However, in the case of plasmons and plasmon–LO–phonon modes one has to consider that these modes can show dispersion in this wavevector range.

In the case of second-order Raman scattering the conservation laws impose

$$\hbar\omega_s = \hbar\omega_i \pm \hbar(\omega_j \pm \omega_{j'}) \tag{7}$$

$$\hbar\mathbf{k}_s = \hbar\mathbf{k}_i \pm \hbar(\mathbf{q}_j \pm \mathbf{q}_{j'}) + \hbar\mathbf{G} \tag{8}$$

Obviously, in the case of multiphonon processes one can observe combinations of excitations whose individual q-vectors may be of the order of the reciprocal lattice constant.

In order to calculate the probability of the annihilation of an incoming photon with energy $\hbar\omega_i$ and the creation of a scattered photon with energy $\hbar\omega_s$ accompanied with the creation or annihilation of an elementary excitation of energy $\hbar\omega_j$, the Raman scattering process can be described in a quantum-mechanical perturbation theory, which expresses explicitely the indirect photon–phonon interaction and resonance effects.

Raman experiments are usually performed in the visible region with photon energies in the eV range, whereas the elementary excitations, like phonons, have eigenenergies in the meV range. Due to this drastic energy mismatch, no direct photon–phonon interaction occurs. Therefore, the photon–phonon interaction is mediated by the electron system, whose excitation energies are in the range of the photon energies. The total process for phonon excitations can be described as a three-step combination of transitions [2, 7, 8], as schematically depicted in Figure 1 for Stokes scattering:

- An electron in the ground state $|0\rangle$ is excited to the state $|e\rangle$ with energy E_e due to the absorption of a photon with energy $\hbar\omega_i$; for this creation of an electron–hole pair the dipole operator p is involved.
- Due to the electron–phonon interaction, described by the operator H_{E-P}, the electron–hole pair is scattered from state $|e\rangle$ to another state $|e'\rangle$ with energy $E_{e'}$, accompanied by the creation of a phonon with energy $\hbar\omega_j$.
- The recombination transition from $|e'\rangle$ to $|0\rangle$ leads to the emission of a scattered photon with energy $\hbar\omega_s = \hbar\omega_i - \hbar\omega_j$.

The total scattering process arises from six time orderings of the three interactions in the perturbation treatment. The by far most dominant term is given by

$$\chi_{\alpha\beta}(\omega_i, \omega_s) \propto \sum_{e,e'} \frac{\langle 0|p_\beta|e'\rangle\langle e'|H_{E-P}|e\rangle\langle e|p_\alpha|0\rangle}{(E_{e'} - \hbar\omega_s)(E_e - \hbar\omega_i)} \tag{9}$$

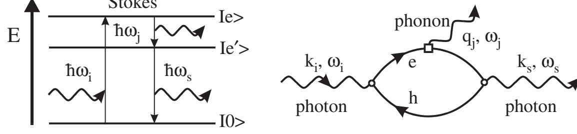

Figure 1. The Raman scattering process as a combination of electron–photon and electron–phonon interactions.

Momentum conservation is required for every single transition, while energy conservation is only required for the total scattering process. For interaction processes on a very short time scale the energy–time uncertainty relation allows the generation of virtual electron–hole pairs without energy conservation, for example, in the case of a below-bandgap excitation, which is used rather frequently for the investigation of wide gap II–VI semiconductors.

The anti-Stokes-to-Stokes intensity ratio in thermal phonon equilibrium far away from resonance (i.e., for equal susceptibility at the frequencies of Stokes and anti-Stokes scattered light) is given by [9]

$$\frac{I_{AS}}{I_S} \propto \left[\frac{\omega_i + \omega_j}{\omega_i - \omega_j}\right]^3 \cdot \exp\left[\frac{-\hbar\omega_j}{k_B T}\right] \tag{10}$$

This equation reflects that phonon states must be thermally occupied in order to appear as anti-Stokes line. For typical optical phonon wavenumber values $\tilde{\nu}_j = \omega_j/(2\pi \cdot c) > 150$ cm^{-1} (i.e., eigenenergy > 18.6 meV) the intensity ratio is strongly dependent on the sample temperature. For example, for ZnSe with $\tilde{\nu}_{LO} = 252$ cm^{-1} one finds at room temperature an anti-Stokes-to-Stokes intensity ratio of 0.32, whereas for $T = 80$ K one expects a ratio of about 0.011; only for very small wavenumber values $\tilde{\nu}_j \leq 50$ cm^{-1} are considerable anti-Stokes intensities observed. Therefore we will discuss only Stokes scattering throughout this work.

2.3. Scattering Mechanisms and Resonance

In the three-step Raman scattering process, different realizations of the electron–phonon interaction may occur, because a phonon can influence the electronic system in two complementary ways: it can modulate the electronic eigenenergies as well as the eigenfunctions.

Because the value of the energy gap depends on the momentary state of lattice deformation, a phonon leads to a modulation of the bandgap. A modulation of the energy eigenvalues (band shifting) means a phonon-induced transition between states $|e\rangle$ and $|e'\rangle$ in the same energy band (i.e., intraband scattering).

The modification of electronic eigenfunctions by the lattice deformation can be described by an admixture of states of adjacent bands; this means transitions between electronic states $|e\rangle$ and $|e'\rangle$ of different bands (i.e., interband scattering). In the susceptibility picture this implies a modification of the electronic interband oscillator strength. This effect is noticeable, for example, in semiconductors of zincblende structure with spin-orbit split valence bands.

The phonon property which causes the modulation of the electronic eigenvalues and/or eigenfunctions can be either the deformation-induced potential or the macroscopic electric field accompanied with the phonon. The former case is the dynamical analogue of the piezomodulation of the electronic band structure; the deformation-potential scattering at the E_0 gap of zincblende II–VI compounds has intraband and interband terms. In contrast to the TO phonon, the LO phonon has a macroscopic electric field, which has two consequences: (i) the corresponding additional restoring force for lattice distortions results in an enhanced frequency of the LO phonon with respect to the TO; (ii) the corresponding electric potential induces an additional light-scattering mechanism, denoted as Fröhlich interaction. This is the dynamical analogue of the electro-optic effect. The Fröhlich scattering for phonons at the Brillouin zone center $q = 0$ has only interband terms (i.e., a low efficiency), but for phonons with finite q values also the much more efficient intraband scattering can occur (symmetry-forbidden Fröhlich scattering). In the same way, the scattering intensity of the LO phonon can be enhanced in the presence of a static electric field (electric field induced Raman scattering), which is relevant for the analysis of interfaces [3]. The size dependence of the Fröhlich-induced electron phonon interaction in nanostructures is an actual item of interest in fundamental physics. It will be discussed in Section 6.1.5.

An item of extreme importance is the resonance behavior, as expressed by the denominators in Eq. (9), when the photon energy of the incident or scattered light closely matches the electron–hole energy. For transitions which do obey the energy conservation law, the contribution to the Raman cross section is enhanced resonantly. The matching of the incident or scattered photon with the electron–hole energy is referred to as incoming or outgoing resonance, respectively. By exploiting these resonances at the critical points in the electronic band structure (e.g., the E_0 or E_1 gap), the sensitivity in the Raman experiment can be drastically enhanced, which is of particular interest for the investigation of thin layers and constitutes a requirement for studying interfaces and nanostructures. Note that this sensitivity enhancement is material-specific, which allows focusing to, for example, interface regions with specific chemical bonds, although their thickness is far below that of the embedding layers.

The strength of resonant enhancement substantially depends on the scattering process: if the electronic states $|e\rangle$ and $|e'\rangle$ belong to different electronic bands (i.e., interband scattering), the energy values E_e and $E_{e'}$ in the denominator factors are considerably different, and a rather weak resonance occurs. However, for intermediate electronic states $|e\rangle$ and $|e'\rangle$ in the same band (i.e., intraband scattering) the energies E_e and $E_{e'}$ are comparable and therefore a much more pronounced resonance behavior is observed. An extremely strong resonance enhancement occurs in the special case when electronic states $|e\rangle$ and $|e'\rangle$ are available whose energy difference equals the phonon energy. Then the conditions for incoming and outgoing are fulfilled simultaneously, leading to double-resonant Raman scattering. This condition can be induced, for example, by the appropriate energetic positions of subbands in quantum wells, or by tuning the electronic energies by applying an electric or magnetic field [10–12].

3. EXPERIMENTAL SETUP

A main advantage of Raman spectroscopy as an optical method is its versatility from the viewpoint of sample preparation and surface conditions. No special treatment of the surfaces is required. Furthermore, Raman spectroscopy allows the investigation of very small samples and can also be applied for a locally resolved analysis with μm resolution: micro-Raman spectroscopy. The analysis may be performed

at low temperatures in a cryostat but also at room temperature in air or even at elevated temperatures. A recent experimental development is the application of Raman spectroscopy for *in-situ* studies during growth, for example, in an ultra high vacuum (UHV) vessel [13, 14] or in a gas ambient.

A typical setup for Raman spectroscopy consists of a laser light source, a spectrometer with a very good stray light suppression, and a photon detector with an extremely high sensitivity and low background level. The latter is especially relevant for interface and nanostructure analysis. These components are discussed in the next subsection. Subsequently, micro-Raman spectroscopy and the technique of *in-situ* growth analysis are treated in Sections 3.2 and 3.3, respectively.

3.1. Raman Spectrometer Components

3.1.1. Light Source

The most commonly used light sources for Raman spectroscopy are Ar^+ and Kr^+ ion lasers, which offer a series of discrete emission lines in the wavelength range from the near infrared to the near ultraviolet. This variety of laser lines is crucial for the analysis of interfaces and nanostructures, because it allows for the variation of penetration depth and for selectively taking advantage of the resonant interaction in the various semiconductor materials. Materials whose fundamental energy gap is in the visible (among the II–VI compounds, e.g., CdTe, CdSe, ZnTe, ZnSe) are transparent for some of the available laser lines and absorbing the others. The possibility of analysis with below-bandgap laserlines is typical for Raman spectroscopy while impossible for photoluminescence. Furthermore, in the absorbing range, the penetration depth can be varied between values beyond 10 μm and values around 10 nm at the wavelengths with maximum absorption. This variation of the depth of information by a factor beyond 1000 is extremely important for the analysis of buried interfaces: The region to be analyzed can be shifted from the surface and near-surface range to the underlying substrate.

The possibility of resonant interaction may be utilized to achieve a sufficient scattering intensity in extremely thin layers (down to single monolayers), but also for a selective enhancement of the scattering signal of one material with respect to others.

For a more versatile tuning of the resonant excitation, lasers with a continuously variable wavelength may be employed. For many years, various organic liquid dyes have been applied as a tunable laser medium. They cover the spectral region from below 400 nm to about 1000 nm. An important improvement was the introduction of a solid-state laser with continuously tunable wavelength. Its laser medium is a Ti–sapphire crystal. It covers the red and near-infrared spectral range between 600 nm and 1 μm and offers a more convenient operation and a constant efficiency over a wide power range, because in contrast to dye lasers no saturation effects occur.

3.1.2. Optics and Monochromator

The selective analysis of the different elements of the Raman tensor (e.g., for studying the sample symmetry properties and crystalline perfection) requires the variation of the polarization of the incident light. This is done by means of a $\lambda/2$ plate or a Fresnel rhombus.

The focusing of the laser beam on the sample is discussed in detail in the next section, with special emphasis on the optimization of lateral resolution in micro-Raman spectroscopy.

For collecting the Raman light a high-quality lens system with a large aperture is applied, which focuses the scattered light onto the entrance slit of the monochromator.

The separate analysis of the individual components of the Raman tensor requires the introduction of a polarization filter in front of the entrance slit.

Because of the extremely low intensity of the Raman scattered light compared with the diffusely reflected laser light that also enters the monochromator, the background reduction in the monochromator must be extremely good. Therefore, in contrast to photoluminescence experiments, for a sufficient separation of the Raman light from the undesired stray light background usually a system of two or even three grating monochromators is required. Several concepts are applied for the combination of these monochromators, varying between a pure addition of their dispersion and a partial use as stray light rejection filter [15]. Which concept is most preferable depends, for example, on the required spectral resolution, the width of the total Raman spectrum, and the intensity of the diffusely reflected laser light.

As a rather recent development, the employment of a single monochromator, together with a holographic notch filter for suppressing the diffuse laser light, should be mentioned. The main advantage of this combination is a high throughput for the Raman light.

3.1.3. Detector System

Until the late 1970s, the common detectors in Raman spectroscopy experiments were photomultipliers. They can achieve a very high efficiency of about 0.2 electrical pulses (counts) for each incident photon over the whole visible spectral range.

Since about 1980, multichannel detector systems have been commercially available, which allow the simultaneous detection of up to about 1000 spectral components of the Raman light on an array of photosensitive pixels. They caused a breakthrough in detecting spectral distributions with a very low intensity level [16] and are a prerequisite for the Raman analysis of interfaces and nanostructures. For optimizing the spectral resolution, even beyond the level that corresponds to the pixel size, the technique of scanning multichannel detection may be applied [17]. The most commonly applied types are CCD (charge coupled device) detectors [18] and, to a lesser extent, diode arrays.

All these detectors are cooled in order to reduce the electronic background. An extensive review was given by Tsang [19].

3.2. Micro-Raman Spectroscopy

In those Raman experiments which do not require microscopic lateral resolution (i.e., "macro"-Raman experiments), the laser beam is focused on the sample by a single spherical or a cylindrical lens, resulting in a point or line focus. The latter offers the advantage of a reduction of the local

power density by several orders, compared to a point focus. In this way heating effects, photoinduced chemical reactions, or screening of electric fields by excessive photocarriers can be avoided.

If, on the other hand, an analysis with a lateral resolution as good as possible is required, (e.g., for the assessment of a lateral strain distribution or compositional inhomogeneities, or for the study of patterned structures), a μm or even sub-μm focus is achieved by the application of a microscope objective: "micro"-Raman spectroscopy. This technique may also be applied for focusing on cleaved side-faces of heterostructures, which gives two new possibilities:

(i) due to the different crystallographic orientation of the side-faces with respect to the top surface, the symmetry selection rules are modified and different phonon modes may be observed: for example, on zincblende (110) surfaces the transverse optical phonon appears, in contrast to the longitudinal one on (001) surfaces.
(ii) a series of Raman spectra can be taken from a side face during a scan from the front edge to the substrate interface, which allows a depth-resolved characterization of the heterostructure with μm resolution.

When focusing down to the μm range, care has to be taken to avoid thermal damaging of the focus region due to the enhanced power density. Therefore, with decreasing focus area, the laser power has to be reduced accordingly (i.e., sub-mW intensities are appropriate).

In micro-Raman spectroscopy the focusing microscope is used as well for collecting the scattered light. Its aperture angle is much wider than that of long-focal lenses. This very efficient collection of the Raman light enables the detection of a sufficient signal in spite of the very small scattering area and the low incident light intensity.

Low-temperature micro-Raman spectroscopy is enabled by the use of extremely compact cryostats in combination with microscope objective lens systems with a working distance up to 8 mm. Of course, they have a low aperture angle, which leads to a reduced collecting efficiency.

Finally, it should be mentioned that a spatial resolution of 150 nm, which is distinctly below the laser wavelength, was reported [20], which was achieved by near-field Raman spectroscopy. This technique utilizes evanescent waves in the near-field region at the end of a glass fiber whose lateral size is below the wavelength of the employed light. Because of the extreme attenuation of these waves, this technique may only be applied for systems with a very high Raman scattering efficiency.

3.3. Online Growth Monitoring

Among the motivations for employing *in-situ* Raman spectroscopy during semiconductor growth processes are

(i) It has an enhanced depth of information as compared to electron-based techniques, which allows the observation of the development of a surface to an interface during overlayer growth.
(ii) During growth of mixed compounds, it allows the study of the composition with a typical accuracy of 0.5%.
(iii) From the anti-Stokes-to-Stokes intensity ratio the sample surface temperature can be deduced.
(iv) No UHV conditions are required, which enables the application during gas phase epitaxy, where no electron-based methods can be used.

For the real-time application of Raman spectroscopy in monitoring growth processes, the signal-to-noise ratio is a crucial aspect. While for steady-state applications no limits for the signal integration time exist, online applications require integration times short enough for monitoring the dynamics of the process under investigation. For epitaxial growth this means 1 to 10 seconds, which is realistic with today's Raman setups, equipped with multichannel detection systems, when resonant signal enhancement is exploited.

Optimizing the scattering efficiency is extremely important, because the input power density has to be kept sufficiently low to avoid influencing the growth process, which imposes a limit in the range from 10 to 50 mW, assuming a focus size in the 100 μm range.

In this context, the aperture angle for collecting the Raman light also plays an important role. In the growth vessel [e.g., an UHV chamber for molecular beam epitaxy (MBE) growth] the sample should be rather close to the window in order to achieve a sufficient light collection efficiency. For this purpose a reentrant window may be used. On the other hand, the distance between the sample and the window must be sufficient to avoid hampering of the layer deposition process.

An example of a setup design for *in-situ* Raman spectroscopy during MBE growth is shown in Figure 2. It is based on a conventional UHV vessel with various Knudsen cells, whose geometrical axes coincide at the substrate position. The extension for Raman spectroscopy consists of two additional windows, whose normal axes also coincide on the sample: one entrance window for the laser light and a second window for the scattered light. The position of the latter

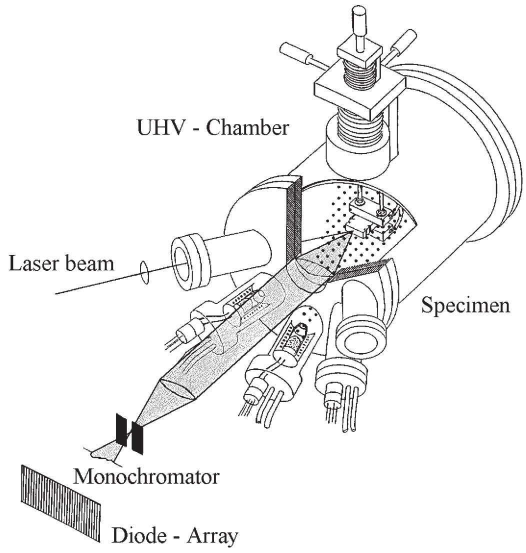

Figure 2. Experimental setup for monitoring MBE growth by Raman spectroscopy. The monochromator system is only indicated by its entrance slit. Reprinted with permission from [22], V. Wagner et al., *J. Raman Spectrosc.* 27, 265 (1996). © 1996, Wiley Interscience.

on the front flange, rather close to the sample, allows an aperture of 1:4 of the lens for collecting the Raman light. Several examples of *in-situ* Raman spectroscopy, which are discussed in this review, originate from this setup.

The development of the series of Raman spectra during the growth process is expected to show an increase of the overlayer signal, together with a decrease of the substrate signal when absorption takes place in the overlayer. However, for a quantitative evaluation, a modelling of the sample as a stack of layers with a specific index of refraction for each layer is required. In the calculation of the development of the Raman intensities with increasing overlayer thickness, transmission and reflectance at each interface, as well as absorption and Fabry–Perot interference in the overlayer, are considered. This procedure is similar to, for example, reflectance spectroscopy and ellipsometry, although in our case it has to be considered that the light is generated within each layer. It was first applied for normal incidence on a sample, consisting of a single layer on a substrate [21]. More recently, it was extended to oblique incidence and multilayer stacks [22].

As a typical application of *in-situ* online Raman scattering, the monitoring of epitaxial ZnS_xSe_{1-x} growth on GaAs(100) is shown in Figure 3. Resonant enhancement of the epilayer signal was obtained by employing for excitation the He–Cd laser line at 2.81 eV, which nearly coincides with the fundamental gap of the epilayer. The integration time per spectrum was 10 s. The starting spectrum only shows the LO phonon of the GaAs substrate at 291 cm^{-1}. During deposition, new peaks arise from the epilayer, which are identified as the vibrations of ZnS_xSe_{1-x} for $x = 0.15$ (for the systematics of compositional determination, see Section 4.2). The first pair of peaks, located at 249 and 319 cm^{-1}, belongs to first-order scattering, and the others belong to second- and third-order processes, which are quite strong due to the resonant excitation. Obviously, the development of the peak intensities with increasing overlayer thickness is essentially influenced by the Fabry–Perot interferences. Their consideration allows a quantitative description of the intensity development in terms of epilayer thickness. The maximum thickness in Figure 3 amounts to 120 nm, which corresponds to a growth rate of 0.4 nm/minute.

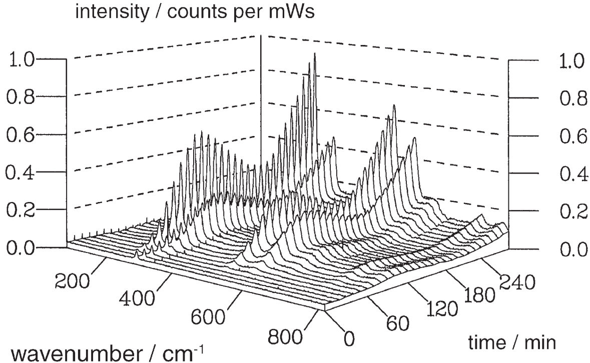

Figure 3. Online *in-situ* Raman spectra vs. deposition time during the growth of ZnS_xSe_{1-x} on GaAs(100) at 300 K. Adapted with permission from [22], V. Wagner et al., *J. Raman Spectrosc.* 27, 265 (1996). © 1996, Wiley Interscience.

Note that the GaAs substrate signal persists, because the wavelengths employed here are not absorbed in the epilayer. The GaAs LO intensity is even enhanced due to favorable interference at some epilayer thicknesses. This illustrates the possibility of enhancing the Raman sensitivity by appropriate choice of layer thickness [21].

Further results of *in-situ* Raman spectroscopy will be presented in Section 5. Besides direct layer growth, they will also deal with the *in-situ* observation of interface intermixing during annealing processes. Although a strongly enhanced temperature leads to a considerable thermal broadening of the phonon peaks in the Raman spectrum (see Section 4.1.2), Raman analysis can be performed up to temperatures far beyond 300 K.

4. ANALYSIS OF CRYSTAL LATTICE PROPERTIES

In this section experimental results of Raman scattering from lattice vibrations of II–VI layers are presented [e.g., ZnSe, epitaxially grown on GaAs(100) substrates]. These spectra are discussed in order to illustrate some aspects of relevance for the analysis of interfaces, surfaces, and quantum dots:

(i) sample properties such as lattice perfection, strain, composition of mixed compounds, and electronic properties in doped layers;
(ii) experimental aspects such as depth of information, resonant intensity enhancement, and polarization dependence.

At atmospheric pressure the binary and ternary II–VI semiconductors usually crystallize in the cubic zincblende-type structure [$F\bar{4}3m(T_d^2)$] or in the hexagonal wurtzite-type structure [$P6_3mc(C_{6v}^4)$]. In zincblende-type structures only phonon modes of F_2 symmetry are allowed. For finite values of wavevector q, these modes occur as TO and LO mode, whose eigenfrequencies are different due to the long range polarization field, which results from the partially ionic crystal bonding. In the wurtzite-type structure the F_2 mode is split in the hexagonal crystal field into A_1 (lattice deformation $\parallel$ c) and E_1 (lattice deformation $\perp$ c), whose eigenfrequencies are close to the F_2 frequency. Furthermore the $2E_2$- and $2B_1$-zone center modes are also allowed in the wurtzite-type structure [23, 24]. Among the wurtzite eigenmodes, A_1 and E_1 are both infrared (IR) and Raman active, E_2 modes are only Raman active, and B_1 are silent modes (i.e., neither IR nor Raman active). The A_1 and E_1 modes are polar modes and thus polarized parallel and perpendicular to the optical axis c, respectively. For a phonon propagation with wavevector $q \perp c$, the E_1 mode occurs as TO and LO mode, whose frequencies are different due to the long range polarization field, whereas A_1 only occurs as transverse mode: A_1(TO). For $q \parallel c$, the A_1 mode has a longitudinal character: A_1(LO) [25].

4.1. Crystalline Perfection and Orientation

Symmetry considerations determine for every crystal structure which component of the tensor $\tilde{\chi}$ may be modulated by a particular eigenmode: group theory provides the

information on which components of the corresponding Raman tensor (susceptibility derivative) have to be zero and which ones may be nonzero. These considerations lead to the so-called Raman selection rules, which serve as important guidelines for designing the scattering experiments and interpreting their results.

For compound semiconductors with zincblende structure (T_d point group symmetry) the Raman tensors for deformation-potential scattering from $q \approx 0$ phonons are given by

$$\mathbf{R}(x) = \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & c \\ 0 & c & 0 \end{pmatrix} \qquad \mathbf{R}(y) = \begin{pmatrix} 0 & 0 & c \\ 0 & 0 & 0 \\ c & 0 & 0 \end{pmatrix}$$

$$\mathbf{R}(z) = \begin{pmatrix} 0 & c & 0 \\ c & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix} \tag{11}$$

where x, y, z are the directions of the lattice deformation. The above tensors for deformation potential scattering have only off-diagonal nonzero elements. In contrast, the Fröhlich scattering, which is symmetry-forbidden for $q = 0$ but can be observed, for example, due to a finite q-vector or the presence of a static electric field, leads to Raman tensors with only diagonal nonzero elements.

The Raman scattering intensity amounts to

$$I \propto |\mathbf{E}_{s\beta} \cdot \mathbf{R}_{\alpha\beta} \cdot \mathbf{E}_{i\alpha}|^2 \tag{12}$$

where E_i and E_s denote the polarization vectors of the incident and scattered light, respectively. For backscattering from a (100) surface (i.e., polarizations in the yz-plane), only the Raman tensor $R(x)$ leads to nonvanishing intensity. Since this implies a lattice deformation in the x-direction, which is also the phonon propagation direction, we deal with a longitudinal phonon (LO). The resulting selection rules for backscattering from a (100) surface for both scattering mechanisms are summarized in Table 1.

In contrast to the (100) surface, for backscattering from (110) surfaces only scattering from TO phonons is allowed, while LO and TO are allowed for backscattering from (111) surfaces; furthermore, each surface orientation has its specific selection rules [3]. The experimental configuration (i.e., directions of wavevectors $\mathbf{k}_i$; $\mathbf{k}_s$ and polarizations $\mathbf{E}_i$; $\mathbf{E}_s$ of incident and scattered light, respectively) is usually given in a compact notation from Porto as $\mathbf{k}_i(\mathbf{E}_i, \mathbf{E}_s)\mathbf{k}_{\bar{s}}$ [for backscattering from a (100) surface e.g., $100(010, 001)\bar{1}00$].

Table 1. Selection rules for first-order Raman scattering from $q \approx 0$ phonons for backscattering from a (100) surface of a T_d-symmetry crystal; DP means deformation-potential scattering and F means Fröhlich scattering.

	Polarization			
Surface	E_i	E_s	TO	LO
100	010	010	—	F
100	001	001	—	F
100	010	001	—	DP
100	011	011	—	DP & F
100	011	$0\bar{1}1$	—	—

As an illustration of the selection rules, Figure 4 shows a Raman spectrum (scattering intensity vs. wavenumber) of an undoped, strain-relaxed ZnSe layer, epitaxially grown on a GaAs(100) substrate. This spectrum was recorded in the backscattering configuration $100(010, 001)\bar{1}00$, as depicted schematically in the inset. The measurement was performed at a sample temperature $T = 80$ K with the excitation wavelength $\lambda = 476.5$ nm ($\tilde{\nu} = 20986$ cm^{-1}). For this wavelength the ZnSe layer is transparent. Therefore not only the ZnSe layer phonon modes but also the GaAs substrate phonon modes can be observed. According to the selection rules for a (100) surface, in the configuration $100(010,001)\bar{1}00$ only Raman scattering from LO phonons is allowed. Indeed, in the spectrum two pronounced peaks appear, which are attributed to the $q \simeq 0$ LO phonons of ZnSe and GaAs. The LO phonon of ZnSe is observed at a wavenumber of 256 cm^{-1} for the sample temperature $T = 80$ K; this corresponds to the phonon wavenumber of undoped ZnSe in the absence of strain. The LO wavenumber of the semi-insulating GaAs amounts to 294.7 cm^{-1}.

Beside the LO modes, two much weaker peaks are observed, which are identified from their wavenumbers as TO phonons. However, due to symmetry-selection rules, scattering from TO phonons is forbidden on (100) surfaces. This weak TO phonon scattering can be induced by crystal defects (e.g., dislocation lines, grain boundaries, etc.) but may also originate from experimental conditions: the exact backscattering geometry is not fulfilled due to (i) finite acceptance angle of the scattered light and (ii) deviation from normal incidence. This so-called *quasi*-backscattering geometry can induce a TO/LO intensity ratio that amounts to a few percent.

For a wurtzite material, like CdSe, the symmetry-selection rules are summarized in Table 2. Backscattering from planes perpendicular to the optical axis c should yield the $A_1(LO)$ and the E_2 mode for parallel polarization [configuration $z(y, y)\bar{z}$], while for crossed polarization only the E_2 mode should appear. In backscattering from surfaces which contain the optical axis c, the $A_1(TO)$ and the E_2 mode are

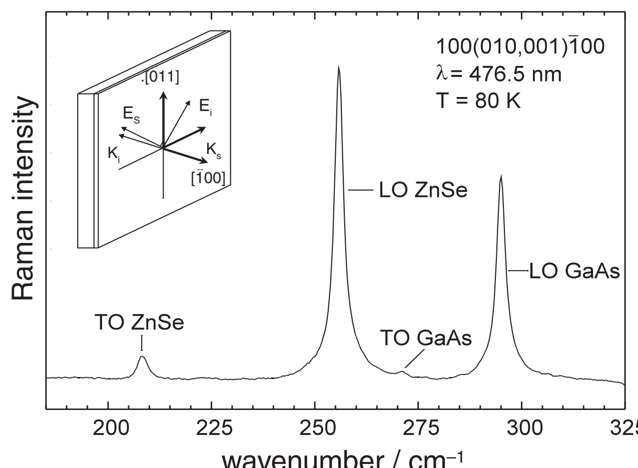

Figure 4. Typical Raman spectrum of a ZnSe/GaAs heterostructure at $T = 80$ K in the scattering configuration $100(010,001)\bar{1}00$. Adapted with permission from [31], J. H. W. E. Hermans, Ph.D. Thesis, RWTH Aachen, 1996. © 1996, Augustinus Publ. Co.

Table 2. Selection rules for 90° scattering and backscattering from various surfaces of a wurtzite crystal.

Geometry	q	Polarization parallel (HH)	Polarization crossed (VH)
Backscattering	$q \| c$	A_1(LO), E_2	E_2
Backscattering	$q \perp c$	A_1(TO), E_2	E_1(TO)
90° scattering		E_2	E_1(TO), E_1(LO)

allowed for parallel polarization [configuration $y(x,x)\bar{y}$], while for crossed polarization only the $E_1(TO)$ mode should be observed. Finally, for 90° scattering, the E_2 mode should occur for parallel and the $E_1(TO)$ and $E_1(LO)$ for crossed polarization. With these three scattering configurations it is possible to detect all zone center phonons of CdSe and to determine the lattice orientation. Because of the dependence of Raman signals on the wavevector and polarization of the incident and scattered light the rotation of the polarization of incident and scattered light leads to modulations of the peak intensities in the deformation potential allowed scattering. From these modulations the crystallite axes parallel to the crystal surface can be obtained with high accuracy.

4.1.1. Resonance and Depth of Information

As already mentioned in Section 2.3, the Raman scattering cross section can show a pronounced resonance when the excitation laser photon energy approaches an energy gap of the semiconductor material. Resonant Raman scattering constitutes the basis for (i) the detection of extremely thin layers and nanostructures and (ii) the selective analysis of one particular layer, embedded between others.

However, one should keep in mind that a variation of the excitation laser wavelength in many cases also leads to a variation of the penetration depth. Strong wavelength-dependent changes in the penetration depth occur in the neighborhood of the critical points in the combined density of the electron states, such as the fundamental electronic energy gap E_0. For ZnSe, the E_0 gap at 300 K amounts to 2.68 eV, which corresponds to 21614 cm^{-1}. Therefore, the Ar–ion laser excitation wavelength $\lambda = 476.5$ nm ($\tilde{\nu} = 20986$ cm^{-1}), which was employed in spectrum (4) is in the transparent range but rather close to the E_0 resonance. In contrast, the excitation lines at 19436 cm^{-1} (Ar–ion laser) and 24207 cm^{-1} (Kr–ion laser) give a comparably off-resonant condition in ZnSe; however, the former laserline leads to a negligible absorption coefficient resulting in a transparency of ZnSe whereas the latter line probes only the upper 95 nm of the ZnSe layer. In this way, the appropriate choice of laser line allows a focussing to the depth range of interest.

4.1.2. Temperature Dependence of Phonon Wavenumber and Linewidth

The phonon mode wavenumbers and linewidths may be influenced by a variety of effects, such as crystalline imperfections, a biaxial strain, free carriers, or a variation of the sample temperature T. One of the conditions for separating these effects is the knowledge of the intrinsic phonon eigenfrequencies and halfwidths as a function of the sample temperature.

Generally, the implication of temperature variation on the phonon properties is due to anharmonic effects in lattice dynamics. Therefore, the temperature dependence increases with increasing temperature, and its quantitative behavior depends on the material, especially on its phonon wavenumber value. For II–VI compounds the phonon wavenumbers are generally below 600 cm^{-1}, which corresponds to a phonon quantum energy <74 meV.

Here, the temperature dependence is discussed for the example material ZnSe, whose low-temperature phonon wavenumber is 256 cm^{-1} (≅31.7 meV). When T is increased, starting from 4.2 K, the phonon wavenumber is nearly constant up to about 80 K. A further T increase to 300 K leads to a wavenumber of 252 cm^{-1} (i.e., a decrease of about 4 cm^{-1}). Although this is a relative variation of only 1.5%, it cannot be neglected, because it is in the same order as strain-induced wavenumber changes.

Just like the phonon wavenumber, the spectral linewidth (full width at half maximum—FWHM) of the phonon is also almost constant in the temperature range $T < 80$ K. For samples with a high structural perfection its value is as low as 1.4 cm^{-1}. The spectral linewidth is directly connected with the phonon lifetime. For the LO phonons in ZnSe the observed intrinsic linewidth for $T < 80$ K corresponds to a lifetime $\tau \approx 4$ ps, in good agreement with the value of $\tau \approx 4.8$ ps determined directly by time-resolved Raman scattering [26]. For temperatures $T > 80$ K the FWHM clearly increases, up to factor of 4 at room temperature.

The corresponding decrease of the phonon lifetime with increasing sample temperature due to anharmonic processes in the crystal may be explained in terms of the decay of an optical phonon into acoustical phonons, for example, according to the Klemens model [27], whose basic idea is a stimulation of the decay into acoustical modes by the increasing T-induced occupation of the acoustical mode states (cf. stimulated emission).

These experimental results on the T-dependence of the optical phonon behavior imply that for high-accuracy experiments concerning, for example, disorder, local inhomogeneities, or strain, T-induced anharmonic effects should be avoided, which is achieved by cooling the sample to about 77 K by liquid nitrogen.

4.2. Composition of Mixed Compounds

Raman spectroscopy from mixed compounds is of special relevance for interfaces and quantum dots, because here intermixing effects are quite common, and Raman spectroscopy is one of the few methods for a nondestructive analysis. Therefore, fundamentals of lattice dynamics in ternary and quaternary compounds will be discussed here and Raman results from various II–VI mixed compounds will be presented.

For the $q \simeq 0$ optical vibrational modes of ternary compounds, such as $ZnSe_{1-x}S_x$, originating from the mixing of two binaries, we distinguish between two types of mode behavior:

- The one-mode behavior, which is phenomenologically quite similar to binary compounds. For every composition of the ternary $AB_{1-x}C_x$ only one TO and one

LO mode exist. With changing composition, the spectral position of these modes varies continuously and approximately linearly between the values of the constituting binary compounds. Usually, the intensity of these modes remains nearly constant.

- The two-mode behavior, which is quite distinct from binary compounds. In this case, for every composition $AB_{1-x}C_x$ two TO and two LO modes exist; they represent the A–B and A–C vibrations, respectively. The mode wavenumbers depend on the composition and the intensities are approximately proportional to the compositional fractions x and $1-x$. The LO–TO wavenumber splitting ($\simeq$mode oscillator strength) of the A–B and A–C vibration modes is approximately proportional to the relative abundance of A–B and A–C bonds, respectively. For very low concentrations of one type of bond ($x \approx 0$ or $x \approx 1$), the corresponding pair of TO and LO modes turns into a single local vibration mode.

The occurrence of either one- or two-mode behavior essentially depends on the mass difference of the constituent elements, which is directly reflected in the phonon wavenumbers of both binaries. For example, $ZnSe_{1-x}S_x$ belongs to the two-mode type, whereas $ZnSe_{1-x}Te_x$ belongs to the one-mode class. One of the most commonly used and cited models is the "modified random element isodisplacement" (MREI) model by Chang and Mitra [28], which is a modified and extended version of the "Random Element Isodisplacement" model by Chen et al. [29].

As an example for the compositional dependence of the phonon wavenumbers in the case of two-mode behavior, Figure 5 shows a series of spectra of (100) oriented $ZnSe_{1-x}S_x$ layers with different compositions ($x = 0$; $x = 0.06$; $x = 0.35$; $x = 0.73$; $x = 1.0$). Due to the GaAs substrates, all spectra show the GaAs LO peak at 292 cm^{-1}. The wavenumbers and intensities of all other peaks strongly depend on the ternary composition. The high-wavenumber mode corresponds to the Zn–S vibration. With decreasing S content its wavenumber continuously decreases from 350 cm^{-1} for pure ZnS ($x = 1$) to 297 cm^{-1} for $x = 0.06$. The latter case may be interpreted as the localized vibrational mode of S in ZnSe. Similarly, the low-wavenumber mode, which represents the Zn–Se vibration, starts at 256 cm^{-1} for pure ZnSe and decreases with increasing S content. The experimentally observed compositional dependence of the wavenumbers of both modes quantitatively agrees with the MREI model. Furthermore, the intensity ratio of both modes I_{Zn-S}/I_{Zn-Se} is approximately proportional to the compositional ratio $x/(1-x)$. The pronounced compositional dependence of the mode wavenumbers (e.g., 0.5 cm^{-1} per % for the Zn–S LO mode) allows an accurate determination of the ternary composition, although the extremely high accuracy of X-ray diffraction cannot be achieved by this technique. In the case of strained layers an additional strain-induced wavenumber shift will be superimposed (see Section 4.3), which in principle might lead to an inaccuracy in the determination of the composition. This problem is circumvented by evaluating the wavenumber difference between the Zn–S and the Zn–Se mode, which is strain-independent, since both modes exhibit the same strain-induced wavenumber shift.

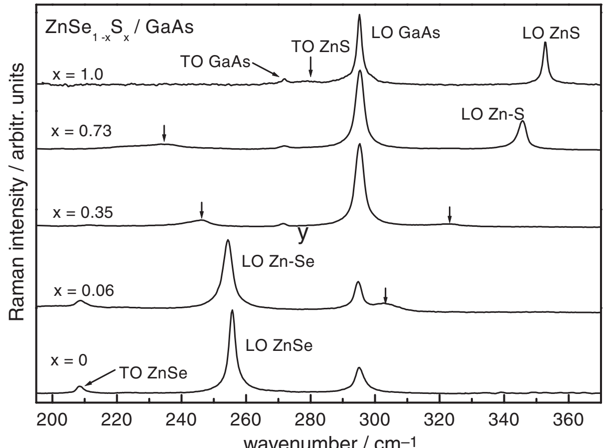

Figure 5. Raman spectra of $ZnSe_{1-x}S_x$ layers on GaAs in the composition region $0 < x < 1$ at $T = 80$ K. Adapted with permission from [31], J. H. W. E. Hermans, Ph.D. Thesis, RWTH Aachen, 1996. © 1996, Augustinus Publ. Co.

Besides the mode wavenumbers, also the peak shape and halfwidths are influenced by the mixing. With respect to the binaries a distinct broadening occurs. For the Zn–S mode, the maximum halfwidth amounts to 16 cm^{-1} for $x = 0.2$, as compared to 3 cm^{-1} for the binary ZnS. The broadening is accompanied by an increasingly asymmetric spectral lineshape. Both effects originate from the compositional disorder, which is inevitably induced by the random distribution of the S and Se atoms in the ternary compound. This disorder leads to a violation of the translation invariance in the crystal lattice and therefore to a relaxation of the $q_{Phonon} \approx 0$ condition in the Raman scattering process. Due to the dispersion of the optical phonon, the scattering for $q_{Phonon} \neq 0$ leads to contributions with reduced wavenumber, which broaden the peaks and make it increasingly asymmetric. The spectral width and lineshape can be described quantitatively in terms of a reduced correlation length, using the "spatial correlation model" [30], which is discussed in detail in Section 6.1.1. A further consequence of the disorder is a relaxation of the selection rules, resulting in the appearance of the symmetry-forbidden TO modes in the Raman spectrum from (100) surfaces.

Beside ternary mixed compounds, also quaternaries may originate spontaneously by intermixing at interfaces between binary layers AB and CD. In addition, they are of high relevance for technological application, because a controlled mixing of binaries AB and CD results in the mixed compounds $A_{1-y}C_yB_{1-x}D_x$, which offer the advantage of an independent tuning of the electronic bandgap and the lattice constant by the appropriate choice of the compositional ratios y of the cations A, C and x of the anions B, D. In this way, quaternary layers can be incorporated into heterostructure stacks without inducing strain. Raman spectroscopy from their vibrational modes is a useful technique for the identification of quaternary layers and for the determination of their composition. For a check of the compositional homogeneity lateral scans by micro-Raman spectroscopy can be applied.

An example of these quaternary compounds is $Zn_{1-y}Mg_ySe_{1-x}S_x$. Although MgSe and MgS crystals naturally have the NaCl structure, $Zn_{1-y}Mg_ySe_{1-x}S_x$ can be stabilized in the zincblende structure by growing the quaternary layers on GaAs substrates. The ternaries $Zn_{1-y}Mg_ySe$ and $ZnSe_{1-x}S_x$, which may be considered as the constituents of $Zn_{1-y}Mg_ySe_{1-x}S_x$, both show a two-mode behavior, as predicted by the MREI model. Therefore, four modes are expected for this quaternary. This was confirmed experimentally by the occurrence of four peaks in the Raman spectrum: the Zn–Se vibration in the range slightly below 250 cm^{-1}, Mg–Se and Zn–S near 320 cm^{-1}, and the Mg–S mode at about 360 cm^{-1} [31].

Another class of quaternaries consists of one anion element, combined with three cation elements, like $Cd_xZn_yMg_{1-x-y}Te$. The room-temperature Raman spectrum of the quaternary alloy $Cd_{0.4}Zn_{0.3}Mg_{0.3}Te$ (Fig. 6) shows three LO–TO mode pairs, which are identified as CdTe-like, ZnTe-like, and MgTe-like modes [32]. Just like in the ternaries discussed above, also in this case the TO phonon peaks are disorder-induced. For the same reason also additional features of the disorder-allowed acoustical modes LA and TA can be seen. The multimode behavior of this alloy can be explained on the basis of the MREI model.

4.3. Biaxial Strain Due to Lattice Mismatch

In most heterostructures strain due to lattice mismatch between adjacent layers plays a crucial role. On the one hand, strain may be favorable, because it is utilized to achieve shifts of electronic bandgaps or to induce the formation of self-organized quantum dots due to relaxation effects (e.g., in the systems InAs/GaAs or CdSe/ZnSe and CdSe/BeTe). They will be the subject of Section 6.3. On the other hand, in many cases strain will be disadvantageous or even detrimental, because it gives rise to the formation of lattice defects upon relaxation, which deteriorate the optical and transport properties. This occurs already for slightly lattice-mismatched material systems, such as ZnSe layers on GaAs. The relative lattice mismatch of only 0.27% induces the relaxation of the ZnSe layer when its thickness exceeds about 150 nm.

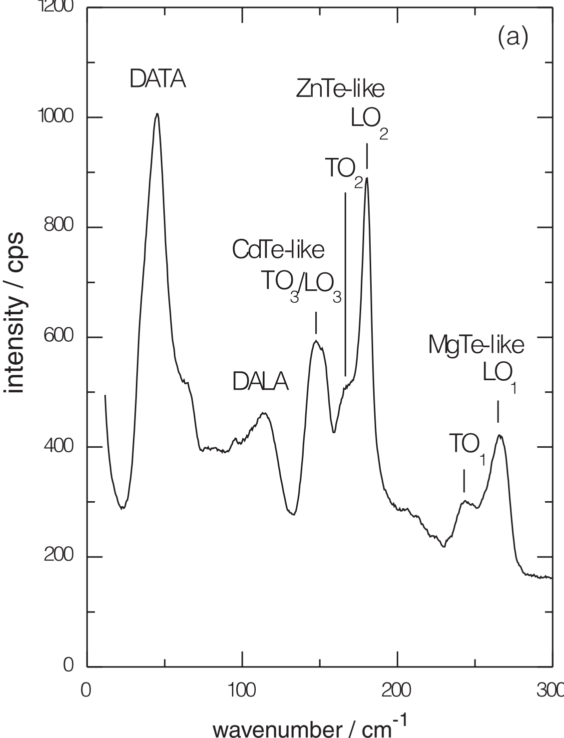

Figure 6. Raman spectrum of the quaternary $Cd_xZn_yMg_{1-x-y}Te$ showing the LO and TO phonons due to the three-mode behavior as well as the disorder-allowed TA and LA. Reprinted with permission from [32], R. Vogelgesang et al., *J. Raman Spectrosc*. 27, 239 (1996). © 1996, Wiley Interscience.

In quantum dots produced by sol/gel processes strain can be also caused by the surrounding matrix. The synthesis of these samples implies sintering processes or the implantation of the dots into the molten matrix material, whose thermal expansion constants are usually different from those of the semiconductor. As a consequence, the matrix can induce an effective pressure on the dot surface upon cooling the sample.

For epitaxial layers with sufficient thickness, strain and distortion can be characterized with an extremely high accuracy by X-ray diffraction. However, for layers in the monolayer range and for those cases where a lateral resolution in the μm range is required, optical methods are a very interesting alternative. Besides photoluminescence spectroscopy, utilizing the strain-induced modification of the excitonic features, Raman spectroscopy is also used for this purpose. The information depth for the usual Raman measurement on II–VI semiconductors with below-bandgap excitation is comparable to X-ray diffractometry. In addition, the information depth of the Raman experiment can be varied by changing the laser wavelength. The lateral resolution in the μm range with a microscope setup offers the interesting ability of investigating laterally structured semiconductor layers. However, the accuracy of the Raman method is distinctly below that of X-ray diffraction.

In Raman spectroscopy, the lattice strain of a thin epilayer due to a biaxial stress leads to small but significant wavenumber shifts and/or splitting of the phonon wavenumbers. Compressive strain induces an increase of the phonon wavenumber, while tensile strain leads to a decrease. In both cases the amount of wavenumber shift is proportional to the strain value. Strain-induced wavenumber shifts can mask other phonon wavenumber shifts (e.g., due to composition or doping). Therefore, it is necessary to separate the strain-induced part of the shift from the other parts.

For a quantitative evaluation of strain-induced phonon wavenumber shifts, results from pressure-dependent Raman experiments can be employed. With the knowledge of the amount of the shift per kbar, the effective pressure due to the lattice mismatch in strained quantum wells and superlattices can be calculated. Besides, pressure-dependent Raman experiments are also used for the investigation of phase transitions [33–37].

In zincblende bulk material, hydrostatic pressure induces a linear shift of all optical phonon wavenumbers, which is proportional to the pressure, while uniaxial as well as biaxial stress leads not only to a wavenumber shift, but also to a splitting of the degenerated TO band for backscattering

from planes containing both unstressed and stressed directions. From the amount of the shift and the splitting one can obtain experimental values for the phenomenological phonon deformation potentials (p, q, r), which describe the changes in the force constant of these phonons, and the mode Grüneisen parameter γ_i. The shift can be subdivided into a hydrostatic part $\Delta\omega_H$ induced by the change of volume and splittings $\Delta\omega$ due to the deformations in shape at constant volume [38–43]. For the important case of biaxial stress the threefold degenerated optical phonon at ω_0 (LO/TO splitting is neglected for the moment) is splitted into a singlet mode ω_s and twofold degenerated doublet mode ω_d:

$$\omega_s = \omega_0 + \Delta\omega_H + 2/3\ \Delta\omega \tag{13}$$

$$\omega_d = \omega_0 + \Delta\omega_H - 1/3\ \Delta\omega \tag{14}$$

with the hydrostatic part

$$\Delta\omega_H = \frac{(p+2q)(S_{11}+2S_{12})}{6\omega_0} \cdot 2\sigma \tag{15}$$

and the splitting

$$\Delta\omega = \begin{cases} \dfrac{(q-p)(S_{11}-S_{12})}{2\omega_0} \cdot \sigma & \text{for } z\|[001] \\ \dfrac{r\,S_{44}}{2\omega_0} \cdot \sigma & \text{for } z\|[111]. \end{cases} \tag{16}$$

If the phonon wavevector is chosen either parallel or perpendicular to the unstressed direction z, as is usually the case, the LO/TO splitting introduces no additional complexities and ω_0 can be simply replaced by ω_{LO} or ω_{TO}, respectively. For pseudomorphic epitaxial layers the in-plane lattice constants have the value of the substrate lattice. For zincblende materials with the [001] growth direction this leads to a tetragonal deformation of the cubic lattice. Due to this deformation, the epilayer lattice constant in the growth direction is also modified. Its value is determined by the Poisson number of the epilayer material. This situation corresponds to a biaxial strain. The relative lattice mismatch f of the epitaxial layer with respect to the substrate is defined as

$$f = \frac{a_s - a_l}{a_l} \tag{17}$$

where a_s and a_l are the bulk lattice constants of the substrate and epilayer, respectively. This mismatch determines the strain component in the layer parallel to the interface,

$$\varepsilon_\| = \varepsilon_{xx} = \varepsilon_{yy} = (a_\| - a_l)/a_l \tag{18}$$

where $a_\|$ is the lattice constant of the pseudomorphic epitaxial layer in the interface plane. Realistic mismatch values for pseudomorphic systems are in the order of some tenth of a percent. The corresponding strain values can be converted into an equivalent stress through the elastic compliance tensor values S_{ij} of the epilayer material:

$$\sigma = \varepsilon_\|/(S_{11}+S_{12}) \tag{19}$$

This results in equivalent stress values σ in the kbar range. For (001) heterostructures one obtains in backscattering for the symmetry-allowed LO phonon of the epilayer by using Eqs. (13), (15), (16), and (19):

$$\omega_{LO} = \omega_{0,LO} + \frac{q\,\varepsilon_\|}{\omega_{0,LO}} + \frac{p\,\varepsilon_\| S_{12}}{\omega_{0,LO}(S_{11}+S_{12})} \tag{20}$$

where ω_{LO} and $\omega_{0,LO}$ are the LO wavenumbers for the strained epilayer and unstrained layer material, respectively. For a pseudomorphic ZnSe epilayer on GaAs(100), one obtains by inserting the p, q, and S_{ij} values of ZnSe a wavenumber shift for the ZnSe LO phonon with respect to its bulk value of about 1.15 cm^{-1}. Thus, although for this slightly mismatched material system ($f = 0.27\%$) the relative LO wavenumber shift for pseudomorphic growth is only about 0.45%, it is by far sufficient for detection by Raman spectroscopy.

At the onset of strain relaxation, the employment of laser lines with different penetration depths allows a depth-dependent strain analysis. In this way, for ZnSe layers on GaAs(100), grown by metalorganic vapor phase epitaxy, the gradual progression of the relaxation from the surface to the epilayer–substrate interface was studied [31].

4.4. Coupled Plasmon–Phonon Modes in Doped Materials

A discussion of doping effects in Raman spectroscopy is of relevance here, because interfaces may induce, for example, carrier trapping, which results in carrier-depleted interface regions between doped layers, which will be the subject of Section 5.1.2.

Doping leads to new eigenmodes of the sample, which are observed in the Raman spectrum. The origin for this modified behavior is the collective charge density oscillation of free carriers, denoted as plasmon, whose wavenumber depends on the carrier concentration. With this charge density oscillation an oscillating macroscopic electric field is associated. This field leads to a coupling of the plasmon with the LO-phonon, because the latter also exhibits a macroscopic electric field. The coupling of these modes results in two new eigenmodes, denoted as plasmon–LO–phonon (PLP) modes, which replace the former LO and plasmon mode. The PLP modes are labeled as Ω_- and Ω_+, and their wavenumbers depend on the carrier concentration. Both PLP modes have a longitudinal character and therefore they may occur only at those wavenumbers for which the dielectric function $\varepsilon(\omega)$ is zero.

For a doped polar semiconductor the dielectric function can be written as the sum of the susceptibility contributions $\chi(\omega)$ of valence electrons (VE), phonons (Ph), and free carriers (FC) [44]:

$$\varepsilon(\omega) = 1 + \chi_{VE}(\omega) + \chi_{Ph}(\omega) + \chi_{FC}(\omega) \tag{21}$$

In the low-wavenumber range, which is relevant for the Raman shifts, the χ_{VE} contribution is constant. Therefore it

is considered formally in the constant $\varepsilon_\infty := 1 + \chi_{VE}$. In contrast, the contributions of the phonon and the free carriers show a pronounced angular-frequency dependence:

$$\chi_{Ph}(\omega) = \frac{\Delta\chi \cdot \omega_{TO}^2}{(\omega_{TO}^2 - \omega^2) - i\omega_{\tau,Ph} \cdot \omega} \tag{22}$$

where ω_{TO} is TO phonon resonance angular frequency, $\Delta\chi$ is the phonon oscillator strength, which originates from the bond polarity, and $\omega_{\tau,Ph}$ represents the phonon damping.

The free carriers experience no restoring force and therefore the eigenfrequency of their oscillator is zero; the free carrier susceptibility can be described by the Drude–Lorentz model

$$\chi_{FC}(\omega) = \frac{-\omega_p^2}{\omega^2 + i\omega_{\tau,FC} \cdot \omega} \tag{23}$$

where ω_p is the plasma angular frequency and $\omega_{\tau,FC}$ is the scattering angular frequency of the free carriers.

When damping effects are neglected, one obtains from the $\varepsilon(\omega) = 0$ condition for longitudinal modes the eigenfrequencies $\Omega_\pm$ of the coupled PLP modes Ω_- and Ω_+:

$$\Omega_\pm^2 = \frac{1}{2}\left(\omega_{LO}^2 + \omega_p^{*2}\right) \pm \frac{1}{2}\left[\left(\omega_{LO}^2 + \omega_p^{*2}\right)^2 - 4\omega_p^{*2}\omega_{TO}^2\right]^{1/2} \tag{24}$$

where

$$\omega_p^* = \left[\frac{\omega_p^2}{\varepsilon_\infty}\right]^{1/2} = \left[\frac{1}{\varepsilon_\infty}\frac{ne^2}{\varepsilon_0 m^*}\right]^{1/2} \tag{25}$$

is the plasma resonance angular frequency. The coupling of the LO phonon with the plasmon leads to a renormalization of the zeros of the dielectric function; note that the plasma resonance angular frequency depends on the free carrier concentration.

Figure 7 shows the doping dependence of the eigenfrequencies of the coupled plasmon–LO–phonon modes of *n*-ZnSe. For low carrier concentrations ($n < 0.5 \cdot 10^{17}$ cm^{-3}), the coupling is very weak: the PLP modes nearly coincide with the original LO and plasmon mode. Strong coupling occurs between 10^{17} and 10^{18} cm^{-3}. For higher concentrations the Ω_+ mode approaches the plasmon mode. Note, however, that the Ω_- mode asymptotically approaches the TO phonon wavenumber instead of the LO, an effect due to the screening of the electric field of the LO phonon by the free carriers.

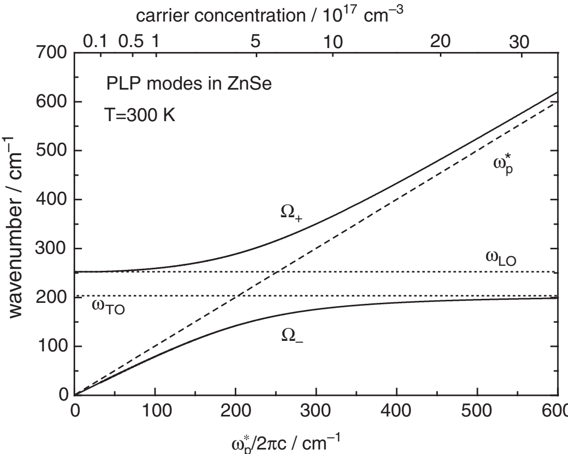

Figure 7. Doping dependence of the eigenfrequencies of the coupled plasmon–LO–phonon modes of *n*-ZnSe. Adapted with permission from [31], J. H. W. E. Hermans, Ph.D. Thesis, RWTH Aachen, 1996. © 1996, Augustinus Publ. Co.

The coupling also affects the polarization selection rules of the PLP modes: a near-phonon PLP mode is observable in an off-diagonal scattering configuration whereas a near-plasmon mode is observable for diagonal scattering. The peakwidth of both modes drastically increases with increasing distance from the phonon frequency, since the damping of the electrons is much higher than that of the phonon.

From Figure 7 it can be concluded that the Ω_+ mode is best suited for doping analysis: it shows the strongest doping dependence, and for our example (*n*-ZnSe) it can be distinguished from the LO phonon for $n > 10^{17}$ cm^{-3}. In the low-doping range, the Ω_- mode often appears quite weakly. Therefore, the doping analysis by Raman spectroscopy in *n*-ZnSe is limited to the range $n > 10^{17}$ cm^{-3}. When comparing different materials, the relevant parameter for the sensitivity of Raman spectroscopy for doping analysis is the effective mass m^* of the free carriers, which appears in Eq. (25). The lower m^*, the higher the Raman sensitivity.

For a quantitative doping level analysis from the PLP modes the finite wavevector transfer in the Raman scattering process has to be taken into account [see Eq. (6)]. The finite q-value of the PLP mode implies a periodic carrier concentration gradient, resulting in an additional restoring force, which means an enhanced eigenfrequency. This spatial dispersion can be taken into account by the hydrodynamical theory [45] as an extension of the Drude model, which yields for the free carrier contribution

$$\chi_{FC}(\omega, q) = -\frac{\omega_p^2}{\omega^2 - \frac{3}{5}v_F^2 q^2 + i\omega_\tau \omega} \tag{26}$$

where v_F is the Fermi velocity. A calculation of the wavevector dependence of the PLP frequencies shows that for *n*-ZnSe the dispersion is negligible for $n < 5 \cdot 10^{17}$ cm^{-3}, due to the relatively large effective carrier mass.

P-doped samples with a rather low carrier concentration constitute an additional challenge because of the very high effective hole mass and the quite low carrier mobility (e.g., for *p*-ZnSe they amount to $m_p^* = 0.6\,m_0$, and $\mu_p = 60$ cm^2/Vs, respectively).

Nevertheless, for nitrogen-doped ZnSe with $p = 2.4 \cdot 10^{17}$ cm^{-3} at 300 K, the comparison of Raman spectra, taken at $T = 12$ and 300 K, showed the thermal activation of *p*-carriers. At 300 K the emerging PLP mode shows a distinct additional broadening compared to the LO, due to the free carrier scattering, although the PLP wavenumber still nearly coincides with the LO [31]. In this way, the sensitivity of PLP Raman scattering for low concentrations together with high carrier masses and low mobilities is demonstrated.

5. EFFECTS OF SIZE RESTRICTION BY INTERFACES

With decreasing layer thickness in heterostructures, and especially with the decreasing size of nanostructures, interfaces and surfaces play an increasingly important role. Crucial aspects of interfaces are their structural, chemical, and doping properties, and as a direct consequence their electronic behavior, which, for example, governs the electrical characteristics of heterostructure devices. In layer and heterostructure growth (e.g., for subsequent nanopatterning), surface analysis has attracted an increasing interest, because the surface structure and quality are decisive for the further growth process, either homo- or heteroepitaxial.

Among the established methods for the experimental analysis are transmission electron microscopy at interfaces and electron spectroscopy methods at surfaces. The former technique yields information about structural perfection and intermixing with a spatial resolution in the atomic range, while the latter techniques are employed, for example, for probing the surface chemistry and for an extremely sensitive adsorbate detection.

Besides these electron-based techniques, recently methods of optical spectroscopy have found increasing interest for interface and surface analysis. At first, this may be surprising, because their rather high information depth (generally $\geq$10 nm) seems to be a drawback for surface and interface analysis. However, if a sufficient sensitivity and selectivity is achieved (i.e., if signals from surfaces and interfaces can be detected and separated from the remaining signal), the relatively high information depth turns into an advantage. During overgrowth it enables the monitoring of the development from surface to interface (*in-situ* growth control; see also Section 3). Furthermore, it allows the selective analysis of buried interfaces in a nondestructive way without a sophisticated and troublesome sample preparation.

Raman spectroscopy fulfills the requirements of sensitivity and selectivity for many material systems. A sufficient sensitivity for single atomic layers was achieved by instrumental progress during the last decades, for example, by tunable lasers for resonant enhancement of the scattering efficiency, and by the employment of extremely sensitive CCD multichannel detectors (see Section 3).

The selectivity for signals from interfaces and surfaces is based on

(i) Characteristic eigenfrequencies of surface and interface vibrational modes.
(ii) A specific polarization behavior of the light scattering process from these modes, due to the surface and interface symmetry properties.
(iii) The tuning of the laser wavelength to an electronic interband resonance of the surface or interface, which may selectively enhance its scattering efficiency by several orders of magnitude.

Our discussion of the consequences of size restriction by interfaces in Raman spectroscopy will start with a treatment of single interfaces and surfaces (Section 5.1). Here we will consider vibrational modes of abrupt and reacted interfaces, which reflect their chemical and structural properties, and we will also discuss electronic band bending, which influences the transport properties at interfaces.

Subsequently, we will draw our attention to quantum wells, multiquantum wells, and superlattices in Section 5.2. These multilayer structures give rise to new phenomena in the Raman spectrum, such as confined optical phonons modes from the individual layers, and folded acoustical phonons from the total stack.

5.1. Single Interfaces and Surfaces

5.1.1. Vibrational Modes

The subjects of this section are spectral eigenmodes which find their origin in a single interface or in a surface. When considering such interface-derived Raman signals, one has to distinguish between two different possible origins:

(i) The characteristic chemical bonds at the interfaces give rise to vibration modes whose wavenumber values are different from the bulk values of the interfacing materials. These modes are denoted as chemical vibrational modes.
(ii) The different dielectric properties of both materials induce vibrational modes which are centered at the interface. They are referred to as dielectric interface modes.

Both types of interface modes will, of course, occur not only at single interfaces but also in multiple layer systems, such as multiquantum wells and superlattices, which are the subject of Section 5.2. In these systems the multiplicity of interfaces gives rise to an enhanced intensity of the interface modes in the Raman spectrum, or even to a modified dynamics due to mode coupling between adjacent interfaces. However, the interface modes are discussed in this section on single interfaces, because their occurrence does not necessarily require multiple interfaces as, for example, folded acoustical phonons do.

The occurrence at interfaces of unique chemical bonds which do not belong to either of the constituting materials is easily understood, for example, for stacks of Si and Ge layers, in which the Si–Ge bonds occur uniquely at the interfaces and lead to new chemical vibrational modes in the Raman spectrum. These modes also may arise for heterostructures consisting of two binary compounds which have no element in common (i.e., systems AB/CD). For growth in [100] direction, the interfaces may contain either A–D or B–C bonds, depending on the switching procedure during growth. For these two types of interfaces bonds, generally quite different vibration wavenumbers are expected, especially when there is a signifcant mass difference between both cations A and C, or between both anions B and D.

The vibrational wavenumbers of chemical interfaces modes can be calculated from a semiempirical linear chain model, whose input parameters are the atomic masses and the bond strengths, which may be derived from the phonon wavenumbers of the corresponding bulk materials. However, in this calculation the strain in the interface bonds has to be taken into account, because at AB/CD interfaces generally strain values up to several percent will occur for the A–D or B–C bonds, even if the compounds AB and CD are lattice matched.

The linear chain calculation yields the eigenfrequency and the eigenmode pattern (i.e., the displacement amplitudes of the involved atoms). The mode pattern shows an extremely strong mode localization at the interface if the mode frequency is distinctly beyond the vibration frequencies of the constituting layers. For AB/CD systems this occurs if the atoms with the lowest masses build the interface (e.g., for ZnSe/BeTe, a strongly localized mode is expected for Be–Se interface bonds). A heavy-atom interface (Zn–Te bonds for ZnSe/BeTe) has a much lower eigenfrequency, which generally merges into the phonon wavenumber intervals of the constituing materials. Therefore this low-wavenumber chemical vibrational mode will penetrate much further into the adjacent layers.

Many material systems do not allow ideally abrupt interfaces but tend to intermixing. This gives rise to layers of reacted compounds whose thickness is in the range of at least several monolayers. The resulting ternary or even quaternary compounds have phonon wavenumbers which are different from those of the original materials. Therefore Raman spectroscopy is very well suited for their direct identification.

Utilizing resonant Raman scattering is an essential experimental technique for achieving a sufficient sensitivity to detect interfacial bond vibrations and to identify reacted interface layers. However, it should be mentioned that a quantitative determination of interface layer thicknesses from Raman spectroscopy is extremely difficult, since the absolute scattering efficiency usually is not known.

Finally, for the case of ideally abrupt interfaces the extremely low thickness of the interface layers (only one monolayer) results in a modified symmetry with respect to the bulk [46]. These symmetry properties should be reflected in the polarization dependence of the interface Raman peaks. Therefore polarization studies are an additional tool in Raman analysis of interfaces and surfaces.

In addition to the chemically induced vibrational modes arising from the different bonds at abrupt or intermixed interfaces, a further class of interface-induced vibration modes may be observed which originates from the different dielectric properties of the constituent layers. Maxwell's equations give rise to the existence of vibrational modes which are centered at the interfaces and show an exponential decay of the vibrational amplitude into the layers on both sides of the interface. For these modes the materials at both sides of the interface must have an opposite sign of the dielectric function $\epsilon(\omega)$ at the angular frequency ω of the dielectric modes. Therefore, a condition for their existence is that the ϵ-value of one of the materials must be negative in this frequency region. This implies that at least one of both materials must show a dielectric resonance (i.e., a phonon with an accompanying dipole moment due to noncovalent atomic bonds). The dielectric interface mode wavenumber then lies between the TO and LO phonon wavenumber of this material. If both constituting materials have noncovalent bonds and corresponding lattice vibrations with a dielectric resonance, two interface modes are expected. For stacks whose individual layer thicknesses are below the decay lengths of the dielectric modes, a coupling of the modes from the different interfaces may occur. This behavior is in contrast to the interface-bond-induced chemical vibration modes, which usually decay already within one or two monolayers. Dielectric interface modes not only occur at interfaces between two materials but also at the interfaces between a material and vacuum or air. Then they are referred to as dielectric surface modes.

Chemical Vibrational Modes from Abrupt Interfaces

The first Raman studies of chemical vibration modes from abrupt interfaces of semiconductor layers were performed on the III–V material systems InAs/GaSb and InAs/AlSb, whose interfaces may consist either of In–Sb or of Ga–As or Al–As bonds, respectively. In Raman spectra from InAs/AlSb samples with In–Sb interfaces the InSb vibration mode was observed near 190 cm^{-1} [47], which is very close to the LO wavenumber value of bulk InSb (196 cm^{-1}). The comparison of InAs/AlSb and InAs/GaSb revealed that intermixing was virtually absent for In–Sb interfaces but took place for Ga–As and was strongest for Al–As [48]. Furthermore, the modified symmetry-selection rules for the interface layers were confirmed by polarization-dependent experiments [46]. The strong dependence of the interface quality on the type of bonds (A–D vs. B–C), which originates from the different chemical bonding strength and diffusion probability, is a commonly observed phenomenon, as can also be seen from examples of II–VI interfaces, discussed below.

The strong correlation between the choice of interface bonds (A–D vs. B–C) and the resulting interface quality was also observed for ZnSe/BeTe superlattices. Here X-ray diffraction, transmission electron microscopy, and Raman spectroscopy unanimously confirm intermixing in the case of Be–Se bonds, whereas abrupt interfaces occur when Zn–Te bonds are employed [49]. In the latter case, confined optical and folded acoustical phonons in the Raman spectrum confirm the high degree of structural perfection and chemical abruptness of the interfaces (see Section 5.2). However, no chemical interface mode is observed, which may seem surprising but is explained by the correlation between the mode wavenumber and the degree of localization, as discussed above. The Zn–Te mode is expected at about 200 cm^{-1}. This is clearly within the wavenumber range of ZnSe vibrations, whose dispersion curve extends from zero to about 252 cm^{-1} (LO-wavenumber) and shows hardly any wavenumber gap between the optical and acoustical branch, because of the nearly equal atomic masses of Zn and Se. Therefore the interface-derived mode merges into the phonon continuum. For interfaces of the type Be–Se, which fulfills the wavenumber requirement for a localized mode (Be–Se vibrational wavenumber $\approx$576 cm^{-1}), its occurrence is hampered by the inferior quality due to intermixing.

Among the II–VI compounds, BeTe takes a special position, for example, with regard to the possible observation of chemical interface vibration modes. This compound, which consists of the smallest group-II element ($m_{Be} = 9$ amu) and the second-heaviest group-VI element ($m_{Te} = 127.6$ amu), has unique properties in two respects: (i) its bond polarity and (ii) its lattice dynamics.

Because of the combination of the row-II cation Be with the row-V anion Te, the electronegativity difference between cation and anion is strongly reduced with respect to other

II–VI compounds, and the bond polarity of BeTe is by far the lowest of all II–VI compounds [50]. This is expected to result in an improved lattice stability, an aspect that has made BeTe and other binary and ternary Be-chalcogenides promising candidates for II–VI optoelectronics [51].

Here we focus to its lattice dynamics, which shows two peculiar features:

(i) Due to the low atomic mass of Be, the optical phonon wavenumbers are very high: they amount to 502 cm^{-1} for the LO and 461 cm^{-1} for the TO vibration, respectively [50].

(ii) The very strong mass asymmetry ($m_{Te} = 14.2 \cdot m_{Be}$) leads to a quite broad interval of forbidden wavenumbers between the dispersion branches of the optical and the acoustical modes ("phonon gap"). This reduces the possibility for interface modes to penetrate into the BeTe layers and, consequently, gives rise to more favorable conditions for the observation of localized interface vibrational modes.

These favorable conditions are fully exploited in CdSe/BeTe heterostructures, consisting of CdSe monolayers, embedded in BeTe layers [52]. Here, no layers of a second compound with bulklike properties are involved. Thus, the BeTe phonon dispersion curve is the only relevant one.

An important motivation for this strongly lattice-mismatched material system ($\Delta a/a = 7\%$) is the formation of spontaneous CdSe quantum dots due to strain relaxation for layer thicknesses beyond about 3 ML. However, the CdSe epilayers of only 1 ML, which are discussed here, should be fully strained.

Note that also in this stack two interface configurations may be chosen: The interface (i.e., the transition bond between the BeTe and the CdSe monolayer) may be either Be–Se or Cd–Te. Just like for the ZnSe/BeTe system, pronounced intermixing occurred for Be–Se interfaces (i.e. for the atomic layer sequence ⋯–Te–Be–Se–Cd–Se–Be–Te–⋯), while the highest abruptness and structural perfection was obtained for Cd–Te interfaces (i.e., for the sequence ⋯–Be–Te–Cd–Se–Cd–Te–Be–⋯). This behavior is deduced from the Raman spectra, shown in Figure 8. Apart from the common GaAs substrate peaks at 265 and 292 cm^{-1}, the upper spectrum (Be–Se interfaces) and the lower one (Cd–Te interfaces) are quite different:

(i) While the sample with the Cd–Te interfaces shows a well defined BeTe LO phonon at the expected wavenumber of 505 cm^{-1}, for Be–Se interfaces a wavenumber-shifted, weaker, and broadened peak appears, which may originate from the ternary $BeSe_xTe_{1-x}$.

(ii) In the wavenumber range between 150 and 220 cm^{-1}, which is the domain of Cd-related vibrations, the sample with Be–Se interfaces only shows a single, very broad peak, while for Cd–Te interfaces a much better resolved structure appears.

The CdSe monolayer-related structure in the Raman spectrum of the heterostructures with Cd–Te interfaces is explained as a superposition of vibrational eigenmodes, whose wavenumbers may be derived from the linear chain model. For the fundamental vibration mode (i.e., maximum

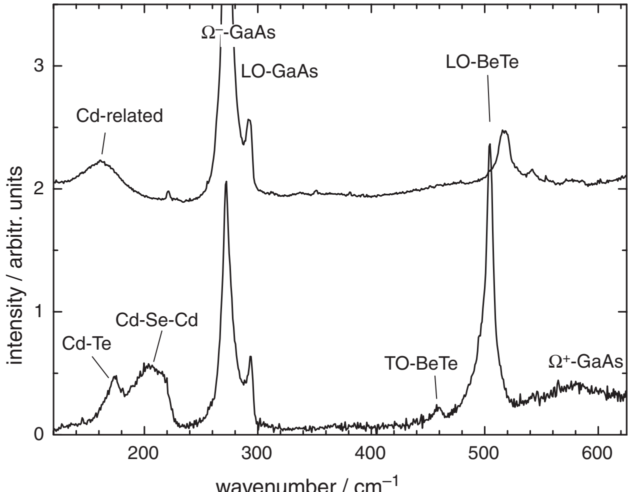

Figure 8. Raman spectra of a stack of 5 × 1 ML CdSe well in BeTe. Upper curve: Be–Se interfaces, lower curve: Cd–Te interfaces. Reprinted with permission from [52], V. Wagner et al., *Appl. Surf. Sci.* 175, 169 (2001). © 2001, Elsevier Science.

amplitude for the central Se atom, lower amplitudes for the next neighbor Cd atoms, strongly reduced amplitudes for the second-next neighbors Te, etc.), the wavenumber value 216 cm^{-1} is obtained, while the next mode (i.e., zero amplitude for the central Se atom, and maximum amplitude but opposite directions for the neighboring Cd atoms, followed by a comparable amplitude for the second-next neighbors Te, etc.) should appear at 169 cm^{-1}. These calculated wavenumbers give a reasonable explanation of the experimental result; however, for a quantitative agreement inhomogeneities have to be invoked, which constitute the onset of quantum dot formation. For this reason they will be discussed in detail in Section 6.3.

For strained CdS/ZnSe superlattices the successful observation of a localized Zn–S interface mode was reported [53]. Here high-quality Zn–S interfaces occur which give rise to a localized mode. The linear chain model predicts a wavenumber of 317 cm^{-1}, which is in very good agreement with the experimental observation. From the atomic masses, a wide separation between the Zn–S interface mode wavenumber and the CdS confined optical phonons would be expected. However, due to the strain-induced blue shift of the CdS phonons, they appear very close to the Zn–S interface mode.

Raman signatures of monolayers at interfaces were also observed for the group V elements on III–V or group IV substrates. Sb on InP(110) or GaAs(110) leads to an epitaxial monolayer, in which the Sb atoms form zigzag chains. The corresponding Raman spectra show very sharp peaks of the monolayer vibration modes, originating from Sb chains [54]. Raman peaks due to molecular vibrations were observed for As and Sb, adsorbed on Si(111) [55].

Chemical Vibrational Modes from Reacted Interfaces

Raman spectroscopy has been successfully applied for the study of reacted interfaces for a wide variety of material systems, for example, metal–semiconductor interfaces, such as Pt/Si [56, 57], and oxidized semiconductor surfaces, such as GaAs [58], InAs [59], and InSb [60]. Here we will focus on

reacted semiconductor–semiconductor interfaces. Interfaces between different III–V epitaxial layers have been investigated, for example, for InGaAs/InP, grown by MOVPE (metal organic vapor phase epitaxy). Here, intermixing-induced InAsP and InGaAsP interface layers were detected, whose thickness showed a systematic dependence of the gas switching procedure at the interfaces [61–63].

II–VI epilayers on III–V substrates were studied, for example, for the lattice-matched systems CdS/InP(110) [24], ZnSe/GaAs(100) [64], and CdTe/InSb(100) [65]. Here, for many growth conditions interlayers of the corresponding III–VI compound were detected: Ga_2Se_3 (Raman peak, e.g., at 155 cm^{-1}) at the ZnSe/GaAs interfaces, and accordingly, at the interface CdTe/InSb elementary Sb (Raman peaks at 113 and 152 cm^{-1}) and In_2Te_3 were observed due to the reaction of the deposited Te with In from the substrate. This reaction was considerably suppressed by starting the CdTe layer growth with an enhanced concentration of Cd in order to induce preferentially Cd–Te bonds instead of In–Te ones [65].

By *in-situ* online Raman spectroscopy (see Section 3.3) the formation of islands, interlayers, or other reaction products at the interface can be observed when recording the temporal evolution of Raman signals either during overlayer deposition or during the annealing of samples with previously abrupt interfaces [22]. Both techniques have been applied for group III elements, deposited onto Sb(111) substrates. It was observed that for deposition of Ga or In at 300 K GaSb or InSb was formed instantaneously; however, while the InSb growth mode is two dimensional, GaSb shows three-dimensional and disordered growth, and for an improved crystalline quality a deposition at elevated temperature (beyond 200 °C) was required [66]. Group III deposition at low temperature (170 K) resulted in abrupt interfaces. Subsequently, intermixing was induced by annealing, while monitoring the compound development by Raman spectroscopy, exploiting the ability to observe the buried interface region below the group III overlayer. The evaluation of the temperature dependence of the III–V formation allowed the determination of the relevant diffusion parameters for InSb, GaSb, and AlSb [66].

Dielectric Interface Vibrational Modes For a dielectric interface vibration with angular frequency ω_{diel} at the interface between the materials A and B Maxwell's equations impose the condition $\epsilon_A(\omega_{diel}) = -\epsilon_B(\omega_{diel})$ [67]. For example, for a ZnSe epilayer on a GaAs substrate, this means at the ZnSe/GaAs interface $\epsilon_{ZnSe}(\omega_{diel}) = -\epsilon_{GaAs}(\omega_{diel}) = -12.9$, and at the ZnSe/air interface $\epsilon_{ZnSe}(\omega_{diel}) = -1$. Because of its harmonic oscillator behavior with a resonance at the TO wavenumber and zero value at LO, the dielectric function of ZnSe fulfills both conditions in the wavenumber interval between TO and LO: the ZnSe/GaAs interface mode should appear about midway between TO and LO, while the ZnSe/air mode (surface mode) is expected very close to the LO, since $\epsilon(\omega_{LO}) = 0$. Thus, a qualitative assignment of interface modes can be made.

As an illustration of a dielectric interface mode, Figure 9 shows a Raman spectrum of a ZnSe layer on GaAs, with a thickness of $d_{ZnSe} = 920$ nm; in this enlarged view in the spectral region of the TO and LO phonon of ZnSe, a weak peak appears at about 218 cm^{-1} (i.e., between the TO and LO wavenumber). Furthermore, a detailed peak shape analysis of the ZnSe LO peak (not shown here) reveals a shoulder on its low-wavenumber side, corresponding to an additional weak Raman peak whose wavenumber is close to the LO. Interestingly, for different ZnSe layer thicknesses these two peaks appear with constant intensity, while, as expected, the TO and LO intensity are proportional to the ZnSe thickness. Therefore, the wavenumber and intensity behavior of the peaks are strong indications of dielectric interface vibrations.

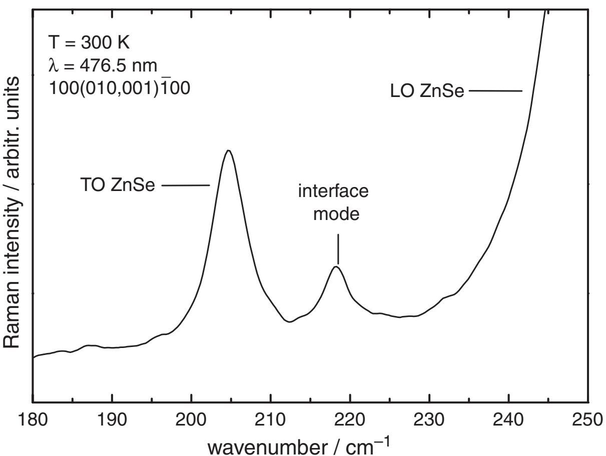

Figure 9. Enlarged view of a Raman spectrum of a ZnSe/GaAs heterostructure, showing an interface mode between the TO and LO phonon of ZnSe. Adapted with permission from [31], J. H. W. E. Hermans, Ph.D. Thesis, RWTH Aachen, 1996. © 1996, Augustinus Publ. Co.

However, for a quantitative interface mode assignment the theory of dielectric modes has to be considered in more detail: (i) their dispersion properties and (ii) the coupling between the modes from the upper interface (epilayer–air) and the lower one (epilayer–substrate). With regard to the dispersion effects, it has to be considered that the interface modes, as derived from Maxwell's theory, propagate parallel to the interface. This implies that they should not appear in the Raman spectrum for ideal backscattering geometry but are only observed due to finite wavevector components $\mathbf{q}_\parallel$ parallel to the interface because of the *quasi*-backscattering geometry and because of surface roughness. These effects lead to $\mathbf{q}_\parallel$ values in the range of some percent of the total q-transfer, that is, about $\mathbf{q}_\parallel \approx 40{,}000$ cm^{-1}, which is relevant not only for the mode wavenumbers but also for their exponential decay length in the ZnSe layer. As a result, theory predicts a coupling between the surface and interface mode for ZnSe layer thicknesses below about 0.3 μm, which induces noticeable wavenumber shifts.

The calculated mode wavenumbers are shown in Figure 10 and compared with experimental results for different ZnSe layer thicknesses between 0.06 and 0.62 μm. The quantitative agreement between theory and experiment confirms the assignment of the observed Raman peaks to the coupled dielectric modes, centered at the ZnSe surface and the ZnSe/GaAs interface.

5.1.2. Electronic Band Bending

At semiconductor surfaces and at crystallographically nonideal interfaces usually unsaturated electronic bonds are present which may tend to capture free electrons from the underlying bulk material and trap them at the surface or interface, respectively. This leads to an accumulation of negative charge, which results in a repulsive potential for the remaining free electrons. As a consequence, the region immediately behind the surface or interface will be depleted from free carriers (depletion layer), which may strongly influence its transport properties. Furthermore, for quantum dots, especially those produced by reactive ion etching, such near-surface regions may reduce the luminescence efficiency. The depletion layer depth increases with increasing trap density and is reduced with increasing doping level, since for high doping already a thin slab provides enough electrons to fill the trap levels. Realistic values for depletion layer depths vary from the nm to the μm range.

The depletion layer carries a net positive charge density which corresponds to the doping level, since in the layer the electric charges of the ionized dopant atoms are uncompensated due to the absence of free electrons. Therefore the interface and the depletion layer together form a dipole bilayer with an electric field inside, which decays linearly with distance from the interface. According to Poisson's equation the depletion layer is described by a quadratic increase of the electrostatic potential toward the interface. This phenomenon is referred to as electronic band bending. It is treated quantitatively, for example, by Rhoderick and Williams [68].

The development of electronic band bending at surfaces due to gas adsorption or the start of an overlayer growth is usually analyzed by photoemission spectroscopy [69]. However, this method, which requires UHV conditions, is limited to overlayer thicknesses of only some monolayers. Therefore it cannot be applied for the analysis of buried interfaces, which are relevant in heterostructures.

Raman spectroscopy, as an optical method, gives access to buried interfaces. Besides, it is sensitive to doping, as was shown in Section 4.4. Therefore Raman spectroscopy is a powerful tool to analyze changes in the free carrier behavior due to electronic traps at interfaces.

Two features in the Raman spectrum are sensitive to band bending variations, namely the coupled PLP modes and the LO phonon. For a doped material one would expect only the PLP peaks Ω_+ and Ω_-. However, because in a depletion layer no free carriers are present, the coupled PLP modes can exist only in the bulk region behind the depletion layer, while in the depletion layer only the pure LO phonon without any coupling to free carriers can exist. Therefore, in the presence of band bending the LO phonon modes as well as the PLP modes are expected in the Raman spectrum, provided the light penetration depth is sufficient to reach the doped region behind the depletion layer. The intensity ratio $I_{\mathrm{LO}}/I_{\mathrm{PLP}}$ is a measure of the depletion layer width and therefore of the density of trap states at the interface or surface [70]. These phenomena are described in detail and with a quantitative evaluation in ref. [3].

As an example of the abilities of Raman scattering for the analysis of electronic trap states at interfaces here scattering results from a ZnSe/GaAs(100) interface are discussed. The GaAs substrate was n-doped with a free carrier concentration $n = 2 \cdot 10^{18}$ cm^{-3}. The influence of the interface was deduced from the Raman spectrum of the GaAs PLP modes and LO phonon. The laser excitation wavelength was 476.5 nm, implying a negligible absorption in the ZnSe layer and a penetration depth of 70 nm in the GaAs substrate. The polarization configuration was off-diagonal: $100(010,001)\bar{1}00$. In order to trace the effects of the ZnSe relaxation, which starts at about 180 nm (see also Section 3.3), Raman spectra were taken for different ZnSe layer thicknesses up to 1.6 μm.

Some representative experimental results are plotted in Figure 11. The Raman spectrum of the GaAs substrate without ZnSe layer shows a broad structure, corresponding to the lower PLP mode Ω_-, at about 265 cm^{-1}, that is, near the

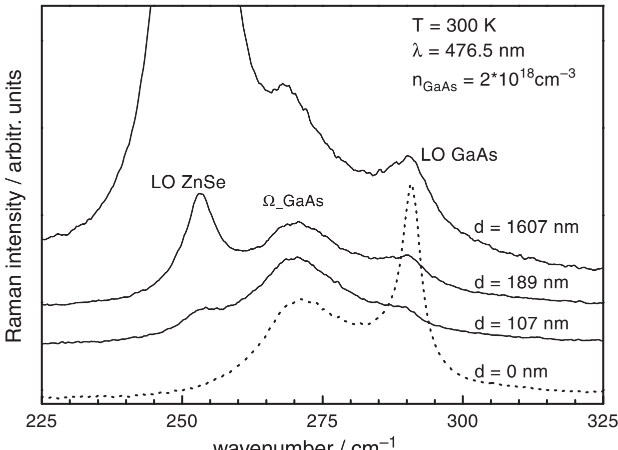

Figure 11. Raman spectra of ZnSe/n-GaAs heterostructures for different ZnSe layer thicknesses $d = 0 \cdots 1.6$ μm. Doping level $n_{\mathrm{GaAs}} = 2 \cdot 10^{18}$ cm^{-3}. Adapted with permission from [31], J. H. W. E. Hermans, Ph.D. Thesis, RWTH Aachen, 1996. © 1996, Augustinus Publ. Co.

TO-wavenumber, as is expected for this high doping level. In addition, the LO phonon is observed at about 292 cm^{-1}, which is typical for undoped GaAs. The simultaneous observation of both features is due to the presence of a depletion layer, which means electronic band bending. It is well known that for a clean GaAs(100) surface with the doping level of our sample the band bending amounts to 0.7 eV, which leads to a depletion layer width of 22 nm. Using this value of the layer width the measured LO/Ω^- intensity ratio can be interpreted in terms of the ratio of the Raman scattering efficiencies for LO and Ω_- without the need to know their absolute values.

After deposition of ZnSe, the Raman spectra in Figure 11 show besides the appearance of the ZnSe LO phonon also a change of the LO/Ω_- intensity ratio of GaAs. First, the LO intensity shows a strong decrease compared to the Ω_- intensity, as plotted for a layer thickness $d = 107$ nm. For larger ZnSe thicknesses the ZnSe LO phonon intensity, of course, increases very strongly, but also the GaAs LO/Ω_- intensity ratio increases again. This behavior reveals a strong dynamics in the depletion layer width, which means a thickness dependence of the electronic trap density at the ZnSe/GaAs interface.

A quantitative evaluation of the Raman spectra in terms of electronic band bending is shown in Figure 12. For this evaluation the ratio of the scattering efficiencies of LO and Ω_- was used, which was obtained from the uncovered surface. Besides the results derived from the spectra of Figure 11 the plot also shows band bending values obtained from spectra with another laser line, taken at 80 K. The results are consistent within ± 50 meV.

The extremely strong reduction of the band bending for ZnSe layer thicknesses below 150 nm proves the very high quality of the ZnSe/GaAs interface. The pseudomorphic ZnSe layer saturates about all the electronic traps at the surface and near-flatband condition is achieved. This very sensitive test underscores the excellent quality of the interface for this MOVPE-grown heterostructure. Its quality is comparable with MBE-grown samples which were analyzed by the same technique [71, 72].

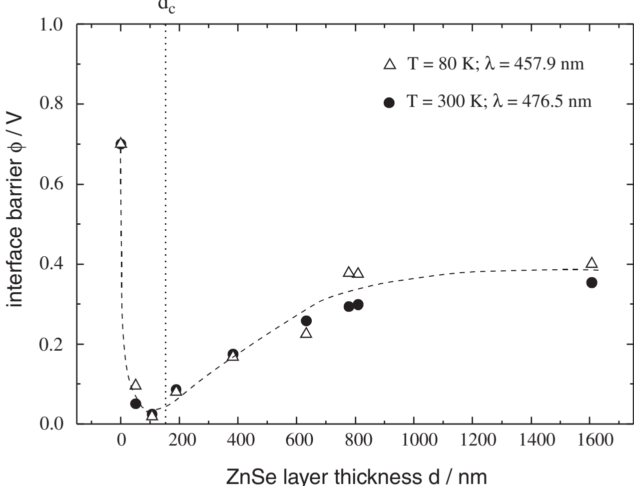

Figure 12. Band bending at the ZnSe/n-GaAs interface for different ZnSe layer thicknesses d, derived from the Raman results in Figure 11. Adapted with permission from [31], J. H. W. E. Hermans, Ph.D. Thesis, RWTH Aachen, 1996. © 1996, Augustinus Publ. Co.

The onset of the renewed increase of the band bending is explained in terms of the strain relaxation beyond the critical layer thickness d_c, which was obtained from ZnSe LO phonon data from the same samples. The gradual increase reflects how during the process of strain relaxation more and more relaxation-induced dislocations reach the heterointerface. The saturation thickness of about 1 μm agrees well with the value obtained from the strain-induced shift of the ZnSe LO phonon (see Section 4.3). The saturation band bending value of 0.4 eV corresponds to the defect density at the interface which is expected from the lattice mismatch between ZnSe and GaAs.

5.2. (Multi)-Quantum Wells and Superlattices

For II–VI materials like ZnSe and CdTe the condition for quantum wells to be thin enough to exhibit quantization effects in the electron wavefunctions implies thicknesses below about 20 nm. If the thickness is further decreased, these thin layers may also exhibit specific vibrational features. The optical phonons, whose wavenumbers are very characteristic for each material, usually cannot penetrate into the neighboring materials because of the wavenumber mismatch. This gives rise to the confinement of the optical phonons in the quantum well layer, which is reflected in specific confined optical phonon (COP) peaks in the Raman spectrum. They are discussed in Section 5.2.1. For periodic thin-layer sequences of two alternating materials in multiquantum wells (MQWs) and in superlattices (SLs), consisting of even thinner layers, these COPs usually occur in both materials.

For acoustical phonons the situation is completely different. Due to the nearly equal sound velocity in most solids, these waves may travel through the total stack of layers in a MQW or SL. However, the periodicity which is superimposed due to the layer stacking leads to a modification of the translational invariance, and as a consequence for Raman scattering also to a modification of the possible values of the momentum transfer in the scattering process. As a result, in contrast to bulk material spectra, in the Raman spectrum of MQW and SL acoustical phonons may be observed. These modes are referred to as folded acoustical phonons (FAPs) and are discussed in Section 5.2.2.

Confined optical and folded acoustical phonons can be utilized for the analysis of, for example, interface sharpness and layer thicknesses. Several excellent extensive reviews exist of the basic aspects of these features and the wide spectrum of experimental results, especially from III–V systems [67, 73–78]. Therefore here only a very short overview of the principles of confined optical and folded acoustical phonons is presented, together with some examples from different II–VI material systems. Of course, the interfaces in MQW and SL may also give rise to dielectric and chemical vibrational modes. These will not be discussed in this section, because they have been treated extensively within the framework of interface-induced phenomena in Section 5.1.1.

5.2.1. Confined Optical Phonons

The amplitude envelope functions of confined optical phonon modes in a MQW or SL can be visualized as the eigenmodes of a vibrating string (basic mode and overtones) in the slabs of one material, essentially unable to penetrate into the adjacent layers of the other material, since these layers have different vibration eigenfrequencies. Therefore, for a MQW or SL which consists of a sequence of alternating layers of materials A and B the allowed wavelengths λ of these confined modes can be described in a good approximation by the condition $d_A = m \cdot \lambda/2$ for those vibrational modes which are confined in material A, and correspondingly for the modes in material B, where m is an integer number, and d_A and d_B are the slab thicknesses of material A and B, respectively [79].

For a slab consisting of n monolayers with a thickness a_0 per monolayer (half of the [001] lattice constant in a zincblende structure), this condition yields for the wavevector q of the confined phonon [67]

$$q = \frac{\pi m}{(n+1)a_0} \qquad \text{with } 1 \leq m \leq n \tag{27}$$

This means that the COP eigenmodes belong to a set of equidistant q-values in the Brillouin zone. The factor $(n+1)$ (instead of the monolayer number n) takes into account the very small but finite decay length of the vibrational amplitude beyond the interfaces. Due to the optical phonon dispersion curve the modes with different index m correspond to different eigenfrequencies, through which they may be distinguished in the Raman spectrum. The negative dispersion of the optical phonons implies a decreasing eigenfrequency with increasing mode index m. For materials whose bulk phonon dispersion curves already were known from neutron scattering experiments, Raman-derived data show a quantitative agreement with the neutron data [67]. This opens up the path to derive phonon dispersion curves from COP wavenumbers in Raman experiments on superlattices (e.g., for materials of which no bulk samples for neutron scattering are available). Beside the possibility of an optical determination of the phonon dispersion curve throughout the whole Brillouin zone, COPs have two additional relevant consequences:

(i) They are a very sensitive nondestructive probe for the lateral homogeneity and interface sharpness of extremely thin layers. Thickness variations and intermixing induce a smearing of q-values and consequently an inhomogeneous broadening of the COP-peaks, especially of those with higher-order number m.
(ii) The confinement-induced wavenumber shift has to be taken into account when analyzing strain or composition-induced peak shifts.

For these reasons the wavenumber shifts of the various confined LO phonon modes of ZnSe ($m = 1, \ldots, 6$), calculated from Eq. (27) and based on the bulk ZnSe LO dispersion, are plotted in Figure 13 vs. the ZnSe layer thickness.

Obviously, the first-order confined mode shows a detectable wavenumber shift only for a layer thickness $d <$ 5 nm, which is, interestingly, far below the onset of electronic confinement near $d = 20$ nm. However, for $d = 2$ nm, the shift of the first-order mode is already 1 cm^{-1}, which is comparable to typical strain-induced shift values.

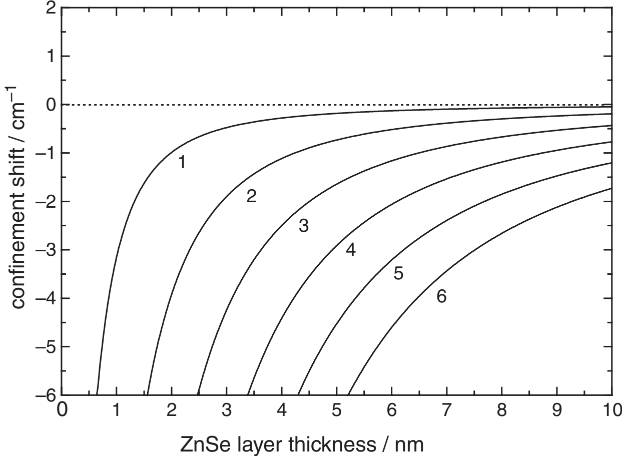

Figure 13. Confinement-induced wavenumber shift of the ZnSe LO phonon, plotted as a function of the ZnSe layer thickness; index: confinement order. Adapted with permission from [31], J. H. W. E. Hermans, Ph.D. Thesis, RWTH Aachen, 1996. © 1996, Augustinus Publ. Co.

Finally, for a correct mode-number assignment of the COP peaks, it should be considered that the odd-order modes ($m = 1, 3$, etc.) appear in the depolarized scattering configuration $z(x, y)\bar{z}$ with x, y, z the main crystal axes, whereas the even-order modes occur in the polarized $z(x, x)\bar{z}$ configuration.

As a first example of confined optical phonons in II–VI materials ZnSe/BeTe superlattices are considered, which exhibit negligible lattice mismatch. Furthermore both materials are almost lattice matched to a GaAs substrate with $\Delta a/a = +0.26\%$ and -0.48%, respectively and can therefore be grown with very high quality. Balance of the residual strain is obtained for a thickness ratio $d_{\text{ZnSe}}/d_{\text{BeTe}} \approx 2$ of the individual layers. In this case the strain-induced shift of the phonon wavenumber in ZnSe is as small as $+1.15$ cm^{-1}. In small period superlattices ($d_{SL} = 40$ Å) consisting of 5 ML BeTe and 9 ML ZnSe layers confined phonons in ZnSe up to the sixth order can be observed [80, 81], which proves the excellent sharpness of the interfaces. More detailed analysis of the influence of interface quality on the confined phonon spectrum is given in ref. [82].

In cubic CdS/ZnS superlattices, the optical phonon structures are dominated by the strain in the individual layers because of the extremely high relative lattice mismatch of 7%. Probably due to this heavy strain, which is likely to induce lattice imperfections, no higher-order confined modes are observed. The essentially strain-induced shift of the ZnS LO phonon amounts to -21.9 cm^{-1}, which agrees very well with the wavenumber shift, expected from the compliance and phonon deformation potential values [83].

For CdSe/CdS superlattices with wurtzite structure on GaAs(111), confined phonons were observed in far-infrared reflectance. Under oblique incidence (angle of incidence = 45°) confined longitudinal modes occured for light polarization parallel to the plane of incidence, while confined transverse modes appeared for polarization perpendicular to this plane [84]. The mode wavenumbers are distinctly shifted due

to the strain in the individual layers, which originates from the lattice mismatch of 3.9%.

CdS/ZnSe superlattices offer the opportunity to stabilize CdS, which naturally exhibits a hexagonal structure, in the cubic zincblende modification, imposed by the embedding ZnSe layers [85]. The layers in the resulting stack are heavily strained due to the very high relative lattice mismatch of 2.64%, which limits the maximum thickness of the individual layers to some monolayers. The strain leads to a strong shift of the ZnSe confined phonon modes. The observed COP wavenumbers of CdS as well as ZnSe are described consistently by a symmetrized strain (i.e. the SL adopts a strain state, which corresponds approximately to that of a freestanding SL). This implies for the ZnSe layers a redshift of 4 cm^{-1} due to tensile strain, while the COP peaks in the CdS layers are blueshifted by 6 cm^{-1} due to compressive strain [53].

5.2.2. Folded Acoustical Phonons

Generally, in light scattering experiments from bulk samples and simple heterostructures acoustical-phonon peaks exhibit a very low wavenumber shift from the laser line (≈4 cm^{-1} for the LA phonon) because of the small momentum transfer in light scattering. Therefore they are the domain of Brillouin scattering. MQWs and SLs, however, exhibit a periodicity length D along the growth direction of the stack, which is strongly enhanced with respect to the bulk periodicity: $D_{MQW} = n_A \cdot a_{0,A} + n_B \cdot a_{0,B}$, which may be one or two orders of magnitude beyond a_0. The enhanced periodicity in the growth direction implies a reduced periodicity in reciprocal space, which means a reduction of the Brillouin zone length to π/D_{SL} instead of its bulk value π/a_0.

For the acoustical-phonon dispersion branch, the reduction of the Brillouin zone length may be considered as a folding [67]. The slope of the dispersion branch (i.e., the SL sound velocity) is obtained from the sound velocities in the materials A and B by a weighted reciprocal averaging [see Eq. (28)]. In the inset of Figure 14 the folding is shown schematically for two superlattices [full line: SL (a), dashed line: SL (b)] with different periodicities $D_a > D_b$. The folded acoustical phonons may appear in the Raman spectrum as peaks at those wavenumbers for which the q-vector of the folded phonon branches equals the momentum transfer vector q_s, which was introduced in Section 2.2 and is plotted as here as a vertical dash-dotted line. The intersections of this line with the phonon dispersion curve yield the wavenumbers of pairs of FAP peaks. The corresponding FAP spectra are shown in Figure 14 for two $ZnSe/ZnSe_{0.9}S_{0.1}$ SLs of 120 periods with periodicities $D_a = 17$ nm and $D_b = 9.8$ nm. Both show a pair of well resolved peaks as proof of a very homogeneous periodicity. Moreover, the wavenumber shift between both pairs indicates the sensitivity of the peak position for changes of the periodicity.

The exact position of the FAP peaks in the Raman spectrum not only depends on the sample periodicity but also on the laser wavelength, which determines the q-transfer. For a quantitative evaluation, the FAP dispersion curve has to be considered in detail. Its behavior can be described according the Rytov continuum model [86], which yields for longitudinal acoustical modes propagating in the growth direction

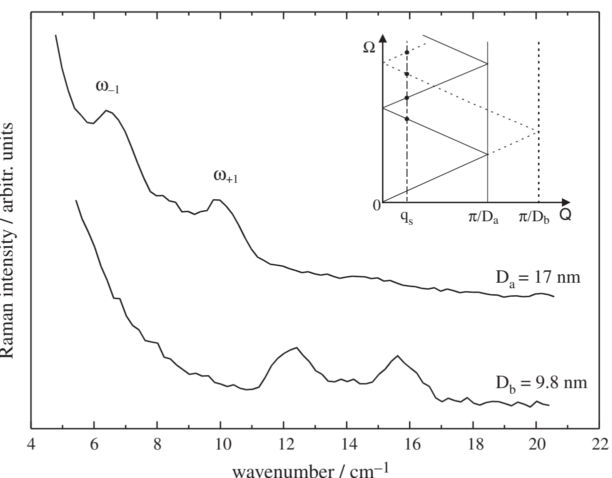

Figure 14. Low-wavenumber Raman spectra for $ZnSe/ZnSe_{0.9}S_{0.1}$ superlattices with different periodicity lengths. The inset shows schematically their wavenumber dependence on the periodicity. Adapted with permission from [31], J. H. W. E. Hermans, Ph.D. Thesis, RWTH Aachen, 1996. © 1996, Augustinus Publ. Co.

of a (100) superlattice, of compounds A and B, with thicknesses d_A, d_B, sound velocities v_A, v_B, and mass densities ρ_A, ρ_B

$$\cos(Q(d_A + d_B)) = \cos\left[\omega\left(\frac{d_A}{v_A} + \frac{d_B}{v_B}\right)\right] - \left(\frac{\eta^2}{2}\right) \cdot \sin\left(\frac{\omega d_A}{v_A}\right) \cdot \sin\left(\frac{\omega d_B}{v_B}\right) \tag{28}$$

In this expression, η is the normalized difference of the acoustical impedance $v \cdot \rho$ of the two constituting bulk materials

$$\eta = \frac{v_A\rho_A - v_B\rho_B}{\sqrt{v_A\rho_A v_B\rho_B}} \tag{29}$$

The first term of Eq. (28) describes the folding of the "average" dispersion curve due to the periodicity of the superlattice and therefore reflects the geometry of the structure. The second term describes the acoustical modulation due to the different acoustical impedance and can lead to a wavenumber splitting of the modes at the Brillouin zone center and edge. The splitting is usually very small because the acoustical impedances of the common semiconductor materials are comparable and therefore $\eta^2/2 \sim 10^{-2}$.

The calculated periodicity dependence of the FAP wavenumbers is shown in Figure 15 for $ZnSe/ZnSe_{0.9}S_{0.1}$ and for ZnSe/ZnS. The $m = 0$ line denotes the bulk phonon, whose wavenumber is of course independent of the superlattice period, and its value is only 2 cm^{-1}. The $m = \pm 1$ lines represent the first pair of FAP peaks. Their increasing slope with decreasing periodicity indicates the increasing sensitivity for thickness fluctuations in very short periodicity SLs, which goes down to fluctuations in the monolayer range.

It should be noted that the appearance of the lowest order folded acoustical phonons just proves a regular in-depth periodicity over the lateral range which is covered by the laser focus, without allowing the assessment of the interface sharpness. For the latter purpose the intensities of the

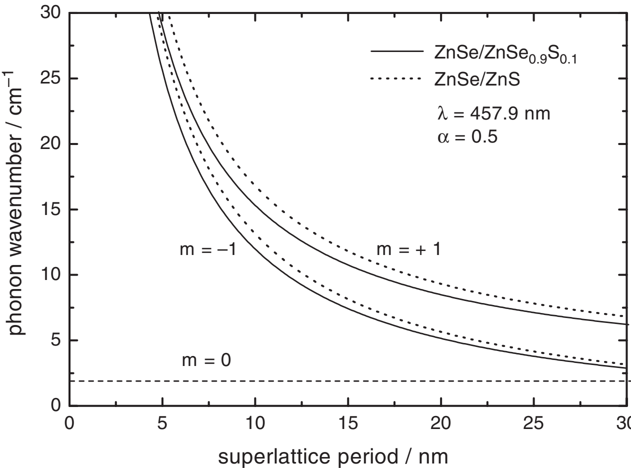

Figure 15. Wavenumber of the folded acoustical phonons as a function of the superlattice periodicity D. Adapted with permission from [31], J. H. W. E. Hermans, Ph.D. Thesis, RWTH Aachen, 1996. © 1996, Augustinus Publ. Co.

higher order FAP pairs ($m = \pm 2$; ± 3, etc.) and especially the confined optical phonons are a sensitive criterion.

For CdS/ZnSe superlattices, FAP modes up to the third order were observed [53] whose wavenumbers agree very well with those calculated with the Rytov model. For a SL with individual layer thicknesses of 1.7 and 1.4 nm, respectively, the intensity ratio of the third-order modes with respect to the first ones amounts to 0.38, which agrees rather well with the theoretically predicted value of 0.33 for a symmetrical SL. In this way, a very good lateral and in-depth homogeneity of the SL is confirmed, as well as a clear interface abruptness. Similarly, for CdS/CdSe strained SLs FAP modes were observed whose wavenumbers are described very well by the Rytov model [83].

Besides cubic SL hexagonal systems were also applied for FAP studies. The observation of FAP modes was reported for hexagonal CdSe/CdS superlattices, which are heavily strained because of the extremely high lattice mismatch of 7% between CdS and CdSe. However, for the evaluation of FAP mode wavenumbers, the strain is of no significant relevance, because it is symmetrical: tensile in one material and compressive in the other. Therefore it has hardly any net effect for the wavenumber of the acoustical phonons, which are eigenmodes of the total stack [85]. However, the strain-induced piezoelectric effect in the individual CdS and CdSe layers enables the observation of FAPs by measuring infrared reflectance spectra at oblique incidence [84].

A quite original application of FAP modes was reported for BeTe/ZnSe superlattices [82]. Here very pronounced FAP peaks were observed at an average wavenumber of 35.8 cm^{-1} and a splitting of 3.1 cm^{-1} for superlattices, whose periodicity consisted of 1.3 nm BeTe and 2.6 nm ZnSe. This result enabled the determination of the hitherto unknown sound velocity of BeTe, since all other input parameters of the SL sound velocity (i.e., the layer thicknesses and the sound velocity in ZnSe) were known. The resulting value of $v_s^{\text{BeTe}} = 4180$ m/s $\pm$ 5%, which is very similar to the v_s value for ZnSe, corresponds to an elastic constant $c_{11} = 8.9 \pm 0.9 \cdot 10^{10}$ N/m^2 and agrees well with first-principle density functional theory calculations, based on the local density approximation [87].

6. NANOSTRUCTURES: QUANTUM WIRES AND QUANTUM DOTS

This section covers the main item of this chapter, that is, the application of Raman spectroscopy to nanostructures such as quantum wires and dots. In these studies on nanostructures the various abilities of Raman spectroscopy are employed, which have been discussed above for bulk materials and for layered structures and interfaces, such as confinement effects and the determination of strain and composition. The examples are classified according to the production method of the nanostructures.

First, Raman results on chemically produced dots in glass matrices will be presented in Section 6.1. For these systems, besides the chemical composition, also the average dot size and the size distribution are main issues. Dot sizes are determined from low-wavenumber Raman spectroscopy, while the chemical composition is derived from the optical phonon wavenumbers. Furthermore, the electron–phonon coupling and the extension of the electronic wavefunction beyond the dot edges are studied.

Section 6.2 deals with wires and dots which were generated lithographically by patterning and etching of quantum well layers. Here strain distributions and the size dependence of strain relaxation are the main subject of the investigations.

As an alternative to the lithographic production of dots, the spontaneous dot formation by three-dimensional growth of strongly lattice-mismatched systems has gained much attention. These self-organized dots are discussed in Section 6.3. Here Raman spectroscopy can provide information, for example, on the onset of dot formation, their chemical composition, stability, and interface sharpness.

6.1. Chemically Produced Dots

6.1.1. Phonon Confinement in Quantum Dots

Quantum dots (QDs) fabricated by precipitation methods are usually embedded in an amorphous matrix, like glass or organic polymers, to stabilize them from aggregation. Theoretical investigations predict that among the optical phonons TO, LO an infinite series of surface optical modes (SO) exist in the nanocrystallite. Because of the eigenfrequency mismatch between the dots and the amorphous matrix the lattice vibrations cannot penetrate into the matrix: the phonon wavefunctions are confined within the dots. In the Raman scattering process, this spatial confinement results in a relaxation of the momentum conservation, which increases with decreasing crystallite radius. This leads to an enhancement of transition probability between the vibrational states and therefore to a shortening of the lifetime of the excited state. Finally, this shortening of the lifetime results in a size-dependent increase of the homogeneous linewidth. The relaxation can be observed in the Raman spectra as a redshift of the LO wavenumber, caused by the negative dispersion of the LO phonons, as well as an asymmetrical broadening of the peakwidth [88–92]. Recently, the appearance of SO phonons as well as the size-dependent

broadening of both LO and SO was accounted for the observed broadening. The broadening should be due to the boundary relaxation at the dot–matrix interface, which is caused by the reduction of the mean free path $L = kr$ in QDs [93]. The lineshape of the confined LO phonon modes can be calculated with the modified model for bulk phonons. In this model the localization of the phonon wavefunctions within crystallites with spherical shapes (or disc- or tube-shaped) and a dispersion function due to the dispersion of the dot sizes in the sample are considered [90, 94]. The calculations result in a dispersion of the phonon momentum, which depends on the crystallite radius r [89, 92, 94]:

$$I(\omega) \sim \int \frac{|C(0, \mathbf{q})|^2}{(\omega - \omega(\mathbf{q}))^2 + \left(\frac{\Gamma_0}{2}\right)^2} d\mathbf{q} \tag{30}$$

For the Fourier coefficient of the confinement function usually a Gaussian function is taken:

$$|C(q)|^2 = \exp\{-q^2 d^2/16\pi^2\} \tag{31}$$

In a simple model the dependence of the redshift of the LO phonon on the crystallite radius r can be deduced from the phonon dispersion relation $\omega(q)$ of the bulk mode, when q is replaced by [38, 95–97]

$$q_n = n\pi/(r + a/2) \tag{32}$$

$\omega(q)$ is given by a fit of the phonon dispersion in form of

$$\omega^2(\mathbf{q}) = A + \{A^2 - B[1 - \cos(qa)]\}^{1/2} \tag{33}$$

Here, A and B are fit parameters. The discussed model is valid only for off-resonance Raman excitation. In resonance Raman spectroscopy there are other factors that can also broaden the linewidth of the LO phonon peak and are not considered in this model. Many groups have already observed the asymmetrical broadening in Raman experiments on II–VI semiconductor dots (e.g., [94, 98]), but the observed amount of the redshift lies below the expected one. This can be caused by different effects. The most important one is that the investigated dots are not small enough: The dot radius should be smaller than the exciton Bohr radius of the respective semiconductor material to obtain measurable shifts (strong confinement regime). Furthermore, matrices, especially those which form bonds with the surface atoms of the crystallite, can induce strain on the crystallite surface. The strain can cause a blueshift of the phonon wavenumbers, which may obscure the confinement redshift [97]. A further explanation of the missing shift supported by some groups [33, 92, 99] is the existence of defects, which are formed during the preparation and which cause the LO wavenumber to shift to higher values. For CdSe clusters the exciton Bohr radius a_0 is 5.6 nm [100, 101]. Thus, for cluster radii below this value the confinement shift should be observable.

This effect was experimentally demonstrated for LO phonons of CdSe clusters in GeO_2 glass matrix [89]. For different samples containing nanocrystals with average diameters between 9.6 and 3.8 nm, the redshift of the LO phonon signal as well as the broadening of the linewidth due to the phonon confinement was clearly observed. The resulting dependence of the peak wavenumbers on the nanocrystal diameter showed a good agreement with the results of calculations from Eqs. (30) and (31) [89].

The size dependence of the LO lineshape can also be proven experimentally by wavelength-dependent Raman investigations on a quantum dot sample with large size inhomogeneities. When changing the excitation wavelength the resonating cluster sizes change, too. Thus, the whole size distribution of a quantum dot sample can be probed and size-dependent Raman spectra can be obtained from one and the same sample. For higher excitation wavelengths the LO phonon line shows the characteristics of confinement: the asymmetrical broadening as well as the appearance of the surface optical mode [102].

6.1.2. Size Determination of Nanocrystallites by Low-Wavenumber Raman Spectroscopy

Because of the strong size dependence of the optoelectronic properties of nanocrystalline samples, the determination of the crystallite sizes is a crucial point in the characterization of nanocrystallites. Besides methods like high resolution transmission electron microscopy and X-ray diffractometry, low-wavenumber Raman spectroscopy was established as a fast method to determine the average dot size. The modes in the low-wavenumber range of quantum dot samples can be attributed to the torsional (depolarization ratio $\rho = 3/4$, $\omega^T_{l,n}$) and spheroidal acoustical modes (depolarization ratio $\rho = 0$, $\omega^S_{l,n}$). The amplitude of the torsional mode is largest at the dot surface. Therefore, size-dependent changes of the interface conditions are expected to influence the intensity of this mode. Thus, the torsional modes should show the highest intensity for the particles with the smallest radius and therefore weak particle matrix interaction [103, 104]. In contrast, the amplitude of the spheroidal mode is displaced within the particle and should have a weaker dependence on the matrix. Effects, arising from the matrix, strain, or shape, mainly have an influence on the eigenfrequencies of the higher wavenumber modes, whereas the influence on the lowest eigenfrequency mode is normally rather small [104, 105]. Theoretical considerations have shown that the spheroidal modes (even l) can be Raman active, while the torsional modes (odd l) are Raman inactive [106]. A further criterion for the identification of the low-wavenumber modes is that spheroidal modes with $l = 0$ are observed only in the polarized geometry, whereas the quadrupolar modes with $l = 2$ are observed in polarized as well as in depolarized geometry. The spheroidal as well as the surface modes show resonance enhancement when the laser energy matches the region of the lowest absorption band [107]. With the knowledge of the elastic constants of the matrix and the dot shape, it is possible to determine the dot radius from the wavenumber of the spheroidal acoustical mode [108–110]: The quantum dots are considered as elastic bodies, which are vibrating with eigenmodes, whose frequencies are proportional to their diameter. The angular eigenfrequencies of the torsional and the spheroidal modes are then given by [103–105]

$$\omega^T_{l,n} = \eta^T_{l,n} v_l / d \tag{34}$$

$$\omega^S_{l,n} = \eta^S_{l,n} v_l / d \tag{35}$$

v_l is the longitudinal sound velocity [m/s]; the factor η depends on the crystallite shape and the matrix. For spherical cluster shapes the following equation for the dependence of the lowest frequency eigenmode ν_{LFR} on the cluster diameter d is obtained [103–105, 107, 108]:

$$d = \xi \frac{v_i}{c\nu_{LFR}} \tag{36}$$

c is the speed of light. The numerical factor ξ depends on the ratio between longitudinal and transversal sound velocity. For CdS and CdSe it is 0.9. The wavenumber positions of the low-wavenumber modes of quantum dots show a dependence on the excitation wavelength. This is due to the fact that each excitation wavelength induces resonance for a specific cluster size [103]. From the shape of the low-wavenumber band this size distribution can be calculated by fitting the peak with a distribution function [Gaussian (symmetric) or Lifshitz–Slyozov (asymmetric)] [108]. An example of low-wavenumber Raman spectra of different semiconductor-doped glasses (Schott glasses, CdS_xSe_{1-x} quantum dots) is shown in Figure 16 [111]. On both Stokes and anti-Stokes sides, the bands appear typically around 10–30 cm^{-1}. The derived diameter for example of OG550 glass was 7.0 ± 0.4 nm.

6.1.3. Composition Determination from Optical Phonons

For the determination of the composition of nanocrystallites, which are embedded in a glass matrix material and often occupy a volume fraction as low as 1%, X-ray diffraction seems to be extremely difficult. Raman spectroscopy offers the advantage of the resonant enhancement of the phonon signal intensity when exciting at an electronic transition of the semiconductor material. In these resonance Raman spectra the mixed-compound phonon peaks appear,

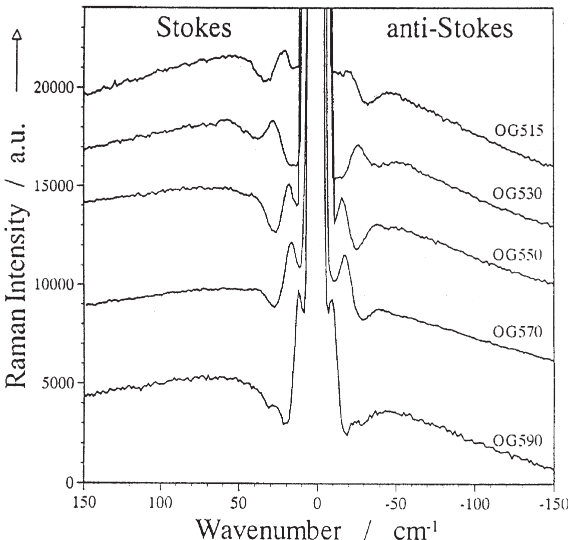

Figure 16. Nonresonant low-wavenumber Raman spectra of different semiconductor doped glasses recorded with laser excitation at 647 nm. Reprinted with permission from [111], T. Bischof et al., *J. Raman Spectrosc.* 27, 297 (1996). © 1996, Wiley Interscience.

which were discussed for bulk material in Section 4.2. Now the nanocrystallite composition is determined from a direct comparison of the nanocrystallite mode frequencies with the known composition dependence for the bulk material. A consideration of possible size effects reveals that these are expected for nanocrystallite sizes below 4 nm. Many relevant systems consist of larger clusters, for example, the CdSSe microcrystals in Schott glass long-pass filters, whose cluster sizes are generally beyond 6 nm. Here resonant Raman spectroscopy was applied successfully for composition determination [111].

Raman spectroscopy from optical phonon modes was also applied for the study of the effects of thermal sintering up to 500 °C on CdTe/CdS "core-shell" clusters (i.e., CdTe cores, embedded in CdS shells) in colloids and films [112, 113]. Comparison of the peaks in the cluster spectra with the well-known LO phonons of CdTe (170 cm^{-1}) and CdS (305 cm^{-1}) revealed that sintering between 100 and 200 °C initiates the CdTe cluster growth. Sintering temperatures of 300–400 °C lead to a release of tributylphosphine-capping ligands and to the formation of bare CdS and CdTe nanocrystals. Finally, above 400 °C the CdTe part of the nanostructures sublimates, leaving behind nearly pure CdS nanocrystallites.

6.1.4. Pressure Effects

In quantum dots produced by sol/gel processes strain can be also caused by the surrounding matrix. The synthesis of these samples implies sintering processes or the implantation of the dots into the molten matrix material. The thermal expansion constants of this matrix are usually different from the constants of the semiconductor. As a consequence, the matrix can induce an effective pressure on the dot surface upon cooling the sample.

For CdS and CdSe quantum dots pressure-dependent Raman experiments resulted in a shift of the LO phonon wavenumber and in a decrease of the LO phonon intensity with increasing pressure. Finally, the LO phonon peak disappears. This disappearance is caused by the transition of the lattice structure from the direct bandgap wurtzite structure into the indirect bandgap rocksalt structure, in which first-order Raman scattering is symmetry forbidden [33, 42, 43, 99, 114–117].

In pressure-dependent Raman spectra of CdS nanocrystals with an average diameter of 8 nm deposited in glass matrix, a linear blueshift with increasing pressure at a rate of 0.47 ± 0.01 and 0.98 ± 0.02 cm^{-1}/kbar, respectively, was observed for the wavenumbers of the LO fundamental and its first overtone [33]. The pressure coefficients are similar to those of the bulk CdS, which is 0.5 ± 0.03 cm^{-1}/kbar for the LO fundamental [33, 37, 117–119]. The peak intensities initially showed an increase with increasing pressure due to resonance enhancement. Beyond 12 kbar the intensities decreased strongly until at 60 kbar the intensity has decreased to 8% of the intensity at 1 bar. In contrast to measurements on bulk CdS, where a complete phase transition occurs above 27 kbar [33, 100, 116–121], the LO intensity did not vanish completely [33, 116]. The initial increase due to resonance effects is also much smaller than in bulk CdS. This reflects the fact that the energy levels in the CdS-glass composites are distributed over a large energy region, caused by the size inhomogeneity of the sample.

Pressure-dependent Raman experiments on CdS colloids with an average diameter of 6 nm show the same pressure coefficients as the glass composites. The pressure for the highest resonance intensity in this sample is about 20 kbar. With further increasing pressure the Raman intensity decreases strongly but shows no sharp cutoff like the bulk [99, 119]. This cutoff is a sign for a lattice reorganization to the rocksalt structure [33]. In some cases the phase transition is incomplete and a weak LO signal due to the mixed rocksalt/wurtzite structure can be observed even at high pressures [99, 118]. A further difference in the observations in the bulk is the hysteresis in the pressure dependence of the LO frequency shift, which is about 5 kbar in QDs compared to 15 kbar in the bulk [35]. Other high pressure studies with microcrystalline CdS show that there is a complete phase transition at pressures below 40 kbar. This difference in the phase transition behavior can be caused by defects on the crystal surface. The defects induce a large strain field in the crystal, which shifts the local phase transition to higher pressures. A second factor, which may cause a shift, is the effect of the surface. The surface tension and reconstruction energy result in a contraction of the lattice constants in small particles [122].

6.1.5. Electron–Phonon Coupling

In the brief treatment of Raman scattering mechanisms in Section 2.3 it was already discussed that in II–VI compounds longitudinal-optical phonons are accompanied by a strong electric field that induces a strong Fröhlich coupling of the phonons to the electric field of the optically excited excitons, which constitute the intermediate states of the Raman scattering process. Therefore, for these materials the Fröhlich mechanism dominates the electron–phonon coupling in resonant Raman scattering.

In order to understand the impact of nanostructures for the electron–phonon coupling efficiency, the Fröhlich interaction mechanism is considered here in more detail. The origin of the electric field of the exciton is the difference in spatial extent of the electron and the hole wavefunction. In bulk materials the electron is much less localized than the hole. From this incomplete overlap and because of the difference in the effective masses, a carrier distribution results in a positive net charge in the central region and a negative net charge on the edges. The Fröhlich mechanism describes the coupling of this electronic charge inhomogeneity with the polar lattice [38, 123–126]. The magnitude of the electron–phonon coupling depends on the shape of the phononic and excitonic carrier distributions and on the polarizability of the excitonic state. Its maximum value occurs for those phonons whose wavelengths match the exciton dimension [38, 123].

Experimentally, the electron–phonon coupling (EPC) efficiency can be derived from resonant Raman scattering and its excitation profile, i.e., the dependence of the scattering efficiency on the incident and scattered photon energy. In this way, incoming and outgoing resonance profiles are obtained. For this purpose, not only first-order Raman scattering but also scattering from phonon overtones is employed. The electron–phonon coupling efficiency is derived from the relative scattering intensities of these modes [125, 126]. For example, in bulk CdS, up to eight overtones are observed in resonant Raman spectra because of the very efficient coupling between excitons and strongly polar lattice vibrations [127, 128].

In small clusters the situation is different in various aspects: In contrast to the bulk the conservation of momentum in quantum dots is relaxed and first-order Fröhlich-induced Raman scattering becomes allowed. The bulk model for calculating the EPC cannot be applied for nanocrystals since it does not imply boundary conditions of the carrier and vibrational confinement. To calculate the size dependence of the EPC, a new model has to be considered, which includes the confinement and also surface effects, like the trapping of the hole at localized surface states. Many authors performed experimental and theoretical investigations of the size-dependent coupling to the optical phonons (LO; TO; SO) of nanocrystallites [95, 96, 123, 125, 129–132]. Different approaches were applied for the calculation of the exciton wavefunction and for boundary conditions for the coupling to the LO and SO phonons. Despite the numerous investigations, up to now no consistent picture was obtained [38, 94, 124, 130, 133–135].

Generally, there are two compensating size effects on the EPC: The first effect is the confinement-induced increasing spatial overlap between the electron and hole wavefunction of the exciton, which is expected to reduce the EPC because of the reduced polarizability of the exciton by the lattice vibration [38, 39, 95, 106, 123, 136]: For sufficiently small clusters, the electron and hole wavefunctions coincide. For these clusters the excitonic polarizability vanishes and so should the EPC [123, 129]. In addition, the effect of the crystallite surface has to be taken into account: The hole can be localized in traps like defects or vacancies on the crystallite surface, for example, in uncoordinated Se-*p*-orbitals. By this trapping the wavefunction overlap is reduced and therefore the polar character of the excitonic charge distribution increases. This charge distribution causes a lattice distorsion which produces an enhancement of the Raman cross section of the LO mode and its overtones [38, 123, 128, 131].

Taking into account both effects one can conclude that with decreasing cluster size there must be first an increase of the EPC due to the trapping-induced decreased overlap between electron and hole (weak confinement regime), followed by a decrease of the EPC due to the increasing overlap between electron and hole with further decreasing crystallite radius (intermediate confinement regime) [127]. This decrease can be observed in the vibrational spectra in which a decreasing number of overtones as well as a decrease of the ratio of the integrated LO-overtone and fundamental intensities are observed [126]. As an example, resonance Raman spectra of CdS bulk and three different CdS nanocrystallite samples with average sizes of 10, 6, and 4 nm showed a clear decrease of the ratio of the integrated intensities of overtone to fundamental with decreasing crystallite size [125]. Further Raman experiments with even smaller CdS crystallites confirmed this decrease [38]. The observed excitation wavelength dependence of the 2LO/1LO ratio, which is due to the inhomogeneous size distribution in these samples, also agrees with this size dependence.

In the weak confinement regime, a decrease of the EPC is also found for higher temperatures: with increasing temperature the trapped hole can be thermally activated across the potential barrier on the surface and therefore becomes delocalized. The result is an increased overlap of electron and hole and thus a strong decrease of the EPC coupling with increasing temperature [127].

Recent calculations, involving all kinds of optical phonons or based on the nonadiabaticity of the electron–phonon system, resulted in an increasing overtone/fundamental ratio with decreasing dot radius in accordance with experiments on CdSe and CuBr QDs [135, 132].

6.2. Lithographically Patterned Wires and Dots

For heterostructure systems, which are the origin of nanostructures such as quantum wires and dots, generally lattice mismatch between the layer materials occurs. This mismatch induces strain, which affects the electronic band structure and consequently the optical properties. In addition, this strain also affects the vibronic properties, as discussed in Section 4.3. The optical as well as the vibronic properties of nanostructures are influenced not only by strain but also by, for example, composition and confinement effects. Fortunately, for the vibronic properties these influences have different features than for the optical behavior. Therefore, mostly a combined analysis by Raman spectroscopy and photoluminescence allows the separation of these effects.

For combinations of materials with a small or moderate lattice mismatch, pseudomorphic growth occurs (i.e., a strained epitaxial layer growth) up to a critical thickness. From this thickness onward, the strain decreases because of the formation of misfit dislocations. The appearance of misfit dislocations can be observed in the Raman spectra as an increase in the intensity of the symmetry-forbidden TO phonon peak as well as a broadening of the LO phonon peak.

The following section treats the pressure dependence of the vibrational properties as well as the strain effects in quantum wells and superlattices. Finally, the last part of this chapter deals with the strain relaxation in etched quantum wires and dots.

6.2.1. Strain Effects in Nanostructures Due to Lattice Mismatch in (Multi)-Quantum Wells

In the MBE growth of layered systems the lattice mismatch between barrier and well induces biaxial strains in the interface regions. These strains cause shifts of the LO phonon wavenumber, which are proportional to the strain. For compressive (tensile) strain a blueshift (redshift) of the phonon wavenumber can be observed [43, 115, 137–139]. The amount of this shift may depend on the layer thickness [39, 140, 141]. For ZnSe on GaAs, from the beginning of the epilayer growth large elastic strains occur parallel to the interface due to the lattice mismatch. This strain causes an distinct blueshift of the phonon wavenumber. At a critical thickness of $h_0 = 80$ nm, the first stable dislocation pairs can be formed [142–144]. At a thickness d_c of 300 nm other arrangements of dislocations are formed [143] and total relaxation by the formation of arrays of misfit dislocations takes place. For thicknesses beyond 600 nm the wavenumber gradually approaches the value of the stress-free LO phonon. The appearance of misfit dislocations and stacking faults leads to a strong decrease of the lattice quality. Therefore, for the growth of a high-quality layer it is necessary to keep the layer thicknesses below the critical thickness. The strains in these layers lead to changes in the vibrational properties, which can be estimated by Raman spectroscopy. By these experiments the dependence of the strain on the layer thickness can be evaluated in one and the same sample [22, 145]. In ZnTe/ZnSe superlattices with a lattice mismatch of about 7% and thicknesses of 0.5–5.0 nm the superlattice is not destroyed by diffusion of Se or Te even for very small layer thicknesses. The Raman spectra of these samples show an asymmetrical LO phonon peak with increasing width for increasing layer thickness [146]. This increasing peakwidth is caused by inhomogeneous strain, whose amount is increasing with increasing layer thickness. The LO wavenumber position depends rather on the ratio d_{Se}/d_{Te} than on the absolute thicknesses of the layers [142]. For these superlattices the LO phonon position shifts with decreasing ratio d_{Se}/d_{Te} from the wavenumber position of pure ZnSe to the wavenumber position of pure ZnTe. The TO phonon peak, which appears because of the strain effects, shows a shift of the wavenumber position, which is linear to $d_{Te}/(d_{Se} + d_{Te})$. The experimental shifts are in good agreement with the shifts calculated from the equations, given in Section 4.3 [22, 39, 137, 145, 147–156]. Biaxial strain in the layer perpendicular to [001] makes the sample quasi-two-dimensional and the pressure-dependent shift is then given by Eqs. (13) and (14) [39, 42, 43, 146].

Besides the strain caused by lattice mismatch, another contribution exists which gains in significance when the sample is cooled to very low temperatures. This thermally induced strain is caused by the different thermal expansion coefficients. At room temperature the amount of the thermal strain is about one order smaller than the lattice mismatch induced strain, whereas for low temperatures this strain can become dominant [155]. The rather small strains for very thin layers can be explained by the growth of a kind of island structure, which can be used for the MBE fabrication of quantum dots (Stranski–Krastanov model: see refs. [157–161]). In contrast to the lattice for a complete layer, the lattice at the edges of these islands is relaxed, which leads to a reduced strain shift. For the investigation of inhomogeneous strains (i.e., local strain fields like quantum islands), the second-order Raman signals have to be used. Due to the momentum conservation, the optical phonons involved in a first-order process originate from the center of the Brillouin zone. Because of this, they have quite long wavelengths, on the order of ≥ 100 nm, so only homogeneous strains with extensions larger than the phonon wavelength can be obtained. The phonons participating in second-order processes mostly originate from the zone boundary and therefore obtain shorter wavelengths in the range of 1 nm. Therefore, small structures, like quantum islands or interface clusters, can give rise to observable shifts of the second-order signals, whereas the first-order signal is an average over a larger area [162]. A discrepancy in magnitude of the

strains calculated from the shift of the first-order signals on the one hand and from the splitting of the second-order bands on the other hand is a sign for inhomogeneous strain fields. This inhomogeneity can be explained when assuming large low strain areas and small high strain areas at the interface, as is the case for small Ga_2Se_3 islands (1–10 nm) at the GaAs/ZnSe interface [162, 163].

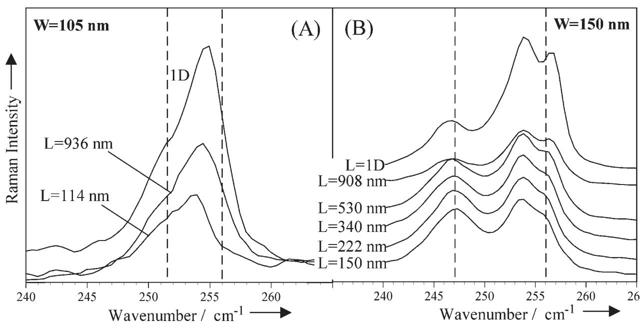
6.2.2. Strain Relaxation in Quantum Wires and Etched Quantum Dots

In the fabrication of etched quantum wires and quantum dots, the strain caused by lattice mismatch in MBE grown layers is partially reduced by the etching process. At their lateral surfaces these structures have the opportunity for relaxation. This ability is increasingly hampered toward the center of the wires or dots. Therefore (e.g. for wires) the overall degree of relaxation depends on the ratio of the relaxed wire edges to the total volume of the wire. Thus, for a reduction of the wire dimensions, like the reduction of the wire width or the wire length, a reduction of the total amount of the strain is possible. As already mentioned above, the first-order Raman signals do not distinguish local strains, so only one signal for the whole wire or dot can be obtained, which consists of the signals of the strained center as well as the relaxed edges. But even in the first-order spectra the strain relaxation can be observed as a shift of the LO phonon wavenumber toward the value of the unstrained material.

The Raman analysis of edge relaxation will be discussed here for the system $Cd_xZn_{1-x}Se$/ZnSe [164–166]. The investigated structures consisted of $Cd_xZn_{1-x}Se$ quantum wells (thickness ≈5 nm), embedded in ZnSe layers on GaAs(100), which had been patterned to wires and dots by e-beam lithography and subsequent wet etching. Wire widths and dot sizes were down to about 15 nm. The Raman spectra are expected to show the LO phonon peaks of $Cd_xZn_{1-x}Se$ and ZnSe. In the size range of these structures no phonon confinement effects are expected, as shown in Figure 13. Thus, the $Cd_xZn_{1-x}Se$ LO phonon wavenumber is fully determined by the composition of the layers and their strain state. The Cd content of all structures was chosen ≤35% in order to limit the lattice mismatch, thus avoiding the onset of relaxation processes before the patterning, which would deteriorate the crystalline perfection. The composition-dependent vibronic behavior of $Cd_xZn_{1-x}Se$ is described by the two-mode model (see Section 4.2). The Zn–Se vibration mode is expected to be much more intense than the Cd–Se mode, because $x \ll 0.5$. Therefore in the following the ZnSe-like mode will be analyzed. With increasing Cd content x, its wavenumber decreases, starting from LO_{ZnSe} (=256 cm^{-1}) with a downshift of about 0.26 cm^{-1} per percent Cd, which results in $LO_{CdZnSe} = 247$ cm^{-1} for $x = 0.35$ [114], thus enabling the spectral separation between the LO peaks of the CdZnSe wires and the ZnSe barriers. However, for lower Cd content ($x \leq 0.2$) this separation will become increasingly difficult.

The Raman spectra for two different compositions and various wire widths and lengths are shown in Figure 17. The Cd content was $x = 0.2$ for spectra (A) and $x = 0.35$ for spectra (B), while the wire widths were either beyond 100 nm (upper spectra) or below 40 nm (lower spectra). These values had been chosen because side-face relaxation effects become observable for wire widths below about 100 nm and full relaxation is achieved at about 40 nm [167]. The wire length was varied between 100 μm (denoted 1D) and the wire width W, thus ending up with a quantum dot geometry. The most pronounced changes occur in the Raman spectra (B) of samples with a Cd content $x = 0.35$, because here the peaks are well separated. The spectra B show the ZnSe LO peak at 256 cm^{-1} (= bulk wavenumber) and additional peaks due to the CdZnSe wires. As a common feature for all wire lengths the 247 cm^{-1} peak occurs, whose wavenumber corresponds to bulk $Cd_{0.35}Zn_{0.65}Se$. Therefore it is explained in terms of the relaxed regions at the side faces and the end faces of the wires. Obviously, its relative intensity increases with decreasing wire length. Finally, especially in the spectrum for the wider wires ($W = 150$ nm), a third feature appears in between, which is attributed to the central region of the wires. Here the ZnSe-like LO phonon of the CdZnSe wires is blueshifted with respect to bulk CdZnSe due to compressive strain. This interpretation is underscored by the decrease of the relative weight of this structure with decreasing wire size.

For the spectra (A), due to the low Cd content of $x = 0.2$, no separation between the ZnSe and CdZnSe phonon peaks is obtained. However, in the superimposed peak a clear shift and shape change is observed, which can be explained along the same line as for the samples with the higher Cd content [164].



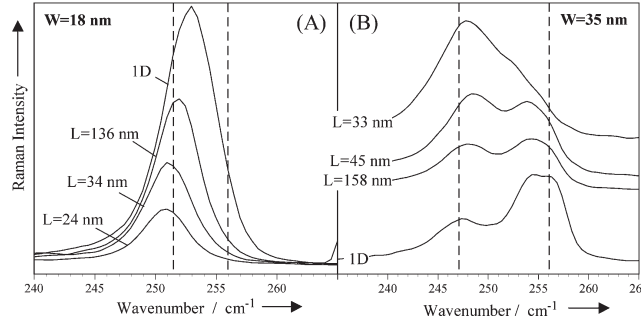


Figure 17. Resonance micro-Raman spectra of $Cd_xZn_{1-x}Se$/ZnSe quantum wires with different wire width W and wire length L. Cd content: $x = 0.2$ for spectra (A) and $x = 0.35$ for spectra (B). Reprinted with permission from [164], B. Schreder et al., *J. Appl. Phys.* 88, 764 (2000). © 2000, American Institute of Physics.

Small shifts of the sum peak when changing the excitation wavelength are due to the change in the resonance conditions of the well and the barrier, which leads to changes in the relative intensities of the two peaks. With decreasing wire width x the LO phonon position of the ZnSe-like phonon shows a redshift toward the wavenumber of the unstrained material, whereas the wavenumber of the ZnSe LO phonon remains constant [168].

In order to evaluate these data as detailed as possible, the expected phonon wavenumbers and their strain-induced local variation were calculated. In this procedure, for each point of the wire cross section the strain was minimized with respect to the nearest neighbors by applying the finite element method [168–170]. In this way, every point of the wire cross section is characterized by a particular phonon wavenumber, dependent on the stress in this point. More detailed calculations of the strain field in short wires or dots result in shear strains at the corners of the wires which also have to be considered in the calculation of the wavenumber shift [171]. The calculated position-dependent wavenumbers show a strong lateral inhomogeneity as well as a clear height dependence. It can be seen from the model that the wire edges are totally relaxed and therefore obtain the bulk phonon wavenumber, whereas the strain in the wire centers is comparable with the strain in the well for the thick wires but decreases with decreasing wire width. Total strain relaxation is predicted for widths below 10 nm.

A comparison of the expected LO phonon wavenumbers, which may be obtained by averaging over the wire height z and the wire width, with experimental results shows that experimentally full relaxation is obtained already for widths below 30 nm. The averaging over wire regions with different strain leads to a theoretically predicted redshift of the position of the resulting wire peak with decreasing wire width due to the increasing influence of the relaxed regions. This phenomenon was experimentally observed [167–170, 172] for samples with various Cd contents and resulted in a temperature-independent wavenumber difference between the LO peaks of CdZnSe and ZnSe [167, 168]. Furthermore, the spectra in Figure 17 show distinct peaks from the relaxed and the strained range. These results indicate a sharp change in the lattice constants between the center and the edge of the wire rather than a step by step relaxation.

For a quantitative evaluation of the Raman peak intensities and shapes in terms of the relative contributions from differently strained regions, the local scattering efficiency has to be taken into account. The resonant enhancement at the electronic bandgap, which was discussed in Section 2.3, may lead to a preferential selectivity for regions with a specific strain value, because the electronic bandgap value is also strain-dependent. This phenomenon was confirmed experimentally by experiments with different laser lines, which resulted in different peak shapes [168, 173]. Systematic investigations of the excitation profiles in resonant Raman scattering revealed that for the system $Cd_xZn_{1-x}Se$/ZnSe the wavelength dependence of the peak shape increases with increasing Cd content and with increasing wire width. This is attributed to more pronounced inhomogeneities [174].

6.2.3. Oxidation at Open Sidewalls

Etching of quantum wires and dots out of $2d$-grown quantum well structures (mesas), which is the topic of this section, inherently creates new interfaces at the sidewalls of those dots and wires. The cleanliness of the side faces is crucial for the optical properties of these systems. The increased surface recombination rate at the sidewalls creates dead layers. The process technology applied for the etching process as well as exposure of the sidewalls to air ambient crucially affects the properties of the dead layers [175–177]. Additionally, oxide layers are expected to affect the sidewall strain relaxation of a strained active layer in very small structures (<50 nm). By using a UHV-compatible process (e.g., dry etching), the influence of sidewall oxidation due to air ambient can be investigated. By coupling the sample preparation via a UHV transport system to a UHV Raman setup, the intentional oxidation of the sidewall can be followed by Raman spectroscopy. So MBE-grown CdZnSe quantum wells embedded in ZnSe grown on GaAs(100) substrates exhibit a systematic downshift of the ZnSe–LO mode upon air contact. This downshift, which does not exist for $2d$ reference mesas and increases with decreasing wire width (e.g., -0.6 cm^{-1} for 40 nm wire width) is attributed to the additional strain component due to the sidewall oxidation [14].

6.3. Self-Organized Dots

Self-organized dots are formed by atomic rearrangement due to strain relaxation in strongly mismatched epilayers (i.e., lattice mismatch in the order of percent) when the epilayer thickness exceeds a critical value, usually only few monolayers. This three-dimensional growth mode is referred to as Stranski–Krastanov growth. For achieving nanostructures, it constitutes a very interesting alternative to lithographically defined dots, because it does not require a highly sophisticated patterning technology. Moreover, it allows direct overgrowth of the dots without interruption of the UHV conditions. Of course, a crucial point is the dot size homogeneity.

These self-organized dots have attracted much attention because they offer an interesting potential as active layers in semiconductor laser diodes. II–VI dots are considered promising candidates for the realization of diodes in the blue and blue-green spectral range.

Raman spectroscopy is applied for studying, for example, the onset of dot formation, their chemical composition, interface sharpness, and stability. The Raman analysis of self-organized dots constitutes a special challenge from the viewpoint of sensitivity, because we deal with extremely low scattering volumina. The dot thickness can be as low as only a few monolayers, and the lateral coverage factor is below one. These drawbacks are overcome by resonant excitation at the electronic transitions of the dots, which selectively enhances their Raman signals. However, one has to avoid the obscuring of the Raman peaks by photoluminescence (PL). This may be achieved either by excitation at the low-energy edge of the PL peak or by utilizing the resonant Raman enhancement at a nonfundamental electronic transition (e.g., $E_0+\Delta_0$).

6.3.1. Onset of Dot Formation

For CdSe/BeTe, Raman studies were performed at the very beginning of quantum dot formation (i.e., thickness fluctuations as low as one monolayer). In this very strongly lattice-mismatched material system ($\Delta a/a = 7\%$) self-organized dots are known to occur for layer thicknesses beyond about 3 ML. In the study which is discussed here, the initial stage of the dot formation process was conserved in CdSe layers of nominally one ML by embedding them between BeTe layers. For reasons of Raman intensity, a stack of five CdSe single MLs was grown, separated by BeTe barrier layers with a thickness of 4.5 nm each. For the interfaces Te–Cd bonds were chosen because they give the best abruptness, as shown in Section 5.1.1. The resulting Raman spectra were partly presented already in Figure 8. Their explanation in terms of CdSe-ML vibrations, (i.e., eigenmodes of the sequence $\cdots$–Be–Te–Cd–Se–Cd–Te–Be–$\cdots$) resulted in a quantitative agreement of the experimental peak positions with the relative positions according to the linear chain model but could not quantitatively explain the peak shape. For obtaining this detailed agreement, additional vibration modes have to be invoked which require the assumption of laterally distributed inclusions of two MLs (i.e., the sequence $\cdots$–Be–Te–Cd–Se–Cd–Se–Cd–Te–Be–$\cdots$). The atomic displacements of the resulting additional eigenmodes are shown in Figure 18, together with the corresponding eigenwavenumbers, as derived from the linear chain model. The essential modifications as compared to the one ML modes are a slight downshift of the Te–Cd interface-centered mode by 5 to 164 cm^{-1} and a splitting of the most strongly confined mode, the former Cd–Se–Cd mode (216 cm^{-1}), yielding two new wavenumbers: 204 and 224 cm^{-1}. Thus, the 190–220 cm^{-1}-structure in Figure 8 is fitted quantitatively as a superposition of three peaks: the central one from the one ML regions and the outer ones from the two ML inclusions.

A further confirmation of this model was obtained from resonance effects in Raman spectra for various laser lines. Due to the different electronic transition energies of the one and two ML regions, a variation of the relative contribution of these regions is expected when changing the incident photon energy. This should result in changes of the peak shape. Indeed, the spectra in Figure 19 show a systematic trend: in the 190–220 cm^{-1}-structure, the edge contributions, which are attributed to the two ML vibrational modes, are more pronounced for the 2.5 eV laser line, while an increase of the laser energy to 2.71 eV results in an increase of the central part, which is attributed to the one ML mode. This trend of an increased contribution of the one ML regions with increasing laser photon energy corresponds to the expected resonance behavior, since the confinement-induced enhancement of the electronic transition energy for one ML regions should exceed the two ML value.

These Raman spectroscopy results, concerning the abruptness of interfaces with Te–Cd bonds and fluctuations of the CdSe layers, which result in one and two ML regions, are fully consistent with transmission electron microscopy results. The latter reveal within each layer a regular distribution of alternating one and two ML regions and, moreover, a correlation between neighboring layers, which leads to a chessboardlike pattern of one and two ML regions.

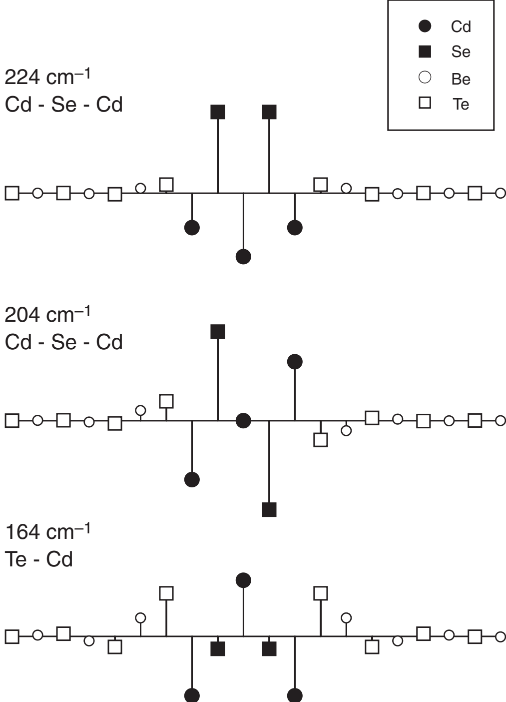

Figure 18. Displacement vectors and wavenumbers of vibration modes, related to two ML CdSe, embedded in CdTe with Cd–Te interface bonds. These modes were obtained by a linear chain calculation with next neighbor interactions. Adapted with permission from [52], V. Wagner et al., *Appl. Surf. Sci.* 175, 169 (2001). © 2001, Elsevier Science.

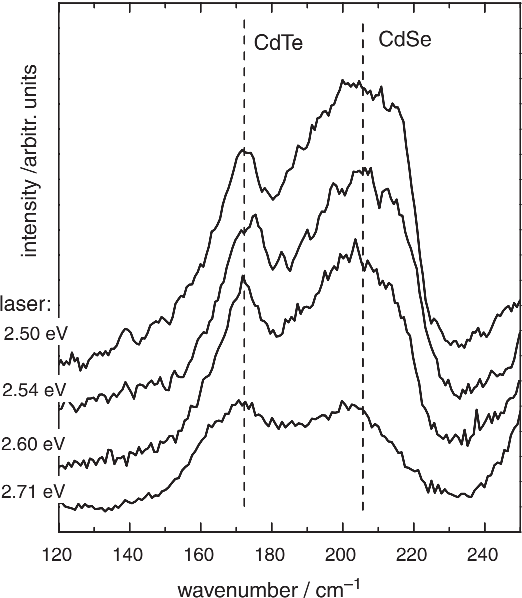

Figure 19. Resonance effects in the Raman spectra of CdSe monolayers, embedded in BeTe. Variation of the incident photon energy from 2.71 to 2.50 eV results in a change of the peak shape due to an increasing contribution of two ML regions. Reprinted with permission from [52], V. Wagner et al., *Appl. Surf. Sci.* 175, 169 (2001). © 2001, Elsevier Science.

6.3.2. Chemical Composition and Stability

CdSe Dots on ZnSe For CdSe growth on ZnSe, the Stranski–Krastanov growth mode is induced by the lattice mismatch of 7%. However, it does not simply result in binary CdSe dots. Instead, transmission electron microscopy (TEM) studies revealed that ternary ZnCdSe dots are formed with a Zn content up to 30%, on top of a ZnCdSe wetting layer with a Zn content of about 15%. In addition, smaller planar Zn-rich quantum islands appear, with a Cd concentration of only 30% [178].

In Raman spectroscopy, the latter can be excited resonantly by a wavelength of 488 nm. They give rise to a ZnSe-like LO phonon mode at 246.4 cm^{-1}, thus confirming the TEM results [179]. The resonant excitation also allows the observation of the 2LO and 3LO multiphonon peaks. In micro-Raman experiments (spot diameter $\approx 0.7\ \mu m$), this situation is stable for sufficiently low input power (about 0.2 mW). However, upon increasing the input power to 5 mW, the mode intensities strongly decrease with irradiation time on a time scale of hundreds of seconds due to a shift of the electronic resonance energy. At the same time, the LO wavenumber is blueshifted by 1.7 cm^{-1}. These results are explained consistently by an outdiffusion of Cd from the planar $Cd_{0.3}Zn_{0.7}Se$ islands, which is induced by the local heating which results from the resonant absorption in the islands [179]. This example underscores on the one hand the caution which has to be taken in micro-Raman spectroscopy to avoid any unintentional changes of the sample; on the other hand it illustrates the possibilities of a selective modification by optical irradiation.

6.3.3. Excitonic Confinement Effects, Probed by Spin Flip Raman Scattering

Because of the excitonic character of its intermediate states, Raman scattering allows the analysis of excitonic states in quantum dots. The most favorable type of scattering for this purpose is spin flip Raman scattering (SFRS). In this scattering process the elementary excitation involved in the sample is a change of the spin orientation (e.g., of an electron or a hole in an external magnetic field B). The corresponding change in photon energy is given by the Zeeman splitting $g \cdot \mu_B \cdot B$, where g is the gyromagnetic ratio (g-factor) of the involved electron or hole, and μ_B is the Bohr magneton. For nonmagnetic semiconductors SFRS induces wavenumber shifts on the order of 1 cm^{-1} per Tesla. These very low values lead to an extremely pronounced resonance behavior, because now $\omega_s \approx \omega_i$, and both factors in the denominator of Eq. (9) vanish nearly simultaneously. This extremely strong resonance offers two major advantages:

(i) The sensitivity for very small scattering volumina (e.g., in interface regions or nanostructures).
(ii) A pronounced material selectivity in heterostructures.

The Raman shift of the SFRS peak (e.g. of the electron spin flip) varies linearly with the magnetic field, and the slope of this line allows the evaluation of the corresponding g-factor with high accuracy. Interestingly, in quantum dots the g-factor which is determined in this way may deviate considerably from the bulk g-value of the dot material and show a shift toward the g-value of the underlying or embedding material. This shift allows an assessment of the extention of the wavefunction beyond the dot.

Beside electrons or holes, the optically excited excitons themselves may also undergo a spin flip [180, 181]. These SFRS processes allow the analysis of the exchange interaction between the electron and the hole in the exciton and, moreover, of its modification in confined systems, such as quantum dots [182]. Due to the exchange interaction Δ_{ex} the field dependence of the excitonic SFRS peak exhibits for low B-fields a positive deviation from the linear dependence, leading to a $\sqrt{\Delta_{ex}^2 + (g\mu_B B)^2}$ field dependence. Therefore the extrapolation of the field dependence to $B = 0$ results in a finite Raman shift, whose energy value yields the excitonic exchange energy Δ_{ex}. Typical bulk values for II–VI materials are of order 0.1 to 1 meV, but for quantum dot sizes below the bulk exciton size a considerable increase of the exchange energy is expected.

Examples of excitonic SFRS in nanostructures have been reported for self-organized III–V quantum dots in the material systems InP/InGaP and InAs/GaAs [183], as well as for II–VI dots: chemically produced CdS dots in a glass matrix [184].

The excitonic SFRS studies which are most relevant for our discussion of self-organized nanostructures deal with CdSe fractional monolayers (≤ 0.5 ML), embedded in ZnSe epilayers [185, 186]. They form islands of various sizes (i.e., with different confinement effects). Moreover, the lateral dimensions and separation of the islands are smaller than the exciton radius. In this laterally inhomogeneous system, the pronounced resonance behavior of SFRS allows one to address each island size separately by the appropriate choice of the laser wavelength.

In this way, the confinement dependence of the exciton exchange energy has been studied. The experimental results reveal for decreasing island size an increase of Δ_{ex}, which is proportional to the exciton confinement energy. The Δ_{ex} range goes from 0.5 meV (bulk value) to 1.2 meV for the smallest islands, whose exciton confinement energy amounts to 30 meV.

The electronic SFRS in these islands shows the expected linear dependence on the B-field. However, its g-factor amounts to 1.15 ± 0.02, which is much closer to ZnSe than to CdSe. Thus, it reflects the penetration of the wavefunctions into the ZnSe, in which the islands are embedded.

7. SUMMARY

In this chapter an overview was presented of the abilities of Raman spectroscopy for the analysis of interfaces, surfaces, and nanostructures, such as quantum wires and dots. Within this framework, the application of *in-situ* Raman spectroscopy for growth monitoring was also discussed.

The required sensitivity and selectivity were obtained by resonant excitation, that is, by the appropriate choice of the laser line, combined with sophisticated multichannel detection equipment, such as a CCD.

It was shown that information is obtained on a wide variety of aspects. Examples were presented for the identification of materials, the study of their crystalline perfection, the composition of mixed compounds, and strain or doping.

Several interface- or surface-induced phenomena were discussed, such as chemical and dielectric vibrational modes and electronic band bending. Examples of interfaces between different II–VI materials as well as II–VI/III–V interfaces were presented. For ZnSe/GaAs(100), the coupling of the dielectric vibrations at the surface and the interface was analyzed, and it was shown that from Raman spectra of the epilayer LO phonon together with the coupled plasmon–LO–phonon mode of the substrate a consistent picture was obtained of the epilayer strain relaxation and the electronic band bending on the substrate side due to the interface defects. Furthermore, examples were presented of the influence of the growth conditions on the interface chemistry and the crystallographic perfection of heterostructures (e.g., for embedded monolayers of CdSe in BeTe and for the onset of CdTe growth on InSb substrates).

For the study of (multi)-quantum wells and superlattices new phenomena in the Raman spectrum were exploited, such as confined optical and folded acoustical phonons. As an example, for the lattice-matched system BeTe/ZnSe the confined optical phonon behavior was evaluated in terms of interface perfection, showing that Zn–Te interfaces are far superior to Be–Se ones. In this material system the folded acoustical phonons were used to determine the elastic constant c_{11} and the sound velocity of BeTe. For heavily strained systems, such as cubic CdS/ZnS and hexagonal CdS/CdSe superlattices, the strain-induced shift of the confined phonon modes was studied.

The Raman studies on nanostructures which were presented here cover lithographically patterned wires and dots, as well as self-organized dots due to Stranski–Krastanov growth and dots in amorphous matrices, produced chemically (e.g., by the sol–gel technique). For these systems, common issues studied by Raman spectroscopy were their composition, their size, and their strain behavior.

For lithographically patterned strained wires and dots, consisting of ZnCdSe embedded in ZnSe layers, the strain relaxation after patterning was studied. In this case, strained and relaxed regions were observed by separate peaks in the Raman spectrum. From their intensity ratio the degree of relaxation was determined, which revealed that relaxed regions can be observed for wire widths below 100 nm and full relaxation occurs below 15 nm.

The onset of the formation of self-organized dots was studied for CdSe, embedded in BeTe. Here thickness fluctuations as low as one ML were detected by selective intensity enhancement of the different regions in resonant Raman scattering. Furthermore, for self-organized ZnCdSe islands in ZnSe, the compositional stability during laser irradiation was studied. Here a distinctly enhanced diffusion during resonant irradiation was observed.

The size of dots in matrices was determined from low-wavenumber Raman spectroscopy, for example, for Schott glasses, consisting of glass matrices, doped with CdS_xSe_{1-x} quantum dots in the range of about 10 nm. For a quantitative evaluation of size distributions the size dependence of the resonance excitation profile had to be taken into account.

The composition of mixed-compound dots was determined from their optical phonon wavenumbers. It was shown that for crystallite sizes beyond 5 nm no confinement effects had to be considered. As an example, the sintering behavior of CdTe/CdS "core-shell" clusters was discussed.

Moreover, the pressure-dependent behavior of quantum dots was addressed. Here, pressure-induced shifts of optical phonon wavenumbers were employed (e.g., for studying the zincblende-to-rocksalt phase transition in CdS colloids with a particle diameter of 8 nm in a glass matrix).

Finally, spin flip Raman spectroscopy was applied for studying the size dependence of the electron–hole exchange interaction and the extension of the electronic wavefunction beyond the edges of nanostructures. The electron–hole exchange in CdSe islands in ZnSe was shown to increase by a factor of about 3 with decreasing island size, while in the same material system the electronic g-factor of the islands was close to the ZnSe value, thus confirming the penetration of the electronic wavefunctions into the embedding ZnSe.

1. INTRODUCTION

A review of the Raman-active modes in single walled carbon nanotubes is presented both from experimental and theoretical standpoints. A discussion is first given of the Raman spectroscopy of isolated tubes which serve as a building block to understand the Raman spectroscopy of tubes that reside in bundles or in solution, and of nanotubes when subjected to external pressure, high temperature, applied potentials, and interstitial or endohedral doping. Using different nanotube systems, such as bundled tubes, double walled tubes, multiwalled tubes, and peapods, an attempt is made to elucidate the influence of van der Waals forces on the fundamental Raman scattering properties of nanotubes.

Raman spectroscopy has served as a sensitive tool for characterizing new forms of carbon by providing information on structural, vibrational, and electronic properties. The chapter starts with a discussion of Raman spectroscopy of an individual single wall carbon nanotube (SWNT) and how such studies provide direct structural information. The Raman spectra obtained from isolated SWNTs are mainly used here to provide detailed information about each of the features in the Raman spectra and about the resonance Raman process responsible for their observation (Section 2). The spectra thus obtained are used to interpret the Raman spectra observed in SWNTs that interact with each other or with an external environment and especially to illuminate the influence of the van der Waals interaction on the Raman scattering properties of nanotubes. The effect on the Raman spectra of nanotubes coupling to each other as they assemble into bundles of SWNTs (Section 3.1) or in multiwall nanotubes (Section 6) is explicitly considered, as well as the effect of subsequent debundling of the SWNTs into small SWNT bundles and even into individual SWNTs by chemical means (Section 3.3). The effect on the Raman spectra of the nanotubes, when the tubes are subjected to external pressure (Section 3.4), high temperature (Section 3.2), applied potentials (Section 3.3), and interstitial doping (Section 3.3), is also reviewed. The Raman spectra of C_{60} encapsulated single-walled tubes (peapods) (Section 4) and of double-walled nanotubes (Section 5) are given particular attention as model systems for studying the coupling of one nanotube to another and of a nanotube to a molecular endohedral species because of the relative simplicity and theoretical tractability of these systems.

2. SPECTRA FROM ISOLATED SINGLE WALL CARBON NANOTUBES

In this section the Raman spectra from isolated SWNTs are presented in the context of the use of Raman spectroscopy to infer information about the coupling of the SWNT basic building block to form other nanotube-based structures.

In Section 2.1 the basic Raman nanotube spectra are presented at the single nanotube level, while Section 2.2 provides pertinent background for understanding the *unusual* aspects of Raman spectroscopy of SWNTs at the single nanotube level. A review of the use of single nanotube spectroscopy to provide the structural (n, m) characterization of SWNTs is presented in Section 2.3 and the connection between Raman spectra observed at the single nanotube level and in SWNT bundles is given in Section 2.4.

2.1. Single Nanotube Spectroscopy

Figure 1 shows typical Raman spectra from an isolated semiconducting and a metallic nanotube on a Si/SiO_2 substrate. The four most important features seen in Figure 1 (and also seen in the spectra for SWNT bundles) are the radial breathing mode where the carbon atoms are all vibrating in phase in an A symmetry mode in the radial direction of the nanotube, the tangential G-band (derived from the graphitelike in-plane mode), the disorder-induced D-band, and its second-order harmonic (the G'-band) [1]. Table 1 provides a summary of the most important spectral features in Figure 1.

The isolated SWNTs used in these single nanotube Raman experiments were prepared by a chemical vapor deposition method on a Si substrate containing nanometer size iron catalyst particles [3]. Since the silicon substrate is oxidized to form a thin SiO_2 surface coating, no significant charge transfer is expected between the SWNTs and the substrate. Since the nanotubes nucleate and grow from well isolated nanometer size catalyst particles, nanotube bundles are not formed. Figure 2b shows an atomic force microscopy (AFM) image of a sample with a high SWNT concentration

Table 1. Vibrational modes observed for Raman scattering in isolated SWNTs.

Notation	Frequency (cm^{-1})	Symmetry	Type of mode
RBM	$248/d_t$	A	in phase radial displacements
D-band	$\sim$1350	—	defect induced, dispersive
G-band	1550–1605	A, E_1, E_2	graphite-related optical mode[a]
G'-band	$\sim$2700	—	overtone of D-band, highly dispersive

Note: Frequencies for the dispersive D-band and G'-band are given for laser excitation at 2.41 eV (514 nm).

[a] The related graphite mode has E_{2g} symmetry.

(6 ± 3 SWNTs per μm^2) for easy visualization. The inset to Figure 2b shows the wide diameter distribution of the SWNT samples ($\sim 1 < d_t < \sim 3$ nm) typically used in single nanotube Raman studies. However, the actual samples used for single nanotube spectroscopy studies have a very low nanotube density, less than 1 SWNT/μm^2, a factor of 10 more dilute than that shown in Figure 2b.

Resonance Raman spectra in the 100 to $\sim$3000 cm^{-1} spectral range from these individual isolated SWNTs are taken with a readily available Raman microprobe instrument, such as a Renishaw Raman microprobe (1 μm laser spot), using $\sim$1 mW laser power, and typical laser excitation, such as $E_{laser} = 514.5\,nm = 2.41\,eV$. The Raman spectra shown in Figure 1 were taken with a Kaiser micro-Raman spectrograph, operating at a laser excitation energy of 1.58 eV. Relatively high laser powers can be used to probe isolated SWNTs because of their unusually high thermal conductivity [4], their excellent high temperature stability, and their good thermal contact to the substrate.

It is possible to observe the spectrum for one isolated carbon nanotube, only $\sim$1 nm in diameter, when the incident photon energy is close to the energy of a transition

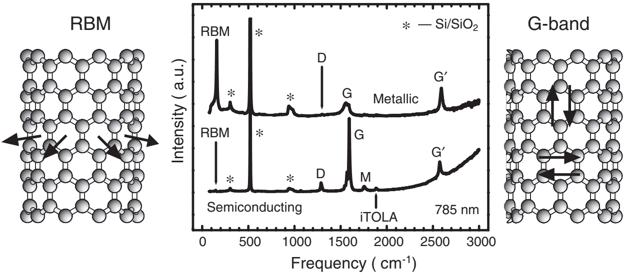

Figure 1. Raman spectra from a metallic (top) and a semiconducting (bottom) SWNT at the single nanotube level using 785 nm (1.58 eV) laser excitation, showing the radial breathing mode (RBM), the D-band, G-band, and G' band features, in addition to weak double resonance features associated with the M-band and the iTOLA feature. Also shown are the mode displacements associated with the RBM (left) and G-band (right) normal mode vibrations. The isolated carbon nanotubes (see Fig. 2b) are sitting on an oxidized silicon substrate, which provides contributions to the Raman spectra denoted by an asterisk, and these Roman features are used for calibration purposes.

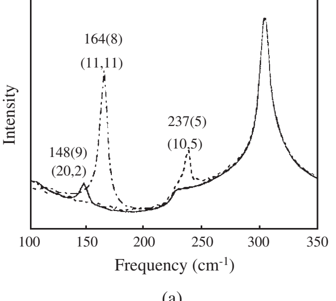

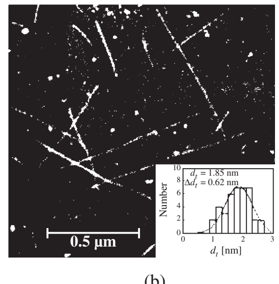

Figure 2. (a) The three Raman spectra (solid, dashed, and dash–dotted curves) come from three different spots on the Si substrate, showing the presence of only one resonant nanotube and one RBM frequency for each of the three laser spots. The RBM frequencies (widths) and the (n, m) assignments for each resonant SWNT are displayed. The 303 cm^{-1} feature comes from the Si substrate and is used for calibration purposes (see Fig. 1) [2]. (b) AFM image of the sample showing isolated single wall nanotubes grown from the vapor phase. The small particles are iron catalyst particles. The inset shows the diameter distribution of this sample ($d_t = 1.85 \pm 0.62$ nm) based on AFM observations of 40 SWNTs. Reprinted with permission from [2], A. Jorio et al., *Phys. Rev. Lett.* 86, 1118 (2001). © 2001, American Physical Society.

between van Hove singularities in the one-dimensional (1D) density of states of the valence and conduction bands, or equivalently a singularity in the joint density of states (JDOS). Under these resonance conditions, the intensity of the Raman signal is strongly increased and becomes comparable to that seen from the silicon substrate (marked by an asterisk in Fig. 1). The enhancement of the resonance process can be seen more clearly in Figure 2a which shows that under favorable resonance Raman conditions, the RBM intensity from only one 1D carbon nanotube can be comparable to that of the silicon spectral features from the quasi-3D Si film substrate (where the Si/C atom ratio within the optical beam is perhaps $\sim 10^6$). In Figure 2a, the resonance of three different isolated SWNTs with the same laser line (1.58 eV or 785 nm), some having their singularity in the joint density of states E_{ii} closer in energy to the laser excitation energy E_{laser}, and some further from E_{laser}. Also determining the Raman intensity is the length of the nanotube, the laser light intensity on the nanotube, and the angle of the optical E field of the laser and the nanotube axis.

Since the energy of these singularities in the JDOS depend strongly on the nanotube diameter, the observation of the Raman spectra using a specific laser excitation energy is highly diameter-selective, as was already pointed out in the first observation of the Raman spectra from single wall carbon nanotubes [5]. The strong dependence on nanotube diameter d_t arises from the proportionality between the nanotube diameter and the number of carbon atoms around the tube circumference [6]. Since the number of allowed wave vectors in 1D relates to the number of carbon atoms around the circumference, the separation between the allowed wave vectors is proportional to $1/d_t$. In addition to the strong diameter selectivity, there is also a weaker selectivity which arises from the chirality of the nanotube and is due to the trigonal warping effect for nanotubes. This trigonal warping effect arises from the corresponding effect in the constant energy surfaces of a 2D graphene sheet shown in Figure 3b. Because of this trigonal warping effect, there is a weak dependence of the electronic energy levels of SWNTs on chiral angle [6], as will be explained below. To gain an understanding of these issues, some background about the geometrical and electronic structure of single wall carbon nanotubes is reviewed.

2.2. Pertinent Background about Carbon Nanotubes

The structure of each nanotube is uniquely described by two integers (n, m), which refer to the number of $\vec{a}_1$ and $\vec{a}_2$ unit vectors of the graphene lattice that are contained in the chiral vector, $\vec{C}_h = n\vec{a}_1 + m\vec{a}_2$, which spans the circumference of each nanotube [6]. From the (n, m) indices, one can calculate the nanotube diameter d_t, the chiral angle θ, the electronic energy bands and the density of electronic states [6, 9], as well as the energies of the interband transitions $E_{ii}(n, m)$ between the van Hove singularities in the valence and conduction band density of states. It is well established [6] that the (n, m) indices are crucial to the nanotube electronic structure. Specifically, SWNTs for which $|n - m| = 3q$ are metallic, and those for which $|n - m| = 3q \pm 1$ are semiconducting, where q is an integer [6, 10]. The Raman spectra

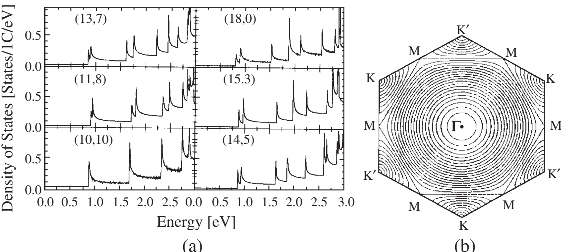

Figure 3. (a) The 1D electronic density of states vs energy (measured from the Fermi level) for several metallic nanotubes of approximately the same diameter, showing the effect of chirality and trigonal warping (see text) on the van Hove singularities in the density of states: (10,10) (armchair), (11,8), (13,7), (14,5), (15,3), and (18,0) (zigzag). Only the densities of states for the conduction π^* band are shown; the mirror image of these plots gives the electronic density of states for the valence π band [7, 8] within the tight binding approximation, assuming the energy overlap integral is $\gamma_0 = 2.9$ eV and the wave function overlap integral vanishes, $s = 0$ [6]. (b) Plot of the 2D equienergy contours of 2D graphite, showing trigonal warping effects in the contours, as we move from the K point in the K–Γ or K–M directions in the 2D graphene Brillouin zone. The equienergy contours are circles near the K point and near the center of the Brillouin zone (Γ). But near the M points on the zone boundary, the contours are straight lines which connect the nearest M points. Reprinted with permission from [7], R. Saito et al., *Phys. Rev. B* 61, 2981 (2000). © 2000, American Physical Society.

of the G-band for metallic and semiconducting nanotubes are qualitatively different from each other, as can be seen in Figure 1 at the single nanotube level, and this difference in lineshape is even more pronounced in SWNT bundles as discussed in Section 3.1. This difference in lineshape can be used to distinguish between metallic and semiconducting nanotubes.

The weak dependence of the electronic energy bands of SWNTs on chiral angle θ relates to the three-fold symmetry of the electronic dispersion relations about the K point of the 2D graphene Brillouin zone (see Fig. 3b), where the graphene valence and conduction bands are degenerate, forming a zero bandgap semiconductor for a 2D graphene sheet (a single basal plane layer of the graphite lattice) [6]. Close to the zone center Γ point, the K point and the K' point (which is related to K by time reversal symmetry), the constant energy contours are circular. But away from the K point, the graphene electronic energy bands exhibit a trigonal warping effect [7, 11–13], as shown in Figure 3b, and this trigonal warping is responsible for the unique energy bands for the conduction and valence bands for each (n, m) SWNT, when the energy bands of the graphene lattice are zone folded to form the energy bands of the SWNTs [7].

The locations of the van Hove singularities for a particular nanotube are found by superimposing the set of *allowed* parallel k-vectors (called cutting lines) on the constant energy contours and looking for the k points where the energy extrema occur. The chirality dependence of the van Hove singularities [7, 8] in the 1D electronic DOS of the conduction band are shown in Figure 3a for several *metallic* (n, m) nanotubes, all having about the same diameter d_t (from 1.31 to 1.43 nm), but having different chiral angles: $\theta =$ 0°, 8.9°, 14.7°, 20.2°, 24.8°, and 30.0° for nanotubes (18,0), (15,3), (14,5), (13,7), (11,8), and (10,10), respectively. Here the energy is measured relative to the Fermi energy, which

is taken to be at $E = 0$. The plots in Figure 3a show that as the chiral angle is varied from the armchair nanotube (10,10) ($\theta = 30°$) to the zigzag nanotube (18,0) ($\theta = 0°$), a splitting of each van Hove singularity, due to the trigonal warping effect, develops in the DOS traces [7, 8], and this splitting increases from zero for $\theta = 30°$ to a maximum for $\theta = 0°$. Because of the dependence of the spacing between cutting lines on $1/d_t$ and because of the trigonal warping effect shown in Figure 3a, every distinct carbon nanotube, denoted by its (n, m) indices, or equivalently by its diameter d_t and chiral angle θ, will have a *unique* set of singularities E_{ii} [2].

This trigonal warping effect consequently causes a spread of the interband energies E_{ii} between the singularities in the JDOS for nanotubes with the same diameter d_t and index i, as shown in Figure 4. Here the integer i labels the singularities in the JDOS, and i increases as the energy relative to the Fermi level E_F increases. As a result of the trigonal warping effect, Figure 4 shows that each nanotube (n, m) has a unique set of interband energies E_{ii} denoting the energy differences between the ith van Hove singularities in the conduction and valence bands. And, conversely, if one interband energy E_{ii} and a nanotube diameter d_t in Figure 4 are specified, then the corresponding unique (n, m) for this nanotube can be identified [2].

2.3. Structural (n, m) Characterization through Raman Spectroscopy

This fact leads to what is special about the resonance Raman effect in *isolated* SWNTs, and this is the structural information that is provided by the single nanotube spectra. Normally the resonance Raman effect just gives spectral information, or information about phonon frequencies, electronic energy levels, and the electron–phonon interaction, but not structural information directly. But in the resonance Raman process for SWNTs, every (n, m) nanotube is in resonance with a unique set of interband energies $E_{ii}(n, m)$,

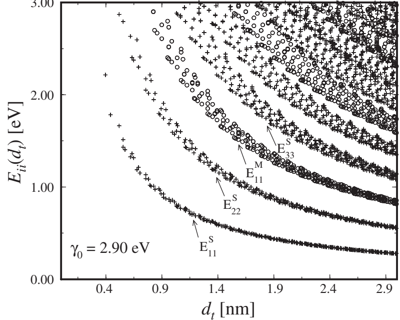

Figure 4. Calculated [14] energy separations E_{ii} between van Hove singularities i in the 1D electronic density of states of the conduction and valence bands for all (n, m) values vs nanotube diameter in the range $0.4 < d_t < 3.0$ nm, using a value for the carbon–carbon energy overlap integral of $\gamma_0 = 2.9$ eV and a nearest neighbor carbon–carbon distance $a_{C-C} = 1.42$ Å [7, 15]. Semiconducting (S) and metallic (M) nanotubes are indicated by crosses and open circles, respectively. The subscript $i = 1$ denotes the index of the lowest energy of a singularity in the joint density of states and the Fermi level for the isolated SWNT is taken at $E = 0$. as shown in Figure 4, so that for this 1D system, resonant Raman spectra can also yield structural information through identification of the (n, m) values that correspond to the observed Raman spectra for a given isolated SWNT. Once (n, m) is known from measurements made on the radial breathing mode feature, Raman studies on isolated carbon nanotubes can be carried out to understand in detail the dependence of *all* the features shown in the spectrum of Figure 1 on diameter d_t, chiral angle θ, laser excitation energy E_{laser}, and other pertinent parameters. Furthermore, the spectra observed for these other features in Figure 1 are also sensitive to d_t and θ and can be used to corroborate the (n, m) assignments.

From knowledge of the characteristics of each feature in the Raman spectra at the single nanotube level, the spectrum of SWNT bundles can be elucidated, and by comparison between the spectra measured on SWNT bundles and for isolated SWNTs, the effect of nanotube–nanotube interactions can be deduced. Resonance Raman characterization of the (n, m) indices for one nanotube is important for scientific studies of SWNTs, insofar as many physical properties, such as transport, optical, mechanical, and other properties, that depend sensitively on the (n, m) indices [6], can be studied systematically at the single nanotube level through use of the resonance Raman effect to identify their (n, m) values. The (n, m) characterization provided by resonance Raman spectroscopy [2] is a general, rapid (a few minutes per spectrum), nondestructive technique that operates under ambient temperature ($\sim$300 K) and pressure conditions and uses readily available Raman characterization instrumentation.

Since the frequency of the RBM feature varies as $1/d_t$

$$\omega_{\text{RBM}} = \alpha/d_t \tag{1}$$

the RBM mode provides a convenient tool for the determination of the tube diameter which is one of the parameters needed for the (n, m) characterization (see Fig. 4). For the Si/SiO_2 substrate (see Fig. 2b), the value for α in Eq. (1) is experimentally found to be 248 cm^{-1} nm by measurement of the RBM spectral feature for a large number of isolated SWNTs [2]. Furthermore, ω_{RBM} is observed to be independent of chiral angle θ. *Ab initio* calculations for isolated SWNTs yield a value of $\alpha = 234$ cm^{-1} nm [16], which is within 5% of the experimental value of 248 cm^{-1} nm.

The determination of (n, m) by resonance Raman scattering depends on the determination of E_{ii} and d_t by exploiting the unique relation between E_{ii} and (n, m) shown in Figure 4 and the direct determination of d_t from the radial breathing mode relation $\omega_{\text{RBM}} = 248/d_t$. Although the determination of E_{ii} is most conveniently carried out by measurement of the radial breathing mode feature, other features (such as the G-band, D-band, and G'-band) in the resonance Raman spectrum (see Fig. 1) are sensitive to d_t and can be used to confirm the (n, m) assignment made from analysis of the RBM spectrum. If a tunable laser were available to be tuned to E_{ii} (which could be detected as the E_{laser} value where the maximum intensity in the Raman spectrum occurs), then a simple measurement of ω_{RBM} to yield d_t and to identify the index i in E_{ii} (see Fig. 4) would

be sufficient to determine (n, m). In practice, such a tunable laser system has thus far been applied only once to single nanotube Raman spectroscopy studies and over a small energy range (~0.15 eV) [17], and this is in part due to the fact that only a few laboratories worldwide have available tunable laser systems working over a broad energy range in conjunction with a Raman microprobe system.

Nevertheless, an (n, m) determination can in most cases be made if a nanotube is within the resonant window of a single available laser excitation line, which in practice is satisfied for E_{laser} within $\sim\pm 0.1$ eV of an interband transition for that nanotube. From the measured ω_{RBM} and use of Eq. (1), the nanotube diameter d_t is found, which determines the i index in E_{ii} from Figure 4. In many cases of practical interest, there is only one (n, m) value that has both a diameter close to the measured d_t value, as determined from the ω_{RBM} measurement, and an E_{ii} value within a few meV of E_{laser}.

One method to determine E_{ii} directly requires measurement of both the Stokes and anti-Stokes radial breathing mode spectra [18, 19], where the ratio of the anti-Stokes to Stokes intensities for the radial breathing mode for a given resonant nanotube is used to sensitively (to 10 meV) determine the energy E_{ii} of the resonant van Hove singularity in the joint density of states [18], thereby providing a unique identification of the (n, m) indices. When the anti-Stokes to Stokes intensities are exactly equal to the Boltzmann factor at the measurement temperature for ω_{RBM}, as in Figure 5 of [1], then E_{laser} is in exact resonance with E_{ii} (i.e., $E_{ii} = E_{\text{laser}}$), resulting in very large intensities for all of the features in the Raman spectra. In general, E_{ii} is not exactly equal to E_{laser} ($E_{ii} \neq E_{\text{laser}}$), resulting in a ratio of the intensities of the anti-Stokes to Stokes signals that is not equal to the Boltzmann factor but rather is modified by how well the resonance condition is satisfied. We use this effect to determine the value of E_{ii}.

In Figure 5 we see experimental traces for the Stokes and anti-Stokes spectra for two different isolated SWNTs taken at $E_{\text{laser}} = 1.579$ eV, where in each case the trace for the anti-Stokes spectra is enhanced by the reciprocal of the Boltzmann factor to yield I_{AS}/I_S, which denotes the ratio of the peak intensities of the anti-Stokes and Stokes features in the normalized radial breathing mode spectra, as presented in Figure 5. Although the radial breathing mode frequencies (and consequently the nanotube diameters) for the spectra in Figure 5a and b are almost the same, the ratios of the anti-Stokes to Stokes intensities I_{AS}/I_S are very different. To the right of each pair of experimental traces is a plot of theoretical curves for the expected intensity of the radial breathing mode based on a simple model which assumes constant matrix elements and a joint density of states with the strong frequency dependence that is expected for a 1D system. The profile of the joint density of states for an isolated SWNT was determined by Raman measurements made on the same isolated SWNT, as the laser frequencies were varied by the use of a tunable laser [17]. The curve fitting of the calculated lineshapes and experimental measurements is done by varying the energy of the experimental van Hove singularity E_{ii} iteratively, in order to obtain the experimentally determined I_{AS}/I_S ratio. For example, the two tubes in Figure 5a and b have experimentally determined

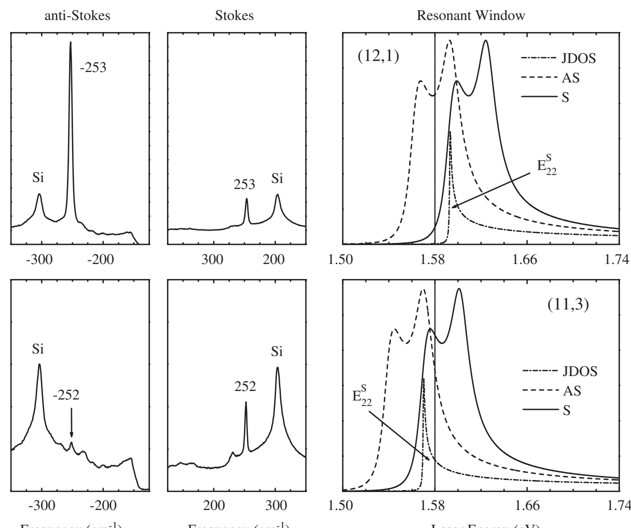

Figure 5. Resonance anti-Stokes and Stokes spectra for an isolated (a) (12,1) and (b) (11,3) SWNT on a Si/SiO_2 substrate using 1.579 eV (785 nm) laser excitation. The peak at 303 cm^{-1} comes from the Si substrate and is used for calibration purposes, while ω_{RBM} for the two tubes is 253 and 252 cm^{-1}, respectively. The anti-Stokes spectra are shown after correcting for the Boltzmann factor $\exp(E_{\text{ph}}/kT)$ to permit easy comparison to be made between the intensities of the Stokes and anti-Stokes spectra. To the right of each pair of experimental spectra is a plot of the calculated anti-Stokes and Stokes spectra predicted for a given profile for the joint density of states (dot–dashed line). Also shown is E_{laser} (solid vertical line) at which the ratio I_{AS}/I_S is evaluated for a selected E^S_{22} value. In the fitting procedure, the energy of the singularity E^S_{22} is varied to obtain the value for the ratio I_{AS}/I_S that is observed experimentally. Reprinted with permission from [18], A. G. Souza Filho et al., *Phys. Rev. B* 63, 24140R (2001). © 2001, American Physical Society.

diameters that differ by only 0.004 nm, but E^S_{22} values that differ by a much more significant amount (33 meV).

In practice, the (n, m) index characterization for isolated nanotubes can be simply carried out by using a single laser excitation energy E_{laser} when the nanotube is in strong resonance with E_{laser}. If the (n, m) values of every nanotube in the sample must be found, then a tunable laser is needed to provide a resonant excitation energy for each nanotube, so that a complete (n, m) Raman characterization can be carried out for each SWNT.

Measurement of the spectral profile of the 1D JDOS for a single wall carbon nanotube near a van Hove singularity gives direct evidence for the sharp singularities in the JDOS, thereby showing how it is possible to get sufficient intensity to observe a Raman spectrum from just one nanotube [17]. The spectral profile of the JDOS is determined by using many laser energies over a narrow energy range, as is provided by a tunable laser, to measure the anti-Stokes to Stokes intensity ratios for an individual SWNT. Evaluating the integrated intensity $I(E_{\text{laser}})$ of the RBM feature as the laser is tuned over the resonant window allows an evaluation of the joint density of states profile $g(E)$. An experimental determination of $g(E)$ shows that the width of the van Hove singularity in the joint density of states has a very small value (~0.5 meV), thus giving rise to the very strong intensity enhancement (~1000) associated with the

sharp 1D van Hove singularities in the joint density of states $g(E)$. Measurements of the Stokes and anti-Stokes spectra over the whole resonance window of a nanotube yield the E_{ii} value more accurately (to 5 meV) than when using a single laser line (~10 meV accuracy). Many physical properties, such as transport, optical, and mechanical properties, are very sensitive to the spectral profile of the electronic density of states, but the profile is difficult to measure directly, because probes, such as scanning tunneling microscopy tips [13], interact too strongly with the nanotube, thereby broadening the van Hove singularities (from less than 1 to more than 10 meV), and consequently also broadening the density of states that is probed by scanning probe methods [13]. Intertube interaction in a SWNT bundle also broadens the linewidth.

2.4. Connecting Single Nanotube and Bundle Raman Spectra

A brief discussion of the various features appearing in the Raman spectra at the single nanotube level is now presented, for later comparison in Section 3.1 with the corresponding results for SWNT bundles. Since most of the measurements on SWNT bundles are for the RBM and G-band, our focus in this section will likewise be on the G-band, since the characteristics of the RBM feature were already discussed.

The G-band in carbon nanotubes, occurring in the 1500–1605 cm^{-1} range (see Fig. 1), is basically derived from the Raman-allowed optical mode E_{2g_2} of graphite by zone folding the 2D graphene Brillouin zone (see Fig. 3b) into the 1D nanotube Brillouin zone, noting that only modes with A, E_1, and E_2 symmetry are Raman active for single wall carbon nanotubes [6, 20]. The G-band is an intrinsic feature of carbon nanotubes that is closely related to vibrations in all sp^2 carbon materials, and the G-band frequency in SWNTs is not dispersive with regard to E_{laser}. This property helps to distinguish features in the harmonics and combination modes that are associated with the nondispersive G-band from those associated with the highly dispersive D-band and G'-band features to be discussed.

The most dramatic features of the G-band spectra are the characteristic differences between the G-band lineshapes for metallic and semiconducting nanotubes, shown in Figure 6. Isolated semiconducting nanotubes (Fig. 6a) characteristically show two dominant Lorentzian features with 6–15 cm^{-1} (full width at half maximum, FWHM) linewidths at room temperature [22], the lower frequency component associated with vibrations along the circumferential direction (ω_G^-), and the higher frequency component (ω_G^+) attributed to vibrations along the direction of the nanotube axis. In contrast, the Raman spectra for metallic nanotubes (Fig. 6b) also have two dominant components with similar origins, but in this case, the upper frequency component ω_G^+ has a Lorentzian lineshape that is almost as narrow as that for the semiconducting nanotubes, but the lower frequency component ω_G^- is a very broad Breit–Wigner–Fano line (see Fig. 6b), with a strong coupling to a continuum, identified with surface plasmons [23]. In general, the coupling of the phonons to surface plasmons is much stronger in SWNT bundles than for isolated SWNTs because the coupling is between the out-of-plane component of the force constant

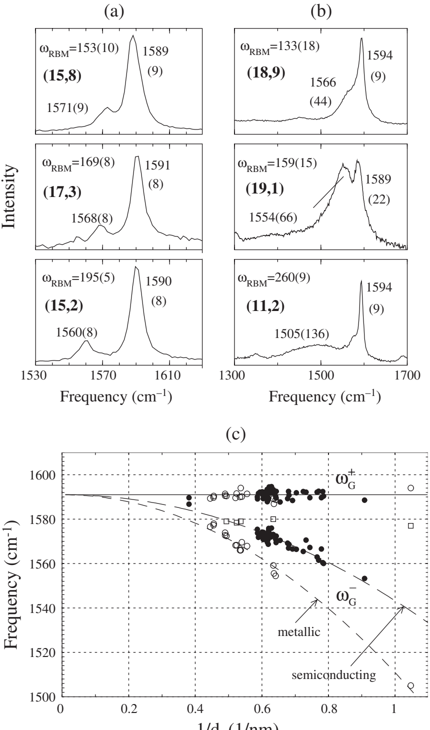

Figure 6. (a,b) Profiles of the G-band spectra for three semiconducting (a) and three metallic (b) nanotubes whose (n, m) indices are determined by analysis of their RBM spectra. The frequencies for ω_G^+ and ω_G^- are indicated in cm^{-1} for each nanotube along with the corresponding linewidths in parentheses. (c) Dependence on reciprocal nanotube diameter $1/d_t$ of ω_G^+ and ω_G^- for both semiconducting nanotubes (solid circles) and metallic nanotubes (open circles). The open squares indicate that a peak near ~1580 cm^{-1} is sometimes observed in the Raman spectra for metallic SWNTs. Reprinted with permission from [21], A. Jorio et al., *Phys. Rev. B* 65, 155412 (2002). © 2002, American Physical Society.

associated with the circumferential ω_G^- mode and the surface plasmon.

Experimental polarization studies on SWNT bundles [24] show that the G-band for a general chiral nanotube consists of six vibrational modes of $A+E_1+E_2$ symmetry along each of the two orthogonal (the axial and circumferential) directions [6], consistent with theoretical predictions. Knowledge of the number of modes is important for the lineshape analysis studies that are used to determine G-band properties. Because of the antenna effect, the strongest coupling of the $\vec{E}$ field of the laser excitation to the nanotube occurs for the optical $\vec{E}$ field along the nanotube axis, and experimentally the most intense modes are found to be the two modes with A symmetry. Therefore, in viewing the Raman spectra of SWNTs with unpolarized light, only two dominant components are generally observed experimentally, one for vibrations in the tangential direction (ω_G^+) and one for vibrations in the circumferential direction (ω_G^-), and this is seen for SWNTs with diameters less than 2 nm, whether they are isolated or in SWNT bundles.

It is the curvature of the nanotube that admixes a small amount of interplanar graphene modes into the circumferential modes of SWNTs, thus lowering their C–C force

constants and mode frequencies, and giving rise to a splitting of the G-band mode frequencies ($\omega_G^+ - \omega_G^-$) into a G^+ axial component and G^- circumferential component, as shown in Figure 6c. Here it is seen that ω_G^+ shows no d_t dependence for either semiconducting or metallic tubes, while ω_G^- has a strong d_t^{-2} dependence that differs according to whether the nanotubes are semiconducting or metallic, and ω_G^- is well fit to the functional form

$$\omega_G^- = \omega_G^+ - \mathscr{C}/d_t^2 \tag{2}$$

where $\mathscr{C} = 45.8$ cm^{-1} nm^2 for semiconducting nanotubes and $\mathscr{C} = 79.5$ cm^{-1} nm^2 for metallic nanotubes. It should be emphasized that this discussion applies to measurements made with unpolarized light, where only the two dominant components in the G-band spectra are considered. At the single nanotube level, no chirality dependence for the G-band ω_G^+ and ω_G^- mode frequencies is found experimentally; nor is $\mathscr{C}$ found to depend on E_{laser}. Therefore it is convenient to use Eq. (2) to obtain an approximate determination of d_t for those SWNTs where the RBM feature is not observed. It should be also mentioned that when polarized light is used, one can distinguish all six components of the G-band expected from theory, the diameter dependence of each component can be found, and some deviation from Eq. (2) is found both experimentally [25] and theoretically [26].

The G-band linewidths for the semiconducting nanotubes at the single nanotube level do not vary much with diameter, with the smallest observed FWHM intensity linewidth values being 6 cm^{-1} [22]. The linewidth for the circumferential ω_G^- component for metallic nanotubes, however, increases very substantially with decreasing d_t, reflecting the increased Breit–Wigner–Fano coupling. These broadening effects in G^- for metallic tubes are more easily observed in SWNT bundles than in isolated SWNTs. Regarding semiconducting SWNTs, the G-band linewidths are not sensitive to chiral angle θ, or to $E_{\text{laser}} - E_{ii}$ [22].

From a theoretical standpoint, zone folding of the graphene sheet to form a nanotube gives rise to Raman-active modes with $A + E_1 + E_2$ symmetry [6] in both the longitudinal (along the tube axis) and transverse (in the circumferential) directions, in addition to a large number of modes with $E_3, E_4, \ldots$ symmetry, which are not Raman-active [6]. Experimental polarization studies on nanotube bundles [24], with an average nanotube diameter $d_t \simeq 1.85$ nm and with $E_{\text{laser}} = 2.41$ eV, have verified the presence of these six modes (three axial and three circumferential modes). These studies have given explicit values for the polarization parameters, namely for the mode frequencies and relative intensities, for each of these six modes for a particular sample of bundled SWNTs [24]. As mentioned above, curvature of the nanotubes is expected to admix some out-of-plane graphite-derived modes with the circumferential G-band mode and thereby to weaken the bonds and lower the force constants in the circumferential direction.

Individual SWNTs are also sensitive to the depolarization or antenna effect, which refers to the tendency of the nanotubes themselves to create a strong local dipole field, so that the optical electric field seen by the nanotube is the vector sum of the applied field and the local field along its axis due to the nanotube dipole antenna. Since the local dipole field is very strong, nanotubes act like polarizers. This antenna effect has been shown by Duesberg et al. to be highly effective for metallic nanotubes or for a very thin nanotube bundle containing only a few nanotubes (see Fig. 7) [27], and they showed that the Raman spectra from a metallic SWNT are strongly suppressed when the light is polarized perpendicular ($\alpha_i = 90°$ in Fig. 7) to the nanotube axis [27].

Polarization measurements at the single nanotube level show that also for isolated semiconducting nanotubes the field component polarized normal to the nanotube axis is completely quenched due to the antenna effect [28]. However, two nanotubes whose axes intersect at some angle each create their own dipole fields, so that the polarization component normal to one of the nanotube axes no longer is completely suppressed, allowing the observation of E_1 and E_2 symmetry modes when $\alpha_i = 90°$ for each of the two tubes. Because of this effect, it is much easier to observe the circumferential modes in SWNT bundles than for isolated SWNTs. The diameter dependence of each of the six G-band modes in the polarized Raman spectra have been studied experimentally, and good agreement was obtained with theoretical predictions [25, 26].

Also observed in the semiconducting and metallic SWNT spectra, both at the single nanotube level and in SWNT bundles, are the D-band and the G'-band features, as seen in Figure 1. The frequencies of the disorder-induced D-band ($1250 < \omega_D < 1450$ cm^{-1}) and of its second-order overtone G'-band ($2500 < \omega_{G'} < 2900$ cm^{-1}) in the Raman spectra of sp^2-bonded carbon materials have been known for many years to exhibit a strongly dispersive behavior as a function of laser excitation energy ($1.0 < E_{\text{laser}} < 4.5$ eV) [29, 30]. The strong linear dispersion of the D-band frequency $\omega_D(E_{\text{laser}})$ in graphite (53 cm^{-1}/eV), and of its second-order overtone

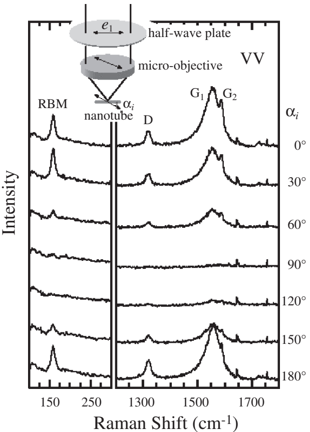

Figure 7. Raman spectra from a thin SWNT bundle where a metallic nanotube is resonant with $E_{\text{laser}} = 1.96$ eV. The spectra were taken with the VV configuration (where the wave vectors for the incident and scattered light are parallel to each other) for various angles α_i between the axis of the bundle and the polarization of the incident laser beam, as depicted in the inset. For $\alpha_i = 0°$ and $\alpha_i = 180°$, the polarization of the incident radiation is parallel to the axis of the SWNTs, as determined from scanning tunneling microscopy (STM) images with an accuracy of ±10°. For $\alpha_i = 90°$, the intensities of all the Raman features (RBM, D-band, G^- and G^+) vanish. Reprinted with permission from [27], G. S. Duesberg et al., *Phys. Rev. Lett.* 85, 5436 (2000). © 2000, American Physical Society.

G' band, has been identified with a double resonance process involving photons, phonons and electronic transitions between linearly dispersive π and π^* states [31–34]. The double resonance model in particular [31, 33, 35] accounts for the observed dispersion of the D-band and the G'-band as a function of photon excitation energy E_{laser} in graphite and in sp^2 carbons. This model was subsequently extended to account for the special properties of the D-band and G'-band of isolated SWNTs and has been successful in accounting for the special features in the D-band and G'-band spectra observed for SWNTs relative to the other sp^2 carbons.

Each van Hove singularity is characterized by an energy E_{ii} and a corresponding electron wave vector k_{ii} where the JDOS (joint density of states) is a maximum. According to double resonance theory, the phonon wave vector at the peak intensity of the D-band and G'-band features occurs at $q_{ii} = -2k_{ii}$. Because of the trigonal warping effect of the electronic structure (see Fig. 8b), the E_{ii}, k_{ii}, and q_{ii} points at resonance are all unique, leading to a nonmonotonic chirality dependent resonance condition for each (n, m) nanotube. The resulting D-band or G'-band frequencies therefore appear to exhibit a significant scatter for a given E_{ii} when ω_D or $\omega_{G'}$ are plotted as a function of tube diameter (see Fig. 8a) [36], because of their nonmonotonic dependence on chiral angle arising from the trigonal warping effect.

Since a given laser energy can excite various (n, m) nanotubes with different diameters and different chiral angles (see Fig. 4) and because the D-band and G'-band are highly dispersive, different D-band and G'-band mode frequencies can be observed at the single nanotube level for different SWNTs using a single laser excitation line. In contrast, for SWNT bundles, a given laser line gives a single D-band or G'-band frequency. This effect results in line broadening in SWNT bundles. The linewidth for the D-band at the single nanotube level can be as small as 6 cm^{-1}, and for the G'-band as small as 11 cm^{-1} under good resonance conditions [22]. The linewidths of the D-band and G'-band in SWNT bundles tend to be significantly larger than for individual SWNTs.

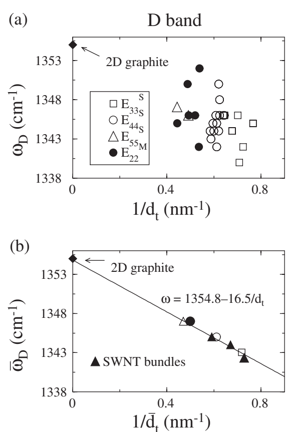

Figure 8. (a) D-band frequencies as a function of reciprocal nanotube diameter for individual SWNTs using $E_{\text{laser}} = 2.41\,\text{eV}$ laser excitation. The data are classified in terms of the E_{ii} interband transition with which the resonancy occurs, including both metallic (M) and semiconducting (S) SWNTs. (b) Plot of $[\bar{\omega}_D(E_{ii})]$, denoting the observed D-band frequencies averaged over all tubes in a given sample that are resonant with a given interband transition E_{ii}, vs $1/\bar{d}_t$, the corresponding average of the reciprocal diameter of the tubes. Data are shown for E_{laser} in resonance with the E_{55}^S, E_{44}^S, E_{33}^S, and E_{22}^M interband transitions in the JDOS. The line is a fit to the data, showing that the D-band frequencies extrapolate (on average) to the graphene (2D graphite) value when $1/\bar{d}_t \to 0$. The solid triangles in (b) denote the D-band frequencies for three different SWNT bundles with different average diameters. Reprinted with permission from [36], A. G. Souza Filho et al., *Phys. Rev. B* 67, 035427 (2003). © 2003, American Physical Society.

In order to compare the SWNT spectra at the single nanotube level with those for SWNT bundles and to gain an understanding of the mechanisms behind the d_t dependence of the D-band and G'-band frequencies, the ω_D and $\omega_{G'}$ peak frequencies are averaged over chiral angles for each E_{ii} and the results are shown in Figure 8b for D-band measurements. For a given interband transition E_{ii}, there is only a small variation in the d_t values for a typical SWNT bundle sample, and this variation is accounted for self-consistently in making the plots in Figure 8. Here the resulting averages of the diameter and D-band frequencies are denoted by $\bar{d}_t(E_{ii})$ and $\bar{\omega}_D(E_{ii})$, respectively, and we plot these pairs of numbers in Figure 8b for $i = 3, 4, 5$ for semiconducting SWNTs and for $i = 2$ for metallic SWNTs, using the same symbols as in Figure 8a [36].

The results of this analysis in Figure 8 give a simple linear dependence of the average $\bar{\omega}_D$ on $1/\bar{d}_t$,

$$\bar{\omega}_D = 1354.8 - 16.5/\bar{d}_t \tag{3}$$

where $1/\bar{d}_t$ is the average $1/d_t$, as shown in Figure 8b. Good agreement in Figure 8b is obtained between the average $\bar{\omega}_D$ results for an ensemble of isolated tubes and the corresponding $\bar{\omega}_D$ results for SWNT bundles measured with the same E_{laser}. The linear downshift of $\bar{\omega}_D$ as a function of $1/\bar{d}_t$, shown in Figure 8b, is attributed to the softening of the spring constants for the vibrations associated with the D-band due to the nanotube curvature. This assertion is based on calculations of the eigenvectors for the D-band [37] which show that the atomic displacements have some components along the nanotube circumference, which soften the modes due to contributions from out-of-plane force constants. Contributions from out-of-plane force constants, which do not occur in graphite, are also responsible for the d_t-dependent downshift of ω_{G^-}, the lower frequency circumferential component of the G-band [38, 39].

However, when the behavior of ω_D vs d_t is investigated at the single nanotube level, within one interband transition, E_{44}^S for example, the D-band frequency ω_D has a tendency to *increase* when the diameter decreases, because E_{ii} is proportional to k_{ii} on the basis of the electronic dispersion relation, and k_{ii} in turn is proportional to $1/d_t$, except for perturbations due to the trigonal warping effect that complicate this simple dependence and give rise to a spread in the data points (see Fig. 8a) [6, 36]. The net result of the formation of E_{ii} subbands is to introduce an opposite dependence of ω_D on d_t when compared to the averaged result shown in Figure 8b [36]. As can be seen in Figure 4, E_{ii} for a given i increases as d_t decreases. Since for a given interband transition E_{ii} the relevant tube diameter range is not so large for

a typical SWNT bundle sample (see Fig. 4), the frequency of the D-band ω_D is mainly determined by the magnitude of the k_{ii} states, and this effect is dominant over the curvature effect throughout the small diameter range over which contributions from resonance within a single E_{ii} subband dominate. When we jump from one van Hove singularity E_{ii} to another singularity E_{jj} ($j \neq i$), the spring constant mechanism becomes dominant in the determination of ω_D. The results shown in Figure 8 also suggest that metallic and semiconducting tubes exhibit the same ω_D diameter-dependent behavior.

A similar analysis carried out on the G'-band spectra at the single nanotube level shows a similar nonmonotonic dependence of $\omega_{G'}$ on chiral angle θ, and a diameter dependence

$$\bar{\omega}_{G'} = 2708 - 35.4/\bar{d}_t \tag{4}$$

Another dispersive feature observed in the Raman spectra is the M-band occurring near 1750 cm^{-1} which has been identified with an in-plane TO + LA combination mode [40] and shows a similar functional d_t dependence for its mode frequency

$$\bar{\omega}_M = \omega_{M,0} - \beta_M/\bar{d}_t \tag{5}$$

where the M-band has two components for which $\omega_{M,0}$ and β_M are, respectively, 1775 cm^{-1} and 18.0 cm^{-1} nm for the M^+ feature and 1754 cm^{-1} and 16.7 cm^{-1} nm for the M^- feature, as determined from single nanotube Raman spectroscopy [40].

One of the unique features of the D-band and the G'-band spectra of SWNT bundles is a step or oscillatory behavior [42–44] superimposed on the linear E_{laser} dependence of both ω_D and $\omega_{G'}$ that is characteristic of graphite and sp^2 carbons. This effect is shown for the G'-band in Figure 9a but also has been observed and studied in the corresponding plot of ω_D vs E_{laser}. The deviation from a linear dispersive behavior is clearly seen in Figure 9b, where the points are obtained after subtraction of the linear solid line fit to the experimental points in Figure 9a. The oscillatory behavior in Figure 9b is identified with quantum effects associated with the strong coupling between the electrons and phonons under resonance conditions. Specifically, the peak near 2.0 eV is identified with the E_{11}^{M} interband transition for metallic nanotubes and the peak near 2.5 eV with the E_{33}^{S} and E_{44}^{S} transitions for semiconducting nanotubes, thus showing the importance of the 1D electronic structure of SWNTs in the physical origin of the D-band and the G'-band spectra. The physical basis for this step or oscillatory behavior was explained by the coupling between electrons and phonons under resonant conditions, consistent with the behavior seen in the plot of the resonance wave vector k_{ii} for SWNTs that are within the resonance window with the various E_{laser} energies (Fig. 9b). Although the oscillations in the D- and G-bands are best observed in SWNT bundles, the mechanism for their origin is best studied in isolated SWNTs. As discussed, the resonant k_{ii} values depend on both the diameter and chirality of the resonant nanotubes, as has been elucidated by studies at the single nanotube level [41]. An independent theory by Kürti et al. [26] that considers the double resonance process in light of the van Hove singularities has been able to explain the anomalous dispersion in SWNT bundles.

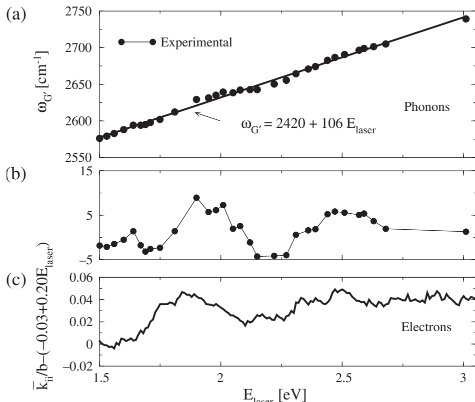

Figure 9. (a) Dependence on the laser excitation energy of $\omega_{G'}$ for the dominant second-order Raman feature for SWNT bundles. In contrast to most sp^2 carbons where $\omega_{G'}$ depends linearly on E_{laser}, the corresponding plot for SWNT bundles shows a superimposed steplike or oscillatory behavior near 2.0 and 2.5 eV for SWNT bundles. (b) The oscillatory component of (a) obtained after subtracting the linear background given by $\omega_{G'} = 2420 + 106E_{\text{laser}}$ in (a). (c) Plot of the E_{laser} dependence of the oscillations in the resonant electron wave vector k_{ii} after normalization to the length of the basis vector b of the reciprocal lattice of 2D graphite and after subtracting the linear background. For each E_{laser} value, the k_{ii} values for each resonant SWNT are calculated, and $\bar{k}_{ii}$ represents an appropriate weighted average of the individual k_{ii} values [41]. The strong correspondence between the E_{laser} dependence of $\omega_{G'}$ for phonons and $\bar{k}_{ii}$ for electrons provides strong support for the identification of each oscillation with a particular interband transition between van Hove singularities in the JDOS. Experimental studies at the single nanotube level have shown that these highly dispersive modes can provide unique information about the electronic structure and the phonon dispersion relations of single wall carbon nanotubes. Some of the new phenomena that have been observed at the single nanotube level will be briefly listed in an effort to stimulate complementary studies in SWNT bundles.

The diameter and chirality dependent D-band and G'-band effects, which are observed at the single nanotube level, are now briefly reviewed. Under special circumstances it has been possible to observe a double resonance process with both the E_{33}^{S} and E_{44}^{S} interband transitions on the same isolated SWNT [45], utilizing the strong dispersion of the G'-band as a function of E_{laser}. Because of the special circumstance under which this two peak G'-band effect can occur, it can be used as an independent confirmation of the (n, m) structural characterization carried out through analysis of the radial breathing mode feature, as discussed in Section 2.2.

Because of the trigonal warping of constant energy surfaces, the D-band and G'-band frequencies produced by cutting lines on opposite sides of the K point in the Brillouin zone will in general be different from each other. If both cutting lines are resonant with the same E_{laser} energy, then it is possible to observe these two contributions, which appear

as a double peak in the Raman spectra of metallic SWNTs. If the frequency difference between the two features is large enough, they can be resolved [45–47].

For the case of metallic SWNTs, the two cutting lines correspond to the same E_{ii}^{M} singularity [46, 47], while for semiconducting SWNTs, the two cutting lines correspond to different E_{ii}^{S} singularities [45, 47]. Unresolved double peak effects for metallic and semiconducting SWNTs are a source of line broadening both at the single nanotube level and for SWNT bundles.

3. SINGLE WALL CARBON NANOTUBE BUNDLES

In this section the Raman spectra for SWNT bundles are presented and discussed in relation to the spectra for isolated SWNTs at the single nanotube level. In Section 3.1, the room temperature baseline Raman spectra for SWNT bundles are presented. The effect of temperature on the RBM, G-band, and D-band mode frequencies for SWNT bundles is discussed in Section 3.2. These temperature-dependent effects are more important for SWNT bundles than for isolated SWNTs because of the poor thermal conductivity between SWNTs within the bundle. In Section 3.3, the effect on the Raman frequencies of the solubilization, debundling, doping, and of applied voltage of SWNTs in SWNT bundles is discussed, while the effect of pressure on the mode frequencies is reviewed in Section 3.4. A comparison is made in Section 3.5 between the perturbations to the Raman frequencies of nanotube bundling and debundling and the effects of the application of pressure, doping, and applied potentials on the Raman spectra of SWNT bundles are also discussed and compared in terms of their effect on the singularities in the joint density of states and on the electrochemical potential.

3.1. Raman Spectra from Single Wall Carbon Nanotube Bundles

Early Raman spectra on SWNTs were taken on samples containing ropes of single wall carbon nanotubes with a narrow diameter distribution in the 1.2–1.4 nm range, and the SWNT bundle samples were prepared by either the electric arc method or by the laser vaporization technique [48, 49]. Raman spectra taken on such a sample for five different laser excitation energies are shown in Figure 10 [5]. Prominent in these spectra are the G-band at ~1590 cm^{-1} and the radial breathing mode at ~186 cm^{-1} [see the trace in Fig. 10 taken for $E_{\text{laser}} = 2.41$ eV (514.5 nm)]. By comparing the various Raman spectra in Figure 10, which were taken at different laser excitation energies E_{laser}, we see large differences in the vibrational frequencies and intensities of the strong A_1 radial breathing mode (see Fig. 11), consistent with a resonance Raman effect involving nanotubes of different diameters for each laser excitation energy.

In Figure 12, we see theoretical calculations showing that for an (n, n) armchair SWNT there are three mode frequencies very close to 1580 cm^{-1}, which have mode symmetries A_{1g}, E_{1g}, and E_{2g} (see Fig. 11), each mode frequency being almost independent of nanotube diameter. A similar behavior is found for the Raman band near 1580 cm^{-1} for zigzag and chiral nanotubes [6, 50]. The atomic displacements associated with the normal modes near ~186 and ~1580 cm^{-1} for a (10,10) nanotube are shown in Figures 1 and 11 [6].

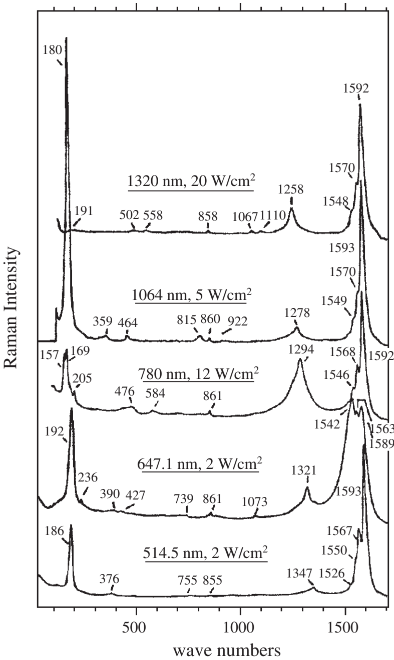

Figure 10. Experimental room temperature Raman spectra for purified single wall carbon nanotubes excited at five different laser excitation wavelengths. The laser wavelength and power density for each spectrum are indicated, as are the vibrational frequencies (in cm^{-1}) [5]. The equivalent incident photon energies for the laser excitation are: 1320 nm → 0.94 eV; 1064 nm → 1.17 eV; 780 nm → 1.58 eV; 647.1 nm → 1.92 eV; 514.5 nm → 2.41 eV. Figure 11. The calculated Raman mode atomic displacements, frequencies, and symmetries for selected normal modes for the (10,10) nanotube. The symmetry and the frequencies for these modes are not strongly dependent on the chirality of the nanotube. In the figure, we show the displacements for only one of the two modes in the doubly degenerate E_{1g} and E_{2g} modes. Reprinted with permission from [6], R. Saito et al., "Physical Properties of Carbon Nanotubes." Imperial College Press, London, 1998. © 1998, Imperial College Press.

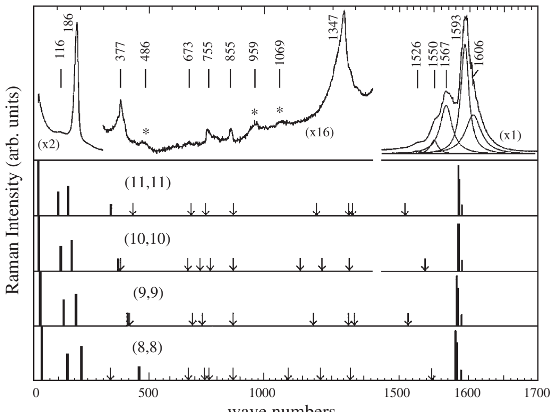

Figure 12. Raman spectra (top) of a rope of single wall carbon nanotubes taken with 514.5 nm laser excitation at ~2 W/cm^2 power level. The features in the spectrum denoted by asterisks are assigned to second-order Raman scattering. The four bottom panels are the calculated Raman spectra (based on a bond polarizability model) for armchair (n, n) nanotubes, $n = 8$ to 11, and the strongest Raman-allowed features are indicated by vertical bars. The arrows in the panels indicate the positions of the remaining weak, Raman-active modes. Reprinted with permission from [5], A. M. Rao et al., *Science* 275, 187 (1997). © 1997,

In contrast to the high frequency band near 1580 cm^{-1}, the feature near ~186 cm^{-1}, which is identified with an A_1 radial breathing mode (ω_{RBM}), is strongly dependent on the nanotube diameter, as shown in Figures 10 and 12. Calculations [51, 52] show high intensities for this radial breathing mode and for the tangential G-band modes (ω_G) near 1580 cm^{-1} (Fig. 12), in agreement with experimental Raman spectra. The other Raman-active modes (see Fig. 12) are predicted to have low Raman cross sections, also in agreement with experiment (Fig. 10). Bond polarizability calculations further predict that the relative intensities of the weaker Raman-active features in the experimental spectra of Figure 10 can be increased by making measurements on carbon nanotubes of lengths (e.g., 100 nm, small compared to an optical wavelength for the laser excitation) [53]. The weak D-band features in the Raman spectrum in Figure 10 at about 1350 cm^{-1} are associated with resonance Raman scattering of phonons near the K point in the 2D Brillouin zone. These identifications are in agreement with experimental and theoretical observations at the single nanotube level, discussed in Section 2.

Historically, these experimental observations of the Raman effect in SWNT bundles [5] also provided the first clear confirmation for the theoretical predictions about the singularities in the 1D electronic density of states of carbon nanotubes through study of both the radial breathing mode features and the G-band mode features. This confirmation of the existence of singularities in the 1D density of states of SWNTs by the resonance Raman effect was soon corroborated by a more direct measurement of the 1D electronic density of states by STM/scanning tunneling spectroscopy [12, 54].

Because of this strong resonance enhancement effect, it was found that only a small concentration of single wall nanotubes in a sample containing other carbon forms can give rise to spectral features showing the characteristic sharp doublet structure in the 1570–1600 cm^{-1} spectral range [55]. The resonance enhancement effect is so strong for small diameter (<2 nm) SWNTs that it is possible to observe the Raman effect from individual SWNTs (see Section 2) and to observe up to fifth order Raman scattering in SWNT bundles (e.g., up to Raman shifts of 6885 cm^{-1} using 488 nm laser excitation) [56].

Since the energies of these sharp features in the 1D electronic density of states are strongly dependent on the nanotube diameter, a change in the laser frequency brings into resonance a different carbon nanotube with a different diameter that satisfies the new resonance condition. This effect is called *diameter selective Raman spectroscopy* and led in 1998 to the first use of Raman spectroscopy to distinguish between metallic and semiconducting nanotubes [57, 58]. The concept of diameter selective spectroscopy follows from Figure 4 where each point on the plot of the energy E_{ii} of the van Hove singularity in the JDOS vs tube diameter d_t denotes a different (n, m) SWNT. For a given diameter distribution in the sample (e.g., 1.37 ± 0.20 nm, for the sample in Fig. 13), we can see in Figure 13 that for E_{laser} below 1.70 and above 2.14 eV, the SWNT bundle contains predominantly semiconducting nanotubes that are resonant with E_{laser}, in agreement with the lineshape shown for these traces in Figure 13, while for E_{laser} in the range 1.83 to 2.14 eV, the G-band shows a very different broad lineshape, characteristic of metallic nanotubes. Here the lower frequency G-band component (designated by G^-) for metallic tubes is described by a Breit–Wigner–Fano lineshape arising from the coupling of the G^- phonons to plasmons through the

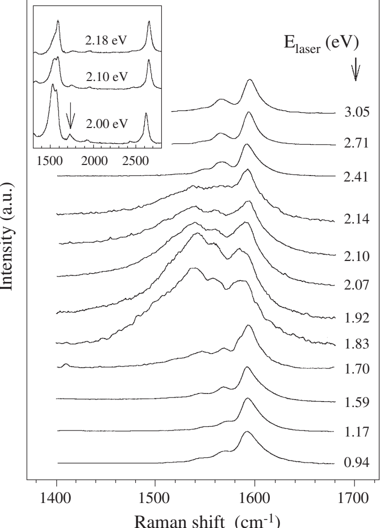

Figure 13. Raman spectra of the tangential modes of carbon nanotubes with diameters in the range $d_t = 1.37 \pm 0.20$ nm, obtained with several different laser excitation energies E_{laser}. The inset shows low resolution Raman spectra between 1300 and 2800 cm^{-1} in the range of laser energies 2.00–2.18 eV where the metallic nanotubes are dominant and the arrow points to a low intensity M-band feature near 1750 cm^{-1} [40] which has its maximum intensity correlated with the maximum intensity of the metallic G-band lineshape. Reprinted with permission from [57], M. A. Pimenta et al., *Phys. Rev. B* 58, R16016 (1998). © 1998, American Physical Society.

tube curvature which allows mixing of out-of-plane phonons with the tangential in-plane phonon modes characteristic of 2D graphite. This coupling is most pronounced for small diameter nanotubes in SWNT bundles relative to isolated SWNTs, since the coupling between phonons in one tube and plasmons in adjacent tubes can readily occur for SWNTs in bundles.

A closely related effect is observed in Figure 14 where Stokes and anti-Stokes spectra for the same SWNT sample with $d_t = 1.49 \pm 0.20$ nm are shown for four different laser excitation energies. Resonance for the scattered photon for the Stokes process occurs when $E_{\text{laser}} - \hbar\omega_G = E_{ii}$, while for the anti-Stokes process, the resonance condition is given by $E_{\text{laser}} + \hbar\omega_G = E_{ii}$. Thus for $E_{\text{laser}} = 2.19$ eV, Figure 4 shows that semiconducting SWNTs in the bundle are resonant for both incident and scattered photons for the anti-Stokes process, but for the Stokes process only a few metallic tubes would be expected to be resonant with the scattered photon. The situation is dramatically different for $E_{\text{laser}} = 1.58$ eV where both the incident and scattered photons are strongly resonant with metallic tubes for both the Stokes and anti-Stokes processes [59]. For $E_{\text{laser}} = 1.92$ eV, the incident photon is not in good resonance for either metallic or semiconducting tubes, while the scattered photon for the Stokes process is in good resonance with metallic tubes and for the anti-Stokes process with semiconducting tubes. For $E_{\text{laser}} = 1.49$ eV, again the incident photons are not in good resonance with the E_{ii} for tubes in the SWNT bundle, but for the scattered photons the resonance in the Stokes process is good with semiconducting tubes, and with metallic tubes in the anti-Stokes process, all of which follows from the plot of E_{ii} vs d_t in Figure 4. Thus the Stokes/anti-Stokes phenomena observed in SWNT bundles can be related to behavior observed at the single SWNT level.

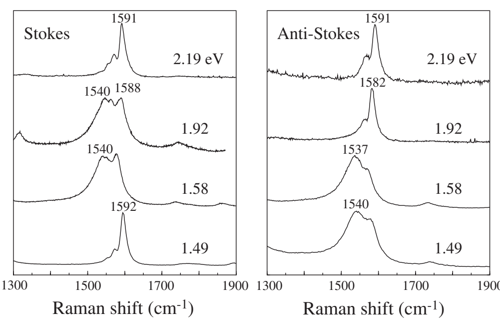

Figure 14. Stokes and anti-Stokes Raman spectra for SWNTs of $d_t = 1.49 \pm 0.20$ nm taken at four different values of E_{laser} to illustrate differences in spectral lineshape between the Stokes and anti-Stokes spectra [59]. For $E_{\text{laser}} = 2.19$ eV, both the Stokes and anti-Stokes processes are in resonance with semiconducting nanotubes: for $E_{\text{laser}} = 1.92$ eV, the Stokes process is in resonance with metallic nanotubes and the anti-Stokes process is in resonance with semiconducting nanotubes. For $E_{\text{laser}} = 1.58$ eV, both processes are in resonance with metallic nanotubes. Finally, for $E_{\text{laser}} = 1.49$ eV, the Stokes process is in resonance with semiconducting nanotubes, and the anti-Stokes process is in resonance with metallic nanotubes. The nanotube-specific resonance Raman process associated with the special characteristics of the 1D density of electronic states is responsible for the observed differences between the Stokes and anti-Stokes lineshapes. Reprinted with permission from [59], S. D. M. Brown et al., *Phys. Rev. B* 61, R5137 (2000). © 2000, American Physical Society.

The G-band lineshape studies and the Stokes/anti-Stokes G-band studies previously described led to the definition of the *resonance window* for metallic tubes within a SWNT bundle as the laser energy range over which the intensity of the G^- component was large enough to be observable. For a SWNT bundle with a diameter distribution of 1.37 ± 0.20 nm, the Stokes resonance window was found to extend from 1.7 to 2.3 eV and the anti-Stokes resonance window was correspondingly downshifted by about 0.2 eV [60]. The early determination of the resonance window from SWNT bundle samples provided a sensitive experimental determination of the energy overlap integral γ_0 for SWNTs [15], which is used for constructing the E_{ii} vs d_t diagram (Fig. 4), within the tight binding approximation, and assuming a zero value for the overlap integral (i.e., $s = 0$). The γ_0 value thus determined yielded (n, m) predictions that were later found to be in good agreement with experimental (n, m) determinations based on RBM mode measurements on isolated SWNTs at the single nanotube level [2].

Studies of the effect of high laser radiation intensity on the Raman spectra of SWNT bundles showed (through observation of the RBM spectra) that the small diameter SWNTs burn off preferentially, thereby affecting the G-band lineshapes irreversibly, depending on whether the smallest diameter SWNTs in the initial SWNT bundle are semiconducting or metallic [61]. High laser intensity also serves to reduce the D-band intensity irreversibly and to enhance the RBM and G-band intensities, indicative of annealing out structural defects in SWNTs [61].

In comparing Raman spectra from SWNT bundles and from individual SWNTs, several differences are noteworthy. (1) The linewidths of the Raman features for isolated tubes are much narrower [22], with FWHM values of the G^+-band and D-band being 6 and 7 cm^{-1}, respectively, for isolated SWNTs, as compared to 15 and 34 cm^{-1} for SWNT bundles [22, 62, 63], reflecting inhomogeneous line broadening that arises from contributions of the various (n, m) nanotubes within the resonant window of the laser. (2) Diameter-dependent effects are observed in the spectra from SWNT bundles, as is clearly seen in the selection of the resonance window in distinguishing between metallic and semiconducting SWNTs (Fig. 13) and in interpreting the Stokes/anti-Stokes spectral lineshapes (Fig. 14). Studies at the single nanotube level are especially useful in addressing diameter-dependent effects in each of the spectral features in the Raman spectrum [1]. (3) Even though chirality-dependent phenomena are observed for many of the features in the Raman spectra at the single nanotube level, the spectra observed for SWNT bundles provides only an average over chiral angles for SWNTs within the resonance window. (4) Certain features in the Raman effect that relate to tube–tube interaction are observed more strongly in SWNT bundles, and these include the reported diameter-independent upshift of the RBM band frequency in SWNT bundles, and the increased strength of the G^- lower frequency component of the G-band in SWNT bundles with a Breit–Wigner–Fano lineshape that arises from the plasmon–phonon coupling [14, 23].

The effect of bundling on the electronic structure of SWNTs has been considered generally from a theoretical standpoint. On the basis of a density functional formalism,

the intertube coupling was calculated within the local density approximation (LDA) for isolated and bundled (8,8), (9,9), (10,10), and (11,11) armchair nanotubes, corresponding to a diameter distribution representative of many experimental samples. The results of this calculation showed that intertube coupling causes a band dispersion of ~0.15–0.20 eV which not only opens up a pseudo-gap at E_F but also broadens the van Hove singularities by the same amount, while the peak positions of the van Hove singularities were found to shift in energy away from E_F [64]. This leads to a net increase of the energy spacing between pairs of van Hove singularities in the electronic JDOS (such as E_{11}^M, etc.) for bundled nanotubes relative to isolated SWNTs [64] (see Table 2). These calculations imply that the force constants for a given nanotube in a SWNT bundle should increase and consequently the mode frequencies would be expected to increase relative to their values in an isolated tube. A general expression is then suggested for the interpretation of radial breathing mode frequency measurements for SWNT bundles, namely $\omega_{\mathrm{RBM}} = \alpha/d_t + \Delta\omega_{\mathrm{RBM}}$. This result implies that the effect of intertube interactions is to upshift the radial breathing mode frequency of a particular SWNT in a bundle relative to that for its ω_{RBM} as an isolated SWNT by $\Delta\omega_{\mathrm{RBM}}$ and perhaps also to modify its coefficient α. The precise value of α and $\Delta\omega_{\mathrm{RBM}}$ would then be expected to depend on the local environment of the tube, the total size of the SWNT bundle, and the location of the SWNT within the SWNT bundle. A detailed procedure was established for the determination of α and $\Delta\omega_{\mathrm{RBM}}$ by Kuzmany et al. [44, 65, 66]. The effect of bundling on ω_G is expected to be small.

3.2. Temperature Dependence

Early studies of Raman-active modes in SWNT bundles reported a softening of the radial breathing mode and tangential G-band frequencies with increasing sample temperature. A few speculations were proposed to explain the origin of these frequency downshifts, attributing them to the stretching of carbon–carbon bonds, defects, and disorder in these materials, as well as to the van der Waals interactions between nanotubes in the bundles [20]. However, no detailed theoretical or experimental basis was provided to support these proposals.

A recent study [67] reexamined the temperature dependence of the RBM, G-band, and D-band, using as-prepared HiPCo SWNTs [68]. Based on experimental data and the results of molecular dynamics simulations, the expected radial breathing mode softening due to three contributing factors was considered: thermal expansion of individual SWNTs in the radial direction, softening of the C–C (intratubular) bonds, and softening of the van der Waals intertubular interactions in SWNT bundles (intertubular interaction). Panels a–d in Figure 15 show a reversible linear shift with temperature of the two RBM frequencies, the G-band frequency, and the D-band frequency observed in the Raman spectrum of as-prepared HiPCo SWNTs. The two RBM peaks, with a peak position of $\omega_{\mathrm{RBM}} \sim 182$ and 264 cm^{-1} at room temperature, correspond to the tube diameters of approximately 1.33 and 0.89 nm, respectively.[1] The temperature dependence in terms of $d\omega_{\mathrm{RBM}}/dT$ was obtained from the slopes of the (linear) plots in Figure 15a and b to be ~ -0.0045 and -0.0090 cm^{-1}/K, respectively. The larger magnitude of $d\omega_{\mathrm{RBM}}/dT$ for ω_{264} relative to ω_{182} suggests that smaller diameter tubes are more susceptible to temperature-induced frequency downshifts. Furthermore, the following experimental values were obtained: $d\omega_{G^+}/dT = -0.0189$ cm^{-1}/K, $d\omega_{G^-}/dT = -0.0238$ cm^{-1}/K, and $d\omega_D/dT = -0.0087$ cm^{-1}/K [67]. The temperature dependences of the G-band and D-band modes (Fig. 15c and d) were used to evaluate the softening of the C–C force constants with temperature [67].

It was found that only a small part of the temperature dependence of ω_{RBM} can be attributed to the very small change in the tube diameter [67]. For nanotubes with diameters $d_t \sim 1.34$ nm, the contribution due to the radial thermal expansion is ~4% over the temperature range $300 < T < 800$ K. Interestingly, this contribution increases to ~10% in the case of nanotubes having $d_t \sim 0.89$ nm, due to the relatively larger curvature of these narrow diameter tubes. The dominant contributions to the RBM mode frequency softening are attributed to temperature-induced softening of the intratubular C–C bond strength and to the SWNT intertubular (van der Waals) interactions [67]. Furthermore, it was found that these factors together contribute to the total change of $\omega_{\mathrm{RBM}}(T)$ with temperature, ~95% and 90%, respectively, for SWNTs having $d_t \sim 1.33$ nm and ~0.89 nm.

In summary, the effect of increased temperature on the Raman spectra of SWNT bundles is to soften all the SWNT phonon modes, some more than others, without a significant effect on the energy of the van Hove singularities.

3.3. Dependence of Debundling, Doping, and Applied External Potential

In this section we consider the effect on the Raman spectra of using chemistry to debundle SWNTs in SWNT bundles, and the spectral modifications resulting from p- and n-type doping and from the application of positive and negative potentials to the SWNT bundles.

In addition to their exotic physical properties, sp^m ($2 < m < 3$) hybridized carbons have been found to exhibit interesting chemical properties [10, 69]. For instance,

[1] In [67], the relation $\omega_{\mathrm{RBM}} = 223/d_t + 14$ is used, yielding $d_t = 1.33$ and 0.89 nm for the tubes with $\omega_{\mathrm{RBM}} = 182$ and 264 cm^{-1}, respectively, while use of the formula $\omega_{\mathrm{RBM}} = 248/d_t$ for isolated SWNTs yields d_t values of 1.36 and 0.94 nm, respectively.

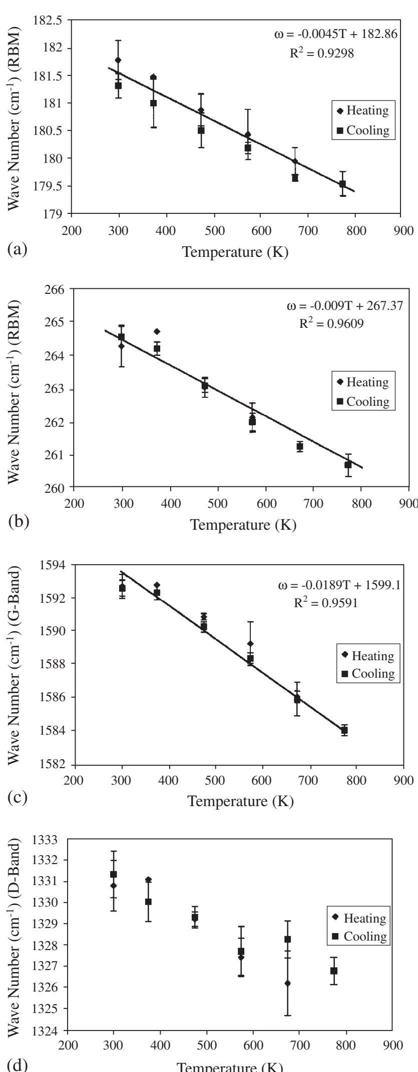

Figure 15. Temperature dependence of Raman frequencies in cm^{-1} of HiPCo SWNTs in SWNT bundles plotted as a function of temperature (K) for the RBM mode at 182 (a) and at 264 cm^{-1} (b) at room temperature, and for the G-band and D-band features in (c) and (d), respectively [67]. Over the temperature range shown in this figure, all modes show a reversible linear shift with temperature upon heating and cooling. Reprinted with permission from [67], N. R. fullerene chemistry blossomed into a rich subfield, allowing researchers to develop recipes for their purification, chromatographic separation, and functionalization in order to yield fullerenes with tailored chemical properties (see Chap. 10 in [10]). Since carbon nanotubes can be viewed as highly elongated fullerene molecules, it was natural to expect that the chemical properties of carbon nanotubes would be explored soon after the discovery of bulk nanotube synthesis methods for SWNT bundles by the pulsed vaporization [48] and electric arc methods [49]. A major impediment of nanotube chemistry is the insolubility of as-prepared carbon nanotubes in known organic solvents. This chemical inertness stems from the fact that a large fraction of the carbon atoms in a nanotube shell exhibits strong covalent bonding with neighboring atoms, as is the case in a single graphene sheet. Toward the end of 1997, recipes were being developed to chemically purify, debundle, and chop nanotubes into short "fullerene pipes" with a view toward preparing solubilized nanotubes. The following year, a major breakthrough was reported, which revealed that nanotubes attached with long chain octadecylamine molecules become soluble in CS_2 and other organic solvents [70]. AFM images showed that the majority of the bundled SWNTs were separated into isolated tubes and small SWNT bundles (2–4 nm in diameter) during the solubilization process [70]. Henceforth in this chapter, solubilized tubes are called debundled tubes.

Besides literally opening doors to the chemical modification of nanotubes, fullerene pipes and debundled tubes provide an opportunity to investigate the effects of finite-tube length [53] and of debundling on the vibrational and electronic properties of nanotubes [64, 71]. The tube–tube interactions within SWNT bundles are weak, similar to the coupling between adjacent graphene planes in 3D crystalline graphite or the intermolecular coupling found in solid C_{60}. This weak intertube coupling is dominated by the van der Waals (vdW) interaction but contains a nonzero covalent component that has been shown theoretically and experimentally to have a significant influence on the vibrational [16, 72–75] and electronic states for carbon nanotubes [76, 77].

In this section, we focus on Raman spectroscopic studies of debundled SWNTs to probe the effect of vdW interactions on the RBM band and on the G-band frequencies ω_{RBM} and ω_G. Almost all of the early Raman spectra on SWNTs were collected on nanotube bundles that were synthesized by the pulsed laser vaporization or the electric arc methods. These bundles contain on the order of 100 well-aligned SWNTs arranged in an approximately closed-packed triangular lattice. A typical Raman spectrum of the arc-derived SWNT bundles obtained using the 1064 nm excitation wavelength (see Fig. 16) exhibits two prominent features at $\omega_{\mathrm{RBM}} \sim 160$ cm^{-1} (radial band) and $\omega_{G^+} = 1591$ cm^{-1} (tangential band). The frequencies of the peaks in the RBM bands have been used extensively to determine the SWNT diameter distribution (see Section 2.3). The line-shape of the G band has been used to determine the semiconducting/metallic nature of SWNTs (see Section 3.1).

In Figure 16, the Raman spectrum of debundled tubes in CS_2 (solid trace) is compared to that obtained for bundled SWNTs (dotted trace), the latter in powder form. The debundled and bundled SWNTs referred to in Figure 16 stem from the same as-prepared arc-derived material. Three G-band modes near 1590 cm^{-1}, previously identified with A_{1g}, E_{1g}, and E_{2g} symmetries (see Section 3.1), are expected for achiral tubes [6] with frequencies that are nearly independent of the tube diameter [20], while for chiral tubes, six G-band modes are Raman-active with $2A_1$, $2E_1$, and $2E_2$ symmetries [20]. In contrast to the high frequency G-band at 1590 cm^{-1}, the low frequency RBM band centered at $\sim$160 cm^{-1} is identified with a band of A_1 symmetry radial breathing modes representing contributions from the various SWNTs within the resonance window of the excitation laser, each contributing at a frequency in accordance with its diameter $\omega_{\mathrm{RBM}} = \alpha/d_t + \Delta\omega_{\mathrm{RBM}}$ [6]. Consistent with the calculated mode frequencies and intensities, other weak

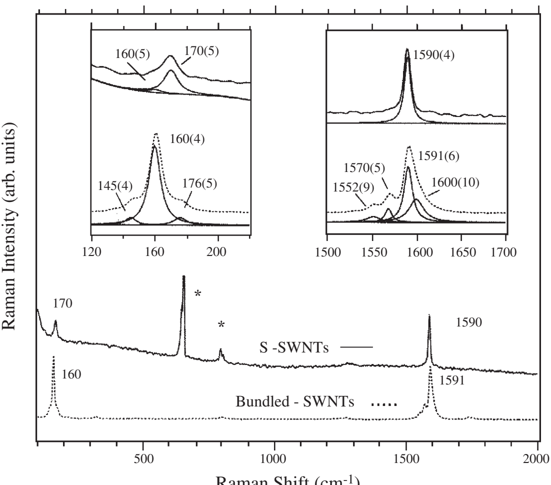

Figure 16. Room temperature Raman spectrum of arc-synthesized bundled SWNTs (dotted curve) and of solubilized SWNTs (solid curve) denoted by S-SWNTs in CS_2. The laser excitation wavelength is 1064 nm. The peaks denoted by asterisks are attributed to CS_2. The *G*-band peak intensities are set to a constant value so that the intensities for the RBM bands for the two spectra can be compared. The left and right insets show, respectively, the deconvolution of the RBM and *G*-band features in the bundled SWNTs and S-SWNTs. The vertical and horizontal axes for the two insets correspond, respectively, to the Raman intensity and frequency. The numbers within parentheses refer to the full width at half maximum intensity of the various constituents of the deconvolved bands. Reprinted with permission from [64], A. M. Rao et al., *Phys. Rev. Lett.* 86, 3895 (2001). © 2001, American Physical Society.

Raman-active features have been observed in the intermediate phonon frequency region between the RBM and *G*-band features [53].

At least two striking differences in the Raman spectra of bundled versus debundled tubes stand out in the spectra of Figure 16. The first difference is the narrower linewidths for the RBM and *G*-bands of the debundled SWNTs in CS_2 relative to those observed in bundled SWNTs, albeit the linewidth of the each Lorentzian component is nearly the same for bundled and debundled tubes. Likewise the linewidths for the G^+-band components for isolated tubes are also considerably smaller than for SWNT bundles, as is also the case for the RBM band, because of the large decrease in inhomogeneous line broadening for isolated SWNTs. In fact, the linewidths for the RBM and *G*-band features for debundled SWNTs can be as narrow as for isolated SWNTs [22]. This is also shown by the Lorentzian lineshape analysis of the *G*-band (right inset of Fig. 16) which reveals at least four narrow components for the bundled SWNTs and a single narrow mode for debundled SWNTs in CS_2. The loss of the G^--band in the debundled spectrum is apparent and can be understood from studies at the single nanotube level which show the suppression of the G^--band in isolated semiconducting tubes due to the antenna effect [1]. Similarly, from the left hand inset in Figure 16 for the RBM band, a reduced number of Lorentzians is observed in the spectrum of the S-SWNT sample when compared to that of the bundled SWNTs, indicating a much narrower tube diameter distribution in the debundled sample.

The second difference revealed in Figure 16 is the upshift of ω_{RBM} for bundles with respect to the corresponding value in isolated tubes due to the space restrictions imposed by the presence of neighboring tubes in a SWNT bundle. The tube–tube interactions within a SWNT bundle have been predicted to cause a ~6–20 cm^{-1} upshift in ω_{RBM}, depending on the detailed considerations of the various theoretical calculations [74, 75, 77]. Figure 16 shows that the RBM band in debundled tubes is upshifted by ~10 cm^{-1} relative to the RBM band in bundled tubes, in apparent contradiction with lattice dynamics predictions of a stiffening of the force constants in a bundled cluster of tubes relative to isolated tubes because the atomic displacements in a bundled tube are somewhat hindered by the radial atomic displacements of neighboring tubes.

In Figure 17, the RBM band (panel a) and the *G*-band (panel b) spectra taken at 1064, 647.1, and 514.5 nm excitations are compared for laser-synthesized bundled SWNTs and solid laser-synthesized debundled tubes (i.e., SWNTs that are first solubilized along their full lengths by organic solvents which are then evaporated). The RBM bands in these solid debundled tubes are consistently upshifted relative to those of SWNTs that are in bundles, as can be seen in all the spectra depicted in Figure 17. On the other hand, the narrowing of the *G*-band observed in the solubilized debundled tubes in CS_2 (see right-hand inset in Fig. 16) is absent in the tangential *G*-band in solid debundled tubes (Fig. 17). Nevertheless, there is essentially no change in the *G*-band peak frequencies as a result of debundling within the resolution of the Raman experiments.

At least two important conclusions can be drawn from the Raman data presented in Figure 17:

(i) Both semiconducting and metallic tubes exhibit about a 10 cm^{-1} upshift in ω_{RBM} when the bundled tubes are solubilized. As Pimenta et al. [57, 58] have argued, the 647.1 nm excitation couples predominantly to metallic tubes in a sample with a mean SWNT diameter of ~1.4 nm.

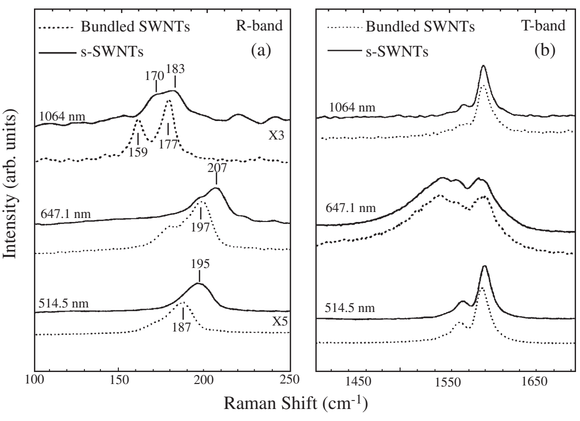

Figure 17. Comparison of the radial breathing mode band (labeled R-band) (panel a) and the tangential *G*-band (labeled T-band) (panel b) of laser-synthesized bundled SWNTs and subsequent solid debundled tubes based on these bundled SWNTs for three different laser excitation wavelengths. Reprinted with permission from [64], A. M. Rao et al., *Phys. Rev. Lett.* 86, 3895 (2001). © 2001, American Physical Society.

(ii) The relatively broader tangential G-band in solid S-SWNTs compared to that of debundled tubes in CS_2 suggests that the organic solvent–nanotube interactions have a smaller influence on the tangential mode lifetime than the tube–tube interactions in solid debundled tubes.

Duesberg et al. [27] have also reported an upshift in ω_{RBM} in their Raman spectrum collected on SWNT bundles of different thicknesses. In Figure 18, the 5 nm thick SWNT bundle (#3 bundle in Fig. 18) showed $\omega_{\mathrm{RBM}} \sim 188$ cm^{-1} while a 1.5 nm thick bundle (#1 bundle in Fig. 18) showed $\omega_{\mathrm{RBM}} \sim 193$ cm^{-1}. These observations are consistent with those discussed in Figures 16 and 17.

We now consider two other perturbations to SWNT bundles which modify their Raman spectra. First we consider the effect of an applied potential, and then we consider the case of doping the SWNT bundles with donors and acceptors. Both of these experiments provide insights into how external perturbations modify the observed Raman spectra.

Electrochemical studies of the resonance Raman spectra of SWNT bundles show that the electrochemical potential, Fermi level, and charge carrier density of SWNTs can be controlled by an externally applied potential, thereby radically changing the Raman spectra as initial or final states become unavailable for the resonance Raman effect [78]. Figure 19a shows the change in the spectra at $E_{\mathrm{laser}} = 1.96$ eV for SWNT bundles ($d_t = 1.25 \pm 0.20$ nm) cast on a Pt substrate immersed in an H_2SO_4 (0.5 M) aqueous solution as the external voltage V is varied from 0 to +1.3 V and then back to 0 V. While the dependence of ω_D and ω_G on V was studied, it was found that the dependence of $\omega_{G'}$ on V could be explained quantitatively in terms of the lowering of the Fermi level with increasing V, thereby emptying states from van Hove singularities in the valence band and, in the case of metallic tubes, also from the constant nonzero density of states between the lowest energy pair of van Hove singularities E_{11}^M, as shown in Figure 19b. The good agreement

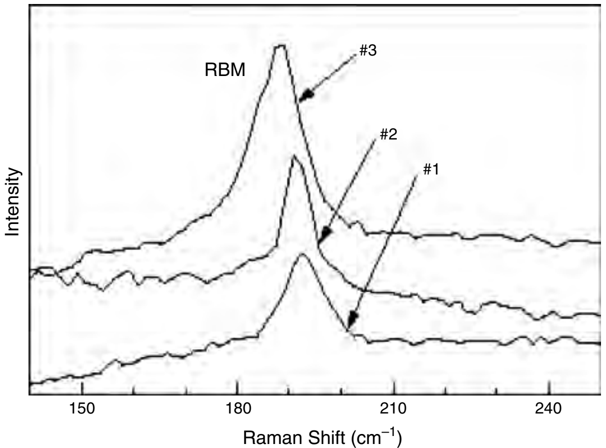

Figure 18. Raman spectra of the radial breathing mode using $E_{\mathrm{laser}} = 1.96$ eV for three different thicknesses of SWNT bundles, with #2 and #3 having a thickness of 5 nm, with #1 having a thickness of 1.5 nm. The results show a dependence of ω_{RBM} and its intensity on the thickness of the SWNT bundle. Reprinted with permission from [27], G. S. Duesberg et al., *Phys. Rev. Lett.* 85, 5436 (2000). © 2000, American Physical Society.

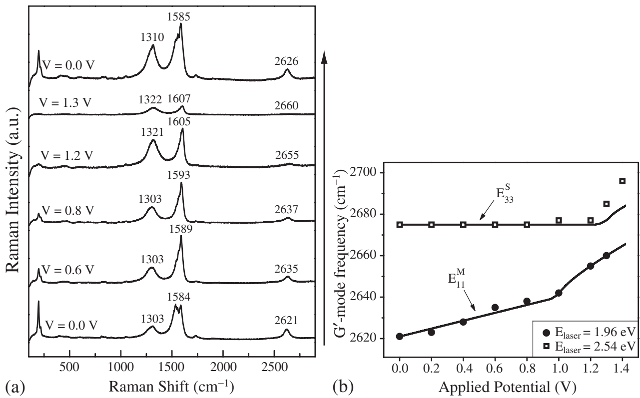

Figure 19. (a) *In-situ* Raman spectra of a SWNT film cast on a platinum surface in an H_2SO_4 0.5 M aqueous solution. The spectra are obtained at the indicated positive applied potentials and $E_{\mathrm{laser}} = 1.96$ eV. The frequencies for the dominant G-band, D-band, and G'-band features are indicated in cm^{-1}. (b) The points denote G'-band frequencies for the same SWNT film as in (a), obtained at the indicated applied potentials for $E_{\mathrm{laser}} = 1.96$ and 2.54 eV. The solid lines in (b) are theoretical curves for the G'-band calculated from charge transfer in SWNT density of states. Reprinted with permission from [78], P. Corio et al., *Chem. Phys. Lett.* 370, 675 (2003).

between experiment and theory regarding the dependence of $\omega_{G'}$ on V and the observation of a different behavior for semiconducting and metallic tubes indicates that the applied voltage V has only a small effect on the energy of the van Hove singularities, but the application of V mainly affects the occupation of valence and conduction band states [78].

Closely connected to these electrochemical experiments are doping experiments where either electrons or holes are added to the nanotubes by the addition of either donor or acceptor dopant species. For the case of saturation-doped SWNT bundles with halogen acceptors (for example, Br_2), the ω_{RBM} and ω_{G^+} frequencies upshift, respectively, by ~74 and ~24 cm^{-1}, relative to the corresponding frequencies in the undoped SWNT bundles. On the other hand, doping with alkali metals like K or Rb leads to a softening (or downshift) of ω_{RBM} and ω_{G^+}, accompanied by dramatic changes in the lineshape for the tangential G-band. For example, the G-band in saturation K-doped or Rb-doped bundles, ω_{G^+}, downshifts by ~35 cm^{-1} and exhibits a characteristic Breit–Wigner–Fano lineshape [80]. The radial breathing mode band in saturation K-doped or Rb-doped bundles is not evident in the Raman spectrum. The RBM band may have shifted to very low frequencies or it may have broadened to such an extent that it cannot be detected above the background signal. These shifts provide evidence for charge transfer between the dopants and SWNT bundles, indicating an ionic character for the doped samples. Doping with halogens transfers electrons from the π states in the SWNTs to the halogens, creating hole carriers in the SWNTs (p-type). Likewise, alkali-metal dopants transfer electrons to the π^* states, making the nanotubes n-type. The authors explained their results within a rigid band model, assuming no modification to the E_{ii} values for their doped SWNTs.

We now offer some explanation for the information provided by these Raman studies on the effect of these perturbations on the nanotubes. With regard to interpreting

the debundling effects discussed previously and depicted in Figures 16, 17, and 18, we note that the shifts in ω_{RBM} or in ω_G observed in doped nanotube bundles have been related to the charge transfer between the nanotubes and the alkali metal (downshift) or halogen (upshift) dopants [79]. In this case, the van Hove singularities do not change much in energy, but the Fermi level (or the filling of electron and hole states) is greatly affected, resulting in large shifts in G-band properties and in the suppression of interband transitions. The effect of positively and negatively applied potentials is similar to that of chemical doping insofar as the values of E_{ii} do not change much, but large shifts in Fermi level (the filling and emptying of electron states) are observed. In contrast, the debundling of SWNTs mainly affects the tube–tube coupling and sensitively affects ω_{RBM} but not ω_G. Clearly, for the spectra depicted in Figure 16, the 10 cm^{-1} upshift in ω_{RBM} upon forming debundled from bundled SWNTs cannot be attributed to charge transfer, since ω_G for debundled tubes exhibits an insignificant frequency shift from the observed frequency in bundled SWNTs. Furthermore, the 10 cm^{-1} upshift in Figures 16 and 17 is not due to the presence of long chain molecules (which are attached to the tube walls or to the tube ends during the debundling process) [70], since the effect of debundling on ω_{RBM} should result in a downshift in frequency, since the attachment of molecules to the SWNT would be expected to weaken the carbon–carbon force constants involved in the normal mode vibrations of the SWNTs. The anomalous upshift of ~10 cm^{-1} has therefore been attributed to a decrease in the energy spacing of the van Hove singularities in debundled tubes relative to the spacings in bundled tubes, thereby allowing the same laser excitation to excite SWNTs with smaller diameters in the debundled SWNTs relative to the bundled SWNTs [64].

3.4. Pressure-Dependent Studies

The study of Raman-active modes in SWNTs as a function of external pressure has been useful in probing both the influence of vdW (van der Waals) interactions on the vibrational modes in carbon nanotubes [80–82] and the pressure-induced structural transitions in SWNTs [80, 82]. Pressure-induced changes in the electrical [83] and optical [84] properties of SWNT bundles have also been reported. In the high-pressure experiments reported to date, SWNT material synthesized either by the electric arc [49] or pulsed laser vaporization [48] methods has been used.

Generalized tight binding molecular dynamic (GTBMD) simulations predicted different pressure dependences for ω_{RBM} in bundled and isolated tubes [80]. These GTBMD calculations showed that the pressure dependence for ω_{RBM} is sensitive to the coupling between the tubes in the SWNT bundles. In the GTBMD scheme, a Lennard–Jones type potential was used to describe the vdW forces between SWNTs in a bundle, using Lennard–Jones parameters similar to those needed to simulate the c-axis bonding in bulk graphite. In the calculations, the hydrostatic pressure, P, was introduced through a radial force $F_P = P \times A$, where A is a cross-sectional area perpendicular to the tube axis [80]. Three scenarios (I, II, and III) by which the external applied pressure can be transmitted to a SWNT bundle were considered (Fig. 20). In model I, the pressure transmitting liquid resides external to the SWNT bundle and pressure is transmitted only to the outer tubes, while the tubes in the interior of the bundle are coupled to the external force through vdW interactions. Model II describes a situation in which the vdW interactions were neglected and the pressure transmitting liquid penetrates the bundle via the interstitial channels to exert uniform pressure on individual tubes within the bundle. This model also applies to isolated tubes, where the pressure transmitting liquid can freely access the entire perimeter of each tube and the vdW interactions are thereby strongly reduced. Finally, model III is identical to model II except for the inclusion of the vdW interactions in the GTBMD calculations.

Large SWNT bundles (containing more than 100 tubes) produced by pulsed laser vaporization of graphite were debundled using chemical methods described in [70]. This procedure resulted in some isolated tubes, but the majority of the tubes were in small bundles containing three to seven tubes, as seen in the height profile analysis of AFM images. A schematic representation of the debundled SWNT sample containing a smaller number of tubes is shown in Figure 21, where the number within the tube represents the number of neighboring tubes. For example, an isolated tube has zero neighboring tubes, and within a bundle of three tubes, each tube has two neighboring tubes. Also the peripheral tubes in a bundle of seven tubes have three neighboring tubes, while the central tube has six neighboring tubes, as shown in the figure.

In Figure 22, the pressure-induced frequency shifts of the RBM (panel a) and the tangential G-band (panel b) frequencies for debundled SWNTs (squares) are compared to those for bundled SWNTs (triangles). In this figure, the difference between the observed frequency at any given pressure and the atmospheric pressure frequency, that is, $[\omega(P) - \omega(0)]$, is plotted along the vertical axis for convenience of comparison [85]. This choice for the ordinate enables us to eliminate the shifts in ω_{RBM} between the bundled and debundled SWNTs, which was discussed in Figures 16 and 17. In Figure 22, the two dominant G-band modes (G^+ and G^-) observed in both bundled and debundled SWNTs are labeled as T_2 and T_1, corresponding to G^+ and G^-, respectively. The solid lines represent fits to the experimental data (linear in panel a; quadratic in panel b in Fig. 22) while the dashed curves represent theoretical pressure dependences for ω_{RBM} and ω_G from models I–III described previously. Interestingly, the experimentally observed pressure dependence for both ω_{RBM} and

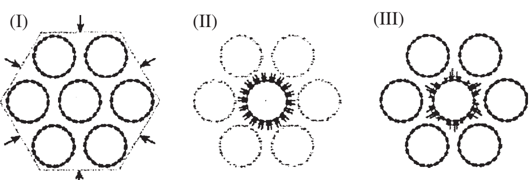

Figure 20. Three scenarios (I, II, and III) by which the external applied pressure can be transmitted to a SWNT bundle (see text). Reprinted with permission from [85], U. Schlecht et al., *J. Nanosci. Nanotechnol.* 3, 139 (2003). American Scientific Publishers.

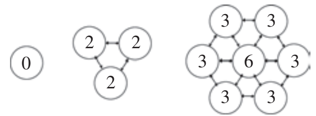

Figure 21. A schematic representation of the number of neighbors in debundled SWNT samples containing a small number of tubes, namely one, three, and seven tubes (see text). ω_G in debundled SWNTs is nearly the same as in bundled SWNTs.

It should be noted that the GTBMD calculations (left panel in Fig. 22) predict different pressure dependences for ω_{RBM} in bundled (model I) and isolated tubes (models II and III). For the pressure dependence of ω_{RBM} in debundled SWNTs, Figure 22 shows an experimentally determined linear shift of $\sim$8.4 cm^{-1}/GPa, which is comparable to the values of 9.7 [81, 86] and 10.1 cm^{-1}/GPa [82] reported, respectively, for $d\omega_{\mathrm{RBM}}/dP$ in arc-derived and laser-derived bundled tubes. Thus, the experimentally determined pressure coefficient for ω_{RBM} in debundled SWNTs is significantly higher than the pressure dependence of $\sim$1.3 cm^{-1}/GPa for ω_{RBM} predicted by model II for isolated tubes [85]. This would imply that the magnitude of the vdW interactions on ω_{RBM}, as reflected in the pressure dependence of the Raman-active radial breathing mode, is nearly the same whether a SWNT resides within a large bundle (with 100 neighboring tubes) or inside a small bundle containing three to seven tubes, indicating the greater importance of near-neighbor intertube interactions. The Raman data described in Figures 16 and 22 collectively suggest that the debundling into small diameter bundles causes a 10 cm^{-1} upshift in ω_{RBM} but does not lead to a change in its dependence to external applied pressure. To unravel these subtle differences, further high pressure Raman studies on a homogeneous sample of isolated SWNTs prepared either by improved chemical methods or by chemical vapor deposition are required.

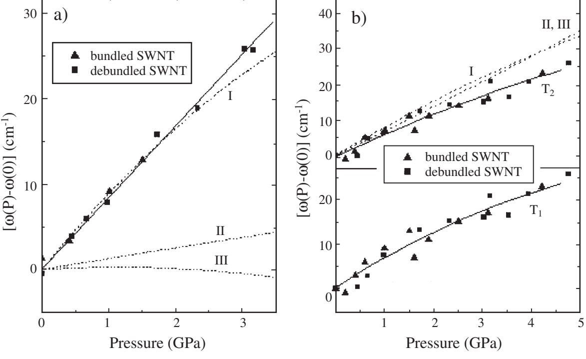

Figure 22. Pressure dependence of Raman modes in solubilized SWNTs and bundled SWNTs. The pressure-induced frequency shifts of the ω_{RBM} (panel a) and tangential G-band frequencies ω_{G^+} and ω_{G^-} (labeled T_2 and T_1, respectively) (panel b) for debundled SWNTs (squares) to those for bundled SWNTs (triangles) are compared. The dashed curves represent the calculated pressure dependence for ω_{RBM} and ω_G from models I, II, and III. Reprinted with permission from [85], U. Schlecht et al., *J. Nanosci. Nanotechnol.* 3, 139 (2003). American Scientific Publishers.

Application of external pressure on a SWNT bundle can be expected to modify the electron density of states resulting in the "band tuning" phenomenon. Since Raman scattering from nanotubes is a resonant process, one might expect the laser excitation E_{laser} to resonate with different diameter tubes in the bundle as the external pressure is ramped from 0 to 5 GPa (Fig. 22). In panel (a) of Figure 22, the radial band cannot be discerned at external pressures above $\sim$3 GPa, while the tangential band persists even at 5 GPa. The loss of intensity of the radial band is most likely due to faceting (hexagonal distortion) of the nanotubes and a constraint on the radial atomic displacements of the carbon atoms by adjacent SWNTs, rather than due to a decrease in the resonance cross-section.

A direct measurement of the pressure dependence of the E_{11}^S and E_{22}^S transition energies is provided by the high pressure optical absorption studies of SWNT films by Kazaoui et al. [84], who experimentally observed that the optical absorption spectra of SWNTs changed reversibly due to external pressure, as shown in Figure 23. The features labeled S1 and S2 in Figure 23 were attributed to allowed electronic transitions E_{11}^S and E_{22}^S between the first and second pair of van Hove singularities in semiconducting SWNTs [84]. By monitoring the peak energy for S1, the authors found that the energy gap downshifts by only $\Delta E_{11}^S \sim$ 0.04 eV over the pressure range of 0–4 GPa (see inset to Fig. 23). This small shift in ΔE_{11}^S would predict a downshift of only 2 cm^{-1} in ω_{RBM} over the pressure range 0–4 GPa, which is much smaller than the experimental observation shown in Figure 22. This value of ΔE_{11}^S due to applied pressure is also relatively small compared to the energy shift of $\Delta E_{11}^M \sim$ 0.15–0.20 eV predicted from the Table 2 calculations [64] for the effect of bundling (intertube interactions) on E_{11}^M for metallic SWNTs (see Section 3.1). The measured ΔE_{11}^S due to applied pressure of 4 GPa is insufficient in magnitude to bring different diameter tubes into resonance with a given laser line E_{laser}.

3.5. Effects of External Perturbations on Raman Spectra

The effects of various perturbations to the Raman spectra have been reviewed in Sections 3.1–3.4, including the effects of bundling (Section 3.1), temperature (Section 3.2), debundling, doping, and applied voltage (Section 3.3), and pressure (Section 3.4). In this section, all of these effects are brought together and are discussed in terms of their effect on: (i) the Raman features of a given SWNT that is assumed to always be in resonance with a tunable laser (whose E_{laser} can be varied to satisfy the resonance condition) and (ii) the Raman measurements that are actually carried out.

First we consider the case of bundling the SWNTs which occurs in a self-assembly process during synthesis when the SWNT bundles are formed. Calculations show that the effect of bundling is to introduce an attractive intertube interaction, which for typical tube bundles (containing approximately 100 SWNTs in an ordered hexagonal arrangement) leads to: (i) an increase in the separation between the van Hove singularities and an upshift in E_{ii} by 0.15–0.20 eV and (ii) an increase in ω_{RBM} by $\sim$10 cm^{-1} [64]. From a physical standpoint, the effect of bundling and debundling mostly affects out-of-plane displacements, so that one would expect bundling and debundling to mainly affect ω_{RBM}, as is observed experimentally. When the experimental spectra on SWNT bundles are taken with the same laser line, then the ω_{RBM} of SWNT bundles would appear *downshifted* by $\sim$10 cm^{-1} relative to the isolated SWNTs, since different tubes of larger diameter would now be brought into resonance. In actuality, this experiment is not carried out, because the starting material is already in bundles.

The experiment that is actually carried out in the laboratory is the inverse experiment of debundling (see Section 3.3), which, from the theoretical argument given previously, has the effect of reducing the separation between the van Hove singularities, bringing into resonance smaller diameter SWNTs, thereby giving rise to a higher ω_{RBM}, in agreement with experimental observations.

These results also suggest that the coupling of the excitation laser energy (E_{laser}) is sensitive to the environment in which the nanotube resides, and thus future studies aimed at correlating nanotube diameters with ω_{RBM} should pay attention to the size of the bundles. Also, a detailed theoretical study of the dependence of E_{ii}, ω_{RBM}, and ω_G on bundle size is needed, including possible differences between semiconducting and metallic tubes. The techniques developed to fit ω_{RBM} to d_t through the relation $\omega_{RBM} = \alpha/d_t + \Delta\omega_{RBM}$ from measured diameter distributions using four or more laser lines [87] would be very useful in carrying out such systematic studies.

Another mechanism by which tubes move in and out of resonance with the excitation energy can be found in the electrochemical studies of SWNT bundles [78]. These experiments show that the electrochemical potential, Fermi level, and charge carrier density of SWNTs can be controlled by an externally applied potential, thereby radically changing the Raman spectra as initial or final states become unavailable for the resonance Raman effect as the applied potential is varied. The applied voltage V is found to affect the energy of the van Hove singularities E_{ii} only mildly, but the application of V mainly affects the emptying of states in the valence band and the occupation of states in the conduction band [78]. More detailed studies at the single nanotube level are needed to clearly establish the shifts in E_{ii} induced by application of a voltage V to isolated metallic and semiconducting SWNTs.

In closely related optical absorption experiments by Kazaoui et al. [88], essentially no shifts in the E_{ii} peak frequencies are observed upon donor doping with Cs and acceptor doping with Br_2, although an attenuation in the peak intensities is observed, consistent with the emptying and filling of states through acceptor and donor doping. Shifts in ω_{RBM} and ω_G with doping have been observed and have been correlated with the optical absorption data.

Other experiments by Kazaoui et al. [84] show that the optical absorption peak energy depends only weakly on pressure, although its intensity decreases strongly as the pressure is increased. This result implies that essentially the same SWNTs remain in resonance with E_{laser} as the pressure is increased. Because of this weak dependence of E_{ii} on pressure, the observed upshifts in ω_{RBM} and ω_G with pressure must be connected to increases in both the out-of-plane (RBM) and the in-plane (G-band) force constants of the *same nanotubes* with increasing pressure. The much larger compressibility of the tube bundles in the radial direction compared to the tangential direction results in a much larger percentage increase in ω_{RBM} as compared to ω_G with pressure, as is seen experimentally. Correspondingly, increasing the temperature [67] weakens the force constants for both the RBM and the G-band, without significantly shifting E_{ii}, so a given laser line remains in resonance with essentially the same SWNTs upon heating the sample.

Future experimental work is needed to provide a more systematic experimental framework which yields a more reliable model to account for the changes in the Raman spectra induced by the various perturbations to SWNTs discussed in Section 3, thereby allowing Raman spectroscopy to provide a sensitive and informative characterization tool for measuring these perturbations.

4. PEAPODS

Peapods refer to single wall carbon nanotubes containing C_{60} (or other fullerene) molecules within their cores. Early samples of peapods were discovered accidentally in high resolution transmission electron microscopy (HRTEM) studies of acid-purified laser-derived SWNT bundles [89–92]. Detailed HRTEM studies revealed the presence of structural defects induced in the tube walls due to acid treatment, which presumably served as entry ports for trace amounts of C_{60} that were coproduced during the nanotube synthesis. Soon after this discovery, an efficient route to prepare peapods became obvious, since nanotube researchers had already used mild oxidation conditions to open nanotube ends and fill the inner core of MWNTs with metals, such as Pb, by exploiting the capillary properties of nanotubes [93, 94]. It is thus not surprising to find that oxidized as-prepared SWNTs with open tube ends when exposed to C_{60} vapors could provide an efficient route for the synthesis of peapods based on vapor-phase transport and the capillary filling of fullerenes [95]. Filling fractions as high as 60% have now been demonstrated in the preparation of

peapods. Some authors have also prepared peapods using synthesis techniques similar to those used to prepare endohedral fullerenes. A controlled insertion of fullerenes inside SWNTs has been reported using plasma irradiation methods where various atoms (Li, Na, K) or molecules (C_{60}) can be encapsulated [96]. HRTEM studies of irradiated tubes showed that controlled amounts of defects could be created in the SWNT sidewall through ion irradiation, and that these defects could serve as additional entry ports (besides the open tube ends) for irradiated C_{60} into the nanotubes. Typical transmission electron microscope images of peapods are shown in Figure 24. A string of evenly spaced encapsulated C_{60} molecules, denoted by $(C_{60})_n$@SWNT, is clearly observed in panel A of Figure 24.

Raman scattering experiments on SWNT bundles [71, 75, 97] at ambient pressure (Figs. 16 and 17) and solubilized SWNTs [5, 85, 98–100] at high pressures (~5 GPa) inside a diamond anvil cell (see Fig. 22) revealed the effect of van der Waals interactions on the Raman-active modes in SWNT bundles [71, 97]. By comparing the experimentally observed radial breathing mode and tangential *G*-band frequencies in the high pressure Raman studies of SWNT bundles to those predicted (using a generalized tight binding model calculation) in the presence or absence of van der Waals interactions, Venkateswaran et al. [75] reported a negligible shift in the tangential *G*-band frequency, but a ~14 cm^{-1} upshift in the radial band frequency due to tube–tube interactions [71, 97]. Likewise, the Raman investigations of peapods could in principle probe the effect of the encapsulation of fullerene molecules on the vibrational and electronic properties of the host SWNTs.

(D) The complete coalescence of C_{60} molecules to form DWNTs at 1200 °C. The inset in (D) shows inner tubes with terminating end caps. Reprinted with permission from [95], S. Bandow et al., *Chem. Phys. Lett.* 337, 48 (2001). © 2001, Elsevier Science.

A detailed Raman study using 10 different laser excitation energies (over the range 1000–413 nm or 1.24–3.0 eV) of empty and fullerene filled SWNTs has been reported by Pfeiffer et al. [101]. Laser-derived SWNTs were used in their preparation of peapods with approximately 60% C_{60} occupancy. Figure 25 shows a collection of Raman spectra obtained at 80 K on empty and C_{60} filled SWNTs. Interestingly, the RBM band in the peapod bundles is qualitatively similar to that observed in empty SWNT bundles and is found to be downshifted by only ~2 cm^{-1} relative to that of empty SWNT bundles. The authors attribute this small frequency downshift to a slightly increased peapod diameter or to a change in the intertube interactions [101]. The tangential *G*-bands of the empty and C_{60} filled SWNTs are also qualitatively similar without a noticeable shift between the two Raman spectra. Similar to the response of empty SWNTs, the peapods exhibit diameter selective resonance Raman scattering [5] (as shown in Fig. 25) and exhibit a strong dependence of the tangential band lineshape on excitation energy (narrow tangential band for the blue–green excitations and Fano-distorted lineshape for red laser excitation) [101]. The Raman spectra for empty SWNTs when *subtracted* from the corresponding Raman spectra for peapods reveal interesting Raman features in the vicinity of the pentagonal pinch mode frequency of C_{60} (Fig. 26) [101]. Two weak modes at 1466 and 1474 cm^{-1} are found with an intensity that is 20 times lower than the intensity of the *G*-mode of SWNTs. The relative intensities of these weak modes change as a function of the excitation energy (Fig. 26). Since each peak in the doublet observed in Figure 26 lies on either side of the expected 1469 cm^{-1} peak for C_{60}, it was concluded that encapsulated C_{60} seems to be strongly affected by the encapsulation, perhaps related to the orientation of the pentagons and hexagons of C_{60} with respect to the closest contact of the C_{60} molecule with respect to the SWNT hexagons, though a detailed interpretation for the origin of two weak peaks rather than one is presently lacking.

In contrast with observations reported by Pfeiffer et al. [101], a comparative Raman study (using 514.5 nm excitation) was done with a purified SWNT bundle reference sample and a peapod sample prepared using the irradiation method [96]. The results of this study showed the presence of the C_{60} A_{1g} Raman peak in the peapod spectrum at 1469 cm^{-1} [96]. From the positions of the peaks in the RBM band, the authors estimated a 1.2–1.3 nm tube diameter, in contrast to the diameters determined from TEM (1.2–1.8 nm). This discrepancy in diameter evaluation is largely due to the fact that nanotubes exhibit resonant Raman scattering, and several laser excitation energies should be used to probe the full range of tube diameters in the peapod sample. Other notable features reported in their work [96] included a low intensity for the 1353 cm^{-1} D-band feature, signifying that little damage is caused to SWNTs by the low level of alkali metal plasma irradiation flux [(1–5) × 10^9 cm^{-3}] used in their experiment. Regarding the C_{60} modes, the low frequency H_g mode, the radial breathing C_{60} mode $A_g(1)$, and the pentagonal pinch $A_g(2)$ mode appear, respectively, at 273, 497, and 1469 cm^{-1}, which are very close to the frequencies for free C_{60} molecules, suggesting a weak interaction between the encapsulated C_{60} and the SWNTs.

Electrochemistry offers more favorable conditions for both reductive and oxidative doping than chemical doping methods. A thin film electrode was prepared by evaporating an ethanolic slurry of peapods on Pt or on an ITO (indium tin oxide) transparent electrode to simultaneously monitor the electronic and vibrational properties of peapods [102]. In this work, the peapods on ITO served as a working electrode for *in-situ* visible near-infrared spectroelectrochemistry spectra taken on peapods as the population of the valence-band electronic states was tuned electrochemically in a solution of 0.2 M $LiClO_4$ in acetonitrile. The electrochemical cell was assembled inside a glove box with a glass optical window for *in-situ* Raman characterization. The intensities of the RBM and G-band modes for the peapod SWNT bundles were observed to decrease as a result of cathodic (panels a) or anodic (panels b) doping as shown in Figure 27, similar to the behavior observed for empty SWNT bundles. The lower frequency RBM component (165–175 cm^{-1}) is less affected by the positive and negative potentials as compared to the higher frequency RBM component (180–190 cm^{-1}), revealing a diameter dependence of the electronic transition energies (i.e., the so-called E_{33}^S transition, between van Hove singularities, E_3^v and E_3^c in the valence and conduction band density of states), whereby wide diameter tubes are depleted of/filled with carriers before those of narrower diameter tubes, as the potential is changed toward more positive/negative values. In analogy to empty tubes, the tangential G-band significantly and monotonically upshifts with increasing anodic potential (panel b) and is less sensitive to cathodic charging (panel a). In contrast to empty SWNT bundles [79], no detectable shifts of the RBM peaks is observed upon progressive cathodic or anodic charging of the peapod sample (Fig. 27). Clearly, the intensities of the RBM peaks decrease as a result of cathodic or anodic charging. These doping-induced behav-

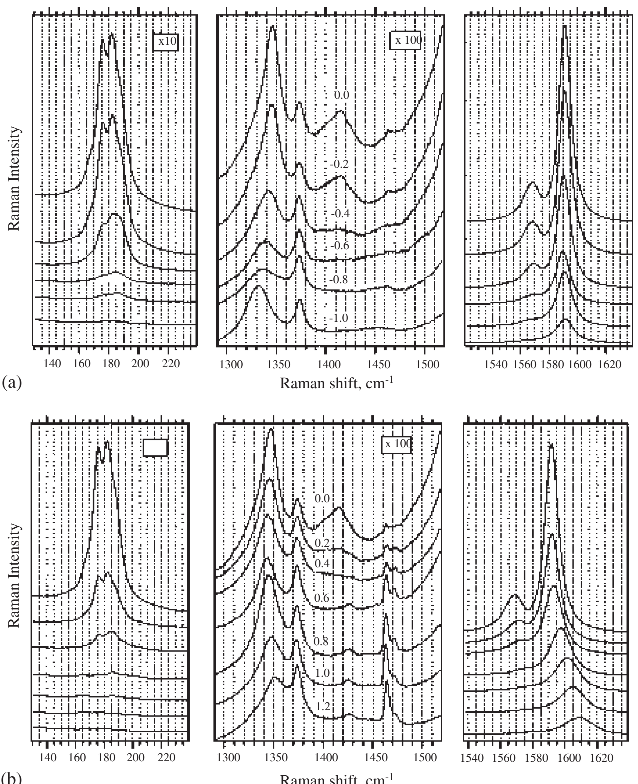

Figure 27. Raman spectra of peapods on Pt electrode (excited at 2.41 eV) in 0.2 M $LiClO_4$ + acetonitrile. (a) Spectra taken for various electrode potentials (vs Ag-pseudo-reference electrode) varying from 0 to –1.0 V (cathodic potentials). The spectra are offset for clarity, but the intensity scale is identical for all spectra in the respective window. As indicated, the intensities are multiplied by a factor of 10 and 100 for the first and second charts, respectively. The peak at 1375 cm^{-1} belongs to the δC–H vibration in acetonitrile. (b) The corresponding spectra taken for various electrode potentials varying from 0 to 1.2 V (anodic potentials). Reprinted with permission from [102], L. Kavan et al., *Chem. Phys. Lett.* 361, 79 (2002). © 2002, Elsevier Science.

iors of the RBM have been attributed to a sharp tube diameter distribution in the peapod sample, and a quenching of the resonance Raman cross-section due to bleaching of the transition between van Hove singularities [102].

Doping-induced shifts in the *D*-band and *G*-band in empty SWNTs are well understood [79, 88], based on charge-transfer-induced charge in the high-frequency interlayer mode (E_{2g_2}) in acceptor and donor graphite intercalation compounds (for a review see [69]). Softening (stiffening) of the E_{2g_2}-derived modes in empty SWNT bundles occurs with increasing charge transfer into (from) the π^* (π) bands. The cathodic downshift per electron and anodic upshifts per hole equals 140 and 460 cm^{-1}, respectively, in graphite. While chemical doping of empty SWNTs exhibits similar doping-induced trends, the effect of cathode charging of peapods [panel (a) in Fig. 27] shows exceptions which are unresolved to date. While the *D*-band softens by ~15 cm^{-1}, the G^--band essentially remains unchanged in frequency, exhibiting a gradual loss in peak intensity with cathodic charging. The zero frequency shift in the G^--band is an unexpected result which needs to be addressed in further electrochemical doping experiments of peapods. The loss in peak intensity is consistent with a loss of Raman cross-section for the G^--band in empty SWNTs [79]. The anodic charging of peapods also shows similar inconsistencies. For example, the G^--band upshifts by ~24 cm^{-1} with a concomitant loss in peak intensity as expected. However, the *D*-band frequency remains essentially unshifted in frequency [panel (b) in Fig. 27].

Like Pfeiffer et al. [101], the strongest Raman line of C_{60} in peapods is observed at 1465 cm^{-1} with a satellite line at 1474 cm^{-1}. A trace of the $H_g(7)$ line at 1430 cm^{-1} is also visible in the central panels in Figure 27. The overall effect of cathodic doping leads to decreased Raman peak intensities, and the C_{60} Raman features eventually drop below detectable limits. On the other hand, anodic doping leads to an increase in the Raman intensity of the $A_g(2)$ mode at 1465 cm^{-1} with a gradual drop in intensity of the satellite peak at 1474 cm^{-1}. This is an interesting observation which may be explained on the basis of the Raman spectra of doped C_{60} prepared by chemical methods.

Several experiments have shown that solid C_{60} can be reduced by alkali metal doping to form A_xC_{60} compounds, where $x = 1, 3, 4$, and 6 [10]. The pentagonal pinch mode frequency observed in solid C_{60} at 1469 cm^{-1} is found to downshift in frequency by approximately 6 cm^{-1} per electron which is transferred from the alkali metal dopant to the host C_{60} solid. In addition, the intensity of pentagonal pinch mode decreases dramatically in A_xC_{60} relative to that in undoped pristine C_{60} [10]. The disappearance of the pentagonal pinch mode in the case of cathode charging of peapods [panel (a) in Fig. 27] may be due to partial doping of the "peas" inside the peapods. Alternatively, the enhancement of the pinch mode during anodic charging of peapods [panel (b) in Fig. 27] may be due to two factors: (i) the Raman peak intensities for the SWNT host goes out of resonance and (ii) C_{60} is well known to resist oxidation. Since no frequency shift of the 1465 cm^{-1} was observed, the authors concluded that there was no transfer of holes to the C_{60} and no dimerization of C_{60} [102]. If dimerization of C_{60} had occurred, it would have resulted in a ~10 cm^{-1} downshift of the $A_g(2)$ mode of C_{60} [103].

Synthesis techniques have now improved to a point where researchers are able to prepare doped peapods, such as Sm–metallofullerene peapods, $(Sm@C_{82})_n$@SWNTs [104–106]. While *in-situ* HRTEM and electron energy loss spectroscopy (EELS) spectroscopic studies have been done, no reports on Raman scattering from this interesting class of peapods have yet been reported. Since EELS studies reveal that the encapsulated Sm ion assumes a +2 charge state in $(Sm@C_{82})_n$@SWNTs, exciting Raman properties can be expected for such metallofullerene peapod samples.

5. DOUBLE WALLED CARBON NANOTUBES

The double wall carbon nanotubes (DWNTs) are a special case of MWNTs containing only two coaxial nanotubes. DWNTs therefore provide a unique opportunity to examine simultaneously the Raman scattering from the very small diameter interior tubes along with Raman scattering from the exterior tubes.

DWNTs were first reported in the products obtained in an electric arc discharge with catalyst mixtures of Ni, Co, Fe, and S in an Ar/H_2 (1:1 volume ratio) atmosphere at 350 Torr [107]. Others have prepared DWNTs from a thermal decomposition of C_2H_2 over ferrocene/sulfur catalysts [108], or of methane over ferrocene/thipohene [109] in the temperature range near ~1000 °C. Several Raman studies have been reported on DWNTs [95, 107–109], but the most comprehensive study thus far was reported by Bandow et al. [95] who made a joint systematic HRTEM and Raman evaluation of the transformation of peapods into DWNTs when the peapod sample was annealed in vacuum at 1200 °C and followed up this work with a more detailed evaluation of the Raman spectra using several different laser excitation energies [110].

Returning to Figure 24, the peapods prepared using purified laser-derived SWNTs (panel A) were systematically annealed in vacuum (~10^{-6} Torr) and characterized by HRTEM and Raman spectroscopy. Surprisingly, the C_{60} molecules showed no change in structural or Raman features until the sample temperature reached 800 °C. At this elevated temperature, the C_{60} molecules do not leave the tube but instead come closer to one another to form C_{60} dimers (indicated by arrows in panel B), which provides the first step toward coalescing several C_{60} molecules into elongated encapsulated tubes. This experiment is a good example to show how the shell of the SWNT serves as a nanoscale reaction chamber. At 1000 °C (panel C) the peapods are observed to transform into DWNTs, and at 1200 °C (panel D), most of the C_{60} molecules have coalesced to form DWNTs for the whole length of the tube. At each step during the transformation, Raman spectra were gathered using 514.5 nm excitation wavelength (Fig. 28). The weakly observable A_g symmetry RBM and pentagonal pinch modes of molecular C_{60} are found to be downshifted by ~10 cm^{-1} relative to their corresponding mode frequencies in molecular C_{60} solids. Several Raman studies on polymerized C_{60} have reported a downshift of the pentagonal pinch

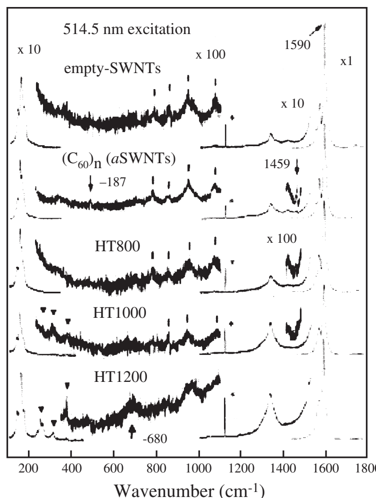

Figure 28. Raman spectra in the radial breathing mode region up to 400 cm^{-1}, in the intermediate frequency range $400 < \omega < 1100$ cm^{-1}, in the range of the *D*-band and of the pentagonal pinch modes of C_{60} and finally in the tangential *G*-band region of SWNTs and DWNTs. Reprinted with permission from [95], S. Bandow et al., *Chem. Phys. Lett.* 337, 48 (2001). © 2001, Elsevier Science.

mode by ~10 cm^{-1} relative to that for isolated C_{60} molecules [79, 103, 111, 112]. In particular, solid C_{60} was found to undergo photoinduced polymerization in the absence of oxygen when excited with laser power densities of greater than 50 W/cm^2, exhibiting a characteristic $A_g(2)$ pinch mode at 1460 cm^{-1} [10, 103]. Thus, the feature at 1459 cm^{-1} in Figure 28 may be due to photoinduced polymerization of encapsulated C_{60} caused by the high laser power used in the experiment. Unfortunately, the authors did not state the laser power density used in their paper.

In the Raman spectrum labeled HT800 we see that heat treatment and the formation of dimers strongly suppress the pentagonal pinch mode, and the RBM is hardly discernible above the background signal (Fig. 28). Dramatic changes in the HT1200 spectrum are seen in which new modes appear in the vicinity of the RBM and in the 400–1100 cm^{-1} region. The appearance of these new modes between 200 and 400 cm^{-1} correlates with the DWNT formation, as seen in the HRTEM images in panel D of Figure 24, and signals the formation of the inner tube inside the DWNT, since the RBM frequency varies as $1/d_t$ where d_t is the tube diameter [see Eq. (1)]. These changes in the Raman activity in the intermediate frequency region (400–1100 cm^{-1}) are consistent with a nonresonant bond polarization model calculation applied to short length SWNTs [53]. The intensity of the *G*-band is also observed to increase in the HT1200 sample, while the *D*-band intensity also increases as the heat treatment temperature increases, perhaps due to the formation of short segments of inner tubes.

The new Raman features which appear in the RBM region as the DWNTs are formed are of particular interest. Again a ~2 cm^{-1} softening for the radial band is observed in the peapod sample [95]. However, unlike Pfeiffer et al. [101], Bandow et al. [95] do not attribute the mode softening due to an expansion of tube diameter in the peapod sample, but instead they attribute the mode downshift to a small charge transfer to the SWNT shell from the encapsulated C_{60} molecules. Also, in the second spectrum from the top in Figure 28, the *G*-band is found to upshift.

From a detailed analysis in which the van der Waals distance of 0.34 nm between the shells of the inner and outer tubes was taken into account, (n, m) indices were elicited from the positions of the new peaks in the RBM region which suggested that the inner tube diameters ranged from 0.93 to 0.59 nm [95]. On average, the diameter difference between the inner and outer tubes was 0.71 ± 0.05 nm, consistent with HRTEM studies.

In another independent experiment, three samples were prepared from the same batch of as-prepared SWNTs for a detailed comparative Raman study: (1) the baseline as-prepared SWNT bundle sample, (2) C_{60} doped SWNT bundles (peapods), and (3) DWNT bundles. Raman characterization was performed using four laser excitation wavelengths, 488.0, 514.5, 647.1, and 1064 nm (2.54, 2.41, 1.92, and 1.16 eV) as shown in Figures 29 and 30 [110], for the RBM bands, and for the *G*-band region, respectively, for these three types of samples. Clearly, diameter-selective Raman scattering from these samples is observed. Collectively, the RBM data can be broadly classified into two regions: (1) In the low frequency region below 250 cm^{-1}, the three samples exhibit nearly identical RBM features with any given laser excitation, suggesting that these features correspond to the exterior tube ($d_t \sim 1.3$–1.6 nm) properties. The encapsulated C_{60}, or the presence of the interior

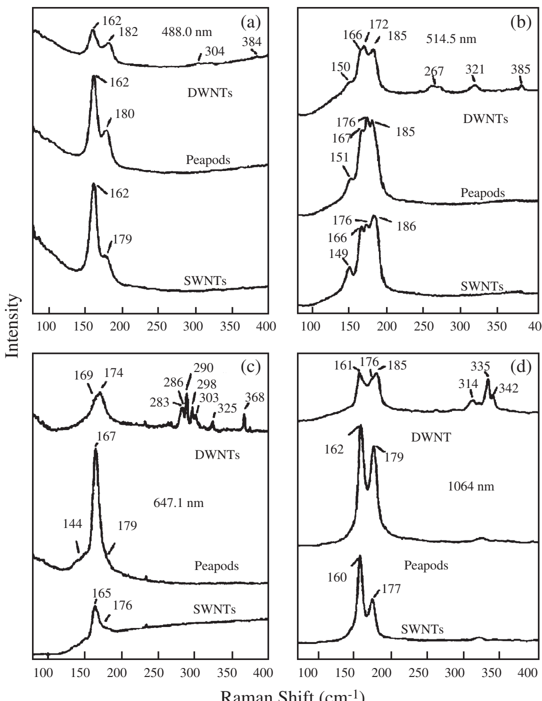

Figure 29. radial breathing mode Raman spectra for SWNTs, DWNTs, and C_{60}-SWNT peapods using different excitation energies of 488.0 nm (2.54 eV) (a), 514.5 nm (2.41 eV) (b), 647.1 nm (1.92 eV) (c), and 1064 nm (1.17 eV) (d). The spectra were fitted to an appropriate sum of Lorentzians and the obtained peak positions are marked on the respective spectra. Reprinted with permission from [110], S. Bandow et al., *Phys. Rev. B* 66, 075416 (2002). © 2002, American Physical Society.

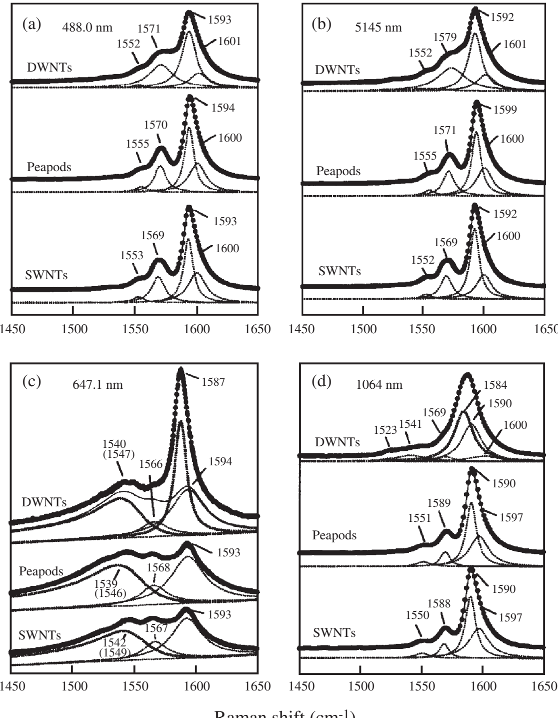

Figure 30. Raman scattering spectra for the tangential *G*-band region for three kinds of bundled nanotubes. The excitation wavelengths are indicated in each panel (see also Fig. 29). Lorentzian components associated with the primary semiconducting tubes are indicated by the thin dotted lines and those with the secondary tubes in DWNTs are indicated by the thick dotted lines in (c) and (d) (see text). The asymmetric Breit–Wigner–Fano (BWF) component is also represented by the thick dotted lines in (c) and (d), where the coupling parameter $(1/q)$ between the discrete phonon mode and the continuum modes, determining the asymmetry of the lineshape, was fixed at -0.35 (from [79]). The numerical values in the parentheses are the renormalized phonon frequencies of the BWF lines (see text). The thin solid line in (c) is a sum of thin dotted Lorentzian components and the BWF component, which is similar to the spectra taken for SWNTs and peapods. Reprinted with permission from [110], S. Bandow et al., *Phys. Rev. B* 66, 075416 (2002). © 2002, American Physical Society.

tube, appears to have a negligible influence on the RBM mode frequencies in this region where the peak positions for the RBM features in the SWNT and DWNT samples are almost identical. (2) For modes with frequencies above 250 cm^{-1}, the DWNT bundles exhibit new peaks that are absent in the SWNT or peapod samples. From the experimentally observed RBM frequencies, the diameters of interior tubes were determined to be between 0.6 and 0.9 nm [110]. The difference between the mean exterior and interior tube diameter is found to be ~0.7 nm, close to twice the stacking distance between graphene sheets in graphite, suggesting that the interior tube is tightly nested inside the exterior tube.

The Raman scattering from the *G*-band carbon atom vibrations shown in Figure 30 is normally detected at ~1593 cm^{-1} for typical SWNT bundles [5]. The diameter dependence of the tangential band is expected on theoretical grounds to be very weak for sp^2 bonded SWNTs [6]. Interestingly, the tangential *G*-band in the DWNT sample when excited with red excitation (panels c and d of Fig. 30) is found to be downshifted by ~7 cm^{-1} relative to its position in the host tubes at 1593 cm^{-1} [110]. This can be understood by looking at the E_{ii} vs $1/d_t$ plot shown in Figure 31. It is clear from Figure 31 that the inner tubes resonate with 647 and 1064 nm excitations, and not with 488 or 514 nm excitations (only one open circle intersects the 514 nm line in Fig. 31) and consequently, the *G*-bands of DWNTs in the 647 and 1064 nm spectra are considerably downshifted from 1592 cm^{-1} (panels c and d in Fig. 30). From a detailed lineshape analysis of the RBM and tangential bands of the DWNT sample, the frequency of the downshifted tangential modes has been identified with interior tubes and associated with wall curvature of the interior nanotube [110]. No features due to the fullerene $A_g(2)$ pentagonal pinch modes within the peapod samples were reported in these studies of the *G*-band spectral region [110].

In summary, based on published research to date, the effects of van der Waals interactions in peapods seem subtler than those in SWNTs bundles. Further experimental evidence to elucidate the van der Waals interaction in peapods is highly desirable. For example, future research should investigate whether the origin of the doublet structure in the peapod Raman spectra (described in Fig. 26) may be due to subtle differences in nanotube interactions with C_{60} molecules frozen in different orientations.

6. CONNECTION TO MULTIWALL NANOTUBES

In this section, we discuss the Raman spectra of multiwall carbon nanotubes (MWNTs) with emphasis on Raman modes that have been observed below ~300 cm^{-1}. Raman-active modes in this spectral region correspond to radial breathing modes that are typically observed in SWNTs and DWNTs. In MWNTs, the inner-most tube can have a very

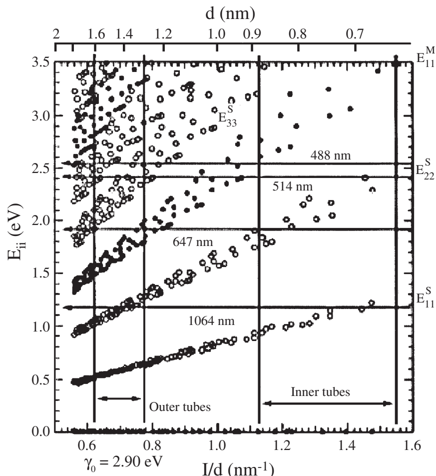

Figure 31. Plot of E_{ii} vs $1/d_t$, which is a replot of the points in Figure 4 where E_{ii} is plotted vs d_t. The solid and open circles correspond respectively to metallic and semiconducting tubes. The primary (outer) and secondary (inner) tube diameters existing in the samples occupy the indicated regions between the thick vertical lines. Reprinted with permission from [110], S. Bandow et al., *Phys. Rev. B* 66, 075416 (2002). © 2002, American Physical Society.

small diameter, in fact as small as the smallest diameter that has yet been found for any SWNTs. This implies that the many shells of the MWNT are able to stabilize very small diameter nanotubes at the core of a MWNT. Figure 32 shows the Raman spectrum using 514.5 nm excitation of high purity MWNTs deposited as a film on a quartz substrate. The MWNTs in this figure are prepared by a thermal decomposition of ferrocene–xylene mixtures at 700 °C [113]. The dominant outer- and inner-tube diameters ranged between 25–30 and 2–7 nm, respectively. Besides the strong D- and G-bands at 1355 and 1582 cm^{-1}, and the second-order bands at 2454, 2704, and 2942 cm^{-1}, weak features can be discerned on either side of the D–G-bands (Fig. 32). The peak marked by an asterisk corresponds to a plasma line frequency, while peaks at 165, 295, and 452 cm^{-1} can be assigned to weak radial breathing modes of inner tubes with approximate diameters of 1.5, 0.84, and 0.55 nm, respectively, with d_t determined from the relation $\omega_{\text{RBM}} \sim 248/d_t$, or alternatively the higher frequency modes can be identified with the second and third harmonics of the first-order ω_{RBM} mode. Other examples of reported radial breathing mode features in MWNTs can be found in the literature [14, 114]. Weak modes at ∼390 and 490 cm^{-1} were observed in the Raman spectrum of purified arc-derived MWNTs by Kataura et al. [14] and they identified these modes with the radial breathing modes of tubes that define the core of the MWNTs (core diameter of ∼0.65–0.5 nm). Chandrabhas et al. [114] have also observed weak modes at 49, 58, 470, and 700 cm^{-1} in their arc-produced MWNTs, as well as stronger features at 1353 and 1583 cm^{-1}, and second-order features at 2455, 2709, and 3250 cm^{-1}. In Figure 32, peaks at 2454 and 2942 cm^{-1} can be associated, respectively, with a K-point overtone ($2 \times 1220 = 2440$ cm^{-1}) or with ($1355 + 1095 = 2450$ cm^{-1}) and ($1355 + 1582 = 2937$ cm^{-1}) combination modes, while the 2704 cm^{-1} band is identified as the second-order ($2 \times 1355 = 2710$ cm^{-1}) G'-band.

In a more recent report, micro-Raman data excited with 514.5 nm excitation for highly oriented pyrolytic graphite (HOPG), SWNTs, and three samples of MWNTs were compared to identify the tube diameter distribution in the nanotube samples (Fig. 33) [115]. The MWNT samples were prepared from a hydrogen arc discharge and HRTEM showed that the outer tube diameters ranged from ∼2 to 28 nm (dominant outer tube diameter ∼10 nm) [115]. In contrast to the Raman spectrum of HOPG, the nanotube spectra show peaks in the RBM region, with some peaks having FWHM linewidths as narrow as 3 cm^{-1} and frequencies as high as 570 cm^{-1}. The ∼392, 387, and 279 cm^{-1} peaks were observed in the spectrum of all three MWNT samples. The presence of the 524 and 570 cm^{-1} peaks suggest inner tube diameters on the order of ∼0.45 nm, consistent with their HRTEM studies [115]. Polarized Raman scattering studies were also performed on a single aligned bundle of MWNTs to confirm that the Raman features observed in the low frequency region all correspond to the RBM of MWNTs.

The most detailed experimental polarization results for Raman spectra presently available are for high purity aligned arrays of MWNTs [116]. These aligned MWNTs were prepared on silica substrates from the thermal decomposition of a ferrocene–xylene mixture and had an average nanotube diameter $d_t \sim 25$ nm, with the MWNTs aligned normal to bare silica substrates [113]. The nanotube diameters in this MWNT sample are probably large enough so that the resonance Raman scattering effect is substantially weaker than is typical for SWNTs ($1 < d_t < 2$ nm). The thickness of the aligned nanotube bundle was intentionally kept below 1 μm so that the focused laser excitation beam (beam diameter $d \sim 1$ μm) overfilled the aligned MWNTs during the polarized Raman scattering measurements. This study measured polarization effects associated with ($\|, \|$) and ($\|, \perp$) scattering for the G-band and the D-band, as well as providing confirmation for a predicted angular dependence of the scattered intensity as a function of the measured angle θ_m between the polarization direction and the nanotube axis [116].

The polarized spectra in Figure 34 for four polarization geometries, labelled (XY), (YX), (YY), and (XX), are shown for the Raman intensities of the D-band and the tangential G-band for these MWNTs in the backscattering

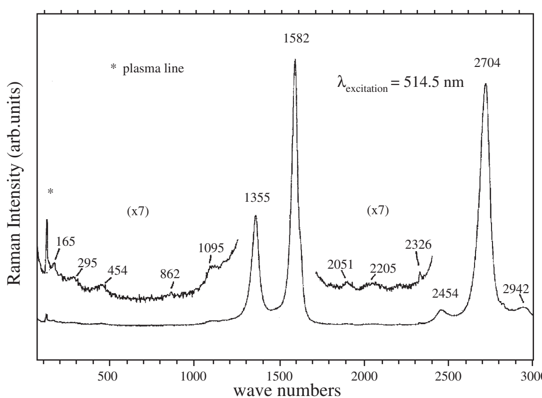

Figure 32. The Raman spectrum for a high purity multiwall nanotube sample for laser excitations $E_{\text{laser}} = 2.41$ eV (514.5 nm) (see text). Reprinted with permission from [113], R. Andrews et al., *Chem. Phys. Lett.* 303, 467 (1999). © 1999, Elsevier Science.

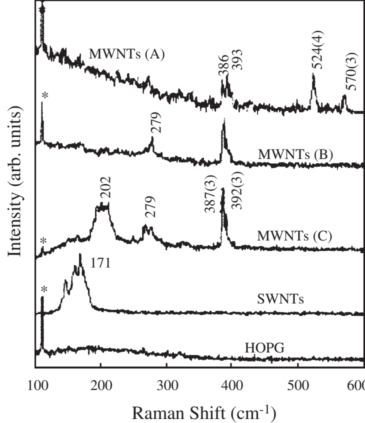

Figure 33. Comparison of the micro-Raman spectra taken at $E_{\text{laser}} = 2.41$ eV (514.5 nm) in the low frequency range for HOPG, SWNTs, and three samples of MWNTs. Reprinted with permission from [115], X, Zhao et al., *Chem. Phys. Lett.* 361, 169 (2002). © 2002, Elsevier Science.

configuration, with the greatest intensities observed for the (XX) polarization geometry. The geometry and notation used to describe these polarization studies on MWNTs are shown in the inset to Figure 34, where x, y, z refer to the coordinates of the MWNTs and X, Y, Z refer to the laboratory frame of the light. In this notation, a backscattering Raman experiment is described by $Z(XY)\overline{Z}$ to indicate light incident along the Z axis with the electric vector in the X direction for the incident light beam, while the Poynting vector for the scattered light is along the $-Z$ direction, with the electric vector for the scattered light beam in the Y direction. For the polarization results on the MWNTs shown in Figures 34 and 35, the backscattering geometry was used with light normal to the nanotube axis, so that the abbreviated notation (XY), giving the directions of the incident and scattered electric field polarizations, is used to label the polarization geometries shown in these figures.

A Lorentzian lineshape analysis for the MWNTs spectra in Figure 34 shows four peaks at 1354, 1576, 1583, and 1624 cm^{-1} in almost all the polarization geometries, but with very different polarization-dependent relative intensities [116]. From Figure 34, the experimental polarized integrated intensity ratios for the tangential band (at 1584 cm^{-1} for the XX spectrum) are I_{XX}/I_{XX}:I_{YY}/I_{XX}:I_{XY}/I_{XX}:I_{YX}/I_{XX} = 1.00:0.29:0.19:0.39 for this MWNT sample. These polarization results can in part be explained by the nanotube geometry which gives rise to slightly different force constants along the nanotube axis relative to the circumferential direction, where the nanotube curvature reduces the force constant. This anisotropy in the force constant accounts physically for the frequency difference between the components at 1575 cm^{-1} (attributed to vibrations in the circumferential direction) and at 1584 cm^{-1} (attributed to vibrations along the nanotube axis) for the (XX) polarization. Similar frequency differences are observed for the other polarization geometries, and all the upshifted and downshifted modes in Figure 34 average to 1580.8 ± 0.8 cm^{-1}, in good agreement with the E_{2g_2} graphite mode frequency. Because of the small number of allowed k vectors in the circumferential direction, we expect the frequency difference between the lowest and middle frequency components to increase with decreasing nanotube diameter [117]. For example, SWNTs with diameters of d_t ~1.4 nm show these two spectral features [5] to be at 1567 and 1593 cm^{-1} (see Section 3.1), and these two mode frequencies also average to ~1580 cm^{-1}. The feature near 1620 cm^{-1} which is quite pronounced in the spectra for MWNTs, and not present in SWNTs, is associated with the maximum in the graphene 2D phonon density of states [118].

No theory has yet been developed to describe polarization effects for MWNTs. Therefore the experimental polarization results for the G-band in Figures 34 and 35 have been interpreted in terms of the theory developed for (10,10) SWNTs [52] as a first approximation. The theory of polarization effects in single wall nanotubes was first used to distinguish between the contributions to the G-band from modes with A_{1g}, E_{1g}, and E_{2g} symmetry [52], which according to bond polarization model calculations [52, 53] for a (10,10) SWNT predict Raman-active frequencies at 1587, 1585, and 1591 cm^{-1}, respectively, all occurring within a range of 6 cm^{-1}, which is much smaller than the observed linewidth of the tangential band for Raman scattering, even for semiconducting nanotubes [52, 119].

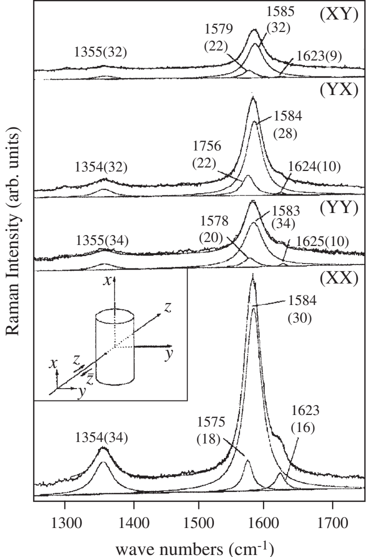

Figure 34. Polarized Raman spectra for MWNTs taken at 514.5 nm (2.41 eV) for four scattering geometries. The peak frequencies for the various features are in cm^{-1} and the FWHM linewidths in cm^{-1} are given in parenthesis. The inset defines the polarization geometries for the aligned nanotubes that lie parallel to the x-axis but there is no preferred angular alignment of the nanotubes in the plane normal to the nanotube axis. Reprinted with permission from [116], A. M. Rao et al., *Phys. Rev. Lett.* 84, 1820 (2000). © 2000, American Physical Society.

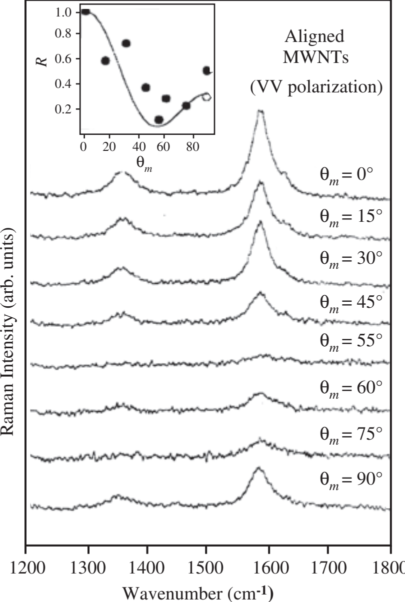

Figure 35. Dependence of the measured Raman intensity for VV scattering as a function of the angle θ_m between the polarization direction and the nanotube axis (see inset to Fig. 34). The inset to this figure shows the dependence of the experimental G-band intensity ratio $R = I_{VV}(\theta_m)/I_{VV}(0)$ (open and filled circles) as a function of θ_m in comparison to the theory for SWNTs [53, 116]. Reprinted with permission from [116], A. M. Rao et al., *Phys. Rev. Lett.* 84, 1820 (2000). © 2000, American Physical Society.

The experimental intensities for the (XX) and (YY) geometries in Figure 34 and in the inset to Figure 34 correspond, respectively, to $\theta_m = 0$ and $\theta_m = 90°$ for the VV polarization configuration, while the (XY) and (YX) geometries, respectively, correspond to $\theta_m = 0$ and $\theta_m = 90°$ for the VH configuration, where V and H denote vertical and horizontal, respectively. Calculations show that the A_{1g} mode is dominant for the tangential band in the (XX) configuration, while in the (YY) configuration, both the A_{1g} and E_{2g} modes should contribute to the scattering intensity. The intensity ratios predicted for the A_{1g} mode at $\theta_m = 0°$, the A_{1g} mode at $\theta_m = 90°$, and the E_{2g} mode at $\theta_m = 90°$ are, respectively, 2.91, 0.72, and 0.33. Thus the theoretical value for the intensity ratio for I_{XX}/I_{YY} is 2.91/1.05 = 1.00/0.36, which is to be compared to the experimental values of $I_{XX}/I_{YY} = 1.00/0.29$. This observation would be consistent with the peak at 1584 cm^{-1} containing the unresolved E_{2g} and A_{1g} modes of the tangential band.

Based on theoretical considerations, the intensity of the tangential A_{1g} mode as a function of θ_m is expected to exhibit a minimum at $\theta_m = \cos^{-1}(1/\sqrt{3}) = 54.7°$ [52]. Figure 35 shows a collection of polarized Raman spectra that were obtained on aligned MWNTs in the VV configuration as a function of θ_m. Clearly the experimental polarized tangential band intensity ratio $R = I_{VV}(\theta_m)/I_{VV}(0)$ exhibits a minimum near $\theta_m = 55°$, in good agreement with the theoretical curve for the intensity of the VV signal vs θ_m shown in the inset to Figure 35. It should be noted that the intensity ratio R denoted by the open circle in the inset to Figure 35 was obtained from the XX and YY data depicted in Figure 34. The data set in Figure 35 also suggests that the G-band intensity is dominated by the intensity of the A_{1g} symmetry mode at 1584 cm^{-1}. It is interesting that the experimental D-band intensity is also a minimum near $\theta_m = 55°$. No theory is yet available for the angular dependence of the D-band intensity.

Returning to Figure 34 we note that the optical absorption spectra of a single wall carbon nanotube, calculated for polarized light by Ajiki and Ando [120, 121], show that the selection rules for optical absorption between the valence and conduction π subbands with subband index n are $\Delta n = 0$ and $\Delta n = 1$ for polarization parallel and perpendicular to the nanotube axis, respectively. The optical absorption for the polarization perpendicular to the nanotube axis is predicted to be suppressed almost completely when the depolarization effect is taken into account. Thus the optical absorption occurs only when the polarization is parallel to the nanotube axis for intersubband transitions, with $\Delta n = 0$ for single wall carbon nanotubes. The depolarization effect should, however, be relaxed in MWNTs, especially as the diameter increases. On the basis of the depolarization effect, we expect more effective excitation of resonant Raman scattering for the (XX) scattering geometry, and for metallic nanotubes, for which the nanotube acts as a radiation pipe for the laser excitation. The polarized VV Raman spectra for aligned MWNTs in Figure 34 appear to be consistent with the optical anisotropy present in the MWNTs. The discrepancy between the experimental polarized Raman intensity ratios (regarding Fig. 34) and theoretical predictions may be due to a depolarization (antenna) effect operative also on the scattered light which tends to enhance the experimental $YX{:}XY$ intensity ratio relative to the calculations.

As the diameter of the MWNTs increases to over 100 nm, the spectra in Figure 32 show features associated with the D-band, the G-band, and the G'-band of sp^2 carbons, and the interlayer separation between adjacent shells in the MWNTs approaches that of 2D turbostratic graphite (0.344 nm), which is characteristic of nanofibers. For yet larger diameter MWNTs, the interlayer separation drops below 0.344 nm so that the interlayer C–C correlations become important, and in this regime the sp^2 carbon is called a vapor grown carbon fiber (VGCF), often refereed to as an “Endo fiber” [122, 123]. In the diameter range above 100 nm, the G-band feature in VGCFs becomes more and more similar to that for the 3D graphite spectra, while the D-band continues to provide information about the disorder in the sample. The G'-band, which is a single Lorentzian line in the Raman spectrum of carbon nanofibers, becomes a doublet feature as interplanar correlations become established. When a VGCF or an carbon nanofiber is broken open, a thin MWNT is typically observed [124].

7. FUTURE DIRECTIONS

In this section we propose future directions for carbon nanotube research, and especially for the use of Raman spectroscopy as a characterization tool for carbon nanotubes. As a first step, synthesis and separation techniques for SWNTs need to advance further. Since many of the SWNT properties depend critically on the (n, m) indices of the SWNT and, especially, on whether the SWNT is semiconducting or metallic, the demands on the control of the carbon nanotube growth process are severe. An approach based on developing a synthesis process for growing only metallic SWNTs or only semiconducting SWNTs seems like a fruitful strategy, but until such a time that a synthesis process of this kind is developed, it will be necessary to focus on SWNT separation processes that overwhelmingly favor either metallic or semiconducting SWNTs. In this connection, Raman spectroscopy should be useful to sensitively measure the efficacy of a given separation method regarding the percentage of metallic and semiconducting SWNTs with $d_t < 2$ nm, as well as the diameter distribution of the SWNTs in the sample. Research to extend present Raman characterization techniques to do such a sample characterization would be highly desirable. Because of the lower sensitivity of Raman spectroscopy to the geometrical structure of carbon nanotubes for tube diameters greater than $\sim$2 nm, we should expect Raman spectroscopy to play a decreasing role in the characterization of large diameter SWNTs and MWNTs.

Detailed combined experimental and theoretical studies are needed to comprehend how E_{ii} and E_F change as a function of external perturbations. Here again investigations should start at the single nanotube level, as discussed, and then should be extended to investigate SWNT bundles as a function of the number of SWNTs in a bundle, to DWNTs, and finally to the inner-most layer of a MWNT. Below a critical diameter d_{critical} it may not be possible to understand the properties of DWNTs or MWNTs because of the large curvature effects of very small diameter SWNTs. At large diameters (>2.5 nm), the sensitivity of Raman scattering

decreases with regard to distinguishing between the detailed structural properties of nanotubes relative to those of general sp^2 carbons.

The effect of intertube interactions to upshift the radial breathing mode frequency relative to that for isolated SWNTs and the use of the expression $\omega_{RBM} = \alpha/d_t + \Delta\omega_{RBM}$ requires detailed systematic study following the pioneering work of Kuzmany et al. regarding the structural characterization of SWNT bundles [44, 65, 66]. More systematic studies are needed of the dependence of α and $\Delta\omega_{RBM}$, the local environment of the tube, the total size of the SWNT bundle, and the location of the SWNT within the SWNT bundle. Experimental observations described in Figures 16 and 22 collectively suggest that the debundling into small diameter bundles causes a 10 cm^{-1} upshift in ω_{RBM} but does not lead to a change in the dependence of ω_{RBM} on external applied pressure. Further high pressure Raman studies on a homogeneous sample of isolated SWNTs prepared either by improved chemical methods or by chemical vapor deposition are needed. These pressure-dependent results also suggest that the coupling of the excitation laser energy (E_{laser}) is sensitive to the environment in which the nanotube resides, and thus future studies aimed at correlating nanotube diameters with ω_{RBM} should pay attention to the size of the bundles, and to the procedures used to functionalize SWNTs.

Future doping experiments should investigate, in the context outlined previously for systematic joint experimental and theoretical studies, the effects of donor and acceptor doping and variation of applied positive and negative voltages to SWNTs, starting with isolated SWNTs and extending the studies to SWNT bundles, including studies of debundling effects. With regard to doping studies, systematic studies of boron and nitrogen doping are of particular interest, since these dopants behave in part as substitutional dopants. Regarding studies, such as investigation of the effect of applied potentials, particular attention should be paid to the use of the G-band to characterize the charge transfer, since the G-band feature in metallic SWNTs is known to be strongly affected by the coupling of phonons to plasmons through the electron–phonon interaction, and the intensity of this interaction is strongly affected by the number of SWNTs in the SWNT bundles. Therefore the use of the G-band feature in the Raman spectra of sp^2 carbons needs to be reexamined theoretically and experimentally. Other Raman features that are also experimentally observed to be sensitive to charge transfer, such as the G'-band, should be further investigated theoretically and experimentally as a sensitive probe of charge transfer in SWNTs.

Raman spectroscopic studies on isolated peapod or DWNT samples could provide a wealth of information about inter- and intratube force constants. The origin of the two weak modes at 1466 and 1474 cm^{-1} in the vicinity of the pentagonal pinch mode frequency of C_{60} (Fig. 26) [101] may be due to subtle differences in the interaction of a pentagonal vs hexagonal face of a C_{60} molecule with the interior surface of a nanotube. Such detailed experimental and theoretical studies of peapods and DWNTs should initially be carried out at the single nanotube level, if possible, to illuminate the physical mechanisms involved. This should be followed by systematic studies on bundles of peapods and DWNTs, including systematic variation of the various perturbations discussed in this chapter, including external pressure, high pressure, applied potentials, endohedral doping, chemical donor and acceptor doping, etc.

GLOSSARY

Anisotropy Pertaining to a material whose electrical or optical properties vary with the direction of propagation of a traveling wave or with different polarizations of a traveling wave.

Armchair nanotube Armchair nanotubes correspond to the roll up of the nanotube so that the indices (n, m) are equal $(n = m)$ and the chiral angle is 30°.

Band tuning The variation of parameters such as chemical composition to vary the electronic band gap of a semiconductor.

Boltzmann factor The factor $\exp(-E/k_BT)$ that compares the energy of a system E to its thermal energy k_BT and gives the probability of occupying the state with energy E.

Breit–Wigner–Fano lineshape Observed Raman lineshape when phonon modes couple to a Raman-active electronic continuum.

Brillouin zone A primitive cell in the reciprocal lattice.

Bundled tubes Single wall nanotubes arranged in a bundle containing between about 10 and 100 nanotubes and when ordered the tubes are arranged in a triangular lattice.

C_{60} or fullerene A C_{60} molecule consists of 60 carbon atoms bonded to each other and occupying corner sites in a regular truncated icosahedron.

Carbon Nanotubes A graphene sheet (2D graphite) rolled into a seamless tube.

Chemical vapor deposition (CVD) A chemical reaction which transforms gaseous molecules, called a precursor, into a solid material, in the form of thin film, powder, or individual nanotubes on the surface of a substrate.

Chiral angle The angle between the chiral vector $(na_1 + ma_2)$ and a_1.

Chiral vector C_h Chiral vector can be expressed by the real space unit vectors the unit cell basis vectors of the graphene lattice $\mathbf{a}_1$ and $\mathbf{a}_2$ of the hexagonal lattice by $C_h = na_1 + m\mathbf{a}_2 \equiv (n, m)$, where n, m are integers, $0 \leq |m| \leq n$.

Chirality The values of n and m determine the chirality, or the angle that the nanotube axis makes with the a_1 axis of the graphene lattice of the nanotube.

Chromatography The chemical method of separating constituents dissolved in one phase (usually mobile) through its equilibration with a second phase (usually stationary).

Density of states (DOS) The spectrum of the number of energy levels per eV usually plotted as a function of energy.

Depolarization effect The change in polarization of the incident optical electric field induced by the polarization of the nanotube.

Electric arc method A method of producing nanotubes through the arc-vaporization of two carbon rods placed end to end with a high electric field between the electrodes to create a plasma of carbon atoms.

Electrochemical potential Amount of energy (work) required to add an amount n of charge-bearing species into

a solution when a potential is applied, and in the limit of zero applied potential reduces to the Fermi level.

Endohedral doping A doping method in which an ion (or ions) is (are) encaged inside the carbon framework of a fullerene molecule or a nanotube.

Fermi energy The energy E_F below which all electron states are filled and above which all are empty at zero temperature.

Hybridization Mixing of different orbitals on the same atom, such as the mixing of a π and σ orbital on a carbon atom.

Interband energies Refers to the difference in energy between a state in the valence band and a state in the conduction band to which a transition is made.

Lorentzian lineshape The functional form of the frequency dependence of a line in the optical absorption spectra and includes its spectral width of the optical absorption line.

Multiwall tubes Coaxial arrangement of single wall carbon nanotubes.

Phonon frequency The frequency of vibration of a quantized lattice vibration in a solid.

Photoinduced polymerization Bonding between isolated neighboring molecules induced by light.

Photons A discrete packet, i.e., a quantum, of electromagnetic energy.

Plasmons The quantized ensemble or gas of charged carriers such as electrons.

Polarization Refers to a vector denoting the sum of dipole moments per unit volume or a vector denoting the direction of the optical electric field.

Radial breathing mode Refers to the vibrational displacements whereby every atom in a carbon nanotube vibrates in phase in the radial direction.

Raman active modes Those vibrational modes of a system that are excited by an incident photon in an inelastic scattering process.

Raman spectroscopy Refers to the response of a system to an inelastic scattering of a photon in a system where the scattered photon that is either upshifted or down shifted in frequency from the incident photon by the natural vibrational frequency of the system.

Resonance Refers to the strong response of a system to an external excitation at a particular frequency of excitation.

Single-walled carbon nanotube (SWNT) The rolling of a single layer of a graphite lattice to form a seamless tube one atom in thickness.

Stokes and Anti-Stokes Most of the Raman scattered photons are shifted to longer wavelengths (Stokes shift) corresponding to emission of a phonon, but a small portion are shifted to shorter wavelengths (anti-Stokes shift) corresponding to the absorption of a phonon.

Surface plasmons Collective excitation of the electrons of a solid or liquid at the surface of the material.

Symmetry mode Refers to the symmetry operations (rotations, reflections, inversion, etc.) that are preserved in the atomic displacements of the atoms as they execute the vibrational mode.

Tangential band A small range of frequencies over which the nearest neighbor carbon atoms vibrate.

Trigonal warping The departure in the symmetry of the constant energy contours away from circles, where the distortion or warping of the constant energy contours shows a three-fold axis of symmetry.

Van der Waals force A weak non-covalent attractive force acting between neutral atoms or molecules.

Van Hove singularities The divergence of the density of states of a one dimensional system such as a carbon nanotube showing a density of states feature with an energy dependence $(E - E_0)^{-1/2}$.

Zigzag nanotube Zigzag nanotubes are formed when either n or m in the nanotube indices (n, m) is zero and the chiral angle is 0°.

1. INTRODUCTION

Reliable fabrication of nanostructures represents one of the most essential steps that are encountered in a variety of applications in the expanding field of nanotechnology. In the specific area of materials encountered in photonic and electronic applications these nanostructures must be also formed on the basis of a predetermined pattern. A number of different approaches have been followed so far for the formation of such patterned nanostructures, including both polymeric resist based methods and novel unconventional methods. A few years ago progress in standard resist based lithography has been reviewed [1] in a special issue of *Chemical Reviews* devoted to nanostructures whereas the different "unconventional" approaches for nanostructure formation have been also reviewed in the same issue [2].

Resist based lithography is the predominant methodology for pattern formation in the general area of electronic and optical device fabrication and the one almost exclusively used by the semiconductor industry, allowing the ever-increasing number of individual elements in a chip so far. Nevertheless, as the discussion on the resolution limits of resists has already started [3, 4] some experts view that other approaches [5] will help in keeping Moore's law [6], which states that the number of transistors integrated on silicon chip doubles every 18 months. Currently, the resist technology has allowed semiconductor devices of critical dimensions down to 130 nm to have already entered production, whereas intense research and development activity is underway for the development of reliable industrial technologies suitable for 90 and 65 nm critical dimension devices [3, 7, 8]. According to the International Technology Roadmap for Semiconductors industrial nanofabrication processes will gradually reach 32 nm gate transistors within the next 10 years, and most probably this progress will be based on 193 nm, 157 nm, and extreme ultraviolet (EUV; 13 nm) lithography. Electron beam and ion beam lithographies are also being extensively studied as alternative nanofabrication methods.

The aforementioned technical goals can be accomplished through the development of resist materials suitable for the aforementioned wavelengths that combine a number of improved performance characteristics allowing subwavelength resolution and effective transfer of the pattern to the substrates of interest [7]. During the last decade the research activities related to lithography and in particular to resist materials have been greatly expanded. The progress in the field has been mostly recorded in the proceedings of the main relevant conferences, which include the annual SPIE Microlithography Conference, the Electron Ion Photon Beam and Nanofabrication (EIPBN) conference, Photopolymer Conferences of the Society for Plastic Engineers (Mid-Hudson), and certain American Chemical Society Symposia in USA, Photopolymer and Micro-Process Conferences in Japan, and the Micro- and Nano-Engineering Conference (MNE) in Europe. Nevertheless, the number of resist related papers published in broader scope journals has been also greatly increased during this last decade.

In this chapter we will discuss aspects of the progress on resist based nanolithography during recent years and in general nanolithography based on the use of photosensitive polymeric films. In particular we will focus on the photosensitive polymeric materials issues. We will discuss mainly chemical approaches but also physicochemical issues and technological challenges.

2. RESIST FUNDAMENTALS

2.1. Resist Based Lithographic Schemes

The basic principles of lithography have been discussed in a number of excellent articles or books in the past [3, 9–13]. Here, we present only some basic concepts necessary for understanding the latest developments in this field.

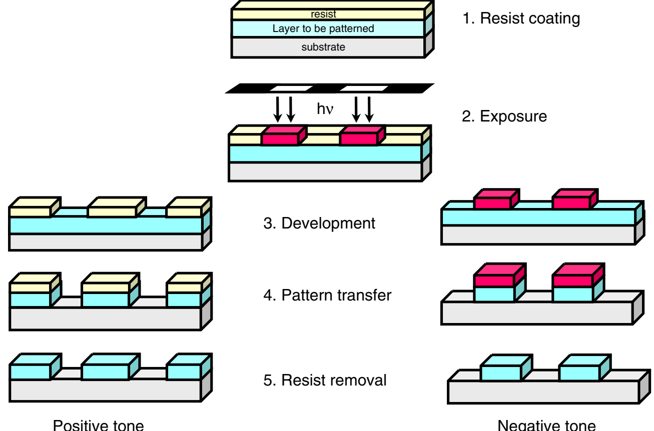
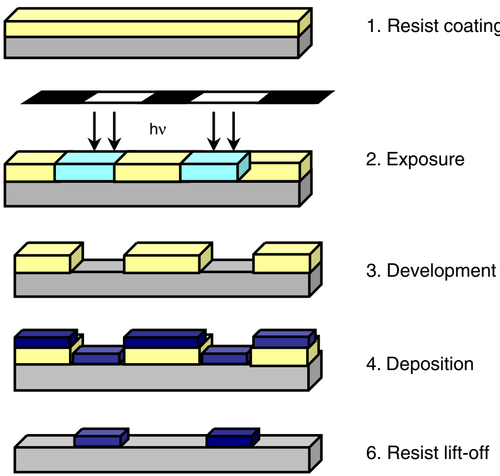
The most common lithographic process is shown in Scheme 1. There, a photosensitive polymeric material is coated over the layer that needs to be patterned and it is exposed through a mask. Radiation causes suitable chemical reactions in the exposed areas that change the polymeric material solubility. In the case where the exposed areas can be selectively removed by a suitable solvent we have positive tone lithography. In the opposite case, where the unexposed areas can be selectively removed, we have negative tone lithography. In a next step, the photosensitive polymeric film acts as a protective mask for the transfer of the pattern to the underlayer using suitable wet chemistry or reactive plasmas. In other words the polymeric film at this stage resists the reagent used for the etching of the bottom layer. The name *photoresist* has come from the main functions of the polymeric material according to this scheme: *photo*sensitivity and *resist*ance to the reagent used for etching of the underlayer. Since the radiation used can be also particles (electrons or ions) instead of photons the more generic term *resist* has been mostly used to characterize these materials.

In addition to the basic scheme presented several variations have been also proposed. The lithography represented by Scheme 1 is also called subtractive lithography since it is based on the deposition of the layer to be patterned and then on the removal (subtraction) of the nonprotected area by the patterned resist areas. An alternative lithographic process is presented in Scheme 2. According to this scheme the layer to be patterned is deposited after the patterning of the photosensitive polymeric material. The polymeric material is finally removed along with the material, which has been deposited on top of it. For this reason this process, which was introduced more than 30 years ago [14], is better known as the "lift-off" process. In this process the photosensitive polymeric material is not actually used to resist the action of a chemical reagent in the sense described in the first scheme, but to protect certain substrate areas during the deposition of the film to be patterned. Nevertheless, since the same or similar photosensitive polymeric materials are used in both schemes the term resist is commonly used in this case as well. The lift-off scheme could be considered a process of "prosthetic" lithography.

Photosensitive polymeric materials are also used in new processes for micro- and nanostructure fabrication proposed



Scheme 1. Typical resist process in semiconductor manufacturing.

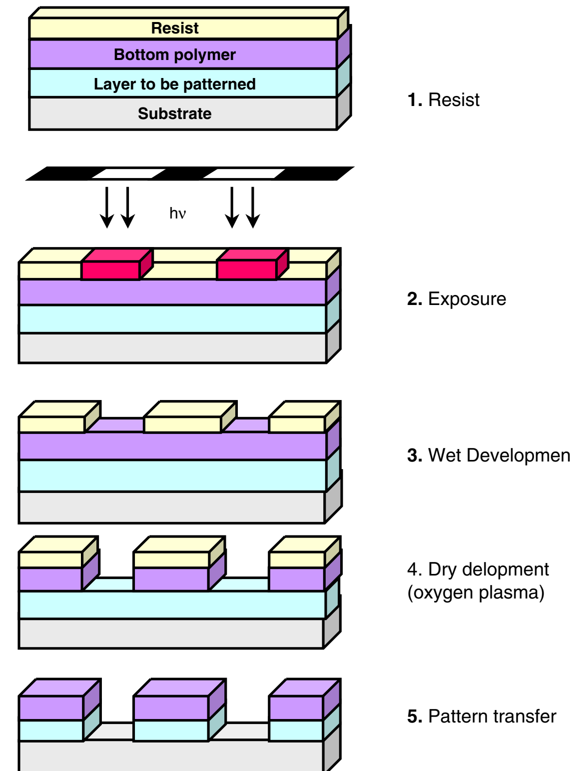


Scheme 2. Principle of lift-off process.

during the last decade, the most interesting probably being nanoimprint lithography [15]. Other radiation-guided processes have also been introduced especially for the patterning of biomolecule layers and the fabrication of microarrays. Some of these processes will be discussed further at the end of this chapter.

On the other hand more complicated resist based processes than the one presented in Scheme 1 have been also introduced in order to facilitate the fabrication of high resolution structures. In the double layer process shown in Scheme 3 two polymer layers are coated over the layer that needs to be patterned. The first, or bottom, polymer layer does not need to be photosensitive but must provide adequate etch resistance to the plasmas used for the patterning of the underlayer. The second, or top, polymer layer must be photosensitive and capable of providing high resolution patterning through wet development, but it is not necessary to provide high etch resistance to the plasmas used for the etching of the underlayer. It must, though, contain an element that does not form volatile oxides in order to provide enough etch resistance to the oxygen plasmas that can be used for the patterning of the first polymer layer. Si containing polymers have been mostly used in the top layer [16–22] but polymeric materials containing other elements that do not form volatile oxides, like W and Ge, have been used as well [23, 24]. In the previously described scheme the top resist layer is usually thinner than the bottom layer, since this bottom layer will actually act as the layer that will provide the etch resistance for the pattern transfer to the substrate of interest. The top layer needs just to resist during the etching of the bottom polymer layer with oxygen plasma, the so-called dry development step. The presence of elements that form nonvolatile oxides in the upper layer usually helps to easily achieve this goal. Thus, often the top layer can be substantially thinner than the resist layers used in the standard, single layer resist processes of Scheme 1. This fact facilitates lithography and often double layer processes are used in order to obtain higher resolution and higher aspect ratio features.

Other processes where a thin layer near the top surface of the resist needs to be imaged have been developed as well. These processes are generally known as top surface



Scheme 3. Double layer resist process.

imaging processes and they are used also in many cases to facilitate lithography and obtain higher resolution. The best known examples of this type are provided by the silylation processes [25–27]. There, light induces chemical reactions, usually cross-linking, in the exposed areas and this way the penetration and reaction of a silylating agent in the resist film are controlled. This silylation agent can be brought either in gas [25] or in liquid [26, 27] phase, giving rise to dry or wet processes correspondingly. The areas where the silylating agent is inserted (i.e., the unexposed areas in the case of systems that cross-link upon exposure) acquire a high etch resistant to oxygen plasmas and thus can form structures during a dry development, or oxygen plasma, step in an analogous manner to the case of double layer processes. Processes that combine double layer and silylation lithography have also been proposed and developed [28–31].

Related to the double layer are also the triple layer processes [11]. In this case between the two polymer layers there is also one additional layer, usually a thin inorganic layer. Thus, after the wet development of the top-imaging layer the pattern is transferred to the thin inorganic layer and then this layer provides the necessary etch resistance to the oxygen plasma used for the etching of the bottom layer. In the case of triple layer processes the top polymer layer does not need to contain an element giving nonvolatile oxides. Thus every resist can be used in such a process and thus many possibilities for the development of ultrahigh resolution processes exist.

2.2. Basic Resist Performance Requirements

According to the lithographic schemes presented resists must possess a number of properties to meet performance requirements needed in high resolution lithography. Here we will discuss briefly the basic requirements that need to be fulfilled.

First, the resists should form uniform films by spin-coating. This practically has led to the adoption of linear polymers as the main resist components. Nevertheless, an increasing research effort has started lately targeting the use of small molecules as main components of resist formulations. Mostly oligomers or polymers of different architecture like dendrimers and cyclic polymers have been used so far as the main resist components [32–36]. This issue is under intense investigation currently toward the design of ultrahigh resolution resists for e-beam and next generation lithography (see also the following relevant sections), that is, resists targeting to sub-50 nm resolution, where polymer MW, radius of gyration, and in general resist component molecular dimensions are thought to play a vital role on the quality of the patterns.

Inorganic resists have also been proposed for ultrahigh resolution patterning [37, 38]. These resists could not be deposited by spin-coating but instead they were deposited by physical vapor deposition methods. Attempts to design spin-coatable inorganic resists have also been reported [39]. Inorganic resists will be discussed along with molecular resists in the section on e-beam lithography.

Resist absorbance at the exposure wavelength is probably the most widely discussed issue in recent years. This is due to the fact that as resolution demands push the technology to shorter and shorter optical wavelengths the selection of polymers, and in general resist components, with suitable absorbance characteristics becomes more challenging. The demand for optimizing absorbance has been the driving force for designing new resists during the last 20 years. In general, resist films must have a moderate absorbance at the wavelength of exposure to allow proper imaging of the film in all its depth. This practically means that we need to have a limited number of chromophores inside the resist. Nevertheless, at short UV wavelengths most organic groups start to absorb. Especially in the 157 nm spectral region the problem is very severe, since C–H and C–C bonds also absorb. On the other hand in EUV (13 nm), X-ray, and charged particle lithography (e-beam, ion beam) the resist absorbance is defined by the atomic composition and material density.

Photochemistry and dissolution change chemistry play a vital role in resist design as well. After exposure, a latent image is formed inside the resist film defined by the distribution of chromophores (or absorbers) inside this material. Depending on the photochemistry that follows and on possible subsequent reactions that lead to the resist solubility change this latent image is probably modified. In the most common today case, that is, in the case of the so-called "chemically amplified resists" [40–44], which are based on photochemical generation of acid that next catalyzes reactions leading to solubility change, acid diffusion determines this latent image modification. The optimization of acid diffusion length defines to a great extent the high resolution performance of a specific resist process.

Development plays also a very important and, often, critical role in resist performance. During this step the latent image is transformed to a real relief structure based on the developer selectivity and the development mechanism. The most common problem during development is the swelling of the resist areas that will not be removed, that is, unexposed areas of positive resists or exposed areas of negative resists. This problem is very often encountered in negative resists based on cross-linking mechanisms but is not limited to these systems. In recent years, swelling is less common due to the adoption of aqueous base developable systems, where development mechanisms minimize swelling, as will be discussed in the next section.

Pattern transfer is the final goal of the resist process in most cases. In microelectronics during recent years the pattern transfer is almost exclusively performed by using reactive plasmas for the etching of the substrate. The chemical composition of resist defines its resistance to these plasmas. Empirical rules based on experimental data and mechanistic considerations can be used to predict the general performance of different materials [45–49]. In general, carbon rings and especially aromatic rings are desirable for improving the etch resistance of the material, due to their low reactivity toward decomposition and formation of gaseous products. On the other hand the presence of reactive groups and in general heteroatoms such as oxygen reduces the etch resistance of the material. In recent years as the lateral structure dimensions shrink, thin photoresist films, lately below 0.4 micrometers, are used to keep aspect ratios lower than about 3 and thus allow the fabrication of dense structures. Consequently, the improvement of the film resistance during the plasma etching step appears critical for effective pattern transfer especially at the sub-100 nm regime. Increased plasma resistance would allow us to obtain high resolution structures with improved aspect ratio.

3. RESIST DESIGN STRATEGIES

3.1. General Considerations

The design of resist materials that could fulfill the requirements discussed represents in most cases a very challenging problem. The resists should encompass suitable components to control the desired properties, components that should also be mutually compatible and if possible should work in a synergistic way toward optimum performance.

A polymer is almost always the basic component of the resist for a number of reasons. The most important include the necessity for film formation properties by spin-coating, as discussed, and the capabilities for dissolution change induced by small extent chemical changes. Indeed, the selection of a suitable strategy for photochemically induced property change, usually solubility change, in a resist film plays a predominant role in the design of a resist material. The main routes followed so far are discussed briefly in the following.

(1) The simpler case is the one where the light induces polymer cross-linking. Thus, the exposed areas become insoluble to the solvents of the unexposed regions.
(2) The second case is referred to as radiation induced polymer main chain scission. In this case the exposed areas become more soluble than the unexposed.
(3) Most interesting is the third case where the light induces chemical changes in characteristic functional groups resulting in hydrophilicity changes that differentiate solubility. Most common is the case where hydrophobic groups change to hydrophilic and thus the solubility of the polymeric film to aqueous developers increases.

The driving force of the research in the area of resists during the last 30 years is the need for the decrease of the electronic device dimensions. This decrease has proceeded according to the aforementioned Moore's law during these years and has resulted in an increase of the electronic device number in memory and microprocessor chips from 10^3 in 1970 to more than 10^9 today. The progress in lithography, including resists, played a critical role in the realization of this tremendous technology evolution. The main direction followed during the last 15 years in lithography technology development was the reduction of exposure wavelength first from 436 to 365 and then to 248 and to 193 nm respectively. Currently there is intense ongoing research for the development of 157 and 13 nm lithographic technologies.

Each time a new exposure wavelength was considered for introduction in lithography new resists had to be developed with absorbance and photochemical properties suitable for exposure at this wavelength of choice. This need determined the evolution of chemistry approaches in the resist field. In the following we will discuss the basic resist approaches that are currently considered for high resolution lithography.

Although this chapter targets mostly the systems used for nanolithography, that is, systems with sub-100 nm resolution capabilities, characteristic systems with resolution in the 0.1–1 μm range will be discussed as well since a lot of new systems proposed for sub-100 nm lithography have evolved from these resist materials.

3.2. Novolac Based Resists with Diazonaphthoquinone Dissolution Inhibitors

The resist system of choice for 436 nm lithography was the one based on novolac polymer matrices and diazonaphthoquinone (DNQ) photosensitizers. Variations of this resist approach were also used in 365 nm lithography. The novolac DNQ system finds up to now very wide use and it can still be considered as the standard resist material [50]. The solubility changing photochemistry in this system is presented in Scheme 4. The starting phenolic polymer has a small dissolution rate in aqueous base. Nevertheless, upon addition of the photosensitizer the solubility drops dramatically and increases again after the photochemical conversion of DNQ to indene carboxylic acid to a rate higher than the one of the starting novolac polymer, as shown in Scheme 5. Thus, the diazonaphthoquinone sensitizer acts in this system as strong **dissolution inhibitor** and its photochemistry offers the desired solubility change. The reasons for this effect and the physical chemistry of dissolution in **aqueous base** were studied in detail by a number of researchers during the

Novolac Diazonaphthoquinone

Diazonaphthoquinone photochemistry

Scheme 4. Solubility change photochemistry in novolac resists.

last decade. An explanation proposed for the strong dissolution inhibition effect of DNQ in phenolic matrices attributes this action to strong hydrogen bonding of the diazo group to the phenolic OH, which gives rise to a chain of hydrogen bonds involving phenolic hydroxyl groups. On the other hand the physical chemistry of phenolic polymer dissolution in aqueous base has been extensively studied. According to the accepted picture the dissolution mechanism proceeds through ionization of phenolic groups by the base, which enhances the polymer dissolution in the aqueous developer. Thus, the developer diffusion into the polymer matrix is the slowest step followed by fast polymer chain removal. This way swelling effects are practically eliminated. This dissolution behavior of phenolic resists contributed at most to their adoption for high resolution lithography as opposed to previously used negative systems based on cross-linking mechanisms, which suffered strongly from swelling problems. The development mechanisms of phenolic polymers have been extensively studied during recent years, mostly by Reiser et al. [51] and Flanagin et al. [52–56].

3.3. Chemically Amplified Resists

High sensitivity was always one of the desirable properties one resist should have in order to be useful for practical applications, especially under exposure with the extremely high cost, and high operational cost, laser source based exposure systems of optical lithography used in the last decade in semiconductor manufacturing. Enhancement of sensitivity was also always of high demand in the area of electron beam lithography to reduce the long times necessary for the writing of complicated circuits. High sensitivity resists had been actually designed for use in electron beam lithography that were also sensitive in deep UV, based on reactions resulting to polymer backbone scission, like polysulfones [57], but these resists had poor performance in pattern transfer through plasma processing. The strategy that came to revolutionize resist design by offering very high sensitivity and at the same time a lot of capabilities to control other resist properties was the so-called "**chemical amplification**" introduced in the early 1980s [58–62]. This strategy was gradually adopted in most resists designed since then and it is currently the basis for 248 and 193 nm resists used in the semiconductor industry [40–44, 63]. Moreover most of the resists proposed for 157 nm, EUV, and next generation lithography are also based on chemical amplification, whereas chemical amplification based resists are also used in electron beam, ion beam, and X-ray lithography.

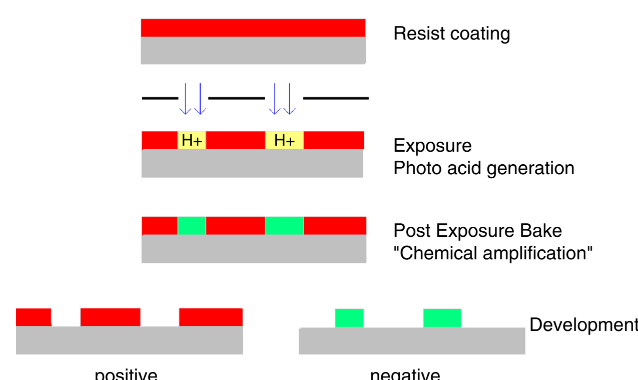
Dissolution rate

Scheme 5. Dissolution rate changes in novolac systems.

The chemical amplification strategy is based on the photogeneration of a catalyst during exposure, which in the next step, typically at elevated temperatures, catalyzes the reactions that result in solubility change. The catalyst produced is, in almost all cases, a Brønsted acid, which then catalyzes, or in some cases only initiates, the desired chemical reactions. Exposure is usually followed by a postexposure bake step, where these reactions take place. Typical reactions that take place in chemically amplified resists are shown in Scheme 6. The photosensitizers used in these resist systems, which are also called photoacid generators, can come from different organic compound classes [64–71]. The most commonly used are the sulfonium or iodonium salts [64, 65]. These types of compounds have been proposed for use in systems where acid catalyzed chemistries are desired a few years before the introduction of chemically amplified resists and they are very effective photoacid generators (PAGs). On the other hand pure organic photoacid generators have also been proposed to improve compatibility with other resist components [66]. Lately a quite intense activity is reported in this area and different new PAGs are evaluated in order to improve among others resist transparency, uniformity, line edge roughness, and outgassing performance of new materials designed for 193 nm, 157 nm, and next generation lithographies [67–71].

Acid catalyzed or acid initiated chemistries can be used in numerous different ways in order to bring about desired solubility changes. Extensive reviews have already been presented covering numerous such systems [40–44]. Here, we discuss briefly just a few representative cases. Since positive systems continue to dominate resist design the most common reactions that are encountered in the commercially available resists today are reactions of acid catalyzed transformation of hydrophobic to hydrophilic groups in order to render them soluble in aqueous base. In Scheme 6 we present three representative such acid catalyzed cases based on (a) deprotection of *t*-BOC groups to phenols, (b) acid catalyzed thermolysis of *t*-butyl acrylate esters, and (c) acid catalyzed deprotection of ketals. These chemistries were first

Scheme 6. Typical reactions encountered in chemically amplified resists.



Scheme 7. Lithography with chemically amplified photoresists.

introduced for 248 nm resists but are currently used also in numerous systems designed for 193 and 157 nm lithography. Acid catalyzed main chain cleavage represents another interesting case [73]. On the other hand one of the first systems proposed for 248 nm lithography was a negative resist based on acid catalyzed cross-linking of phenolic polymer by melamine through *trans*-etherification reactions [74]. Similar formulations were used in e-beam lithography and X-ray lithography (commercially available resist SAL 601). Another negative resist system is based on acid initiated cationic polymerization of epoxy polymers. Quite a few such systems were reported as will be further discussed in the e-beam resist section. Some negative systems have also been used for ultrahigh resolution lithography by e-beam exposure and they will be also discussed in the relevant section.

The process needed when using chemically amplified resists is more complicated than the conventional lithography process presented in Scheme 1, since it requires an extra step (i.e., the postexposure bake step) as shown in Scheme 7. This step plays actually a dominant role in the final lithographic performance since it controls the kinetics of the reactions resulting in solubility change. First, the photogenerated acid has to diffuse in order to catalyze the desired reactions and the diffusion length has to be controlled in order not to cause undesirable pattern alterations. Second, the temperature and the length of the step also have to be optimized according to a complicated diffusion–reaction kinetics encountered in most polymeric resist systems. In addition to diffusion and reaction processes taking place during the postexposure bake step similar phenomena that can strongly influence the lithographic performance are also encountered at the time intervals between the different processing steps. Most important are the ones between exposure and postexposure bake, depending on the *Tg* of the specific polymeric material, the *Ea* of the possible reactions, and the presence of potential contaminants, mostly basic compounds, in the atmosphere. These issues have been discussed in a large number of publications based on both experimental and simulation studies. These publications have appeared mostly in proceedings of lithography symposia and conferences like SPIE Microlithography, EIPBN, Micro-process, and MNE. Lately there is intense activity that involves the use of physicochemical methods in order to monitor the chemical reactions and acid diffusion processes taking place in the chemically amplified resist systems [75–78].

These processing issues will be covered here only briefly and to the extent they directly influence the resist design strategies. Thus, we have to mention that a family of resists, the so-called ESCAPs (environmentally stable chemically amplified positive resists), have been introduced to address environmental contamination [79, 80]. According to this approach the adoption of tert-butyl acrylate esters instead of *t*-BOC protected phenols allows the postapply bake to take place at higher temperatures, without thermal stability problems, and this way the free volume inside the film is reduced, minimizing also contaminant uptake from the environment. On the other hand base additives at small quantities are also introduced inside the resist film to control acid diffusion phenomena [81]. These basic additives can also be photosensitive in order to render to acids by the light at the exposed areas but to function as bases in the unexposed ones, where they need to scavenge the diffused acid [82, 83].

Finally, it should be mentioned that the basic processing issues encountered in the chemically amplified resists were presented a couple of years ago by Hinsberg and co-workers [84] and Ito [85].

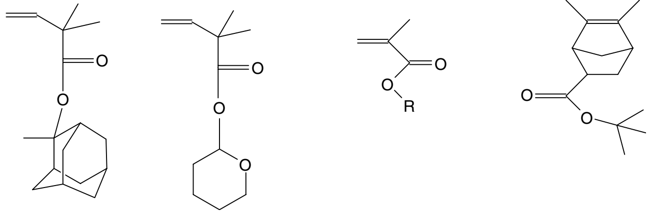
4. RESISTS FOR SUB-100 nm PATTERNING

4.1. The 193 nm Resists

Resists suitable for exposure at 193 nm have been introduced in production in recent years for sub-130 nm lithography. These resists are also believed to be the main choice for the production of 90 nm critical dimension circuits during the next few years and probably their use could be further extended. Reviews covering the efforts toward 193 nm resist design have appeared in the scientific literature in recent years [44, 86]. On the other hand new materials are still being proposed and the resolution limits to be reached are still under investigation. Here, we will discuss the main topics related to the resist materials considered and developed.

The main challenge that had to be addressed in the design of resists suitable for 193 nm lithography was the unacceptably high absorbance of aromatic polymers used up to that point as main resist components. Aromatic polymers offered high resistance to the plasmas used in pattern transfer and thus served as a suitable platform to build useful functionalities in previous wavelengths. Nevertheless, at 193 nm these polymers could be imaged only in top-surface imaging processes [88–91].

On the other hand methacrylate homopolymers and in particular poly(methyl methacrylate) (PMMA) were first used as single layer resists in 193 nm to demonstrate resolution capabilities offered by this wavelength [92, 93]. Acid catalyzed resist systems based on acrylate copolymers were then proposed to improve sensitivity [94] and imaging properties. These polymers, though, had very poor etch resistance and thus new components had to be introduced to bring the necessary improvements. The strategy proposed first by Kaimoto et al. [95] and Endo et al. [96], and adopted by most researchers in the field, was the incorporation of cycloaliphatic groups in the polymer. Empirical etch resistance prediction models and experimental studies proved the suitability of this type of component. Thus, one approach for 193 nm resist polymer design was based on the use of (meth)acrylate copolymers [97–107] synthesized from monomers such as the ones shown in Scheme 8. There, in addition to the cycloaliphatic moiety containing monomer, other monomers bear an acid cleavable group necessary for the imaging through a chemical amplification mechanism, possibly a carboxylic acid group for easier change to a base soluble material and probably a secondary hydrophilic group for adhesion and probably compatibility reasons. The exact chemical composition in each case is mostly unknown and it is the result of fine structure tuning toward optimum performance. Resist compositions in 193 nm involve also the selection of a suitable photoacid generator, possibly a base component, and even other additives to control the overall performance. In this (meth)acrylate platform described belong some of the commercial resists now available for 193 nm. The (meth)acrylate backbone offers many possibilities for copolymer optimization and thus high performance systems have been obtained. Nevertheless, in most cases the etch resistance is still considered as rather moderate due to the presence of a high number of ester groups which show high reactivity in the plasma environment. For this reason the cycloaliphatic component(s) content is increased to the maximum level allowed by the need to fulfill other resist properties as well. In a characteristic case reported by NEC researchers all the copolymer components contain cycloaliphatic moieties properly functionalized [106]. Photoacid structure effects in similar systems have also been studied [107].



Scheme 8. Typical monomers that are used in copolymers for 193 nm lithography.

As an alternative to the (meth)acrylate backbone systems, polyolefines have been also introduced and adopted by many researchers in the field [108–114]. Examples of such systems provide norbornene *alt* copolymers with maleic anhydride. A typical monomer used in the synthesis of the copolymers is also shown in Scheme 8. The resists based on such copolymers exhibit higher etch resistance compared to the (meth)acrylates, but their composition is most difficult to be optimized. For instance they very often present adhesion problems, unacceptably high *Tg*, and also self-life problems. Nevertheless, high quality, high resolution patterns with such type of resists have been demonstrated. Lately novel polymers that belong to this family have also been proposed. A characteristic example of a novel material based on cyclopolymers has also been reported [115].

Other polycarbocycle compounds have been also examined as possible components of 193 nm resists. In particular cholic acid derivatives have been mostly evaluated as dissolution inhibitors and relevant resist formulations have been presented [114]. Furthermore, the possibility of including a percentage of an aromatic component in 193 nm resists has been also considered. As indicated by Toshiba researchers [116, 117], the UV spectrum of polyaromatics is redshifted in the 193 nm region compared to the simple aromatic rings resulting to an increased transparency in this region. Thus, 193 nm resist formulations containing a certain extent of naphtahalene components have been presented, but the transparency was not still adequate. On the other hand anthracene compounds [118] have been examined as possible etch resistance additives and recently new anthracene derivatives have been presented and evaluated for this application [119].

Silicon containing polymers were also considered as the basis of bilayer resist formulations. Si in this case was incorporated in a pendant group [120]. High quality patterns have been demonstrated with resists of this type. Nevertheless, concerns for outgassing and contamination of lenses with difficult to remove Si species have limited the use of such resists.

Outgassing is referred to as the undesirable formation of gaseous products during illumination of the resist [121]. This is due to photochemical processes that result in direct bond breaking. The phenomenon was first discussed in the case

of 193 nm lithography, since at this wavelength the photon energy is high enough to induce breaking of certain organic molecule bonds. These direct photochemical processes cannot obscure the main solubility changing chemistry in chemically amplified systems but they mostly raise concerns about possible contamination of the lenses with gaseous products. It has been reported that carbon species can be removed from the lenses using relatively easy procedures based on treatment with oxygen. Nevertheless, things are much worse with Si containing species, which can form silicon oxides and thus eventually destroy the lenses.

Lately, the etch resistance enhancement with the addition of Si nanoparticles in the resist formulation has also been proposed [122]. Most interesting seems to be the case of incorporating silsesquioxane groups in 193 nm resist formulations by using polymerizable compounds bearing such groups to synthesize methacrylate copolymers [122, 123]. These approaches will be also discussed in the next sections.

Development mechanistic studies related to 193 nm resists have been also reported [124]. On the other hand it has also been pointed out that diluted developers could present some advantages for process optimization in these nonaromatic resist systems [125–127], but the semiconductor industry is very reluctant to adopt changes from the standard base concentration (0.26 N) used today.

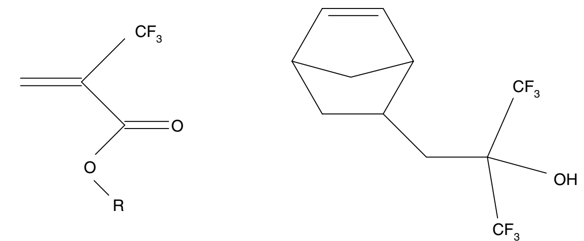
At the end of this section on resist materials for 193 nm lithography efforts for negative resists will be briefly discussed. The demand for negative tone resists is very limited during recent years despite the fact that resists of this tone are considered to present advantages for certain types of patterns. New chemistries have been reported for negative resists, mostly acid catalyzed esterifications and *trans*-esterifications. Moderate resolution results, compared with the positive systems, have been reported [128–131].

4.2. The 157 nm Resists

Lithography at 157 nm is currently the most serious candidate to succeed the 193 nm lithography in the production of integrated circuits. It is believed that it will be the technology of choice for devices having critical dimensions of 65 nm, which according to the Semiconductor Industry Association roadmap will probably enter in production during the next few years [7, 8]. Thus, at the moment a huge research effort worldwide has been directed for the timely development of the relevant components that are necessary. The progress in this area is being reviewed relatively often mainly in the SPIE, Photopolymer, Microprocess, and International Sematech Conferences, helping give timely information to the research community.

The development of photoresists with acceptable lithographic performance at this wavelength represents one of the major challenges. The most critical issue for 157 nm resist development is the accomplishment of adequate transparency, since traditional resist platforms are too opaque to allow imaging in sufficiently thick films. Indeed even C–C bonds and C–H bonds absorb considerably strongly at this wavelength and thus almost all organic materials are too opaque to be used as main components of single layer resists. This difficulty was well recognized a few years ago [132–137], along with the severe outgassing problems anticipated and first investigated [138–140] or the different photochemical pathways that are possible at this wavelength [141, 142], when 157 nm lithography appeared as a strong candidate for entering the semiconductor industry in coming years. The absorbance of typical organic polymers is mostly in the range of 5–10 μm^{-1}. Although aromatic polymers exhibit generally high absorbance values aliphatic polymers also absorb unacceptably high. Only two main classes of polymeric materials have reduced absorbance at this wavelength: first, polymers containing a high percentage of C–F bonds and, second, polymers containing a high percentage of Si–O bonds. Nevertheless, existing polymers bearing high percentages of either type of bonds are far from fulfilling criteria to provide resist materials with desired performance, such as presence of imageable functional groups for positive lithography, aqueous base development, high resolution patterning, etch resistance, etc. Thus, a huge research effort is in progress in recent years aiming at the synthesis of novel polymers that could be the basis of candidate 157 nm resists materials.

Partial fluorination for absorbance reduction of polymers that were used in longer wavelengths was the main strategy followed [143–153]. Since models for predicting absorbance of different materials at the 157 nm had, at least in the beginning, a rather limited prediction capability a lot of new polymers had to be synthesized and evaluated experimentally. A few groups appeared to be extremely useful in this absorbance reduction effort. Through this effort great progress in absorbance reduction has been achieved so far. Characteristic groups that were proved very effective in reducing the total resist absorbance are shown in Scheme 9. Polymers with absorbance in the order of 1 μm^{-1}, or even slightly below, have been recently reported. Thus, lithographic performance has been substantially improved as the necessary film thickness for single layer resists in this case is 200–250 nm. Nevertheless, a number of problems still have to be solved. The materials must additionally satisfy numerous other requirements, such as adhesion, high resistance to etching by reactive plasmas, controlled dissolution behavior, and aqueous base development. Therefore, the design of materials suitable for 157 nm resist applications presents a great challenge. For instance etch resistance of heavily fluorinated resist materials is low. Incorporation of fluorine can dramatically affect the physicochemical characteristics of the resist, making aqueous base dissolution more difficult and reducing adhesion. The presence of a big number of fluorinated groups causes problems in film homogeneity, since these groups tend to phase separate from the rest for the resist components. Surface composition differentiation



Scheme 9. Monomers that are used for increased transparency in copolymers for 157 nm lithography.

phenomena are also expected. Thus, irregular development in such systems is common.

Siloxanes and silsesquioxanes offer an alternative route for designing resist materials with optimized performance at 157 nm. Thus research is also taking place in this area in order to develop appropriate materials with high resolution positive imaging capabilities [154, 155]. Siloxanes with small vinyl content have been used in the past as solvent developable negative resists in deep UV and recently negative behavior has also been shown in 193 nm. On the other hand even simple siloxanes, like poly(dimethyl siloxane) (PDMS), behave as negative resists under ion beam and electron beam exposure. The same behavior has been observed in 157 nm [155]. Thus, novel polymers have to be designed in order to formulate positive tone resists, with aqueous base development capability. A few years ago synthesis of polysiloxanes with acid-sensitive side groups was reported. The main drawback of these materials appears to be their low glass transition temperature, and thus novel designs are under investigation for 157 nm lithography. Details of this research effort have not been reported, although very good lithographic results of sub-100 nm resolution have been shown in lithography symposia in the last year. Silsesquioxanes of the ladder-type structure have also been extensively examined as negative materials, mostly for e-beam applications, in recent years. Recently a fluorocarbinol-substituted polymer with acid-labile ester functionalities has been suggested as a promising positive tone material for 157 nm applications [154]. Finally, silsesquioxanes of the cage-type structures, belonging to the same family with the ones first studied for 193 nm lithography, have been recently investigated for 157 nm lithography [155]. Partial fluorination can also be applied in these systems for absorbance optimization.

Outgassing, first discussed in the section devoted to the 193 nm resists, is a much more important issue at 157 nm. The high photon energy (7.6 eV) at this wavelength is enough to directly break a great number of the molecular bonds encountered in organic molecules. As discussed in the 193 nm resist section outgassing from carbon based resists is not considered so a big problem since it is relatively easy to avoid deposition of the gaseous products on the lenses or even to clean it afterward. In the contrary potential damage of lenses is mostly a big concern when Si containing polymers are used, since in this case Si species can form nonremovable silicon oxides on the lens surface. Specific protocols for the evaluation of deposits on the lenses have been proposed. It has been shown that outgassing of Si containing species from polymers bearing Si in the side chain is unacceptable. On the other hand in siloxane and silsesquioxane polymers only traces of Si containing species, if any, have been detected [140]. The fact that the SiO bond is almost transparent at 157 nm and the binding of Si to two different chain atoms in siloxanes, or to three different chain atoms in silsesquioxanes, reduce substantially the outgassing risk.

4.3. E-Beam Resists

Electron beam lithography is the technology providing the highest resolution structures and, thus, it is the predominant tool used in nanolithography. On the other hand often electron beam lithography could also serve as a benchmark to evaluate the ultimate resolution capabilities of the different resist systems.

The best known high resolution e-beam resist is poly(methyl methacrylate) (PMMA), which actually is one of the simpler resist systems, since it is a one component resist. Although this resist was introduced more than 30 years ago [14, 156], it is still intensively studied. The interest in this resist has been partly renewed after Chen and Ahmed demonstrated sub-10 nm lithographic features [157] in the early 1990s, and since then it can be considered the main vehicle used in nanolithography investigations.

The radiation chemistry involved in the imaging of this resist has been extensively studied and is discussed in most of the standard lithography sources, for instance in [11]. General considerations on the behavior of polymeric materials under exposure in high energy radiation are also available [158, 159]. PMMA is a typical example of a polymer where chain scission occurs under high energy exposure, whereas cross-linking is predominant in other polymer types, for instance in polystyrene. Chain scission also takes place under exposure of PMMA to X-rays [161] but also to deep UV irradiation [162]. In any case, due to this chain scission imaging mechanism, the ultimate resolution is not determined by the size of the starting macromolecule but by the size of the produced chain fragments after exposure.

On the other hand PMMA is known to have very low sensitivity and poor etch resistance to the plasmas used for pattern transfer. For this reason over the last 30 years many efforts were undertaken in order to modify its structure with the goal to improve its performance in these aspects. Copolymers of methyl (methacrylalate) with other acrylate monomers were mostly proposed by many researchers and substantial improvement in sensitivity was obtained with quite a few of them, for instance in copolymers with methacrylic acid [163, 164]. Nevertheless, the PMMA sensitivity remained generally low (doses close to or higher than 100 μ C/cm^2 for 20 keV exposure are needed in most of the cases). Thus, PMMA was not preferred for use in mask fabrication where other systems based on poly(alkyl sulfones), like PBS, were developed [165–168] in the mid 1970s. More recently, though, certain acrylate polymers, like poly(fluoroalkyl methacrylates) [169] or poly(methyl chloroacrylates) [170, 171] proved to give improved sensitivities, whereas copolymers bearing phenyl moieties [172] improved etch resistance. Thus some commercial products based on these chemistries are now available. Especially interesting is the case of the resist ZEP520, which is a copolymer of methyl *a*-chloro acrylate and *a*-methyl styrene and provides good sensitivity, good resolution capabilities, and improved etch resistance.

In recent years many efforts have been devoted in improving the characteristics of PMMA and also other resists of similar imaging chemistry, like ZEP520, by using special additives, usually for etch resistance enhancement. These additives include fullerene derivatives, silicon and metal nanoparticles, and anthracene derivatives. Different fullerene additives, bearing solubility promotion moieties, have been used in ZEP520 by Ishi and co-workers [173–176]. On the other hand Gonsalves and co-workers use silicon oxide and metal nanoparticles in ZEP520 [122, 177, 178]. The incorporation of these nanoparticles in addition to the

etch resistance enhancement has been reported to improve energy deposition profiles, thus enhancing resolution. The activity in this area has been also recently reviewed by these authors and co-workers [122]. In a related approach PMMA has been used as host of tungsten polyoxometallates that are investigated as possible components of lithographic materials or of molecular electronic systems [179].

On the other hand intense effort is devoted to understanding and improving development characteristics of PMMA. PMMA is characterized by very well controlled dissolution behavior, without swelling, despite the fact that it is developed traditionally in organic solvent mixtures [180–182]. First, ultrasonic agitation proved very effective in nanolithography applications [183, 184]. Recently also some new developers have been tried, such as pure isopropyl alcohol and water/alcohol mixtures with very good results from the point of view of resolution [185–187]. Some of these processes developed aim at the use of PMMA structures in nanoimprint lithography.

Development studies have been reported also lately in order to improve high resolution performance of ZEP520 resist. These studies have led to a new processing scheme (SAGEX) where the resist is first cross-linked in order to improve development uniformity [188, 189].

In addition to PMMA and in general to acrylate systems that undergo chain scission by high energy radiation, other resist systems especially popular for e-beam nanolithography recently are negative systems based on small molecules. One such system represents calixarenes, which can be viewed as cyclic oligomer analogs of phenolic resists, of $\sim$1 nm dimensions. These materials were first proposed by Fujita and co-workers in 1996 [190], but currently quite a few groups work with them. Although they are difficult to dissolve, optimized processes can provide acceptable films by spin coating [190–192]. Upon exposure to e-beam radiation calixarenes give negative tone imaging [190, 193, 194, 196–206]. Organic solvents are used as developers. Different derivatives have been reported in order to improve solubility and sensitivity, which currently is higher than 0.7 mC/cm^2. Despite these problems the calixarenes are used in different nanolithography applications since they can provide sub-10 nm resolution. On the other hand Fujita and co-workers [195] have shown that low MW polystyrene (MW < 1000) can also give comparable resolution but at similar or higher doses.

Similar to calixarenes, a low MW molecular system represents the hydrogen silsesquioxanes, which also give negative tone imaging upon e-beam exposure. These systems were proposed by Namatsu and co-workers [207, 208] and since then a few other groups have also worked with these due to the high resolution capabilities they provide. They work also as negative resists, forming acceptable films by spin-coating. According to the mechanism proposed by Namatsu et al. [208], radiation breaks Si–H bonds and the system cross-links by the mediation of water molecules, which render the formed radicals to silanol groups. The starting material is provided by Dow Corning, but stability (shelf-life) problems have to be taken into account [213]. On the other hand simpler polymers like poly(dimethyl siloxane) are known to cross-link under exposure to e-beam radiation at relatively low doses. Recently sub-100 nm structures with such systems have been presented, and their pattern transfer behavior when used as double layer resists has been investigated [214, 215].

Certain modified fullerenes have been also used as molecular negative e-beam imaging materials [216–218]. Fullerenes are known also to react photochemically [219] to form larger molecules, and a similar mechanism is proposed for their e-beam reactivity as well [220]. Vapor deposition is mostly used for their deposition, whereas the doses needed are very high (on the order of 25 mC/cm^2).

Ion beam sputtering is used for the film deposition in the case of inorganic resist systems [37, 38, 221]. These are mostly different metal halides like $LiF(AlF_3)$ or silica. Almost isolated lines (60 nm periodicity) have been reported with these materials [221]. The doses in these cases are very high (few C/cm^2). Ion beam exposure can be used with these systems for improved sensitivity [222].

A very interesting work targeting the development of both negative and positive molecular electron beam resists has been presented by Shirota and co-workers in a number of communications [223–228]. The work of the group has been reviewed in a recent paper in *Proceedings of SPIE* [36]. Considerations of different chemistry routes, including chemical amplification mechanisms, have been reported. On the other hand other molecular systems like dendrimers and hyperbranched polymers have been reported as mentioned in a previous section [32–34], where chemically amplified systems have been presented as well. In all these cases the interest comes from the use of alternatives to the standard linear polymers, which form the basis in current resists. Thus systems based on well-defined molecular structures that could give benefits regarding line edge and surface roughness are envisioned. On the other hand issues like sensitivity, compatibility with current resist process requirements (e.g., aqueous base development, spin-coating, shelf-life stability, pattern transfer properties) have to be taken into account. In many cases such resist systems can find applications in optical lithography or in EUV, but currently the e-beam is mostly used to benchmark resolution capabilities.

On the other hand extensive use of chemically amplified resists that are the same or very close in composition to counterparts designed for optical lithography has taken place in electron beam lithography during the last decade. These resists offer the very significant advantage of high sensitivity, which is very important in electron beam lithography due to the inherent low throughput of the method. In most cases the resolution regime targeted is close to 100 nm, but lately a lot of effort has been devoted to the evaluation of the resolution limits of such systems. Both positive and negative systems have been evaluated. In the case of negative systems a lot of work has been done with systems based both on epoxides [229–233] and on melamine as cross-linker [234–238]. In the first case both solvent developable and aqueous base developable systems have been widely explored while in the second case the aqueous base development is standard. Commercial melamine based products are very well known such as SAL 601 (Shipley) and AZPN (Clariant). Quite a few reports on the use of these systems have been reported. Top surface imaging silylation processes have also been used that can reverse the tone of negative systems to positive [239, 240]. On the other hand standard deep UV positive resists, like UV III of Shipley, have also been evaluated

[238, 241]. In many cases the reported best resolution results are close to 50 nm. Currently a lot of effort has been devoted to the understanding of the factors that may limit the resolution of chemically amplified resists, in relation to the work also started for EUV lithography. Especially popular negative commercial resist systems in these applications lately are Sumitomo NEB 22 and NEB 31 [242–244]. Recently [244] some more information on the chemical composition of these resists was disclosed, along with studies on the influence of resist components in lithographic performance.

4.4. Resists for EUV and Other Next Generation Lithographic Technologies

With the term next generation lithography we mean nowadays mostly technologies competing to succeed optical lithography (including 157 nm) in production of integrated circuits. In this group we include extreme UV lithography (13 nm), along with projection particle technologies including electron and ion beams, low energy e-beam lithography, and X-ray lithography. Currently EUV [245] is considered as the strongest candidate and it will be discussed first.

The resist transparency at EUV is controlled by the atomic composition and density of the material and not by the molecular bonding, as was the case in the optical lithography regimes. Several theoretical and experimental investigations on the absorbance of polymeric films in the EUV region have been reported [246–250] . Since it is considered that EUV resists will be mostly used for patterning features of sub-50 nm lateral dimensions [7, 8], and taking into account that the aspect ratio targeted is ∼3, or slightly smaller, the higher resist thickness expected to be used at this wavelength is less than 150 nm. At this thickness the transparency of polymeric systems conventionally used in microlithography, such as the aromatic polymer based 248 nm resists, seems adequate. Thus, single layer resist processes are mostly investigated in recent years, although trilayer or top surface imaging schemes had first been considered. Nevertheless, new challenges have to be overcome in the design of EUV resists. These challenges actually come from the very high resolution targets imposed.

First, film thickness reduction was recognized by many researchers as an important issue that can influence the pattern quality. Resist film uniformity and adhesion studies have been reported [251–254]. Lately an increasing activity focuses also on Tg changes in thin polymeric films. These Tg changes have implications on the optimization of the thermal processing parameters but, more important, indicate strong interfacial phenomena that are expected to strongly affect critical performance aspects such as development rates and etching. Second, the molecular size of the candidate resist components has been recognized as a parameter that can influence the ultimate resist performance, especially line edge roughness. Thus, first reports of so-called molecular resists have appeared as discussed in the e-beam section. Third, dissolution differentiation mechanisms also need further consideration. For instance, doubts are raised about the suitability of catalytic mechanisms as the ones encountered in chemically amplified resists for sub-50 nm lithography. On the other hand high resist sensitivity is highly desirable; a target of 5 mJ/cm^2 has been imposed, to compensate the low fluences of most of the exposure sources available so far. Finally outgassing is also a concern, although first reports are considered rather encouraging [255, 256].

First lithographic results, both open field exposures but also high resolution results, have been reported in a few cases [257–264], showing good potential for the technology. Especially encouraging is the behavior of ESCAP-type 248 nm resists in this wavelength and the sensitivity target of the 5 mJ/cm^2 seems to show that it can be reached [263].

The requirements and challenges related to resists that can be used in other next generation lithographic technologies are similar to the ones presented for EUV. So far resists developed for optical or e-beam lithography have been mainly used in these applications [265–272]. Especially in the case of X-ray lithography there is considerable experience, since this technology has been investigated for more than two decades. Different chemically amplified resists, especially resists designed for deep UV (248 nm), have been mostly used, in addition to the conventional PMMA-type resists. A comparison of resist performance at EUV and X-ray, showing in general similar behavior despite the big difference in absorbance, has also been reported recently [260].

Similar is the situation in the case of e-beam projection lithography, where very high sensitivity is an important demand. Sensitivity issues are also mostly considered in the case of ion beam lithography. In the case of low energy beam lithography, which mostly refers to energies lower than ∼2 keV, the small penetration depth of electrons inside the resist imposes an extra demand for addressing thin film resist issues. Scanning tunneling microscope based lithography could also be considered as an extreme case of low energy e-beam lithography, where conventional e-beam resists have also been used.

5. POLYMERIC MATERIALS IN UNCONVENTIONAL LITHOGRAPHIC PROCESSES

As discussed in the first section of this chapter, in recent years a number of unconventional patterning schemes have appeared in the scientific literature aiming mostly at the fabrication of nanostructures. Polymeric materials issues involved in these schemes will be discussed here.

We will start with one very recent development related to the use of two photon processes in lithography [273–277]. These processes were well recognized as capable of providing ways of overcoming diffraction limits in optical lithography. Nevertheless, they were impractical due to the high intensities that were required in order for multiphoton processes to take place. Lately there is a lot of activity for both intensity enhancement and for improved response of the resist material. In the last case, which is more within the scope of this chapter, lately new photoacid generators have been reported [275, 276] with faster response versus multiphoton excitation compared to the standard ones. A new route has been probably opened in the resist design approaches based on these developments.

One other area of intense activity during recent years is related to self-assembling processes in thin films. Such processes encountered in polymers of certain architectures have

drawn the attention of the scientific community as possible novel routes for the formation of ordered nanostructures with applications in the fabrication of electronic and photonic devices [277–279]. Different types of simple ordered structures are being reported. Among them special interests present cases where self-assembling phenomena are mixed with radiation guided processes resulting in the formation of novel-type structures [279]. There has been also some effort for using materials, such as block copolymers, with a self-assembling tendency in standard lithographic schemes aiming at the improvement of lithographic properties, but with moderate results so far [277, 278]. Nevertheless, this direction could probably draw more interest in the near future since in a lot of cases (e.g., in resists based on fluoropolymers) self-assembling phenomena could probably be controlled for the enhancement of lithographic performance.

Resists are also used in numerous novel applications aiming at microstructure fabrication for use in specific microsystems, or MEMs. In most cases these structures have dimensions in the microdomain [280, 281] and, thus, they are not considered here where the emphasis is on nanolithography. An exception is probably the case of biomolecule microarrays. In this case thin biomolecule layers need to be patterned for use in chemical or biochemical analytical applications including DNA and protein analysis. Mechanical delivery methods like microspotting and ink-jetting or direct light guided *in-situ* synthesis [282] are the predominant methodologies used. Photoresists have been used in limited cases so far in such applications. First positive resists like PMMA were used to pattern monolayers by lift-off processes where biomolecules are physisorbed or chemisorbed [283]. In another approach, photoresists served after patterning as layers for selective physi/chemisorption of certain biomolecules [284]. A double layer scheme, based on a negative epoxy-based photoresist, has also been proposed for oligonucleotide synthesis [285]. Lately, chemically amplified positive photoresists processable under biocompatible conditions were proposed for patterning biomolecules by lift-off in successive lithographic steps [286, 287].

6. SUMMARY

Photoresist technology has been enormously improved during the last decade. The demand for fabricating structures of dimensions decreasing from sub-quarter micrometer to sub-100 nm regimes has led to the introduction of a plethora of new polymeric materials. Most of these materials are based on the chemical amplification principle introduced during the 1980s. Positive tone materials, developable in aqueous base, are almost exclusively used in the semiconductor industry and are predominant in other applications.

Although the design of photoresists suitable for exposure at decreasing optical wavelengths (248, 193, 157 nm) was the main driving force for new resist materials development, novel issues have started lately to draw considerable attention. Thus, designs of photoresists suitable for sub-50 nm have to take account of physicochemical issues like ultrathin film homogeneity, surface phenomena, microphase separation, and molecular size. Novel photoresist chemistries would also probably be needed in the near future.

Finally novel areas for photoresist applications emerge in the area of microsystems and in the broader field of nanotechnology including bionanotechnology.

GLOSSARY

Chemically amplified resists Resist materials in which the radiation causes the formation of a chemical species inside the resist film, which species further catalyses or initiates a series of chemical events that result to solubility change. Thus, in these materials the radiation action is "enhanced" by chemistry. In most chemically amplified resist systems radiation generates Brønsted acids that act further as catalysts or cationic polymerization initiators.

Dissolution inhibitor A chemical compound or a functional group, which reduces the solubility of a polymeric film. For instance, diazonaphthoquinone sensitizers act as dissolution inhibitors in novolac photoresists, whereas tert-butyl ester groups can be considered as dissolution inhibitors in certain positive chemically amplified resists. The dissolution inhibitors usually undergo radiation induced chemical changes that finally result to enhanced resist solubility as shown in Scheme 5.

Lithography Processing technology for patterning films and surfaces. When electromagnetic radiation is used to guide the patterning process, as in the case of processes shown in Schemes 1, 2, and 3, the term *photolithography* is also used. When other forms of radiation are used, or if emphasis on the specific spectral range is desired, the technology is named accordingly, (e.g., *e-beam lithography*, *ion beam lithography*, *UV lithography*, *X-ray lithography*, *193 nm lithography* etc.).

Positive/negative tone process When radiation exposure results to the removal of the exposed area the patterning process is characterized as positive, as shown in Scheme 1. On the other hand when the unexposed area is removed the patterning process is characterized as negative.

Resist Radiation sensitive material, usually having an organic polymer as the basic component, used for the patterning of films or surfaces. Typical resist-based patterning processes are shown in Schemes 1, 2 and 3 of this chapter. When the resist is sensitive to electromagnetic radiation the term *photoresist* is also used. Depending on the radiation type the terms *e-beam resist, X-ray resist, UV resist, 193 m resist* etc. are also used.

1. INTRODUCTION

Resonant tunneling structures (RTSs) or double barrier RTS (DBRTSs) have attracted a lot of attention because of their possible application in microwave and millimeter wave technologies as well as their application in multivalued logic systems. A resonant tunneling structure in it simplest form consisting of the low bandgap material, GaAs, sandwiched between two wide bandgap semiconductors, AlGaAs, was first investigated by Esaki and Tsu in the early 1970s [1]. Interest has been building up since Sollner et al. [2] reported in 1983 a negative differential resistance (NDR) with a large peak to valley ratio in current. This breakthrough was possible due to the improvements in epitaxial growth techniques.

The fast switching time and NDR in RTS can be utilized in many ways in realizing novel device structures. RTS has been incorporated in the emitter and base of bipolar transistors to obtain unique performance [3–11]. Liu et al. reports a multiple negative-differential-resistance InGaP/GaAs RT bipolar transistor where double and quaternary NDR phenomena are observed at room temperature [12]. RTS has been incorporated in FET structures to obtain high-speed low power electronics [13–15]. RT bipolar/unipolar transistors have been successfully demonstrated for applications in high-density memories using multivalued logic [16–20] and high speed analog-to-digital (A/D) converters with potential applications that include ultrahigh speed A/D converters [21]. RTS has been widely implemented in different combinations in FET and bipolar transistors to realize different digital logic and adder circuits [22–27]. Gonzalez et al. [28] reports the implementation of a multivalued logic signed digital full adder using a standard 0.6 μm CMOS process. The circuit is based on a two peak NDR device obtained by combining a MOS and an NDR device. Recently, Lind et al. [29] reported the fabrication of a resonant tunneling permeable base transistor where a room temperature peak-to-valley ratio (PVR) in current of 8 was achieved. HEMTs have also been successfully incorporated with RTS to realize the different analog and digital applications [30–33]. RTSs in different forms have been utilized in analog and mixed signals circuitry to obtain high frequency oscillators, frequency multipliers, and current mirrors [34–38]. The high switching speed of RTD has enabled its use as a local oscillator in timing extraction in optical communication systems [39]. RTS has also been used in optical modulators and millimeter and submillimeter wave applications [40, 41].

The fabrication of RTD and related devices is not only confined to GaAs based material systems. Kikuchi et al. [42] reports the fabrication of AlN/GaN/AlN resonant tunneling structure where the room temperature PVR of 3 was measured. See and Paul [43] have reported a PVR of 2.43 at a peak current density of 282 kA/cm^2 using a 5 $\times$ 5 μm^2 Si/SiGe sample. Structures using ZnO/Zn$_{0.8}$Mg$_{0.2}$O, CdF$_2$/CaF$_2$, InAlAsSb/InGaAs, amorphous SiO$_2$/Si/SiO$_2$, amorphous SiC/Si, and InGaAs/AlAs/InGaAsP double barrier structures have also been reported [44–50].

Transport in RTS has been widely investigated as evident from the extensive literature. Nonequilibrium quantum transport, three-dimensional transport, and quantum transport using hydrodynamic formulation has been reported [51–55]. The Wigner function has been widely used to model open systems like resonant tunneling structures [56–60]. Jensen and Ganguly [57] report the computation of current–voltage characteristics and incorporation of scattering using the Wigner function and compare that to the standard

technique using the transmission coefficient approach. The incorporation of scattering in the Wigner function formulation has been reported by Mains and Haddad [58] and Jensen and Bout [59]. The transient response of resonant tunneling structures has been reported by Frensley [60] and Pinaud [61].

Shot microwave, and flicker noise has been widely investigated and reported [61–71]. Davies et al. [65] report the computation of shot noise using a classical description based upon the rate equation for sequential tunneling. Suppression of shot noise in asymmetric DBRTS has been reported by Liu et al. [66]. Enhancement of shot noise when the DBRTS is biased in the negative differential resistance region is reported by Iannaconne et al. [67]. Sun and Milburn [68] report the computation of current noise in DBRTS and the treatment includes both coherent and incoherent quantum tunneling processes. Blanter and Buttiker [69] report the transition from sub-Poissonian to super-Poissonian shot noise in DBRTS that takes place near the instability threshold. Ng and Surya [70] and Ouacha and Willander [71] report the theory and measurement of flicker noise in DBRTS. Resonant tunneling in quantum cascade lasers has been reported by Sirtori et al. [72] and the physics of resonant tunneling in quantum dots has been reported by Luscombe et al. [73].

2. RESONANT TUNNELING MECHANISM

Resonant tunneling structures have an interesting property of transmitting electrons through a quantum well (QW) with high transmission probability if the electrons are incident at energies equal to one of the virtual energy levels of the QW. Electrons with energies other than the virtual energy levels have a very low probability of transmission or in other words they are not allowed to pass. Figure 1, shows the conduction band diagram of a typical DBRTS. The barriers are composed of a higher bandgap semiconductor (e.g., AlGaAs), and the QW is formed in the lower bandgap semiconductor, namely GaAs. The discussion is restricted to heterostructures with type-I transitions (i.e., ΔE_C and ΔE_V, both being positive).

The operation of a RTS has been explained in the light of a resonant Fabry–Perot effect [74]. In the absence of scattering mechanisms, which can destroy the phase coherence of an electron wave, the amplitude of the resonant modes builds up in the QW. Concomitantly, the electron wave leaks out in both directions and in doing so cancels the reflected waves and enhances the transmitted waves. On the other hand, if the time evolution of the electron wave function in the well is long compared to the scattering time, the collisions randomize the phase of the wave function. In this case, the electrons tunnel through both the barriers sequentially and the RTS has a lower quantum mechanical transmission peak.

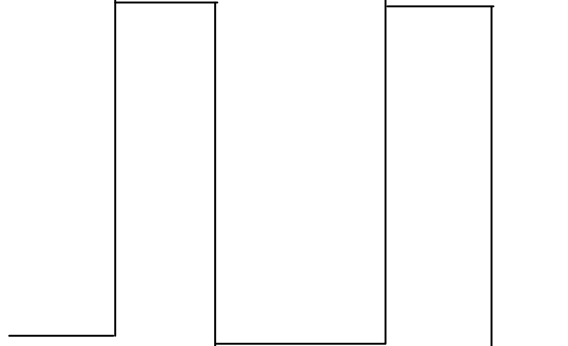

Figure 1. Conduction band profile of a typical DBRTS.

3. METHODS OF ANALYSIS

Matrix methods using the continuity of the wave function and its first derivative, at any heterointerface, have been used quite extensively to determine the incident energy dependence of transmission probability. Ando and Itoh [75] approximated the arbitrary potential well by multistep functions and then used a matrix method to determine the transmission coefficient. The position dependence of electron effective mass, m_n^*, and the permittivity were also approximated by multistep functions. Using the envelope wave function under effective mass approximation the amplitudes of the incident and reflected wave functions at any segment n, $\varphi_n(x) = A_n e^{jk_n x} + B_n e^{-jk_n x}$ with $k_n = \sqrt{2m_n^*(E - U_n)/\hbar^2}$ where E is the incident electron energy and U_n is the potential, were related to that at the reference segment by the following matrix equation:

$$\begin{pmatrix} A_j \\ B_j \end{pmatrix} = \prod_{l=0}^{j-1} M_l \begin{pmatrix} A_0 \\ B_0 \end{pmatrix}$$

The matrix M_l is generated by invoking the continuity of the wave function $\varphi(x)$ and its first derivative by properly accounting for the effective mass,

$$\frac{1}{m_n^*} \frac{d\varphi_n}{dx}$$

at the interface n. The transmission probability at any energy $D(E)$ is given as

$$D(E) = \frac{m_0^*}{m_{N+1}^*} \frac{k_0}{k_{N+1}} |A_{N+1}|^2$$

where $n = N + 1$ and $A_0 = 1$ are assumed.

Though the matrix method is straightforward it becomes slow with the increase in heterointerfaces and prone to round-off errors. Lui and Fukuma [76] approximated the arbitrary potential well by piecewise linear functions and then used a numerical method to calculate the transmission coefficient. In the treatment presented here we will use the method of logarithmic derivates to determine the transmission probability and other parameters required to investigate the system

3.1. Logarithmic Derivatives

Using logarithmic derivatives [77], defined as the ratio of the derivative of the wave function $\Psi(x)$ and the wave function $\Psi'(x)$

$$\Xi(x, E_x) = \frac{2\hbar}{m^*} \frac{\Psi'(x)}{\Psi(x)}$$

the one electron Schrödinger equation within the effective mass approximation can be written as [78]

$$\frac{d\Xi(x, E_x)}{dx} = -j\left[\frac{m^*}{2\hbar}\Xi(x, E_x)^2 + \frac{4}{\hbar}(V_{\text{TOTAL}} - E_x)\right] \quad (1)$$

where m^* is the electronic effective mass, $\hbar$ is the modified Planck's constant, and $V_{\text{TOTAL}} = \Delta E_C$ is the conduction band offset. In general, $V_{\text{TOTAL}} = \Delta E_C + V_a(x) + V_{\text{sc}}(x)$, where V_{sc} is due to the accumulation of the space charge inside the quantum well and V_a is due to the applied bias voltage and needs to be evaluated to calculate the current–voltage characteristics. Equation (1) can be solved numerically and for a piecewise constant potential profile, the recurrence relation may be written as

$$\Xi_n(x, E_x) = \sqrt{\frac{2m^*A}{8}}\tanh\left[-j\sqrt{\frac{2m^*A}{8}}\Delta x + \arctan h\left(\Xi_{n+1}\sqrt{\frac{m^*}{8A}}\right)\right] \quad (2)$$

where $A = -[\Delta E_C - E_x]$, $\Delta x = x_{n+1} - x_n$.

The transmission coefficient is calculated as

$$D(E_x) = \sqrt{1 - \rho(E_x)^2} \quad (3)$$

where

$$\rho(E_x) = \frac{\Xi_n(x, E_x) - \Xi_0}{\Xi_n(x, E_x) + \Xi_0} \quad (4)$$

is the reflection coefficient and

$$\Xi_0 = \sqrt{\frac{2m^*}{\hbar^2}(E_x - \Delta E_C)} \quad (5)$$

In Figure 2, the transmission probability of a simple DBRTS is plotted as a function of the incident electron energy. The structure as shown in the inset is composed of $Al_{0.3}Ga_{0.7}As$ as barriers and GaAs as QW. The QW is 30 Å wide with 30 Å barriers. The conduction band offset is assumed to be 0.25 eV and the effective masses in the barrier and QW are $0.09m_0$ and $0.067m_0$, respectively. Here m_0 is the free electron mass. The peaks in the transmission probabilities correspond to the eigenstates and the widths are related to the lifetime of the carriers of the QW. The dips in the transmission probability for energies greater than the band offset are due to the reflections from the edges of the QW.

The barrier height dependence of transmission probability is investigated in Figure 3. Conduction band offsets of 0.1, 0.2, and 0.3 eV are considered. The QWs with band offsets of 0.1 and 0.2 eV have two eigenstates which move toward higher energy with increasing ΔE_C. The QW with $\Delta E_C = 0.3$ eV has an additional eigenstate close to 0.3 eV. Figure 4 shows the nature of the transmission probability curves with varying QW width. QW widths of 30, 50, and 100 Å with $\Delta E_C = 0.3$ eV are considered. With increasing QW widths more eigenstates are accommodated within the QW. Figure 5 shows the nature of the transmission probability curves in the presence of scattering. The simulated results are with localized elastic and inelastic (phase breaking) scattering at the center of the QW. With elastic scattering at the center of the QW the odd-resonant energies shift toward higher energies. On the other hand, with phase

breaking scattering at the center of the QW the transmission coefficient decreases.

3.2. Carrier Group Velocity and Density of States

Current density in its simplest form, $J = qnv$, is expressed as a product of the carrier concentration, n, and the corresponding drift velocity, v. The determination of the carrier concentration requires the density of states (DOS) and the carrier statistics. The formulation of the local DOS as well as the drift velocity will be presented in terms of the logarithmic derivatives.

3.2.1. Group Velocity

The definition of logarithmic derivative can be recasted in the form [79]

$$\begin{aligned}\frac{\Psi'(x)}{\Psi(x)} &= \alpha(x) + j\beta(x)\\ &= \frac{m^*}{2\hbar}[-\mathrm{Im}(\Xi(x, E_x)) + j\,\mathrm{Re}\Xi(x, E_x))]\end{aligned}$$

which upon integration from $x = 0$ to any x

$$\Psi(x) = \Psi(0)e^{\int_0^x \alpha(x)\,dx}e^{j\int_0^x \beta(x)\,dx} \tag{6}$$

where $\Psi(x)$ is the wave function at point x and $\Psi(0)$ is the wave function of the incident particle at $x = 0$. Depending upon the energy of the incident particle the composite wave, Eq. (6), in the well and in the barriers may build up, giving rise to resonant tunneling, or simply tunnel through the device structures as in ordinary tunneling. At resonance, the logarithmic derivative of an electron outside a symmetrical structure is purely real and has a constant value. The wave function described by (6), in this case, reduces to positive traveling plane waves outside the barrier.

The average probability current density at any x, of the quantum mechanical system

$$\begin{aligned}S(x) &= \frac{1}{2}\mathrm{Re}\left(\frac{2\hbar}{jm^*(x)}\Psi'\Psi\right)\\ &= \frac{1}{2}\,|\Psi(0)|^2\,\mathrm{Re}(\Xi(x, E_x))e^{2\int_0^x \alpha(x)\,dx}\end{aligned} \tag{7}$$

when equated to the particle current as obtained from conservation principle

$$S(x) = v_g(x)\,|\Psi(x)|^2 \tag{8}$$

yields the group velocity which is expressed as

$$v_g(x) = \frac{1}{2}\mathrm{Re}(\Xi(x, E_x)) \tag{9}$$

The group velocities of the electron at the first and second resonant energies are plotted in Figure 6. A 100 Å QW with conduction band offset of 0.25 eV is considered. It should be noticed that the velocity peaks at the same location where the electron wave function is at its minimum.

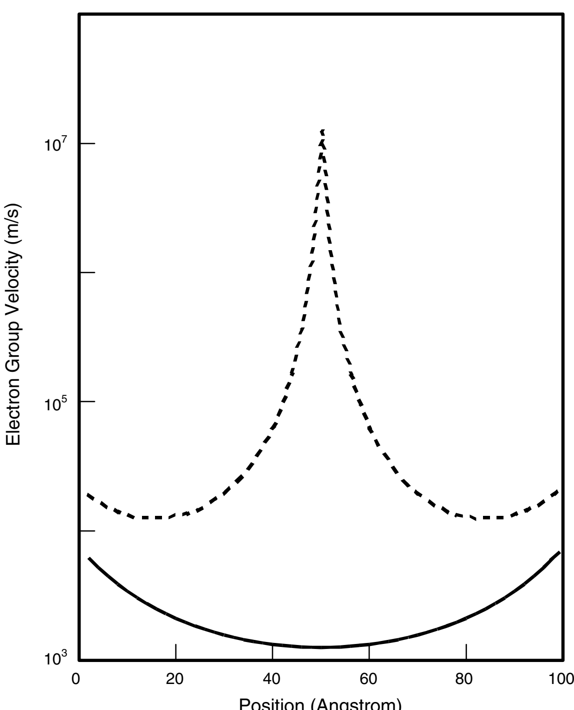

Figure 6. Electron group velocity for the first (solid line) and second (dashed line) eigenstates.

3.2.2. Density of States

For a given DBRTS, the one-dimensional density of states is given as [80, 81]

$$N(x, E_x) = \frac{2}{\pi} \mathrm{Im}[G^R(x, x, E_x)] \tag{10}$$

where $G^R(x, x, E_x)$ is the retarded Green's function and is obtained as the solution of the following Schrödinger equation:

$$\left[E_x - H_0 + \frac{j\hbar}{2\tau_\varphi(x, E_x)}\right] G^R(x, x, E_x) = \delta(x - x_1) \tag{11}$$

The Hamiltonian

$$H_0 = -\frac{\hbar^2}{2m^*}\left(\frac{d^2}{dx^2} + \Delta E_C(x)\right)$$

is the unperturbed part of the total Hamiltonian and τ_ϕ is the phase breaking time. The calculation of DOS necessitates the computation of only the diagonal elements of the retarded Green's function and the off-diagonal elements are less significant. The diagonal elements of the Green's function can be computed by using the logarithmic derivatives $\Xi(x, E_x)$and are expressed as

$$N(x, E_x) = \mathrm{Im} \frac{-\frac{j4}{\hbar}}{\Xi^+(x, E_x) - \Xi^-(x, E_x)} \tag{12}$$

where

$$\Xi(x, x_1, E_x) = \frac{2\hbar}{jm^*} \frac{\frac{\partial G^R(x, x_1, E_x)}{\partial x}}{G^R(x, x_1, E_x)} \tag{13}$$

The global DOS $N(E_x)$ is obtained by integrating Eq. (12) along the QW,

$$N(E_x) = \int_0^{L_W} N(x, E_x)dx \tag{14}$$

where L_W is the length of the QW.

3.3. Self-Consistent *I–V* Calculation

The determination of the current–voltage characteristic that takes into account the potential due to the space charge developed within the QW demands that the Schrödinger and Poisson equations are solved self-consistently. Kluksdahl et al. [82] report self-consistently calculated current–voltage characteristics using the Wigner function to model quantum transport. In this section we use the method of logarithmic derivatives to self-consistently calculate the current–voltage characteristics.

The total current flowing from the emitter to the collector is given in terms of the currents from the emitter to the collector J^+ and from the collector to the emitter J^-, respectively [80, 83],

$$\begin{aligned} J^+ dE_x &= J_{E\to C}(E_x)dE_x \\ &= \frac{qm^*kTD^+(E_x)}{2\pi^2\hbar^3} \frac{e^{qV_{\text{Applied}}/kT}}{e^{qV_{\text{Applied}}/kT} - 1} \\ &\quad \cdot \ln\left[\frac{1 - e^{(E_F - E_x)/kT}}{1 + e^{(E_F - E_x - qV_{\text{Applied}})/kT}}\right] dE_x \end{aligned} \tag{15a}$$

$$\begin{aligned} J^- dE_x &= J_{C\to E}(E_x)dE_x \\ &= \frac{qm^*kTD^-(E_x)}{2\pi^2\hbar^3} \frac{1}{e^{qV_{\text{Applied}}/kT} - 1} \\ &\quad \cdot \ln\left[\frac{1 - e^{(E_F - E_x)/kT}}{1 + e^{(E_F - E_x - qV_{\text{Applied}})/kT}}\right] dE_x \end{aligned} \tag{15b}$$

where V_{Applied} is the applied bias. So the total current is given by

$$J = \int_0^\infty [J^+(E_x) - J^-(E_x)]\, dE_x \tag{16}$$

The expression for J^+ and J^- assumes a Fermi–Dirac distribution with E_F as the Fermi level. D^+ (D^-) is the transmission probability looking from the emitter toward the collector (collector toward emitter).

The contribution of space charge will change the potential profile in the quantum well as dictated by Poisson's equation. The charge concentration in the quantum well is written as

$$n^\pm(x) = \int_0^\infty n^\pm(x, E_x)\, dE_x \tag{17}$$

where

$$n^\pm(x, E_x) = \frac{J^\pm(E_x)}{qv_g^\pm(x, E_x)} \tag{18}$$

where the superscript + (−) indicates the contribution due to the current J^+ (J^-). The total charge is obtained as

$$n(x) = \int_0^\infty dE_x \sum_\pm n^\pm(x, E_x) \tag{19}$$

The updated potential profile is obtained by solving Poisson's equation and is given by

$$\phi(x) = \phi(0) - \frac{q}{\varepsilon} \int dx' \int dx''\, n(x'') \tag{20}$$

where ε is the dielectric constant and $V_{sc}(x) = -q\phi(x)$.

The self-consistently obtained current–voltage characteristic is shown in Figure 7. The structure considered is similar to that shown in Figure 1 with 30 Å barriers and 50 Å QWs. The doping concentrations of the contact GaAs layers are 2×10^{18} cm^{-3}. The Fermi level E_F is assumed to be 0.03 eV above the bottom of the conduction band at the emitter contact. The total applied voltage is the sum of the voltage drops across the DBRTS, the voltage drop across the depletion region at the collector contact, V_d, and the drop across the accumulation region at the emitter contacts, V_a. V_d and V_a are determined by solving the equations [75]

$$V_d = \frac{qn_s^2}{2\varepsilon_{\text{collector}} N_D}$$
$$e^{qV_a/kT} - \frac{qV_a}{kT} - 1 = \frac{q^2 n_s^2}{2\varepsilon_0 kTN_D} \tag{21}$$

where N_D is the doping concentration at the contact layers. The current peaks at an applied bias of 0.13 V and corresponds to the first virtual state of the DBRTS. On the same plot, current obtained when the voltage was scanned from 0.6 to 0 V, is shown. The two graphs are different in the region showing negative differential resistance and this is attributed to the presence of space charge within the QW. The observed bistability is a strong function of the width of the QW.

In Figure 8, current–voltage characteristics are plotted in the presence of elastic and phase breaking scattering. Comparing Figures 7 and 8, it is to be noticed that in the presence of elastic scattering the peak current shifts to higher bias that is attributed to the shift in the first resonant energy as depicted in Figure 5. In the presence of phase breaking scattering a drastic reduction in the peak current magnitude is observed and is in accordance with Figure 5.

Figure 9a and b shows the self-consistently obtained group velocity as a function of the incident electron energy and position inside the QW for positive and negative voltage sweeps, respectively [78]. Figure 10a and b shows the self-consistently obtained effective density of states as a function of incident electron energy and position [80]. Figure 10a is obtained by assuming $\tau_\varphi = \infty$ or, in other words, scattering was not considered. Figure 10b is obtained by self-consistently calculating τ_φ.

4. CARRIER DYNAMICS (TUNNELING TIME)

DBRTS, biased in the NDR region, is widely investigated for possible applications requiring very high frequency oscillations. The determination of the high frequency of oscillation is based upon the evaluation of the lifetime of the resonant states. The study of traversal or tunneling time of

Jahan, Self-consistent Study of the Effect of Transverse Magnetic Field on the Performance of the Double Barrier Resonant Tunneling Structure, M.S. Thesis, University of Connecticut, Storrs, CT, 1993.

an electron through a resonant tunneling structure, in general, has attracted much attention. The early work on tunneling time using the phase method was by Wigner [84]. Phase time can be defined locally as it is an asymptotic quantity [85]. The concept of dwell time was proposed by Smith [86] and was used by Leavens and Aers [87]. The speed of operation of NDR devices has been investigated by several authors, namely Ricco and Azbel [88], Luryi [89], and Harada and Kuroda [90]. Luryi [89] estimated the speed of operation by calculating the *RC* delay of a single barrier. Harada and Kuroda [90] studied the time evolution of an electron wave packet localized in a QW. Ricco and Azbel [88] proposed that the average time spent by an electron in the device (dwell time) should provide a good measure of the time constant required for the system to approach its final configuration. The concept of a Larmor clock to calculate particle lifetime was introduced by Baz [91] which later was extended by Rybachenko [92] and Buttiker [93]. Büttiker and Landauer [94] calculated tunneling time using the WKB approximation by considering tunneling through a time-modulated barrier. Tunneling time through a single barrier in the presence of a transverse magnetic field has been addressed by Guéret et al. [95] These calculations can be extended to study the effect of the different structure parameters, such as barrier width or height, on tunneling time. The readers will find the review article by Landauer and Martin [96] very informative in dealing with topics on tunneling time.

Tunneling time for a DBQWS of length L can be written as [78, 79, 83, 96–99]

$$\tau^{\pm}(E_x) = \int_0^L \frac{dx}{v_g^{\pm}(x, E_x)} \tag{22}$$

where the $\pm$ sign implies that the electron is moving from the emitter (collector) to the collector (emitter) electrode. It has been argued by Anwar et al. [79] that the traversal time thus defined is the sum of the time required for the electron to build up inside the QW and the corresponding decay time. In the event the buildup and decay times are equal, the traversal time τ_T equals twice the electron lifetime. Table 1 provides a comparison of the calculated traversal time and lifetime obtained from numerical calculation [99].

The dependence of traversal time on barrier thickness for a given QW width is depicted in Figure 11 [99]. For symmetric barriers, traversal time increases exponentially with barrier thickness. To investigate the sensitivity of traversal time on barrier widths an asymmetric structure is considered as shown in Figure 12 [99]. The QW width is fixed at 100 Å and traversal times for the two lowest resonant energy levels are shown. It is observed that the traversal time is rather insensitive to the variation of the width of the left (emitter) barrier, whereas it is increases exponentially with the increase of the right (collector) barrier width.

The self-consistently calculated traversal time (the time it takes for the carrier to traverse the DBRTS) is plotted as a function of the applied bias in Figure 13. The self-consistent calculation takes into account the space charge formed within the QW. A double barrier resonant tunneling structure consisting of a 100 Å wide quantum well is used while the barriers are 30 Å wide. Traversal time initially decreases with increasing bias and the rate slows down followed by a change in slope around 0.17 V and can be correlated with the device in the negative differential resistance region as seen from the I–V characteristics. The decrease beyond 0.2 V is correlated to the positive differential resistance region of the I–V characteristics.

The effect of barrier width on the traversal time has been investigated by varying both the emitter and the collector barrier widths. The traversal times for the symmetric and the asymmetric cases are then compared. It is observed that the traversal time for a given incident energy is a function of the degree of the asymmetry of the structure.

Table 1. Comparison of the traversal time, τ_T, with the lifetime, τ, obtained from simulation [90], for a symmetrical well.

V_0 (mV)	L_w (Å)	d (Å)	Lifetime, $\tau^{[90]}$ (ps)	Traversal time, τ (ps)
400	20	20	0.022	0.04549
		40	0.37	0.751
		60	6.1	12.31
	50	20	0.23	0.458
		40	8.9	17.93
		60	360.0	716.0
	100	20	2.1	4.23
		40	110.0	223.88
		60	5900.0	11769.0

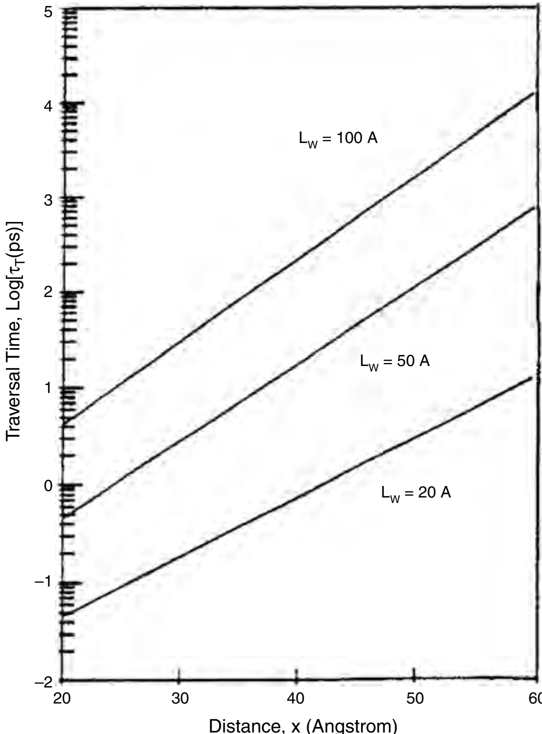

Figure 11. Traversal time of a symmetric DBRTS with QW width as a parameter. The barriers are 80 Å wide. Reprinted with permission from [99], A. F. M. Anwar, On Modelling of Quantum Well Devices, Ph.D. Dissertation, Clarkson University, Potsdam, NY, 1988.

In Figure 14, the quantity τ_V^+/τ_V^- is plotted as a function of energy and bias voltage for structures II (70–50–50 Å) and III (50–50–70 Å) respectively. A flatter surface means less bistability. It is observed from the figures that as the collector barrier is made wider the surface of the plot becomes flatter as compared to the case if emitter barrier is made wider. Thus, the wider emitter structure shows greater bistability than the wider collector structure. The observed bistability can be explained in terms of the space charge developed inside the quantum well which is a strong function of the asymmetry of DBQWS. Bistability in tunneling time depends on the difference in the amount of space charge between two sweeps for a particular bias voltage. As is evident from Figure 15, the space charges for structure III for both positive and negative sweeps are of the same order of magnitude, whereas, for structure II, they differ by an order of magnitude. This can be explained in terms of two current components $J^+$and J^-. For all structures, J^+ is of the same order of magnitude for both sweeps. J^- for structures I and III is the same for positive sweep. However, J^- for structure II is a few orders of magnitude higher in the potential range of 0 to 0.03 V and then follows the rest. In the negative sweep, the J^- characteristics are the same in the voltage range beyond 0.04 V. In the range 0 to 0.04 V, J^- for structure III is twice that of structure I (50–50–50 Å), whereas, the structure II current is a few orders of magnitudes higher. Though J^- is negligible compared to J^+, its behavior controls the extent of the bistable region in traversal time. We believe that a comparatively larger J^- in structure II is responsible for the difference in space charge

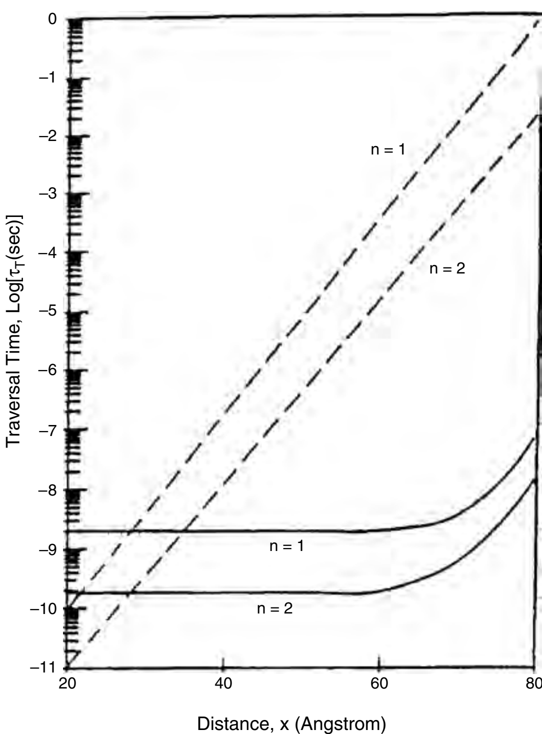

Figure 12. Traversal time for the first two eigenstates of a 100 Å wide asymmetric QW. Solid lines represent traversal time with varying d_L with $d_R = 30$ Å. Dashed lines represent traversal time with varying d_R with $d_L = 30$ Å. Reprinted with permission from [99], A. F. M. Anwar, On Modelling of Quantum Well Devices, Ph.D. Dissertation, Clarkson University, Potsdam, NY, 1988.

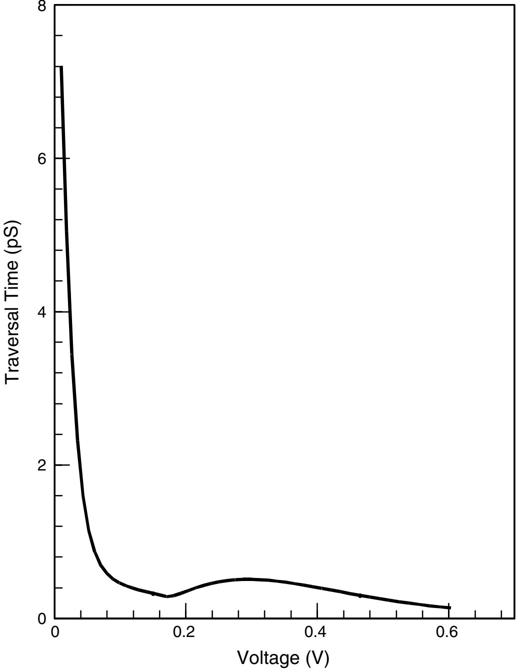

Figure 13. Self-consistently calculated traversal time as a function of applied bias.

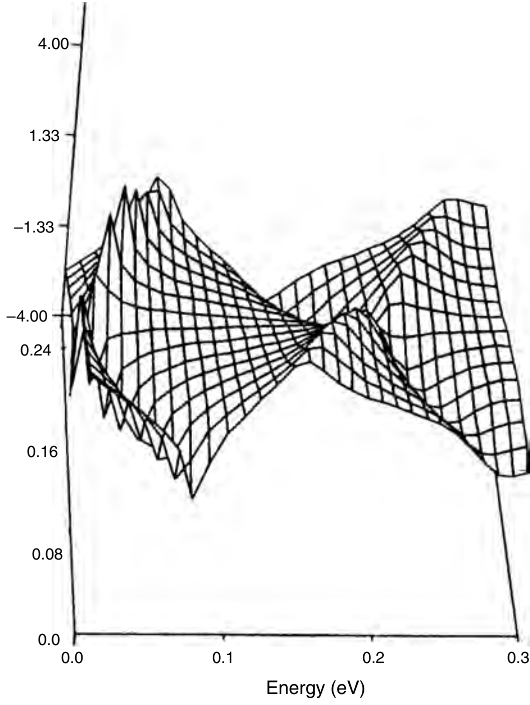

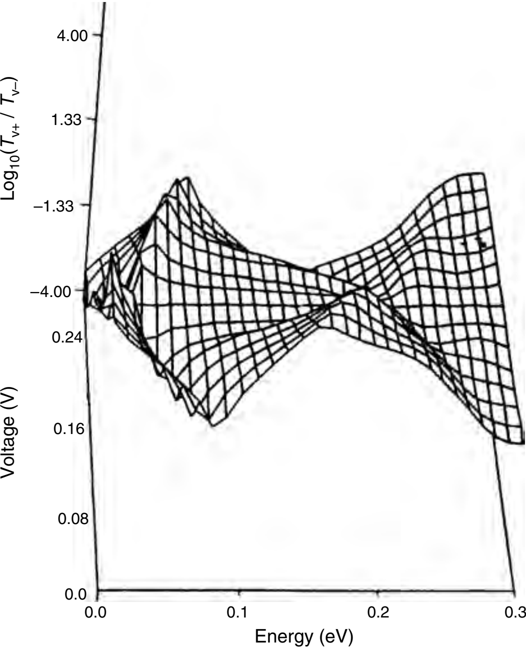

Figure 14. The ratio of τ_{v+} and τ_{v-} are plotted for structure II and structure III. Reprinted with permission from [78], A. F. M. Anwar and M. M. Jahan, *IEEE J. Quantum Electron*. 31, 3 (1995). © 1995, IEEE.

and may explain the large bistability in this structure. Also to be noted is that the space charge for structure III is much greater than that for structure II. This can be explained by noting that structure III has a higher transmission than structure II and the group velocity is of the same order of magnitude. In this connection, it is instructive to study the behavior of effective group velocity that is calculated by evaluating the quantity $J/[qn(x)]$.

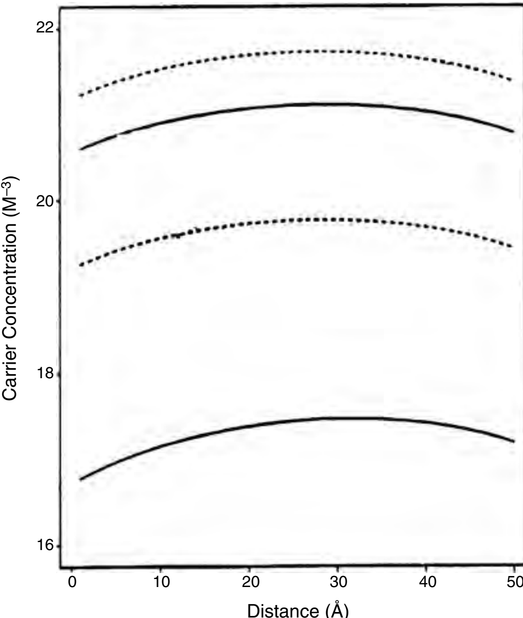

Figure 15. Space charge is plotted as a function of position. Solid and dashed lines represent positive and negative voltage sweep, respectively. Figure 16. Traversal time as a function of applied bias. Structure I (solid line), structure II (dashed line), and structure III (dotted line).

The issue of group velocity can further be studied as a function of incident energy and position along the structure. Figure 9 shows the results for structure II for both positive and negative sweep of bias voltage. It is observed that the two sweep group velocities differ significantly in the neighborhood of 0.04 eV. As mentioned earlier, this behavior in the low energy region makes the two sweep space charge differ significantly. However, for structures I and II, the difference in behavior in the low energy region is less pronounced and hence the space charge for two sweeps also differs less.

Figure 16 shows the plot of effective tunneling time as a function of bias voltage for all three structures. Here again it is observed that a wider emitter structure requires a longer time than a wider collector structure.

5. DBRTS CAPACITANCE

The promise of ultrahigh speed operation of a DBRTS has stimulated a host of research devoted to the understanding of the factors that affect the frequency of operation of the device [100–104]. Capacitance and the associated conductance of the device are particularly important in this regard. The capacitance of a DBRTS consists of three principal components: (a) accumulation region capacitance C_a, (b) depletion region capacitance C_d, and (3) capacitance due to stored charge in the quantum well C_w. This warrants the inclusion of the capacitance C_w due to stored charge in the quantum well [102].

Brown et al. [100] calculated the capacitance by approximating DBRTS as a parallel plate capacitor with a spacing that is a sum of the widths of the depletion region, the accumulation region, and the structure itself. The neglect of space charge in the quantum well was not justified and was later pointed out by Hu and Stapleton [102]. Consequently, Hu and Stapleton provide a scheme [102, 103] to include the effects of space charge inside the quantum well in the calculation of the capacitance of DBRTS. They assumed a horizontal bar to replace the actual conduction band profile and used the Airy function to solve the trapezoidal barrier. As the discussion in the last paragraph suggests, the assumption of a horizontal conduction band in the quantum well might not be a valid approximation. Fernando and Frensley [104] solved the periodic time-dependent Schrödinger equation under a weak ac field to determine the high frequency characteristics of DBRTS.

Figure 17 shows the equivalent circuit of DBRTS. C_a and C_d are in series and C_w is in parallel to the combination. Also in parallel is the conductance of DBRTS, G. C_w is calculated as

$$C_w = A\frac{dQ}{dV}\frac{dV}{dV_{\text{Applied}}} \tag{23}$$

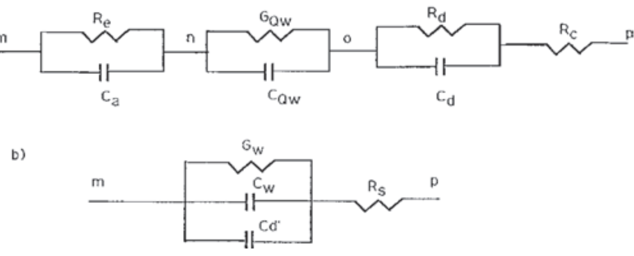

Figure 17. Small signal equivalent circuit of a DBRTS.

where Q is the total space charge in the quantum well due to traversing electrons, A is the cross-sectional area of the device, V is the voltage across the DBRTS, and V_{Applied} is the total applied bias. The calculation of $Q = -q\int_0^{L_w} n(x)\,dx$ requires the computation of the current–voltage characteristics of DBRTS.

The total capacitance is plotted as a function of the applied bias in Figure 18. The stored charge in the QW redistributes upon the application of an applied bias due to the perturbation of the eigenstates.

The frequency, f, at which a DBRTS oscillates is obtained from the requirement that the real part of the impedance be negative:

$$f = \frac{1}{2\pi C}\left(\frac{G}{R_s} - G^2\right) \tag{24}$$

For a 11–45–11 Å GaAs/AlAs DBRTS an oscillation frequency of 430 GHz is obtained which is in agreement with the experimental observation of 420 GHz by Brown et al. [100].

6. SHOT NOISE

In this section shot noise is calculated in a DBRTS by taking the space charge accumulated inside the quantum well into account. The calculation is self-consistent in nature and is obtained by simultaneously solving the Schrödinger and Poisson equations. The calculation shows the suppression of shot noise in the positive differential resistance (PDR) region and an enhancement in the NDR of the DBRTS. This behavior is explained in terms of the auto- and cross-power density spectrum of current in the presence of space charge in the quantum well. The calculated shot noise factor shows a suppression in the PDR region ($\gamma = 0.31$) and an enhancement in the NDR region ($\gamma = 9$) as observed experimentally.

Shot noise [80, 105–108] is observed in almost all electronic devices and is due to the fluctuations in device current. The fluctuations are attributed to the discreteness and randomness of the carrier flowing through the device. Therefore, any process that will affect the random nature of the carriers or eliminate the discreteness of charge will give rise to shot noise that deviates from the full shot noise. Although it is not possible to eliminate the discrete nature of the charge, however, it is possible to affect the randomness associated with the emission of the carriers in the device. This is the phenomenon that occurs in a DBRTS where the stored space charge in the quantum well alters the randomness of the injected carriers and may result either in the suppression or enhancement of shot noise [102]. It is customary to represent the deviation from the full shot noise behavior by shot noise factor γ. $\gamma > I$ for shot noise enhancement and $\gamma < I$ for shot noise suppression.

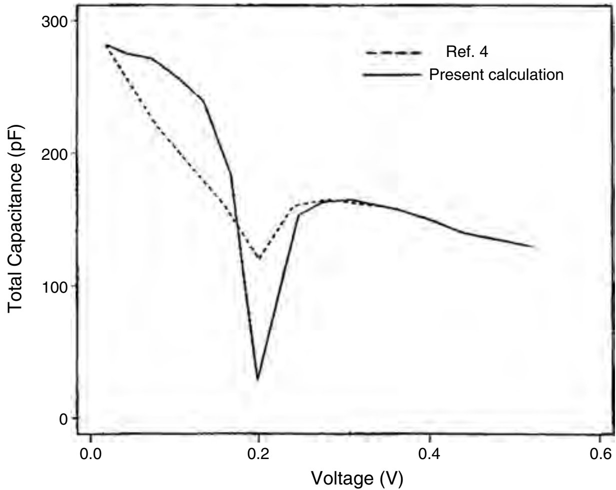

Figure 18. Total capacitance of a DBRTS.

Li et al. [106] reported the measurement of shot noise suppression of DBRTS below 10 kHz. Ran and Barnes [107] showed that shot noise may be significantly lowered by using quantum wells. They assumed distributions for both the velocity and the density of carriers incident on the quantum well structure and then used the results of quantum mechanics for describing the transport through the well. Brown [105] has presented a theoretical analysis of the suppression and enhancement of shot noise. In his analysis, the space charge is modeled as delta function at the center of the quantum well. However, the calculation was not self-consistent in nature and an exact space charge distribution was not taken into account.

The treatment presented here takes into account an exact space charge distribution and is used to compute the shot noise factor self-consistently. As an electron traverses through a DBRTS, it spends a finite amount of time inside the structure and thus the space charge gets accumulated in the quantum well. The magnitude of the space charge contributed by a traversing electron is a function of the energy level. The contribution of space charge due to an electron is also affected by the presence of other electrons. This gives rise to two different types of power density spectrums: the auto-power density spectrum (APDS) that is related to the state itself and the cross-power density spectrum (CPDS) that depends on the cross-correlation among different current carrying states. To make a self-consistent calculation of shot noise, these correlation terms need to be computed by solving the Schrödinger and Poisson equations simultaneously as has been described in previous sections.

The self-consistently calculated potential energy $V_{\text{SC}}(x)$ may also be expressed in the form [80]

$$V_{\text{SC}}(x) = \sum_{i=1}^{N} V_{\text{SC}}(x, E_x^i) \tag{25}$$

where $V_{\text{SC}}(x, E_x^i)$ denotes the space charge induced potential due to the flow of current at E_x^i. By considering $V_{\text{SC}}(x, E_x^i)$ as a perturbation potential, the shift in the eigenenergy levels and the modified $D(Ex)$ can readily be evaluated. The shift in the energy levels produces an effective perturbation in the output current that may be written as

$$(\Delta J)^2 = \sum_{i=1}^{N}\sum_{j=1}^{N}\left[\Delta J(E_x^i, E_x^i)\right]^2 \tag{26}$$

where $\Delta J(E_x^i, E_x^i)$ is the current density at E_x^i due to perturbation of E_x^j. $(\Delta J)^2$ contains all the mean square information about APDS and CPDS and is used to calculate the shot noise factor of the structure. Shot noise power spectrum S is obtained as [80]

$$S = \frac{(\Delta J)^2}{\delta f} \tag{27}$$

where δf is the measurement bandwidth. Shot noise factor γ is expressed as

$$\gamma = \frac{S}{2qJ} \tag{28}$$

where J is the total current density, and q is the electronic charge, 1.6×10^{-19} Coulomb.

In Figure 19, the shot noise factor is plotted as a function of bias voltage. The plot shows a suppression of shot noise factor ($\gamma < I$) in the PDR region and an enhancement ($\gamma > I$) in the NDR region. The departure of γ from the full shot noise ($\gamma = I$) behavior is the consequence of the space charge developed inside the quantum well. The stored charge affects shot noise in essentially two different manners in the PDR and NDR regions. Figure 20 shows the space charge that is stored in the quantum well as a function of bias voltage. The space charge affects the I–V characteristics on two fronts: (a) First, a voltage drop is associated with the space charge which effectively reduces the net voltage across the DBRTS. Consequently, the current gets peaked at a voltage which is little higher than the case if no space charge were considered. (b) Second, space charge introduces a perturbation which affects the energy levels as well as transmission coefficients of the quantum well. In general, the effect of the perturbation is to introduce a positive shift into the transmission peaks along the energy scale. The latter phenomenon may enhance or diminish the current depending on the bias of the DBRTS. For example, if the device is biased in the PDR region, the positive shift in energy will reduce the current. On the other hand, current will increase if the device is biased in the NDR region. It is the global effect of these two mechanisms that brings about a net decrease of current in the NDR region and a net increase in the PDR region. The similar ratiocination also applies to the noise current. In Figure 19, experimental data reported by Brown [105] are also shown. The agreement of the calculated shot noise factor and the experimentally obtained one is good.

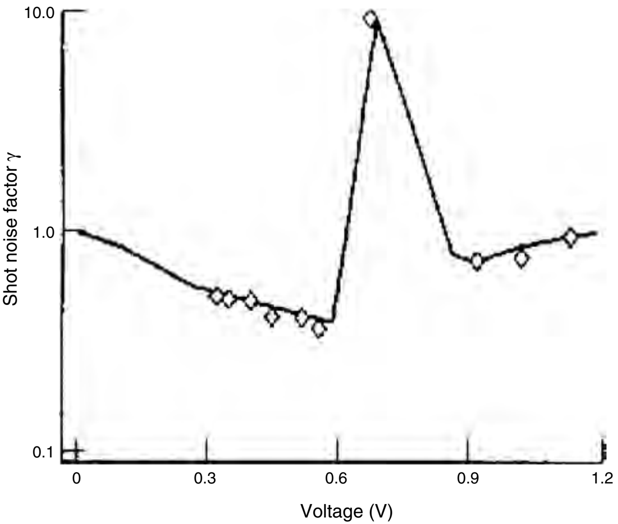

Figure 19. Shot noise as a function of applied bias. Measured data (diamond) and calculated results (solid line). Reprinted with permission from [80], M. M. Jahan, Self-consistent Study of the Effect of Transverse Magnetic Field on the Performance of the Double Barrier Resonant Tunneling Structure, M.S. Thesis, University of Connecticut, Storrs, CT, 1993.

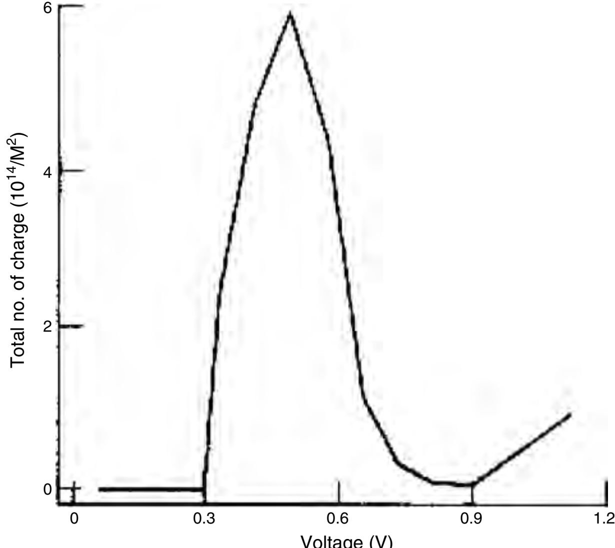

Figure 20. Space charge as a function of applied bias. Reprinted with permission from [80], M. M. Jahan, Self-consistent Study of the Effect of Transverse Magnetic Field on the Performance of the Double Barrier Resonant Tunneling Structure, M.S. Thesis, University of Connecticut, Storrs, CT, 1993.

7. CONCLUSION

In recent years DBRTS has provided the means to realize transport in reduced dimension. This has necessitated the formulation of carrier transport that incorporates the effect of scattering in reduced dimension. Moreover, DBRTS has facilitated the realization of devices with unique performance.

GLOSSARY

FET Transistor in which output drain current is controlled by the voltage applied to the gate. In a MOSFET an oxide insulator is present in between the metal and semiconductor.

Negative differential resistance (NDR) Where the current decreases with increasing voltage observed in current-voltage characteristics.

PVR The ratio of the peak (maximum) current to that of the valley (minimum) current.

Quantum well (QW) A quantum well is like a well where a particle can be trapped. Layers made by using different

semiconductor materials may result in the trapping of carriers (electrons, holes) in a particular layer. The trapped carriers and confined and are restricted to make certain movements or move in certain directions. The presence of QWs has resulted in modern electronic devices such as high electron mobility transistors (HEMTs), heterojunction bipolar transistors (HBTs) and photonic devices such as QWIPs.

Schottky barrier height Potential barrier in between the metal and semiconductor in metal semiconductor contact.

1. INTRODUCTION

One of the most important physical parameters to describe the quality of a piece of semiconductor material is the electron scattering length l_e. Also referred to as the mean-free path, it stands for the average distance between the randomly distributed scatterers in the material, such as lattice defects, impurities, and phonons. The electron mean-free path is typically a few nanometers (1 nm $= 10^{-9}$ m) in silicon and about 100–200 nm in high-quality compound semiconductors such as GaAs. The electrical resistance of a semiconductor device is closely associated with the scattering length l_e. Conventional semiconductor devices are much larger than the electron scattering length. As a result, electrons have to encounter a large number of random scattering events to travel from one device lead to another. In the last two decades, advanced semiconductor technologies have allowed the fabrication of devices that are smaller than the electron scattering length. In such devices, electrons may travel from one electric lead to another without encountering any scattering event from randomly distributed scatterers such as impurities. Instead, the electrons are scattered only at the device boundaries, that is, moving like billiard balls. Such electron transport is referred to as ballistic transport [1–3]. There had been a long debate in history on whether there is any electric resistance in such ballistic electron devices. Some had believed that the absence of scattering means that the resistivity inside the device is zero. Although this is, as will be discussed later, wrong because the concept of resistivity does not hold any longer in the ballistic transport regime, it was realized quite clearly that the electron transport in a ballistic device is very different from the transport in a traditional, macroscopic semiconductor device.

Consider a conventional semiconductor device that is much larger than the electron scattering length. Any electric current induced by an applied voltage consists of electrons diffusing in an electric field, as shown in Figure 1. The diffusive transport can be described by Ohm's law, which states a linear relation between the current and electric field (or applied voltage). However, if we examine the electron transport at the microscopic scale, we would find that every electron is accelerated between two subsequent scattering events by the electric field. As a result, the velocity component of the electron in the opposite direction of the electric field increases constantly until the next scattering event occurs. Since the current carried by the electron is equal to its velocity multiplied by the electron charge e, the current is time dependent, even in the presence of a constant electric field. This is seemingly in contradiction to Ohm's law. Actually, Ohm's law is valid at the macroscopic scale because of the existence of the large number of scattering events, which counteract the acceleration effect of the electric field, causing the average velocity of all electrons to be proportional to the strength of the electric field. The above discussion reveals that, at a scale that is smaller than the average distance between impurities or other scatterers, Ohm's law does not hold, and that new transport properties are expected to arise in these ballistic devices of a dimension smaller than l_e.

A number of new device concepts have been generated based on ballistic electron transport in the last two decades. Among these novel devices are only a few that have been demonstrated to work at room temperature. Quite understandably, being capable of operating at room temperature is an important criterion for practical applications. In this chapter, we review these recent breakthroughs in room-temperature ballistic devices. The theoretical framework to treat ballistic electron transport, namely, the scattering

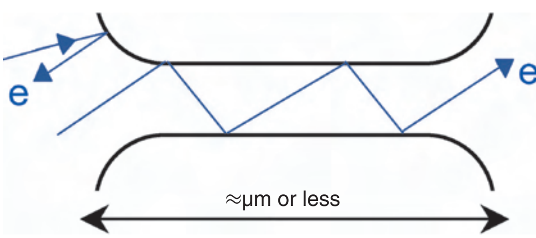
Diffusive electron transport in a macroscopic device

Figure 1. Schematic view of the diffusive electron transport in a macroscopic semiconductor device. The device size is much larger than the electron scattering length. As a result, the electrons experience a large number of scattering events from randomly distributed scatterers such as lattice defects and phonons (represented by the asterisks), and the electron transport is hence referred to as diffusive.

approach developed by Landauer and Büttiker, will be introduced. We will also discuss the promising possibilities for practical applications of these devices from the point of view of their new device properties. The chapter is organized as follows. After a short introduction to the ballistic transport in Section 1.1, an overview of the general aspects of nonlinear ballistic electron transport is presented in Section 1.2, which forms a basis for the few types of room-temperature nanodevices and nanomaterials discussed in Sections 2–4. In Section 5, promising results on near room-temperature operations of quantum-effect-based nanodevices are discussed. Finally, Section 6 provides conclusions and an outlook of future developments.

1.1. Overview of Ballistic Electron Transport

Ballistic electron transport is normally realized in mesoscopic semiconductor structures. The word "mesoscopic" refers to dimensions between the atomic scale and the macroscopic scale. The simplest mesoscopic ballistic device is a narrow, uniform semiconductor channel, as shown in Figure 2. At a finite applied voltage, a current flows through the channel. If the length of the channel is shorter than l_e, the electron transport inside the channel is ballistic. The electrons, when moving from one side of the channel to the other, do not experience any random scattering event from scatterers such as lattice defects, impurities, and phonons, but are scattered only by the designed device boundary. This



Ballistic electron transport in a mesoscopic device

Figure 2. Schematic view of the ballistic electron transport in a mesoscopic semiconductor device, which is smaller than the electron scattering length. In the device, the electrons do not experience any scattering event from random scatterers such as lattice defects and phonons, and are only scattered by the designed device boundary.

means that, even at a finite applied voltage, the electric field, and therefore the voltage drop inside the central part of the channel, which has a constant width, have to be zero in order to fulfill the requirement of the conservation of current: the current flow into one end of the channel must be the same as the current flow out of the channel at the other end. Therefore, inside the channel, current flows without the existence of a finite electric field. The striking phenomenon appears to be similar to the superconductivity effect, but occurring in a completely different physics system under a different physical condition. Such an effect of current flow without the presence of an electric field has been observed regardless of the length and width of the channel, as long as the channel is shorter than the electron mean-free path. Nevertheless, to drive a current through the entire device, a finite voltage has to be applied. The applied voltage will only drop at the entrance and exit of the channel, where finite resistance arises because most of the electrons are backscattered and only a fraction of the electrons can enter the channel [4]. As a consequence, the electric field exists only in the close vicinity of the entrance and exit of the channel. Clearly, local quantities such as resistivity and conductivity lose their meaning, and can no longer be defined in a ballistic semiconductor device. Only nonlocal quantities such as the total resistance or conductance can be used.

The conductance of a ballistic semiconductor device G is determined by an important nonlocal quantity: the transmission coefficient $T_{\beta\leftarrow\alpha}$ of the ballistic electrons going from one electric contact (also often referred to as the electric lead, carrier reservoir, or device terminal) α to anther contact β. If more than one transverse quantum confinement mode in the device is occupied, $T_{\beta\leftarrow\alpha}$ is the sum of the transmission probabilities of the electrons at each occupied transverse quantum confinement mode i:

$$T_{\beta\leftarrow\alpha} = \sum_i t_{\beta\leftarrow\alpha,\,i} \tag{1}$$

As described by the Landauer–Büttiker formula [5–7], the current flow through the narrow channel is given by

$$I = \frac{2e}{h}\sum_i t_{\beta\leftarrow\alpha,\,i}(\mu_\alpha - \mu_\beta) \tag{2}$$

where μ_α and μ_β are the chemical potentials of the electrons at the left and right contacts of the channel. If the electrons at each transverse mode transfer through the channel perfectly (without being reflected back), which was found to be the case if the boundary of a narrow channel is smooth and if the temperature is sufficiently low [8, 9], the overall conductance of the channel becomes quantized:

$$G = N\frac{2e^2}{h} \tag{3}$$

Here, N stands for the total number of the occupied transverse quantum confinement modes by the electrons in the channel, and spin degeneracy is assumed. This quantized conductance is fundamentally similar to the quantized Hall conductance at a high magnetic field: both are direct manifestations of one-dimensional electron transport [10]. Therefore, the quantum Hall effect has also been

elegantly described in the theoretical framework of the Büttiker–Landauer formalist [11].

It has been expected that devices based on ballistic electron transport have superb performance. Since electrons are free from random scattering events, ballistic electron devices may have a very high intrinsic working speed and a quick response. Secondly, the strongly temperature-dependent phonon scatterings, which in some cases lead to serious degradation in device performance in a traditional electron transport device, do not exist in a ballistic device by its nature. Therefore, ballistic devices in general are less temperature dependent.

It is easiest to realize ballistic electron transport at cryogenic temperatures using III–V compound semiconductor materials because of the long electron mean-free path obtained under both conditions. For example, l_e exceeding 160 μm has been observed in a high-quality GaAs–AlGaAs heterostructure at temperature $T = 0.1$ K [12]. Therefore, it is even possible to use conventional photolithography to fabricate devices smaller than l_e and realize ballistic transport at low temperatures. There have been a great number of studies on ballistic electron transport, and many striking phenomena were discovered in various types of ballistic devices. Examples are the above-mentioned quantized conductance in a point contact [8, 9], electron focusing experiments [13–16], negative bend resistance [17], quenched and negative Hall effects [18–20], and lateral hot ballistic electron devices [21, 22].

New transport properties realized in the ballistic transport regime have inspired inventions of novel device concepts. Many of the new concepts are based on the fact that the only scatterings that the ballistic electrons experience are those from the designed device boundaries. By simply tailoring the boundary of a ballistic device, the electron transport can be, to a large extent, modified and controlled. It is hence possible to generate new device functionalities by simply tailoring the device shape. In contrast, due to the nature of the diffusive electron transport, the properties of a traditional device are not sensitive to a change in the device boundary.

Despite great experimental efforts, only a small number of successful experiments have demonstrated ballistic transport at room temperature. From the application point of view, it is highly desirable that new types of ballistic devices are capable of operating at room temperature. At room temperature, the electron mean-free path in a III–V semiconductor heterostructure is typically from 100 to 200 nm. Device dimensions smaller than or at least comparable to l_e at $T = 300$ K are therefore required. This is, however, very difficult if using a GaAs–AlGaAs heterostructure due to the large depletion length (around 100 nm) close to the etched device boundary. The much shorter depletion length (below 30 nm) in, for example, InGaAs–InAlAs or InGaAs–InP material systems, makes it possible to fabricate much smaller devices that work at room temperature. In general, it is also easier to achieve a higher sheet carrier density in an InGaAs–InAlAs heterostructure (up to around 1×10^{12} cm^{-2}) than in a GaAs–AlGaAs system. The higher carrier density not only reduces the depletion length, but also increases the Fermi velocity, and hence enhances the electron mean-free path.

Figure 3 schematically shows a device fabricated by Hirayama and Tarucha using an AlGaAs/InGaAs/GaAs modulation-doped heterostructure [23]. This is, to the author's knowledge, the first device that has been demonstrated to show ballistic electron transport properties at room temperature. The four straight insulated lines (represented by the dark lines in the figure) were made by a focused ion beam (FIB) of Ga. The FIB beam diameter was about 80 nm. The FIB scanned lines separated the four electric contacts, numbered 1, 2, 3, and 4.

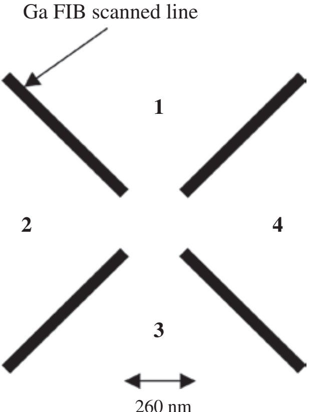


Figure 3. Schematic view of a device fabricated by Hirayama and Tarucha [23]. The four straight insulating lines (represented by the dark lines in the figure) were made by a focused Ga ion beam. Four electric contacts, numbered 1–4, were separated by the insulating lines.

During the experiments, Hirayama and Tarucha measured the so-called four-terminal bend resistance $R_{12,43} = V_{43}/I_{12}$ by sending a current I_{12} through contacts 1 and 2 and detecting the voltage between 4 and 3. If the electron transport is diffusive, the bend resistance $R_{12,43}$ would be positive. However, the experiment showed that $R_{12,43}$ was negative in the ballistic transport regime, which can be understood by considering the transmission coefficients of the ballistic electrons. Suppose that $I_{12} < 0$, and that electrons are ejected into the junction from contact 1. Instead of turning the corner between contacts 1 and 2 and transmitting into contact 2, the electrons enter the junction like billiard balls, and tend to go straight into contact 3. This results in an accumulation of electrons in contact 3, and therefore a positive V_{43} (instead of a negative voltage in a diffusive device) between contacts 4 and 3. The negative bend resistance is hence an indication of the existence of ballistic electron transport.

In the experiments, negative $R_{12,43}$ was observed from $T = 1.5$ K all the way up to room temperature, although the magnitude of the negative bend resistance was reduced by a factor of about 8 at $T = 290$ K. The result was interpreted in terms of the temperature-dependent mean-free path. At low temperature, l_e is much larger than the size of the junction in the center, and purely ballistic transport was realized. At $T = 290$ K, however, l_e is only about 135 nm, which is shorter than the length of the junction (260 nm), leading to the decrease of the magnitude of the negative bend resistance. Nevertheless, since the mean-free path at room temperature is still comparable to the length of the junction, some electrons still travel ballistically without being scattered when passing through the junction, although most electrons will experience at least one scattering event.

This is the reason why the bend resistance is still negative at room temperature. Furthermore, as Hirayama and Tarucha pointed out, at a higher temperature, more electrons will gain thermal energy above the Fermi level. These higher energy electrons might enhance the ballistic nature of the system. Recently, Hieke et al. similarly showed negative bend resistance in small cross junctions made from an InGaAs–InP modulation-doped quantum-well wafer [24]. The structures were fabricated by electron-beam lithography and deep dry etching. The experiments also indicated the partly ballistic electron transport in their devices at room temperature. Another important result of this study is the demonstration of low depletion length in such InP–InGaAs etched structures.

1.2. Nonlinear Ballistic Electron Transport

In this review, we focus on the recently demonstrated new types of ballistic devices that have been shown not only to operate at room temperature, but also to have great potentials in practical applications. All three types of devices are based on nonlinear ballistic electron transport, which is not at all simply by coincidence.

Nonlinear transport is particularly important in mesoscopic structures, and many striking phenomena discovered in ballistic devices are in the nonlinear regime, as shown in a number of experiments [25–40] and theoretical investigations [41–48]. First of all, a very small applied voltage suffices to drive the electron transport into the nonlinear regime. This is because of the small device dimension, and the fact that, in general, the applied voltage drops quite locally in the regions where the dimension of the electron path is changed, such as the opening and exit of a narrow channel, as mentioned earlier. Secondly, in a multiple-terminal ballistic device, the angular distribution of the electrons may largely determine the electron transmission probabilities between the terminals, and consequently, also the transport properties of the device. In contrast to the electron transport in a macroscopic semiconductor device, where the large number of scattering events completely randomize the direction of the electron velocities, a voltage applied to a ballistic device will change the angle of every electron in a predictable manner. As will be shown later, this has a direct influence on the transmission probabilities, and therefore also on the current distribution in the device. This is a new type of nonlinear effect which does not exist in a macroscopic device. In particular, it was recently realized that the geometrical symmetry of a ballistic device can also have a very pronounced influence on the nonlinear device properties [33–37]. One such example, which will be shown in Section 2, is called a ballistic rectifier. It is a completely new type of rectifying device because the nonlinear effect was based neither on a doping junction nor on a barrier structure. The ballistic rectifier has been demonstrated to operate at room temperature and at frequencies up to at least 50 GHz. A semiclassical model of the device is shown in Section 2.2.

Based on a similar working principle to the ballistic rectifier, a new class of nanostructured artificial material has also been constructed, as will be shown in Section 3. The nanomaterial turns out to be in analog with the so-called photogalvanic crystals. It was discovered more than 30 years ago that some natural crystals can generate a direct electron current under uniform illumination [49–51]. Referred to as the photogalvanic effect, the phenomenon has been identified to be a macroscopic manifestation of the absence of centrosymmetry in the elementary crystal structure, despite the macroscopic homogeneity of these crystals. In this case, light serves as a source of external fluctuation by imposing an unbiased, time-periodic electric field on the crystals, and the generation of direct electron current can be viewed as an extremely fast rectification at the frequency of the light. Recently, similar geometries to those found in photogalvanic crystals were realized to be useful for biomolecular separation devices consisting of arrays of symmetry-breaking microscopic obstacles [52–55].

Furthermore, it is naturally expected that, if the device dimension is comparable to the electron wavelength, quantum effects will take place. For a narrow channel or a device with a narrow constriction such as a quantum point contact, an applied voltage changes both the phase of the electrons and the electron distribution among the transverse quantum confinement modes in the channel, hence leading to a change in the conductance. In Section 4, three-terminal ballistic devices based on such a nonlinear effect will be discussed. The effect can also be well described with an extended Büttiker–Landauer formula.

In Section 5, the recently discovered quantum behavior of nanometer-sized ballistic rectifiers at temperatures very close to room temperature will be presented. Quantum devices generally have the advantages of being ultrasensitive and ultrafast. The results indicated the promising possibility of realizing room-temperature operations of quantum-effect-based nanoelectronic devices.

After the review on these nonlinear, room-temperature ballistic devices, ranging from basic device physics and modeling to the device performance and prospects of real applications, we conclude with an outlook in Section 6 on expected future developments in this yet new, but promising field.

2. BALLISTIC RECTIFIERS AND SEMICLASSICAL MODEL

In this section, a new type of semiconductor rectifier is introduced. The device, referred to as a ballistic rectifier, is based on a completely different working principle from a semiconductor diode since no doping junction or barrier structure has been used. The rectifying effect relies on the nature of the ballistic electron transport, and also on tailoring the device geometry. After the experimental results shown in Section 2.1, a semiclassical model of nonlinear ballistic electron transport will be introduced in Section 2.2, which yields an analytical description of the ballistic rectifying effect.

2.1. Experimental Results

There were quite a number of studies on mesoscopic semiconductor cross junctions in the early days of the realization of ballistic transport. A variety of novel phenomena have been observed in such devices, such as electron focusing

[13–15], negative bend resistances [17], and the quenched or negative Hall effect [18, 19]. While these experiments were performed in the linear transport regime, a ballistic rectifier operates in the nonlinear regime. Furthermore, a triangular scatterer was introduced to break the device symmetry which, as shown below, plays a key role in generating the rectifying effect. Figure 4(a) is an atomic force microscope image of the central part of one of the first ballistic rectifiers [34]. The dark areas in Figure 4(a) are the regions that were etched away and became insulating for the electrons. As a result, the triangular antidot was defined in the cross junction, which consists of the two narrow channels (labeled "source" S and "drain" D) and the two wide channels (labeled "upper" U and "lower" L). The triangular antidot acted as an artificial scatterer which, as shown in the following, induced a pronounced nonlinear effect.

The modulation-doped GaAs–AlGaAs heterostructure, from which the ballistic rectifier was fabricated, contains a two-dimensional electron gas (2DEG) located 37 nm below the wafer surface. The sheet density of the 2DEG is about 5×10^{11} cm^{-2} and the mobility is about 5×10^5 cm^2/V · s at a temperature $T = 4.2$ K. Standard electron-beam lithography and wet chemical etching are used in the fabrication. Since the electron mean-free path $l_e = 5.8$ μm is longer than the central part of the device, the electron transport is ballistic at 4.2 K.

Like a typical four-terminal measurement, the (input) current is applied through leads S and D, and the output voltage is detected via L and U. The typical electron trajectories, illustrated by the arrows in Figure 4(a), suggest an accumulation of electrons in the lower lead, and hence a negative voltage between L and U. Obviously, this cannot happen when the applied voltage or current is zero since the same number of electrons will go along the opposite directions of the arrows. For a nonzero applied current, $I_{SD} \neq 0$; however, as shown by a detailed model [47, 56], the electron transmission along the arrows in Figure 4(a) is changed by the applied electric field, while the transmission in the reversed direction is virtually unaffected (details in Section 2.2). This gives rise to a finite negative voltage between L and U, V_{LU}.

Even though the mirror symmetry along the S–D axis is broken by the triangular antidot, the symmetry along the central L–U axis remains. As a consequence, the output voltage V_{LU} is expected to remain the same if the sign of the applied current I_{SD} is changed, that is,

$$V_{LU}(I_{SD}) = +V_{LU}(-I_{SD}). \quad (4)$$

Correspondingly, $R_{SD,LU}(I_{SD}) = -R_{SD,LU}(-I_{SD})$, where $R_{SD,LU} = V_{LU}/I_{SD}$ is the four-terminal resistance. Such a picture is almost perfectly supported by the experimental V_{LU} versus I_{SD} curves at $T = 4.2$ K (solid line) and 77 K (dotted line) shown in Figure 5. The slight deviation from Eq. (4) is attributed to the unintentional breaking of the desired symmetry along the L–U axis by the imperfection of the fabrication. The imperfection is expected to contribute mainly a linear term to the V_{LU} versus I_{SD} curves, in a way similar to a change of one of the four resistors in an otherwise balanced resistor bridge.

The experimental results demonstrate that new device functionalities can be realized by simply tailoring the shape of a ballistic device because the only scattering events that the electrons undergo are from the device boundary. The device shown in Figure 4, called a ballistic rectifier, operated similarly to a bridge rectifier [see Fig. 4(b)], but the working principle is completely different. First, only a single device is used here rather than four diodes in the bridge rectifier. The mechanism is also entirely different since no doping junction or barrier structure along the current direction is used in the ballistic rectifier. The pronounced nonlinear effect comes from the breaking symmetry and the properties of the ballistic electron transport. Furthermore, as will be shown in Section 2.2, the ballistic rectifier has no intrinsic voltage or current threshold, and can be used for the detection of very weak signals without the need of an external bias.

The nonlinearity in the I–V characteristics is remarkably different from that of a two-terminal nonlinear device, such as a diode, where the nonlinearity always appears on top of a large linear term. For the ballistic rectifier with the four-terminal geometry, there can be, however, no linear term present in the relationship between the output voltage and the applied current, as shown by Eq. (4). The striking nonlinearity is a result of the broken symmetry along the S–D axis and the mirror symmetry along the U–L axis.

As the temperature was increased from 4.2 K, the electron scattering from phonons increased, resulting in a lower

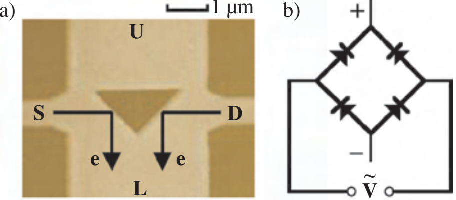

Figure 4. (a) Atomic force microscope image of the central part of a ballistic rectifier. The dark areas were etched away, forming the triangular antidot in the middle and the four channels S, D, L, and U. The current is applied via S and D, and the output voltage is measured between L and U. The device operates similarly to a bridge rectifier (b), but the ballistic rectifier is based on a completely new working principle. Adapted from [34].

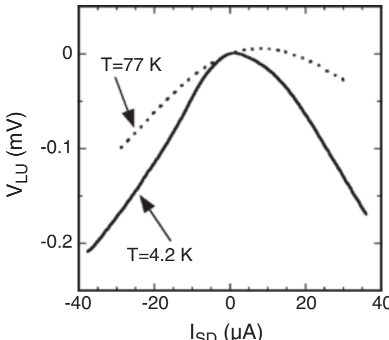

Figure 5. The output voltage between the lower and upper leads V_{LU} as a function of the input current through the source and drain leads I_{SD} measured at $T = 4.2$ K (solid line) and 77 K (dotted line). Ideally, the curves should be perfectly symmetric with respect to the vertical axis at $I_{SD} = 0$. However, the imperfection in the fabrication caused the slight asymmetry in the curves. Adapted from [34].

electron mobility and a shorter mean-free path. At $T = 77$ K, a weaker rectification than that at 4.2 K was observed, as shown by the dotted line in Figure 1(a). The less pronounced nonlinear behavior was attributed to the shorter l_e (about 1–2 μm) at 77 K. Since l_e was comparable to the distance between the openings of the *S* or *D* channels and the antidot, the electron transport was only partially ballistic.
